Editorial contributors

The editors would like to thank the following people who have made particular contributions to the 25th edition:

Section editor, Trauma

Robert Handley BSc MB ChB FRCS(Ed)
The Trauma Service, John Radcliffe Hospital, Oxford, UK

Editorial advisor, Paediatrics

Mark D. Stringer MS FRCS FRCP FRCS(Paed)
Department of Anatomy and Structural Biology, University of Otago, Dunedin, New Zealand; Formerly Professor of Paediatric Surgery, Leeds, UK

Imaging consultant

Stephen Eustace MB BCH MRCP FRCR FFR RCSI
Consultant Radiologist, Mater Misericordiae University Hospital, Dublin, Ireland

Historical footnotes

John G. Fairer TD BA LLB MB BS FRCA
Formerly Anaesthetist, Charing Cross Hospital Medical School, London, UK

Andrew Wainwright BSc ChB FRCS(Tr and Orth)
Consultant Orthopaedic Surgeon, Nuffield Orthopaedic Centre NHS Trust, Oxford, UK

List of contributors

Derek Alderson MD FRCS

Barling Chair of Surgery, Queen Elizabeth Hospital, Birmingham, UK

Gina M. Allen BM DCH MRCP MRCP FRCS

Consultant Radiologist, Royal Orthopaedic Hospital and Universities Hospitals, Birmingham, UK

Jonathan R. Anderson FRCS

Consultant in Cardiothoracic Surgery, Hammersmith Hospital, London, UK

Nicholas C.M. Armitage DM FRCS

Consultant Colorectal and General Surgeon, Nottingham University Hospitals Trust, Nottingham, UK

Shazad Ashraf BSc(Hons) MB ChB(Hons)

Bobby Moore Research Fellow, CRUK at the Weatherall Institute of Molecular Medicine, Oxford, UK

D.L. Back BSc(Hons) MBBS FRCS(Ed) (Orth)

Consultant Orthopaedic Surgeon, Guy's and St Thomas' Hospital, London, UK

Sarah J. Barton MBBS DMCC MRCS

Registrar, Trauma and Orthopaedics, Plymouth, UK

Grant J.E.M. Bates BSc BM BCh FRCS

Consultant ENT Surgeon, The Radcliffe Infirmary, and Senior Clinical Lecturer, University of Oxford, Oxford, UK

David H. Bennett BSc DM FRCS

Department of Surgery, The Royal Bournemouth Hospital, Bournemouth, UK

Satyajit Bhattacharya MS MPhil FRCS

Consultant Hepato-pancreato-biliary Surgeon, The Royal London Hospital, London, UK

Kenneth D. Boffard BSc(Hons) MB BCh FRCS FRCS(Ed) FRCPS(Glas)

FCS(SA) FACS

Professor and Clinical Head, Department of Surgery, Johannesburg Hospital and University of Witwatersrand, Johannesburg, South Africa

Andrew W. Bradbury BSc MD FRCS(Ed)

Professor of Vascular Surgery, Birmingham Heartlands Hospital, Birmingham, UK

J. Andrew Bradley PhD FRCS FMedSci

Professor of Surgery, University of Cambridge and Director of Transplantation, Addenbrooke's Hospital, Cambridge, UK

Karim Brohi BSc FRCS FRCA

Consultant, Vascular and Trauma Section, The Royal London Hospital, Whitechapel, London, UK

Kevin Burnand MB BS FRCS MS

Professor of Vascular Surgery, St Thomas' Hospital, London, UK

Christopher L.H. Chan BSc PhD FRCS

Senior Lecturer and Consultant Surgeon, Barts and the London NHS Trust, London, UK

Sue Clark MD FRCS (Gen Surg)

Consultant Colorectal Surgeon, St Mark's Hospital, Harrow, UK

Kevin Conlon MCh MBA FRCSI FACS FRCS

Chair of Surgery, Adelaide and Meath Hospital Dublin incorporating The National Children's Hospital, Tallaght, Dublin, Ireland

Paul Cool MD MedSc(Res) FRCS(Ed) FRCS(Orth)

Consultant Orthopaedic and Oncological Surgeon, Robert Jones and Agnes Hunt Orthopaedic Hospital, Oswestry, UK

Lord Darzi of Denham KBE HonFREng FMedSci

Paul Hamlyn Chair of Surgery, Professor of Surgery and Head of Department, Department of Biosurgery and Surgical Technology, Imperial College London, UK

Pradip K. Datta MS FRCS(Ed) FRCS(Eng) FRCSI FRCS(Glas)

Honorary Consultant Surgeon, Caithness General Hospital, Wick, UK; and Member of Council and College Tutor, Royal College of Surgeons of Edinburgh

Mark Davies FRCS FRCS(Tr & Orth)

Consultant Foot and Ankle Surgeon, The London Foot and Ankle Centre, London, UK

Sanjay De Bakshi MS FRCS(Eng) FRCS(Ed)

Consultant Surgeon, Calcutta Medical Research Institute, Kolkata, India

Brian R. Davidson MB ChB MD FRCPs(Glas) FRCS
Professor of HPB and Liver Transplant Surgery, Royal Free and University College School of Medicine, London, UK

Sunny Deo FRCS(Tr & Orth)
Consultant Orthopaedic Surgeon, Great Western Hospital, Swindon, UK

Len Doyal BA MSc
Emeritus Professor of Medical Ethics, St Bartholomew's and The Royal London School of Medicine and Dentistry, Queen Mary and Westfield College, University of London, UK

Preface

This is the 25th and hence Silver Jubilee edition of this world famous textbook. It has stood the test of time as evidenced by increasing sales, edition by edition, a tribute to the foresight of the original authors Hamilton Bailey and McNeill Love. Both set out to produce a high quality, comprehensive textbook to be enjoyed by both undergraduates and postgraduates. Part of their magic formula was to combine clear and concise text with numerous clinical photographs collected from their own archives. Most important was the frequent use of anecdote and aphorism to highlight points of clinical relevance, further enhanced by autobiographical notes beloved by all devotees of the book. We, the editors of this auspicious edition, therefore feel a particular responsibility following in the footsteps of the original authors and our colleague editors who continued this tradition over past editions. It is always difficult to blend the old with the new but this we have attempted to do. We present to the reader a comprehensive, modern surgical textbook which, we hope, retains the feel of the original. We have ensured that the text is liberally illustrated with high quality reproductions and line drawings. Some of Bailey and Love's original illustrations have been retained because they capture specific points so well that we have felt obliged to keep them. Similarly the autobiographical notes remain but have been updated. We have been particularly fortunate in this endeavour in retaining the services of Dr J.G. Fairer who, as a labour of love, has spent many hours ensuring the veracity of these notes. To help the budding young surgeon faced with that heart-sinking question from their boss, 'What instrument is that in your hand?' followed by 'And who was he?', we have started a new page in the appendix which gives answers to a few of the most common queries. Let us know if you think it is useful.

Despite the retention of some of the historical attributes that have made the book so popular over previous editions, the reader will find that the 25th edition is a book for our time. Whereas the past informs the present, it must never enslave the future. Thus each chapter starts with learning objectives and the text is liberally sprinkled with summary boxes that provide the busy student an easy aide memoire when revising for ubiquitous exams. We have given considerable thought to the order of the chapters and have grouped them into themed sections with the first concentrating on principles of surgery generic to all specialties. We believe this format provides a more logical sequence for the reader to that found in previous editions. We have also attempted to reduce repetition. For instance, most paediatric problems have been removed from the specialty chapters and are dealt with in a new chapter entitled 'Principles

of paediatric surgery'. We are grateful to Mark Stringer, our paediatric advisor, who has masterminded this transition. Mark has also reviewed all the pertinent specialty chapters to ensure that where reference to paediatric conditions remains, it has been brought up to date. Other chapters have been merged to streamline the text. Where old chapters have been retained, they have been thoroughly revised and where appropriate new chapters have been introduced. The quality of diagnostic imaging reproduced has significantly benefited by review of our imaging advisor, Stephen Eustace, who has ensured a high standard of reproduction throughout.

Surgical textbooks need to be refreshed continually in order to keep up with ever-increasing developments. Continual renewal is an essential part of progress. Thus R.C.G. Russell, senior editor of four previous editions, has now stepped down. We thank Chris for his devotion to the book and his exemplary editorial skills that have undoubtedly contributed to its continued popularity. We welcome Ronan O'Connell to the editorial team. Ronan, as a past editor of the *British Journal of Surgery*, has brought new energy and strategic thinking into the organisation and content of the book. This, in turn, has invigorated the remaining two editors and hopefully enlivened the sections they are responsible for.

We have chosen our contributors carefully. Each was selected not only for surgical knowledge and expertise but also clarity in communication. Their instructions were to be ruthless in excising old material and to ensure current relevance of chapter content and that any recommendations for management were, as far as possible, evidence-based. We trust that this approach shines through. Without such a dedicated and meticulous group of contributors, this edition could never compete with the high quality of its predecessors. Their efforts are much appreciated. Our publishers have done sterling work to ensure that the production of the book is of the highest quality. They have striven for excellence including the elimination of typographical and grammatical errors. Nevertheless, in a volume of this size, some errors will inevitably have crept in. We have no doubt that these will, as in the past, be reported to us by our hawk-eyed readers, a valued Bailey and Love tradition.

Undergraduate and trainee curricula are continually changing as surgery evolves and becomes more specialised. There can be no doubt, however, that a house cannot be built on sand; a firm foundation is required. It is essential for all those who wish to pursue a career in surgery to have this firm base. They must be conversant with the general principles of surgery and have an appreciation of the basics of all specialties out with their own. Hence they need a reliable textbook that can provide this broad

canvas. We very much hope that the Silver Jubilee Edition of this venerable textbook fulfils this requirement.

Norman S. Williams
Christopher J.K. Bulstrode
P. Ronan O'Connell

Acknowledgements

Chapter 7, *Principles of oncology*, contains some material from 'Principles of oncology' by Robert J. Steele and Amy Leslie which appeared in the 24th edition. The material has been revised and updated by the current authors.

Chapter 8, *Surgical audit and research*, contains some material from 'An Approach to surgical audit and research' by Mark Emberton and Jan van der Meulen which appeared in the 24th edition. The material has been revised and updated by the current authors.

Chapter 10, *Diagnostic imaging*, contains some material from 'Diagnostic and interventional radiology' by Alison M. McLean and Matthew Matson and 'Musculoskeletal imaging' by David J. Wilson and Gina M. Allen which both appeared in the 24th edition. The material has been revised and updated by the current authors.

Chapter 13, *Preoperative preparation*, contains some material from 'Preparing a patient for surgery' by Peter Driscoll and Christopher J.K. Bulstrode which appeared in the 24th edition. The material has been revised and updated by the current authors.

Chapter 17, *Nutrition and fluid therapy*, contains some material from 'Nutrition' by Gordon L. Carlson and Edwin C. Clark which appeared in the 24th edition. The material has been revised and updated by the current author.

Chapter 24, *Neck and spine*, contains some material from 'The spine, vertebral column and spinal cord' by Richard C.S. Kerr and James Wilson-MacDonald which appeared in the 24th edition. The material has been revised and updated by the current author.

Sayings of the great

Both Hamilton Bailey and McNeill Love, when medical students, served as clerks to Sir Robert Hutchison, 1871–1960, who was Consulting Physician to the London Hospital and President of the Royal College of Physicians. They never tired of quoting his ‘medical litany’, which is appropriate for all clinicians and, perhaps especially, for those who are surgically minded.

From inability to leave well alone;
From too much zeal for what is new and contempt for
what is old;
From putting knowledge before wisdom,
science before art, cleverness before common sense;
From treating patients as cases; and
From making the cure of a disease more grievous than its
endurance,
Good Lord, deliver.

To which may be added:

The patient is the centre of the medical universe around
which all our works revolve and towards which all our
efforts trend.

J.B. Murphy, 1857–1916, Professor of Surgery,
Northwestern University, Chicago, IL, USA

To study the phenomenon of disease without books is to
sail an uncharted sea, while to study books without
patients is not to go to sea at all.

Sir William Osler, 1849–1919,
Professor of Medicine, Oxford, UK

A knowledge of healthy and diseased actions is not less necessary to be understood than the principles of other sciences. By an acquaintance with principles we learn the cause of disease. Without this knowledge a man cannot be a surgeon. ... The last part of surgery, namely operations, is a reflection on the healing art; it is a tacit acknowledgement of the insufficiency of surgery. It is like an armed savage who attempts to get that by force which a civilised man would by stratagem.

Hunter, 1728–1793, Surgeon, St George’s Hospital,
London, UK

Investigating Nature you will do well to bear ever in mind that in every question there is the truth, whatever our notions may be. This seems perhaps a very simple consideration; yet it is strange how often it seems to be disregarded. If we had nothing but pecuniary rewards and worldly honours to look to, our profession would not be one to be desired. But in its practice you will find it to be attended with peculiar privileges; second to none in intense interest and pure pleasures. It is our proud office to tend the fleshy tabernacle of the immortal spirit, and our path, if rightly followed, will be guided by unfettered truth and love unfeigned. In the pursuit of this noble and holy calling I wish you all God-speed.

Promoter’s address, Graduation in Medicine,
University of Edinburgh, August, 1876, by Lord Lister,
the Founder of Modern Surgery

The metabolic response to injury

LEARNING OBJECTIVES

To understand:

- Classical concepts of homeostasis
- Mediators of the metabolic response to injury
- Physiochemical and biochemical changes that occur during injury and recovery
- Changes in body composition that accompany surgical injury
- Avoidable factors that compound the metabolic response to injury
- Concepts behind optimal perioperative care

BASIC CONCEPTS IN HOMEOSTASIS

In the eighteenth and nineteenth centuries, a series of eminent scientists laid the foundations of our understanding of homeostasis and the response to injury. The classical concepts of homeostasis and the response to injury are:

- ‘The stability of the “milieu intérieur” is the primary condition for freedom and independence of existence.’ (Claude Bernard) i.e. body systems act to maintain internal constancy
- ‘Homeostasis: the co-ordinated physiological process which maintains most of the steady states of the organism.’ (Walter Cannon) i.e. complex homeostatic responses involving the brain, nerves, heart, lungs, kidneys and spleen work to maintain body constancy
- ‘There is a circumstance attending accidental injury which does not belong to the disease, namely that the injury done, has in all cases a tendency to produce both the deposition and means of cure.’ (John Hunter) i.e. responses to injury are, in general, beneficial to the host and allow healing/survival

In essence, the concept evolved that the constancy of the ‘milieu intérieur’ allowed for the independence of organisms, that complex homeostatic responses sought to maintain this constancy, and that within this range of responses were the elements of healing and repair. These ideas pertained to normal physiology and mild/moderate injury. In the modern era, such concepts do not account for disease evolution following major injury/sepsis or the injured patient who would have died but for artificial organ support. Such patients exemplify less of the classical homeostatic

control system (signal detector–processor–effector regulated by a negative feedback loop) and more of the ‘open loop’ system, whereby only with medical/surgical resolution of the primary abnormality is a return to classical homeostasis possible. Current understanding of such events as the response to major sepsis/injury relies on chaos theory and the use of a structured network knowledge-base approach.

As a consequence of modern understanding of the metabolic response to injury, elective surgical practice seeks to reduce the need for a homeostatic response by minimising the primary insult (minimal access surgery and ‘stress-free’ perioperative care). In emergency surgery, where the presence of tissue trauma/sepsis/hypovolaemia often compounds the primary problem, there is a requirement to augment artificially homeostatic responses (resuscitation) and to close the ‘open’ loop by intervening to resolve the primary insult (e.g. surgical treatment of major abdominal sepsis) and provide organ support (critical care) while the patient comes back to a situation in which homeostasis can achieve a return to normality (Summary box 1.1).

Summary box 1.1

Basic concepts

- Homeostasis is the foundation of normal physiology
- ‘Stress-free’ perioperative care helps to restore homeostasis following elective surgery
- Resuscitation, surgical intervention and critical care can return the severely injured patient to a situation in which homeostasis becomes possible once again

Claude Bernard, 1813–1878, Professor of Physiology, The College de France, Paris, France.

Walter Bradford Cannon, 1871–1945, Professor of Physiology, Harvard University Medical School, Boston, MA, USA.

John Hunter, 1728–1793, Surgeon, St. George’s Hospital, London, England. He is regarded as ‘The Father of Scientific Surgery’.

This chapter aims to review the mediators of the stress response, the physiochemical and biochemical pathway changes associated with surgical injury and the changes in body composition that occur following surgical injury. Emphasis is laid on why knowledge of these events is important to understand the rationale for modern ‘stress-free’ perioperative and critical care.

THE GRADED NATURE OF THE INJURY RESPONSE

It is important to recognise that the response to injury is graded: the more severe the injury, the greater the response (Fig. 1.1). This concept not only applies to physiological/metabolic changes but also to immunological changes/sequelae. Thus, following elective surgery of intermediate severity, there may be a transient and modest rise in temperature, heart rate, respiratory rate, energy expenditure and peripheral white cell count. Following major trauma/sepsis, these changes are accentuated, resulting in a systemic inflammatory response syndrome (SIRS), hypermetabolism, marked catabolism, shock and even multiple organ dysfunction (MODS).

Not only is the metabolic response graded, but it also evolves with time. In particular, the immunological sequelae of major injury evolve from a pro-inflammatory state driven primarily by the innate immune system (macrophages, neutrophils, dendritic cells) into a compensatory anti-inflammatory response syndrome (CARS) characterised by suppressed immunity and diminished resistance to infection. In patients who develop infective complications, the latter will drive on-going systemic inflammation, the acute phase response and continued catabolism.

MEDIATORS OF THE METABOLIC RESPONSE TO INJURY

The classical neuroendocrine pathways of the stress response consist of afferent nociceptive neurones, the spinal cord,

thalamus, hypothalamus and pituitary (Fig. 1.2). Corticotrophin-releasing factor (CRF) released from the hypothalamus increases adrenocorticotrophic hormone (ACTH) release from the anterior pituitary. ACTH then acts on the adrenal to increase the secretion of cortisol. Hypothalamic activation of the sympathetic nervous system causes release of adrenalin and also stimulates release of glucagon. Intravenous infusion of a cocktail of these 'counter-regulatory' hormones (glucagon, glucocorticoids and catecholamines) reproduces many aspects of the metabolic response to injury. There are, however, many other players, including alterations in insulin release and sensitivity, hypersecretion of prolactin and growth hormone (GH) in the presence of low circulatory insulin-like growth factor-1 (IGF-1) and inactivation of peripheral thyroid hormones and gonadal function. Of note, GH has direct lipolytic, insulin-antagonising and pro-inflammatory properties (Summary box 1.2).

Summary box 1.2

Neuroendocrine response to injury/critical illness

The neuroendocrine response to severe injury/critical illness is biphasic:

- *Acute phase* characterised by an actively secreting pituitary and elevated counter-regulatory hormones (cortisol, glucagon, adrenaline). Changes are thought to be beneficial for short-term survival
- *Chronic phase* associated with hypothalamic suppression and low serum levels of the respective target organ hormones. Changes contribute to chronic wasting

Figure 1.1 Hypermetabolism and increased nitrogen excretion are closely related to the magnitude of the initial injury and show a graded response.

The innate immune system (principally macrophages) interacts in a complex manner with the adaptive immune system (T cells, B cells) in co-generating the metabolic response to injury (Fig. 1.2). Pro-inflammatory cytokines including interleukin-1 (IL-1), tumour necrosis factor alpha (TNF α), IL-6 and IL-8 are produced within the first 24 hours and act directly on the hypothalamus to cause pyrexia. Such cytokines also augment the hypothalamic stress response and act directly on skeletal muscle to induce proteolysis while inducing acute phase protein production in the liver. Pro-inflammatory cytokines also play a complex role in the development of peripheral insulin resistance. Other important pro-inflammatory mediators include nitric oxide [(NO) via inducible nitric oxide synthetase (iNOS)] and a variety of prostanoids [via cyclo-oxygenase-2 (Cox-2)].

Within hours of the upregulation of pro-inflammatory cytokines, endogenous cytokine antagonists enter the circulation [e.g. interleukin-1 receptor antagonist (IL-1Ra) and TNF-soluble receptors (TNF-sR-55 and 75)] and act to control the pro-inflammatory response. A complex further series of adaptive changes includes the development of a Th2-type counter-inflammatory response [regulated by IL-4, -5, -9 and -13 and transforming growth factor beta (TGF β)] which, if accentuated and prolonged in critical illness, is characterised as the CARS and results in immunosuppression and an increased susceptibility to opportunistic (nosocomial) infection (Summary box 1.3).

Figure 1.2 The integrated response to surgical injury (first 24–48 h): there is a complex interplay between the neuroendocrine stress response and the pro-inflammatory cytokine response of the innate immune system.

Summary box 1.3

Systemic inflammatory response syndrome (SIRS) following major injury

- Is driven initially by pro-inflammatory cytokines (e.g. IL-1, IL-6 and TNF α)
- Is followed rapidly by increased plasma levels of cytokine antagonists and soluble receptors (e.g. IL-1Ra, TNF-sR)
- If prolonged or excessive may evolve into a counter-inflammatory response syndrome (CARS)

There are many complex interactions between the neuroendocrine, cytokine and metabolic axes. For example, although cortisol is immunosuppressive at high levels, it acts synergistically with IL-6 to promote the hepatic acute phase response. ACTH release is enhanced by pro-inflammatory cytokines and the noradrenergic system. The resulting rise in cortisol levels may form a weak feedback loop attempting to limit the pro-inflammatory stress response. Finally, hyperglycaemia may aggravate the inflammatory response via substrate overflow in the mitochondria, causing the formation of excess free oxygen radicals and also altering gene expression to enhance cytokine production.

At the molecular level, the changes that accompany systemic inflammation are extremely complex. In a recent study using network-based analysis of changes in mRNA expression in leucocytes following exposure to endotoxin, there were changes in the expression of more than 3700 genes with over half showing decreased expression and the remainder increased expression. The cell surface receptors, signalling mechanisms and transcription factors that initiate these events are also complex, but an

early and important player involves the nuclear factor kappa B (NF κ B)/*relA* family of transcription factors. A simplified model of current understanding of events within skeletal muscle is shown in Figure 1.3.

THE METABOLIC STRESS RESPONSE TO SURGERY AND TRAUMA: THE 'EBB AND FLOW' MODEL

In the natural world, if an animal is injured, it displays a characteristic response, which includes immobility, anorexia and catabolism (Summary box 1.4).

Summary box 1.4

Physiological response to injury

The *natural* response to injury includes:

- Immobility/rest
- Anorexia
- Catabolism

The changes are designed to aid survival of moderate injury in the absence of medical intervention.

In 1930, Sir David Cuthbertson divided the metabolic response to injury in humans into 'ebb' and 'flow' phases (Fig. 1.4). The

Sir David Paton Cuthbertson, 1900–1989, Biochemist, Director of the Rowett Research Institute, Glasgow, Scotland.

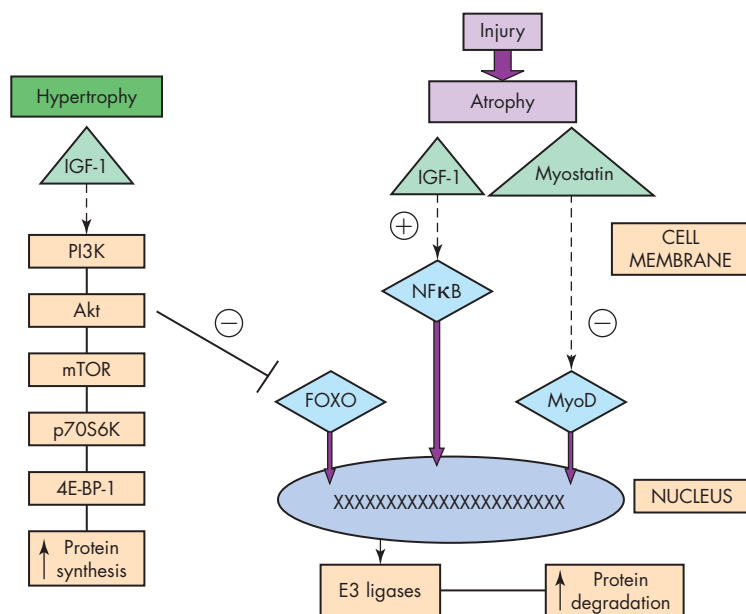

Figure 1.3 The major catabolic and anabolic signalling pathways involved in skeletal muscle homeostasis. FOXO, forkhead box sub-group O; IGF-1, insulin-like growth factor-1; mTOR, mammalian target of rapamycin; MyoD, myogenic differentiation factor D; NFκB, nuclear factor kappa B; PI3K, phosphatidylinositol 3-kinase; p70S6K, p70S6 kinase; 4E-BP-1, eukaryotic initiation translation factor 4E binding protein 1.

ebb phase begins at the time of injury and lasts for approximately 24–48 hours. It may be attenuated by proper resuscitation, but not completely abolished. The ebb phase is characterised by hypovolaemia, decreased basal metabolic rate, reduced cardiac output, hypothermia and lactic acidosis. The predominant hormones regulating the ebb phase are catecholamines, cortisol and aldosterone (following activation of the renin–angiotensin system). The magnitude of this neuroendocrine response depends on the degree of blood loss and the stimulation of somatic afferent nerves at the site of injury. The main physiological role of the ebb phase is to conserve both circulating volume and energy stores for recovery and repair.

Following resuscitation, the ebb phase evolves into a hypermetabolic flow phase, which corresponds to the SIRS. This phase involves the mobilisation of body energy stores for recovery and repair, and the subsequent replacement of lost or damaged tissue. It is characterised by tissue oedema (from vasodilatation and increased capillary leakage), increased basal metabolic rate (hypermetabolism), increased cardiac output, raised body temperature, leucocytosis, increased oxygen consumption and increased gluconeogenesis. The flow phase may be subdivided into an initial catabolic phase, lasting approximately 3–10 days, followed by an anabolic phase, which may last for weeks if extensive recovery and repair are required following serious

injury. During the catabolic phase, the increased production of counter-regulatory hormones (including catecholamines, cortisol, insulin and glucagon) and inflammatory cytokines (e.g. IL-1, IL-6 and TNFα) results in significant fat and protein mobilisation, leading to significant weight loss and increased urinary nitrogen excretion. The increased production of insulin at this time is associated with significant *insulin resistance* and, therefore, injured patients often exhibit poor glycaemic control. The combination of pronounced or prolonged catabolism in association with insulin resistance places patients within this phase at increased risk of complications, particularly infectious and cardiovascular. Obviously, the development of complications will further aggravate the neuroendocrine and inflammatory stress responses, thus creating a vicious catabolic cycle (Summary box 1.5).

Summary box 1.5

Purpose of neuroendocrine changes following injury

The constellation of neuroendocrine changes following injury acts to:

- Provide essential substrates for survival
- Postpone anabolism
- Optimise host defence

These changes may be helpful in the short term, but may be harmful in the long term, especially to the severely injured patient who would otherwise not have survived without medical intervention.

Figure 1.4 Phases of the physiological response to injury (after Cuthbertson 1930).

KEY CATABOLIC ELEMENTS OF THE FLOW PHASE OF THE METABOLIC STRESS RESPONSE

There are several key elements of the flow phase that largely determine the extent of catabolism and thus govern the

metabolic and nutritional care of the surgical patient. It must be remembered that, during the response to injury, not all tissues are catabolic. Indeed, the essence of this coordinated response is to allow the body to reprioritise limited resources away from peripheral tissues (muscle, adipose tissue, skin) and towards key viscera (liver, immune system) and the wound (Fig. 1.5).

Hypermetabolism

The majority of trauma patients (except possibly those with extensive burns) demonstrate energy expenditures approximately 15–25% above predicted healthy resting values. The predominant cause appears to be a complex interaction between the central control of metabolic rate and peripheral energy utilisation. In particular, central thermodyregulation (caused by the pro-inflammatory cytokine cascade), increased sympathetic activity, abnormalities in wound circulation [ischaemic areas produce lactate, which must be metabolised by the adenosine triphosphate (ATP)-consuming hepatic Cori cycle; hyperaemic areas cause an increase in cardiac output], increased protein turnover and nutritional support may all increase patient energy expenditure. Theoretically, patient energy expenditure could rise even higher than observed levels following surgery or trauma, but several features of standard intensive care (including bed rest, paralysis, ventilation and external temperature regulation) counteract the hypermetabolic driving forces of the stress response. Furthermore, the skeletal muscle wasting experienced by patients with prolonged catabolism actually limits the volume of metabolically active tissue (Summary box 1.6; see next section).

Summary box 1.6

Hypermetabolism

Hypermetabolism following injury:

- Is mainly caused by an acceleration of futile metabolic cycles
- Is limited in modern practice on account of elements of routine critical care

Alterations in skeletal muscle protein metabolism

Muscle protein is continually synthesised and broken down with a turnover rate in humans of 1–2% day⁻¹, and with a greater amplitude of changes in protein synthesis (\pm twofold) than breakdown (\pm 0.25-fold) during the diurnal cycle. Under normal circumstances, synthesis equals breakdown and muscle bulk remains constant. Physiological stimuli that promote net muscle protein accretion include feeding (especially extracellular amino acid concentration) and exercise. Paradoxically, during exercise, skeletal muscle protein synthesis is depressed, but it increases again during rest and feeding.

During the catabolic phase of the stress response, muscle wasting occurs as a result of an increase in muscle protein degradation (via enzymatic pathways), coupled with a decrease in muscle protein synthesis. The major site of protein loss is peripheral skeletal muscle, although nitrogen losses also occur in the respiratory muscles (predisposing the patient to hypoventilation and chest infections) and in the gut (reducing gut motility). Cardiac muscle appears to be mostly spared. Under extreme conditions of catabolism (e.g. major sepsis), urinary nitrogen losses can reach 14–20 g day⁻¹; this is equivalent to the loss of 500 g of skeletal muscle per day. It is remarkable that muscle catabolism cannot be inhibited fully by providing artificial nutritional support as long as the stress response continues. Indeed, in critical care, it is now recognised that ‘hyperalimination’ represents a metabolic stress in itself, and that nutritional support should be at a modest level to attenuate rather than replace energy and protein losses.

The predominant mechanism involved in the wasting of skeletal muscle is the ATP-dependent ubiquitin–proteasome pathway (Fig. 1.6), although the lysosomal cathepsins and the calcium–calpain pathway play facilitatory and accessory roles.

Clinically, a patient with skeletal muscle wasting will experience asthenia, increased fatigue, reduced functional ability, decreased quality of life and an increased risk of morbidity and mortality. In critically ill patients, muscle weakness may be further worsened by the development of critical illness myopathy, a multifactorial condition that is associated with impaired excitation–contraction–coupling at the level of the sarcolemma and the sarcoplasmic reticulum membrane (Summary box 1.7).

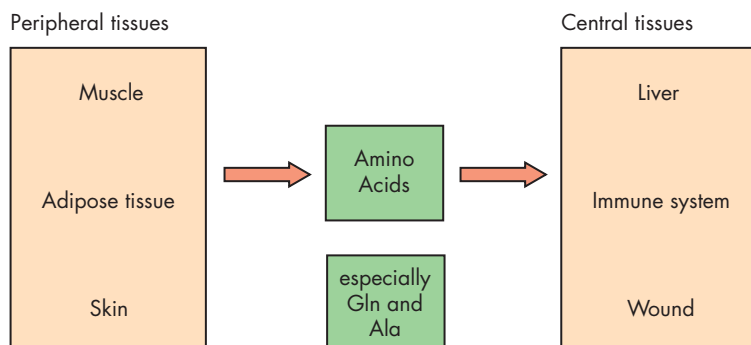

Figure 1.5 During the metabolic response to injury, the body reprioritises protein metabolism away from peripheral tissues and towards key central tissues such as the liver, immune system and wound. One of the main reasons why the reutilisation of amino acids derived from muscle proteolysis leads to net catabolism is that the increased glutamine and alanine efflux from muscle is derived, in part, from the irreversible degradation of branched chain amino acids. Gln, glutamine; Ala, alanine.

Carl Ferdinand Cori, 1896–1984, Professor of Pharmacology, and later of Biochemistry, Washington University Medical School, St. Louis, MI, USA and his wife Gerty Theresa Cori, 1896–1957, who was also Professor of Biochemistry at the Washington University Medical School. In 1947 the Coris were awarded a share of the Nobel Prize for Physiology or Medicine ‘for their discovery of how glycogen is catalytically converted’.

Figure 1.6 The intercellular effector mechanisms involved in degrading myofibrillar protein into free amino acids. The ubiquitin–proteasome pathway is a complex multistep process, which requires adenosine triphosphate (ATP) and results in the tagging of specific proteins with ubiquitin for degradation of proteasome. E1, ubiquitin-activating enzyme; E2, ubiquitin-conjugating enzyme; E3, ubiquitin ligase.

Summary box 1.7

Skeletal muscle wasting

- Provides amino acids for protein synthesis in central organs/tissues
- Is mediated at a molecular level mainly by activation of the ubiquitin–proteasome pathway
- Can result in immobility and contribute to hypostatic pneumonia and death if prolonged and excessive

Alterations in hepatic protein metabolism: the acute phase protein response (APPR)

The liver and skeletal muscle together account for > 50% of daily body protein turnover. Skeletal muscle has a large mass but a low turnover rate (1–2% day⁻¹), whereas the liver has a relatively small mass (1.5 kg) but a much higher protein turnover rate (10–20% day⁻¹). Hepatic protein synthesis is divided roughly 50:50 between renewal of structural proteins and synthesis of export proteins. Albumin is the major export protein produced by the liver and is renewed at the rate of about 10% day⁻¹. The transcapillary escape rate (TER) of albumin is about 10 times the rate of synthesis, and short-term changes in albumin concentration are most probably due to increased vascular permeability. Albumin TER may be increased threefold following major injury/sepsis.

In response to inflammatory conditions, including surgery, trauma, sepsis, cancer or autoimmune conditions, circulating peripheral blood mononuclear cells secrete a range of pro-inflammatory cytokines, including IL-1, IL-6 and TNF α . These cytokines, in particular IL-6, promote the hepatic synthesis of positive acute phase proteins, e.g. fibrinogen and C-reactive protein (CRP). The APPR represents a ‘double-edged sword’ for surgical patients as it provides proteins important for recovery and repair, but only at the expense of valuable lean tissue and energy reserves.

In contrast to the positive acute phase reactants, the plasma concentrations of other liver export proteins (the negative acute phase reactants) fall acutely following injury, e.g. albumin. However, rather than represent a reduced hepatic synthesis rate, the fall in plasma concentration of negative acute phase reactants is thought principally to reflect increased transcapillary escape, secondary to an increase in microvascular permeability (see above). Thus, increased hepatic synthesis of positive acute phase reactants is not compensated for by reduced synthesis of negative reactants (Summary box 1.8).

Summary box 1.8

Hepatic acute phase response

The hepatic acute phase response represents a reprioritisation of body protein metabolism towards the liver and is characterised by:

- *Positive reactants* (e.g. CRP): plasma concentration \uparrow
- *Negative reactants* (e.g. albumin): plasma concentration \downarrow

Insulin resistance

Following surgery or trauma, postoperative hyperglycaemia develops as a result of increased glucose production combined with decreased glucose uptake in peripheral tissues. Decreased glucose uptake is a result of insulin resistance which is transiently induced within the stressed patient. Suggested mechanisms for this phenomenon include the action of pro-inflammatory cytokines and the decreased responsiveness of insulin-regulated glucose transporter proteins. The degree of insulin resistance is proportional to the magnitude of the injurious process. Following routine upper abdominal surgery, insulin resistance may persist for approximately 2 weeks.

Postoperative patients with insulin resistance behave in a

similar manner to individuals with type II diabetes mellitus and are at increased risk of sepsis, deteriorating renal function, polyneuropathy and death.

The mainstay management of insulin resistance is intravenous insulin infusion. Insulin infusions may be used in either an *intensive* approach (i.e. sliding scales are manipulated to normalise the blood glucose level) or a *conservative* approach (i.e. insulin is administered when the blood glucose level exceeds a defined limit and discontinued when the level falls). Studies of postoperatively ventilated patients in the intensive care unit (ICU) have suggested that maintenance of normal glucose levels using intensive insulin therapy can significantly reduce both morbidity and mortality. Furthermore, intensive insulin therapy is superior to conservative insulin approaches in reducing morbidity rates. However, the mortality benefit of intensive insulin therapy over a more conservative approach has not been proven conclusively. The observed benefits of insulin therapy are probably simply as a result of maintenance of normoglycaemia, but the glycaemia-independent actions of insulin may also exert minor, organ-specific effects (e.g. promotion of myocardial systolic function).

CHANGES IN BODY COMPOSITION FOLLOWING INJURY

The average 70-kg male can be considered to consist of fat (13 kg) and fat-free mass (or lean body mass: 57 kg). In such an individual, the lean tissue is composed primarily of protein (12 kg), water (42 kg) and minerals (3 kg) (Fig. 1.7). The protein mass can be considered as two basic compartments, skeletal muscle (4 kg) and non-skeletal muscle (8 kg), which includes the visceral protein mass. The water mass (42 l) is divided into intercellular (28 l) and extracellular (14 l) spaces. Most of the mineral mass is contained in the bony skeleton.

The main labile energy reserve in the body is fat, and the main labile protein reserve is skeletal muscle. While fat mass can be reduced without major detriment to function, loss of protein mass results not only in skeletal muscle wasting, but also depletion of visceral protein status. Within lean tissue, each 1 g of nitrogen is contained within 6.25 g of protein, which is contained in approximately 36 g of wet weight tissue. Thus, the loss of 1g of nitrogen

Figure 1.7 The chemical body composition of a normal 70-kg male. FFM, fat-free mass; LBM, lean body mass.

in urine is equivalent to the breakdown of 36 g of wet weight lean tissue. Protein turnover in the whole body is of the order of 150–200 g day⁻¹. A normal human ingests about 70–100 g protein day⁻¹, which is metabolised and excreted in urine as ammonia and urea (i.e. approximately 14 g N day⁻¹). During total starvation, urinary loss of nitrogen is rapidly attenuated by a series of adaptive changes. Loss of body weight follows a similar course (Fig. 1.8), thus accounting for the survival of hunger strikers for a period of 50–60 days. Following major injury, and particularly in the presence of on-going septic complications, this adaptive change fails to occur, and there is a state of ‘autocannibalism’, resulting in continuing urinary nitrogen losses of 10–20 g N day⁻¹ (equivalent to 500 g of wet weight lean tissue day⁻¹). As with total starvation, once loss of body protein mass has reached 30–40% of the total, survival is unlikely.

Critically ill patients admitted to the ICU with severe sepsis or major blunt trauma undergo massive changes in body composition (Fig. 1.8). Body weight increases immediately on

Figure 1.8 Changes in body weight that occur in serious sepsis, after uncomplicated surgery and in total starvation.

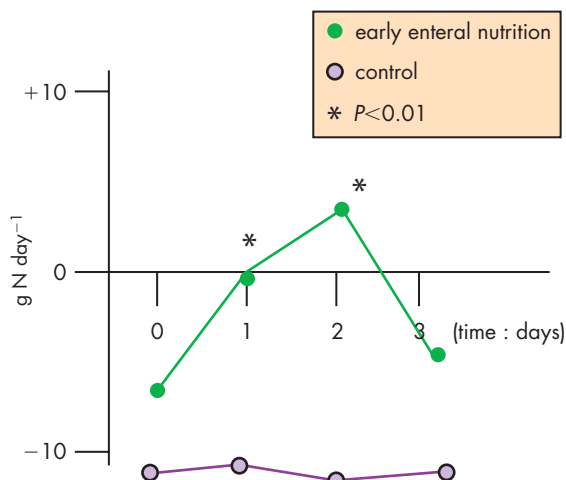

Figure 1.9 Effect of immediate enteral nutrition on nitrogen balance in patients managed with an enhanced recovery protocol following major colorectal surgery.

resuscitation with an expansion of extracellular water by 6–10 l within 24 hours. Thereafter, even with optimal metabolic care and nutritional support, total body protein will diminish by 15% in the next 10 days, and body weight will reach negative balance as the expansion of the extracellular space resolves. In marked contrast, it is now possible to maintain body weight and nitrogen equilibrium following major elective surgery (Fig. 1.9). This can be achieved by blocking the neuroendocrine stress response with epidural analgesia and providing early enteral feeding. Moreover, the early fluid retention phase can be avoided by careful intra-operative management of fluid balance, with avoidance of excessive administration of intravenous saline (Summary box 1.9).

Summary box 1.9

Changes in body composition following major surgery/critical illness

- Catabolism leads to a decrease in fat mass and skeletal muscle mass
- Body weight may paradoxically increase because of expansion of extracellular fluid space

AVOIDABLE FACTORS THAT COMPOUND THE RESPONSE TO INJURY

As noted previously, the main features of this metabolic response are initiated by the immune system, cardiovascular system, sympathetic nervous system, ascending reticular formation and limbic system. However, the metabolic stress response may be further exacerbated by anaesthesia, dehydration, starvation (including preoperative fasting), sepsis, acute medical illness or even severe psychological stress (Fig. 1.10). Thus, any attempt to limit or control these other factors is beneficial to the patient (Summary box 1.10).

Summary box 1.10

Avoidable factors that compound the response to injury

- Continuing haemorrhage
- Hypothermia
- Tissue oedema
- Tissue underperfusion
- Starvation
- Immobility

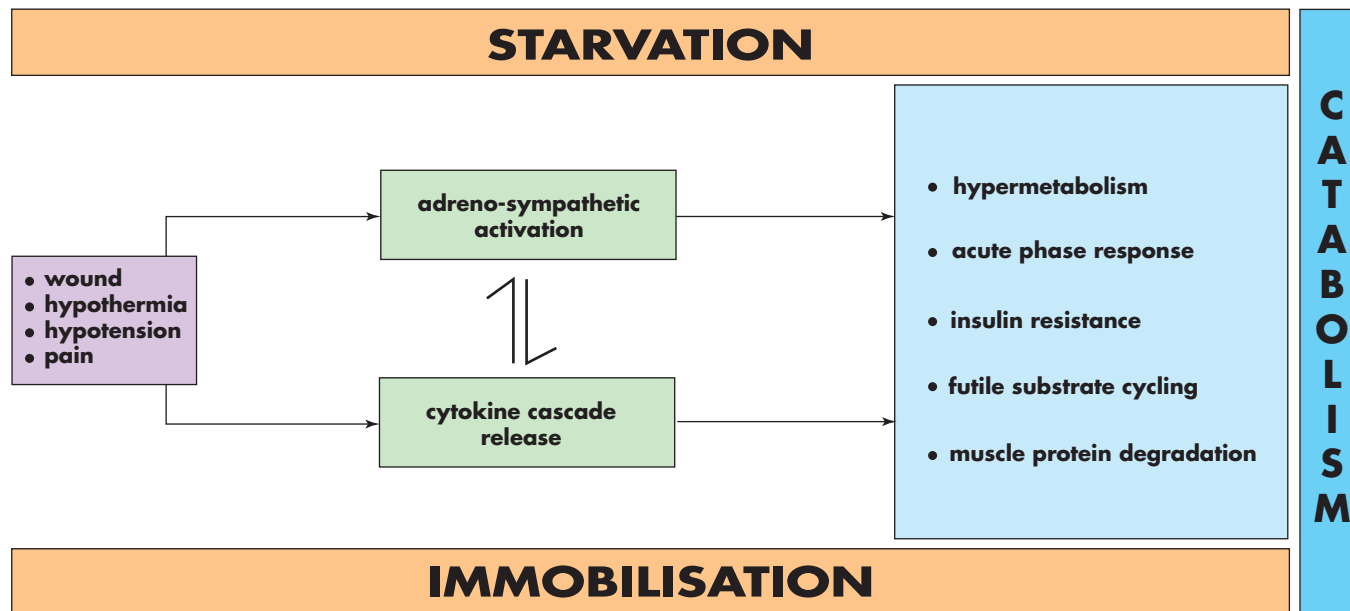

Figure 1.10 Factors that exacerbate the metabolic response to surgical injury include hypothermia, controlled pain, starvation, immobilisation, sepsis and medical complications.

Volume loss

During simple haemorrhage, pressor receptors in the carotid artery and aortic arch, and volume receptors in the wall of the left atrium, initiate afferent nerve input to the central nervous system (CNS), resulting in the release of both aldosterone and antidiuretic hormone (ADH). Pain can also stimulate ADH release. ADH acts directly on the kidney to cause fluid retention. Decreased pulse pressure stimulates the juxtaglomerular apparatus in the kidney and directly activates the renin-angiotensin system, which in turn increases aldosterone release.

Aldosterone causes the renal tubule to reabsorb sodium (and consequently also conserve water). ACTH release also augments the aldosterone response. The net effects of ADH and aldosterone result in the natural oliguria observed after surgery and conservation of sodium and water in the extracellular space. The tendency towards water and salt retention is exacerbated by resuscitation with saline-rich fluids. Salt and water retention can result in not only peripheral oedema, but also visceral oedema (e.g. stomach). Such visceral oedema has been associated with reduced gastric emptying, delayed resumption of food intake and prolonged hospital stay. Careful limitation of intraoperative administration of colloids and crystalloids (e.g. Hartmann's solution) so that there is no net weight gain following elective surgery has been proven to reduce postoperative complications and length of stay.

Hypothermia

Hypothermia results in increased elaboration of adrenal steroids and catecholamines. When compared with normothermic controls, even mild hypothermia results in a two- to threefold increase in postoperative cardiac arrhythmias and increased catabolism. Randomised trials have shown that maintaining normothermia by an upper body forced-air heating cover reduces wound infections, cardiac complications and bleeding and transfusion requirements.

Tissue oedema

During systemic inflammation, fluid, plasma proteins, leucocytes, macrophages and electrolytes leave the vascular space and accumulate in the tissues. This can diminish the alveolar diffusion of oxygen and may lead to reduced renal function. Increased capillary leak is mediated by a wide variety of mediators including cytokines, prostanooids, bradykinin and nitric oxide. Vasodilatation implies that intravascular volume decreases, which induces shock if inadequate resuscitation is not undertaken. Meanwhile, intracellular volume decreases, and this provides part of the volume necessary to replenish intravascular and extravascular extracellular volume.

Systemic inflammation and tissue underperfusion

The vascular endothelium controls vasomotor tone and microvascular flow, and regulates trafficking of nutrients and biologically active molecules. When endothelial activation is excessive, compromised microcirculation and subsequent cellular hypoxia contribute to the risk of organ failure. Maintaining

normoglycaemia with insulin infusion during critical illness has been proposed to protect the endothelium, probably in part, via inhibition of excessive iNOS-induced NO release, and thereby contribute to the prevention of organ failure and death. Administration of activated protein C to critically ill patients has been shown to reduce organ failure and death and is thought to act, in part, via preservation of the microcirculation in vital organs.

Starvation

During starvation, the body is faced with an obligate need to generate glucose to sustain cerebral energy metabolism (100 g of glucose day⁻¹). This is achieved in the first 24 hours by mobilising glycogen stores and thereafter by hepatic gluconeogenesis from amino acids, glycerol and lactate. The energy metabolism of other tissues is sustained by mobilising fat from adipose tissue. Such fat mobilisation is mainly dependent on a fall in circulating insulin levels. Eventually, accelerated loss of lean tissue (the main source of amino acids for hepatic gluconeogenesis) is reduced as a result of the liver converting free fatty acids into ketone bodies, which can serve as a substitute for glucose for cerebral energy metabolism. Provision of at least 2 litres of intravenous 5% dextrose as intravenous fluids for surgical patients who are fasted provides 100 g of glucose day⁻¹ and has a significant protein-sparing effect. Avoiding unnecessary fasting in the first instance and early oral/enteral/parenteral nutrition form the platform for avoiding loss of body mass as a result of the varying degrees of starvation observed in surgical patients.

Immobility

Immobility has long been recognised as a potent stimulus for inducing muscle wasting. Inactivity impairs the normal meal-derived amino acid stimulation of protein synthesis in skeletal muscle. Avoidance of unnecessary bed rest and active early mobilisation are essential measures to avoid muscle wasting as a consequence of immobility.

CONCEPTS BEHIND OPTIMAL PERIOPERATIVE CARE

Current understanding of the metabolic response to surgical injury and the mediators involved has led to a reappraisal of traditional perioperative care. There is now a strong scientific rationale for avoiding unmodulated exposure to stress, prolonged fasting and excessive administration of intravenous (saline) fluids. It is also important to realise that modulating the stress/inflammatory response at the time of surgery may have long-term sequelae over periods of months or longer. For example, β -blockers and statins have recently been shown to improve long-term survival after major surgery. It has been suggested that these effects may be due to suppression of innate immunity at the time of surgery. Equally, the use of epidural analgesia to reduce pain, block the cortisol stress response and attenuate postoperative insulin resistance may, via effects on the body's protein economy, favourably affects many of the patient-centred outcomes that are important to postoperative recovery but have largely been unmeasured to date, such as functional capacity, vitality and ability to return to work (Summary box 1.11).

Alexis Frank Hartmann, 1898–1964, Paediatrician, St. Louis, MO, USA.

Summary box 1.11

A proactive approach to prevent unnecessary aspects of the surgical stress response

- Minimal access techniques
- Blockade of afferent painful stimuli (e.g. epidural analgesia)
- Minimal periods of starvation
- Early mobilisation

Shock and blood transfusion

LEARNING OBJECTIVES

To understand:

- The pathophysiology of shock and ischaemia–reperfusion injury
- The different patterns of shock and the principles and priorities of resuscitation
- The appropriate monitoring and endpoints of resuscitation
- The use of blood and blood products and the benefits and risks of blood transfusion

INTRODUCTION

Shock is the most common and therefore the most important cause of death among surgical patients. Death may occur rapidly as a result of a profound state of shock or be delayed, resulting from the consequences of organ ischaemia and reperfusion injury. It is important, therefore, that every surgeon understands the pathophysiology and diagnosis of shock and haemorrhage, as well as the priorities for their management.

SHOCK

Shock is a systemic state of low tissue perfusion, which is inadequate for normal cellular respiration. With insufficient delivery of oxygen and glucose, cells switch from aerobic to anaerobic metabolism. If perfusion is not restored in a timely fashion, cell death ensues.

Pathophysiology

Cellular

As perfusion to the tissues is reduced, cells are deprived of oxygen and must switch from aerobic to anaerobic metabolism. The product of anaerobic respiration is not carbon dioxide but lactic acid. When enough tissue is underperfused, the accumulation of lactic acid in the blood produces systemic metabolic acidosis.

As glucose within cells is exhausted, anaerobic respiration ceases and there is failure of the sodium/potassium pumps in the cell membrane and intracellular organelles. Intracellular lysosomes release autodigestive enzymes and cell lysis ensues. Intracellular contents, including potassium, are released into the bloodstream.

Microvascular

As tissue ischaemia progresses, changes in the local milieu result in activation of the immune and coagulation systems. Hypoxia and acidosis activate complement and prime neutrophils, resulting in the generation of oxygen free radicals and cytokine release. These mechanisms lead to injury of the capillary endothelial cells.

These in turn further activate the immune and coagulation systems. Damaged endothelium loses its integrity and becomes 'leaky'. Spaces between endothelial cells allow fluid to leak out and tissue oedema ensues, exacerbating cellular hypoxia.

Systemic

Cardiovascular

As preload and afterload decrease there is a compensatory baroreceptor response resulting in increased sympathetic activity and release of catecholamines into the circulation. This results in tachycardia and systemic vasoconstriction (except in sepsis – see below).

Respiratory

The metabolic acidosis and increased sympathetic response result in an increased respiratory rate and minute ventilation to increase the excretion of carbon dioxide (and so produce a compensatory respiratory alkalosis).

Renal

Decreased perfusion pressure in the kidney leads to reduced filtration at the glomerulus and a decreased urine output. The renin–angiotensin–aldosterone axis is stimulated resulting in further vasoconstriction and increased sodium and water reabsorption by the kidney.

Endocrine

As well as activation of the adrenal and renin–angiotensin systems, vasopressin (antidiuretic hormone) is released from the hypothalamus in response to decreased preload and results in vasoconstriction and reabsorption of water in the renal collecting system. Cortisol is also released from the adrenal cortex, contributing to the sodium and water reabsorption and sensitising the cells to catecholamines.

Ischaemia–reperfusion syndrome

During the period of systemic hypoperfusion, cellular and organ damage progresses because of the direct effects of tissue hypoxia

and local activation of inflammation. Further injury occurs once normal circulation is restored to these tissues. The acid and potassium load that has built up can lead to direct myocardial depression, vascular dilatation and further hypotension. The cellular and humoral elements activated by the hypoxia (complement, neutrophils, microvascular thrombi) are flushed back into the circulation where they cause further endothelial injury to organs such as the lungs and kidneys. This leads to acute lung injury, acute renal injury, multiple organ failure and death. Reperfusion injury can currently only be attenuated by reducing the extent and duration of tissue hypoperfusion.

Classification of shock

There are numerous ways to classify shock but the most common and clinically applicable way is that based on the initiating mechanism (Summary box 2.1).

All states are characterised by systemic tissue hypoperfusion and different states may coexist within the same patient.

Summary box 2.1

Classification of shock

- Hypovolaemic
- Cardiogenic
- Obstructive
- Distributive
- Endocrine

Hypovolaemic shock

Hypovolaemic shock is caused by a reduced circulating volume. Hypovolaemia may be due to haemorrhagic or non-haemorrhagic causes. Non-haemorrhagic causes include poor fluid intake (dehydration) and excessive fluid loss because of vomiting, diarrhoea, urinary loss (e.g. diabetes), evaporation and 'third-spacing', in which fluid is lost into the gastrointestinal tract and interstitial spaces, as for example in bowel obstruction or pancreatitis.

Hypovolaemia is probably the most common form of shock and is to some degree a component of all other forms of shock. Absolute or relative hypovolaemia must be excluded or treated in the management of the shocked state, regardless of cause.

Cardiogenic shock

Cardiogenic shock is due to primary failure of the heart to pump blood to the tissues. Causes of cardiogenic shock include myocardial infarction, cardiac dysrhythmias, valvular heart disease, blunt myocardial injury and cardiomyopathy. Cardiac insufficiency may also be caused by myocardial depression resulting from

endogenous factors (e.g. bacterial and humoral agents released in sepsis) or exogenous factors, such as pharmaceutical agents or drug abuse. Evidence of venous hypertension with pulmonary or systemic oedema may coexist with the classic signs of shock.

Obstructive shock

In obstructive shock there is a reduction in preload because of mechanical obstruction of cardiac filling. Common causes of obstructive shock include cardiac tamponade, tension pneumothorax, massive pulmonary embolus and air embolus. In each case there is reduced filling of the left and/or right sides of the heart leading to reduced preload and a fall in cardiac output.

Distributive shock

Distributive shock describes the pattern of cardiovascular responses characterising a variety of conditions including septic shock, anaphylaxis and spinal cord injury. Inadequate organ perfusion is accompanied by vascular dilatation with hypotension, low systemic vascular resistance, inadequate afterload and a resulting abnormally high cardiac output.

In anaphylaxis, vasodilatation is caused by histamine release, whereas in high spinal cord injury there is failure of sympathetic outflow and adequate vascular tone (neurogenic shock). The cause in sepsis is less clear but is related to the release of bacterial products (endotoxins) and the activation of cellular and humoral components of the immune system. There is maldistribution of blood flow at a microvascular level with arteriovenous shunting and dysfunction of the cellular utilisation of oxygen.

In the later phases of septic shock there is hypovolaemia from fluid loss into the interstitial spaces and there may be concomitant myocardial depression, which complicates the clinical picture (Table 2.1).

Endocrine shock

Endocrine shock may present as a combination of hypovolaemic, cardiogenic and distributive shock. Causes of endocrine shock include hypo- and hyperthyroidism and adrenal insufficiency. Hypothyroidism causes a shock state similar to that of neurogenic shock as a result of disordered vascular and cardiac responsiveness to circulating catecholamines. Cardiac output falls because of low inotropy and bradycardia. There may also be an associated cardiomyopathy. Thyrotoxicosis may cause a high-output cardiac failure.

Adrenal insufficiency leads to shock as a result of hypovolaemia and a poor response to circulating and exogenous catecholamines. Adrenal insufficiency may result from pre-existing Addison's disease or it may be a relative insufficiency caused by a pathological disease state such as systemic sepsis.

Table 2.1 Cardiovascular and metabolic characteristics of shock

	Hypovolaemia	Cardiogenic	Obstructive	Distributive
Cardiac output	Low	Low	Low	High
Vascular resistance	High	High	High	Low
Venous pressure	Low	High	High	Low
Mixed venous saturation	Low	Low	Low	High
Base deficit	High	High	High	High

Thomas Addison, 1795–1860, Physician, Guy's Hospital, London, England, described the effects of disease of the suprarenal capsules in 1849.

Severity of shock

Compensated shock

As shock progresses the body's cardiovascular and endocrine compensatory responses reduce flow to non-essential organs to preserve preload and flow to the lungs and brain. In compensated shock there is adequate compensation to maintain the central blood volume and preserve flow to the kidneys, lungs and brain. Apart from a tachycardia and cool peripheries (vasoconstriction, circulating catecholamines) there may be no other clinical signs of hypovolaemia.

However, this cardiovascular state is only maintained by reducing perfusion to the skin, muscle and gastrointestinal tract. There is a systemic metabolic acidosis and activation of humoral and cellular elements within the underperfused organs. Although clinically occult, this state will lead to multiple organ failure and death if prolonged because of the ischaemia–reperfusion effect described above. Patients with occult hypoperfusion (metabolic acidosis despite normal urine output and cardiorespiratory vital signs) for more than 12 hours have a significantly higher mortality rate, infection rate and incidence of multiple organ failure (see below).

Decompensation

Further loss of circulating volume overloads the body's compensatory mechanisms and there is progressive renal, respiratory and cardiovascular decompensation. In general, loss of around 15% of the circulating blood volume is within normal compensatory mechanisms. Blood pressure is usually well maintained and only falls after 30–40% of the circulating volume has been lost.

Mild shock

Initially there is tachycardia, tachypnoea and a mild reduction in urine output and the patient may exhibit mild anxiety. Blood pressure is maintained although there is a decrease in pulse pressure. The peripheries are cool and sweaty with prolonged capillary refill times (except in septic distributive shock).

Moderate shock

As shock progresses, renal compensatory mechanisms fail, renal perfusion falls and urine output dips below $0.5 \text{ ml kg}^{-1} \text{ h}^{-1}$. There is further tachycardia and now the blood pressure starts to fall. Patients become drowsy and mildly confused.

Severe shock

In severe shock there is profound tachycardia and hypotension. Urine output falls to zero and patients are unconscious with laboured respiration.

Pitfalls

The classic cardiovascular responses described (Table 2.2) are not seen in every patient. It is important to recognise the limitations of the clinical examination and to recognise patients who are in shock despite the absence of classic signs.

Capillary refill

Most patients in hypovolaemic shock will have cool, pale peripheries with prolonged capillary refill times; however, the actual capillary refill time varies so much in adults that it is not a specific marker of whether a patient is shocked, and patients with short capillary refill times may be in the early stages of shock. In distributive (septic) shock the peripheries will be warm and capillary refill will be brisk despite profound shock.

Tachycardia

Tachycardia may not always accompany shock. Patients who are on β -blockers or who have implanted pacemakers are unable to mount a tachycardia. A pulse rate of 80 in a fit young adult who normally has a pulse rate of 50 is very abnormal. Furthermore, in some young patients with penetrating trauma, when there is haemorrhage but little tissue damage, there may be a paradoxical bradycardia rather than tachycardia accompanying the shocked state.

Blood pressure

It is important to recognise that hypotension is one of the last signs of shock. Children and fit young adults are able to maintain blood pressure until the final stages of shock by dramatic increases in stroke volume and peripheral vasoconstriction. These patients can be in profound shock with a normal blood pressure.

Elderly patients who are normally hypertensive may present with a 'normal' blood pressure for the general population but be hypovolaemic and hypotensive relative to their usual blood pressure. β -Blockers or other medications may prevent a tachycardic response. The diagnosis of shock may be difficult unless one is alert to these pitfalls.

Consequences

Unresuscitable shock

Patients who are in profound shock for a prolonged period of time become 'unresuscitable'. Cell death follows from cellular ischaemia, and the ability of the body to compensate is lost. There is myocardial depression and loss of responsiveness to fluid or inotropic therapy. Peripherally there is loss of the ability to maintain systemic vascular resistance and further hypotension ensues. The peripheries no longer respond appropriately to vasoconstrictor agents. Death is the inevitable result.

Table 2.2 Clinical features of shock

	Compensated	Mild	Moderate	Severe
Lactic acidosis	+	++	++	+++
Urine output	Normal	Normal	Reduced	Anuric
Level of consciousness	Normal	Mild anxiety	Drowsy	Comatose
Respiratory rate	Normal	Increased	Increased	Laboured
Pulse rate	Mild increase	Increased	Increased	Increased
Blood pressure	Normal	Normal	Mild hypotension	Severe hypotension

This stage of shock is the combined result of the severity of the insult and delayed, inadequate or inappropriate resuscitation in the earlier stages of shock. When patients present in this late stage and have minimal responses to maximal therapy it is important that the futility of treatment is recognised and that valuable resources are not wasted.

Multiple organ failure

As techniques of resuscitation have improved, more and more patients are surviving shock. When intervention is timely and the period of shock is limited, patients may make a rapid, uncomplicated recovery; however, the result of prolonged systemic ischaemia and reperfusion injury is end-organ damage and multiple organ failure.

Multiple organ failure is defined as two or more failed organ systems (Table 2.3). There is no specific treatment for multiple organ failure. Management is by supporting organ systems with ventilation, cardiovascular support and haemofiltration/dialysis until there is recovery of organ function. Multiple organ failure currently carries a mortality rate of 60%. Thus, prevention is vital by early aggressive identification and reversal of shock.

Table 2.3 Effects of organ failure

Lung	Acute respiratory distress syndrome
Kidney	Acute renal insufficiency
Liver	Acute liver insufficiency
Clotting	Coagulopathy
Cardiac	Cardiovascular failure

RESUSCITATION

Immediate resuscitation manoeuvres for patients presenting in shock are to ensure a patent airway and adequate oxygenation and ventilation. Once 'airway' and 'breathing' are assessed and controlled, attention is directed to cardiovascular resuscitation.

Conduct of resuscitation

Resuscitation should not be delayed in order to definitively diagnose the source of the shocked state; however, the timing and nature of resuscitation will depend on the type of shock and the timing and severity of the insult. Rapid clinical examination will provide adequate clues to make an appropriate first determination, even if a source of bleeding or sepsis is not immediately identifiable. If there is initial doubt about the cause of shock it is safer to assume the cause is hypovolaemia and begin with fluid resuscitation, followed by an assessment of the response.

In patients who are actively bleeding (major trauma, aortic aneurysm rupture, gastrointestinal haemorrhage) it is counter-productive to institute high-volume fluid therapy without controlling the site of haemorrhage. Increasing blood pressure merely increases bleeding from the site, and fluid therapy cools the patient and dilutes available coagulation factors. Thus, operative haemorrhage control should not be delayed and resuscitation should proceed in parallel with surgery.

Conversely, a patient with bowel obstruction and hypovolaemic shock must be adequately resuscitated before undergoing surgery otherwise the additional surgical injury and hypovolaemia induced during the procedure will exacerbate the inflammatory activation and increase the incidence and severity of end-organ insult.

Fluid therapy

In all cases of shock, regardless of classification, hypovolaemia and inadequate preload must be addressed before other therapy is instituted. Administration of inotropic or chronotropic agents to an empty heart will rapidly and permanently deplete the myocardium of oxygen stores and dramatically reduce diastolic filling and therefore coronary perfusion. Patients will enter the unresuscitatable stage of shock as the myocardium becomes progressively more ischaemic and unresponsive to resuscitative attempts.

First-line therapy, therefore, is intravenous access and administration of intravenous fluids. Access should be through short, wide-bore catheters that allow rapid infusion of fluids as necessary. Long, narrow lines such as central venous catheters have too high a resistance to allow rapid infusion and are more appropriate for monitoring than fluid replacement therapy.

Type of fluids

There is continuing debate over which resuscitation fluid is best for the management of shock. There is no ideal resuscitation fluid and it is more important to understand how and when to administer them. In most studies of shock resuscitation there is no overt difference in response or outcome between crystalloid solutions (normal saline, Hartmann's solution, Ringer's lactate) and colloids (albumin or commercially available products). Further, there is less volume benefit to the administration of colloids than had previously been thought, with only 1.3 times more crystalloid than colloid administered in blinded trials. On balance there is little evidence to support the administration of colloids, which are more expensive and have worse side-effect profiles.

Most importantly, the oxygen-carrying capacity of crystalloids and colloids is zero. If blood is being lost, the ideal replacement fluid is blood, although crystalloid therapy may be required while awaiting blood products.

Hypotonic solutions (e.g. dextrose) are poor volume expanders and should not be used in the treatment of shock unless the deficit is free water loss (e.g. diabetes insipidus) or patients are sodium overloaded (e.g. cirrhosis).

Dynamic fluid response

The shock status can be determined dynamically by the cardiovascular response to the rapid administration of a fluid bolus. In total, 250–500 ml of fluid is rapidly given (over 5–10 min) and the cardiovascular responses in terms of heart rate, blood pressure and central venous pressure (CVP) are observed. Patients can be divided into 'responders', 'transient responders' and 'non-responders'.

Responders show an improvement in their cardiovascular status, which is sustained. These patients are not actively losing fluid but require filling to a normal volume status.

Transient responders show an improvement but then revert to their previous state over the next 10–20 min. These patients either have moderate on-going fluid losses (either overt haemorrhage or further fluid shifts reducing intravascular volume).

Non-responders are severely volume depleted and are likely to have major on-going loss of intravascular volume, usually through persistent uncontrolled haemorrhage.

Alexis Frank Hartmann, 1898–1964, Paediatrician, St. Louis, MO, USA.
Sydney Ringer, 1835–1910, Professor of Clinical Medicine, University College Hospital, London, England.

Vasopressor and inotropic support

Vasopressor or inotropic therapy is not indicated as first-line therapy in hypovolaemia. As discussed above, administration of these agents in the absence of an adequate preload rapidly leads to decreased coronary perfusion and depletion of myocardial oxygen reserves.

Vasopressor agents (phenylephrine, noradrenaline) are indicated in distributive shock states (sepsis, neurogenic shock), in which there is peripheral vasodilatation and a low systemic vascular resistance, leading to hypotension despite a high cardiac output. When the vasodilatation is resistant to catecholamines (e.g. absolute or relative steroid deficiency), vasopressin may be used as an alternative vasopressor.

In cardiogenic shock or when myocardial depression complicates a shock state (e.g. severe septic shock with low cardiac output), inotropic therapy may be required to increase cardiac output and, therefore, oxygen delivery. The inodilator dobutamine is the agent of choice.

Monitoring

The *minimum* standard for monitoring of the patient in shock is continuous heart rate and oxygen saturation monitoring, frequent non-invasive blood pressure monitoring and hourly urine output measurements. Most patients will need more aggressive invasive monitoring including CVP and invasive blood pressure monitoring (Summary box 2.2).

Summary box 2.2

Monitoring for patients in shock

Minimum

- Electrocardiogram
- Pulse oximetry
- Blood pressure
- Urine output

Additional modalities

- Central venous pressure
- Invasive blood pressure
- Cardiac output
- Base deficit and serum lactate

Cardiovascular

As a minimum, cardiovascular monitoring should include continuous heart rate [electrocardiogram (ECG)], oxygen saturation and pulse waveform and non-invasive blood pressure. Patients

whose state of shock is not rapidly corrected with a small amount of fluid should have CVP monitoring and continuous blood pressure monitoring through an arterial line.

Central venous pressure

There is no 'normal' CVP for a shocked patient, and reliance cannot be placed on an individual pressure measurement to assess volume status. Some patients may require a CVP of 5 cmH₂O, whereas others may require a CVP of 15 cmH₂O or higher. Further, ventricular compliance can change from minute to minute in the shocked state, and CVP is a poor reflection of end-diastolic volume (preload).

CVP measurements should be assessed dynamically as the response to a fluid challenge (see above). A fluid bolus (250–500 ml) is infused rapidly over 5–10 min. The normal CVP response is a rise of 2–5 cmH₂O, which gradually drifts back to the original level over 10–20 min. Patients with no change in their CVP are empty and require further fluid resuscitation. Patients with a large, sustained rise in CVP have high preload and an element of cardiac insufficiency or volume overload.

Cardiac output

Cardiac output monitoring allows an assessment of not only the cardiac output but also the systemic vascular resistance and, depending on the technique used, end-diastolic volume (preload) and blood volume. Invasive cardiac monitoring using pulmonary artery catheters is becoming less frequent as new non-invasive monitoring techniques such as Doppler ultrasound, pulse waveform analysis and indicator dilution methods provide similar information without many of the drawbacks of more invasive techniques.

Measurement of cardiac output, systemic vascular resistance and preload can help distinguish the types of shock that are present (hypovolaemia, distributive, cardiogenic), especially when they coexist. The information provided guides fluid and vasopressor therapy by providing real-time monitoring of the cardiovascular response.

Measurement of cardiac output is desirable in patients who do not respond as expected to first-line therapy or who have evidence of cardiogenic shock or myocardial dysfunction. Early consideration should be given to instituting cardiac output monitoring in patients who require vasopressor or inotropic support.

Systemic and organ perfusion

Ultimately, the goal of treatment is to restore cellular and organ perfusion. Ideally, therefore, monitoring of organ perfusion should guide the management of shock (Table 2.4). The best measures of

Table 2.4 Monitors for organ/systemic perfusion

	Clinical	Investigational
Systemic perfusion	Base deficit; lactate; mixed venous oxygen saturation	
Organ perfusion		
Muscle	–	Near-infrared spectroscopy; tissue oxygen electrode
Gut	–	Sublingual capnometry; gut mucosal pH; laser Doppler flowmetry
Kidney	Urine output	–
Brain	Level of consciousness	Tissue oxygen electrode; near-infrared spectroscopy

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler Principle' in 1842.

organ perfusion and the best monitor of the adequacy of shock therapy remain the urine output; however, this is an hourly measure and does not give a minute-to-minute view of the shocked state. The level of consciousness is an important marker of cerebral perfusion, but brain perfusion is maintained until the very late stages of shock and, hence, is a poor marker of adequacy of resuscitation.

Currently, the only clinical indicators of perfusion of the gastrointestinal tract and muscular beds are the global measures of lactic acidosis (lactate and base deficit) and the mixed venous oxygen saturation.

Base deficit and lactate

Lactic acid is generated by cells undergoing anaerobic respiration. The degree of lactic acidosis, as measured by the serum lactate level and/or the base deficit, is a sensitive tool for both the diagnosis of shock and the monitoring of the response to therapy. Patients with a base deficit of over 6 mmol l^{-1} have much higher morbidity and mortality rates than those with no metabolic acidosis. Further, the duration of time in shock with an increased base deficit is important, even if all other vital signs have returned to normal (occult hypoperfusion – see below).

These parameters are measured from arterial blood gas analyses and, therefore, the frequency of measurements is limited and they do not provide minute-to-minute data on systemic perfusion or the response to therapy. Nevertheless, the base deficit and/or lactate should be measured routinely in these patients until they have returned to normal levels.

Mixed venous oxygen saturation

The percentage saturation of oxygen returning to the heart from the body is a measure of the oxygen delivery and extraction by the tissues. Accurate measurement is via analysis of blood drawn from a long central line placed in the right atrium. Estimations can be made from blood drawn from lines in the superior vena cava but these values will be slightly higher than those of a mixed venous sample (as there is relatively more oxygen extraction from the lower half of the body). Normal mixed venous oxygen saturation levels are 50–70%. Levels below 50% indicate inadequate oxygen delivery and increased oxygen extraction by the cells. This is consistent with hypovolaemic or cardiogenic shock.

High mixed venous saturation levels (>70%) are seen in sepsis and some other forms of distributive shock. In sepsis there is disordered utilisation of oxygen at the cellular level and arteriovenous shunting of blood at the microvascular level. Thus, less oxygen is presented to the cells, cells cannot utilise what little oxygen is presented and venous blood has a higher oxygen concentration than normal.

Patients who are septic should, therefore, have mixed venous oxygen saturation levels of >70%. Levels lower than this indicate that the patient is not only in septic shock but also in hypovolaemic or cardiogenic shock. Although the mixed venous oxygen saturation level is in the ‘normal’ range, it is low for the septic state and inadequate oxygen is being supplied to cells that cannot utilise oxygen appropriately. This must be corrected rapidly. Hypovolaemia should be corrected with fluid therapy and low cardiac output caused by myocardial depression or failure should be treated with inotropes (dobutamine) to achieve a mixed venous saturation level of >70% (normal for the septic state).

New methods for monitoring regional tissue perfusion and oxygenation are becoming available, the most promising of which are muscle tissue oxygen probes, near-infrared spectroscopy and sublingual capnometry. Although these techniques provide information regarding perfusion of specific tissue beds, it is as yet unclear whether there are significant advantages over existing measurements of global hypoperfusion (base deficit, lactate).

Endpoints of resuscitation

It is much easier to know when to start resuscitation than when to stop. Traditionally patients have been resuscitated until they have a normal pulse, blood pressure and urine output; however, these parameters are monitoring organ systems whose blood flow is preserved until the late stages of shock. Therefore, a patient may be resuscitated to restore central perfusion to the brain, lungs and kidneys and yet the gut and muscle beds continue to be underperfused. Thus, activation of inflammation and coagulation may be on-going and, when these organs are finally perfused, it may lead to reperfusion injury and ultimately multiple organ failure.

This state of normal vital signs and continued underperfusion is termed occult hypoperfusion (OH). With current monitoring techniques it is manifested only by a persistent lactic acidosis and low mixed venous oxygen saturation level. The duration that patients spend in this hypoperfused state has a dramatic effect on outcome. Patients with OH for more than 12 hours have a two to three times higher mortality rate than that of patients with a limited duration of shock.

Resuscitation algorithms directed at correcting global perfusion endpoints (base deficit, lactate, mixed venous oxygen saturation) rather than traditional endpoints have been shown to improve mortality and morbidity in high-risk surgical patients; however, it is clear that, despite aggressive regimens, some patients cannot be resuscitated to normal parameters within 12 hours by fluid resuscitation alone. More research is under way to identify the pathophysiology behind this and investigate new therapeutic options.

HAEMORRHAGE

Haemorrhage must be recognised and managed aggressively to reduce the severity and duration of shock and avoid death and/or multiple organ failure. Haemorrhage is treated by arresting the bleeding, and not by fluid resuscitation or blood transfusion. Although necessary as supportive measures to maintain organ perfusion, attempting to resuscitate patients who have on-going haemorrhage will lead to physiological exhaustion (coagulopathy, acidosis and hypothermia) and subsequently death.

Pathophysiology

Haemorrhage leads to a state of hypovolaemic shock. As discussed above, this hypoperfused state results in cellular anaerobic metabolism and lactic acidosis. This acidosis leads to decreased function of the coagulation proteases, resulting in coagulopathy and further haemorrhage. This is exacerbated by ischaemic endothelial cells activating anti-coagulant pathways. Additionally, there is reduced perfusion to tissues, and the blood supply to the gut and muscle beds is reduced early in the compensatory process. Underperfused muscle is unable to generate heat and hypothermia ensues. Coagulation functions poorly at low temperatures and there is further haemorrhage, further hypoperfusion

and worsening acidosis and hypothermia. These three factors result in a downward spiral leading to physiological exhaustion and death (Fig. 2.1).

Medical therapy has a tendency to worsen this effect. Intravenous blood and fluids are cold and exacerbate hypothermia. Further heat is lost by opening body cavities during surgery. Surgery usually leads to further bleeding and many crystalloid fluids are themselves acidic (e.g. normal saline has a pH of 6.7).

Every effort must therefore be made to rapidly identify and stop haemorrhage and to avoid (preferably) or limit physiological exhaustion from coagulopathy, acidosis and hypothermia.

Definitions

Revealed and concealed haemorrhage

Haemorrhage may be revealed or concealed. Revealed haemorrhage is obvious external haemorrhage, such as exsanguination from an open arterial wound or from massive haematemesis from a duodenal ulcer.

Concealed haemorrhage is contained within the body cavity and must be suspected, actively investigated and controlled. In trauma, haemorrhage may be concealed within the chest, abdomen, pelvis or retroperitoneum or in the limbs, with contained vascular injury or associated with long-bone fractures. Examples of non-traumatic concealed haemorrhage include occult gastrointestinal bleeding or ruptured aortic aneurysm.

Primary, reactionary and secondary haemorrhage

Primary haemorrhage is haemorrhage occurring immediately as a result of an injury (or surgery). Reactionary haemorrhage is delayed haemorrhage (within 24 hours) and is usually caused by dislodgement of clot by resuscitation, normalisation of blood pressure and vasodilatation. Reactionary haemorrhage may also result from technical failure such as slippage of a ligature.

Secondary haemorrhage is caused by sloughing of the wall of a vessel. It usually occurs 7–14 days after injury and is precipitated by factors such as infection, pressure necrosis (such as from a drain) or malignancy.

Surgical and non-surgical haemorrhage

Surgical haemorrhage is the result of a direct injury and is amenable to surgical control (or other techniques such as angioembolisation). Non-surgical haemorrhage is the general

Figure 2.1 Physiological exhaustion: the triad of death.

ooze from all raw surfaces due to coagulopathy; it cannot be stopped by surgical means (except packing) but requires correction of the coagulation abnormalities.

Degree and classification

The adult human has approximately 5 litres of blood (70 ml kg⁻¹ children and adults, 80 ml kg⁻¹ neonates). Estimation of the amount of blood that has been lost is difficult and inaccurate and is usually an underestimation of the actual value.

External haemorrhage is obvious but it may be difficult to estimate the actual volume lost. In the operating room, blood collected in suction apparatus can be measured and swabs soaked in blood weighed.

The haemoglobin level is a poor indicator of the degree of haemorrhage as it represents a concentration and not an absolute amount. In the early stages of rapid haemorrhage, the haemoglobin concentration is unchanged (as whole blood is lost). Later, as fluid shifts from the intracellular and interstitial spaces into the vascular compartment, the haemoglobin and haematocrit levels will fall.

The degree of haemorrhage can be classified into classes 1–4 based on the estimated blood loss required to produce certain physiological compensatory changes (Table 2.5). Although conceptually useful there is variation across ages (the young compensate well, the old very poorly), between individuals (athletes vs. the obese) and because of confounding factors (e.g. concomitant medications, pain).

Treatment should therefore be based upon the degree of hypovolaemic shock according to vital signs, preload assessment, base deficit and, most importantly, the dynamic response to fluid therapy. Patients who are non-responders or transient responders are still bleeding and must have the site of haemorrhage identified and controlled.

Table 2.5 Traditional classification of haemorrhagic shock

	Class			
	1	2	3	4
Blood volume lost as percentage of total	< 15%	15–30%	30–40%	> 40%

Management

Identify haemorrhage

External haemorrhage may be obvious but the diagnosis of concealed haemorrhage may be more difficult. Any shock should be assumed to be hypovolaemic until proved otherwise and, similarly, hypovolaemia should be assumed to be due to haemorrhage until this has been excluded.

Immediate resuscitative manoeuvres

Direct pressure should be placed over the site of external haemorrhage. Airway and breathing should be assessed and controlled as necessary. Large-bore intravenous access should be instituted and blood drawn for cross-matching (see below). Emergency blood should be requested if the degree of shock and on-going haemorrhage warrants this.

Identify the site of haemorrhage

Once haemorrhage has been considered, the site of haemorrhage must be rapidly identified. Note that this is not to definitively

identify the exact location but rather to define the next step in haemorrhage control (operation, angioembolisation, endoscopic control).

Clues may be in the history (previous episodes; known aneurysm; non-steroidal therapy for gastrointestinal bleeding) or examination (nature of blood: fresh, melaena; abdominal tenderness; etc.). For shocked trauma patients the external signs of injury may suggest internal haemorrhage, but cavitory haemorrhage must be excluded with rapid investigations (chest and pelvic radiography, abdominal ultrasound or diagnostic peritoneal aspiration).

Investigations for blood loss must be appropriate to the patient's physiological condition. Rapid bedside tests are more appropriate for profound shock and exsanguinating haemorrhage than investigations such as computerised tomography, which takes a long time and for which patient monitoring and treatment are difficult. Patients who are not actively bleeding can have a more methodical, definitive work-up.

Haemorrhage control

The bleeding, shocked patient must be moved rapidly to a place of haemorrhage control. This will usually be in the operating room but may be in other areas of the hospital such as the angiography or endoscopy suites. These patients require full surgical and anaesthetic support and full monitoring, and equipment must be available for their care.

Control must be achieved rapidly to prevent the patient entering the triad of coagulopathy–acidosis–hypothermia and becoming physiologically exhausted. There should be no unnecessary investigations or procedures before haemorrhage control, to minimise the duration and severity of shock. This includes prolonged attempts to volume-resuscitate the patient before surgery, which will result in further hypothermia and clotting factor dilution until the bleeding is stopped. Attention should be paid to correction of coagulopathy with blood component therapy to aid surgical haemorrhage control.

Surgery may need to be limited to the minimum necessary to stop bleeding and control sepsis. More definitive repairs can be delayed until the patient is physiologically capable of sustaining the procedure. This concept of tailoring the operation to match the patient's physiology and staged procedures to prevent physiological exhaustion is called 'damage control surgery'; this is a term borrowed from the military whereby the continued functioning of a damaged ship is ensured above conducting complete repairs, which would prevent a rapid return to battle.

Once haemorrhage is controlled, patients should be aggressively resuscitated and warmed and coagulopathy corrected. Attention should be paid to fluid responsiveness and the end-points of resuscitation to ensure that patients are fully resuscitated and to reduce the incidence and severity of organ failure (Summary box 2.3).

Summary box 2.3

Damage control surgery

- Arrest haemorrhage
- Control sepsis
- Protect from further injury
- Nothing else

TRANSFUSION

The transfusion of blood and blood products has become commonplace since the first successful transfusion in 1829 (Table 2.6). Although the incidence of severe transfusion reactions and infections is now very low, in recent years it has become apparent that there is an immunological price to be paid for the transfusion of heterologous blood, which leads to increased morbidity and decreased survival in certain population groups (trauma, malignancy). Supplies are also limited and, therefore, the use of blood and blood products must always be judicious and justifiable in terms of clinical need.

Blood and blood products

Blood is collected from donors who have been previously screened to exclude any donor whose blood may have the potential to harm the patient or to prevent possible harm that donating a unit of blood may have on the donor. In the UK, up to 450 ml of blood is drawn, a maximum of three times a year. Each unit is tested for evidence of hepatitis B, hepatitis C, human immunodeficiency virus (HIV)-1, HIV-2 and syphilis. Donations are leucodepleted as a precaution against variant Creutzfeldt–Jakob disease (this may also reduce the immunogenicity of the transfusion). The ABO and Rhesus D blood group is determined, as well as the presence of irregular red cell antibodies. The blood is then processed into sub-components.

Whole blood

Whole blood is now rarely available in civilian practice as it is an ineffective use of the limited resource; however, whole blood

Table 2.6 History of blood transfusion

1492	Pope Innocent VIII suffers a stroke and is made to drink blood from three 10-year-old boys (paid a ducat each). All three boys died, as did the pope later that year
1665	Richard Lower in Oxford conducts the first successful canine transfusions
1667	Jean-Baptiste Denis reports successful sheep–human transfusions
1670	Animal–human transfusions are banned in France because of the poor results
1829	James Blundell performs the first successful documented human transfusion in a woman suffering post-partum haemorrhage.
1900	Karl Landsteiner discovers the ABO system
1914	The Belgian physician Albert Hustin performs the first non-direct transfusion, using sodium citrate as an anti-coagulant
1926	The British Red Cross institutes the first blood transfusion service in the world
1939	The Rhesus system is identified and recognised as the major cause of transfusion reactions

Hans Gerhard Creutzfeldt, 1885–1946, Neurologist, Kiel, Germany.
Alfons Maria Jakob, 1884–1931, Neurologist, Hamburg, Germany.

transfusion has significant advantages over packed cells as it is coagulation factor rich and, if fresh, more metabolically active than stored blood.

Packed red cells

Packed red blood cells are cells that are spun down and concentrated. Each unit is approximately 330 ml and has a haematocrit of 50–70%. Packed cells are stored in a SAG-M solution (saline–adenine–glucose–mannitol) to increase their shelf-life to 5 weeks at 2–6°C. (Older storage regimens included storage in CPD – citrate–phosphate–dextrose solutions – giving cells a shelf-life of 2–3 weeks).

Fresh-frozen plasma

Fresh-frozen plasma (FFP) is rich in coagulation factors; it is removed from fresh blood and stored at –40 to –50°C with a 2-year shelf-life. It is the first-line therapy in the treatment of coagulopathic haemorrhage (see below). Rhesus D-positive FFP may be given to a Rhesus D-negative woman.

Cryoprecipitate

Cryoprecipitate is a supernatant precipitate of FFP and is rich in factor VIII and fibrinogen. It is stored at –30°C with a 2-year shelf-life. It is given in low-fibrinogen states or in cases of factor VIII deficiency.

Platelets

Platelets are supplied as a pooled platelet concentrate containing about 250×10^9 cells per litre. Platelets are stored on a special agitator at 20–24°C and have a shelf-life of only 5 days. Platelet transfusions are given to patients with thrombocytopenia or with platelet dysfunction who are bleeding or undergoing surgery.

Patients are increasingly presenting on anti-platelet therapy such as aspirin or clopidogrel for reduction of cardiovascular risk. Aspirin therapy rarely poses a problem but control of haemorrhage on the more potent platelet inhibitors can be extremely difficult. Patients on clopidogrel who are actively bleeding and undergoing major surgery may require almost continuous infusion of platelets during the course of the procedure. Arginine vasopressin or its analogues [e.g. desmopressin acetate (DDAVP)] have also been used in this patient group, although with limited success.

Prothrombin complex concentrates

Prothrombin complex concentrates (PCCs) are highly purified concentrates prepared from pooled plasma. They contain factors II, IX and X; factor VII may be included or produced separately. PCCs are indicated for the emergency reversal of anti-coagulant (warfarin) therapy in uncontrolled haemorrhage.

Autologous blood

It is possible for patients undergoing elective surgery to pre-donate their own blood up to 3 weeks before surgery for retransfusion during the operation. Similarly, during surgery blood can be collected in a cell saver; this washes and collects red blood cells, which can then be returned to the patient.

Indications for blood transfusion

Blood transfusions should be avoided if possible and many previous uses of blood and blood products are now no longer

considered appropriate. The indications for blood transfusion are as follows:

- acute blood loss, to replace circulating volume and maintain oxygen delivery;
- perioperative anaemia, to ensure adequate oxygen delivery during the perioperative phase;
- symptomatic chronic anaemia without haemorrhage or impending surgery.

Transfusion trigger

Historically, patients were transfused to achieve a haemoglobin level of $> 10 \text{ g dl}^{-1}$. This has now been shown to be not only unnecessary but also associated with increased morbidity and mortality compared with lower target values. A haemoglobin level of 6 g dl^{-1} is acceptable in patients who are not bleeding, not about to undergo major surgery and not symptomatic (Table 2.7). There is some controversy as to the optimal haemoglobin level in some patient groups such as those with cardiovascular disease, sepsis and traumatic brain injury. Although conceptually a higher haemoglobin level improves oxygen delivery, there is little clinical evidence at this stage to support higher levels in these groups.

Blood groups and cross-matching

Human red blood cells have many different antigens on their cell surface. Two groups of antigens are of major importance in surgical practice – the ABO and Rhesus systems.

ABO system

These are strongly antigenic and are associated with naturally occurring antibodies in the serum. The system consists of three allelic genes – A, B and O – which control the synthesis of enzymes that add carbohydrate residues to cell surface glycoproteins. Expression of the A and B genes results in specific residues being added whereas the O gene is an amorph and does not transform the glycoprotein.

The system allows for six possible genotypes although there are only four phenotypes (Table 2.8). Naturally occurring antibodies are found in the serum of those lacking the corresponding antigen. Blood group O is the universal donor type as it contains no antigens to provoke a reaction. Conversely, group AB individuals are ‘universal recipients’ and can receive any ABO blood type as they have no circulating antibodies.

Rhesus system

The Rhesus D [Rh(D)] antigen is strongly antigenic and is present in approximately 85% of the population in the UK. Antibodies to the D antigen are not naturally present in the serum of the remaining 15% of individuals but their formation may be stimulated by the transfusion of Rh-positive red cells or they may be acquired during delivery of a Rh(D)-positive baby.

Table 2.7 Perioperative red blood cell transfusion criteria

Haemoglobin level (g dl^{-1})	Indication
<6	Probably will benefit from transfusion
6–8	Transfusion unlikely to be of benefit in the absence of bleeding or impending surgery
>8	No indication for transfusion

Table 2.8 ABO blood group system

Phenotype	Genotype	Antigens	Antibodies	Frequency (%)
O	OO	O	Anti-A, Anti-B	46
A	AA or AO	A	Anti-B	42
B	BB or BO	B	Anti-A	9
AB	AB	AB	None	3

Acquired antibodies are capable of crossing the placenta during pregnancy and, if present in a Rh(D)-negative mother, they may cause severe haemolytic anaemia and even death (hydrops fetalis) in a Rh(D)-positive fetus *in utero*.

The other minor blood group antigens may be associated with naturally occurring antibodies or they may stimulate the formation of antibodies on relatively rare occasions.

Transfusion reactions

If antibodies present in the recipient's serum are incompatible with the donor's cells, a transfusion reaction will result. This usually takes the form of an acute haemolytic reaction. Severe immune-related transfusion reactions caused by ABO incompatibility result in severe and potentially fatal complement-mediated intravascular haemolysis and multiple organ failure. Transfusion reactions from other antigen systems are usually milder and self-limiting.

Febrile transfusion reactions are non-haemolytic and are usually caused by a graft-versus-host response from leucocytes in transfused components. There is fever, chills or rigors. The blood transfusion should be stopped immediately. This form of transfusion reaction is rare with leuco-depleted blood.

Cross-matching

To prevent transfusion reactions, all transfusions are preceded by ABO and Rhesus typing of both donor and recipient blood to ensure compatibility. The recipient's serum is then mixed with the donor's cells to confirm ABO compatibility and to test for Rhesus and any other blood group antigen-antibody reactions.

Full cross-matching of blood takes 45 min in most laboratories. In more urgent situations, 'type-specific' blood is provided, which is only ABO/Rhesus matched and can be issued within 10–15 min. When blood must be given in an emergency, group O (universal donor) blood is given (O⁻ to female patients, O⁺ to male patients).

When prescribing and administering blood it is essential that the correct patient receives the correct transfusion. Two individuals should check the patient details against the prescription and the label of the donor blood. Additionally, the donor blood serial number should also be checked against the issue slip for that patient. Provided that these principles are strictly adhered to the number of severe and fatal ABO incompatibility reactions can be minimised.

Complications of blood transfusion

Complications from blood transfusion can be categorised as those arising from a single transfusion and those related to massive transfusion.

Complications from a single transfusion

Complications from a single transfusion include:

- incompatibility haemolytic transfusion reaction;
- febrile transfusion reaction;

- allergic reaction;
- infection:
 - bacterial infection (usually as a result of faulty storage);
 - hepatitis;
 - HIV;
 - malaria;
- air embolism;
- thrombophlebitis;
- transfusion-related acute lung injury (usually from FFP).

Complications from massive transfusion

Complications from massive transfusion include:

- coagulopathy;
- hypocalcaemia;
- hyperkalaemia;
- hypokalaemia;
- hypothermia.

Additionally, patients who receive repeated transfusions over long periods of time (e.g. patients with thalassaemia) may develop iron overload. (Each transfused unit of red blood cells contains approximately 250 mg of elemental iron.)

Management of coagulopathy

Correction of coagulopathy is not necessary if there is no active bleeding or haemorrhage is not anticipated (no impending surgery); however, coagulopathy following or during massive transfusion should be anticipated and managed aggressively. Standard guidelines are as follows:

- FFP if prothrombin time (PT) or partial thromboplastin time (PTT) $> 1.5 \times$ normal;
- cryoprecipitate if fibrinogen $< 0.8 \text{ g l}^{-1}$;
- platelets if platelet count $< 50 \times 10^9 \text{ ml}^{-1}$.

However, in the presence of non-surgical haemorrhage these tests take time to arrange and they may underestimate the degree of coagulopathy. Treatment should then be instituted on the basis of clinical evidence of non-surgical bleeding.

There are pharmacological adjuncts to blood component therapy, although their indications and efficacy are yet to be established. Anti-fibrinolytics such as tranexamic acid and aprotinin are the most commonly administered. Recombinant factor VIIa is also under investigation for the treatment of non-surgical haemorrhage.

Blood substitutes

Blood substitutes are an attractive alternative to the costly process of donating, checking, storing and administering blood, and they may avoid the immunogenic and potential infectious complications associated with transfusion.

There are several oxygen-carrying blood substitutes under investigation in animal or early clinical trials. Blood substitutes

are either biomimetic or abiotic. Biomimetic substitutes mimic the standard oxygen-carrying capacity of the blood and are haemoglobin based. Abiotic substitutes are synthetic oxygen carriers and are currently primarily perfluorocarbon based.

Haemoglobin is seen as the obvious candidate for developing an effective blood substitute. Various engineered molecules are under clinical trial, based on human, bovine or recombinant technologies. Second-generation perfluorocarbon emulsions are also showing potential in clinical trials.

Wounds, tissue repair and scars

CHAPTER 3

LEARNING OBJECTIVES

To understand:

- Normal healing and how it can be adversely affected
- How to manage wounds of different types, of different structures and at different sites
- Aspects of disordered healing which lead to chronic wounds
- The variety of scars and their treatment

INTRODUCTION

Wound healing is a mechanism whereby the body attempts to restore the integrity of the injured part. However, this falls far short of the regeneration of tissue by pluripotent cells, seen in some amphibians, and is often detrimental, as seen in the problems created by scarring such as adhesions, keloids, contractures and cirrhosis of the liver, to name but a few. Several factors may influence healing (Summary box 3.1).

Summary box 3.1

Factors influencing healing of a wound

- Site of the wound
- Structures involved
- Mechanism of wounding
 - Incision
 - Crush
 - Crush avulsion
- Contamination (foreign bodies/bacteria)^a
- Loss of tissue
- Other local factors
 - Vascular insufficiency (arterial or venous)
 - Previous radiation
 - Pressure
- Systemic factors
 - Malnutrition or vitamin and mineral deficiencies
 - Disease (e.g. diabetes mellitus)
 - Medications (e.g. steroids)
 - Immune deficiencies [e.g. chemotherapy, acquired immunodeficiency syndrome (AIDS)]
 - Smoking

a. In explosions, the contamination may consist of tissue such as bone from another individual.

However, a clean incised wound in a healthy person where there is no skin loss will follow a set pattern, as outlined below.

NORMAL WOUND HEALING

This is variously described as taking place in three or four phases, the most commonly agreed being:

- 1 the inflammatory phase;
- 2 the proliferative phase;
- 3 the remodelling phase (maturing phase).

Occasionally, a haemostatic phase is referred to as occurring before the inflammatory phase, or a destructive phase following inflammation consisting of the cellular cleansing of the wound by macrophages (Fig. 3.1).

The inflammatory phase begins immediately after wounding and lasts 2–3 days. Bleeding is followed by vasoconstriction and thrombus formation to limit blood loss. Platelets stick to the damaged endothelial lining of vessels, releasing adenosine diphosphate (ADP), which causes thrombocytic aggregates to fill the wound. When bleeding stops, the platelets then release several cytokines from their alpha granules. These are platelet-derived growth factor (PDGF), platelet factor IV and transforming growth factor beta (TGF β). These attract inflammatory cells such as polymorphonuclear lymphocytes (PMN) and macrophages. Platelets and the local injured tissue release vasoactive amines such as histamine, serotonin and prostaglandins, which increase vascular permeability, thereby aiding infiltration of these inflammatory cells. Macrophages remove devitalised tissue and micro-organisms while regulating fibroblast activity in the proliferative phase of healing. The initial framework for structural support of cells is provided by fibrin produced by fibrinogen.

A more historical (Latin) description of this phase is described in four words: rubor (redness), tumour (swelling), calor (heat) and dolor (pain).

The proliferative phase lasts from the third day to the third week consisting mainly of fibroblast activity with the production of collagen and ground substance (glycosaminoglycans and proteoglycans), the growth of new blood vessels as capillary loops (angiogenesis) and the re-epithelialisation of the wound surface. Fibroblasts require vitamin C to produce collagen. The wound tissue formed in

Figure 3.1 The phases of healing. (a) Early inflammatory phase with platelet-enriched blood clot and dilated vessels. (b) Late inflammatory phase with increased vascularity and increase in polymorphonuclear lymphocytes (PMN) and lymphocytes (round cells). (c) Proliferative phase with capillary buds and fibroblasts. (d) Mature contracted scar.

the early part of this phase is called granulation tissue. In the latter part of this phase, there is an increase in the tensile strength of the wound due to increased collagen, which is at first deposited in a random fashion and consists of type III collagen.

The remodelling phase is characterised by maturation of collagen (type I replacing type III until a ratio of 4:1 is achieved). There is a realignment of collagen fibres along the lines of tension, decreased wound vascularity and wound contraction due to fibroblast and myofibroblast activity.

NORMAL HEALING IN SPECIFIC TISSUES

Bone

The phases are as above, but periosteal and endosteal proliferation leads to callus formation, which is immature bone consisting of osteoid (mineralised by hydroxyapatite and laid down by osteoblasts). In the remodelling phase, cortical structure and the medullary cavity are restored. If fracture ends are accurately opposed and rigidly fixed, callus formation is minimal and primary healing occurs. If a gap exists, then secondary healing may lead to delayed union, non-union or malunion.

Nerve

Distal to the wound, Wallerian degeneration occurs. Proximally, the nerve suffers traumatic degeneration as far as the last node of

Ranvier. The regenerating nerve fibres are attracted to their receptors by neurotrophism, which is mediated by growth factors, hormones and other extracellular matrix trophins. Nerve regeneration is characterised by profuse growth of new nerve fibres which sprout from the cut proximal end. Overgrowth of these, coupled with poor approximation, may lead to neuroma formation.

Tendon

While following the normal pattern of wound healing, there are two main mechanisms whereby nutrients, cells and new vessels reach the severed tendon. These are *intrinsic*, which consists of vincular blood flow and synovial diffusion, and *extrinsic*, which depends on the formation of fibrous adhesions between the tendon and the tendon sheath. The random nature of the initial collagen produced means that the tendon lacks tensile strength for the first 3–6 weeks. Active mobilisation prevents adhesions limiting range of motion, but the tendon must be protected by splintage in order to avoid rupture of the repair.

ABNORMAL HEALING

Some of the adverse influences on wound healing are listed in Summary box 3.1. Delayed healing may result in loss of function or poor cosmetic outcome. The aim of treatment is to achieve healing by primary intention and so reduce the inflammatory and proliferative responses (Summary box 3.2).

Summary box 3.2

A classification of wound closure and healing

- By primary intention
 - Wound edges opposed. Normal healing. Minimal scar
- By secondary intention
 - Wound left open. Heals by granulation, contraction and epithelialisation
 - Increased inflammation and proliferation
 - Poor scar
- By tertiary intention (also called delayed primary intention)
 - Wound initially left open
 - Edges later opposed when healing conditions favourable

Healing by primary intention is also known as healing by first intention. Because of minimal surrounding tissue trauma, it causes the least inflammation and leaves the best scar. Delayed primary intention healing occurs when the wound edges are not opposed immediately, which may be necessary in contaminated or untidy wounds. The inflammatory and proliferative phases of healing have become well advanced when closure of the wound is carried out. This is also called healing by tertiary intention in some texts and will result in a less satisfactory scar than after healing by primary intention. Secondary healing or healing by secondary intention occurs in the wound that is left open and allowed to heal by granulation, contraction and epithelialisation.

Augustus Volney Waller, 1816–1870, a General Practitioner of Kensington, London, UK (1842–1851), who subsequently worked as a Physiologist in Bonn, Germany; Paris, France; Birmingham, England; and Geneva, Switzerland.

Louis Antoine Ranvier, 1835–1922, Physician and Histologist who was a Professor in the College of France, Paris, France, described these nodes in 1878.

TYPES OF WOUNDS – TIDY VS. UNTIDY

The site injured, the structures involved in the injury and the mechanism of injury (e.g. incision or explosion) all influence healing and recovery of function. This has led to the management of wounds based upon their classification into tidy and untidy (Summary box 3.3; Fig. 3.2a and b). The surgeon's aim is to convert untidy to tidy by removing all contaminated and devitalised tissue.

Summary box 3.3

Tidy vs. untidy wounds

Tidy	Untidy
Incised	Crushed or avulsed
Clean	Contaminated
Healthy tissues	Devitalised tissues
Seldom tissue loss	Often tissue loss

Primary repair of all structures (e.g. bone, tendon, vessel and nerve) may be possible in a tidy wound, but a contaminated wound with dead tissue requires debridement on one or several occasions before definitive repair can be carried out (the concept of 'second look' surgery). This is especially true in injuries caused by explosions, bullets or other missiles, where the external wound

Figure 3.2 (a) Tidy incised wound on the finger. (b) Untidy avulsed wound on the hand.

itself may appear much smaller than the wider extent of the injured tissues deep to the surface. Multiple debridements are often required after crushing injuries in road traffic accidents or in natural disasters such as earthquakes, where fallen masonry causes widespread muscle damage and compartment syndromes (see below).

MANAGING THE ACUTE WOUND

The surgeon must remember to examine the whole patient according to acute trauma life support (ATLS) principles. A stab wound in the back can be missed just as easily in the reality of the accident and emergency room as in a fictitious detective novel. The wound itself should be examined, taking into consideration the site and the possible structures damaged (Fig. 3.3). It is essential to assess movement and sensation while watching for pain and listening to the patient.

A bleeding wound should be elevated and a pressure pad applied. Clamps should not be put on vessels blindly as nerve damage is likely and vascular anastomosis is rendered impossible.

In order to facilitate examination, adequate analgesia and/or anaesthesia (local, regional or general) are required. General anaesthesia is often needed in children. In limb injuries, particularly those of the hand, a tourniquet should be used.

After assessment, a thorough debridement is essential. Abrasions, 'road rash' (following a fall from a motorbike) and explosions all cause dirt tattooing and require the use of a scrubbing brush or even excision under magnification. A wound should be explored and debrided to the limit of blood staining. Devitalised tissue must be excised until bleeding occurs with the obvious exception of nerves, vessels and tendons. These may survive with adequate revascularisation subsequently or by being covered with viable tissue such as that brought in by skin or muscle flaps.

The use of copious saline irrigation or pulsed jet lavage (where the instrumentation is available) can be less destructive than knife or scissors when debriding. Muscle viability is judged by the colour, bleeding pattern and contractility.

In a tidy wound, repair of all damaged structures may be attempted. A fascicular repair of nerves under magnification (loupes or microscope) using 8/0 or 10/0 monofilament nylon is usual. Vessels such as the radial or ulnar artery may be repaired using similar techniques. Tendon repairs, particularly those in the

Figure 3.3 Facial trauma – apparent tissue loss but none found after careful matching.

hand, benefit from early active mobilisation as this minimises adhesions between the tendon and the tendon sheath (see above for extrinsic tendon healing mechanism).

Skin cover by flap or graft may be required as skin closure should always be without tension and should allow for the oedema typically associated with injury and the inflammatory phase of healing. A flap brings in a new blood supply and can be used to cover tendon, nerve, bone and other structures that would not provide a suitable vascular base for a skin graft. A skin graft has no inherent blood supply and is dependent on the recipient site for nutrition.

SOME SPECIFIC WOUNDS

Bites

Most bites involve either puncture wounds or avulsions. Small animal bites are common in children (Fig. 3.4) and require cleansing and treatment according to the principles outlined in Summary box 3.4, usually under general anaesthetic.

Summary box 3.4

Managing the acute wound

- Cleansing
- Exploration and diagnosis
- Debridement
- Repair of structures
- Replacement of lost tissues where indicated
- Skin cover if required
- Skin closure without tension
- All of the above with careful tissue handling and meticulous technique

Ear, tip of nose and lower lip injuries are most usually seen in victims of human bites. A boxing-type injury of the metacarpo-phalangeal joint may result from a perforating contact with the teeth of a victim. Anaerobic and aerobic organism prophylaxis is required as bite wounds typically have high virulent bacterial counts.

Puncture wounds

Wounds caused by sharp objects should be explored to the limit of tissue blood staining. Needle-stick injuries should be treated according to the well-published protocols because of hepatitis and human immunodeficiency virus (HIV) risks. X-ray examination should be carried out in order to rule out retained foreign bodies in the depth of the wound.

Figure 3.4 Dog bite in a child.

Haematomata

If large, painful or causing neural deficit, a haematoma may require release by incision or aspiration. In the gluteal or thigh region, there may be an associated disruption of fat in the form of a fat fracture, which results in an unsightly groove but intact skin. An untreated haematoma may also calcify and therefore require surgical exploration if symptomatic.

Degloving

Degloving occurs when the skin and subcutaneous fat are stripped by avulsion from its underlying fascia, leaving neurovascular structures, tendon or bone exposed. A degloving injury may be open or closed. An obvious example of an open degloving is a ring avulsion injury with loss of finger skin (Fig. 3.5). A closed degloving may be a rollover injury, typically caused by a motor vehicle over a limb. Such an injury will extend far further than expected, and much of the limb skin may be non-viable (Fig. 3.6). Examination under anaesthetic is required with a radical excision of all non-bleeding skin, as judged by bleeding dermis. Fluorescein can be administered intravenously while the patient is anaesthetised. Under ultraviolet light, viable (perfused) skin will show up as a fluorescent yellowish green colour, and the non-viable skin for excision is clearly mapped out. However, the main objection to this method is that of possible anaphylactic shock due to fluorescein sensitivity. Most surgeons therefore rely upon serial excision until punctate dermal bleeding is obvious. Split-skin grafts can be harvested from the degloved non-viable skin and meshed (Fig. 3.7) to cover the raw areas resulting from debridement.

Figure 3.5 Degloving hand injury.

Figure 3.6 Degloving buttock injury.

Figure 3.7 Meshed split-skin graft.

Compartment syndromes

Compartment syndromes typically occur in closed lower limb injuries. They are characterised by severe pain, pain on passive movement of the affected compartment muscles, distal sensory disturbance and, finally, by the absence of pulses distally (a late sign). They can occur in an open injury if the wound does not extend into the affected compartment.

Compartment pressures can be measured using a pressure monitor and a catheter placed in the muscle compartment. If pressures are constantly greater than 30 mmHg or if the above clinical signs are present, then fasciotomy should be performed. Fasciotomy involves incising the deep muscle fascia and is best carried out via longitudinal incisions of skin, fat and fascia (Fig. 3.8). The muscle will be then seen bulging out through the fasciotomy opening. The lower limb can be decompressed via two incisions, each being lateral to the subcutaneous border of the tibia. This gives access to the two posterior compartments and to the peroneal and anterior compartments of the leg. In crush injuries that present several days after the event, a late fasciotomy can be dangerous as dead muscle produces myoglobin which, if suddenly released into the bloodstream, causes myoglobinuria with glomerular blockage and renal failure. In the late treatment of lower limb injuries, therefore, it may be safer to amputate the limb.

Figure 3.8 Fasciotomy of the lower leg.

High-pressure injection injuries

The use of high-pressure devices in cleaning, degreasing and painting can cause extensive closed injuries through small entry wounds. The liquid injected spreads along fascial planes, a common site being from finger to forearm. The tissue damage is dependent upon the toxicity of the substance and the injection pressure. Treatment is surgical with wide exposure, removal of the toxic substance and thorough debridement. Preoperative X-rays may be helpful where air or lead-based paints can be seen. It should be noted that amputation rates following high-pressure injection injuries are reported as being over 45%. Delayed or conservative treatment is therefore inappropriate.

CHRONIC WOUNDS

Leg ulcers

In developed countries, the commonest chronic wounds are leg ulcers. An ulcer can be defined as a break in the epithelial continuity. A prolonged inflammatory phase leads to overgrowth of granulation tissue, and attempts to heal by scarring leave a fibrotic margin. Necrotic tissue often at the ulcer centre is called slough. The more common aetiologies are listed in Summary box 3.5.

Summary box 3.5

Aetiology of leg ulcers

- Venous disease leading to local venous hypertension (e.g. varicose veins)
- Arterial disease, either large vessel (atherosclerosis) or small vessel (diabetes)
- Arteritis associated with autoimmune disease (rheumatoid arthritis, lupus, etc.)
- Trauma – could be self-inflicted
- Chronic infection – tuberculosis/syphilis
- Neoplastic – squamous or basal cell carcinoma, sarcoma

A chronic ulcer, unresponsive to dressings and simple treatments, should be biopsied to rule out neoplastic change, a squamous cell carcinoma known as a Marjolin's ulcer being the commonest. Effective treatment of any leg ulcer depends on treating the cause, and diagnosis is therefore vital. Arterial and venous circulation should be assessed, as should sensation throughout the lower limb. Surgical treatment is only indicated if non-operative treatment has failed or if the patient suffers from intractable pain. Meshed skin grafts (Fig. 3.7) are more successful than sheet grafts and have the advantage of allowing mobilisation, as any tissue exudate can escape through the mesh. It should be stressed that the recurrence rate is high in venous ulceration, and patient compliance with a regime of hygiene, elevation and elastic compression is essential.

Pressure sores

These can be defined as tissue necrosis with ulceration due to prolonged pressure. Less preferable terms are bed sores, pressure ulcers and decubitus ulcers. They should be regarded as preventable but

Jean-Nicholas Marjolin, 1780–1850, Surgeon, Paris, France, described the development of carcinomatous ulcers in scars in 1828.

occur in approximately 5% of all hospitalised patients (range of 3% to 12% in published literature). There is a higher incidence in paraplegic patients, in the elderly and in the severely ill patient. The commonest sites are listed in Summary box 3.6.

Summary box 3.6

Pressure sore frequency in descending order

- Ischium
- Greater trochanter
- Sacrum
- Heel
- Malleolus (lateral then medial)
- Occiput

A staging system for description of pressure sores devised by the American National Pressure Ulcer Advisory Panel is shown in Summary box 3.7.

Summary box 3.7

Staging of pressure sores

- | | |
|---------|--|
| Stage 1 | Non-blanchable erythema without a breach in the epidermis |
| Stage 2 | Partial-thickness skin loss involving the epidermis and dermis |
| Stage 3 | Full-thickness skin loss extending into the subcutaneous tissue but not through underlying fascia |
| Stage 4 | Full-thickness skin loss through fascia with extensive tissue destruction, maybe involving muscle, bone, tendon or joint |

If external pressure exceeds the capillary occlusive pressure (over 30 mmHg), blood flow to the skin ceases leading to tissue anoxia, necrosis and ulceration (Fig. 3.9). Prevention is obviously the best treatment with good skin care, special pressure dispersion cushions or foams, the use of low air loss and air-fluidised beds and urinary or faecal diversion in selected cases. Pressure sore awareness is vital, and the bed-bound patient should be turned at least every 2 hours, with the wheelchair-bound patient being taught to lift themselves off their seat for 10 seconds every 10 minutes.

Figure 3.9 Pressure ulcer.

Surgical management of pressure sores follows the same principles involved in acute wound treatment (Summary box 3.4). The patient must be well motivated, clinically stable with good nutrition and adhere to the preventative measures advised post-operatively. Preoperative management of the pressure sore involves adequate debridement, and the use of vacuum-assisted closure (VAC) may help to provide a suitable wound for surgical closure (see below). The aim is to fill the dead space and to provide durable sensate skin. Large skin flaps that include muscle are best and, occasionally, an intact sensory innervated area can be included (e.g. extensor fascia lata flap with lateral cutaneous nerve of the thigh). If possible, use a flap that can be advanced further if there is recurrence and that does not interfere with the planning of neighbouring flaps that may be used in the future.

Vacuum-assisted closure

Applying intermittent negative pressure of approximately -125 mmHg appears to hasten debridement and the formation of granulation tissue in chronic wounds and ulcers. A foam dressing is cut to size to fit the wound. A perforated wound drain is placed over the foam, and the wound is sealed with a transparent adhesive film. A vacuum is then applied to the drain (Fig. 3.10). Negative pressure may act by decreasing oedema, by removing interstitial fluid and by increasing blood flow. As a result, bacterial counts decrease and cell proliferation increases, thereby creating a suitable bed for graft or flap cover.

NECROTISING SOFT-TISSUE INFECTIONS

These are rare but often fatal. They are most commonly polymicrobial infections with Gram-positive aerobes (*Staphylococcus aureus*, *Staphylococcus pyogenes*), Gram-negative aerobes (*Escherichia coli*, *Pseudomonas*, *Clostridium*, *Bacteroides*) and β -haemolytic *Streptococcus*. There is usually a history of trauma or surgery with wound contamination. Sometimes, the patient's own defence mechanism may be deficient. These infections are characterised by sudden presentation and rapid progression. The fact that deeper tissues are involved often leads to a late or missed diagnosis (Fig. 3.11). Clinical signs are shown in Summary box 3.8.

Figure 3.10 Vacuum-assisted closure (VAC) dressing of a large wound.

Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology (1891–1900) and of Medicine (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.

Figure 3.11 Necrotising fasciitis of the anterior abdominal wall.

Summary box 3.8

Sign of necrotising infections

- Oedema beyond area of erythema
- Crepitus
- Skin blistering
- Fever (often absent)
- Greyish drainage ('dishwater pus')
- Pink/orange skin staining
- Focal skin gangrene (late sign)
- Final shock, coagulopathy and multiorgan failure

There are two main types of necrotising infections: clostridial (gas gangrene) and non-clostridial (streptococcal gangrene and necrotising fasciitis). The variant of necrotising fasciitis with toxic shock syndrome results from *Streptococcus pyogenes* and is often called the 'flesh-eating bug' in this situation. Treatment is surgical excision with tissue biopsies being sent for culture and diagnosis. Wide raw areas requiring skin grafting often result.

SCARS

The maturation phase of wound healing has been discussed above and represents the formation of what is described as a scar. The immature scar becomes mature over a period lasting a year or more, but it is at first pink, hard, raised and often itchy. The disorganised collagen fibres become aligned along stress lines with their strength being in their weave rather than in their amount (this has been compared with steel wool being slowly woven into a cable). As the collagen matures and becomes denser, the scar becomes almost acellular as the fibroblasts and blood vessels reduce. The external appearance of the scar becomes paler, while the scar becomes softer, flattens and its itchiness diminishes. Most of these changes occur over the first 3 months but a scar will continue to mature for 1–2 years. Tensile strength will continue to increase but will never reach that of normal skin.

Scars are often described as being atrophic, hypertrophic and keloid. An atrophic scar is pale, flat and stretched in appearance, often appearing on the back and areas of tension. It is easily traumatised as the epidermis and dermis are thinned. Excision and resuturing may only rarely improve such a scar.

A hypertrophic scar is defined as excessive scar tissue that does not extend beyond the boundary of the original incision or wound. It results from a prolonged inflammatory phase of wound

healing and from unfavourable scar siting (i.e. across the lines of skin tension). In the face, these are known as the lines of facial expression.

A keloid scar is defined as excessive scar tissue that extends beyond the boundaries of the original incision or wound (Fig. 3.12). Its aetiology is unknown, but it is associated with elevated levels of growth factor, deeply pigmented skin, an inherited tendency and certain areas of the body (e.g. a triangle whose points are the xiphisternum and each shoulder tip).

The histology of both hypertrophic and keloid scars shows excess collagen with hypervascularity, but this is more marked in keloids where there is more type B collagen.

The treatment of both is difficult and is summarised in Summary box 3.9.

Summary Box 3.9

Treatment of hypertrophic and keloid scars

- Pressure – local moulds or elasticated garments
- Silicone gel sheeting (mechanism unknown)
- Intralesional steroid injection (triamcinolone)
- Excision and steroid injection^a
- Excision and postoperative radiation (external beam or brachytherapy)^a
- Intralesional excision (keloids only)
- Laser – to reduce redness (which may resolve in any event)
- Vitamin E or palm oil massage (unproven)

a. All excisions have high rates of recurrence.

Hypertrophic scars improve spontaneously with time, whereas keloids do not.

AVOIDABLE SCARRING

If the acute wound has been managed correctly (Summary box 3.4), most of the problems described here should not occur. However, the surgeon should always stress that there will be a scar of some description after wounding, be it planned or accidental. A dirt-ingrained (tattooed) scar is usually preventable by proper initial scrubbing and cleansing of the wound (Fig. 3.13). Late treatment may require excision of the scar or pigment destruction by laser.

Figure 3.12 Multiple keloid scars.

Laser is an abbreviation for light amplification by stimulated emission of radiation. A laser is an intense beam of monochromatic light.

Figure 3.13 Dirt-ingrained scar.

Mismatched or misaligned scars result from a failure to recognise normal landmarks such as the lip vermilion/white roll interface, eyelid and nostril free margins and hair lines such as those relating to eyebrows and moustache. Treatment consists of excision and resuturing.

Poorly contoured scars can be stepped, grooved or pincushioned. Most are caused by poor alignment of deep structures such as muscle or fat, but trapdoor or pincushioned scars are often unavoidable unless the almost circumferential wound can be excised initially. Late treatment consists of scar excision and correct alignment of deeper structures or, as in the case of a trapdoor scar, an excision of the scar margins and repair using W- or Z-plasty techniques.

Suture marks may be minimised by using monofilament sutures that are removed early (3–5 days). Sutures inserted under tension will leave marks. The wound can be strengthened post suture removal by the use of sticky strips. Fine sutures (6/0 or smaller) placed close to the wound margins tend to leave less scarring. Subcuticular suturing avoids suture marks either side of the wound or incision.

CONTRACTURES

Where scars cross joints or flexion creases, a tight web may form restricting the range of movement at the joint. This may be referred to as a contracture and can cause hyperextension or hyperflexion deformity (Fig. 3.14). In the neck, it may interfere with head extension (Fig. 3.15). Treatment may be simple involving multiple Z-plasties (Fig. 3.16) or more complex requiring the inset of grafts or flaps. Splintage and intensive physiotherapy are often required postoperatively.

Surgical infection

CHAPTER

4

LEARNING OBJECTIVES

To understand:

- The factors that determine whether a wound will become infected
- The classification of sources of infection and their severity
- The indications for and choice of prophylactic antibiotics
- The characteristics of the common surgical pathogens and their sensitivities
- The spectrum of commonly used antibiotics in surgery and the principles of therapy
- The misuse of antibiotic therapy with the risk of resistance [such as methicillin-resistant *Staphylococcus aureus* (MRSA)] and emergence (such as *Clostridium difficile* enteritis)

To learn:

- Koch's postulates
- The management of abscesses

To appreciate:

- The importance of aseptic and antiseptic techniques and delayed primary or secondary closure in contaminated wounds

To be aware of:

- The causes of reduced resistance to infection (host response)

To know:

- The definitions of infection, particularly at surgical sites
- What basic precautions to take to avoid surgically relevant health care-associated infections

PHYSIOLOGY AND PRESENTATION

Background

Surgical infection, particularly surgical site infection (SSI), has always been a major complication of surgery and trauma and has been documented for 4000–5000 years. The Egyptians had some concepts about infection as they were able to prevent putrefaction, testified by mummification skills. Their medical papyruses also describe the use of salves and antiseptics to prevent SSIs. This 'prophylaxis' had also been known earlier by the Assyrians, although less well documented. It was described again independently by the Greeks. The Hippocratic teachings described the use of anti-microbials, such as wine and vinegar, which were widely used to irrigate open, infected wounds before delayed primary or secondary wound closure. A belief common to all these civilisations, and indeed even later to the Romans, was that, whenever pus localised in an infected wound, it needed to be drained.

Galen recognised that this localisation of infection (suppuration) in wounds, inflicted in the gladiatorial arena, often heralded recovery, particularly after drainage (*pus bonum et laudabile*). Sadly, this dictum was misunderstood by many later healers, who thought that it was the production of pus that was desirable. Until well into the Middle Ages, some practitioners promoted suppuration in wounds by the application of noxious substances, including faeces, in the misguided belief that healing could not occur without pus formation. Theodoric of Cervia, Ambroise Paré and Guy de Chauliac observed that clean wounds, closed primarily, could heal without infection or suppuration.

The understanding of the causes of infection came in the nineteenth century. Microbes had been seen under the micro-

Hippocrates was a Greek Physician, and by common consent 'The Father of Medicine'. He was born on the Greek island of Cos off Turkey about 460 BC and probably died in 375 BC.

Galen, 130–200, a Roman Physician, who commenced practice as Surgeon to the Gladiators at Pergamum (now Bregama in Turkey) and later became personal Physician to the Emperor Marcus Aurelius and to two of his successors. He was a prolific writer on many subjects amongst them Anatomy, Medicine, Pathology and Philosophy. His work affected medical thinking for 15 centuries after his death. (Gladiator is Latin for 'Swordsmen').

Theodoric of Cervia. Theodoric, 1210–1298, who was Bishop of Cervia published a book on Surgery ca. 1267.

Ambroise Paré, 1510–1590, a French Military Surgeon, who also worked at the Hotel Dieu, Paris, France.

Guy de Chauliac, ?1298–1368, was Physician and Chaplain to Pope Clement VI at Avignon, France. He was the author of 'Chirurgia Magna' which was published about 1363.

scope, but Koch laid down the first definition of infective disease (Koch's postulates; Summary box 4.1).

Summary box 4.1

Koch's postulates proving the agency of an infective organism

- It must be found in considerable numbers in the septic focus
- It should be possible to culture it in a pure form from that septic focus
- It should be able to produce similar lesions when injected into another host

The Austrian obstetrician Ignac Semmelweis showed that puerperal sepsis could be reduced from over 10% to under 2% by the simple act of hand-washing between cases, particularly between post-mortem examinations and the delivery suite. He was ignored by his contemporaries.

Louis Pasteur recognised that micro-organisms were responsible for spoiling wine, turning it into vinegar. Joseph Lister applied this knowledge to the reduction of colonising organisms in compound fractures by using antiseptics. This allowed surgery without infection. However, his toxic phenol spray and principles of antiseptic surgery soon gave way to aseptic surgery at the turn of the century. Instead of killing the bacteria in the tissues (antiseptic technique), the conditions under which the operation was performed were kept free of bacteria (aseptic technique). This technique is still employed in modern operating theatres.

The concept of a 'magic bullet' (*Zauberkegel*) that could kill microbes but not their host became a reality with the discovery of sulphonamide chemotherapy in the mid-twentieth century. The discovery of the antibiotic penicillin is attributed to Alexander Fleming, but it was isolated by Florey and Chain. The first patient to receive penicillin was Police Constable Alexander in Oxford. He had a severe staphylococcal bacteraemia with metastatic abscesses. He responded to treatment, made a partial recovery before the penicillin ran out, then relapsed and died. Since then, there has been a proliferation of antibiotics with broad-spectrum activity.

However, most staphylococci are now resistant to penicillin, whereas streptococci remain sensitive, although they are now seen less commonly in surgical practice. Many bacteria develop resistance through the acquisition of β -lactamases, which break up the β -lactam ring in many antibiotics. The acquisition of extended spectrum β -lactamases (ESBLs) is an increasing

Robert Koch, 1843–1910, Professor of Hygiene and Bacteriology, Berlin, Germany, stated his 'Postulates' in 1882.

Ignac Semmelweis, 1818–1865, Professor of Obstetrics, Budapest, Hungary.

Louis Pasteur, 1822–1895, was a French Chemist, Bacteriologist and Immunologist who was Professor of Chemistry at the Sorbonne, Paris, France.

Joseph Lister, (Lord Lister), 1827–1912, Professor of Surgery, Glasgow, Scotland, (1860–1869), Edinburgh, Scotland, (1869–1877), and King's College Hospital, London, (1877–1892).

Sir Alexander Fleming, 1881–1955, Professor of Bacteriology, St Mary's Hospital, London, England, discovered *Penicillium Notatum* in 1928.

Howard Walter Florey, (Lord Florey of Adelaide), 1898–1968, Professor of Pathology, The University of Oxford, Oxford, England.

Sir Ernst Boris Chain, Professor of Biochemistry, Imperial College, London, England. Fleming, Florey and Chain shared the 1945 Nobel Prize for Physiology or Medicine for their work on Penicillin.

concern in some Gram-negative organisms that cause urinary tract infections. In addition, there is increasing concern about the rising resistance of many other bacteria to antibiotics, in particular the emergence of methicillin-resistant *Staphylococcus aureus* (MRSA) and glycopeptide-resistant enterococci (GRE), which are also relevant in general surgical practice.

The synergy between aerobic Gram-negative bacilli and anaerobic *Bacteroides* spp. also presents a challenge to SSI prevention, especially abscesses after abdominal surgery. Broad-spectrum antibiotics can be given empirically to treat such infections but, if the organisms and their sensitivity are known, then more specific, narrow-range antibiotics can be given. The introduction of antibiotics for prophylaxis and for treatment, together with advances in anaesthesia and critical care medicine, has made possible surgery that would not previously have been considered. Faecal peritonitis is no longer inevitably fatal, and incisions made in the presence of such contamination can heal primarily without infection in 80–90% of patients with appropriate antibiotic therapy. Despite this, it is common practice in many countries to delay wound closure in patients in whom the wound is known to be contaminated or dirty. Waiting for the wound to granulate and then performing a delayed primary or secondary closure may be considered a better option (Summary box 4.2).

Summary box 4.2

Advances in the control of infection in surgery

- Aseptic operating theatre techniques have replaced toxic antiseptic techniques
- Antibiotics have reduced postoperative infection rates after elective and emergency surgery
- Delayed primary, or secondary, closure remains useful in contaminated wounds

Surgical site infection in patients who have contaminated wounds, who are immunosuppressed or undergoing prosthetic surgery, is now the exception rather than the rule since the introduction of prophylactic antibiotics. The evidence for this is of the highest level. However, the value of prophylactic antibiotics in clean, non-prosthetic surgery remains controversial, although SSI rates after such surgery is high when judged by close, unbiased, post-discharge surveillance, using strict definitions.

PHYSIOLOGY

Micro-organisms are normally prevented from causing infection in tissues by intact epithelial surfaces. These are broken down in trauma and by surgery. In addition to these mechanical barriers, there are other protective mechanisms, which can be divided into:

- *chemical*: low gastric pH;
- *humoral*: antibodies, complement and opsonins;
- *cellular*: phagocytic cells, macrophages, polymorphonuclear cells and killer lymphocytes.

Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology, (1891–1900), and of Medicine, (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.

All these natural mechanisms may be compromised by surgical intervention and treatment.

Reduced resistance to infection has several causes (Summary box 4.3).

Summary box 4.3

Causes of reduced host resistance to infection

- Metabolic: malnutrition (including obesity), diabetes, uraemia, jaundice
- Disseminated disease: cancer and acquired immunodeficiency syndrome (AIDS)
- Iatrogenic: radiotherapy, chemotherapy, steroids

Host response is weakened by malnutrition, which can be recognised clinically, and most easily, as recent rapid weight loss that can be present even in the presence of obesity. Metabolic diseases such as diabetes mellitus, uraemia and jaundice, disseminated malignancy and AIDS are other contributors to infection and a poor healing response, as are iatrogenic causes including the immunosuppression caused by radiotherapy, chemotherapy or steroids (Summary box 4.4, and Figs 4.1 and 4.2).

Summary box 4.4

Risk factors for increased risk of wound infection

- Malnutrition (obesity, weight loss)
- Metabolic disease (diabetes, uraemia, jaundice)
- Immunosuppression (cancer, AIDS, steroids, chemotherapy and radiotherapy)
- Colonisation and translocation in the gastrointestinal tract
- Poor perfusion (systemic shock or local ischaemia)
- Foreign body material
- Poor surgical technique (dead space, haematoma)

Figure 4.1 Major wound infection and delayed healing presenting as a faecal fistula in a patient with Crohn's disease.

Burrill Bernard Crohn, 1884–1983, Gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.

Figure 4.2 Delayed healing relating to infection in a patient on high-dose steroids.

When enteral feeding is suspended during the perioperative period, and particularly with underlying disease such as cancer, immunosuppression, shock or sepsis, bacteria (particularly aerobic Gram-negative bacilli) tend to colonise the normally sterile upper gastrointestinal tract. They may then translocate to the mesenteric nodes and cause the release of endotoxins (lipopolysaccharide in bacterial cell walls), which further increases susceptibility to infection and sepsis, through activation of macrophages and pro-inflammatory cytokine release (Fig. 4.3). The use of selective decontamination of the digestive tract (SDD) is based on the prevention of this colonisation. In the circumstances of reduced resistance, bacteria that are not normally pathogenic may start to behave as pathogens. This is known as opportunistic infection. Opportunistic infection with fungi is an example, particularly when prolonged and changing antibiotic regimens have been used.

Figure 4.3 Gut failure, colonisation and translocation related to the development of multiple organ dysfunction syndrome (MODS) and systemic inflammatory response syndrome (SIRS). IL, interleukin; TNF, tumour necrosis factor.

The chance of developing an SSI after surgery is also determined by the pathogenicity of the organisms present and by the size of the bacterial inoculum. Devitalised tissue, excessive dead space or haematoma, all the results of poor surgical technique, increase the chances of infection. The same applies to foreign materials of any kind, including sutures and drains. If there is a silk suture in tissue, the critical number of organisms needed to start an infection is reduced logarithmically. Silk should not be used to close skin as it causes suture abscesses for this reason. These principles are important in prosthetic orthopaedic and vascular surgery, when large quantities of foreign material (prostheses and grafts) are deliberately left in the wound (Summary box 4.5)!

Summary box 4.5

Factors that determine whether a wound will become infected

- Host response
- Virulence and inoculum of infective agent
- Vascularity and health of tissue being invaded (including local ischaemia as well as systemic shock)
- Presence of dead or foreign tissue
- Presence of antibiotics during the 'decisive period'

There is a delay before host defences can become mobilised after a breach in an epithelial surface, whether caused by trauma or surgery. The acute inflammatory, humoral and cellular defences take up to 4 hours to be mobilised. This is called the 'decisive period', and it is the time when the invading bacteria may become established in the tissues. It is therefore logical that prophylactic antibiotics should be given to cover this period and that they could be decisive in preventing an infection from developing. The tissue levels of antibiotics should be above the minimum inhibitory concentration (MIC_{90}) for the pathogens likely to be encountered.

Local and systemic presentation

The infection of a wound can be defined as the invasion of organisms through tissues following a breakdown of local and systemic host defences, leading to cellulitis, lymphangitis, abscess and bacteraemia. The infection of most surgical wounds is referred to as superficial surgical site infection (SSSI). The other categories include deep SSI (infection in the deeper musculofascial layers) and organ space infection (such as an abdominal abscess after an anastomotic leak).

Pathogens resist host defences by releasing toxins, which favour their spread, and this is enhanced in anaerobic or frankly necrotic wound tissue. *Clostridium perfringens*, which is responsible for gas gangrene, releases proteases such as hyaluronidase, lecithinase and haemolysin, which allow it to spread through the tissues. Resistance to antibiotics can be acquired by previously sensitive bacteria by transfer through plasmids.

The human body harbours approximately 10^{14} organisms. They can be released into tissues by surgery, contamination being most severe when a hollow viscus perforates (e.g. faecal peritonitis following a diverticular perforation). Any infection that follows surgery may be termed primary or secondary (Summary box 4.6).

Summary box 4.6

Classification of sources of infection

- Primary: acquired from a community or endogenous source (such as that following a perforated peptic ulcer)
- Secondary or exogenous (HAI): acquired from the operating theatre (such as inadequate air filtration) or the ward (e.g. poor hand-washing compliance) or from contamination at or after surgery (such as an anastomotic leak)

Infection that follows surgery or admission to hospital is termed health care-associated infection (HAI). There are four main groups: respiratory infections (including ventilator-associated pneumonia), urinary tract infections (mostly related to urinary catheters), bacteraemia (mostly related to indwelling vascular catheters) and SSIs.

MAJOR AND MINOR SURGICAL SITE INFECTIONS

A major SSI is defined as a wound that either discharges significant quantities of pus spontaneously or needs a secondary procedure to drain it (Fig. 4.4). The patient may have systemic signs such as tachycardia, pyrexia and a raised white count [systemic inflammatory response syndrome (SIRS)] (Summary box 4.7).

Summary box 4.7

Major wound infections

- Significant quantity of pus
- Delayed return home
- Patients are systemically ill

Minor wound infections may discharge pus or infected serous fluid but should not be associated with excessive discomfort, systemic signs or delay in return home (Fig. 4.5). The differentiation between major and minor and the definition of SSI is important in audit or trials of antibiotic prophylaxis. There are scoring systems for the severity of wound infection, which are particularly useful in surveillance and research. Examples are the Southampton (Table 4.1) and ASEPIS systems (Table 4.2).

Figure 4.4 Major wound infection with superficial skin dehiscence.

Figure 4.5 Minor wound infection that settled spontaneously without antibiotics.

Table 4.1 Southampton wound grading system

Grade	Appearance
0	Normal healing
I	Normal healing with mild bruising or erythema
Ia	Some bruising
Ib	Considerable bruising
Ic	Mild erythema
II	Erythema plus other signs of inflammation
IIa	At one point
IIb	Around sutures
IIc	Along wound
IId	Around wound
III	Clear or haemoserous discharge
IIIa	At one point only (≤ 2 cm)
IIIb	Along wound (> 2 cm)
IIIc	Large volume
IIId	Prolonged (> 3 days)
Major complication	
IV	Pus
IVa	At one point only (≤ 2 cm)
IVb	Along wound (> 2 cm)
V	Deep or severe wound infection with or without tissue breakdown; haematoma requiring aspiration

Table 4.2 The ASEPSIS wound score

Criterion	Points
Additional treatment	0
Antibiotics for wound infection	10
Drainage of pus under local anaesthesia	5
Debridement of wound under general anaesthesia	10
Serous discharge ^a	Daily 0–5
Erythema ^a	Daily 0–5

Separation of deep tissues ^a	Daily 0–10
Isolation of bacteria from wound	10
Stay as in-patient prolonged over 14 days as result of wound infection	5

a. Scored for 5 of the first 7 days only, the remainder being scored if present in the first 2 months.

Accurate surveillance can only be achieved using trained, unbiased and blinded assessors. Most include surveillance for a 30-day postoperative period. The US Centers for Disease Control (CDC) definition insists on a 30-day follow-up period for non-prosthetic surgery and 1 year after implanted hip and knee surgery.

Types of localised infection

Abscess

An abscess presents all the clinical features of acute inflammation originally described by Celsus: *calor* (heat), *rubor* (redness), *dolor* (pain) and *tumour* (swelling). To these can be added *functio laesa* (loss of function: if it hurts, the infected part is not used). They usually follow a puncture wound of some kind, which may have been forgotten, as well as surgery, but can be metastatic in all tissues following bacteraemia.

Pyogenic organisms, predominantly *Staphylococcus aureus*, cause tissue necrosis and suppuration. Pus is composed of dead and dying white blood cells that release damaging cytokines, oxygen free radicals and other molecules. An abscess is surrounded by an acute inflammatory response and a pyogenic membrane composed of a fibrinous exudate and oedema and the cells of acute inflammation. Granulation tissue (macrophages, angiogenesis and fibroblasts) forms later around the suppurative process and leads to collagen deposition. If it is not drained or resorbed completely, a chronic abscess may result. If it is partly sterilised with antibiotics, an antibioma may form.

Abscesses contain hyperosmolar material that draws in fluid. This increases the pressure and causes pain. If they spread, they usually track along planes of least resistance and point towards the skin. Wound abscesses may discharge spontaneously by tracking to a surface, but may need drainage through a surgical incision. Most abscesses relating to surgical wounds take 7–10 days to form after surgery. As many as 75% of SSIs present after the patient has left hospital and may thus be overlooked by the surgical team. Their cost and management, which may be inadequate, is transferred to primary care (Summary box 4.8).

Aulus Aurelius Cornelius Celsus, 25 BC–50 AD, a Roman Surgeon. He was the author of 'De Re Medico Libri Octo'.

Summary box 4.8

Abscesses

- Abscesses need drainage with curettage
- Modern imaging techniques may allow guided aspiration
- Antibiotics are indicated if the abscess is not localised (e.g. evidence of cellulitis)
- Healing by secondary intention is encouraged

Abscess cavities need cleaning out after incision and drainage and are encouraged to heal by secondary intention. All loculi need to be opened and curetted before resolution can occur. Persistent chronic abscesses may lead to sinus or fistula formation. In a chronic abscess, lymphocytes and plasma cells are seen. There is tissue sequestration and later calcification. Certain organisms are associated with chronicity, sinus and fistula formation. Common ones are *Mycobacterium* and *Actinomyces*. They should not be forgotten when these complications occur.

Perianastomotic contamination may be the cause of an abscess but, in the abdomen, abscesses are more usually the result of anastomotic leakage. An abscess in a deep cavity such as the pleura or peritoneum may be difficult to diagnose or locate even when there is strong clinical suspicion that it is present (Fig. 4.6). Plain or contrast radiographs may not be helpful, but ultrasonography, computerised tomography (CT), magnetic resonance imaging (MRI) and isotope scans are all useful and may allow guided aspiration without the need for surgical intervention.

Figure 4.6 Plain radiograph showing a subphrenic abscess with a gas/fluid level (white arrow). Gastrografin is seen leaking from the oesophagojejunal anastomosis (after gastrectomy) towards the abscess (black arrow).

The role of antibiotics in the treatment of wound abscesses is controversial unless there are signs of spreading infection such as cellulitis, lymphangitis or related sepsis. Surgical decompression and curettage of abscesses must be adequate whether antibiotics are used or not. Primary closure can be used, but delayed primary or secondary suture is safest once granulation tissue is mature and the wound is clean.

Cellulitis and lymphangitis

Cellulitis is the non-suppurative invasive infection of tissues. There is poor localisation in addition to the cardinal signs of inflammation. Spreading infection presenting in surgical practice is typically caused by organisms such as β -haemolytic streptococci (Fig. 4.7), staphylococci (Fig. 4.8) and *C. perfringens*. Tissue destruction, gangrene and ulceration may follow, which are caused by release of proteases.

Systemic signs (the old-fashioned term toxæmia) are common: SIRS, chills, fever and rigors. These follow the release of organisms, exotoxins and cytokines into the circulation. However, blood cultures are often negative.

Lymphangitis is part of a similar process and presents as painful red streaks in affected lymphatics. Cellulitis is usually located at the point of injury and subsequent tissue infection. Lymphangitis is often accompanied by painful lymph node groups in the related drainage area (Summary box 4.9).

Summary box 4.9

Cellulitis and lymphangitis

- Non-suppurative, poorly localised
- Commonly caused by streptococci, staphylococci or clostridia
- SIRS is common
- Blood cultures are often negative

SYSTEMIC INFLAMMATORY RESPONSE AND MULTIPLE ORGAN DYSFUNCTION SYNDROMES (MODS)

Sepsis is defined as the systemic manifestation of SIRS, with a documented infection, the signs and symptoms of which may

Figure 4.7 Streptococcal cellulitis of the leg following a minor puncture wound.

Figure 4.8 Staphylococcal cellulitis of the face and orbit following severe infection of an epidermoid cyst of the scalp.

also be caused by multiple trauma, burns or pancreatitis without infection. Serious infection, such as secondary peritonitis, may lead to SIRS through the release of lipopolysaccharide endotoxin from the walls of dying Gram-negative bacilli (mainly *Escherichia coli*) or other bacteria or fungi. This and other toxins cause the release of cytokines (Fig. 4.3, page 34). SIRS should not be confused with bacteraemia although the two may coexist (see Table 4.3).

Table 4.3 Definitions of systemic inflammatory response syndrome (SIRS) and sepsis

SIRS

Two of:

- hyperthermia ($> 38^{\circ}\text{C}$) or hypothermia ($< 36^{\circ}\text{C}$)
- tachycardia ($> 90 \text{ min}^{-1}$, no β -blockers) or tachypnoea ($> 20 \text{ min}^{-1}$)

white cell count $> 12 \times 10^9 \text{ l}^{-1}$ or $< 4 \times 10^9 \text{ l}^{-1}$

Sepsis is SIRS with a documented infection

Severe sepsis or sepsis syndrome is sepsis with evidence of one or more organ failures [respiratory (acute respiratory distress syndrome), cardiovascular (septic shock follows compromise of cardiac function and fall in peripheral vascular resistance), renal (usually acute tubular necrosis), hepatic, blood coagulation systems or central nervous system]

Theodor Escherich, 1857–1911, Professor of Paediatrics, Vienna, Austria, discovered the Bacterium Coli Commune in 1886.

Septic manifestations and multiple organ dysfunction syndrome (MODS) are mediated by the release of cytokines such as the interleukins (IL-6), tumour necrosis factor alpha (TNF α) and other substances released from polymorphonuclear and phagocytic cells. In its most severe form, MODS may progress into multiple system organ failure (MSOF). In this state, the body's resistance to infection is reduced (Summary box 4.10).

Summary box 4.10

Definitions of infected states

- SSI is an infected wound or deep organ space
- SIRS is the body's systemic response to an infected wound
- MODS is the effect that the infection produces systemically
- MSOF is the end-stage of uncontrolled MODS

Bacteraemia and sepsis

Bacteraemia is unusual following superficial SSIs but common after anastomotic breakdown (deep space SSI). It is usually transient and can follow procedures undertaken through infected tissues (particularly instrumentation in infected bile or urine). Bacteraemia is important when a prosthesis has been implanted, as infection of the prosthesis can occur. Sepsis accompanied by MODS may follow anastomotic breakdown. Aerobic Gram-negative bacilli are mainly responsible, but *Staphylococcus aureus* and fungi may be involved, particularly after the use of broad-spectrum antibiotics (Summary box 4.11).

Summary box 4.11

Bacteraemia and sepsis

- Sepsis is common after anastomotic breakdown
- Bacteraemia is dangerous if the patient has a prosthesis
- Sepsis may be associated with MODS

Specific wound infections

Gas gangrene

This is caused by *C. perfringens*. These Gram-positive, anaerobic, spore-bearing bacilli are widely found in nature, particularly in soil and faeces. This is relevant to military and traumatic surgery and colorectal operations. Patients who are immunocompromised, diabetic or have malignant disease are at greater risk, particularly if they have wounds containing necrotic or foreign material, resulting in anaerobic conditions. Military wounds provide an ideal environment as the kinetic energy of high-velocity missiles or shrapnel ($1/2 \cdot mv^2$; m is mass, v is velocity) causes extensive tissue damage. The cavitation which follows passage of a missile causes a 'sucking' entry wound, leaving clothing and environmental soiling in the wound in addition to devascularised tissue. Gas gangrene wound infections are associated with severe local wound pain and crepitus (gas in the tissues, which may also be noted on plain radiographs). The wound produces a thin, brown, sweet-smelling exudate, in which Gram staining will reveal bacteria. Oedema and spreading gangrene follow the release of collagenase, hyaluronidase, other proteases and alpha toxin. Early systemic complications with circulatory collapse and MSOF follow if prompt action is not taken (Summary box 4.12).

Summary box 4.12

Gas gangrene

- Caused by *Clostridium perfringens*
- Gas and smell are characteristic
- Immunocompromised patients are most at risk
- Antibiotic prophylaxis is essential when performing amputations to remove dead tissue

Antibiotic prophylaxis should always be considered in patients at risk, especially when amputations are performed for peripheral vascular disease with open necrotic ulceration. Once a gas gangrene infection is established, large doses of intravenous penicillin and aggressive debridement of affected tissues are required. The use of hyperbaric oxygen is controversial.

Clostridium tetani

This is another anaerobic, terminal spore-bearing, Gram-positive bacterium that can cause tetanus following implantation into tissues or a wound (which may have been trivial or unrecognised and forgotten). The spores are widespread in soil and manure, and so the infection is more common in traumatic civilian or military wounds. The signs and symptoms of tetanus are mediated by the release of the exotoxin tetanospasmin, which affects myoneural junctions and the motor neurones of the anterior horn of the spinal cord. A short prodromal period, which has a poor prognosis, leads to spasms in the distribution of the short motor nerves of the face followed by the development of severe generalised motor spasms including opisthotonus, respiratory arrest and death. A longer prodromal period of 4–5 weeks is associated with a milder form of the disease. The entry wound may show a localised small area of cellulitis; exudate or aspiration may give a sample that can be stained to show the presence of Gram-positive rods. Prophylaxis with tetanus toxoid is the best preventative treatment but, in an established infection, minor debridement of the wound may need to be performed and antibiotic treatment with benzylpenicillin provided in addition. Relaxants may also be required, and the patient may require ventilation in severe forms, which may be associated with a high mortality. The use of anti-toxin using human immunoglobulin ought to be considered for both at-risk wounds and established infection.

The toxoid is a formalin-attenuated vaccine and should be given in three separate doses to give protection for a 5-year period, after which a single 5-yearly booster confers immunity. It should be given to all patients with open traumatic wounds who are not immunised. At-risk wounds are those that present late, when there is devitalisation of tissue or when there is soiling. For these wounds, a booster of toxoid should be given or, if not immunised at all a three-dose course, together with prophylactic benzylpenicillin, but the use of anti-toxin is controversial because of the risk of toxicity and allergy.

Synergistic spreading gangrene (synonym: subdermal gangrene, necrotising fasciitis)

This is not caused by clostridia. A mixed pattern of organisms is responsible: coliforms, staphylococci, *Bacteroides* spp., anaerobic streptococci and peptostreptococci have all been implicated, acting in synergy. Abdominal wall infections are known

as Meleney's synergistic hospital gangrene and scrotal infection as Fournier's gangrene (Fig. 4.9). Patients are almost always immunocompromised with conditions such as diabetes mellitus. The wound initiating the infection may have been minor, but severely contaminated wounds are more likely to be the cause. Severe wound pain, signs of spreading inflammation with crepitus and smell are all signs of the infection spreading. Untreated, it will lead to widespread gangrene and MSOF. The subdermal spread of gangrene is always much more extensive than appears from initial examination. Broad-spectrum antibiotic therapy must be combined with aggressive circulatory support. Locally, there should be wide excision of necrotic tissue and laying open of affected areas. The debridement may need to be extensive, and patients who survive may need large areas of skin grafting.

TREATMENT OF SURGICAL INFECTION

Now that patients are discharged more quickly after surgery and many procedures are performed as day cases, many SSIs are

Figure 4.9 A classic presentation of Fournier's gangrene of the scrotum with 'shameful exposure of the testes' following excision of the gangrenous skin.

Frank Lamont Meleney, 1889–1963, Professor of Clinical Surgery, Columbia University, New York, NY, USA.
Jean Alfred Fournier, 1832–1915, Syphilologist, the Founder of the Venereal and Dermatological Clinic, Hôpital St. Louis, Paris, France.

missed by the surgical team unless they undertake a prolonged and carefully audited follow-up with primary care doctors. Suppurative wound infections take 7–10 days to develop, and even cellulitis around wounds caused by invasive organisms (such as the β -haemolytic *Streptococcus*) takes 3–4 days to develop. Major surgical infections with systemic signs (Fig. 4.10), evidence of spreading infection, cellulitis or bacteraemia need treatment with appropriate antibiotics. The choice may need to be empirical initially but is best based on culture and sensitivities of isolates harvested at surgery. Although the identification of organisms in surgical infections is necessary for audit and wound surveillance purposes, it is usually 2–3 days before sensitivities are known (Figs 4.11 and 4.12). It is illogical to withhold antibiotics until these are available but, if clinical response is poor by the time sensitivities are known, then antibiotics can be changed. This is unusual if the empirical choice of antibiotics is sensible; change of antibiotics promotes resistance and risks complications, such as *C. difficile* enteritis.

If an infected wound is under tension, or there is clear evidence of suppuration, sutures or clips need to be removed, with curettage if necessary, to allow pus to drain adequately. There is no evidence that subcuticular continuous skin closure contributes to or prevents suppuration. In severely contaminated

Figure 4.11 Mixed streptococcal infection of a skin graft with very poor 'take'.

Figure 4.12 After 5–6 days of antibiotics, the infection shown in Fig. 4.11 is under control, and the skin grafts are clearly viable.

Figure 4.10 Classic swinging pyrexia related to a perianastomotic wound abscess that settled spontaneously on antibiotic therapy.

wounds, such as an incision made for drainage of an abscess, it is logical to leave the skin open. Delayed primary or secondary suture can be undertaken when the wound is clean and granulating (Figs 4.13 and 4.14). Leaving wounds open after a 'dirty' operation, such as laparotomy for faecal peritonitis, is not practised as widely in the UK as in the USA or mainland Europe (Summary box 4.13).

Summary box 4.13

Surgical incisions through infected or contaminated tissues

- When possible, tissue or pus for culture should be taken before antibiotic cover is started
- The choice of antibiotics is empirical until sensitivities are available
- Wounds are best managed by delayed primary or secondary closure

When taking pus from infected wounds, specimens should be sent fresh for microbiological culture. Swabs should be placed in transport medium, but the larger the volume of pus sent, the more likely is the accurate identification of the organism

Figure 4.13 Skin layers left open to granulate after laparotomy for faecal peritonitis. The wound is clean and ready for closure.

Figure 4.14 Secondary closure of wound.

involved. Providing the microbiologist with as much information as possible and discussing the results with him or her gives the best chance of the most appropriate antibiotic treatment. If bacteraemia is suspected, but results are negative, then repeat specimens for blood culture may need to be taken.

A rapid report on infective material can be based on an immediate Gram stain. Aerobic and anaerobic culture on conventional media allows sensitivities to be assessed by disc diffusion. Measurements of minimum inhibitory antibiotic concentrations (MIC_{90} in $mg\ l^{-1}$), together with measurements of endotoxin and cytokine levels, are usually only needed for research studies.

Many dressings are now available for use in wound care. These

are listed in Table 4.4. Polymeric films are used as incision drapes and also to cover sutured wounds, but are not indicated for use in wound infections. Agents that can be used to help debride open infected wounds and others to absorb excessive exudate or to encourage epithelialisation and the formation of granulation tissue are also listed (Fig. 4.15). Most contribute to the ideal moist wound environment, and there are others that provide an antibacterial to the wound. There is now a plethora of dressings containing silver or povidone iodine antiseptics, but the use of topical antibiotics should be avoided because of the risks of allergy and resistance.

Prophylaxis

Prophylactic antibiotics

If antibiotics are given empirically, they should be used when local wound defences are not established (the decisive period). Ideally, maximal blood and tissue levels should be present at the time at which the first incision is made and before contamination occurs. Intravenous administration at induction of anaesthesia is optimal. In long operations, those involving the insertion of a prosthesis, when there is excessive blood loss or when unexpected contamination occurs, antibiotics may be repeated 8 and 16 hours later. The choice of an antibiotic depends on the expected spectrum of organisms likely to be encountered, the cost and local hospital policies, which are based on experience of local resistance trends (Summary box 4.14).

Summary box 4.14

Choice of antibiotics for prophylaxis

- Empirical cover against expected pathogens with local hospital guidelines
- Single-shot intravenous administration at induction of anaesthesia
- Repeat only in prosthetic surgery, long operations or if there is excessive blood loss
- Continue as therapy if there is unexpected contamination
- Benzylpenicillin should be used if *Clostridium* gas gangrene infection is a possibility
- Patients with heart valve disease or a prosthesis should be protected from bacteraemia caused by dental work, urethral instrumentation or visceral surgery

Figure 4.15 Infected animal bite/wound of the upper thigh, treated by open therapy following virulent staphylococcal infection. Deep cavity wounds such as this can be debrided and kept moist with many of the modern dressings listed in Table 4.4.

Table 4.4 Surgical dressings

Type	Name (example)	Indications and comments
Debriding agents	BenoxyI–benzoic acid Aserbine–benzoic acid Variclene–lactic acid	Used only in necrotic sloughing skin ulcers. Provide acidic environment. Claimed to enhance healing with debriding action
Enzymatic agents	Varidase–streptokinase/streptodornase	Activate fibrinolysis and liquefy pus on chronic skin ulcers
Bead dressings	Debrisan Iodosorb Other paste dressings	Remove bacteria and excess moisture by capillary action in deep granulating wounds. Antimicrobials May be added but with questionable topical benefit
Polymeric films	Opsite Bioclusive Tegaderm	Primary adhesive transparent dressing for sutured wounds or donor sites
Foams	Silastic (elastomer) Lyof foam Allevyn	Elastomeric dressing can be shaped to fit deep cavities and granulating wounds. Absorbent and non-adherent
Hydrogels	Geliperm Intrasite	Maintain moist environment. Polymers can absorb exudate or antiseptics (but adding antiseptics is of doubtful benefit). Semi-permeable, allow gas exchange
Hydrocolloids	Comfeel Granuflex	Complete occlusion. Promote epithelialisation and granulation tissue. Maintain moisture without gaseous exchange across them
Fibrous polymers	Kaltostat Sorbsan	Absorptive alginate dressings. Derived from natural (seaweed) source. Like polymeric hydrocolloids and hydrogels, they can be used to pack deep wounds
Biological membranes	Porcine skin, amnion	Used for superficial chronic skin ulcers. No proven advantage
Simple miscellaneous	Gauzes: viscose/cotton with non-adherent coating (Melolin) Tulles: non-adherent paraffin impregnation	Simple absorptive dressings only used as secondary dressings to absorb exudate. Added anti-microbials probably confer no benefit. Added charcoal absorbents may reduce swelling. Relatively cheap but of questionable effectiveness

The use of the newer, broad-spectrum antibiotics for prophylaxis should be avoided. Table 4.5 gives some examples of prophylaxis that can be used in elective surgical operations.

Lower limb amputation should be covered against *C. perfringens* using 1.2 g of benzylpenicillin intravenously at induction of anaesthesia and 6-hourly thereafter for 48 hours.

Patients with known valvular disease of the heart (or with any implanted vascular or orthopaedic prosthesis) should have prophylactic antibiotics during dental, urological or open viscus surgery. Single doses of broad-spectrum penicillin, for example amoxicillin, orally or intravenously administered, are sufficient for dental surgery. In urological instrumentation, a second-generation cephalosporin, such as cefuroxime, is sufficient, but in open viscus surgery, the addition of an imidazole such as metronidazole should be considered.

Preoperative preparation

Short preoperative hospital stay lowers the risk of acquiring MRSA, multiply resistant coagulase-negative staphylococci

(MRCNS) and other organisms and the acquisition of HAIs. Medical staff should always wash their hands between patients, but compliance in some health-care working staff (particularly doctors!) is poor. Although the need for clean hospitals, emphasised by the media, is logical, the 'clean your hands campaign' is beginning to result in falls in the incidence of MRSA bacteraemias. The value of personal hygiene is obvious (to both patients and surgeons). Staff with open, infected skin lesions should not enter the operating theatres. Ideally, neither should patients, especially if they are having a prosthesis implanted. Antiseptic baths (usually chlorhexidine) are popular in Europe, but there is no hard evidence for their value in reducing wound infections. Preoperative shaving should be avoided except for aesthetic reasons or to prevent adherence of dressings. If it is to be undertaken, it should be undertaken immediately before surgery as the SSI rate after clean wound surgery may be doubled if it is performed the night before, because minor skin injury enhances superficial bacterial colonisation. Cream depilation is messy and hair clipping is best, with the lowest rate of infection (Summary box 4.15).

Table 4.5 Suggested prophylactic regimens for operations at risk

Type of surgery	Organisms encountered	Prophylactic regimen suggested
Vascular	<i>Staphylococcus epidermidis</i> (or MRCNS) <i>Staphylococcus aureus</i> (or MRSA) Aerobic Gram-negative bacilli (AGNB)	Three doses of flucloxacillin with or without gentamicin, vancomycin or rifampicin if MRCNS/MRSA a risk
Orthopaedic	<i>Staphylococcus epidermidis/aureus</i>	One to three doses of a broad-spectrum cephalosporin (with anti-staphylococcal action) or gentamicin beads
Oesophagogastric	Enterobacteriaceae Enterococci (including anaerobic/ viridans streptococci)	One to three doses of a second-generation cephalosporin and metronidazole in severe contamination
Biliary	Enterobacteriaceae (mainly <i>Escherichia coli</i>) Enterococci (including <i>Streptococcus faecalis</i>)	One dose of a second-generation cephalosporin
Small bowel	Enterobacteriaceae Anaerobes (mainly <i>Bacteroides</i>)	One to three doses of a second-generation cephalosporin with or without metronidazole
Appendix/colorectal	Enterobacteriaceae Anaerobes (mainly <i>Bacteroides</i>)	Three doses of a second-generation cephalosporin (or gentamicin) with metronidazole (the use of oral, poorly absorbed antibiotics is controversial)

MRCNS, multiply resistant coagulase-negative staphylococci; MRSA, methicillin-resistant *Staphylococcus aureus*.

Summary box 4.15

Avoiding surgical site infections

- Staff should always wash their hands between patients
- Length of patient stay should be kept to a minimum
- Preoperative shaving should be avoided if possible
- Antiseptic skin preparation should be standardised
- Attention to theatre technique and discipline
- Avoid hypothermia perioperatively and ensure supplemental oxygenation in recovery

Scrubbing and skin preparation

For the first operation of the day, aqueous antiseptics should be used, and the scrub should include the nails. Subsequent scrubbing should merely involve washing to the elbows, as repeated extensive scrubbing releases more organisms than it removes.

One application of an alcoholic antiseptic is adequate for skin preparation of the operative site. This leads to a more than 95% reduction in bacterial count. Antiseptics in common use are listed in Table 4.6.

Theatre technique and discipline also contribute to low infection rates. Numbers of staff in the theatre and movement in and out of theatre should be kept to a minimum. Careful and regular surveillance is needed to ensure the quality of theatre ventilation, instrument sterilisation and aseptic technique. Operator skill in gentle manipulation and dissection of tissues is much more difficult to audit, but dead spaces and haematomas should be avoided and the use of diathermy kept to a minimum. There is no evidence that drains, incision drapes or wound guards help to reduce wound infection.

There is the highest level of evidence-based medicine that the perioperative avoidance of hypothermia and supplemental oxygen during recovery can significantly reduce the rate of SSIs.

Postoperative care of wounds

Similar attention to standards is needed in the postoperative care of wounds. Secondary (exogenous) SSIs, as well as other HAIs, can be related to poor hospital standards. For example, outbreaks of MRSA infections are rare but serious, particularly with the advent of epidemic MRSA (E-MRSA) and new resistant strains that may express the Panton–Valentine leucocidin. The presence of this organism in wounds, and the number of MRSA bacteraemias, can be a marker of inadequate postoperative wound care, and it can be very difficult and expensive to screen for, identify and eradicate. Even in the community, new strains of MRSA (C-MRSA) are being recognised.

Careful audit should lead to changes in practice, and follow-up should ensure that audit loops are closed. It is critical that surgeons manage their own audit; league tables kept by non-medical or related personnel must be accurate. Scoring systems are useful in audit but, in general, have only been used in wound infection research (Tables 4.2 and 4.3, pages 36 and 38). Nevertheless, accurate audit ought to involve the use of trained, blinded observers in post-discharge surveillance of all HAIs, using validated and reproducible definitions.

CLASSIFICATION OF SURGICAL WOUNDS

Potential for infection

The best measure of wound contamination at the end of an operation is to sample tissue in the wound edge. The theoretical degree of contamination, proposed by the National Research Council (USA) over 40 years ago, relates well to infection rates (Table 4.7). When wounds are heavily contaminated or when an incision is made into an abscess, therapeutic antibiotics may be justified. In these cases, infection rates of more than 15% are expected. There is undisputed evidence that prophylactic antibiotics are effective in clean-contaminated and contaminated

Table 4.6 Classification of antiseptics commonly used in general surgical practice

Name	Presentation	Uses	Comments
Chlorhexidine (Hibiscrub)	Alcoholic 0.5% Aqueous 4%	Skin preparation Skin preparation. Surgical scrub in dilute solutions in open wounds	Has cumulative effect. Effective against Gram-positive organisms and relatively stable in the presence of pus and body fluids
Povidone–iodine (Betadine)	Alcoholic 10% Aqueous 7.5%	Skin preparation Skin preparation. Surgical scrub in dilute solutions in open wounds	Safe, fast-acting, broad spectrum. Some sporicidal activity. Anti-fungal iodine is not free but combined with polyvinylpyrrolidone (povidone)
Cetrimide (Savlon)	Aqueous	Hand-washing Instrument and surface cleaning	<i>Pseudomonas</i> spp. may grow in stored contaminated solutions. Ammonium compounds have good detergent action (surface-active agent)
Alcohols	70% ethyl, isopropyl	Skin preparation	Should be reserved for use as disinfectants
Hypochlorites	Aqueous preparations (Eusol, Milton, Chloramine T)	Instrument and surface cleaning (debriding agent in open wounds?)	Toxic to tissues
Hexachlorophane	Aqueous bisphenol	Skin preparation Hand-washing	Has action against Gram-negative organisms

Table 4.7 SSI rates relating to wound contamination

Type of surgery	Infection rate (%)	Rate before prophylaxis
Clean (no viscus opened)	1–2	The same
Clean-contaminated (viscus opened, minimal spillage)	< 10	Gastric surgery up to 30% Biliary surgery up to 20%
Contaminated (open viscus with spillage or inflammatory disease)	15–20	Variable but up to 60%
Dirty (pus or perforation, or incision through an abscess)	< 40	Up to 60% or more

operations. Infection rates after non-prosthetic clean surgery may be higher than expected when carefully audited by post-discharge surveillance. Breast surgery, for example, is associated with a high risk of infection, or wound complications, which may be interpreted as a failure to heal and related to a high body mass index (BMI). The value of antibiotic prophylaxis is controversial in non-prosthetic clean surgery, with most trials showing no clear benefit.

BACTERIA INVOLVED IN SURGICAL INFECTION

Streptococci

Streptococci form chains and are Gram positive on staining (Fig. 4.16). The most important is the β -haemolytic *Streptococcus*, which resides in the pharynx of 5–10% of the population. In the Lancefield A–G carbohydrate antigens classification, it is the group A *Streptococcus*, also called *Streptococcus pyogenes*, that is

The name Eusol is derived from Edinburgh University Solution Of Lime. Rebecca Graighill Lancefield, 1895–1981, an American Bacteriologist, classified streptococci in 1933.

the most pathogenic. It has the ability to spread, causing cellulitis, and to cause tissue destruction through the release of enzymes such as streptolysin, streptokinase and streptodornase.

Streptococcus faecalis is an enterococcus in Lancefield group D. It is often found in synergy with other organisms, as is the γ -haemolytic *Streptococcus* and *Peptostreptococcus*, which is an anaerobe.

**Figure 4.16** Streptococci.

Both *Streptococcus pyogenes* and *Streptococcus faecalis* may be involved in wound infection after large bowel surgery, but the α -haemolytic *Streptococcus viridans* is not associated with wound infections.

All the streptococci remain sensitive to penicillin and erythromycin. The cephalosporins are a suitable alternative in patients who are allergic to penicillin.

Staphylococci

Staphylococci form clumps and are Gram positive (Fig. 4.17). *Staphylococcus aureus* is the most important pathogen in this group and is found in the nasopharynx of up to 15% of the population. It can cause exogenous suppuration in wounds (and implanted prostheses). Strains resistant to antibiotics (e.g. MRSA) can cause epidemics and more severe infection. It is controversial but, if MRSA infection is found in a hospital, all doctors, nurses and patients may need to be swabbed so that carriers can be identified and treated. In parts of northern Europe, the prevalence of MRSA infections has been kept at very low levels using 'search and destroy' methods, which use these screening techniques and the isolation or treatment of carriers. Patients found to be positive on screening may be denied access to hospital. Some MRSA strains are now also resistant to vancomycin. Local policies on the management of MRSA depend on the prevalence of MRSA, the type of hospital or clinical speciality and the availability of facilities. Widespread swabbing, ward closures, isolation of patients and disinfection of wards all have to be carefully considered and involve all groups of practitioners. They may be expensive but necessary options.

Infections are usually suppurative and localised (see wound abscess, above). Most hospital *Staphylococcus aureus* strains are now β -lactamase producers and are resistant to penicillin, but most strains (MSSA) remain sensitive to flucloxacillin, vancomycin, aminoglycosides, some cephalosporins and fusidic acid (used in osteomyelitis). There are several novel and innovative antibiotics becoming available that have high activity against resistant strains. Some have the advantage of good oral activity (linezolid), some have a wide spectrum (tigecycline), have good activity in bacteraemia (daptomycin) but are relatively expensive, and some have side-effects involving marrow, hepatic and renal toxicity. Their use is justified but needs to be controlled by tight local policies and guidelines that involve clinical microbiologists.

Staphylococcus epidermidis (previously *Staphylococcus albus*), also known as coagulase-negative staphylococci (CNS), was regarded as a commensal but is now recognised as a major threat

Figure 4.17 Staphylococcal pus.

in prosthetic (vascular and orthopaedic) surgery and in indwelling vascular catheters. They can be multiply resistant (MRCNS) to many antibiotics and represent an important cause of HAI.

Clostridia

Clostridial organisms are Gram-positive, obligate anaerobes, which produce resistant spores (Fig. 4.18). *Clostridium perfringens* is the cause of gas gangrene, and *C. tetani* causes tetanus after implantation into tissues or a wound (see specific wound infections, above).

Clostridium difficile is the cause of pseudomembranous colitis. This is another HAI, now more common than the incidence of MRSA bacteraemia, which is caused by the overuse of antibiotics. The cephalosporins and other anti-staphylococcal antibiotics seem to be the most implicated, but the inappropriate sequential use of several antibiotics puts patients most at risk. The key symptom of bloody diarrhoea can occur in small epidemics through poor hygiene. The elderly are particularly at risk and, in its most severe form, a severe colitis may lead to perforation and the need for emergency colectomy. There is a high mortality associated with this. Treatment involves resuscitation and antibiotic therapy with an imidazole or vancomycin. The fibrinous exudate is typical and differentiates the colitis from other inflammatory diseases; the recognition of the toxin is an early accurate diagnostic test.

Aerobic Gram-negative bacilli

These bacilli are normal inhabitants of the large bowel. *Escherichia coli* and *Klebsiella* spp. are lactose fermenting; *Proteus* is non-lactose fermenting. Most organisms in this group act in synergy with *Bacteroides* to cause SSIs after bowel operations (in particular, appendicitis, diverticulitis and peritonitis). *Escherichia coli* is a major cause of the HAI of urinary tract infection, although most aerobic Gram-negative bacilli (AGNB) may be involved, particularly in relation to urinary catheterisation. There is increasing concern about the development of ESBLs in many of this group of bacteria, which confer resistance to many antibiotics.

Pseudomonas spp. tend to colonise burns and tracheostomy wounds, as well as the urinary tract. Once *Pseudomonas* has colonised wards and intensive care units, it may be difficult to

Figure 4.18 *Clostridium tetani* (drumstick spores).

Theodor Albrecht Edwin Klebs, 1834–1913, Professor of Bacteriology successively at Prague, Czechoslovakia; Zurich, Switzerland and The Rush Medical College, Chicago, IL, USA.

eradicate. Surveillance of cross-infection is important in outbreaks. Hospital strains become resistant to β -lactamase as resistance can be transferred by plasmids. Wound infections need antibiotic therapy only when there is progressive or spreading infection with systemic signs. The aminoglycosides are effective, but some cephalosporins and penicillin may not be. Many of the carbapenems (e.g. meropenem) are useful in severe infections, whereas the quinolones have been made ineffective through their overuse and the development of ESBLs.

Bacteroides

Bacteroides are non-spore-bearing, strict anaerobes that colonise the large bowel, vagina and oropharynx. *Bacteroides fragilis* is the principal organism that acts in synergy with AGNB to cause SSIs, including intra-abdominal abscesses, after colorectal or gynaecological surgery. They are sensitive to the imidazoles (e.g. metronidazole) and some cephalosporins (e.g. cefotaxime).

PRINCIPLES OF ANTI-MICROBIAL TREATMENT

Anti-microbials may be used to prevent (see Prophylaxis, above) or treat established surgical infection (Summary box 4.16).

Summary box 4.16

Principles for the use of antibiotic therapy

- Antibiotics do not replace surgical drainage of infection
- Only spreading infection or signs of systemic infection justifies the use of antibiotics
- Whenever possible, the organism and sensitivity should be determined

The use of antibiotics for the treatment of established surgical infection ideally requires recognition and determination of the sensitivities of the causative organisms. Antibiotic therapy should not be held back if they are indicated, the choice being empirical and later modified depending on microbiological findings. However, once antibiotics have been administered, the clinical picture may become confused and, if a patient's condition does not rapidly improve, the opportunity to make a precise diagnosis may have been lost. It is unusual to have to treat SSIs with antibiotics, unless there is evidence of spreading infection, bacteraemia or systemic complications (SIRS and MODS). The appropriate treatment of localised SSIs is interventional radiological drainage of pus or open drainage and debridement.

There are two approaches to antibiotic treatment:

- A *narrow-spectrum antibiotic* may be used to treat a known sensitive infection; for example, MRSA (which may be isolated from pus) is usually sensitive to vancomycin or teicoplanin, but not flucloxacillin.
- *Combinations of broad-spectrum antibiotics* can be used when the organism is not known or when it is suspected that several bacteria, acting in synergy, may be responsible for the infection. For example, during and following emergency surgery requiring the opening of perforated or ischaemic bowel, any of the gut organisms may be responsible for subsequent peritoneal or bacteraemic infection. In this case, a triple-therapy combination of broad-spectrum penicillin, such as ampicillin

or mezlocillin, with an aminoglycoside, such as gentamicin, and metronidazole, may be used pre- and postoperatively to support the patient's own body defences.

An alternative to the penicillins is a cephalosporin, e.g. cefuroxime. This has been a popular alternative as gentamicin toxicity and monitoring of levels are avoided, but the aminoglycosides remain inexpensive and effective. Other alternatives are piperacillin–tazobactam or monotherapy using a carbapenem.

In surgical units in which resistant *Pseudomonas* or other Gram-negative species (such as *Klebsiella*) have become 'resident opportunists', it may be necessary to rotate anti-pseudomonal and anti-Gram-negative antibiotic therapy (Summary box 4.17).

Summary box 4.17

Treatment of commensals that have become opportunist pathogens

- They are likely to have multiple antibiotic resistance
- It may be necessary to rotate antibiotics

The use of these routines, subsequent wound infection and the alternation of combinations of chemotherapy should be monitored by the infection control team and local hospital protocols. In treating patients who have surgical infection with systemic signs (SIRS and MODS), a failure to respond to antibiotics may indicate that there has been a failure of infection source control. If response is poor after 3–4 days, there should be a re-evaluation with a review of charts and further investigations requested to exclude the development or persistence of infection such as a collection of pus.

New antibiotics should be used with caution and, wherever possible, sensitivities should first be obtained. There are certain general rules on which the choice of antibiotics may be based. For example, it is unusual for *Pseudomonas aeruginosa* to be found as a primary infecting organism unless the patient has had surgical or hospital treatment. Local antibiotic sensitivity patterns vary from centre to centre and from country to country, and the sensitivity patterns of common pathogens should be known to the hospital microbiologist who should be involved.

ANTIBIOTICS USED IN TREATMENT AND PROPHYLAXIS OF SURGICAL INFECTION

Anti-microbials may be produced by living organisms (antibiotics) or by synthetic methods. Some are bactericidal, e.g. penicillins and aminoglycosides, and others are bacteriostatic, e.g. tetracycline and erythromycin. In general, penicillins act upon the bacterial cell wall and are most effective against bacteria that are multiplying and synthesising new cell wall materials. The aminoglycosides act at the ribosomal level, preventing or distorting the production of proteins required to maintain the integrity of the enzymes in the bacterial cell. Hospital and Formulary guidelines should be consulted for doses and monitoring of antibiotic therapy.

Penicillin

Benzylpenicillin has proved most effective against Gram-positive pathogens, including most streptococci, the clostridia and some of the staphylococci that do not produce β -lactamase. It is still effective against *Actinomyces*, which is a rare cause of chronic wound infection, and may be used specifically to treat spreading

streptococcal infections. Penicillin is valuable even if other antibiotics are required as part of multiple therapy for a mixed infection. All serious infections, e.g. gas gangrene, require high-dose intravenous benzylpenicillin.

Flucloxacillin

This is a β -lactamase-resistant penicillin and is therefore of use in treating most community-acquired staphylococcal infections, but it has poor activity against other pathogens.

Ampicillin and amoxicillin

These β -lactam penicillins can be taken orally or may be given parenterally. Both are effective against Enterobacteriaceae, *Enterococcus faecalis* and the majority of group D streptococci, but not species of *Klebsiella* or pseudomonads. Their use is now rare as there are more effective alternatives.

Mezlocillin and azlocillin

These are ureidopenicillins with good activity against species of *Enterobacter* and *Klebsiella*. Azlocillin is effective against *Pseudomonas*. Each has some activity against *Bacteroides* and enterococci, but all are susceptible to β -lactamases. Combined with an aminoglycoside, mezlocillin is a valuable treatment for severe mixed infections, particularly those caused by Gram-negative organisms in immunocompromised patients. *There are more appropriate alternatives.*

Clavulanic acid is available combined with amoxicillin (Augmentin) and can be taken orally. This anti- β -lactamase protects amoxicillin from inactivation by β -lactamase-producing bacteria. It is of value in treating infections caused by *Klebsiella* strains and β -lactamase-producing *E. coli* but is not active against *Pseudomonas* spp. It can be used for localised cellulitis or superficial staphylococcal infections and infected human and animal bites. It is available for oral or intravenous therapy.

Cephalosporins

There are several β -lactamase-susceptible cephalosporins that are of value in surgical practice: cefuroxime, cefotaxime and ceftazidime are widely used. The first two are most effective in intra-abdominal skin and soft-tissue infections, being active against *Staphylococcus aureus* and most Enterobacteriaceae. As a group, the enterococci (*Streptococcus faecalis*) are not sensitive to the cephalosporins. Ceftazidime, although active against the Gram-negative organisms and *Staphylococcus aureus*, is also effective against *Pseudomonas aeruginosa*. These cephalosporins may be combined with an aminoglycoside, such as gentamicin, and an imidazole, such as metronidazole, if anaerobic cover is needed. Newer cephalosporins may be effective against organisms such as MRSA, but their spectra are usually limited.

Aminoglycosides

Gentamicin and tobramycin have similar activity and are effective against Gram-negative Enterobacteriaceae. Gentamicin is effective against many strains of *Pseudomonas*, although resistance has been recognised. All aminoglycosides are inactive against anaerobes and streptococci. Serum levels immediately before and 1 hour after intramuscular injection must be taken 48 hours after the start of therapy, and dosage should be modified to satisfy peak and trough levels. Ototoxicity and nephrotoxicity may follow sustained high toxic levels. These antibiotics have a marked post-antibiotic effect, and single, large doses are effective and may be

safer. Use needs to be discussed with the microbiologist, and local policies should be observed.

Vancomycin

This glycopeptide is most active against Gram-positive bacteria and has proved to be effective against MRSA, although vancomycin resistance (VISA) is increasingly being reported. However, it is ototoxic and nephrotoxic, so serum levels should be monitored. It is effective against *C. difficile* in cases of pseudomembranous colitis.

Imidazoles

Metronidazole is the most widely used member of the imidazole group and is active against all anaerobic bacteria. It is particularly safe and may be administered orally, rectally or intravenously. Infections caused by anaerobic cocci and strains of *Bacteroides* and clostridia can be treated, or prevented, by its use. Metronidazole is useful for the prophylaxis and treatment of anaerobic infections after abdominal, colorectal and pelvic surgery.

Carbapenems

Meropenem, ertapenem and imipenem are members of the carbapenems. They are stable to β -lactamase, have useful broad-spectrum anaerobic as well as Gram-positive activity and are effective for the treatment of resistant organisms, such as ESBL-resistant urinary tract infections or serious mixed-spectrum abdominal infections (peritonitis).

Quinolones

Quinolones, such as ciprofloxacin, were active against a wide spectrum of organisms. Their widespread use has been related to the development of resistant organisms, and their role in treating surgical infection is limited.

HIV, AIDS AND THE SURGEON

The type I human immunodeficiency virus (HIV) is one of the viruses of surgical importance as it can be transmitted by body fluids, particularly blood. It is a retrovirus that has become increasingly prevalent through sexual transmission, both homo- and heterosexual, in intravenous drug addiction, through infected blood in treating haemophiliacs, in particular, and in sub-Saharan Africans. The risk in surgery is probably mostly through 'needle-stick' injury during operations.

After exposure, the virus binds to CD4 receptors with a subsequent loss of CD4+ cells, T helper cells and other cells involved in cell-mediated immunity, antibody production and delayed hypersensitivity. Macrophages and gut-associated lymphoid tissue (GALT) are also affected. The risk of opportunistic infections (such as *Pneumocystis carinii* pneumonia, tuberculosis and cytomegalo virus) and neoplasms (such as Kaposi's sarcoma and lymphoma) is thereby increased.

In the early weeks after HIV infection, there may be a flu-like illness and, during the phase of seroconversion, patients present

Sub-Saharan Africans come from that part of the African Continent which lies south of the Sahara Desert.
Moritz Kaposi, 1837–1902, Professor of Dermatology, Vienna, Austria, described pigmented sarcoma of the skin in 1872.

the greatest risk of HIV transmission. It is during these early phases that drug treatment, highly active anti-retroviral therapy (HAART), is most effective through the ability of these drugs to inhibit reverse transcriptase and protease synthesis, which are the principal mechanisms through which HIV can progress. Within 2 years, untreated HIV can progress to AIDS in 25–35% of patients, which is considered to be fatal.

Involvement of surgeons with HIV patients (universal precautions)

Patients may present to surgeons for operative treatment if they have a surgical disease and they are known to be infected or 'at risk', or because they need surgical intervention related to their illness for vascular access or a biopsy when they are known to have HIV infection or AIDS. Universal precautions have been drawn up by the CDC in the United States and largely adopted by the NHS in the UK (in summary):

- when there is a risk of splashing, particularly with power tools;
- use of a full face mask ideally, or protective spectacles;
- use of fully waterproof, disposable gowns and drapes, particularly during seroconversion;
- boots to be worn, not clogs, to avoid injury from dropped sharps;
- double gloving needed (a larger size on the inside is more comfortable);
- allow only essential personnel in theatre;
- avoid unnecessary movement in theatre;
- respect is required for sharps, with passage in a kidney dish;
- a slow meticulous operative technique is needed with minimised bleeding.

After contamination

Needle-stick injuries are commonest on the non-dominant index finger during operative surgery. Hollow needle injury carries the

greatest risk of HIV transmission. The injured part should be washed under running water and the incident reported. Local policies dictate whether post-exposure HAART should be given. Occupational advice is required after high-risk exposure together with the need for HIV testing and the option for continuation in an operative specialty.

Surgery in the tropics

LEARNING OBJECTIVES

To be aware of:

- The common surgical conditions that occur in the tropics

To appreciate:

- That many patients do not seek medical help until late in the disease course

To know:

- The emergency presentations of the various conditions as patients in developing countries do not seek treatment until they are very ill

To be able to:

- Diagnose and treat these conditions, particularly as emergencies, in western hospitals because of the ease of global travel

To realise:

- That ideal management needs good teamwork between the surgeon, physician, radiologist, pathologist and microbiologist

INTRODUCTION

Most surgical conditions in the tropics are associated with parasitic infestations. With the ease of international travel, diseases that are common in the tropics and developing countries may be seen in the UK, especially presenting as emergencies.

This section deals with the conditions that a surgeon might occasionally encounter in a visitor to these shores. Details of the life cycles of the parasites will not be dealt with. Readers are, however, advised to refer to the 24th edition of this book should they wish details of the parasitology. The principles of surgical treatment are dealt with in the appropriate sections although, for operative details, the reader should refer to a relevant textbook.

AMOEBIASIS

Introduction

Amoebiasis is caused by *Entamoeba histolytica*. The disease is common in the Indian subcontinent, Africa and parts of Central and South America where almost half the population is infected. The majority remain asymptomatic carriers. The mode of infection is via the faeco-oral route, and the disease occurs as a result of substandard hygiene and sanitation. Amoebic liver abscess, the commonest extraintestinal manifestation, occurs in less than 10% of the infected population and, in endemic areas, is much more common than pyogenic abscess. Patients who are immunocompromised or alcoholic are more susceptible to infection.

Pathogenesis

The organism enters the gut through food or water contaminated with the cyst. In the small bowel, the cysts hatch, and

a large number of trophozoites are released and carried to the colon where flask-shaped ulcers form in the submucosa. The trophozoites multiply, ultimately forming cysts, which enter the portal circulation or are passed in the faeces as an infective form that infects other humans as a result of insanitary conditions.

Having entered the portal circulation, the trophozoites are filtered and trapped in the interlobular veins of the liver. They multiply in the portal triads causing focal infarction of hepatocytes and liquefactive necrosis as a result of proteolytic enzymes produced by the trophozoites. The areas of necrosis eventually coalesce to form the abscess cavity. The term 'amoebic hepatitis' is used to describe the microscopic picture in the absence of macroscopic abscess. This is a differentiation in theory only as the medical treatment is the same.

The right lobe is involved in 80% of cases, the left in 10% and the rest are multiple. The right lobe of the liver is involved more often possibly because blood from the superior mesenteric vein runs on a straighter course through the portal vein into the larger lobe. The abscesses are most common high in the diaphragmatic surface of the right lobe. This may cause pulmonary symptoms and chest complications. The abscess cavity contains chocolate-coloured, odourless, 'anchovy sauce'-like fluid that is a mixture of necrotic liver tissue and blood. There may be secondary infection of the abscess. This causes the pus to be smelly. While pus in the abscess is sterile unless secondarily infected, trophozoites may be found in the abscess wall in a minority of cases. Untreated abscesses are likely to rupture.

Chronic infection of the large bowel may result in a granulomatous lesion along the large bowel, most commonly seen in the caecum, called an amoeboma (Summary box 5.1).

Summary box 5.1

Amoebiasis – pathology

- *Entamoeba histolytica* is the most common pathogenic amoeba in man
- The vast majority of carriers are asymptomatic
- Insanitary conditions and poor personal hygiene encourage transmission of the infection
- In the small intestine, the parasite hatches into trophozoites, which invade the submucosa producing ulcers
- In the portal circulation, the parasite causes liquefactive necrosis in the liver producing an abscess. This is the commonest extraintestinal manifestation
- The majority of abscesses occur in the right lobe
- A mass in the course of the large bowel may indicate an amoeboma

Clinical features

The typical patient with amoebic liver abscess is a young adult male with a history of pain and fever and insidious onset of non-specific symptoms such as anorexia, fever, night sweats, malaise, cough and weight loss, which gradually progress to more specific symptoms of pain in the right upper abdomen, shoulder tip pain, hiccoughs and a non-productive cough. A past history of bloody diarrhoea or travel to an endemic area raises the index of suspicion.

Examination reveals a patient who is toxic and anaemic. The patient will have upper abdominal rigidity, tender hepatomegaly, tender and bulging intercostal spaces, overlying skin oedema, a pleural effusion and basal pneumonitis – the last symptom is usually a late manifestation. Occasionally, a tinge of jaundice or ascites may be present. Rarely, the patient may present as an emergency due to the effects of rupture into the peritoneal, pleural or pericardial cavity.

Amoeboma

This is a chronic granuloma arising in the large bowel, most commonly seen in the caecum. It is prone to occur in longstanding amoebic infection that has been treated intermittently with drugs without completion of a full course, a situation that arises from indiscriminate self-medication, particularly in developing countries.

This can easily be mistaken for a carcinoma. An amoeboma should be suspected when a patient from an endemic area with generalised ill health and pyrexia has a mass in the right iliac fossa with a history of blood-stained mucoid diarrhoea. Such a patient is highly unlikely to have a carcinoma as altered bowel habit is not a feature of right-sided colonic carcinoma.

Investigations

The haematological and biochemical investigations reflect the presence of a chronic infective process: anaemia, leucocytosis, elevated erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), hypoalbuminaemia and deranged liver function tests, particularly elevated alkaline phosphatase.

Serological tests are more specific, with the majority of patients showing antibodies in serum. These can be detected by tests for complement fixation, indirect haemagglutination (IHA), indirect immunofluorescence and enzyme-linked immunosorbent

assay (ELISA). They are extremely useful in detecting acute infection in non-endemic areas. IHA has a very high sensitivity rate in acute amoebic liver abscess in non-endemic regions and remains elevated for some time. The persistence of antibodies in a large majority of the population in endemic areas precludes its use there as a diagnostic investigation. In these cases, tests such as counter-immunoelectrophoresis are more useful for detecting acute infection.

An out-patient rigid sigmoidoscopy (using a disposable instrument) can be very useful particularly if the patient complains of bloody mucoid diarrhoea. Most amoebic ulcers occur in the rectosigmoid and are therefore within reach of the sigmoidoscope; shallow skip lesions and ‘flask-shaped’ or ‘collar-stud’ undermined ulcers may be seen, and can be biopsied or scrapings can be taken along with mucus for immediate microscopic examination. The presence of trophozoites distinguishes the condition from ulcerative colitis.

Imaging techniques

On ultrasound, an abscess cavity in the liver is seen as a hypochoic or anechoic lesion with ill-defined borders; internal echoes suggest necrotic material or debris (Fig. 5.1). The investigation is very accurate and is used for aspiration, both diagnostic and therapeutic. Where there is doubt about the diagnosis, a computerised tomography (CT) scan may be helpful (Fig. 5.2).

Diagnostic aspiration is of limited value except for establishing the typical colour of the aspirate, which is sterile and odourless unless it is secondarily infected.

A CT scan may show a raised right diaphragm, a pleural effusion and evidence of pneumonitis (Fig. 5.3a and b).

An ‘apple-core’ deformity on barium enema would arouse suspicion of a carcinoma. A colonoscopy and biopsy are mandatory as the macroscopic appearance may be indistinguishable from carcinoma. In doubtful cases, vigorous medical treatment is given, and the patient’s colon is imaged again in 3–4 weeks, as these masses are known to regress completely on a full course of drug therapy. However, it must be borne in mind that an amoeboma and carcinoma can coexist (Summary box 5.2).

Figure 5.1 Ultrasound of the liver showing a large amoebic liver abscess with necrotic tissue in the right lobe.

Figure 5.2 Computerised tomographic (CT) scan showing an amoebic liver abscess in the right lobe.

Figure 5.3 Computerised tomographic (CT) scans showing multiple amoebic liver abscesses with extension into the chest.

Summary box 5.2

Diagnostic pointers for infection with *Entamoeba histolytica*

- Bloody mucoid diarrhoea in a patient from an endemic area or following a recent visit to such a country
- Upper abdominal pain, fever, cough, malaise
- In chronic cases, a mass in the right iliac fossa = amoeboma
- Sigmoidoscopy shows typical ulcers – biopsy and scrapings may be diagnostic
- Serological tests are highly sensitive and specific outside endemic areas
- Ultrasound and CT scans are the imaging methods of choice

Treatment

Medical treatment is very effective and should be the first choice in the elective situation, with surgery being reserved for complications. Metronidazole and tinidazole are the effective drugs. After treatment with metronidazole and tinidazole, diloxanide furoate, which is not effective against hepatic infestation, is used for 10 days to destroy any intestinal amoebae.

Aspiration is carried out when imminent rupture of an abscess is expected. Aspiration also helps in the penetration of metronidazole, and so reduces the morbidity when carried out with drug treatment in a patient with a large abscess. If there is evidence of secondary infection, appropriate drug treatment is added. The threshold for aspirating an abscess in the left lobe is lower because of its predilection for rupturing into the pericardium.

Surgical treatment should be reserved for the complications of rupture into the pleural (usually the right side), peritoneal or pericardial cavities. Resuscitation, drainage and appropriate lavage with vigorous medical treatment are the key principles. In the large bowel, severe haemorrhage and toxic megacolon are rare complications. In these patients, the general principles of a surgical emergency apply. Resuscitation is followed by resection of bowel with exteriorisation. Then the patient is given vigorous supportive therapy. All such cases are managed in the intensive care unit.

An amoeboma that has not regressed after full medical treatment should be managed with a colonic resection, particularly if cancer cannot be excluded (Summary box 5.3).

Summary box 5.3

Amoebiasis – treatment

- Medical treatment is very effective
- In large abscesses, repeated aspiration is combined with drug treatment
- Surgical treatment is reserved for complications such as rupture into the pleural, peritoneal or pericardial cavities
- Acute toxic megacolon and severe haemorrhage are intestinal complications that are treated with intensive supportive therapy followed by resection and exteriorisation
- When an amoeboma is suspected in a colonic mass, cancer should be excluded by appropriate imaging

ASCARIS LUMBRICOIDES (ROUNDWORM)

Introduction

Ascaris lumbricoides, commonly called the roundworm, is the commonest intestinal nematode to infect the human and affects a quarter of the world's population. The parasite causes pulmonary symptoms as a larva and intestinal symptoms as an adult worm.

Pathology and life cycle

The eggs can survive in a hostile environment for a long time. The hot and humid conditions in the tropics are ideally suited for the eggs to turn into embryos. The fertilised eggs are present in soil contaminated with infected faeces. Faeco-oral contamination causes human infection.

As the eggs are ingested, the released larvae travel to the liver via the portal system and then through the systemic circulation to reach the lung. The process of maturation takes up to 8 weeks. The developed larvae reach the alveoli, are coughed up, swallowed and continue their maturation in the small intestine. Sometimes, the young worm migrates from the tracheobronchial tree into the oesophagus, thus finding its way into the gastrointestinal tract, from where it can migrate to the common bile duct or pancreatic duct. The mature female, once in the small bowel, produces innumerable eggs that are fertilised and thereafter excreted in the stool to perpetuate the life cycle. Eggs in the biliary tract can form a nidus for a stone.

Clinical features

The larval stage in the lungs causes pulmonary symptoms – dry cough, chest pain, dyspnoea and fever – referred to as Loeffler's syndrome. The adult worm can grow up to 45 cm long. Its presence in the small intestine causes malnutrition, failure to thrive and abdominal pain. Worms that migrate into the common bile duct can produce ascending cholangitis and obstructive jaundice, while features of acute pancreatitis may be caused by a worm in the pancreatic duct.

Small intestinal obstruction can occur, particularly in children, due to a bolus of adult worms incarcerated in the terminal ileum. This is a surgical emergency. Rarely, perforation of the small bowel may occur from ischaemic pressure necrosis from the bolus of worms.

A high index of suspicion is necessary if one is not to miss the diagnosis. If a person from a tropical developing country, or one who has recently returned from an endemic area, presents with pulmonary, gastrointestinal, hepatobiliary and pancreatic symptoms, ascariasis infestation should be high on the list of possible diagnoses.

Investigations

Increase in the eosinophil count is common, in keeping with most other parasitic infestations. Stool examination may show ova. Sputum or bronchoscopic washings may show Charcot–Leyden crystals or the larvae.

Chest X-ray may show fluffy exudates in Loeffler's syndrome. A barium meal and follow-through may show a bolus of worms in the ileum (Fig. 5.4) or lying freely within the small bowel (Fig. 5.5). An ultrasound may show a worm in the common bile duct (Fig. 5.6) or pancreatic duct (Fig. 5.7). On magnetic resonance cholangiopancreatography (MRCP), an adult worm may be seen in the common bile duct in a patient presenting with features of obstructive jaundice (Fig. 5.8) (Summary box 5.4).

Summary box 5.4

Ascariasis – pathogenesis

- It is the commonest intestinal nematode affecting man
- Typically found in a humid atmosphere and poor sanitary conditions; hence is seen in the tropics and developing countries
- Larvae cause pulmonary symptoms; adult worms cause gastrointestinal, biliary and pancreatic symptoms
- Distal ileal obstruction due to bolus of worms; ascending cholangitis and obstructive jaundice from infestation of the common bile duct
- Acute pancreatitis when a worm is lodged in the pancreatic duct
- Perforation of the small bowel is rare

Treatment

The pulmonary phase of the disease is usually self-limiting and requires symptomatic treatment only. For intestinal disease, patients should ideally be under the care of a physician for treatment with anthelmintic drugs. Certain drugs may cause rapid death of the adult worms and, if there are many worms in the terminal ileum, the treatment may actually precipitate acute intestinal obstruction from a bolus of dead worms. Children who present with features of intermittent or subacute obstruction should be given a trial of conservative management in the form of intravenous fluids, nasogastric suction and hypertonic saline enemas. The last of these helps to disentangle the bolus of worms and also increases intestinal motility.

Surgery is reserved for complications such as intestinal obstruction that has not resolved on a conservative regimen, and when perforation is suspected. At laparotomy, the bolus of worms in the terminal ileum is milked through the ileocaecal valve into the colon for natural passage in the stool. Postoperatively,

Figure 5.5 Barium meal and follow-through showing roundworms in the course of the small bowel with barium seen inside the worms in an 18-year-old patient who presented with bouts of colicky abdominal pain and bilious vomiting, which settled with conservative management (courtesy of Dr P. Bhattacharaya, Kolkata, India).

Figure 5.6 Ultrasound scan showing a roundworm in the common bile duct (CBD). The patient presented with obstructive jaundice and had asymptomatic gallstones. On endoscopic retrograde cholangiopancreatography (ERCP), part of the worm was seen outside the ampulla in the duodenum and was removed through the endoscope. Subsequent laparoscopic cholecystectomy was uneventful.

hypertonic saline enemas may help in the extrusion of the worms. Strictures, gangrenous areas or perforations need resection and anastomosis. If the bowel wall is healthy, enterotomy and removal of the worms may be performed (Fig. 5.9).

Figure 5.7 Ultrasound scan showing a roundworm in the pancreatic duct (PD). The patient presented with acute pancreatitis. The worm was seen to be moving in real time and was removed endoscopically (courtesy of Dr P. Bhattacharaya, Kolkata, India).

Figure 5.8 Magnetic resonance cholangiopancreatography (MRCP) showing a roundworm in the common bile duct (CBD). The worm could not be removed endoscopically. The patient underwent an open cholecystectomy and exploration of the CBD.

As a result of perforation due to roundworm, the parasites may be found lying free in the peritoneal cavity. The site of perforation may be brought out as an ileostomy because, in the presence of a large number of worms, closure or an anastomosis may be at risk of breakdown from the activity of the worms. Exteriorisation, although the ideal operation in severe sepsis, is unfortunately sometimes not done because of the reluctance on the part of the patient to accept such a procedure as good stoma care is not always available. In such circumstances, resection of the diseased ileum, closure of the distal bowel and end-to-side ileotransverse anastomosis is a good alternative.

When a patient is operated upon as an emergency for a

Figure 5.9 Roundworms removed at laparotomy in a 16-year-old patient who presented with acute intestinal obstruction (courtesy of the Pathology Museum, Calcutta Medical Research Institute, Kolkata, India).

suspected complication of roundworm infestation, the actual diagnosis at operation may turn out to be acute appendicitis, typhoid perforation or tuberculous stricture, and the presence of roundworms is an incidental finding. Such a patient requires the appropriate surgery depending upon the pathology.

Common bile duct or pancreatic duct obstruction from a roundworm can be treated by endoscopic removal, failing which open exploration of the common bile duct is necessary. Cholecystectomy is also carried out. A full course of anti-parasitic treatment must follow any surgical intervention (Summary box 5.5).

Summary box 5.5

Ascariasis – diagnosis and management

- Barium meal and follow-through will show worms scattered in the small bowel
- Ultrasound may show worms in the common bile duct and pancreatic duct
- Conservative management with anthelmintics is the first line of treatment even in obstruction
- Surgery is a last resort – various options are available

ASIATIC CHOLANGIOHEPATITIS

Introduction

This disease, also called oriental cholangiohepatitis, is caused by infestation of the hepatobiliary system by *Clonorchis sinensis*. It has a high incidence in the tropical regions of South-east Asia, particularly among those living in the major sea ports and river estuaries. The organism, which is a type of liver fluke, resides in snails and fish that act as intermediate hosts. Ingestion of infected fish and snails when eaten raw or partly cooked causes the

infection in humans and other fish-eating mammals, which are the definitive hosts.

Pathology

In humans, the parasite matures into the adult worm in the intrahepatic biliary radicles where they may reside for many years. The intrahepatic bile ducts are dilated with epithelial hyperplasia and periductal fibrosis. These changes may lead to dysplasia causing cholangiocarcinoma – the most serious complication of this parasitic infestation.

The eggs or dead worms may form a nidus for stone formation in the gall bladder or common bile duct, which becomes thickened and much dilated in the late stages. Intrahepatic bile duct stones are also caused by the parasite producing mucin-rich bile. The dilated intrahepatic bile ducts may lead to cholangitis, liver abscess and hepatitis.

Diagnosis

The disease may remain dormant for many years. Clinical features are non-specific, for example fever, malaise, anorexia and upper abdominal discomfort. The complete clinical picture can consist of fever with rigors due to ascending cholangitis, obstructive jaundice due to stones, biliary colic and pruritis. Acute pancreatitis may occur because of obstruction of the pancreatic duct by an adult worm. If any person or an emigrant to the west from an endemic area complains of symptoms of biliary tract disease, *Clonorchis* infestation should be considered in the differential diagnosis.

In advanced cases, liver function tests are abnormal. Confirmation of the condition is by examination of stool or duodenal aspirate, which may show the eggs or adult worms. Ultrasound scan findings can be characteristic showing the uniform dilatation of small peripheral intrahepatic bile ducts with only minimal dilatation of the common hepatic and common bile ducts, although the latter are dilated when the obstruction is caused by stones. The thickened duct walls show increased echogenicity and non-shadowing echogenic foci in the bile ducts representing the worms or eggs. Endoscopic retrograde cholangiopancreatography (ERCP) will confirm these findings (Summary box 5.6).

Summary box 5.6

Asiatic cholangiohepatitis – pathogenesis and diagnosis

- Occurs in the Far Eastern tropical zones
- Causative parasite is *Clonorchis sinensis*
- Produces bile duct hyperplasia, intrahepatic duct dilatation and stones
- Increases the risk of cholangiocarcinoma
- May remain dormant for many years
- When active, there are biliary tract symptoms in a generally unwell patient
- Stool examination for eggs or worms is diagnostic
- Ultrasound scan of hepatobiliary system and ERCP are also diagnostic

Treatment

Praziquantel and albendazole are the drugs of choice. However, the surgeon faces a challenge when there are stones not only in the gall bladder but also in the common bile duct. Cholecystectomy with

exploration of the common bile duct is performed when indicated. Repeated washouts are necessary during the exploration, as the common bile duct is dilated and contains stones, biliary debris, sludge and mud. This should be followed by choledochoduodenostomy. As this is a disease with a prolonged and relapsing course, some surgeons prefer to do a choledochojejunostomy to a Roux loop. The Roux loop is brought up to the abdominal wall, referred to as 'an access loop', which allows the interventional radiologist to deal with any future stones.

As a public health measure, people who have emigrated to the west from an endemic area should be offered screening for *Clonorchis* infestation in the form of ultrasound of the hepatobiliary system. This condition can be diagnosed and treated and even cured when it is in its subclinical form. Most importantly, the risk of developing the dreadful disease of cholangiocarcinoma is eliminated (Summary box 5.7).

Summary box 5.7

Asiatic cholangiohepatitis – treatment

- Medical treatment can be curative
- Surgical treatment is cholecystectomy, exploration of the common bile duct and some form of biliary–enteric bypass
- Prevention – consider offering hepatobiliary ultrasound as a screening procedure to recently arrived migrants to the west from endemic areas

FILARIASIS

Introduction

Filariasis is mainly caused by the parasite *Wuchereria bancrofti* carried by the mosquito. A variant of the parasite called *Brugia malayi* and *Brugia timori* is responsible for causing the disease in about 10% of sufferers. The condition affects more than 90 million people worldwide, two-thirds of whom live in India, China and Indonesia. According to the World Health Organization (WHO), filariasis is the second most common cause, after leprosy, of long-term disability.

Once bitten by the mosquito, the matured eggs enter the human circulation to hatch and grow into adult worms; the process of maturation takes about 1 year. The adult worms mainly colonise the lymphatic system.

Diagnosis

It is mainly males who are affected because females in general cover a greater part of their bodies, thus making them less prone to mosquito bites. In the acute presentation, there are episodic attacks of fever with lymphadenitis and lymphangitis.

Cesar Roux, 1857–1934, Professor of Surgery and Gynaecology, Lausanne, Switzerland, described this method of forming a jejunal conduit in 1908.
Otto Eduard Heinrich Wucherer, 1820–1873, a German Physician who practised in Brazil, South America.
Joseph Bancroft, 1836–1894, an English Physician working in Australia.

Occasionally, adult worms may be felt subcutaneously. Chronic manifestations appear after repeated acute attacks over several years. The adult worms cause lymphatic obstruction resulting in massive lower limb oedema. Obstruction to the cutaneous lymphatics causes skin thickening, not unlike the 'peau d'orange' appearance in breast cancer, thus exacerbating the limb swelling. Secondary streptococcal infection is common (Fig. 5.10). Recurrent attacks of lymphangitis cause fibrosis of the lymph channels, resulting in a grossly swollen limb with thickened skin producing the condition of elephantiasis (Fig. 5.11). Bilateral lower limb filariasis is often associated with scrotal and penile elephantiasis. Early on, there may be a hydrocele underlying scrotal filariasis (Fig. 5.12).

Chyluria and chylous ascites may occur. A mild form of the disease can affect the respiratory tract, causing dry cough, and is

Figure 5.10 Bilateral lower limb filariasis with bacterial infection on the right side.

Figure 5.11 Elephantiasis of the lower limb (courtesy of Dr A. Golash, Kolkata, India).

peau d'orange is French for 'orange skin'.

Figure 5.12 Filariasis of the scrotum with hydrocele.

referred to as tropical pulmonary eosinophilia. The condition of filariasis is clinically very obvious, and thus investigations in the full-blown case are superfluous. Eosinophilia is common, and a nocturnal peripheral blood smear may show the immature forms or microfilariae. The parasite may also be seen in chylous urine, ascites and hydrocele fluid.

Treatment

Medical treatment with diethylcarbamazine is very effective in the early stages before the gross deformities of elephantiasis have developed. In the early stages of limb swelling, intermittent pneumatic compression helps, but the treatment has to be repeated over a prolonged period.

A hydrocele is treated by the usual operation of excision and eversion of the sac with, if necessary, excision of redundant skin. Operations for reducing the size of the limb are hardly ever done these days because the procedures are so rarely successful (Summary box 5.8).

Summary box 5.8

Filariasis

- Caused by *Wuchereria bancrofti* that is carried by the mosquito
- Lymphatics are mainly affected, resulting in gross limb swelling
- Eosinophilia; immature worms seen in a nocturnal peripheral blood smear
- Gross forms of the disease cause a great deal of disability and misery
- Early cases are very amenable to medical treatment
- Intermittent pneumatic compression gives some relief
- The value of various surgical procedures is largely unproven

HYDATID DISEASE

Introduction and pathology

Commonly called dog tape worm, hydatid disease is caused by *Echinococcus granulosus*. While it is common in the tropics, in the UK, the occasional patient may come from a rural sheep-farming community.

The dog is the definitive host and, as a pet, is the commonest source of infection transmitted to the intermediate hosts – humans, sheep and cattle. In the dog, the adult worm reaches the small intestine, and the eggs are passed in the faeces. These eggs are highly resistant to extremes of temperature and may survive for long periods. In the dog's intestine, the cyst wall is digested, allowing the protoscolices to develop into adult worms. Close contact with the infected dog causes contamination by the oral route, with the ovum thus gaining entry into the human gastrointestinal tract.

The cyst is characterised by three layers, an outer *pericyst* derived from compressed host organ tissues, an intermediate hyaline *ectocyst* which is non-infective and an inner *endocyst* that is the germinal membrane and contains viable parasites which can separate forming daughter cysts. A variant of the disease occurs in colder climates caused by *Echinococcus multilocularis*, in which the cyst spreads from the outset by actual invasion rather than expansion.

Classification

In 2003, the WHO Informal Working Group on Echinococcosis (WHO-IWGE) proposed a standardised ultrasound classification based on the status of activity of the cyst. This is universally accepted, particularly because it helps to decide on the appropriate management. Three groups have been recognised:

- Group 1: Active group – cysts larger than 2 cm and often fertile.
- Group 2: Transition group – cysts starting to degenerate and entering a transitional stage because of host resistance or treatment, but may contain viable protoscolices.
- Group 3: Inactive group – degenerated, partially or totally calcified cysts; unlikely to contain viable protoscolices.

Clinical features

As the parasite can colonise virtually every organ in the body, the condition can be protean in its presentation. When a sheep farmer, who is otherwise healthy, complains of a gradually enlarging painful mass in the right upper quadrant with the physical findings of a liver swelling, a hydatid liver cyst should be considered. The liver is the organ most often affected. The lung is the next most common. The parasite can affect any organ (Figs 5.13, 5.14a and b) or several organs in the same patient (Fig. 5.15a and b).

The disease may be asymptomatic and discovered coincidentally at post mortem or when an ultrasound or CT scan is done for some other condition. Symptomatic disease presents with a swelling causing pressure effects. Thus, a hepatic lesion causes dull pain from stretching of the liver capsule, and a pulmonary lesion, if large enough, causes dyspnoea. Daughter cysts may communicate with the biliary tree causing obstructive jaundice and all the usual clinical features associated with it in addition to symptoms attributable to a parasitic infestation (Fig. 5.16). Features of raised intracranial pressure or unexplained headaches in a patient from a sheep-rearing community should raise the suspicion of a cerebral hydatid cyst.

Figure 5.13 Computerised tomographic (CT) scan showing a hydatid cyst of the pancreas. A differential diagnosis of hydatid cyst or a tumour was considered. At exploration, the patient was found to have a hydatid cyst, which was excised followed by a 30-month treatment with albendazole, and remains free of disease.

The patient may present as an emergency with severe abdominal pain following minor trauma when the CT scan may be diagnostic (Fig. 5.17). Rarely, a patient may present as an emergency with features of anaphylactic shock without any obvious cause. Such a patient may subsequently cough up white material that

contains scolices that have travelled into the tracheobronchial tree from rupture of a hepatic hydatid on the diaphragmatic surface of the liver.

Diagnosis

There should be a high index of suspicion. Investigations show a raised eosinophil count; serological tests such as ELISA and immunoelectrophoresis point towards the diagnosis. Ultrasound and CT scan are the investigations of choice. The CT scan shows a smooth space-occupying lesion with several septa (Fig. 5.18). An ultrasound of the biliary tract may show abnormality in the gall bladder and bile ducts. Hydatid infestation of the biliary system (Fig. 5.19) should then be suspected. Ultimately, the diagnosis is made by a combination of good history and clinical examination supplemented by serology and radiological imaging techniques (Summary box 5.9).

Summary box 5.9

Hydatid disease – diagnosis

- In the UK, the usual sufferer is a sheep farmer
- While any organ may be involved, the liver is by far the most commonly affected
- Elective clinical presentation is usually in the form of a painful lump arising from the liver
- Anaphylactic shock due to rupture of the hydatid cyst is the emergency presentation
- CT scan is the best imaging modality – the diagnostic feature is a space-occupying lesion with a smooth outline with septa

Treatment

Here, the treatment of hepatic hydatid is outlined as the liver is most commonly affected, but the same general principles apply whichever organ is involved.

Figure 5.14 Anteroposterior (a) and lateral (b) views of computerised tomographic (CT) scans showing a large hydatid cyst of the right adrenal gland. The patient presented with a mass in the right loin and underwent an adrenalectomy (courtesy of Dr P. Bhattacharaya, Kolkata, India).

Figure 5.15 Computerised tomographic (CT) scan showing disseminated hydatid cysts of the abdomen (a) and pelvis (b). The patient was started on albendazole and lost to follow-up (courtesy of Dr P. Bhattacharaya, Kolkata, India).

These patients should be treated in a tertiary unit where good teamwork between an expert hepatobiliary surgeon, an experienced physician and an interventional radiologist is available. Surgical treatment by minimal access therapy is best summarised by the mnemonic PAIR – puncture, aspiration, injection and reaspiration. This is done after adequate drug treatment with albendazole, although praziquantel has also been used, both these drugs being available only on a ‘named patient’ basis.

Whether the patient is treated only medically or in combination with surgery will depend upon the clinical group (which gives an idea as to its activity), the number of cysts and their anatomical position. Radical total or partial pericystectomy with

omentoplasty or hepatic segmentectomy (especially if the lesion is in a peripheral part of the liver) are some of the surgical options. During the operation, scolicalid agents are used, such as hypertonic saline (15–20%), ethanol (75–95%) or 1% povidone iodine, although some use a 10% solution. This may cause sclerosing cholangitis if biliary radicles are in communication with the cyst wall. A laparoscopic approach to these procedures is being tried.

Obviously, cysts in other organs need to be treated in accordance with the actual anatomical site along with the general principles described. An asymptomatic cyst which is inactive (group 3) may just be observed (Summary box 5.10).

Figure 5.16 Magnetic resonance cholangiopancreatography (MRCP) showing a large hepatic hydatid cyst with daughter cysts communicating with the common bile duct causing obstruction and dilatation of the entire biliary tree (courtesy of Dr B. Agarwal, New Delhi, India).

Figure 5.17 Computerised tomographic (CT) scan of the upper abdomen showing a hypodense lesion of the left lobe of the liver; the periphery of the lesion shows a double edge. This is the lamellar membrane of the hydatid cyst that separated after trivial injury. The patient was a 14-year-old girl who developed a rash and pain in the upper abdomen after dancing. The rash settled down after a course of anti-histamines. The CT scan was done 2 weeks later for persisting upper abdominal pain.

Figure 5.18 Computerised tomographic (CT) scan showing a hydatid cyst with septa in the left lobe of the liver.

Summary box 5.10

Hydatid cyst of the liver – treatment

- Ideally managed in a tertiary unit by a multidisciplinary team of hepatobiliary surgeon, physician and interventional radiologist
- Leave asymptomatic and inactive cysts alone – monitor size by ultrasound
- Active cysts should first be treated by a full course of albendazole
- Several procedures are available – PAIR, pericystectomy with omentoplasty and hepatic segmentectomy; it is important to choose the most appropriate option
- Increasingly, a laparoscopic approach is being tried

Figure 5.19 Ultrasound of the gall bladder (GB) and common bile duct (CBD) showing a dilated CBD. This is the same patient as in Fig. 5.18; the patient presented with jaundice from sludge in the CBD due to daughter cysts travelling down biliary channels in communication with the cyst.

LEPROSY

Introduction

Leprosy, also called Hansen's disease, is a chronic infectious disease caused by the acid-fast bacillus, *Mycobacterium leprae*, that is widely prevalent in the tropics. Globally, India, Brazil, Nepal, Mozambique, Angola and Myanmar (Burma) account for 91% of all the cases; India alone accounts for 78% of the world's disease. Patients suffer not only from the primary effects of the disease but also from social discrimination, sadly compounded by the inappropriate term 'leper' for one afflicted with this disease. The use of the term 'leper', still used metaphorically to denote a social outcast, does not help to break down the social barriers that continue to exist against the sufferer.

Pathology

The disease is transmitted from the nasal secretions of a patient, the infection being contracted in childhood or early adolescence. After an incubation period of several years, the disease presents with skin, upper respiratory or neurological manifestations. The bacillus is acid fast but weakly so compared with *Mycobacterium tuberculosis*.

The disease is broadly classified into two groups – lepromatous and tuberculoid. In lepromatous leprosy, there is widespread dissemination of abundant bacilli in the tissues with macrophages and a few lymphocytes. This is a reflection of the poor immune response, resulting in depleted host resistance from the patient. In tuberculoid leprosy, on the other hand, the patient shows a strong immune response with scant bacilli in the tissues, epithelioid granulomas, numerous lymphocytes and giant cells. The tissue damage is proportional to the host's immune response. There are various grades of the disease between the two main spectra (Summary box 5.11).

Gerhard Henrik Armauer Hansen, 1841–1912, a Physician in charge of a Leper hospital near Bergen, Norway.

Summary box 5.11

***Mycobacterium leprae* – pathology**

- Leprosy is a chronic curable infection caused by *Mycobacterium leprae*
- It occurs mainly in tropical regions and developing countries
- The majority of cases are located in the Indian subcontinent
- Transmission is through nasal secretions
- It is attributed to poor hygiene and insanitary conditions
- The incubation period is several years
- The initial infection occurs in childhood
- Lepromatous leprosy denotes a poor host immune reaction
- Tuberculoid leprosy occurs when host resistance is stronger than virulence of the organism

Clinical features and diagnosis

The disease is slowly progressive and affects the skin, upper respiratory tract and peripheral nerves. In tuberculoid leprosy, the damage to tissues occurs early and is localised to one part of the body with limited deformity of that organ. Neural involvement is characterised by thickening of the nerves, which are tender. There may be asymmetrical well-defined anaesthetic hypopigmented or erythematous macules with elevated edges and a dry and rough surface – lesions called leprids. In lepromatous leprosy, the disease is symmetrical and extensive. Cutaneous involvement occurs in the form of several pale macules that form plaques and nodules called lepromas. The deformities produced are divided into primary, which are caused by leprosy or its reactions, and secondary, resulting from effects such as anaesthesia of the hands and feet.

Nodular lesions on the face in the acute phase of the lepromatous variety are known as 'leonine facies' (looking like a lion). Later, there is wrinkling of the skin giving an aged appearance to a young individual. There is loss of the eyebrows and destruction of the lateral cartilages and septum of the nose with collapse of the nasal bridge and lifting of the tip of the nose (Fig. 5.20). There may

Figure 5.20 Lateral view of the face showing collapse of the nasal bridge due to destruction of nasal cartilage by leprosy.

Figure 5.21 Frontal view of the face showing eye changes in leprosy – paralysis of orbicularis oculi and loss of eyebrows.

be paralysis of the branches of the facial nerve in the bony canal or of the zygomatic branch. Blindness may be attributed to exposure keratitis or iridocyclitis. Paralysis of the orbicularis oculi causes incomplete closure of the eye, epiphora and conjunctivitis (Fig. 5.21). The hands are typically clawed (Fig. 5.22a and b) because of involvement of the ulnar nerve at the elbow and the median nerve at the wrist. Anaesthesia of the hands makes these patients vulnerable to frequent burns and injuries. Similarly, clawing of the toes (Fig. 5.23) occurs as a result of involvement of the posterior tibial nerve. When the lateral popliteal nerve is affected, it leads to foot drop, and the nerve can be felt to be thickened behind the upper end of the fibula. Anaesthesia of the feet predisposes to trophic ulceration (Fig. 5.24), chronic infection, contraction and autoam-

Figure 5.22 Typical bilateral claw hand from leprosy due to involvement of the ulnar and median nerves.

putation. Involvement of the testes causes atrophy, which in turn results in gynaecomastia (Fig. 5.25a and b). Confirmation of the diagnosis is obtained by a skin smear or skin biopsy, which shows the classical histological and microbiological features (Summary box 5.12).

Summary box 5.12

Leprosy – diagnosis

- Typical clinical features and awareness of the disease should help to make a diagnosis
- The face has an aged look about it with collapse of the nasal bridge and eye changes
- Thickened peripheral nerves, patches of anaesthetic skin, claw hands, foot drop and trophic ulcers are characteristic
- Microbiological examination of the acid-fast bacillus and typical histology on skin biopsies are confirmatory

Figure 5.23 Claw toes from involvement of the posterior tibial nerve by leprosy; also note autoamputation of toes of the right foot.

Figure 5.24 Bilateral trophic ulceration of the feet due to anaesthesia of the soles resulting from leprosy; also note claw toes on the left foot.

Figure 5.25 Typical leonine facies in leprosy (a) and gynaecomastia (b).

Treatment

A team approach between an infectious diseases specialist, plastic surgeon, ophthalmologist, hand and orthopaedic surgeon is important. Multiple drug therapy for 12 months is the key to treatment. This is carried out according to the WHO guidelines using rifampicin, dapsone and clofazimine. During treatment, the patient may develop acute manifestations. These are controlled with steroids.

Surgical treatment is indicated in advanced stages of the disease for functional disability of limbs, cosmetic disfigurement of

the face and visual problems. These entail major reconstructive surgery, the domain of the plastic surgeon. Deformities of the hands and feet require various forms of tendon transfer, which need to be carried out by specialist hand or orthopaedic surgeons.

The general surgeon may be called upon to treat a patient when the deformity is so advanced that it requires amputation, or in an emergency situation when abscesses need to be drained.

All surgical procedures obviously need to be done under anti-leprosy drug treatment. This is best achieved by a team approach. Educating the patients about the dreadful sequelae of the disease so that they seek medical help early is important. It is also necessary to educate the general public that patients suffering from the disease should not be made social outcasts (Summary box 5.13).

Summary box 5.13

Leprosy – treatment

- Multiple drug therapy for a year
- Team approach
- Surgical reconstruction requires the expertise of a hand surgeon, orthopaedic surgeon and plastic surgeon
- Education of the patient and general public should be the keystone in prevention

POLIOMYELITIS

Introduction

Poliomyelitis is an enteroviral infection that sadly still affects children in developing countries – this is in spite of effective vaccination having been universally available for several decades. The virus enters the body by inhalation or ingestion. Clinically, the disease manifests itself in a wide spectrum of symptoms – from a few days of mild fever and headache to the extreme variety consisting of extensive paralysis of the bulbar form that may not be compatible with life because of involvement of the respiratory and pharyngeal muscles.

Diagnosis

The disease targets the anterior horn cells causing lower motor neurone paralysis. Muscles of the lower limb are affected twice as frequently as those of the upper limb (Fig. 5.26). Fortunately, only 1–2% of sufferers develop paralytic symptoms but, when they do occur, the disability causes much misery (Fig. 5.27). When a patient develops fever with muscle weakness, Guillain–Barré syndrome needs to be excluded. The latter has sensory symptoms and signs, and cerebrospinal fluid (CSF) analysis should help to differentiate the two conditions.

Georges Guillain, 1876–1961, Professor of Neurology, The Faculty of Medicine, Paris, France.

Jean Alexandre Barré, 1880–1967, Professor of Neurology, Strasbourg, France.

Guillain and Barré described this condition in a joint paper in 1916 whilst serving as Medical Officers in the French Army during the First World War.

Figure 5.26 Polio affecting predominantly the upper limb muscles with wasting of the intercostal muscles.

Management

Surgical management is directed mainly towards the rehabilitation of the patient who has residual paralysis, the operations being tailored to that particular individual's disability. Children especially may show improvement in their muscle function for up to 2 years after the onset of the illness. Thereafter, many patients learn to manage their disability by incorporating various manoeuvres ('trick movements') into their daily life. The surgeon must be cautious in considering such a patient for any form of surgery.

Surgical treatment lies with the orthopaedic surgeon who needs to work very closely with the physiotherapist in both assessing and rehabilitating the patient. In the chronic form of the disease, operations are only considered after a very careful and detailed assessment of the patient's needs.

Figure 5.27 A group photograph at the Rehabilitation Centre for Children at Barisha, Kolkata, India. This centre used to treat exclusively children with polio deformities. As a result of a successful eradication programme, the centre now concentrates on deformities caused by other diseases. The patient on the extreme left had his knees arthrodesed as a young boy and now works for the centre (courtesy of Dr S.M. Lakhotia, MS, Dr P.K. Jain, MD, DA, Kolkata, India).

Surgical principles

(The following section has been contributed by Dr A. Golash, FRCSEd, Kolkata, India)

The goals of surgical treatment are to correct significant muscle imbalances and deformities of bones and soft tissues. The options are orthoses for static joint instabilities, operations such as tendon transfers for dynamic muscle imbalance and arthrodesis for permanent stabilisation of a flail joint.

The following are the common problems encountered and the suggested surgical solutions (Table 5.1).

Foot and ankle

The most common deformities are claw toes, cavovarus foot, dorsal bunion, talipes equinus, talipes equinovarus, talipes cavovarus, talipes equinovarus and talipes calcaneus. Surgical intervention is only undertaken once the exact pattern of muscle paralysis and resultant deformity has been determined.

Knee

The common knee deformities are flexion contracture, quadriiceps paralysis, genu recurvatum and flail knee. Flexion contracture of the knee is caused by a contracture of the iliotibial band (Fig. 5.28a and b) or isolated paralysis of the quadriiceps muscle. Contractures of less than 20° can be treated by capsulotomy and hamstring lengthening. More severe contractures are corrected by supracondylar extension osteotomy of the femur. Quadriiceps paralysis is treated by the transfer of one or more of the following tendons – biceps femoris, semitendinosus, sartorius and tensor fascia lata to quadriiceps tendon and patella. Genu recurvatum is treated by tibial osteotomy and the transfer of one or more of the hamstring muscles to the patella. Flail knee is managed by the use of a long leg brace or knee arthrodesis.

Hip

Common problems are flexion and abduction contractures, hip instability due to paralysis of the gluteal muscles and paralytic hip dislocation. Flexion and abduction contracture of the hip is

Figure 5.28 A 12-year-old patient with polio showing marked wasting of the left upper arm muscles with flexion contractures of the left knee and hip; there is equinus deformity of the foot (courtesy of Dr S.M. Lakhotia, MS, Dr P.K. Jain, MD, DA, Kolkata, India).

Table 5.1 Description and treatment of muscle imbalances in poliomyelitis

Paralysed muscle	Deformity	Treatment
Tibialis anterior	Equinus	Passive stretching and serial casting. Posterior capsulotomy and tendo achilles lengthening + anterior transfer of peroneus longus to the base of the second metatarsal
	Claw toes	Transfer of long toe extensors into the metatarsal neck + interphalangeal joint fusion
	Cavovarus	Plantar fasciotomy, release of intrinsic muscles + transfer of peroneus longus to the base of the second metatarsal, extensor hallucis longus to the neck of the first metatarsal
Tibialis anterior and tibialis posterior	Talipes equinovarus	Serial casting followed by peroneus longus transfer to the base of the second metatarsal and one of the long toe flexors to the tibialis posterior
Tibialis anterior, toe extensors and peroneal muscles	Severe equinovarus deformity	Tendo achilles lengthening, anterior transfer of tibialis posterior to the base of the third metatarsal or middle cuneiform + anterior transfer of long toe flexors
Soleus/gastrocnemius	Talipes calcaneus	Tibialis anterior transfer to the calcaneal tuberosity and tendo achilles insertion

Achilles, the Greek Hero, was the son of Peleus and Thetis. When he was a child his mother dipped him in the Styx, one of the rivers of the Underworld, so that he should be invulnerable in battle. The heel by which she held him did not get wet, and was, therefore, not protected. Achilles died from a wound in the heel which he received at the siege of Troy.

usually accompanied by varying degrees of external rotation contracture; these can be corrected by complete release of the hip muscles. Very severe deformities need a complete release along with transfer of the crest of ilium.

Paralysis of the gluteus maximus and medius muscles results in an unstable hip that can prove very tiring along with an unsightly limp. Function can be improved by transferring muscles (external oblique, ilio-psoas) to replace gluteal muscles.

Trunk

Unbalanced paralysis causes scoliosis along with pelvic obliquity (Fig. 5.29). Complex bony procedures are needed to correct this deformity.

Shoulder

Disabilities caused by paralysis of the shoulder muscles can be corrected, to a certain extent, by tendon and muscle transfer (trapezius to deltoid) or by arthrodesis of the joint.

Elbow

Active elbow flexion and extension can be restored by muscle and tendon transfers. Elbow flexion can be restored by one of the following methods: flexorplasty, transfer of the pectoralis major muscle, transfer of the latissimus dorsi muscle or anterior transfer of the triceps tendon. Extension of the elbow can be restored by the posterior transfer of the deltoid muscle.

Wrist and hand

Treatment options are tendon transfer and wrist arthrodesis. Weakness of thumb opposition can be corrected by sublimis opponensplasty (Summary box 5.14).

Figure 5.29 A young patient with polio showing paralysis of the lower limb and paraspinal muscles causing marked scoliosis and a deformed pelvis.

Summary box 5.14

Poliomyelitis

- A viral illness that is preventable
- Presents with protean manifestations of fever, headache and muscular paralysis without sensory loss, more frequently affecting the lower limbs
- Treatment is mainly medical and supportive in the early stages
- Surgery should only be undertaken after very careful assessment as most patients learn to live with their disabilities
- Surgery is considered for the various types of paralysis in the form of tendon transfers and arthrodesis, which is the domain of a specialised orthopaedic surgeon

TROPICAL CHRONIC PANCREATITIS

Introduction

Tropical chronic pancreatitis is a disease affecting the younger generation from poor socio-economic strata in developing countries, seen mostly in southern India. The aetiology remains obscure with malnutrition, dietary, familial and genetic factors being possible causes. Alcohol ingestion does not play a part in the aetiology.

Aetiology and pathology

Cassava (tapioca) is a root vegetable that is readily available and inexpensive and is therefore consumed as a staple diet by people from a poor background. It contains derivatives of cyanide that are detoxified in the liver by sulphur-containing amino acids. The less well-off among the population lack such amino acids in the diet. This results in cyanogen toxicity causing the disease. Several members of the same family have been known to suffer from this condition; this strengthens the theory that cassava toxicity is an important cause because family members eat the same food.

Macroscopically, the pancreas is firm and nodular with extensive periductal fibrosis, with intraductal calcium carbonate stones of different sizes and shapes that may show branches and resemble a staghorn. The ducts are dilated. Microscopically, fibrosis is the predominant feature – intralobular, interlobular and periductal – with plasma cell and lymphocyte infiltration. There is a high incidence of pancreatic cancer in these patients (Summary box 5.15).

Summary box 5.15

Pathology of tropical chronic pancreatitis

- Almost exclusively occurs in developing countries and is due to malnutrition; alcohol is not a cause
- Cassava ingestion is regarded as an aetiological factor because of its high content of cyanide compounds
- Dilatation of pancreatic ducts with large intraductal stones
- Fibrosis of the pancreas
- A high incidence of pancreatic cancer in those affected by the disease

Diagnosis

The patient, usually male, is almost always below the age of 40 years and from a poor background. The clinical presentation is abdominal pain, thirst, polyuria and features of gross pancreatic insufficiency causing steatorrhoea and malnutrition. The patient looks ill and emaciated.

Initial routine blood and urine tests confirm that the patient has type 1 diabetes mellitus. This is known as fibrocalculous pancreatic diabetes, a label that is aptly descriptive of the typical pathological changes. Serum amylase is usually normal; in an acute exacerbation, it may be elevated. A plain abdominal X-ray shows typical pancreatic calcification in the form of discrete stones in the duct (Fig. 5.30). Ultrasound and CT scanning of the pancreas confirm the diagnosis. An ERCP as an investigation should only be done when the procedure is also being considered as a therapeutic manoeuvre for removal of ductal stones in the pancreatic head by papillotomy (Summary box 5.16).

Summary box 5.16

Diagnosis of tropical chronic pancreatitis

- The usual sufferer is a type 1 diabetic under 40 years of age
- Serum amylase may be elevated in an acute exacerbation
- Plain X-ray shows stones along the pancreatic duct
- Ultrasound and CT scan of the pancreas confirm the diagnosis
- ERCP may be used as a supplementary investigation and a therapeutic procedure

Treatment

The treatment is mainly medical with exocrine support using pancreatic enzymes, treatment of diabetes with insulin and the management of malnutrition. Treatment of pain should be along

Figure 5.30 Plain X-ray of the abdomen showing large stones along the main pancreatic duct typical of tropical chronic pancreatitis (courtesy of Dr V. Mohan, Chennai, India).

the lines of the usual analgesic ladder: non-opioids, followed by weak and then strong opioids and, finally, referral to a pain clinic.

Surgical treatment is necessary for intractable pain particularly when there are stones in a dilated duct. Removal of the stones, with a side-to-side pancreaticojejunostomy to a Roux loop, is the procedure of choice. As most patients are young, pancreatic resection is only very rarely considered, and then only as a last resort, when all available methods of pain relief have been exhausted (Summary box 5.17).

Summary box 5.17

Tropical chronic pancreatitis – treatment

- Mainly medical – pain relief, insulin for diabetes and pancreatic supplements for malnutrition
- Surgery is reserved for intractable pain
- Procedures are side-to-side pancreaticojejunostomy; resection in extreme cases

TUBERCULOSIS OF SMALL INTESTINE

Introduction

Infection by *Mycobacterium tuberculosis* is common in the tropics. In these days of international travel and increased migration into the UK, tuberculosis in general and intestinal tuberculosis in particular are no longer clinical curiosities in the west. Any patient, particularly one who has recently arrived from an endemic area and who has features of generalised ill health and altered bowel habit, should arouse the suspicion of intestinal tuberculosis.

Pathology

When a patient with pulmonary tuberculosis swallows infected sputum, the organism colonises the lymphatics of the terminal ileum, causing transverse ulcers with typical undermined edges. The serosa is usually studded with tubercles. Histology shows caseating granuloma with giant cells (Fig. 5.31). This pathological entity, referred to as the ulcerative type, denotes a severe form of the disease in which the virulence of the organism outstrips the resistance of the host.

The other variety, called the hyperplastic type, occurs when host resistance is stronger than the virulence of the organism. It is caused by the drinking of infected milk. There is a marked inflammatory reaction causing hyperplasia and thickening of the terminal ileum because of its abundance of lymphoid follicles, thus causing narrowing of the lumen and obstruction. In both types, there may be marked mesenteric lymphadenopathy. Macroscopically, this type may be confused with Crohn's disease. The small intestine shows areas of stricture and fibrosis most pronounced at the terminal ileum (Fig. 5.32). As a result, there is shortening of the bowel with the caecum being pulled up into a subhepatic position (Summary box 5.18).

Burrill Bernard Crohn, 1884–1983, Gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.

Figure 5.31 Histology of ileocaecal tuberculosis showing epithelioid cell granuloma (black arrows) with caseation (blue arrow) (courtesy of Dr A.K. Mandal, New Delhi, India).

Figure 5.32 Emergency limited ileocolic resection: specimen showing tuberculous stricture in the terminal ileum and perforation of a transverse ulcer just proximal to the stricture.

Summary box 5.18

Tuberculosis – pathology

- Increasingly being seen in the UK, mostly among immigrants
- Two types are recognised – ulcerative and hyperplastic
- The ulcerative type occurs when the virulence of the organism is greater than the host defence
- The opposite occurs in the hyperplastic type
- Small bowel strictures are common in the hyperplastic type, mainly affecting the ileocaecal area
- In the ulcerative type, the bowel serosa is studded with tubercles
- Localised areas of ascites occur in the form of cocoons
- The lungs and other organs may also be involved simultaneously

Clinical features

Patients present electively with weight loss, chronic cough, malaise, evening rise in temperature with sweating, vague abdominal pain with distension and alternating constipation and diarrhoea. As an emergency, they present with features of distal small bowel obstruction from strictures of the small bowel, particularly the terminal ileum. Rarely, a patient may present with features of peritonitis from perforation of a tuberculous ulcer in the small bowel (Fig. 5.32).

Examination shows a chronically ill patient with a ‘doughy’ feel to the abdomen from areas of localised ascites. In the hyperplastic type, a mass may be felt in the right iliac fossa. In addition, some patients may present with fistula-in-ano, which is typically multiple with undermined edges and watery discharge.

As this is a disease mainly seen in developing countries, patients may present late as an emergency from intestinal obstruction. Abdominal pain and distension, constipation and bilious and faeculent vomiting are typical of such a patient who is in extremis.

There may be features of other system involvement such as the genitourinary tract, when the patient complains of frequency

of micturition. Clinical examination does not show any abnormality. The genitourinary tract should then be investigated (Summary box 5.19).

Summary box 5.19

Tuberculosis – clinical features

- Intestinal tuberculosis should be suspected in any patient from an endemic area who presents with weight loss, malaise, evening fever, cough, alternating constipation and diarrhoea and intermittent abdominal pain with distension
- The abdomen has a doughy feel; a mass may be found in the right iliac fossa
- The emergency patient presents with features of distal small bowel obstruction – abdominal pain, distension, bilious and faeculent vomiting
- Peritonitis from a perforated tuberculous ulcer in the small bowel can be another emergency presentation

Investigations

Raised ESR and CRP, low haemoglobin and a positive Mantoux test are usual, although the last is not significant in a patient from an endemic area.

Sputum for culture and sensitivity (the result may take several weeks) and staining by the Ziehl–Neelsen method for acid-fast bacilli (the result is obtained much earlier) should be done.

A barium meal and follow-through (or small bowel enema) shows strictures of the small bowel, particularly the ileum, typically with a high subhepatic caecum with the narrow ileum entering the caecum directly from below upwards in a straight line rather than at an angle (Figs 5.33a and b and 5.34a). Laparoscopy reveals the typical picture of tubercles on the bowel serosa,

Charles Mantoux, 1877–1947, Physician, Le Cannet, Alpes Maritimes, France, described the intra-dermal tuberculin skin test in 1908.

Franz Heinrich Paul Ziehl, 1859–1926, Neurologist, Lubeck, Germany.
Friedrich Carl Adolf Neelsen, 1854–1894, Pathologist, Prosector, the Stadt-Krankenhaus, Dresden, Germany.

Figure 5.33 Series of a barium meal and follow-through showing strictures in the ileum with the caecum pulled up into a subhepatic position.

multiple strictures, a high caecum, enlarged lymph nodes, areas of caseation and ascites. Culture of the ascitic fluid may be helpful. A chest X-ray is essential (Fig. 5.34b).

If the patient complains of urinary symptoms, urine is sent for

microscopy and culture, and the finding of sterile pyuria should alert the clinician to the possibility of tuberculosis of the urinary tract, when the appropriate investigations should be done.

In the patient presenting as an emergency, urea and electrolytes

Figure 5.34 Barium meal and follow-through (a) and chest X-ray (b) in a patient with extensive intestinal and pulmonary tuberculosis, showing ileal strictures with high caecum and pulmonary infiltration.

show evidence of gross dehydration. Plain abdominal X-ray shows typical small bowel obstruction – valvulae conniventes of dilated jejunum and featureless ileum with evidence of fluid between the loops (Summary box 5.20).

Summary box 5.20

Intestinal tuberculosis – investigations

- Raised inflammatory markers, anaemia and positive sputum culture
- Ultrasound of the abdomen may show localised areas of ascites
- Chest X-ray shows pulmonary infiltration
- Barium meal and follow-through shows multiple small bowel strictures particularly in the ileum with a subhepatic caecum
- If symptoms warrant, the genitourinary tract is also investigated

Treatment

On completion of medical treatment, the patient's small bowel is reimaged to look for significant strictures. If the patient has features of subacute intermittent obstruction, bowel resection, in the form of limited ileocolic resection (Fig. 5.32) with anastomosis between the terminal ileum and ascending colon, strictureplasty or right hemicolectomy, is performed as deemed appropriate. The surgical principles and options in the elective patient are very similar to those for Crohn's disease.

The emergency patient presents a great challenge. Such a patient is usually from a poor socio-economic background, hence the late presentation of acute, distal, small bowel obstruction. The patient is extremely ill from dehydration, malnutrition, anaemia and probably active pulmonary tuberculosis. Vigorous resuscitation should precede the operation. At laparotomy, the minimum life-saving procedure is carried out, such as a side-to-side ileotransverse anastomosis for a terminal ileal stricture. If the general condition of the patient permits, a one-stage resection and anastomosis may be performed.

Thereafter, the patient should ideally be under the combined care of the physician and surgeon for a full course of anti-tuberculous chemotherapy and improvement in nutritional status; this may require 3–6 months of care. The patient who had a simple bypass procedure is reassessed and, when the disease is no longer active (as evidenced by return to normal of inflammatory markers, weight gain, negative sputum culture), an elective right hemicolectomy is done. This may be supplemented with strictureplasty for short strictures at intervals.

Perforation is treated by thorough resuscitation followed by resection of the affected segment. Anastomosis is performed provided it is regarded as safe to do so when peritoneal contamination is minimal and widespread disease is not encountered; otherwise, as a first stage, resection and exteriorisation is done followed by restoration of bowel continuity as a second stage later on after a full course of anti-tuberculous chemotherapy and improvement in nutritional status (Summary box 5.21).

Summary box 5.21

Tuberculosis – treatment

- Patients should ideally be under the combined care of a physician and surgeon
- Vigorous supportive and full drug treatment is mandatory in all cases
- Symptomatic strictures are treated by the appropriate resection, e.g. local ileocolic resection or strictureplasty as an elective procedure once the disease is completely under control
- Acute intestinal obstruction from distal ileal stricture is treated by thorough resuscitation followed by side-to-side ileotransverse bypass
- Once the patient has recovered with medical treatment, then the second-stage definitive procedure of right hemicolectomy is done
- One-stage resection and anastomosis can be considered if the patient's general condition permits
- Perforation is treated by appropriate local resection and anastomosis or exteriorisation if the condition of the patient is very poor; this is later followed by restoration of bowel continuity after the patient has fully recovered with anti-tuberculous chemotherapy

TYPHOID

Introduction

Typhoid fever is caused by *Salmonella typhi*, also called the typhoid bacillus. This is a Gram-negative organism. Like most infections occurring in developing countries in the tropics, the organism gains entry into the human gastrointestinal tract as a result of poor hygiene and inadequate sanitation. It is a disease normally managed by physicians, but the surgeon is called upon to treat the patient with typhoid fever because of perforation of a typhoid ulcer.

Pathology

Following ingestion of contaminated food or water, the organism colonises the Peyer's patches in the terminal ileum causing hyperplasia of the lymphoid follicles followed by necrosis and ulceration. The microscopic picture shows erythrophagocytosis with histiocytic proliferation (Fig. 5.35). If the patient is left untreated or inadequately treated, the ulcers may lead to perforation and bleeding. The bowel may perforate at several sites including the large bowel.

Diagnosis

A typical patient is from an endemic area or who has recently visited such a country and suffers from a high temperature for 2–3 weeks. The patient may be toxic with abdominal distension from paralytic ileus. The patient may have melaena due to haemorrhage from a typhoid ulcer; this can lead to hypovolaemia.

Blood and stool cultures confirm the nature of the infection and exclude malaria. Although obsolete in the UK, the Widal test

Daniel Elmer Salmon, 1850–1914, Veterinary Pathologist, Chief of the Bureau of Animal Industry, Washington DC, USA.
 Johann Conrad Peyer, 1653–1712, Professor of Logic, Rhetoric and Medicine, Schaffhausen, Switzerland, described the lymph follicles in the intestine in 1677.
 Georges Fernand Isidore Widal, 1862–1929, Professor of Internal Pathology, and later of Clinical Medicine, The Faculty of Medicine, Paris, France.

Figure 5.35 Histology of enteric perforation of the small intestine showing erythrophagocytosis (arrows) with predominantly histiocytic proliferation (courtesy of Dr A.K. Mandal, New Delhi, India).

is still done in the Indian subcontinent. The test looks for the presence of agglutinins to O and H antigens of *Salmonella typhi* and *paratyphi* in the patient's serum. In endemic areas, laboratory facilities may sometimes be limited. Certain other tests have been developed which identify sensitive and specific markers for typhoid fever. Practical and cheap kits are available for their rapid detection that need no special expertise and equipment. These are Multi-Test Dip-S-Ticks to detect immunoglobulin G (IgG), Tubex to detect immunoglobulin M (IgM) and TyphiDot to detect IgG and IgM. These tests are particularly valuable when blood cultures are negative (due to pre-hospital treatment or self-medication with antibiotics) or facilities for such an investigation are not available.

In the second or third week of the illness, if there is severe generalised abdominal pain, this heralds a perforated typhoid ulcer. The patient, who is already very ill, deteriorates further with classical features of peritonitis. An erect chest X-ray or a lateral decubitus film (in the very ill, as they usually are) will show free gas in the peritoneal cavity. In fact, any patient being treated for typhoid fever who shows a sudden deterioration accompanied by abdominal signs should be considered to have a typhoid perforation until proven otherwise (Summary 5.22).

Summary box 5.22

Diagnosis of bowel perforation secondary to typhoid

- The patient presents in, or has recently visited, an endemic area
- The patient has persistent high temperature and is very toxic
- Positive blood or stool cultures for *Salmonella typhi* and the patient is already on treatment for typhoid
- After the second week, signs of peritonitis usually denote perforation, which is confirmed by the presence of free gas seen on X-ray

Treatment

Vigorous resuscitation with intravenous fluids and antibiotics in an intensive care unit gives the best chance of stabilising the

patient's condition. Metronidazole, cephalosporins and gentamicin are used in combination. Chloramphenicol, despite its potential side-effect of aplastic anaemia, is still used occasionally in developing countries. Laparotomy is then carried out.

Several surgical options are available, and the most appropriate operative procedure should be chosen judiciously depending upon the general condition of the patient, the site of perforation, the number of perforations and the degree of peritoneal soiling. The alternatives are closure of the perforation (Fig. 5.36a and b) after freshening the edges, wedge resection of the ulcer area and closure, resection of bowel with or without anastomosis (exteriorisation), closure of the perforation and side-to-side ileotransverse anastomosis, ileostomy or colostomy where the perforated bowel is exteriorised after refashioning the edges. After closing an ileal perforation, the surgeon should look for other sites of perforation or necrotic patches in the small or large bowel that might imminently perforate, and deal with them appropriately. Thorough peritoneal lavage is essential. The linea alba is closed leaving the rest of the abdominal wound open for delayed closure, as wound infection is almost inevitable and dehiscence not uncommon. In the presence of rampant infection, laparostomy may be a good alternative.

When a typhoid perforation occurs within the first week of illness, the prognosis is better than if it occurs after the second or third week because, in the early stages, the patient is less

Figure 5.36 Typhoid perforation of the terminal ileum.

nutritionally compromised and the body's defences are more robust. Furthermore, the shorter the interval between diagnosis and operation, the better is the prognosis (Summary box 5.23).

Summary box 5.23

Treatment of bowel perforation from typhoid

- Manage in intensive care
- Resuscitate and give intravenous antibiotics
- Laparotomy – choice of various procedures
- Commonest site of perforation is the terminal ileum
- Having found a perforation, always look for others
- In the very ill patient, consider some form of exteriorisation
- Close the peritoneum and leave the wound open for secondary closure

Principles of paediatric surgery

LEARNING OBJECTIVES

To recognise and understand:

- The important anatomical, physiological and psychological differences between adults and children
- The structured approach to managing children with major trauma
- The pathology and the principles of management of common paediatric surgical conditions
- The spectrum of congenital malformations relevant to general surgery

INTRODUCTION

Children are not small adults. They suffer from different disorders and their physical and psychological responses are different. Their capacity for adaptation is greater but they must endure any consequences of disease and its management for longer. In contrast to adults they rarely have comorbidity from degenerative diseases or lifestyle problems but they can suffer the unique consequences of congenital malformations. Children must be treated within the context of their families. This chapter focuses on aspects of paediatric surgery relevant to general surgery.

ANATOMY AND PHYSIOLOGY

Anatomical differences between adults and children are important in surgery. Infants and small children (Table 6.1) have a wider abdomen, a broader costal margin and a shallower pelvis. Thus, the edge of the liver is more easily palpable below the costal margin and the bladder is an intra-abdominal organ. The ribs are more horizontal and respiratory function is more dependent on diaphragmatic movement. The umbilicus is relatively low lying. In the small child, transverse supraumbilical incisions are preferred to vertical midline ones for laparotomy. Abdominal scars grow with the child and may migrate – a gastrostomy sited in the epigastrium of the infant may end up as a scar over the costal margin (Summary box 6.1).

Table 6.1 Common terms

Preterm	< 37 completed weeks of gestation
Full term	Between 37 and 42 completed weeks of gestation
Neonate	Newborn baby up to 28 days of age
Infant	Up to 1 year of age
Child	All ages up to 16 years but often divided into preschool child (usually < 5 years), child and adolescent (puberty up to 16 years)

Summary box 6.1

Anatomy of the paediatric abdomen

- The abdomen is wider and the bladder intra-abdominal
- Transverse supraumbilical incisions are preferred to vertical midline ones
- Scars may migrate during growth

Thermoregulation is important in children undergoing surgery. The body surface area to weight ratio decreases with age and small children therefore lose heat more rapidly. Babies have less subcutaneous fat and immature peripheral vasomotor control mechanisms. The operating theatre must be warm and the infant's head (which may account for up to 20% of the body surface area compared with 9% in an adult) should be insulated. Infusions and respiratory gases may need to be warmed. The central temperature should be monitored and a warm air blanket is advisable during lengthy operations.

Infants undergoing surgery are vulnerable in other ways. Impaired gluconeogenesis renders them more susceptible to hypoglycaemia; blood glucose must be monitored and maintained above 2.6 mmol l^{-1} . Newborns are at risk of clotting deficiencies and should be given intramuscular vitamin K before major surgery. They are less able to concentrate urine or conserve sodium and have a greater obligatory water loss to excrete a given solute load. Fluid and sodium requirements are relatively high. Infants are prone to gastro-oesophageal reflux and have less well-developed protective reflexes, rendering them more at risk of pulmonary aspiration; adequate nasogastric aspiration is essential in those with gastrointestinal obstruction. Immaturity of the immune system increases the risk of infection, which can present with non-specific features such as poor feeding, vomiting and listlessness (Summary box 6.2).

Summary box 6.2

Special features that must be considered in children when preparing for surgery

Problem	Action
Thermoregulation	Warm fluids, warm theatre, insulate child
Hypoglycaemia	Maintain glucose above 2.6 mmol l ⁻¹
Clotting	Give intramuscular vitamin K preoperatively to neonates
Fluid and electrolyte balance	Allow for higher sodium and fluid needs
Less postoperative catabolism	Relatively lower postoperative energy requirements
Gastro-oesophageal reflux	Use a nasogastric tube to prevent aspiration
Atypical presentations of infection	High index of suspicion
Psychology	Trained staff, day surgery for minor operations

The surgical management of children requires a working knowledge of normal weights, vital signs and fluid and electrolyte requirements at different ages (Table 6.2). Moderate (5–10%) dehydration is manifest by a decreased urine output, dry mouth, and sunken eyes and fontanelle. Severe dehydration (> 10%) causes decreased skin turgor, drowsiness, tachycardia and signs of hypovolaemia. Body weight is a critical measurement in children, not least because this is a major determinant of drug doses and fluid balance. Serial measures of weight and height provide a valuable index of general growth and nutrition (Fig. 6.1). Impaired growth is an important sign of disease in children and may be the dominant presenting feature in an adolescent with Crohn's disease. Delay in achieving normal developmental milestones can also be an indicator of ill health in children.

HISTORY AND EXAMINATION

The history should include details of any prenatal or neonatal problems as well as the relevant family medical and social background. Time, patience and a genuine interest are required to gain a rapport with the child and his/her parents or carers. Children should be told what to expect from an examination, investigation or surgical procedure in terms that they can understand. Fear, anxiety and pain can be reduced by involving parents and carers and by looking after the child in an appropriate environment with play facilities. Nursing and medical staff must be attuned to the needs of children. General health concerns are best discussed with a paediatrician, as is any concern about child abuse or neglect.

PRINCIPLES OF OPERATIVE SURGERY

Operative paediatric surgery demands meticulous and gentle technique, strict haemostasis, fine suture materials (with or without magnification aids) and attention to surgical principles,

Burrill Bernard Crohn, 1884–1983, Gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.

Table 6.2 Basic paediatric data

(a) Weight

Age	Weight (kg)
Term neonate	3.5
1 year	10
5 years	20
10 years	30

Approximate guide: weight (kg) = 2 × (age in years + 4).

(b) Vital signs

Age (years)	Heart rate (beats min ⁻¹)	Systolic blood pressure (mmHg)	Respiratory rate (breaths min ⁻¹)
< 1	110–160	70–90	30–40
2–5	90–140	80–100	25–30
5–12	80–120	90–110	20–25

Systolic blood pressure ≈ 80 + (age in years × 2) mmHg.
Circulating blood volume ≈ 80 ml kg⁻¹ (90 ml kg⁻¹ in infants).

(c) Maintenance fluid requirements

Weight	Daily fluid requirement (ml kg ⁻¹ day ⁻¹)
Neonate	120–150
First 10 kg	100
Second 10 kg	50
Subsequent kg	20

(d) Maintenance electrolyte requirements

Weight	Sodium (mmol kg ⁻¹ 1 day ⁻¹)	Potassium (mmol kg ⁻¹ 1 day ⁻¹)	Energy (kcal kg ⁻¹ day ⁻¹)
< 10 kg	2–4	1.5–2.5	110
> 10 kg	1–2	0.5–1.0	40–75

Small bowel length in a term infant (duodenojejunal flexure to ileocaecal valve) ≈ 275 cm (adult length is almost 6 m).

e.g. maintaining well-vascularised tissues, avoiding tension and minimising tissue necrosis and contamination. Bipolar diathermy is particularly useful. Anatomy in children is clearer than in adults because there is less fat and the tissues are better demarcated.

Postoperatively, children often recover more quickly than adults. Postoperative analgesia must be adequate and appropriate, recognising the potential for respiratory depression with opioids. Nursing care by appropriately trained staff involves monitoring the airway and vital signs together with arterial oxygen saturation, fluid balance, temperature, pain control and glucose homeostasis. Maintenance intravenous fluids, e.g. 0.45% saline with 2.5% dextrose or isotonic saline, are being increasingly used instead of more hypotonic saline solutions to reduce the risk of iatrogenic hyponatraemia. Neonates require intravenous fluids with higher concentrations of glucose.

Abdominal wounds in infants and children can be safely closed with absorbable sutures using either a layered or mass closure technique. Non-absorbable sutures may occasionally be necessary, such as in the malnourished adolescent on steroids for inflammatory bowel disease. Wound dehiscence is rare and

Figure 6.1 Growth chart for boys aged 5–18 years using the nine centile UK chart (Chart © Child Growth Foundation, reproduced with permission).

almost always the result of poor surgical technique. The use of single-layer interrupted extramucosal sutures for intestinal anastomosis is safe and effective. Clean skin incisions are best closed with absorbable subcuticular sutures. Surgical stapling devices are frequently used in paediatric gastrointestinal and thoracic surgery but staple lines should be oversewn. Endoscopic minimally invasive approaches can be used at all ages to achieve the same advantages as in adults, but instruments and insufflation pressures must be tailored to the size of the child (Summary box 6.3).

Summary box 6.3

Special features of surgical technique in children

- Gentle tissue handling
- Bipolar diathermy is preferred to unipolar during dissection
- Abdominal incisions can be closed with absorbable sutures
- Bowel can be anastomosed with interrupted single-layer extramucosal sutures
- Skin can be closed with absorbable subcuticular sutures

Stomas are necessary in some children. A gastrostomy may be required for nutritional support, particularly in the neurologically

disabled child. Temporary intestinal stomas are used in the management of anorectal malformations, necrotising enterocolitis and Hirschsprung's disease; infants with a proximal colostomy or ileostomy frequently require salt supplements to avoid sodium deficiency, which causes poor weight gain.

Surgeons who operate on children should consider the long-term outcomes, i.e. the effects of surgical disease and its treatment during maturation and adult life. For example, ileal resection in the neonate may later be complicated by vitamin B12 deficiency, malabsorption of fat-soluble vitamins, gallstones, renal oxalate stones and, rarely, perianastomotic ulceration. Long-term concerns include the potential impact of surgical conditions and their treatment on future function (e.g. continence); fertility and sexuality; inheritance risks; psychosocial adaptation; and the potential risk of late malignancy (e.g. undescended testis, choledochal cyst, duplication cyst).

PAEDIATRIC TRAUMA

Trauma is a leading cause of death in children and adolescents in western countries. Many of these deaths are avoidable if prompt and effective treatment is given.

Primary survey

The structured approach to the child with major injuries advocated by the Advanced Trauma Life Support (ATLS) programmes is essential. The focus of the primary survey is on the airway and cervical spine, breathing, circulation and the control of bleeding, the assessment of conscious level, pupil size and reactivity and a rapid overview of all injuries. The shorter neck and relatively larger tongue of the child mean that respiratory obstruction will occur if the neck is overextended during maintenance of the airway. The assessment of breathing includes respiratory rate, signs of distress and the adequacy of chest expansion. The circulation is evaluated from vital signs, capillary refill time (normally ≤ 2 s), skin colour and temperature, and mental status. Normal ranges for heart rate, systolic blood pressure and respiratory rate are age-dependent (Table 6.2). Systolic blood pressure is often normal until at least 25% of the circulating blood volume has been lost.

Resuscitation

Life-threatening problems are treated as they are identified during the primary survey. High-flow oxygen should be provided in any patient with cardiorespiratory compromise. Endotracheal intubation and ventilation are required if oxygenation is inadequate, to control a flail chest or in children with a serious head injury (Glasgow Coma Score ≤ 8). Pneumothorax and haemothorax are treated by chest tube drainage. Seriously injured children require two large peripheral intravenous cannulae; additional sites of venous access include the long saphenous vein at the ankle, the femoral vein, the external jugular vein and, in babies, the scalp veins. Central venous access should only be attempted by an expert. Intraosseous infusion is particularly useful in small children (Fig. 6.2) (Summary box 6.4).

The Glasgow Coma Score was introduced in 1977 by William Bryan Jennet, Professor of Neurosurgery and Graham Michael Teasdale, a Neurosurgeon of the University Department of Neurosurgery, at the Institute of Neurological Sciences, The Southern General Hospital, Glasgow, Scotland.

Summary box 6.4

Fluid resuscitation of the hypovolaemic child after trauma

- Infuse 10 ml kg⁻¹ of normal saline or colloid
- ↓
- Assess cardiovascular response
- ↓
- Infuse 10 ml kg⁻¹ of normal saline or colloid
- ↓
- Assess cardiovascular response
- ↓
- Repeat if necessary
- ↓
- If still hypovolaemic after a total of 40 ml kg⁻¹ of crystalloid, transfuse packed red cells and consider urgent surgery

During resuscitation, details of the injury and past medical history are sought. Baseline blood tests and radiographs of the cervical spine (lateral), chest and pelvis are obtained. A major spinal cord injury can be present in a child without radiographic abnormalities and, after major trauma, a cervical spine injury should be assumed until it can be excluded by full neurological assessment; the neck must be immobilised. Other considerations include use of intravenous analgesia and, in the unconscious or ventilated child or those with major abdominal injuries, a nasogastric tube (orogastric if suspicion of a basal frontal skull fracture) and urethral catheter (if no evidence of urethral injury).

Secondary survey and emergency management

In a stable patient, the secondary survey attempts to identify all injuries in a systematic way by detailed clinical examination and appropriate investigations. Emergency treatment of chest and abdominal injuries is as follows:

- **Chest.** Children have relatively elastic ribs that rarely fracture. Lung contusion is common. A major thoracic injury may exist despite a normal chest radiograph. In all cases the airway is secured, oxygen is given and hypovolaemia is corrected with intravenous fluids. Tension pneumothorax requires prompt

Figure 6.2 The intraosseous needle is inserted into the medullary cavity of the proximal tibia about 1–3 cm below the tibial tuberosity.

clinical diagnosis and immediate needle thoracocentesis (second intercostal space, mid-clavicular line) followed by chest tube drainage. Massive haemothorax is treated by chest tube drainage (fifth intercostal space, mid-axillary line). Cardiac tamponade may follow blunt or penetrating injury and requires emergency needle pericardiocentesis. Diaphragmatic rupture after blunt abdominal trauma is detected by chest radiography or computerised tomography (CT) scan; surgical repair is undertaken once the patient is stable.

- **Abdomen.** Blunt trauma is generally more common than penetrating injuries. The liver and spleen are more vulnerable in children because they are less well protected by the pliable rib cage. The abdomen must be carefully inspected for signs of patterned bruising, which indicates forceful compression against a rigid skeleton. Intra-abdominal or intrathoracic bleeding is likely in the shocked child with no obvious source of haemorrhage. Plasma amylase levels should be measured but may be normal despite pancreatic injury. The definitive radiological investigation of major abdominal trauma in the haemodynamically stable child is a CT scan with intravenous contrast (Fig. 6.3). When expert ultrasound scanning is readily available it can demonstrate free intra-abdominal fluid and solid organ injuries but it is not as sensitive and specific as CT. Diagnostic peritoneal lavage is obsolete in children because modern imaging is superior and the presence of intraperitoneal blood is not by itself a reason for laparotomy. Bowel perforation or deep penetrating trauma are indications for laparotomy.

Isolated splenic and/or liver injury can be safely and effectively managed non-operatively in the majority of children with blunt abdominal trauma; haemorrhage is frequently self-limiting. Unnecessary surgery and the long-term risks of splenectomy can be avoided.

Successful non-operative management of isolated blunt liver or spleen trauma requires:

- haemodynamic stability after resuscitation with no more than 40–60 ml kg⁻¹ of fluid;
- a good-quality CT scan;
- no evidence of hollow visceral injury;
- frequent, careful monitoring and immediate availability of necessary surgical expertise/facilities.

Figure 6.3 Abdominal computerised tomography scan after intravenous contrast in an 11-year-old boy showing a ruptured spleen (successfully managed non-operatively).

Children with ongoing intra-abdominal bleeding require laparotomy, but preliminary angiography and arterial embolisation can be useful in some cases of hepatic trauma. Bile leaks are uncommon and can usually be managed with radiological techniques. Uncomplicated non-operative cases of liver/spleen trauma can be discharged home after 5 days but activity should be restricted for 3–6 weeks and contact sports avoided for 2–3 months. Blunt renal trauma is also generally managed conservatively but an acutely non-functioning kidney following abdominal trauma may need urgent exploration with a view to revascularisation.

Patterns of injury

Patterns of injury often reflect the mechanism. For example, lap belt trauma from a motor vehicle crash may cause injury to the duodenum or jejunum and lumbar spine, bicycle handlebar injuries are associated with pancreatic or liver trauma (Fig. 6.4), straddle injuries may damage the urethra and pelvis, and run-over injuries may cause severe crushing of the chest and/or abdomen. Non-accidental injury must be considered if any of the following are present: multiple injuries at different stages of healing; different types of injury (e.g. soft tissue, fractures, burns or scalds, cuts and bruises); significant delay between the injury and seeking medical advice; an inconsistent or vague history; or inappropriate parental behaviour. Liaison with a paediatrician is essential in such cases (Summary box 6.5).

Summary box 6.5

Paediatric trauma

- Use ATLS principles
- Overextension of the neck will compromise the airway
- Cervical spine injury can be present without radiographic signs
- Intraosseous vascular access is helpful in small children
- Lung contusion can occur without rib fractures
- Patterned skin bruising suggests underlying organ injury
- In a stable child, abdominal injuries are best assessed by CT
- Isolated liver or splenic injury can usually be managed non-operatively

Figure 6.4 Abdominal computerised tomography scan showing a transection through the neck of the pancreas (arrow) from a bicycle handlebar injury.

COMMON PAEDIATRIC SURGICAL CONDITIONS

Inguinoscrotal disorders

Embryology

Most genital abnormalities in boys are the result of abnormal development. The testis develops from the urogenital ridge on the posterior abdominal wall. Gonadal induction to form a testis is regulated by genes on the Y chromosome. During gestation, the testis migrates down towards the internal ring, guided by mesenchymal tissue (gubernaculum). Inguinoscrotal descent of the testis is mediated by testosterone from the fetal testis. A tongue of peritoneum precedes the migrating testis through the inguinal canal (the processus vaginalis). This peritoneal pouch normally becomes obliterated after birth but failure of this process can lead to the development of an inguinal hernia or hydrocele (Fig. 6.5).

Inguinal hernia

Inguinal hernias in children are almost always indirect and due to a patent processus vaginalis. They are much more frequent in boys, especially if born prematurely. An inguinal hernia will develop in at least one in 50 boys and about 15% are bilateral. Rarely, bilateral inguinal hernias in a phenotypic girl may be the presenting feature of androgen insensitivity syndrome (testicular feminisation) and the hernia sac may then contain a testis.

An inguinal hernia typically causes an intermittent swelling in the groin or scrotum on crying or straining (Fig. 6.6). Unless an inguinal swelling is observed, diagnosis relies on the history and the presence of palpable thickening of the spermatic cord (or round ligament in girls). Some inguinal hernias present as a firm, tender, irreducible lump in the groin or scrotum as a result of obstruction by the external ring. The infant may be vomiting and irritable. Most incarcerated hernias in children can be successfully reduced by sustained gentle compression ('taxis') aided by cautious analgesia. Surgery is delayed for 24 hours to allow resolution of oedema. If reduction is impossible, emergency surgery is required because of the risk of strangulation of bowel (or ovary) and/or damage to the testis.

Inguinal herniotomy is performed via an inguinal skin crease incision and involves dissection, division and proximal ligation of the hernial sac. This is not a minor procedure in a neonate. In older infants, inguinal herniotomy is usually undertaken as a day-case operation provided that there is appropriate anaesthetic expertise (Summary box 6.6).

(a) Inguinal hernia (b) Hydrocele

Figure 6.5 Inguinal hernia (a) and hydrocele (b) in children are the result of incomplete obliteration of the processus vaginalis.

Figure 6.6 (a) An infant with a right inguinal hernia (the swelling is partially obscured by suprapubic fat) and (b) a boy with a right hydrocele.

Summary box 6.6

Inguinal hernias

- More common in premature boys
- 15% are bilateral
- Almost always indirect with a patent processus vaginalis
- Present with a groin lump that appears on straining or crying
- Incarcerated hernias can usually be reduced with gentle pressure
- If reduction is impossible emergency surgery is needed
- In infants, they must be repaired promptly to prevent the risk of strangulation
- The hernial sac is isolated then ligated and divided proximally

Hydrocele

A patent processus vaginalis that is too narrow to prevent the development of an inguinal hernia may nevertheless allow peritoneal fluid to track down around the testis to form a hydrocele. Hydroceles are unilateral or bilateral, asymptomatic, non-tender scrotal swellings. They may be tense or lax but typically transilluminate. The majority resolve spontaneously as the processus

continues to obliterate but surgical ligation is recommended in boys older than 2 years.

Undescended testis

This occurs when the testis is arrested along its normal pathway of descent. At birth, about 4% of full-term boys have unilateral or bilateral undescended testes (cryptorchidism), but by 3 months of age this figure is 1.5% and it changes little thereafter. The incidence is higher in preterm infants because the testis descends through the inguinal canal during the third trimester of pregnancy. Examination of the testes should be performed with warm hands once the boy has relaxed. The testis is usually palpable after gently massaging the contents of the inguinal canal towards the scrotum.

A *retractile* testis is typically present in the scrotum in early infancy; it can be manipulated into the bottom of the scrotum without tension but tends to be pulled up by the cremaster muscle. With time, the testis resides permanently in the scrotum; however, follow-up is advisable as, rarely, the testis subsequently ascends into the inguinal canal. An *ectopic* testis lies outside its normal line of descent, most often in the perineum or femoral triangle. An *undescended* testis may be palpable in the groin or at the neck of the scrotum or it may be impalpable if absent or located in the abdomen or inguinal canal.

Useful investigations include:

- *laparoscopy* – the optimum method of visualising the anatomy (Fig. 6.7);
- *ultrasound scan* – this has a limited role in detecting an inguinal testis in an obese boy;
- *hormonal* – in cases of bilateral impalpable testes, the presence of testicular tissue can be confirmed by recording a rise in serum testosterone in response to intramuscular injections of human chorionic gonadotrophin; these boys require specialist endocrine review.

Orchidopexy is usually undertaken as a day-case procedure. The testis is mobilised through an inguinal incision, preserving the vas deferens and testicular vessels. The associated patent processus vaginalis is ligated and divided and the testis is placed in a subdartos scrotal pouch. Orchidectomy is often advised for the

Figure 6.7 Laparoscopic view of a right-sided intra-abdominal testis visible at the internal ring. Vas (single arrow) and testicular vessels (double arrow).

unilateral intra-abdominal testis, which cannot be corrected by orchidopexy because of the future risk of malignancy. In cases of bilateral intra-abdominal testes, microvascular transfer and staged orchidopexy are two options available to preserve the testes if the testicular vessels are too short to permit a single-stage orchidopexy. The benefits of orchidopexy include:

- **Fertility.** To optimise spermatogenesis the testis needs to be in the scrotum below body temperature at a young age. Orchidopexy during the second year of life is currently recommended by paediatric surgeons. Fertility after orchidopexy for a unilateral undescended testis is near normal. Men with a history of bilateral intra-abdominal testes are usually sterile.
- **Malignancy.** Undescended testes are histologically abnormal and at an increased risk of malignancy. The greatest risk is for bilateral intra-abdominal testes. Early orchidopexy for a unilateral undescended testis may reduce the risk but this is not proven.
- **Cosmetic and psychological.** In an older boy a prosthetic testis can be inserted to replace an absent one (Summary box 6.7).

Summary box 6.7

The undescended testis

- A retractile testis can be drawn down into the bottom of the scrotum
- An undescended testis may be in the groin or impalpable in the abdomen
- An ectopic testis lies outside the normal line of descent
- Orchidopexy involves mobilising the testis and placing it in a subdartos pouch
- Orchidopexy before 2 years of age improves fertility, may reduce the risk of malignancy and has psychological benefits

The acute scrotum

Testicular torsion is most common in adolescents but may occur at any age, including in the perinatal period. The pain is not always centred on the scrotum but may be felt in the groin or lower abdomen. Oedema and erythema of the scrotal skin can be absent. Sometimes there is a history of previous transient episodes. Torsion of the testis must be relieved within 6–8 hours of the onset of symptoms for there to be a good chance of testicular salvage. At operation, viability of the testis is assessed after derotation. Three-point fixation of the contralateral testis with non-absorbable sutures corrects any anatomical predisposition to torsion (e.g. the bell-clapper testis). Expert assessment of testicular blood flow by colour Doppler ultrasound may help in the differential diagnosis but the scrotum must be explored urgently if torsion cannot be excluded.

A hydatid of Morgagni is an embryological remnant found on the upper pole of the testis. *Torsion of a testicular appendage* characteristically affects boys just before puberty (Fig. 6.8), possibly because of enlargement of the hydatid in response to gonadotrophins. The pain often increases over a day or two. Occasionally, the tormented hydatid can be felt or seen (blue dot sign). Excision of the appendage leads to rapid resolution of

Giovanni Battista Morgagni, 1682–1771, Professor of Anatomy, Padua, Italy for 59 years. He is regarded as 'The Founder of Morbid Anatomy'.

Figure 6.8 Acute scrotal pathology at different ages.

symptoms. Viral or bacterial *epididymo-orchitis* may cause an acute scrotum in infants and toddlers but the diagnosis is often only made after scrotal exploration. Other conditions that rarely cause acute scrotal symptoms and signs include idiopathic scrotal oedema (typically painless, bilateral inguinoscrotal redness and swelling in a young boy), an incarcerated inguinal hernia, vasculitis or a scrotal haematoma (Summary box 6.8).

Summary box 6.8

Diagnosis and treatment of the acute scrotum

- Torsion of the testis must be assumed until proven otherwise
- Testicular torsion can present with acute inguinal or abdominal pain
- Urgent surgical exploration is crucial if testicular torsion cannot be excluded
- Torsion of a testicular appendage usually occurs just before puberty
- An incarcerated inguinal hernia must be considered in the differential diagnosis

Abnormalities of the penis

Hypospadias

Failure of complete urethral tubularisation in the male fetus results in hypospadias, a common congenital anomaly affecting about one in every 200–300 boys. In most cases the urethra opens just proximal to the glans penis but in severe cases the meatus may be on the penile shaft or in the perineum. The dorsal foreskin is hooded and there is a variable degree of chordee (a ventral curvature of the penis most apparent on erection) (Fig. 6.9). Glanular hypospadias may be a solely cosmetic concern but more proximal varieties interfere with micturition and erection. In severe forms of hypospadias, additional genitourinary anomalies and intersex disorders should be excluded. Surgical correction of distal hypospadias is frequently undertaken before 2 years of age, often as a single-stage operation. Proximal varieties may require complex staged procedures. Surgery aims to achieve a terminal urethral meatus so that the boy can stand to micturate with a normal stream, a straight erection and a penis that looks normal.

Ritual circumcision must be avoided in infants with hypospadias because the foreskin is often required for later reconstructive surgery.

Figure 6.9 Hypospadias – note the hooded foreskin and the ventral meatus.

Figure 6.10 True phimosis from balanitis xerotica obliterans.

Circumcision

At birth, the foreskin is adherent to the glans penis. These adhesions separate spontaneously with time, allowing the foreskin to become retractile. At 1 year of age, about 50% of boys have a non-retractile foreskin. By 4 years this has declined to 10% and by 16 years to just 1%. Ballooning of the normal non-retractile foreskin may occur with micturition. Gentle retraction of the foreskin at both times helps to maintain hygiene but forcible retraction should never be attempted. The presence of preputial adhesions, when the foreskin remains partially adherent to the glans, is normal and resolves spontaneously.

Circumcision is one of the earliest recorded operations and remains an important tradition in some cultures. Routine neonatal circumcision is performed in some western societies but the practice has been increasingly criticised. Proponents point out that circumcision reduces the incidence of urinary tract infection in infant boys; however, circumcision is not without risk of significant morbidity. The medical indications for circumcision are:

- *Phimosis*. This term is often wrongly applied to describe a normal, non-retractile foreskin. True phimosis is seen as a whitish scarring of the foreskin and is rare before 5 years of age (Fig. 6.10). It is caused by a localised skin disease known as balanitis xerotica obliterans, which also affects the glans penis and can cause urethral meatal stenosis.
- *Recurrent balanoposthitis*. A single episode of inflammation of the foreskin, sometimes with a purulent discharge, is not uncommon and usually resolves spontaneously; antibiotics are sometimes needed. Recurrent attacks are unusual but may be an indication for circumcision.
- *Recurrent urinary tract infection*. Circumcision is occasionally justified in boys with an abnormal upper urinary tract and recurrent urinary infection. It may also help boys with spina bifida who need to perform clean intermittent urethral catheterisation.

An emerging and still controversial indication for circumcision is in the prevention of sexually acquired human immunodeficiency virus (HIV) infection in communities where this disease is common; large clinical trials have recently shown that circumcision reduces the risk of HIV transmission.

Circumcision for medical reasons is best performed under general anaesthesia. A long-acting local anaesthetic regional block can be given to reduce postoperative pain. Circumcision is not a trivial operation; bleeding and infection are well-recognised complications and more serious hazards, such as injury to the glans, may occur if the procedure is not carried out by adequately trained personnel (Summary box 6.9).

Summary box 6.9

Circumcision

- Medical indications are phimosis and recurrent balanoposthitis
- Circumcision is not indicated for an otherwise healthy non-retractile foreskin
- Complications include bleeding and damage to the glans

Umbilical hernia

In the embryo the umbilical ring is a relatively large defect in the ventral abdominal wall transmitting several structures that subsequently connect the fetus to the placenta (Fig. 6.11). An umbilical hernia is common and caused by incomplete closure of the umbilical ring. Most resolve spontaneously within a year or two of birth and surgical repair is rarely necessary. Incarceration in an umbilical hernia is rare.

Infantile hypertrophic pyloric stenosis

In this acquired disorder, hypertrophy of the circular muscle layer increases the length and diameter of the pylorus. Boys are

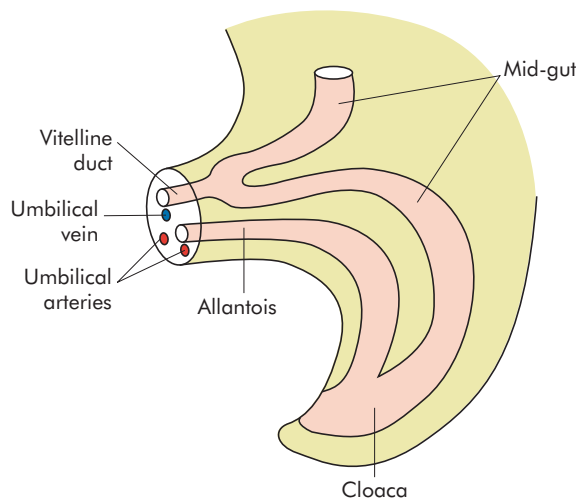

Figure 6.11 The embryonic umbilical ring; both the vitelline duct and the allantois can leave remnants (Meckel's diverticulum and urachus respectively).

affected four times more commonly than girls. The incidence is variable but in the UK it affects about three in every 1000 live-born infants. The aetiology is unknown but in some families there is a strong genetic predisposition. Infantile hypertrophic pyloric stenosis (IHPS) is classically associated with projectile vomiting between 2 and 8 weeks of age; it is rare after 3 months of age. Typically, the baby feeds hungrily and vomits non-bilious milk curds towards the end of a feed.

In most cases, IHPS can be diagnosed clinically. During a test feed there is visible gastric peristalsis passing from left to right across the upper abdomen and in a relaxed baby the pyloric 'tumour' is palpable as an 'olive' in the epigastrium or right upper quadrant. The diagnosis can be confirmed by an ultrasound scan, which shows the thickened pyloric muscle. IHPS is readily treated by surgery but the infant must first be adequately rehydrated and electrolyte/acid-base disturbances corrected; this may take 48 hours or more. IHPS classically causes a hypochloraemic alkalosis, the severity of which is related to the length of the history. Mild dehydration and alkalosis can be corrected by giving maintenance fluids ($120\text{--}150\text{ ml kg}^{-1}\text{ day}^{-1}$) of 0.45% saline with 5% dextrose containing 20 mmol of potassium chloride per litre. Extra fluid is needed to correct more severe dehydration. Oral feeding is discontinued and the stomach emptied with an 8–10 Fr nasogastric tube; on-going gastric losses should be replaced with normal saline containing potassium chloride. Blood glucose must be monitored and maintained.

Ramstedt's pyloromyotomy is performed under general anaesthesia with endotracheal intubation and muscle relaxation. Via a transverse right upper quadrant muscle cutting incision, the pyloric tumour is delivered by gentle traction on the stomach. A serosal incision is made anterosuperiorly from the pyloroduodenal junction, where the muscle layer is thin, to the gastric antrum (Fig. 6.12). This region is relatively avascular. The pyloric muscle, which has a gritty consistency, is then separated widely down to the submucosa using artery forceps. The end result should be an

Wilhelm Conrad Ramstedt, 1867–1963, Surgeon, The Rafaelklinik, Münster, Germany, performed his first pyloromyotomy in 1911.

Figure 6.12 Pyloromyotomy for infantile hypertrophic pyloric stenosis.

intact bulging submucosa from duodenal fornix to gastric antrum. Perforation of the duodenal fornix is uncommon and not serious provided that it is recognised and repaired immediately. Minor bleeding as a result of venous congestion stops spontaneously but occasionally a larger gastric serosal vessel needs cautious diathermy coagulation. With experience, pyloromyotomy can be safely performed through a circumumbilical incision or laparoscope with superior cosmesis.

Postoperatively, intravenous fluids are continued until oral feeding is re-established within 24 hours. Minor, transient vomiting is common and self-limiting. Surgical complications such as duodenal perforation, haemorrhage, wound infection and wound dehiscence are uncommon and avoidable. Pyloromyotomy has no significant long-term sequelae (Summary box 6.10).

Summary box 6.10

Infantile hypertrophic pyloric stenosis

- Most commonly affects boys aged 2–8 weeks
- Characterised by projectile vomiting after feeds
- Gastric peristalsis can be seen and a lump felt
- Fluid and electrolyte disturbances must be corrected before surgery
- Pyloromyotomy splits the hypertrophied muscle leaving the mucosa intact

Other common or serious causes of vomiting in infancy are shown in Table 6.3. Gastro-oesophageal reflux is common and tends to resolve spontaneously with maturity. Persistent symptoms require treatment with thickened feeds and anti-reflux medication. Complications such as failure to thrive or respiratory problems demand further investigation and, in some cases, fundoplication.

Intussusception

Intussusception, the invagination of one portion of the intestine into an adjacent segment, is uncommon but may be life-threatening. Intussusception typically causes a strangulating bowel obstruction, which can progress to gangrene and perforation (Fig. 6.13). Intussusception is classified according to the site of the inner intussusceptum and outer intussusciens. In children,

Table 6.3 Vomiting in infancy

Bile-stained	
<i>Neonate</i>	Intestinal malrotation with volvulus Duodenal/intestinal atresia/stenosis Hirschsprung's disease Necrotising enterocolitis Incarcerated inguinal hernia Meconium ileus
<i>Older infant</i>	Intestinal malrotation with volvulus Intussusception (often non-bilious initially) Incarcerated inguinal hernia
Non-bilious	Infantile hypertrophic pyloric stenosis Gastro-oesophageal reflux Feeding difficulties (technique/volume) Non-specific marker of illness, e.g. infection (urinary tract infection, meningitis, gastroenteritis, respiratory), metabolic disorder, raised intracranial pressure, congenital adrenal hyperplasia, etc.

more than 80% are ileocolic, beginning several centimetres proximal to the ileocaecal valve with their apex in the ascending or transverse colon.

In the majority of affected infants, intussusception is caused by hyperplasia of gut lymphoid tissue, which may in turn be secondary to viral infection. In 10% of children, intussusception is secondary to a pathological lead point such as a Meckel's diverticulum, enteric duplication cyst or even small bowel lymphoma. Such cases are more likely in children over the age of 2 years and in those with recurrent intussusception.

Intussusception can develop at any age and affect either sex but the peak incidence is between 5 and 10 months of age. Classically, a previously healthy infant presents with colicky pain and vomiting (milk then bile). Between episodes the child initially appears well. Later, they may pass a 'redcurrant jelly' stool. Clinical signs include dehydration, abdominal distension and a palpable sausage-shaped mass in the right upper quadrant. Rectal

Figure 6.13 Operative appearances of an ileocolic intussusception causing small bowel obstruction.

examination may reveal blood or rarely the apex of an intussusceptum (Summary box 6.11).

Summary box 6.11

Presentation of intussusception

- Bilious vomiting in an infant is a sign of intestinal obstruction until proved otherwise
- Intussusception classically presents with colicky pain and vomiting
- Intussusception should be considered in any infant with bloody stools
- Peak incidence is between 5 and 10 months of age

A plain radiograph commonly shows signs of small bowel obstruction and a soft-tissue opacity. Diagnosis can be confirmed by an abdominal ultrasound scan or contrast enema. After resuscitation with intravenous fluids, broad-spectrum antibiotics and nasogastric drainage, non-operative reduction of the intussusception can be attempted using an air or barium enema (Fig. 6.14). Successful reduction can only be accepted if there is free reflux of barium or air into the small bowel, together with resolution of symptoms and signs in the patient. Non-operative reduction is contraindicated if there are signs of peritonitis or perforation, with a known pathological lead point or in the presence of profound shock. In experienced units, more than 70% of intussusceptions can be reduced non-operatively. Strangulated bowel and pathological lead points are unlikely to reduce. Perforation of the colon during pneumatic or hydrostatic reduction is a recognised hazard but is rare. Recurrent intussusception

Figure 6.14 Air enema reduction of an intussusception (the arrows mark the soft tissue shadow of the intussusceptum).

occurs in up to 10% of patients after non-operative reduction (Summary box 6.12).

Summary box 6.12

Management of intussusception

- Strangulation will result without treatment
- Most are ileocolic
- Diagnosis can be confirmed by ultrasound scan or contrast enema
- Fluid and electrolyte resuscitation is essential
- Most intussusceptions can be reduced non-operatively using an air or barium enema
- If there are signs of peritonitis or perforation then proceed to urgent surgery

If non-operative reduction is contraindicated or unsuccessful, or if a pathological lead point is suspected, surgery is necessary. Via a right-sided transverse abdominal incision the intussusception is milked back by gentle compression from its apex. Both the intussusceptum and the intussusciens must be carefully inspected for areas of non-viability. An irreducible intussusception or one complicated by infarction or a pathological lead point requires resection and primary anastomosis.

Acute abdominal pain

Between one-third and one-half of children admitted to hospital with acute abdominal pain have non-specific abdominal pain. Another one-third have acute appendicitis. Relatively benign conditions such as constipation and urinary tract infection account for most of the remainder. A small proportion of children have more serious pathology.

History and examination

Time and patience are required to accurately evaluate the child with acute abdominal pain. The child is frightened and the parents are worried. Young children find it difficult to accurately describe or localise abdominal pain. The abdomen must be thoroughly inspected and, if necessary, repeatedly reassessed after analgesia. The genitalia, chest and neck must also be examined. A gentle abdominal examination of the sleeping toddler, before removing their clothes, may reveal tenderness, guarding or a mass. Rectal examination is not routinely necessary except if pelvic appendicitis is suspected. *Active observation* (Jones) is a valuable concept that acknowledges that a definitive diagnosis is not always possible when the patient is first seen. The surgeon reassesses the child after a few hours rather than waiting for any deterioration. Clear fluids and simple analgesics are allowed. This policy reduces the need for investigations and results in the removal of fewer innocent appendices (Summary box 6.13).

Peter Ferry Jones. Formerly Professor of Clinical Surgery, The University of Aberdeen, Aberdeen, Scotland.

Summary box 6.13

Work-up of children with acute abdominal pain

- A careful history and examination and active observation are paramount
- Routine tests include urine analysis, microscopy and culture
- Frequently helpful tests: abdominal ultrasound scan (can diagnose pelvic and urinary tract pathology, intussusception and other conditions)
- Occasionally helpful tests: a plain supine abdominal radiograph (particularly in the preschool child with pain and vomiting), urea and electrolytes and full blood count
- Selective specific investigations: blood culture, stool culture, plasma amylase, diagnostic laparoscopy

Acute non-specific abdominal pain

The clinical features of non-specific abdominal pain are similar to acute appendicitis but the pain is poorly localised, not aggravated by movement and rarely accompanied by guarding. The site and severity of maximum tenderness often vary during the course of repeated examinations. Symptoms are typically self-limiting within 48 hours. The aetiology of non-specific abdominal pain in children is obscure but viral infections and transient intussusception account for some cases. Mesenteric adenitis, a viral infection causing widespread reactive lymphadenopathy, fever and diffuse abdominal pain is another cause. In some children, recurrent acute abdominal pain can be an expression of underlying psychosocial problems.

Acute appendicitis

Classical features are abdominal pain with localised tenderness and guarding in the right iliac fossa. Vomiting is common. Loose stools may occur with pelvic appendicitis. Some children complain of pain on micturition but this is abdominal pain rather than true dysuria; urine microscopy may show a sterile pyuria. The pulse rate and temperature tend to be normal or slightly elevated early on but a pyrexia of 39°C or greater accompanied by lower abdominal tenderness and guarding suggests a perforated appendix. The chest must always be examined because of the possibility of referred pain from a right lower lobe pneumonia. Most children with acute appendicitis prefer to lie still but there is the occasional stoic who remains active. Bowel sounds can still be audible in the child with peritonitis.

Acute appendicitis can be a difficult diagnosis in the preschool child who is more likely to present with peritonitis or an appendix mass: symptoms are poorly communicated, often non-specific and easily confused with gastroenteritis or urinary infection; abdominal signs may be modified by antibiotics given for a presumed throat or ear infection; obstructing faecoliths are more common; and the greater omentum is poorly developed.

The treatment of acute appendicitis in children is surgical but only after adequate resuscitation with intravenous fluids, analgesia and broad-spectrum antibiotics. Appendicectomy can be performed laparoscopically or through a small muscle-splitting right iliac fossa incision. Peritoneal lavage with warm saline is essential with perforated appendicitis but a drain is only necessary in some cases of appendix abscess. An appendix mass usually responds to conservative management with antibiotics followed

by interval appendectomy 4–6 weeks later but some surgeons advocate early appendectomy (Summary box 6.14).

Summary box 6.14

Acute appendicitis

- Vomiting and loose stools may be present
- Tenderness and guarding in the right iliac fossa is characteristic
- Exclude referred pain from right lower lobe pneumonia
- Take special care in diagnosing appendicitis in the preschool child
- Surgery is the treatment of choice but only after fluid resuscitation and antibiotics

Other causes of acute abdominal pain in children

- *Intestinal obstruction.* Consider intussusception, inguinal hernia, adhesions and Meckel's diverticulum.
- *Constipation.* Often overdiagnosed as a cause of acute abdominal pain, particularly as the plain abdominal radiograph of a dehydrated ill child frequently shows faecal loading. Constipation is more often a cause of acute abdominal pain in a child who has been treated for Hirschsprung's disease or an anorectal malformation.
- *Urinary tract disorders.* Urinary tract infection is an uncommon cause of acute abdominal pain. Urinary symptoms, fever and vomiting tend to predominate. Urinalysis, microscopy and culture are useful but a sterile pyuria may accompany acute appendicitis. Boys with pelviureteric junction obstruction can present with acute or recurrent abdominal pain and no urinary symptoms.
- *Gastroenteritis.* May cause colicky abdominal pain. Onset of pain before the diarrhoea and the presence of lower abdominal tenderness should raise suspicion of appendicitis. Pelvic tenderness on rectal examination may be a useful pointer to appendicitis.
- *Tropical diseases.* Ascariasis, typhoid and amoebiasis cause acute abdominal pain.

There are numerous rarer causes of acute abdominal pain in children including Henoch–Schönlein purpura, sickle cell disease, primary peritonitis, acute pancreatitis, biliary colic, testicular torsion, gynaecological pathology (e.g. ovarian cysts and tumours, pelvic inflammatory disease, haematometrocolpos) and urinary stone disease (Summary box 6.15).

Summary box 6.15

Rarer causes of acute abdominal pain in children

- Obstruction from intussusception, adhesions, Meckel's diverticulum or a hernia
- Constipation
- Urinary tract disorders
- Gastroenteritis
- Ascariasis
- Typhoid

Eduard Heinrich Henoch, 1820–1910, Professor of Diseases of Children, Berlin, Germany, described this form of purpura in 1868.
Johann Lucas Schönlein, 1793–1864, Professor of Medicine, Berlin, Germany, published his description of this form of purpura in 1837.

Urinary tract infection

Urinary tract infection in children should be diagnosed, investigated and treated promptly. Unlike adults, children often have an underlying urinary tract abnormality and they are at risk of developing renal scarring from ascending infection. Infection and obstruction is a particularly hazardous combination. Older children often complain of dysuria and frequency whereas infants with a urinary tract infection may simply present with vomiting, fever and/or poor feeding. Definite infection is confirmed by urine microscopy and culture showing a pure growth of a urinary pathogen with a colony count of $> 10^5$ organisms per ml and an associated pyuria. However, urine specimens from children are easily contaminated during collection and results must be interpreted with care.

A proven urinary tract infection should initially be investigated by ultrasound scan. Micturating cystography and radioisotope renography are helpful in excluding vesicoureteric reflux and renal scarring. Treatment is aimed at relieving symptoms, correcting an underlying cause and preventing renal scarring.

Vesicoureteric reflux is a common cause of urinary tract infection in children and is graded according to severity. Milder grades of reflux often improve with age but spontaneous resolution is less likely with more severe grades. Vesicoureteric reflux is initially treated with antibiotic prophylaxis. Surgical reimplantation of the ureter or endoscopic treatment to prevent ureteric reflux are reserved for children with symptomatic breakthrough infections, severe reflux, progressive renal scarring or associated urinary tract anomalies.

Children with *neuropathic bladders* (e.g. spina bifida) are at risk of secondary upper renal tract complications. Management of these children must take into account their dexterity and motivation. An adequate capacity, low-pressure bladder can frequently be managed by clean intermittent catheterisation but a high pressure bladder is hazardous and other strategies such as bladder augmentation may be necessary. Some of these children empty their bladder via a non-refluxing catheterisable channel fashioned from the appendix, the bowel or a redundant ureter interposed between the abdominal wall and bladder (Mitrofanoff) (Summary box 6.16).

Summary box 6.16

Urinary tract infection in children

- Needs prompt diagnosis, investigation and treatment to avoid permanent damage to kidneys
- Children often have an underlying urinary tract anomaly
- Symptoms are non-specific in infants
- Urine can be contaminated during collection
- The urinary tract should be checked with ultrasound in a confirmed urinary tract infection

Constipation

The passage of hard or infrequent stools is common in children. Severe constipation may be secondary to an anal fissure, Hirschsprung's disease, an anorectal malformation or a neuropathic bowel. A detailed history and examination of the abdomen, anus and spine will identify most causes. Rectal

Paul Mitrofanoff, B. 1934, Professor of Paediatric Surgery, Rouen, France.

examination and plain abdominal radiography may be helpful in severe cases. In the absence of specific underlying pathology, the child is best managed jointly with a paediatrician using a combination of diet, extra fluids, reward systems, laxatives and, in some cases, psychological intervention.

Rectal prolapse

Mucosal rectal prolapse can occur in toddlers and is exacerbated by straining or squatting on a potty. It is typically intermittent and frequently self-limiting. Rarely, it may be secondary to cystic fibrosis or spinal dysraphism. The differential diagnosis includes a prolapsing rectal polyp. Underlying factors such as constipation should be treated. Recurrent prolapse usually responds to injection sclerotherapy. Strapping the buttocks is ineffective.

Rectal bleeding

The aetiology and management of rectal bleeding depends on the age of the child, the type and quantity of bleeding and the associated symptoms. Unlike adults, malignancy is exceptionally rare. In infants, an anal fissure, necrotising enterocolitis, intussusception and allergic enterocolitis are possible causes. In older children, more common causes include an anal fissure, a juvenile polyp (Fig. 6.15) and certain gastroenteritides (e.g. *Campylobacter* infection); Meckel's diverticulum, duplication cyst and inflammatory bowel disease are less common. A careful history and examination together with stool microscopy and culture and a full blood count help to select those children who require further investigation by endoscopy, isotope scans, etc.

A Meckel's diverticulum (see Chapter 65) is a remnant of the vitelline duct that connected the embryonic mid-gut to the yolk sac. It is usually located about 60 cm proximal to the ileocaecal valve and is present in about 2% of individuals. Most Meckel's diverticula are clinically silent but if they contain ectopic gastric mucosa this can cause peptic ulceration and profuse (relatively painless) dark red rectal bleeding (Fig. 6.16). This complication occurs most often in young children. A technetium scan may confirm the presence of ectopic gastric mucosa. A Meckel's diverticulum may also be complicated by an obstructing band between the diverticulum and the umbilicus, diverticulitis, intussusception, intestinal volvulus, perforation or neoplasia. A pathological diverticulum should be completely excised (Summary box 6.17).

Summary box 6.17

Rectal problems in children

- **Constipation:** in severe cases exclude Hirschsprung's disease and an anorectal malformation
- **Rectal bleeding:** consider anal fissure, intussusception, colitis and Meckel's diverticulum

Figure 6.15 Colonic juvenile polyp – these are typically pedunculated.

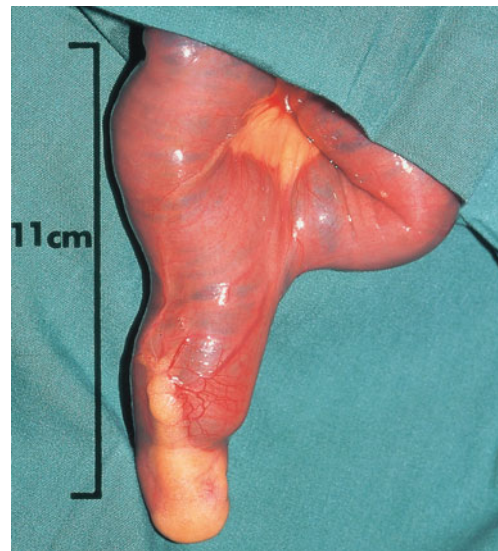

Figure 6.16 Meckel's diverticulum containing ectopic gastric mucosa.

Swallowed or inhaled foreign bodies

Coins are the most frequently swallowed foreign bodies in children. Once beyond the cardia, they almost never cause complications in a normal gastrointestinal tract. A plain radiograph of the chest and neck should establish if the coin is lodged in the oesophagus, in which case it should be removed endoscopically under general anaesthesia. Button batteries must be removed urgently if they remain in the oesophagus or stomach because they can cause gastrointestinal perforation or poisoning. The need to remove sharp objects depends on their size, the age of the child and their position in the gut.

An inhaled foreign body in a small child typically causes sudden-onset coughing and stridor. If there is worsening dyspnoea or signs of hypoxia then the infant should be given back blows in a head-down position. A Heimlich manoeuvre should be used in an older child. In a symptomatic but stable child, a unilateral wheeze or decreased air entry strongly suggests a residual foreign body. If the object is radiolucent, inspiratory and expiratory chest radiographs may show a hyperinflated lung from air trapping (Fig. 6.17). Such cases require bronchoscopy (Summary box 6.18).

Summary box 6.18

Swallowed or inhaled objects

- Most swallowed objects pass spontaneously
- Batteries need watching - they must pass quickly if their contents are not to leak
- Objects jammed in the airways or oesophagus need removing

Henry Jay Heimlich, B. 1920, Thoracic Surgeon, Xavier University, Cincinnati, OH, USA.

Figure 6.17 An inspiratory (left) and expiratory (right) chest radiograph demonstrating left-sided pulmonary air trapping after inhalation of a radiolucent foreign body.

CONGENITAL MALFORMATIONS

Excluding cutaneous haemangiomas and birthmarks, approximately 2% of babies are born with a major structural malformation. These may be isolated or multiple. Many are the result of genetic or teratogenic effects. There is an expanding cohort of adults who have sequelae from a congenital malformation or its treatment. Occasionally, a congenital abnormality presents for the first time in adulthood.

Most congenital malformations develop during embryonic life between the third and eighth weeks of gestation. During this phase the three germ layers (endoderm, mesoderm, ectoderm) give rise to rudimentary organ systems. Some malformations are caused by incomplete morphogenesis (e.g. oesophageal atresia) whereas others arise from redundant morphogenesis (e.g. Meckel's diverticulum).

Many major structural malformations can be detected and monitored before birth by prenatal ultrasound scan. Termination of pregnancy or planned delivery in a specialist centre can be considered for severe malformations. Prenatal diagnosis not only detects anatomical defects such as congenital diaphragmatic hernia and urinary tract anomalies but can also identify chromosomal abnormalities such as Down's syndrome and genetic disorders such as cystic fibrosis.

The incidence of congenital malformations is variable (Table 6.4). Some examples relevant to the general surgeon are briefly outlined in the following sections.

Oesophageal atresia

A blind proximal pouch with a distal tracheo-oesophageal fistula is the most common type (Fig. 6.18). Affected infants typically present soon after birth with frothy saliva and cyanotic episodes, exacerbated by any attempt to feed. The preceding pregnancy may have been complicated by maternal polyhydramnios. The diagnosis is confirmed by failure to pass a 10 Fr orogastric tube into the stomach; the tube is visible within an upper oesophageal pouch on the chest radiograph. The presence of abdominal gas signifies the tracheo-oesophageal fistula. Associated anomalies are common and include cardiac, renal and skeletal defects.

John Langdon Haydon Down (sometimes given as Langdon-Down), 1838–1896, Physician, The London Hospital, London, England, published 'Observations on an ethnic classification of idiots' in 1866.

Table 6.4 Incidence of selected congenital malformations in live-born infants

Malformation	Incidence
Thoracic	
Congenital diaphragmatic hernia	1:3000
Oesophageal atresia/tracheo-oesophageal fistula	1:3500
Cardiac	
Congenital heart disease	1:150
Gastrointestinal	
Gastroschisis	1:7500
Hirschsprung's disease	1:5000
Anorectal malformations	1:4–5000
Hepatobiliary	
Biliary atresia	1:17 000
Choledochal cyst	1:50 000
Urogenital	
Hypospadias	1:250
Pelviureteric junction obstruction	1:1000

The standard method of surgical repair is via a right-sided extrapleural thoracotomy within a day or two of birth. The fistula is divided and the tracheal side oversewn. The oesophageal ends are then anastomosed. Potential postoperative complications include anastomotic leak, stricture, recurrent fistula formation and gastro-oesophageal reflux. Infants with pure oesophageal atresia and no tracheo-oesophageal fistula are usually best managed by a temporary gastrostomy and delayed primary repair. Except for very-low-birthweight babies and those with major congenital heart disease, most infants with repaired oesophageal atresia have a good prognosis.

Congenital diaphragmatic hernia

Typically, there is a left-sided posterolateral diaphragmatic defect associated with herniation of abdominal viscera into the chest

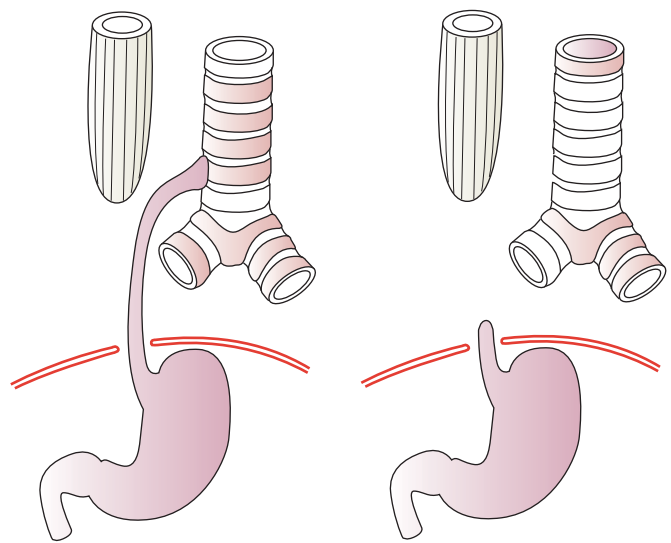

Figure 6.18 The two main varieties of oesophageal atresia. Atresia with a distal tracheo-oesophageal fistula, shown on the left, is the most common (about 85% of cases).

and pulmonary hypoplasia. Many cases are now detected by prenatal ultrasound scan. Prognosis is related to the severity of pulmonary hypoplasia. Despite intensive respiratory support, up to 30% of babies born with this condition die from neonatal respiratory failure. If the infant can be adequately oxygenated and stabilised, the diaphragmatic defect can be repaired. Attempts to salvage severely affected infants by fetal surgery (Harrison) have not yet improved overall survival rates. Small diaphragmatic hernias may present with respiratory or gastrointestinal symptoms in later childhood.

Intestinal atresia

Duodenal atresia (atresia = no lumen) may take the form of a completely obstructing membrane (Fig. 6.19) or the proximal and distal duodenum may be completely separated. The condition may be suspected from prenatal ultrasound scan findings of a 'double bubble' in the fetal abdomen together with maternal polyhydramnios. There is an association with Down's syndrome. Postnatally, the infant develops bilious vomiting if the atresia is distal to the ampulla. A plain abdominal radiograph is usually diagnostic (Fig. 6.20). Repair is by duodenoduodenostomy. Occasionally, there is a duodenal membrane with a small central perforation (duodenal stenosis), which may delay the onset of obstructive symptoms until later childhood.

The anatomy of jejunal/ileal atresia varies from an obstructing membrane through to widely separated blind-ended bowel ends associated with a mesenteric defect. Atresias may be single or multiple and are probably secondary to a prenatal vascular or mechanical insult causing sterile infarction of a segment of gut. They present with intestinal obstruction soon after birth. The proximal bowel is often extremely dilated and needs to be tapered prior to anastomosis to the distal bowel.

Intestinal obstruction and atresia may also occur in neonates with cystic fibrosis who develop inspissated meconium in the terminal ileum (meconium ileus). Meconium is a sterile mixture of epithelial cells, mucin and bile, formed as the fetus starts to swallow amniotic fluid. Any congenital intestinal obstruction may be complicated by meconium peritonitis, an aseptic peri-

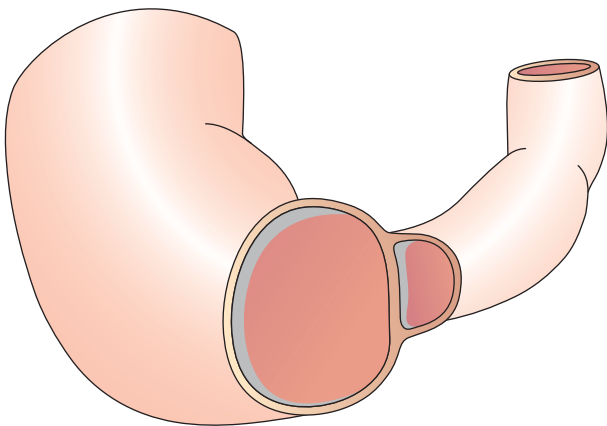

Figure 6.19 Congenital septum of duodenal obstruction at the commencement of the third part of the duodenum. The proximal gut is enormously dilated.

Michael R. Harrison, B. 1943, Chief of Paediatric Surgery, San Francisco, CA, USA. A pioneer of foetal surgery.

Figure 6.20 Neonatal radiograph showing the 'double bubble' of duodenal atresia.

tonitis developing late in intrauterine life or immediately after birth as a result of intestinal perforation. Typically, the baby is born with a firm, distended, discoloured abdomen and signs of intestinal obstruction. A plain abdominal radiograph may show dilated intestinal loops and areas of calcification. Occasionally, the cause of the intestinal perforation resolves spontaneously before birth but most neonates with meconium peritonitis will need surgery. Babies with uncomplicated meconium ileus (no associated atresia, volvulus or perforation) can sometimes be successfully treated by hyperosmolar contrast enemas to clear the inspissated meconium.

Intestinal malrotation

By the 12th week of gestation, the mid-gut has returned to the fetal abdomen from the extra-embryonic coelom and has begun rotating counterclockwise around the superior mesenteric artery axis. In classical intestinal malrotation, this process fails; the duodenojejunal flexure lies to the right of the midline and the caecum is central, creating a narrow base for the small bowel mesentery, which predisposes to mid-gut volvulus (Fig. 6.21). Malrotation with volvulus is life-threatening and typically presents with bilious vomiting. Bile-stained vomiting in the infant is a sign of intestinal obstruction until proved otherwise.

As the gut strangulates, the baby may pass bloodstained stools and becomes progressively sicker. An upper gastrointestinal contrast study confirms the malrotation (Fig. 6.21). Resuscitation and urgent surgery are needed to untwist the volvulus, widen the base of the small bowel mesentery, straighten the duodenum and position the bowel in a non-rotated position (Ladd's procedure). The appendix is usually removed to avoid leaving it in an abnormal site within the abdomen.

Abdominal wall defects

In gastroschisis, the fetal gut is extruded through a defect in the abdominal wall just to the right of the umbilicus. At birth, the

William Edwards Ladd, Professor of Child Surgery, The University of Harvard, Boston, MA, USA.

Figure 6.21 (a) Classical intestinal malrotation with a high central caecum and a duodenojejunal flexure to the right of the midline. (b) The narrow origin of the small bowel mesentery predisposes to mid-gut volvulus.

bowel is non-rotated, foreshortened and covered by a fibrinous peel (Fig. 6.22). After reduction of the bowel and closure of the defect, gastroschisis has a good prognosis although gut dysmotility delays recovery. Some infants have an intestinal atresia, which must also be repaired.

Exomphalos is a different type of anterior abdominal wall defect in which the fetal liver and gut are covered with a membranous sac from which the umbilical cord arises. It may be associated with chromosomal or cardiac anomalies.

Biliary atresia

The extrahepatic bile ducts are occluded causing obstructive jaundice and progressive liver fibrosis in early infancy. Biliary

Figure 6.22 A newborn infant with gastroschisis.

atresia should be considered in any infant who remains jaundiced after 2 weeks of age. Affected infants have conjugated hyperbilirubinaemia and are at risk of a coagulopathy, which can be corrected by vitamin K. After excluding infective and metabolic causes of neonatal jaundice, the most useful investigations are an abdominal ultrasound scan (small irregular gall bladder and no visible bile ducts), a biliary radionuclide scan (no excretion) and a needle liver biopsy. Biliary atresia is treated by a Kasai portoenterostomy in which the occluded extrahepatic bile ducts are excised and a jejunal Roux loop is anastomosed to the hepatic hilum. Effective bile drainage is more likely if the operation is performed before 8 weeks of age and may obviate the subsequent need for liver transplantation.

Alimentary tract duplications

Alimentary tract duplications are rare. They are usually single, variable in size, and spherical or tubular. Most are located on the mesenteric border of the intestine. Typically, they are lined by alimentary tract mucosa and share a common smooth muscle wall and blood supply with the adjacent bowel, with which they may communicate. Duplications can contain heterotopic gastric mucosa and be associated with spinal anomalies. Most duplications present in infancy or early childhood with intestinal obstruction, haemorrhage, intussusception or perforation (Fig. 6.23). Presentation in adult life is also described. Rarely, this is because of malignant degeneration, which has been reported more often with rectal duplication cysts.

Complete excision is the treatment of choice.

Hirschsprung's disease

Hirschsprung's disease is characterised by the congenital absence of intramural ganglion cells (aganglionosis) and the presence of hypertrophic nerves in the distal large bowel. The absence of ganglion cells is due to a failure of migration of vagal neural crest cells into the developing gut. The affected gut is tonically contracted causing functional bowel obstruction. The aganglionosis is restricted to the rectum and sigmoid colon in 75% of patients (short segment), involves the proximal colon in 15% (long segment) and affects the entire colon

Mario Kasai, Formerly Professor of Surgery, the University of Tokyo, Tokyo, Japan.
Cesar Roux, 1857–1934, Professor of Surgery and Gynaecology, Lausanne, Switzerland described this method of forming a jejunal conduit in 1908.
Harald Hirschsprung, 1830–1916, Physician, The Queen Louise Hospital for Children, Copenhagen, Denmark, described congenital megacolon in 1887.

Figure 6.23 An ileal duplication cyst after derotating a localised intestinal volvulus.

and a portion of terminal ileum in 10% (total colonic aganglionosis). A transition zone exists between the dilated, proximal, normally innervated bowel and the narrow, distal aganglionic segment.

Hirschsprung's disease may be familial or associated with Down's syndrome or other genetic disorders. Gene mutations have been identified on chromosome 10 (involving the *RET* proto-oncogene) and on chromosome 13 in some patients. Hirschsprung's disease typically presents in the neonatal period with delayed passage of meconium, abdominal distension and bilious vomiting but it may not be diagnosed until later in childhood or even adult life, when it manifests as severe chronic constipation. Enterocolitis is a potentially fatal complication of the disease.

Definitive diagnosis of Hirschsprung's disease depends on histological examination of an adequate rectal biopsy by an experienced pathologist. A contrast enema may show the extent of the aganglionic segment (Fig. 6.24). Surgery aims to remove the aganglionic segment and bring down healthy ganglionic bowel to the anus; these 'pull-through' operations (e.g. Swenson, Duhamel, Soave and transanal procedures) can be done in a single stage or in several stages after first establishing a proximal stoma in normally innervated bowel. Most patients achieve good bowel control but a significant minority experience residual constipation and/or faecal incontinence.

Anorectal malformations

The anus is either imperforate or abnormally sited. Associated malformations of the sacrum and genitourinary tract are common. In boys, a perineal fistula (a 'low' defect) or an imperforate anus with a rectourethral fistula (Fig. 6.25) is most commonly seen. In girls, an anterior anus (low defect) or an imperforate anus with a fistula opening in the posterior vestibule (not vagina) is most common. Cloacal malformations, in which the rectum and genitourinary tract share a common outflow channel, are also seen in girls.

Diagnosis of a low malformation is usually possible by inspection of the infant's perineum alone. A lateral prone radiograph at about 24 hours of age can help by showing the distance between the rectal gas bubble and the anal skin. Most low malformations are treated by an anoplasty soon after birth. Higher, more com-

Figure 6.24 Barium enema in an infant showing a 'transition zone' in the proximal sigmoid colon between the dilated proximal normally innervated bowel and the contracted aganglionic rectum.

plex defects need a temporary colostomy; after detailed investigations, reconstructive surgery is undertaken at a few months of age. In the posterior sagittal anorectoplasty developed by Pena, dissection and reconstruction are performed through a midline sacroperineal incision. Any fistula is divided, the distal rectal pouch is mobilised and placed within the pelvic muscles of continence, and an inversion anoplasty is fashioned. Functional outcome is related to the type of anorectal malformation (low defects are associated with constipation, higher defects with faecal incontinence) and the integrity of the sacrum and pelvic muscles. For children with residual intractable faecal incontinence, antegrade colonic enemas administered via a catheterisable appendicostomy (Fig. 6.26) (the Malone procedure) enable the child to achieve social continence (Summary box 6.19).

Summary box 6.19

Congenital causes of intestinal obstruction

- *Intestinal atresia*: may be multiple
- *Cystic fibrosis*: can present with intestinal obstruction from inspissated meconium
- *Intestinal malrotation*: predisposes to potentially lethal midgut volvulus
- *Alimentary tract duplications*: may present with obstruction, haemorrhage or intussusception
- *Hirschsprung's disease*: typically presents with delay in passing meconium after birth
- *Anorectal malformations*: check the anus in babies with intestinal obstruction

The bladder is filled with contrast via the fistula and the radio-paque dot has been placed on the infant's perineum over the normal site of the anus. B, bladder; R, rectum.

Urinary tract malformations

Many of these malformations are now detected by prenatal ultrasound scan. Others present in childhood with urinary infection, obstruction or an abdominal mass. Urinary tract disorders in children are investigated by urine microscopy and culture, ultrasound scan, assessment of renal function and a combination of radioisotope renography (uptake and excretion), contrast radiology and endoscopy.

In many infants, prenatally diagnosed mild to moderate hydronephrosis resolves spontaneously. Those with more significant pelviureteric junction obstruction may be asymptomatic or present in later childhood with urinary tract infection or loin pain. Pyeloplasty is indicated for symptoms or impaired renal function. In boys, partial membranous obstruction in the poste-

Figure 6.26 Appendicostomy for the delivery of antegrade colonic enemas.

rior urethra (valves) can cause a severe prenatal obstructive uropathy. This condition demands urgent investigation and treatment soon after birth to preserve bladder and kidney function. Renal failure develops in about one-third of affected boys despite early endoscopic ablation of the obstructing valves. Other congenital urinary tract malformations include ureteric abnormalities (e.g. duplex, ureterocoele, vesicoureteric reflux), multicystic dysplastic kidney and bladder exstrophy.

Necrotising enterocolitis

This is an acquired inflammatory condition of the neonatal gut, mostly affecting premature infants. It is not congenital. Immaturity, formula feeds (breast milk is protective), bacterial infection and impaired gut blood flow have been implicated in the pathogenesis. The neonate typically develops abdominal distension, bloody stools and bilious aspirates with signs of systemic sepsis. Patchy or extensive pneumatosis intestinalis progresses to necrosis and perforation of the gut (Fig. 6.27). A variable length of small and large bowel may be affected and the colon is frequently involved. Milder cases respond to antibiotics, gut rest and parenteral nutrition whereas more severe cases need urgent intestinal resection of infarcted bowel. A primary anastomosis is possible if the disease is reasonably localised.

PAEDIATRIC SURGICAL ONCOLOGY

Neoplasms are less common in children than adults but they are a leading cause of death (along with trauma) in children over 1 year of age. In western countries, leukaemia, central nervous system tumours, lymphomas and neuroblastoma account for most paediatric malignancies. The outlook for most childhood cancers has improved dramatically as a result of effective chemotherapy and collaborative multicentre clinical trials. Neuroblastoma and

Figure 6.27 Operative appearances of neonatal necrotising enterocolitis. Note the intramural gas characteristic of this condition.

nephroblastoma are among the more common solid abdominal tumours.

Neuroblastoma is a malignancy of neuroblasts in the adrenal medulla or sympathetic ganglia and typically presents as an abdominal or paravertebral mass. It metastasises to lymph nodes, bones and liver and causes elevated urinary catecholamines. Small localised tumours are excised. More advanced tumours are treated by chemotherapy and surgery. Survival is related to tumour biology and stage (> 90% for small localised tumours, < 50% for advanced tumours).

Wilms' tumour (nephroblastoma) is a malignant renal tumour derived from embryonal cells; it typically affects children aged from 1 to 4 years. A mutation in the Wilms' tumour suppressor gene (*WT1*) is responsible for some cases. It usually presents as an abdominal mass. The tumour extends into the renal vein and vena cava and metastasises to lymph nodes and lungs. Treatment is with chemotherapy and surgery. Survival depends on tumour spread, completeness of surgical excision and histology but exceeds 70% even among patients with advanced tumours.

The maintenance of chronic central venous access is a critical part of the management of many children with cancer. A wide variety of access devices exist: external catheters and totally implantable ports with single or multiple lumens inserted via peripheral or central veins. External catheters made of silicone elastomer and commonly known as Broviac or Hickman catheters are inserted percutaneously or surgically into a central vein. A cuff around the extravascular subcutaneous portion of the line allows tissue ingrowth and subsequent catheter fixation. The internal jugular vein is often used for operative insertion and

is exposed through a short transverse cervical incision above the medial end of the clavicle between the heads of sternomastoid (Fig. 6.28). Meticulous catheter placement and postoperative care are important in minimising complications.

Principles of oncology

CHAPTER

7

LEARNING OBJECTIVES

To understand:

- The biological nature of cancer
- The principles of cancer prevention and early detection

To appreciate:

- The principles of cancer aetiology and the major known causative factors

- The likely shape of future developments in cancer management
- The multidisciplinary management of cancer
- The principles of palliative care

WHAT IS CANCER?

History

Cancer has always been with us: dinosaur fossils from over 60 million years ago show evidence of malignancy; Egyptian mummies had cancer. The name itself comes to us through Greek and Latin words for a crab, from the Greek *καρκινος* to the Latin *cancer*, and refers to the claw-like blood vessels extending over the surface of an advanced breast cancer. It is possible that cancer appeared on earth with the first vertebrates and that the earliest known tumour occurred in the jaw of an armoured fish about 350 million years ago. Given this history, we have to accept that cancer, at least for the higher vertebrates, is part of life itself.

The study of cancer has always been part of clinical medicine: theories have moved from divine intervention, through the humours, and are now firmly based on the cellular origin of cancer. Rudolf Virchow has the credit for being the first to demonstrate that cancer is a disease of cells and that the disease progressed as a result of abnormal proliferation. His views were encapsulated by his famous dictum 'omnes cellula e cellula' (every cell from a cell). In 1914, Theodor Boveri drew attention to the importance of chromosomal abnormalities in cancer cells and, by the 1940s, thanks to the work of Oswald Avery, we knew that DNA was the genetic material within the chromosomes. The key discovery came in 1953 when Watson

and Crick described the structure of DNA and, as they put it themselves, 'It has not escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material'. This discovery paved the way for the study of what has become known as the molecular biology of cancer. We can now investigate, and sometimes even understand, the biochemical mechanisms whereby cancer cells are formed and which mediate their abnormal behaviour.

The psychopath within

Cancer cells are psychopaths. They have no respect for the rights of other cells. They violate the democratic principles of normal cellular organisation. Their proliferation is uncontrolled; their ability to spread is unbounded. Their inexorable, relentless progress destroys first the tissue and then the host.

In order to behave in such an unprincipled fashion, cells have to acquire a number of characteristics before they are fully malignant. No one characteristic is sufficient, and not all characteristics are necessary. These features, based on an article by Hanahan and Weinberg, are given in Summary box 7.1.

Summary box 7.1

Malignant transformation

- Establish an autonomous lineage
 - Resist signals that inhibit growth
 - Acquire independence from signals stimulating growth
- Obtain immortality
- Evade apoptosis
- Acquire angiogenic competence
- Acquire the ability to invade
- Acquire the ability to disseminate and implant
- Evade detection/elimination
- Genomic instability
- Jettison excess baggage
- Subvert communication to and from the environment/milieu

Establish an autonomous lineage

This involves developing independence from the normal signals that control supply and demand. The healing of a wound is a physiological process; the cellular response is exquisitely coordinated so that proliferation occurs when it is needed and ceases when it is no longer required. The whole process is controlled by a series of signals telling cells when to divide and when not to divide. Cancer cells escape from this normal system of checks and balances: they grow and proliferate in the absence of external stimuli; they proliferate and grow despite signals telling them not to. Their division is inappropriate and remorseless. Oncogenes are a key factor in this process. An oncogene is an aberrant form of a normal cellular gene. Oncogenes were originally identified as sequences within the genome of viruses that could cause cancer. Initially, they were thought to be of viral origin but, surprisingly, turned out to be parts of the normal genome that were hitchhiking between cells, using the virus as a vector. Viral oncogenes (*v-onc*) had sequence homology with normal cellular genes (*c-onc*) and are now presumed to be mutated versions of genes concerned with normal cellular husbandry. The implication of this is that we all carry within us the seeds of our own destruction: genetic sequences that, through mutation, can turn into active oncogenes and thereby cause malignant transformation.

Obtain immortality

According to the Hayflick hypothesis, normal cells are permitted to undergo only a finite number of divisions. For humans, this number is between 40 and 60. The limitation is imposed by the progressive shortening of the end of the chromosome, the telomere, that occurs each time a cell divides. Telomeric shortening is like a molecular clock and, when its time is up, it is time for that lineage to die out. Cancer cells can use the enzyme telomerase to rebuild the telomere at each cell division, so there is no telomeric shortening; it is as if the clock had never ticked, and the lineage will never die out. The cancer cell has achieved immortality.

Evade apoptosis

Apoptosis is a form of programmed cell death. Death occurs, not as the direct result of external events beyond the control of the

Leonard Hayflick, B. 1928. In 1962, whilst working at the Wistar Institute in Philadelphia, he noted that normal mammalian cells growing in culture had a limited, rather than an indefinite, capacity for self-replication.

cell, but as the direct result of internal cellular events instructing the cell to die. Unlike necrosis, apoptosis is an orderly process. The cell dismantles itself and packages itself up neatly for disposal (Fig. 7.1). There is a minimal inflammatory response. Apoptosis is a physiological process: cells in the web space of the embryo die by apoptosis; lymphocytes that could react to self also die by apoptosis. The process was rediscovered in 1972 and named apoptosis from the Greek *αποπτωσις*, meaning the act of falling (as a dead leaf from a tree). Cells that should not be where they find themselves to be should, normally, die by apoptosis: death by apoptosis is an important self-regulatory mechanism in growth and development. Genes, such as *p53*, that can activate apoptosis function as tumour suppressor genes. Loss of function in a tumour suppressor gene will contribute to malignant transformation. Cancer cells will be able to evade apoptosis, which means that the wrong cells can be in the wrong places at the wrong times.

Acquire angiogenic competence

A mass of tumour cells cannot, in the absence of a blood supply, grow beyond a diameter of about 1 mm. This places a severe restriction on the capabilities of the tumour: it cannot grow much larger and it cannot spread widely within the body. However, if the mass of tumour cells is able to attract or to construct a blood supply, then it is able to quit its dormant state and behave in a far more aggressive fashion. The ability of a tumour to form blood vessels is termed angiogenic competence and is a key feature of malignant transformation.

Acquire the ability to invade

Cancer cells have no respect for the structure of normal tissues. They can, like tanks crossing farmland, demolish fences and boundaries. Cancer cells acquire the ability to breach the basement membrane and thus gain direct access to blood and lymph vessels. Cancer cells use three main mechanisms to facilitate invasion: they cause a rise in the interstitial pressure within a tissue; they secrete enzymes that dissolve extracellular matrix; and they acquire motility. Unrestrained proliferation and a lack of contact inhibition mean that cancer cells can directly exert pressure on the surrounding tissue and literally push themselves beyond the normal limits. Cancer cells secrete collagenases and

Figure 7.1 Electron micrograph of apoptotic bodies engulfed by a macrophage.

proteases that chemically dissolve any extracellular boundaries that would otherwise limit their spread through tissues. Cancer cells, by modulating the expression of cell surface molecules called integrins, are able to detach themselves from the extracellular matrix. The abnormal integrins associated with malignancy can also transmit signals from the environment to the cytoplasm and nucleus of the cancer cells ('outside-in signalling'), and these signals can induce increased motility.

Acquire the ability to disseminate and implant

As soon as motile cancer cells gain access to vascular and lymphovascular spaces, they have acquired the potential to use the body's natural transport mechanisms to distribute themselves throughout the body. Distribution is not, of itself, sufficient to cause tumours to develop at distant sites. The cells also need to acquire the ability to implant. As Paget pointed out over a century ago, there is a crucial relationship here between the seed (the tumour cell) and the soil (the distant tissue). Most of the cancer cells discharged into the circulation probably do not form viable metastases: circulating cancer cells can be identified in patients who never develop clinical evidence of metastatic disease. Clumping may be important in permitting metastases: outer cells protecting inner cells from immunological attack [like the testudo (tortoise) used by Roman legionnaires]. These outer protective cells may, on occasion, be normal lymphocytes.

Cancer can spread in this embolic fashion, but can also spread when individual cells migrate and implant. Whether spread occurs in groups or as individual cells, there is still the problem of crossing the vascular endothelium (and basement membrane) to gain access to the tissue itself. Cancer cells probably implant themselves in distant tissues by exploiting, and subverting, the normal inflammatory response. By expressing inflammatory cytokines, the cancer cells can fool the endothelium of the host tissue into becoming activated and allowing cancer cells access to the extravascular space. Activated endothelium expresses receptors that bind to integrins and selectins on the surface of leucocytes, and this binding allows the leucocytes to move across the endothelial barrier. Cancer cells simply subvert this physiological mechanism.

Evade detection/elimination

Cancer cells are simultaneously both 'self' and 'not self'. Although derived from normal cells ('self'), they are, in terms of their genetic make-up, behaviour and characteristics, foreign ('not self'). They are more like alien predators. As such, cancer cells ought to provoke an immune response and be eliminated. It is often hard to prove that something never happened. It is hard to prove that cancer cells are often eliminated by the body's own defence mechanisms, but it is entirely possible that malignant transformation is a more frequent event than the emergence of clinical cancer. The possible role of the immune system in eliminating nascent cancers was proposed by Paul Ehrlich in 1909 and

revisited by both Sir Frank McFarlane Burnet and Lewis Thomas in the late 1950s. Cancer cells, or at least those that give rise to clinical disease, appear to gain the ability to escape detection by the immune system. This may be through suppressing the expression of tumour-associated antigens, a stealth approach, or it may be through actively coopting one part of the immune system to connive in helping the tumour to escape detection by other parts of the immune surveillance system – bribing a guard to distract his colleagues.

Genomic instability

A cancer is a genetic ferment. Cells are dividing without proper checks and balances. DNA is being copied, and the proofreaders have been retired or ignored. Mutations are arising all the time within tumours, and some of these mutations, particularly those in tumour suppressor genes, may have the ability to encourage the development and persistence of further mutations ('the mutator that mutates the mutator'). This gives rise to the phenomenon of genomic instability – as it evolves, a cancer contains an increasing variety and number of genetic aberrations: the greater the number of such abnormalities, the greater the chance of increasingly deviant behaviour.

Jettison excess baggage

Cancer cells are geared to excessive and remorseless proliferation. They do not need to develop or retain those specialised functions that make them good cellular citizens. They can therefore afford to repress or permanently lose those genes that control such functions. They become leaner and meaner. This may bring some short-term advantages. The longer term disadvantage is that what is today superfluous may, tomorrow, be essential. This can leave cancer cells vulnerable to external stress and may, in part, explain why some treatments for cancer work.

Subvert communication to and from the environment/milieu

Providing false information is a classic military strategy. Degrading the command and control systems of the enemy is an essential component of modern warfare. Cancer cells almost certainly use similar tactics in their battle for control over their host. Given the complexity of communication between and within cells, this is not an easy statement either to disprove or to prove. Nor does it offer any easy targets for therapeutic manipulation.

Malignant transformation

The characteristics of the cancer cell arise as a result of mutation. Only very rarely is a single mutation sufficient to cause cancer; multiple mutations are usually required. Colorectal cancer provides the classical example of how multiple mutations are necessary for the complete transformation from normal cell to malignant cell. Vogelstein and his colleagues identified the genes required and also postulated not only that it is necessary to have mutations in all the

Stephen Paget, 1855–1926, Surgeon, The West London Hospital, London, England. Paget's 'seed and soil' hypothesis is contained in his paper 'The Distribution of Secondary Growths in Cancer of the Breast', in the *Lancet*, 1889.

Paul Ehrlich, 1854–1915, Professor of Hygiene, The University of Berlin, and later Director of The Institute for Infectious Diseases, Berlin, Germany. In 1908 he shared the Nobel Prize for Physiology or Medicine with Elie Metchnikoff, 1845–1916, 'In recognition of his work on immunity'. Metchnikoff was Professor of Zoology at Odessa in Russia, and later worked at the Pasteur Institute in Paris, France.

Sir Frank McFarlane Burnet, 1899–1985, an Australian Virologist, at the Walter and Eliza Hall Institute, Melbourne, WA, Australia. Burnet shared the 1960 Nobel Prize for Physiology or Medicine with Sir Peter Brian Medawar, 1915–1987, Jodrell Professor of Zoology, University College, London, England, 'for their discovery of acquired immunological tolerance'.

Lewis Thomas, 1913–1993, an American Pathologist and Immunologist, who became President to the Sloan Kettering Memorial Institute, New York, NY, USA. Bert Vogelstein, B. 1949, Molecular Biologist, Johns Hopkins Hospital, Baltimore, MD, USA.

relevant genes, but also that these mutations must be acquired in a specific sequence. This could be regarded as the poker hand view of the problem of transformation: not only do you need the right cards, but you need them in the right order. An alternative view is that malignant transformation involves the acquisition of mutations within a set of distinct regulatory pathways; within each pathway transforming mutations are mutually exclusive.

Cancer is usually regarded as a clonal disease. Once a cell has arisen with all the mutations necessary to make it fully malignant, it is capable of giving rise to an infinite number of identical cells, each of which is fully malignant. These cells divide, invade, metastasise and destroy but, ultimately, each is the direct descendant of that original, primordial, transformed cell. There is certainly evidence, mostly from haematological malignancies, to support the view that tumours are monoclonal in origin, but recent evidence challenges the universality of this assumption. Some cancers may arise from more than one clone of cells. Epigenetic modification refers to heritable changes in DNA that are not related to the nucleotide sequence of the molecule. Epigenetic modification may give rise to distinct cancer cell lineages with differing biological properties. The interactions between cells from each lineage and the tissue within which such cells find themselves may determine the overall clinical behaviour of a tumour – and we return to Stephen Paget’s seed and soil hypothesis from the late nineteenth century.

It takes a tissue to make a tumour. This provocative sentence encapsulates a more general approach to the problem of malignant transformation than the traditional, cell-based, reductionist view. ‘No man is an island unto himself’, and no cancer cell exists in isolation, uninfluenced by its physical and biochemical environment. This view applies the principles of systems biology to cancer and stimulates attempts to understand the role of the exchange of information between a cancer cell and its milieu in sustaining the malignant process.

The growth of a tumour

If it is accepted that a cancer starts from a single transformed cell, then it is possible, using straightforward arithmetic, to describe the progression from a single cell to a mass of cells large enough to kill the host. The division of a cell produces two daughter cells. The relationship 2^n will describe the number of cells produced after n generations of division. There are between 10^{13} and 10^{14} cells in a typical human being. A tumour 10 mm in diameter will contain about 10^9 cells. As $2^{30} = 10^9$, this implies that it would take 30 generations to reach the threshold of clinical detectability and, as $2^{45} = 3 \times 10^{13}$, fewer than 15 subsequent generations to produce a tumour that, through sheer bulk alone, would be fatal. This is an oversimplification because cell loss is a feature of many tumours and, for squamous cancers, as many as 99% of the cells produced may be lost, mainly by exfoliation. It will, in the presence of cell loss, take many cellular divisions to produce a clinically evident tumour – abundant opportunity for further mutations to occur during the preclinical phase of tumour growth. The growth of a

John Donne, 1573–1631, Metaphysical poet, and Dean of St. Paul’s Cathedral, London, England. The quotation is from Donne’s ‘Meditation XVII’.

System Biology: a discipline in which a living entity is viewed as an integrated network in which the study of the interactions between genes, molecules and chemical reactions is as important as the study of the individual components of the network. The approach is synthetic rather than reductionist and embraces, rather than ignores, the inconvenient complexity of living organisms.

typical human tumour can be described by an exponential relationship, the doubling time of which increases exponentially – so called Gompertzian growth (see Fig. 7.2). This Gompertzian pattern has several important implications for the diagnosis and treatment of cancer (Summary box 7.2).

Summary box 7.2

Clinical implications of Gompertzian growth

- The majority of the growth of a tumour occurs before it is clinically detectable
- By the time they are detected, tumours have passed the period of most rapid growth, that period when they might be most sensitive to anti-proliferative drugs
- There has been plenty of time, before diagnosis, for individual cells to detach, invade, implant and form distant metastases
- ‘Early tumours’ are genetically old: plenty of time for mutations to have occurred, mutations that might confer spontaneous drug resistance (a probability greatly increased by the existence of cell loss)
- The rate of regression of a tumour will depend upon its age (the Norton–Simon hypothesis extends this: the rate of regression of a tumour will depend upon its growth rate at the time of treatment)

THE CAUSES OF CANCER

The interplay between nature and nurture

Both inheritance and environment are important determinants of whether or not an individual develops cancer. Although environ-

Figure 7.2 The Gompertzian curve describing the growth of a typical tumour. In its early stages, growth is exponential but, as the tumour grows, the growth rate slows. This decrease in growth rate probably arises because of difficulties with nutrition and oxygenation. The tumour cells are in competition: not only with the tissues of the host, but also with each other.

Benjamin Gompertz, 1779–1865. An insurance actuary who was interested in calculating annuities. To do this he needed to describe mathematically the relationship between life-expectancy and age. He was able to do this using the function (the Gompertzian Function) that bears his name. The Gompertzian function provides an excellent fit to data points plotting tumour size against time.

mental factors have been implicated in more than 80% of cases of cancer, this would still leave plenty of scope for the role of genetic inheritance: not just the 20% of tumours for which there is no clear environmental contribution but also, as environment alone can rarely cause cancer, the genetic contribution to the 80% of tumours to whose occurrence environmental factors contribute. As a plain example: not all smokers develop lung cancer; lung cancer can occur in people who have never smoked.

The knowledge we have concerning the causes of cancer can be used to design appropriate strategies for prevention or earlier diagnosis. As we find out more about the genes associated with cancer, genetic testing and counselling will play an increasing role in the prevention of cancer. These considerations are incorporated into Table 7.1 on the inherited cancer syndromes, and Table 7.2 on the environmental contribution to cancer.

Table 7.1 Inherited syndromes associated with cancer

Syndrome	Gene(s) implicated	Inheritance	Associated tumours and abnormalities	Strategies for prevention/early diagnosis
Familial adenomatous polyposis (FAP)/Gardner syndrome	<i>APC</i> gene	D	Colorectal cancer under the age of 25 years Papillary carcinoma of the thyroid Cancer of the ampulla of Vater Hepatoblastomas Primary brain tumours (Turcot's syndrome) Osteomas of the jaw CHRPE (congenital hypertrophy of the retinal pigment epithelium)	Prophylactic panproctocolectomy
Hereditary non-polyposis colorectal cancer (HNPCC)	DNA mismatch repair genes (<i>MLH1</i> , <i>MSH2</i> , <i>MSH6</i>)	D	Colorectal cancer (typically in the 40s and 50s)	Surveillance colonoscopies/polypectomies Non-steroidal anti-inflammatory drugs
HNPCC1	<i>MSH2</i>		Endometrium, stomach, hepatobiliary (Lynch's syndrome 1)	
HNPCC2	<i>MLH1</i>			
HNPCC3	<i>PMS1</i>			
Peutz–Jeghers syndrome	<i>STK11</i>	D	Bowel cancer, breast cancer, freckles round the mouth	Surveillance colonoscopy, mammography
Cowden's syndrome	<i>PTEN</i>	D	Multiple hamartomas of skin, breast and mucus membranes Breast cancer Neuroendocrine tumours Endometrial cancer, thyroid cancer	Active surveillance
Retinoblastoma	<i>RB</i>	D	Retinoblastoma Pinealoma Osteosarcoma	Surveillance of the uninvolved eye
Multiple endocrine neoplasia (MEN) type 1	<i>Menin</i>	D	Parathyroid tumours Islet cell tumours Pituitary tumours	Awareness of associations and paying attention to relevant symptoms
MEN type 2A	<i>RET</i>	D	Medullary carcinoma of the thyroid Pheochromocytoma Parathyroid tumours	Regular screening of blood pressure, serum calcitonin and urinary catecholamines Prophylactic thyroidectomy

THE MANAGEMENT OF CANCER

Management is more than treatment

The traditional approach to cancer concentrates on diagnosis and active treatment. This is a very limited view and one that, in terms of the public health, may not have served society particularly well. It implies an attitude to the occurrence of cancer that is too fatalistic and an assumption that, once active treatment is complete, there is little more to be done. Prevention is forgotten and rehabilitation is ignored. The management of cancer can be considered as taking place along two axes: one is an axis of scale, from the individual to the world population; the other is an axis based on the unnatural history of the disease, from prevention through to rehabilitation or palliative care (see Fig. 7.3).

Prevention

Table 7.2 summarises the approaches that can be used in the prevention of cancer. In 1998, Sir Richard Doll estimated that 30% of cancer deaths were due to tobacco use and that up to 50% of cancer deaths were related to diet. Even allowing for overlap

(smokers often have a poor diet), these are impressive figures and add some perspective to the often inflated claims made for the achievements of cancer treatment. Doll estimated that cancers related to occupation accounted for less than 4% of cancer deaths, and that environmental pollution accounted for less than 5% of deaths. Public attitudes to risk are not always logically consistent, and many well-intentioned attempts at cancer prevention fall foul of this simple fact.

Screening

Screening involves the detection of disease in an asymptomatic population in order to improve outcomes by early diagnosis. It follows that a successful screening programme must achieve early diagnosis, and that the disease in question has a better outcome when treated at an early stage. The criteria that must be fulfilled for the disease, screening test and the screening programme itself are given in Summary box 7.3.

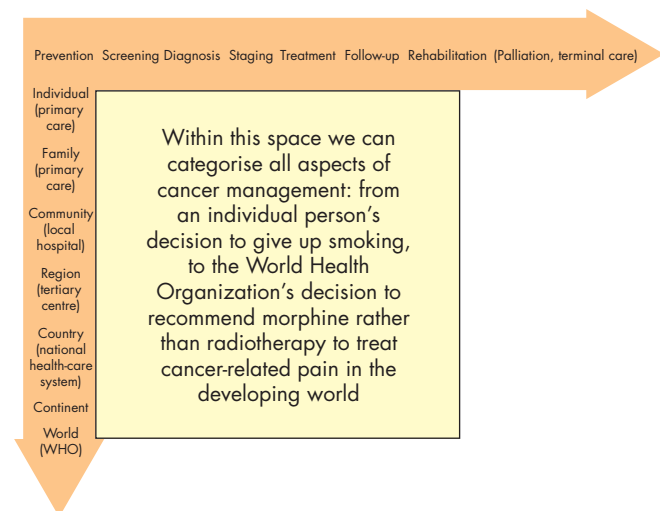

Figure 7.3 The management of cancer spans the natural history of the disease and all humankind, from the individual to the population of the world. WHO, World Health Organization.

Sir William Richard Shaboe Doll, 1912–2005, Regius Professor of Medicine, Oxford University, Oxford, England, and Sir Austin Bradford Hill, Professor of Medical Statistics, The London School of Hygiene and Tropical Medicine, London, England published one of the definitive reports linking smoking to lung cancer in 1950.

Summary box 7.3

Criteria for screening

The disease

- Recognisable early stage
- Treatment at an early stage more effective than at a later stage
- Sufficiently common to warrant screening

The test

- Sensitive and specific
- Acceptable to the screened population
- Safe
- Inexpensive

The programme

- Adequate diagnostic facilities for those with a positive test
- High-quality treatment for screen-detected disease to minimise morbidity and mortality
- Screening repeated at intervals if the disease is of insidious onset
- Benefit must outweigh physical and psychological harm

Merely to prove that screening picks up disease at an early stage, and that the outcome is better for patients with screen-detected disease than for those who present with symptoms, is an insufficient criterion for the success of a screening programme. This is because of inherent biases in screening, which make screen-detected disease appear to be associated with better outcomes than symptomatic disease. These biases are lead time bias, selection bias

and length bias. Lead time bias describes the phenomenon whereby early detection of a disease will always prolong survival from the time of diagnosis when compared with disease picked up at a later stage in its development whether or not the screening process has altered the progression of the tumour (Fig. 7.4). Selection bias describes the finding that individuals who accept an invitation for screening are, in general, healthier than those who do not. It follows that individuals with screen-detected disease will tend, independently of the condition for which screening is being performed, to live longer. Length bias is brought about by the fact that slow-growing tumours are likely to be picked up by screening, whereas fast-growing tumours are likely to arise and produce symptoms in between screening rounds. Thus, screen-detected tumours will tend to be less aggressive than symptomatic tumours. Because of these biases, it is essential to carry out population-based randomised controlled trials and to compare a whole population offered screening (including those who refuse to be screened and those who develop cancer after a negative test) with a population that has not been offered screening. This research design has been applied to both breast cancer and colorectal cancer: in both cases, there was reduction in disease-specific mortality.

Diagnosis and classification

Accurate diagnosis is the key to the successful management of cancer. Diagnosis lies at the heart of the epidemiology of

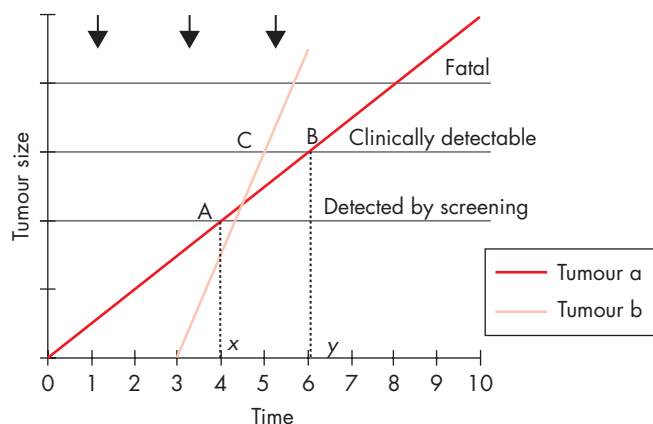

Figure 7.4 Lead time and length bias. Tumour a is a steadily growing tumour; its progress is uninfluenced by any treatment. The arrows indicate the timing of tests in a screening programme. The horizontal lines indicate three thresholds: detectability by screening; clinical detectability; and death due to tumour progression. Point A indicates the time at which the tumour would be diagnosed in a screening programme, and point B indicates the time at which the tumour would be diagnosed clinically, that is in the absence of any screening programme. If the date of diagnosis is used as the start time for measuring survival, then it is clear that, in the absence of any effect from treatment, the screening programme will, artefactually, add to the survival time. The amount of ‘increased’ survival is equal to $y - x$ years, in this example, just over 2 years. This artefactual inflation of survival time is referred to as lead time bias. Tumour b is a rapidly growing tumour; again, its progress is uninfluenced by treatment. It grows so rapidly that, in the interval between two screening tests, it can cross both the threshold for detectability by screening and that of clinical detectability. It will continue to progress rapidly after diagnosis, and the measured survival time will be short. This phenomenon, whereby those tumours that are ‘missed’ by the screening programme are associated with decreased survival, is called length bias.

cancer; if there is an inaccurate picture of the pattern of a disease, reliable inferences about its distribution and causes cannot be drawn. Precise diagnosis is crucial to the choice of correct therapy; the wrong operation or cytotoxic therapy, no matter how superbly carried out or how ingeniously designed, is useless. An unequivocal diagnosis is the key to an accurate prognosis; the answer to the question ‘Doctor, how long have I got...?’ is dependent upon knowing precisely what it is that is wrong. Only rarely can a diagnosis of cancer confidently be made in the absence of tissue for pathological or cytological examination. Cancer is a disease of cells and, for accurate diagnosis, the abnormal cells need to be seen. Different tumours are classified in different ways: most squamous epithelial tumours are simply classed as well (G1), moderate (G2) or poorly (G3) differentiated (Fig. 7.5). Adenocarcinomas are also often classified as G1, 2 or 3, but prostate cancer is an exception with widespread use of the Gleason system. The Gleason system grades prostate cancer according to the degree of differentiation of the two most prevalent architectural patterns. The final score is the sum of the two grades and can vary from 2 (1 + 1) to 10 (5 + 5), with the higher scores indicating poorer prognosis. The management of malignant lymphomas is based firmly upon histopathological classification: the first distinction is between Hodgkin’s lymphoma (HL) and the non-Hodgkin’s lymphoma (NHL). Each of these main types of lymphoma is then subclassified according to a different scheme. The World Health Organization/Revised European–American lymphoma (WHO/REAL) system classifies Hodgkin’s lymphoma into classical HL (nodular sclerosis HL; mixed cellularity HL; lymphocyte depletion HL; lymphocyte-rich classical HL) and nodular lymphocyte-predominant HL. The WHO/REAL classification of NHL is considerably more complex and recognises 27 distinct pathological subtypes. It is perhaps no coincidence that the non-surgical treatment of lymphomas is, by and large, more successful than the non-surgical treatment of solid tumours. This suggests that precise and accurate subtyping of tumours enables appropriate selection of treatment and, in turn, this is associated with better outcome.

Investigation and staging

It is not sufficient simply to know what a cancer is; it is imperative to know its site and extent. If it is localised, then loco-regional treatments such as surgery and radiation therapy may be curative. If the disease is widespread, then, although such local interventions may contribute to cure, they will be insufficient, and systemic treatment, for example with drugs or hormones, will be required. Staging is the process whereby the extent of disease is mapped out. Formerly, staging was a fairly crude process based on clinical examination and chest X-ray and the occasional ultrasound; nowadays, it is a highly sophisticated process, heavily reliant on the technology of modern imaging. These technological advances bring with them the implication that patients staged as having localised disease in 2007 are not comparable to patients described in 1985 as having localised disease. Many of these latter patients would, had they been imaged using the

Thomas Hodgkin, 1798–1866, Curator of the Museum and Demonstrator of Morbid Anatomy, Guy’s Hospital, London, England, described lymphadenoma in 1832.

Figure 7.5 Three carcinomas showing different degrees of differentiation. Left to right: well differentiated, moderately differentiated and poorly differentiated.

technology of 2007, have had occult metastatic disease detected. This leads to the paradox of stage shift, also named, by Alvan Feinstein, the Will Rogers phenomenon. A change in staging system, or in the techniques used to provide baseline information concerning staging, can produce ‘benefits’ to patients at all stages of the disease. These benefits are, however, entirely artefactual and depend simply upon patients in each stage being enriched by patients with improved prognosis. The important cross-check to protect against being misled by stage shift is that the prognosis for the entire group (i.e. all stages pooled) has not been changed. Table 7.3 shows a worked example of stage shift.

The International Union against Cancer (UICC) is responsible for the TNM (tumour, nodes, metastases) staging system for cancer. This system is compatible with, and relates to, the American Cancer Society (AJCC) system for stage grouping of cancer. Examples of clinico-pathological staging systems for colon cancer are shown in Tables 7.4 and 7.5.

Therapeutic decision making and the multidisciplinary team

As the management of cancer becomes more complex, it becomes impossible for any individual clinician to have the intel-

Table 7.3 Stage shift

Before new staging test				After new staging test				
Stage	Distribution (%)	Cure rate (%)	Number cured	Stage	Distribution (%)	Cure rate (%)	Number cured	‘Improvement’ in cure rate (%)
I	70	90	63	I	50	94	47	4
II	10	80	8	II	10	80	8	0
III	10	80	8	III	10	80	8	0
IV	10	50	5	IV	30	70	21	20
All	100		84	All	100		84	0

The cure rate improves in both stage I and stage IV, and there is no change in cure rates for stage II and stage III, after the introduction of a new staging investigation. The overall cure rate is, however, unchanged.

Will Rogers (properly William Penn Adair Rogers), 1879–1935, American Actor, Humorist and Wit.

There is much confusion about the use of the terms ‘multidisciplinary’ and ‘multiprofessional’: we use ‘multidisciplinary’ to imply the presence of various medically-qualified specialists (pathologists, radiologists etc.) and ‘multiprofessional’ implies the presence of specialists from non-medical backgrounds (nurses, social workers, radiographers).

Table 7.4 Staging of colorectal cancer

TNM	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Tis	Intraepithelial or intramucosal carcinoma

lectual and technical competence that is necessary to manage all the patients presenting with a particular type of tumour. The era of feigned omniscience is past. The formation of multidisciplinary teams represents an attempt to make certain that each and every patient with a particular type of cancer is managed appropriately. Teams should not only be multidisciplinary, they should be multi-professional (Summary box 7.4).

Summary box 7.4**Members of the multiprofessional team**

- Site-specialist surgeon
- Surgical oncologist
- Plastic and reconstructive surgeon
- Clinical oncologist/radiotherapist
- Medical oncologist
- Diagnostic radiologist
- Pathologist
- Speech therapist
- Physiotherapist
- Prosthetist
- Clinical nurse specialist (rehabilitation, supportive care)
- Palliative care nurse (symptom control, palliation)
- Social worker/counsellor
- Medical secretary/administrator
- Audit and information coordinator

There is widespread agreement, on the basis of remarkably little evidence, that multidisciplinary teams are essential for high-quality care. This gives rise to a belief, both quaint and naïve, that simply forming the team is sufficient and that the calibre and personal skills of the team members are of little consequence. There is remarkably little agreement, either in theory or in practice, as

Table 7.5 Relationships between staging systems for colorectal cancer

to the decision-making processes that are employed within the context of the multidisciplinary teams. There is a danger that the imprimatur of the team may be used to provide legitimacy for the opinions and prejudices of the dominant members of the team. The decision of the team should reflect an informed judgement made after discussion among equals, not the unqualified dogma espoused by the loudest voice. The advantages and disadvantages of multidisciplinary teams are summarised in Table 7.6. The challenge for the future is to reconcile a corporate approach to decision making with a respect for the individuality of each individual patient: their tumour, their circumstances, and their informed choices. There should be no class solutions in oncology.

Vernon B. Astler, Surgeon, The Medical School of the University of Michigan, Ann Arbor, MI, USA.

Frederick A. Collier, Pathologist, The Medical School of the University of Michigan, Ann Arbor, MI, USA.

Cuthbert Esquire Dukes, 1890–1977, Pathologist, St. Mark's Hospital, London, England.

Table 7.6 The advantages and disadvantages of the multidisciplinary team

Advantages	Disadvantages
Open debate concerning management	An opportunity for rampant egotism and showing off
Patient has the advantage of many simultaneous opinions from many different specialties	Less confident and less articulate members of the team may not be able to express their views, even though their views may be extremely important
Decision making is open, transparent and explicit	May degenerate into a rubber-stamping exercise in which the class solutions implied by guidelines are unthinkingly applied to disparate individuals
Team members educate each other	Decisions are made in the absence of patients and their carers: the commodification of the person
A useful educational experience for trainees and students	Clinicians are able to avoid having to take responsibility for their decisions and their actions: the fig-leaf of 'corporate responsibility'
	Time-consuming and resource intensive: takes busy clinicians away from clinical practice for hours at a time

Principles of cancer surgery

For most solid tumours, surgery remains the definitive treatment and the only realistic hope of cure. However, surgery has several roles in cancer treatment including diagnosis, removal of primary disease, removal of metastatic disease, palliation, prevention and reconstruction.

Diagnosis and staging

In most cases, the diagnosis of cancer has been made before definitive surgery is carried out but, occasionally, a surgical procedure is required to make the diagnosis. This is particularly true of patients with malignant ascites where laparoscopy has an important role in obtaining tissue for diagnosis. Laparoscopy is also widely used for the staging of intra-abdominal malignancy, particularly oesophageal and gastric cancer. By this means, it is often possible to diagnose widespread peritoneal disease and small liver metastases that may have been missed on cross-sectional imaging. Laparoscopic ultrasound is a particularly useful adjunct for the diagnosis of intrahepatic metastases. Other examples in which surgery is central to the diagnosis of cancer include orchidectomy where a patient is suspected of having testicular cancer and lymph node biopsy in a patient with lymphoma. Recently, sentinel node biopsy in melanoma and breast cancer has attracted a great deal of interest. Here, a radiolabelled colloid is injected into or around the primary tumour, and the regional lymph node tumour is then scanned with a gamma camera that will pinpoint the lymph node nearest to the tumour. This lymph node can then be removed for histological diagnosis. Until recently, staging laparotomy was an important aspect of the staging of lymphomas but, with more accurate cross-sectional imaging and the much more widespread use of chemotherapy, this practice is now largely redundant.

Removal of primary disease

Radical surgery for cancer involves removal of the primary tumour and as much of the surrounding tissue and lymph node drainage as possible in order not only to ensure local control but also to prevent spread of the tumour through the lymphatics. Although the principle of local control is still extremely important, it is now recognised that ultraradical surgery probably has

little effect on the development of metastatic disease, as evidenced by the randomised trials of radical vs. simple mastectomy for breast cancer. It is important, however, to appreciate that high-quality, meticulous surgery taking care not to disrupt the primary tumour at the time of excision is of the utmost importance in obtaining a cure in localised disease and preventing local recurrence.

Removal of metastatic disease

In certain circumstances, surgery for metastatic disease may be appropriate. This is particularly true for liver metastases arising from colorectal cancer where successful resection of all detectable disease can lead to long-term survival in about one-third of patients. With multiple liver metastases, it may still be possible to take a surgical approach by using *in situ* ablation with cryotherapy or radiofrequency energy. Another situation where surgery may be of value is pulmonary resection for isolated lung metastases, particularly from renal cell carcinoma.

Palliation

In many cases, surgery is not appropriate for cure but may be extremely valuable for palliation. A good example of this is the patient with a symptomatic primary tumour who also has distant metastases. In this case, removal of the primary may increase the patient's quality of life but will have little effect on the ultimate outcome. Other examples include bypass procedures such as an ileotransverse anastomosis to alleviate symptoms of obstruction caused by an inoperable caecal cancer or bypassing an unresectable carcinoma at the head of the pancreas by cholecysto- or choledochojunostomy to alleviate jaundice.

Principles underlying the non-surgical treatment of cancer

The relationship between dose and response and the principle of selective toxicity

Non-surgical treatments, in common with surgery, have the potential to cause harm as well as benefit. Surgery is difficult to

in situ is Latin for 'in the place'.

quantify; it is hard to describe a mastectomy in units of measure. Both drugs and radiation can be expressed in reproducible units: milligrams in the case of drugs; Grays (Gy) in the case of radiation. Thus, in contrast to surgery, it is possible to construct dose–response relationships for both the benefits (such as tumour cure rate) and harms (such as tissue damage that is both severe and permanent) associated with non-surgical interventions. These curves (see Fig. 7.6) have the same general shape: they are sigmoidal. The practical consequence of this is that, over a relatively narrow dose range, we move from failure to success, from tolerability to disaster. It is possible, in theory, using dose–response curves to calculate an optimal dose for treating each tumour: the dose is that which is associated with the maximal probability of an uncomplicated cure. Lying behind the concept

of the probability of an uncomplicated cure is the principle of selective toxicity: treatment must be delivered in such a way as to ensure that the damage done to the tumour is more than the damage done to the normal tissues. The treatment should be selectively toxic to the tumour and, as far as possible, should spare the normal tissues from damage. It is this simple principle that underpins both the selection of agents used to treat cancer and the schedules employed to deliver them. Although the graphical representations of the relationships between dose, response and the probability of uncomplicated cure are conceptually simple and intuitively appealing, they are, in clinical practice, completely impractical. The construction of full dose–response curves for all possible combinations of tumours and normal tissues is neither feasible nor ethical (you cannot knowingly

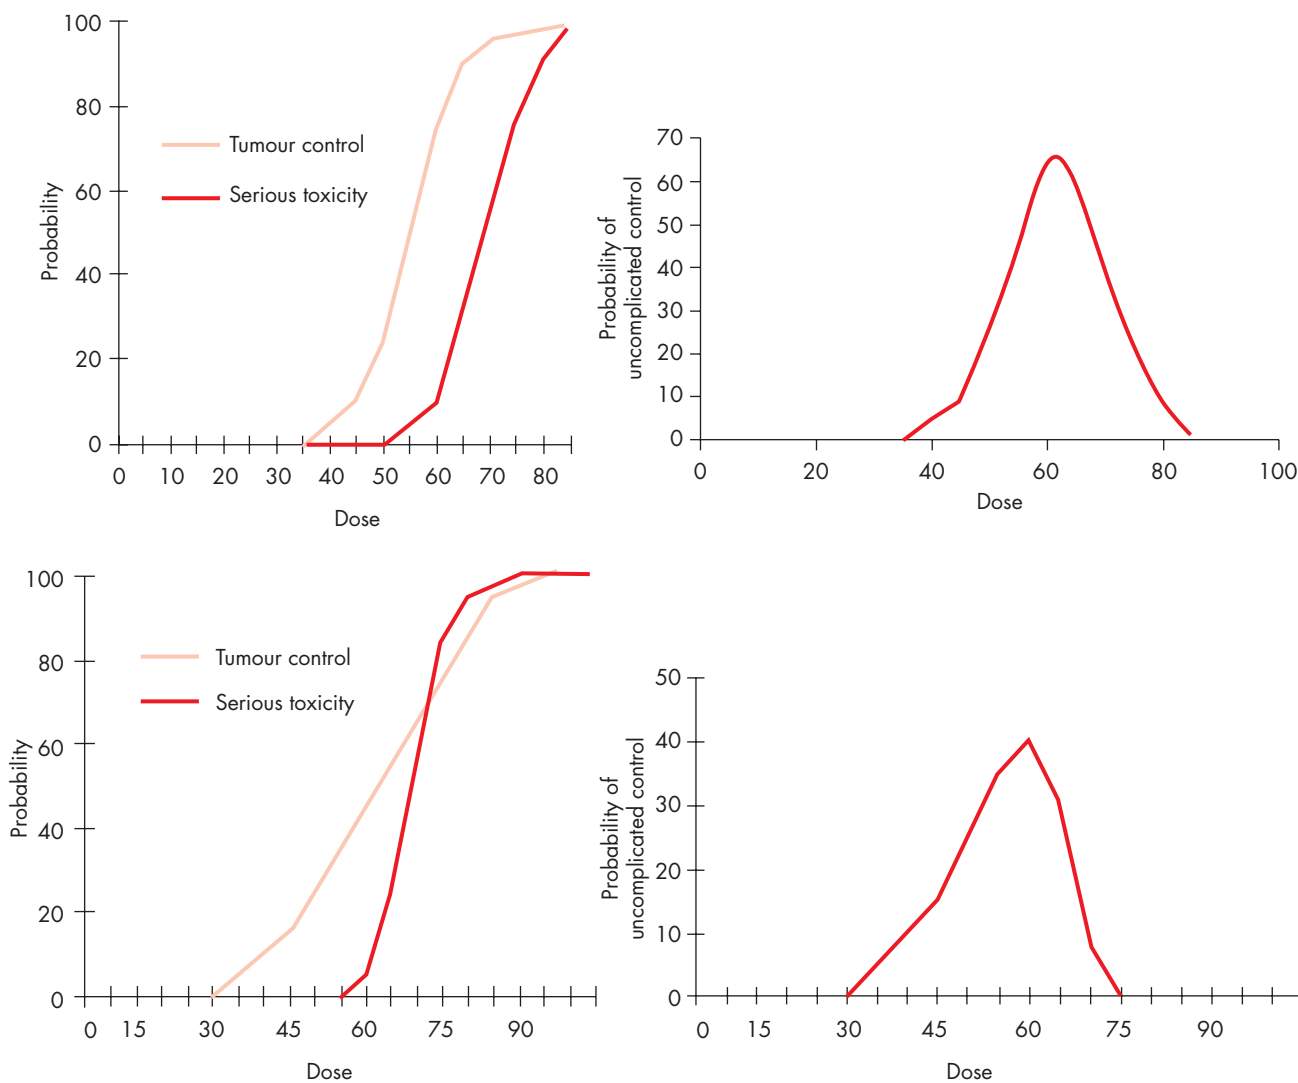

Figure 7.6 A schematic illustration of the relationship between dose, response and the probability of uncomplicated cure. The upper figures show ideal circumstances with steep dose–response relationships for both normal tissue damage and tumour control. The lower figures show something more like the real world. The dose–response relationship for tumour control is flatter, because tumours are heterogeneous and, consequently, the probability of uncomplicated cure is lower – even for the optimal dose (40% in the lower figure compared with 70% in the upper figure).

Louis Harold Gray, 1905–1965, Director, The British Empire Cancer Campaign Research Unit in Radiobiology, Mount Vernon Hospital, Northwood, Middlesex, England. A Gray (Gy) is the SI unit for the absorbed dose of ionizing radiation.

expose a patient to a high risk of suffering harm, simply to provide another data point). Reliance, when it comes to defining optimal doses and schedules, must be on incomplete clinical data and a knowledge of the general shape of the relationship between dose and response.

General strategies in the non-surgical management of cancer

Curative surgery for cancer is guided by one simple principle: the physical removal of all identifiable disease. The principles underlying the non-surgical management of cancer are more complex. First, we have to consider the spatial distribution of the effects of our therapies: surgery and radiotherapy are local or, at best, locoregional treatments; drugs offer a therapy that is systemic (Fig. 7.7). Second, there is the question of the intent underlying the treatment. Occasionally, radiotherapy, chemotherapy or the combination of the two may be used with curative intent (Table 7.7). More usually, chemotherapy or radiotherapy is used to lower the risk of recurrence after primary treatment with surgery, so called adjuvant therapy. Implicit within the concept of adjuvant therapy is the realisation that much of what is done is unnecessary or futile, or both. The need for adjuvant therapy, to treat the risk that residual disease might be present after apparently curative surgery, is an acknowledgement of the current inability to detect or predict, with sufficient precision, the presence of residual disease. It also explains why the incremental benefits from adjuvant treatments are so small and why the existence of these benefits can only be proven using randomised controlled trials including many thousands of patients. As illustrated in Figures 7.8 and 7.9, our current approach to the selection of patients for post-surgical adjuvant treatment is both intellectually impoverished and inefficient. Patients would be far better off if, rather than so much time and effort having been invested in attempting to discover new 'cures' for cancer, equivalent resources had been devoted to devising clinically useful tests to detect residual cancer cells persisting after apparently successful initial therapy.

Radiotherapy

Within a month of their discovery in 1895, X-rays were being used to treat cancer. Despite over 100 years of use, and despite

Figure 7.7 Schematic diagram to show the spatial scope of cancer treatments. Chemotherapy is systemic; surgery is mainly a local treatment. Radiotherapy is usually local or locoregional, but can, as in radioiodine therapy for thyroid cancer, be systemic.

some outstanding clinical achievements, it is still not known how best to use radiation to treat cancer. Part of the difficulty arises because it is not known precisely how radiation treatment affects tumours or normal tissues. Up until about 20 years ago, it was assumed that the biological effects of radiation resulted from radiation-induced damage to the DNA of dividing cells. Nowadays, it is known that, although this undoubtedly explains some of the biological effects of radiation, it does not provide a full explanation. Radiation can, both directly and indirectly, influence gene expression: over 100 radiation-inducible effects on gene expression have now been described. These changes in gene expression are responsible for a considerable proportion of the biological effects of radiation upon tumours and normal tissues. It is pretentious, but true, to state that radiotherapy is a precisely targeted form of gene therapy for cancer.

The practicalities of radiation therapy are reasonably straightforward: define the target to treat; design the optimal technical set-up to provide uniform irradiation of that target; and choose that schedule of treatment that delivers radiation to that target in such a way as to maximise the therapeutic ratio (Fig. 7.10). One

Table 7.7 Examples of malignancies that may be cured without the need for surgical excision

Malignancy	Potentially curative treatment
Leukaemia	Chemotherapy (± radiotherapy)
Lymphoma	Chemotherapy (± radiotherapy)
Small cell lung cancer	Chemotherapy (± radiotherapy)
Tumours of childhood (rhabdomyosarcoma, Wilms' tumour)	Chemotherapy (± radiotherapy)
Early laryngeal cancer	Radiotherapy
Advanced head and neck cancer	Chemoradiation (synchronous chemotherapy and radiotherapy)
Oesophageal cancer	Chemoradiation (synchronous chemotherapy and radiotherapy)
Squamous cell cancer of the anus	Chemoradiation (synchronous chemotherapy and radiotherapy)
Advanced cancer of the cervix	Radiotherapy (± chemotherapy)
Medulloblastoma	Radiotherapy (± chemotherapy)
Skin tumours (BCC, SCC)	Radiotherapy

BCC, basal cell carcinoma; SCC, squamous cell carcinoma.

Max Wilms, 1867–1918, Professor of Surgery, Heidelberg, Germany.

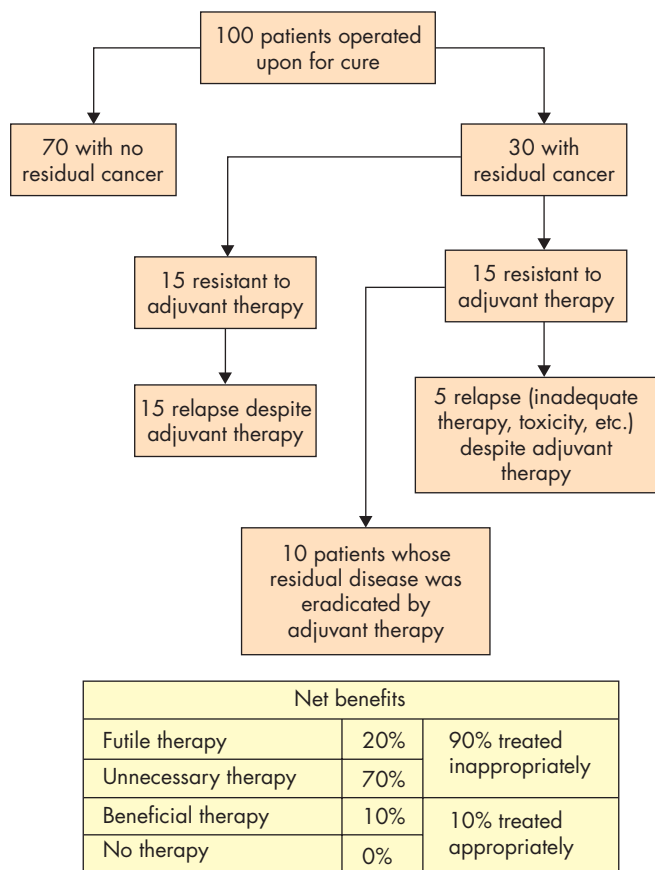

Figure 7.8 The concept of adjuvant therapy.

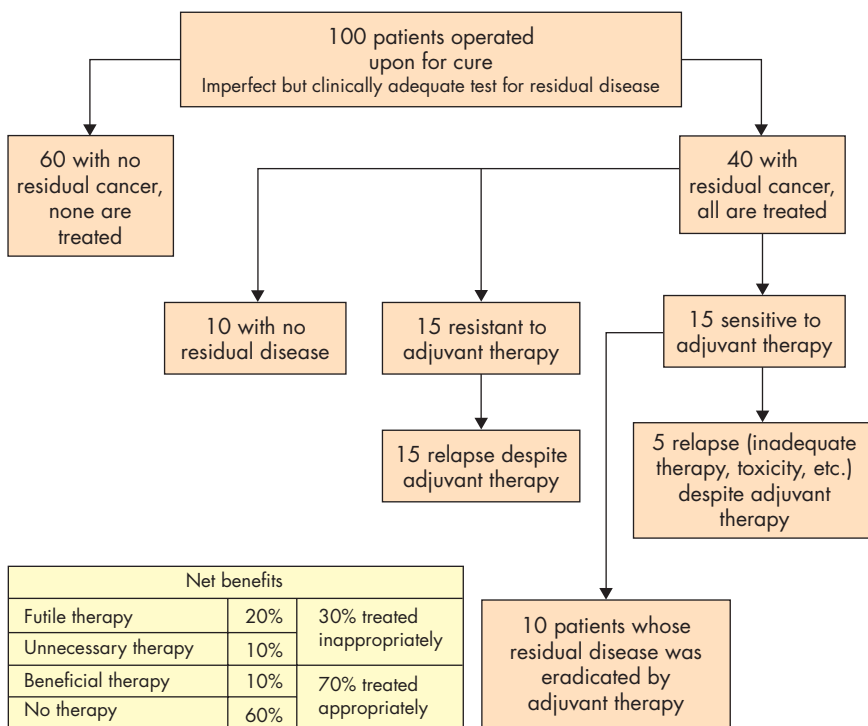

Figure 7.9 The concept of adjuvant therapy and testing for minimal residual disease.

of the main problems with assessing a therapeutic ratio for a given schedule of radiation is that there is a dissociation between the acute effects on normal tissues and the late damage. The acute reaction is not a reliable guide to the adverse consequences of treatment in the longer term. As the late effects following irradiation can take over 20 years to develop, this poses an obvious difficulty: if the radiation schedule is changed, it will be known within 2 or 3 years whether or not the new schedule has improved tumour control; it may, however, be two decades before it is known, with any degree of certainty, whether the new technique is safe. Fractionated radiotherapy selectively spares late, as opposed to immediate, effects. For any given total dose, the smaller the dose per treatment (the larger the number of fractions), the less severe the late effects will be. The problem is that the greater the number of fractions of daily treatment, the longer the overall treatment time will be and the greater the opportunity will be for the tumour to proliferate during treatment. All fractionation is a compromise and, as a recent systematic review has shown, the evidence base for many widely accepted treatment schedules is remarkably slight. Thirty years ago, Withers defined the four Rs of radiotherapy (see Summary box 7.5); subsequently, we have added a fifth 'R' – intrinsic radiosensitivity. The clinical practice of radiation oncology operates within the limits defined by these five Rs.

Summary box 7.5

The five Rs of radiotherapy

- **Repair.** If given sufficient time between fractional doses of radiation, cells will repair the radiation-induced damage. Repair half-times are typically 3–6 hours. Fractionation offers a means whereby any differentials in repair capacity between tumour and normal cells may be exploited.
- **Reoxygenation.** Hypoxic cells are relatively radioresistant compared with well-oxygenated cells. Normal tissues are well oxygenated; tumours are often hypoxic. This is an obvious therapeutic disadvantage.
- **Repopulation.** As radiotherapy kills cancer cells, rapid proliferation of tumour cells is stimulated. Thus, during protracted treatment, production of cells by the tumour may equal, or even exceed, radiation-induced cell loss. It is thus better that the overall treatment time is as short as possible.
- **Redistribution.** The sensitivity of cells to radiation varies according to their position within the cell cycle. This may lead to a degree of synchronisation of cellular division within the tumour: ideally, fractions of radiotherapy should be timed to coincide with vulnerable phases of the cell cycle (late G2 and M).
- **Radiosensitivity.** Low dose rate irradiation experiments demonstrate that cells derived from tumours differ in their intrinsic sensitivity to radiation. Some cells are so intrinsically resistant to treatment that no clinically viable schedule of radiation therapy would eliminate them. Conversely, some cells may be so sensitive that virtually any schedule would be successful – the majority of cells will lie somewhere between these extremes.

Chemotherapy and biological therapies

As with radiotherapy, so with chemotherapy: selective toxicity is the fundamental principle underlying the use of chemotherapy in clinical practice. The importance of the principle is further emphasised by the fact that, by itself, chemotherapy is rarely sufficient to cure cancer. Chemotherapy is often (in effect if not in intent) a palliative rather than a curative intervention. As such, its use should be influenced by the cardinal principle of palliative treatment: treatment aimed at relieving symptoms should not, itself, produce unacceptable symptoms. To use the language of another era: we should not be ‘making the cure of a disease more grievous than its endurance’. There are now over 95 different drugs licensed by the US Food and Drug Administration (FDA) for the treatment of cancer. Of these, over 65% are cytotoxic drugs, 15% are hormonal therapies and 15% are designed to interact with specific molecular targets – so called targeted therapies. Over 50% of these agents have been licensed since 1990: in terms of potential progress, achievement over the past 15 years has been equivalent to that in the previous 40 years. There are now many more options than there were 20 years ago and, perhaps more importantly, lessons have been learnt about how better to deploy resources. The classes of cytotoxic drugs, their mode of action and clinical indications are summarised in Table 7.8.

The newer ‘targeted’ therapies available for treating cancer present particular dilemmas. They offer modest prolongation of survival, often with minimal toxicity, but at considerable financial cost. When compared with conventional therapies, these drugs typically cost over £50 000 (US\$94 000) per quality-adjusted life-year gained and, when overall resources are limited, they may

be considered unaffordable: Table 7.9 (page 109) puts into context the cost-effectiveness of various clinical interventions. The current cost of targeted therapies should not obscure their importance: they represent the first attempts to translate advances in molecular biology into clinical practice. The discoveries of the mid-twentieth century are finally bearing fruit.

Principles of combined treatment

Cytotoxic drugs are rarely used as single agents; radiotherapy and chemotherapy are often given together. The rationale behind combination, as opposed to single-agent, drug therapy is straightforward and is somewhat analogous to that for combined antibiotic therapy: it is a strategy designed to combat drug resistance. By the time of diagnosis, many tumours will contain cancer cells that, through spontaneous mutation, have acquired resistance to cytotoxic drugs. Unlike antibiotic resistance, there is no need for previous exposure to the drug. Spontaneous mutation rates are high enough to allow the play of chance to permit the development, and subsequent expansion, of clones of cells resistant to drugs to which they have never been exposed. If drugs were used as single agents, then the further expansion of these *de novo* resistant subclones would limit cure. The problem can be mitigated by combining drugs together from the outset.

There are three main principles upon which the choice of drugs for combination therapy is based, the first of which should be self-evident: use drugs active against the diseases in question; use drugs with distinct modes of action; use drugs with non-overlapping toxicities. By using drugs with different biological effects, for example by combining an anti-metabolite with an agent that actively damages DNA, it may be possible to obtain a truly synergistic effect. It is inadvisable to combine drugs with similar adverse effects: combining two highly myelosuppressive drugs may produce an unacceptably high risk of neutropenic sepsis. Where possible, combinations should be based upon a consideration of the toxicity profiles of the drugs concerned (Summary box 7.6).

Summary box 7.6

Basic principles of combined therapy

- Use effective agents
- Use agents with different modes of action (synergy)
- Use agents with non-overlapping toxicities
- Consider spatial cooperation

In considering the combination of radiotherapy and chemotherapy, radiation could be considered as just another drug. There is, in addition to synergy and toxicity, another factor to consider in the combination of drugs and radiation – the concept of spatial cooperation. Chemotherapy is a systemic treatment; radiotherapy is not. Radiotherapy is, however, able to reach sites, such as the central nervous system and testis, that drugs may not reach effectively. This is why, for example in patients treated primarily with chemotherapy for leukaemias, lymphomas and small cell lung cancer, prophylactic cranial irradiation is part of the treatment protocol.

A synergistic effect is one in which the damage caused by giving the agents together is greater than the damage caused when the drugs are given separately.

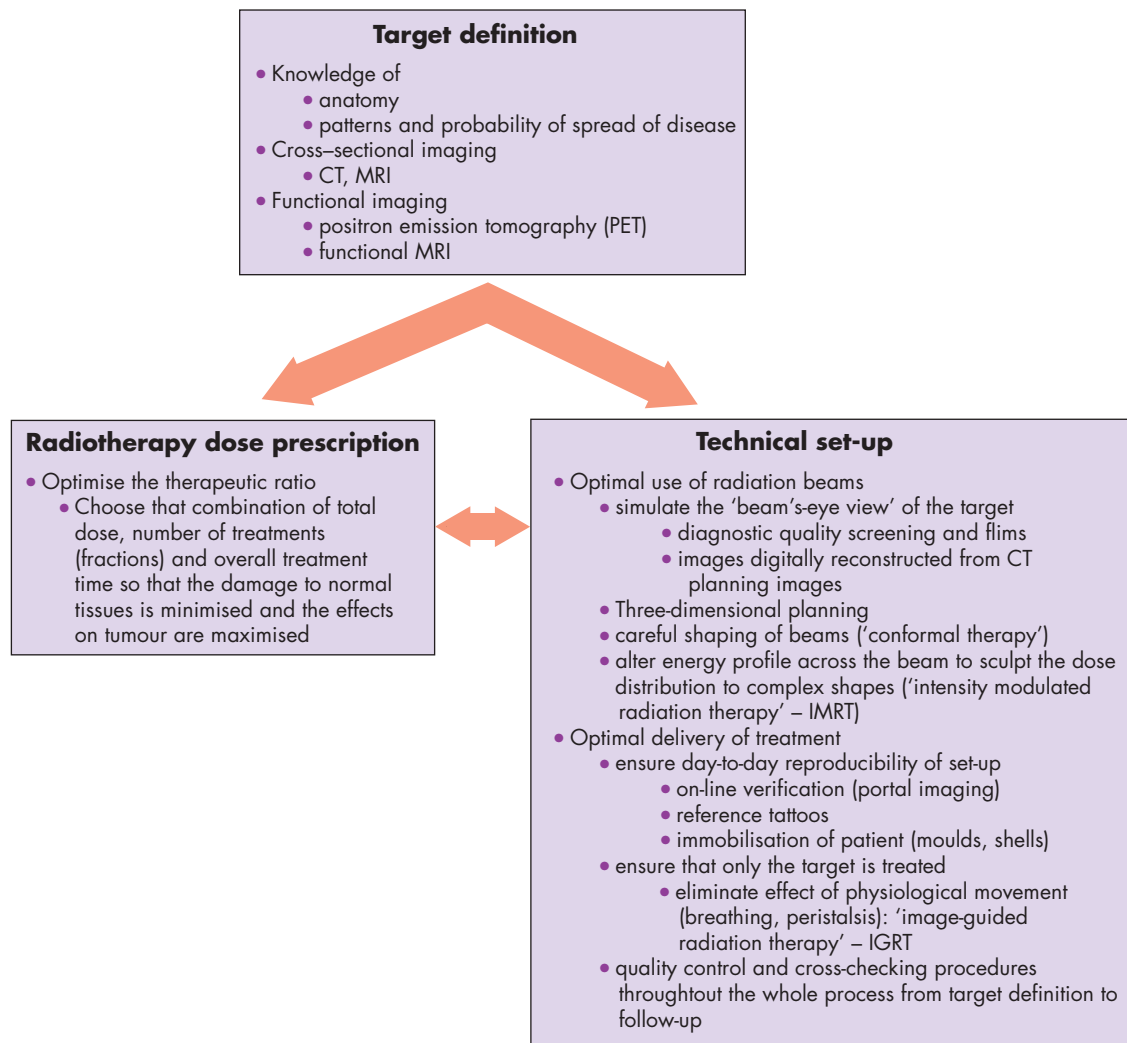

Figure 7.10 The processes involved in clinical radiotherapy. CT, computerised tomography; MRI, magnetic resonance imaging.

Palliative therapy

The distinction between palliative and curative treatment is not always clear cut. The distinction will become increasingly blurred as professional and public attitudes towards the management of cancer change. Ten years ago, cancer was perceived as a disease that was either cured or it was not; patients either lived or died. There was little appreciation that, for many patients, cancer might be a chronic disease. Nowadays, we are increasingly aware that many of the so called curative treatments are simply elegant exercises in growth delay. Five-year survival is not necessarily tantamount to cure. With the development of targeted therapies that regulate, rather than eradicate, cancer, this state of affairs is likely to continue. The aim of treatment will be growth control rather than the extirpation of every last cancer cell. Patients will live with their cancers, perhaps for years. They will die *with* cancer, but not necessarily *of* cancer. Against this background, the distinction between curative and palliative therapy seems somewhat arbitrary. The distinction may be arbitrary, but the control and relief of symptoms is crucial to the successful management of patients with cancer. Much of the fear associated

with cancer is due to past failures to control patients' symptoms: there are folk memories of indignity and distress that affect peoples' current attitudes. Reluctance to attend for screening tests may be profoundly influenced by fears based on the past experiences of relatives and friends.

Patients fear the symptoms, distress and disruption associated with cancer almost as much as they fear the disease itself. Palliative treatment has as its goal the relief of symptoms. Sometimes, this will involve treating the underlying problem, as with palliative radiotherapy for bone metastases; sometimes it will not. Sometimes, it may be inappropriate to treat the cancer itself, but that does not imply that there is nothing more to be done; it simply means that there may be better ways to assuage the distress and discomfort caused by the tumour. Palliative medicine in the twenty-first century is about far more than optimal control of pain: its scope is wide, its impact immense (Table 7.10). The most important factor in the successful palliative management of a patient with cancer is that referral is made early enough in the course of the disease. There should be no abrupt change between curative and palliative modes of management; any such transition should be seamless.

Table 7.8 A summary of chemotherapeutic and biological agents currently used in cancer treatment

Class	Examples	Putative mode of action	Tumour types that may be sensitive to drug
Drugs that interfere with mitosis	Vincristine, vinblastine	Interfere with the formation of microtubules: 'spindle poisons'	Lymphomas Leukaemias Brain tumours Sarcomas
	Taxanes: Taxol, paclitaxel	Stabilise microtubules	Breast cancer Non-small cell lung cancer Ovarian cancer Prostate cancer Head and neck cancer
Drugs that interfere with DNA synthesis (anti-metabolites)	5-Fluorouracil (5-FU)	Inhibition of thymidylate synthase, false substrate for both DNA and RNA synthesis	Breast cancer Gastrointestinal cancer
	Capecitabine	Orally active prodrug that is metabolised to 5-FU. Inhibition of thymidylate synthase, false substrate for both DNA and RNA synthesis	Breast cancer Gastrointestinal cancer
	Methotrexate	Inhibition of dihydrofolate reductase	Breast cancer Bladder cancer Lymphomas Cervix cancer
	6-Mercaptopurine 6-Thioguanine Cytosine arabinoside	Inhibits <i>de novo</i> purine synthesis Inhibits <i>de novo</i> purine synthesis False substrate in DNA synthesis	Leukaemias Leukaemias Leukaemias
	Gemcitabine	Inhibits ribonucleotide reductase	Lymphomas Non-small cell lung cancer Pancreatic cancer
Drugs that directly damage DNA or interfere with its function	Mitomycin C	DNA cross-linking, preferentially active at sites of low oxygen tension (a bioreductive drug)	Anal cancer Bladder cancer Gastric cancer Head and neck cancer Rectal cancer
	Cis-platinum	Forms adducts between DNA strands and interferes with replication	Germ cell tumours Ovarian cancer Non-small cell lung cancer Head and neck cancer Oesophageal cancer
	Carboplatin	Forms adducts between DNA strands and interferes with replication	Germ cell tumours Ovarian cancer Non-small cell lung cancer Head and neck cancer
	Oxaliplatin	Forms adducts between DNA strands and interferes with replication	Colorectal cancer
	Doxorubicin	Intercalates between DNA strands and interferes with replication	Breast cancer Lymphomas Sarcomas Kaposi's sarcoma
	Cyclophosphamide	A prodrug converted via hepatic cytochrome p450 to phosphoramidate mustard; causes DNA cross-links	Breast cancer Lymphomas Sarcomas
	Ifosfamide	Related to cyclophosphamide, causes DNA cross-links	Small cell lung cancer Sarcomas
	Bleomycin	DNA strand breakage via formation of metal complex	Germ cell tumours Lymphomas

Table 7.8 A summary of chemotherapeutic and biological agents currently used in cancer treatment – *continued*

Class	Examples	Putative mode of action	Tumour types that may be sensitive to drug
Drugs that directly damage DNA or interfere with its function – <i>continued</i>	Irinotecan	Inhibits topoisomerase 1 and thereby prevents the DNA from unwinding and repairing during replication	Colorectal cancer
	Etoposide	Inhibits topoisomerase 2; prevents the DNA from unwinding and repairing during replication	Small cell lung cancer Germ cell tumours Lymphomas
	Dacarbazine	A nitrosourea that requires activation by hepatic cytochrome p450. Methylates guanine residues in DNA	Brain tumours Sarcoma Melanoma
	Temozolomide	A nitrosourea but, unlike dacarbazine, does not require activation by hepatic cytochrome p450. Methylates guanine residues in DNA	Glioblastoma multiforme Melanoma
	Actinomycin D	Intercalation between DNA strands, DNA strand breaks	Rhabdomyosarcoma Wilms' tumour
Hormones	Tamoxifen	Blocks oestrogen receptors	Breast cancer
	Anastrozole	An aromatase inhibitor that blocks post-menopausal (non-ovarian) oestrogen production	Breast cancer
	Exemestane	An aromatase inhibitor that blocks post-menopausal (non-ovarian) oestrogen production	Breast cancer
	Letrozole	An aromatase inhibitor that blocks post-menopausal (non-ovarian) oestrogen production	Breast cancer
	Leuprolide	Analogue of gonadotrophin-releasing hormone; continued use produces downregulation of the anterior pituitary with a consequent fall in testosterone levels	Prostate cancer
	Goserelin	Analogue of gonadotrophin-releasing hormone; continued use produces downregulation of the anterior pituitary with a consequent fall in testosterone levels	Prostate cancer
	Buserelin	Analogue of gonadotrophin-releasing hormone; continued use produces downregulation of the anterior pituitary with a consequent fall in testosterone levels	Prostate cancer
	Cabergoline	Blocks prolactin release, a long-acting dopamine agonist	Prolactin-secreting pituitary tumours
	Bromocriptine	Dopamine agonist, blocks stimulation of the anterior pituitary	Pituitary tumours
	Cyproterone acetate	Blocks the effect of androgens	Prostate cancer
Flutamide	Blocks the effect of androgens	Prostate cancer	
Nilutamide	Blocks the effect of androgens	Prostate cancer	
Bicalutamide	Blocks the effect of androgens	Prostate cancer	
Inhibitors of receptor tyrosine kinases	Gefitinib	Inhibits EGFR tyrosine kinase	Non-small cell lung cancer
	Imatinib	Blocks the ability of mutant BCR-ABL fusion protein to bind ATP Inhibition of mutant c-KIT	Chronic myeloid leukaemia Gastrointestinal stromal tumours (GIST)
	Erlotinib	Inhibits EGFR tyrosine kinase	Non-small cell lung cancer Pancreatic cancer
	Sunitinib	Promiscuous tyrosine kinase inhibitor (PDGFR, VEGFR, KIT, FLT)	Renal cancer GIST refractory to Imatinib

Table 7.8 A summary of chemotherapeutic and biological agents currently used in cancer treatment – *continued*

Class	Examples	Putative mode of action	Tumour types that may be sensitive to drug
Inhibitors of receptor tyrosine kinases – <i>continued</i>	Lapatinib	Inhibits tyrosine kinases associated with EGFR and HER2	
Protease inhibitors	Bortezomib	Interferes with proteasomal degradation of regulatory proteins; in particular, prevents NF kappa B from preventing apoptosis	Multiple myeloma
Differentiating agents	All <i>trans</i> -retinoic acid	Induces terminal differentiation	Acute promyelocytic leukaemia
Farnesyl transferase inhibitors	Lonafarnib	Inhibition of farnesyl transferase and consequent inactivation of <i>ras</i> -dependent signal transduction	Leukaemia
	Tipifarnib	Inhibition of farnesyl transferase and consequent inactivation of <i>ras</i> -dependent signal transduction	Acute leukaemia Myelodysplastic syndrome
Antibodies directed to cell surface antigens	Trastuzumab	Antibody directed against HER2 receptor	Breast cancer
	Cetuximab	Antibody directed against EGFR receptor	Colorectal cancer Head and neck cancer
	Bevacizumab	Antibody directed against VEGFR	Colorectal cancer
	Rituximab	Antibody against CD20 antigen	Lymphomas
	Alemtuzumab	Antibody against CD52 antigen	Lymphomas
Inducers of apoptosis	Arsenic trioxide	Induces apoptosis by caspase inhibition Inhibition of nitric oxide	Acute promyelocytic leukaemia
Immunological mediators	Interferon alpha-2b	Activates macrophages, increases the cytotoxicity of T lymphocytes, inhibits cell division (and viral replication)	Renal carcinoma Melanoma Hairy cell leukaemia
	Thalidomide	Anti-inflammatory, stimulates T cells, anti-angiogenic	Myeloma

EGFR, epidermal growth factor receptor; NF, nuclear factor; PDGFR, platelet-derived growth factor receptor; VEGFR, vascular endothelial growth factor receptor.

Table 7.9 Comparison of various estimates of cost-effectiveness for selected clinical interventions

Intervention	Cost (in 2002 US dollars) per quality-adjusted life-year (QALY)
Annual CT chest screening for lung cancer in a 60-year-old male ex-smoker vs. no screening	\$2.4 million
Laparoscopic inguinal hernia repair vs. expectant management in adults with inguinal hernia	\$610
Stroke unit care vs. usual care in survivors of acute stroke	\$1600
Lifetime vitamin D + calcium supplements vs. no supplements to prevent/treat osteoporosis in 70-year-old women	\$8500
Letrazole vs. tamoxifen in the first-line management of post-menopausal women with advanced breast cancer	\$120 000
Erlotinib vs. usual care in the treatment of relapsed non-small cell lung cancer	\$104 000

CT, computerised tomography

Data from CEA (Tufts New England Medical Center) register (accessed via <http://www.tufts-nemc.org/cearegistry/> on 15 November 2006) and the UK National Institute for Health and Clinical Excellence (accessed via <http://www.nice.org.uk/page.aspx?c=153> on 15 November 2006).

Currently, in the UK, interventions costing less than US\$60 000 (2002) are considered 'affordable', that is they fall below the WTP ('willingness to pay') threshold.

End-of-life care

End-of-life care is distinct from palliative care. Patients treated palliatively may survive for many years; end-of-life care concerns the last few months of a patient's life. Many issues, such as symptom control, are common to both palliative care and to end-of-

life care, but there are also problems that are specific to the sense of approaching death. These may include a heightened sense of spiritual need, profound fear and the specific needs of those who are facing bereavement. 'I don't mind dying, I just don't want to be there when it happens' is a statement that expresses both the acceptance and the fear of death. We all live our own lives and

we all die our own deaths. The concept of the 'good death' has been embedded in many cultures over many centuries. As health-care professionals, we deal with many deaths and sometimes forget that, for someone who wishes to die a 'good death', there are no replays: we only have one chance to get it right. This is why end-of-life care is worth considering in its own right and not as something synonymous with, or a mere appendage to, palliative care. Some of the issues unique to end-of-life care are summarised in Summary box 7.7.

Woody Allen, B. 1935, American Screen-writer, Director and Actor who, in his film 'Death', uses this version of a remark originally made by Mark Twain, (Samuel Langhorne Clemens), 1835–1910, the American Author.

Issues at the end of life

- Appropriateness of active intervention
- Euthanasia
- Physician-assisted suicide
- Living wills
- Bereavement
- Spirituality
- Support to allow death at home
- The problem of the medicalisation of death

FUTURE DEVELOPMENTS IN THE MANAGEMENT OF CANCER

Developed world

Over the next 10 years, the cost of health care in general, and of cancer care in particular, will rise faster than our ability to afford it. The stark implication is that inequalities in care will increase, rather than decrease. Those who can afford expensive new treatments will be able to obtain them; those who are less well-off will have to do without. As cancer becomes a chronic disease, the duration of therapy will increase: instead of 3–6 months of relatively inexpensive chemotherapy, 3–4 years of extremely expensive biological therapy may be the norm. This compounds the problem of the unaffordability of treatment. There are some tough decisions to be made. One solution to this apparent dilemma is obvious but, politically, difficult to grasp: more effort needs to be put into the prevention and early detection of cancer. This makes sense in terms of both economics and social justice. Unfortunately, preventative and screening technologies lack the backing of the medico-industrial complex: there is more money to be made from treating with drugs than in attempting to persuade people to take exercise and eat a healthy diet or, for that matter, to send a sample of their faeces to a laboratory for faecal occult blood testing.

Developing world

Just as modern technology will increase the inequality in cancer services within the developed world so, for similar reasons, it will widen the gulf in cancer services between the developed world and the developing world. In many African countries, the annual per capita spending on health is less than US\$50. Given this lack of resources, it is barely possible to diagnose, let alone treat, cancer. The problem is compounded by the high rate of human immunodeficiency virus (HIV) infection in the developing world. In southern Africa, over 50% of patients with cancer of the cervix are HIV positive. Both the HIV infection and the cancer are potentially preventable, by the use of condoms and human papillomavirus vaccination respectively. In addition, there are the other tumours related to acquired immunodeficiency syndrome (AIDS) to consider: Kaposi's sarcoma, lymphomas, squamous carcinomas of the conjunctiva. All cause morbidity, some are fatal and, in an impoverished country in the developing world, are fundamentally untreatable. The high prevalence of smoking among young people in China presages an epidemic of

Moritz Kaposi, 1837–1902, Professor of Dermatology, Vienna, Austria, described pigmented sarcoma of the skin in 1872.

lung cancer in that enormous population within the next 25 years.

A HEALTH WARNING

This has been a relatively simple account of a complex group of diseases. If cancer were simple, it would already have been cured. Investigating, understanding and treating cancer is fraught with ambiguities. However, we have deliberately tried to avoid ambiguity and have presented a series of gross oversimplifications: for every argument presented as fact, there are several counterarguments. We have, for example, stated that mutations are the driving force in forming tumours: one contrary view is that all tumours originate from gross rearrangements of chromosomes, and that mutations occur as secondary events. Another contrary view is that epigenetic events, such as global hypomethylation of genomic DNA, precede the acquisition of mutations and that, in order to flourish, a transforming event must occur within an epigenetic environment that is favourable. In this, as in many other instances, the conventional wisdom has been provided. The challenge for the future is to find out how much of conventional wisdom is true, and how much is not.

Surgical audit and research

CHAPTER

8

LEARNING OBJECTIVES

To understand:

- The planning and conduct of audit and research
- How to write up a project
- How to review a journal article and determine its value

INTRODUCTION

It is essential for a surgeon to understand the educational and legal framework in which he or she works. The agenda for medical education and clinical governance requires surgeons to expand their skills to encompass audit and research capabilities as useful tools for continued outcome measurement, service improvement and innovations for the benefit of patient care. The aim of this chapter is to enable improvements in patient experience as a result of a successful audit cycle or by recognising the need for research to determine a new and innovative way of treatment. It will also show how to keep track of personal clinical results. In addition, much clinical work is tedious and repetitive. Rigorous evaluation of even the most simple techniques and conditions can help to keep a surgeon stimulated throughout a long career and ensure good outcomes for patients, with benefits to society as a whole.

Large numbers of clinical papers appear in the surgical literature every year. Many are flawed, and it is important that a surgeon has the skills to examine publications critically. The best way to develop a critical understanding of the research and audit undertaken by others is to perform studies of one's own. The hardest part of audit and research is writing it up, and the hardest article to write is the first. This chapter also contains the information required to write a surgical paper and to evaluate the publications of others.

AUDIT OR RESEARCH?

It is important to determine at an early stage whether a project is audit or research, and sometimes that is not as easy as it seems. The decision will determine the framework in which the study is undertaken. Table 8.1 contains the information needed to make the decision and the formal processes that should be used for each.

AUDIT AND SERVICE EVALUATION

Clinical audit is a process used by clinicians who seek to improve patient care. The process involves comparing aspects of care

(structure, process and outcome) against explicit criteria. Keeping track of personal outcome data and contributing to a clinical database ensures that a surgeon's own performance is monitored continuously and can be compared with a national data set to ensure compliance with agreed standards. If the care falls short of the criteria chosen, some change in the way that care is organised should be proposed. This change may be required at one of many levels. It might be an individual who needs training or an instrument that needs replacing. At times, the change may need to take place at the team level. Sometimes, the only appropriate action is change at an institutional level (e.g. a new antibiotic policy), regional level (provision of a tertiary referral centre) or, indeed, national level (screening programmes and health education campaigns).

Essentially two types of audits may be encountered: national audits (e.g. in the UK, the National Institute for Health and Clinical Excellence – NICE) and local/hospital audits. Both are designed to improve the quality of care. In an ideal world, national audits should be driven by needs identified in local and hospital-based audits that are closest to the patient. For example, hospital topics are often identified at the departmental morbidity and mortality meetings, where issues related to patient care are discussed. The reporting process might identify a possible national issue, and a national audit could be designed to be completed by the local audit department and surgical teams. The Vascular Society of Great Britain and Ireland is currently involving all its members in an evaluation of process and outcomes during carotid surgery. Issues that are of local importance are addressed within the local hospital, region or hospital trust (in the UK).

Audits are formal processes that require a structure. The following steps are essential to establish an audit cycle:

- 1 Define the audit question in a multidisciplinary team.
- 2 Identify the body of evidence and current standards.
- 3 Design the audit to measure performance against agreed standards based on strong evidence. Seek appropriate advice (local audit department in UK).
- 4 Measure over an agreed interval.
- 5 Analyse results and compare performance against agreed standards.

Table 8.1 Research, audit or service evaluation?

Research	Clinical audit	Service evaluation
The attempt to derive generalisable new knowledge including studies that aim to generate hypotheses as well as studies that aim to test them	Designed and conducted to produce information to inform the delivery of best care	Designed and conducted solely to define or judge current care
Quantitative research – designed to test a hypothesis	Designed to answer the question: ‘Does this service reach a predetermined standard?’	Designed to answer the question: ‘What standard does this service achieve?’
Qualitative research – identifies/explores themes following established methodology		
Addresses clearly defined questions, aims and objectives	Measures against a standard	Measures current service without reference to a standard
Quantitative research – may involve evaluating or comparing interventions, particularly new ones	Involves an intervention in use ONLY. (The choice of treatment is that of the clinician and patient according to guidance, professional standards and/or patient preference)	Involves an intervention in use ONLY. (The choice of treatment is that of the clinician and patient according to guidance, professional standards and/or patient preference)
Qualitative research – usually involves studying how interventions and relationships are experienced		
Usually involves collecting data that are additional to those for routine care but may include data collected routinely. May involve treatments, samples or investigations additional to routine care	Usually involves analysis of existing data but may include administration of simple interviews or questionnaires	Usually involves analysis of existing data but may include administration of simple interviews or questionnaires
Quantitative research – study design may involve allocating patients to intervention groups	No allocation to intervention groups: the health-care professional and patient have chosen intervention before clinical audit	No allocation to intervention groups: the health-care professional and patient have chosen intervention before service evaluation
Qualitative research uses a clearly defined sampling framework underpinned by conceptual or theoretical justifications		
May involve randomisation	No randomisation	No randomisation

Although any of the above may raise ethical issues, under current guidance, research requires ethics committee review, whereas audit and service evaluation do not. Advice (in UK) from National Research Ethics Service (<http://www.nres.npsa.nhs.uk/recs>)

- 6 Undertake gap analysis:
 - If all standards are reached, reaudit after an agreed interval.
 - If there is a need for improvement, identify possible interventions such as training, and agree with the involved parties.
- 7 Reaudit.

Research study

During the design of the audit project, it might become apparent that there is a limited body of evidence available. In this case, the study should be structured as a research proposal. Research is designed to generate new knowledge and might involve testing a new treatment or regimen.

IDENTIFYING A RESEARCH TOPIC

The hardest part of research is to come up with a good idea. Once an idea has been formed, or a question asked, it needs to be transformed into a hypothesis. It is helpful to approach surgeons

who regularly publish articles and who have a special interest in the surgical area being considered. As ideas are suggested, keep thinking whether the question posed really matters. Spend some time refining the question because this is probably the most important part of the study. Choosing the wrong topic at this stage can lead to many wasted hours. Once a topic has been identified, do not rush into the study. It is worth spending a considerable time investigating the subject in question. The worst possible thing is to find at the end of a long arduous study that the research or audit has already been done.

First port of call for information is the medical library. Look for current articles about the proposed research; review articles and meta-analyses can be particularly helpful. At this stage, most clinicians go to an electronic library and perform a database search. It is very important to learn how to do an accurate and efficient search as early as possible. Details are beyond the scope of this chapter, but most librarians will help out if a little interest and enthusiasm is shown. Current techniques involve searching on Medline or other collected databases but, as electronic information advances and the worldwide web becomes more user

friendly, new search strategies may emerge. Collections of reviews are becoming available – the Cochrane Collaboration brings together evidence-based medical information and is available in most libraries (Table 8.2).

Once a stack of articles on the subject has been obtained, it is important that these are carefully perused. If the proposed project is still looking good after some thorough reading, it is worth further discussion with authors who have written a paper on a similar subject. All scientists are flattered by interest in their work. Now it should be possible to start to plan the research project.

PROJECT DESIGN

During the first phase, it is very important to keep in the mind some important questions (Summary box 8.1).

Summary box 8.1

Questions to answer before undertaking research

- Why do the study?
- Will it answer a useful question?
- Is it practical?
- Can it be accomplished in the available time and with the available resources?
- What findings are expected?
- What impact will it have?

Next to choosing the subject for study, time spent carefully designing a project is never wasted. There are many different types of scientific study. The design used totally depends on the study. Beloved of present scientists, the randomised controlled trial (RCT) is regarded as the best method of scientific research. It must not be forgotten that much surgical practice has been advanced by other different types of study such as those listed in Table 8.3. For example, testing a new type of operation often requires a pilot study to assess feasibility followed by a formal RCT.

Research can be qualitative or quantitative. Quantitative research allows hard facts to speak for themselves. A medical condition is analysed systematically using hard, objective end-points such as death or amputation. In qualitative research, data often come from patient narratives, and the psychosocial impact of the disease and its treatment are analysed, for example narratives from patients with breast cancer. These sorts of data are often collected using quality-of-life measurements. A variety of different quality-of-life questionnaires exist to suit several different clinical situations. Much of the best research is both quantitative and qualitative.

As finances for health care are always limited, it is also important to include a cost–benefit analysis in any major area of research so that the value of the proposed intervention or change in treatment can be assessed.

Research should also be focused according to national (and international) strategies. Best Research for Best Health is the

The Cochrane Collaboration was formed in 1993 and named after Archibald Leman Cochrane, 1909–1988, Director of the Medical Research Council Epidemiology Unit, Cardiff, Wales, and later the first President of the Faculty of Community Medicine (now the Faculty of Public Health) of the Royal College of Physicians of London, England

Table 8.3 Types of study

Type of study	Definition
Observational	Evaluation of condition or treatment in a defined population Retrospective: analysing past events Prospective: collecting data contemporaneously
Case-control	Series of patients with a particular disease or condition compared with matched control patients
Cross-sectional	Measurements made on a single occasion, not looking at the whole population but selecting a small similar group and expanding results
Longitudinal	Measurements are taken over a period of time, not looking at the whole population but selecting a small similar group and expanding results
Experimental	Two or more treatments are compared. Allocation to treatment groups is under the control of the researcher
Randomised	Two randomly allocated treatments
Randomised controlled	Includes a control group with standard treatment

current NHS research strategy for England and Wales. The aim is to support outstanding individuals, working in world-class facilities, conducting leading-edge research that is focused on the needs of patients and the public (<http://www.dh.gov.uk/en/Policyandguidance/Researchanddevelopment/index.htm>).

Sample size

Calculating the number of patients required to perform a satisfactory investigation is a very important prerequisite to the study. An incorrect sample size is probably the most frequent reason for research being invalid. Often, surgical trials are marred by the possibility of error caused by the inadequate number of patients investigated.

- *Type I error.* Benefit is perceived when really there is none (false positive)
- *Type II error.* Benefit is missed when it was there to be found (false negative)

Calculating the number of patients required in the study can overcome this bias. Unfortunately, it very often reveals that a larger number of patients is needed for the study than can possibly be obtained from available resources. This often means expanding enrolment by using a multicentre study. There is no point in embarking on a trial if it will never be possible to recruit an adequate population to answer the research question. Never forget that more patients will need to be randomised than the final sample size to take into account patients who die, drop out or are lost to follow-up.

The following is an example calculation for a study to recruit patients into two groups. In order to calculate a sample size, it is common practice to set the level of power for the study at 80%

with a 5% significance level. This means that, if there is a difference between study groups, there is an 80% chance of detecting it. Based on previous studies, realistic expectations of differences between groups should be used to calculate the sample size. The formula below uses the figures of a reduction in event rate from 30% to 10% (e.g. a new treatment expected to reduce the complication rate such as wound infection from 30% = r to 10% = s).

$$8 \times [r(100-r) + s(100-s)] / (r-s)^2 \quad (8.1)$$

e.g. $8 \times [30(100-30) + 10(100-10)] / (30-10)^2 = 60$ needed in each group

Eliminating bias

It is important to imagine how a study could be invalidated by thinking of things that could go wrong. One way to eliminate any bias inherent in the data collection is to have observers or recorders who do not know which treatment has been used (blinded observer). It might also be possible to ensure that the patient is unaware of the treatment allocation (single blind). In the best randomised studies, neither patient nor researcher is aware of which therapy has been used until after the study has finished (double blind). Randomised trials are essential for testing new drugs. In practice, however, in some surgical trials, randomisation may not be possible or ethical.

Study protocol

Now that the question to pose has been decided, and it has been checked that sufficient patients will be available to enrol into the study, it is time to prepare the detail of the trial. At this stage, a study protocol should be constructed to define the research strategy. It should contain a paragraph on the background of the proposed study, the aims and objectives, a clear methodology, definitions of population and sample sizes and methods of proposed analysis. It should include the patient numbers, inclusion and exclusion criteria and the timescale for the work. At this stage, it is useful to construct a flow diagram giving a clear summary of the research protocol and its requirements (Fig. 8.1). It is helpful to imagine the paper that will be written about the study, before it is performed. This may prevent errors in data collection.

When a study is planned, sufficient time should be reserved at the beginning for fund-raising and obtaining ethical and hospital approval, if required, and afterwards for collecting and writing up the data. A data collection form should be designed or a computer collection package developed. Do not forget that, if data are collected on computer, appropriate safeguards for privacy and confidentiality will be necessary to comply with legislation on data protection. It is important to ensure the cooperation of any other specialties or clinicians who will be involved in the study and to agree on the sharing of responsibility for the trial. This will also help to prevent disagreement about who takes the credit once a study is ready for presentation and publication.

Regulatory framework

In the UK, the implementation of the research governance framework by the Department of Health requires that independent ethical review is undertaken of all health and social care research (<http://www.dh.gov.uk/assetRoot/04/12/24/27/04122427.pdf>).

This is done by contacting the local ethics committee and following the guidance from the National Research Ethics Service

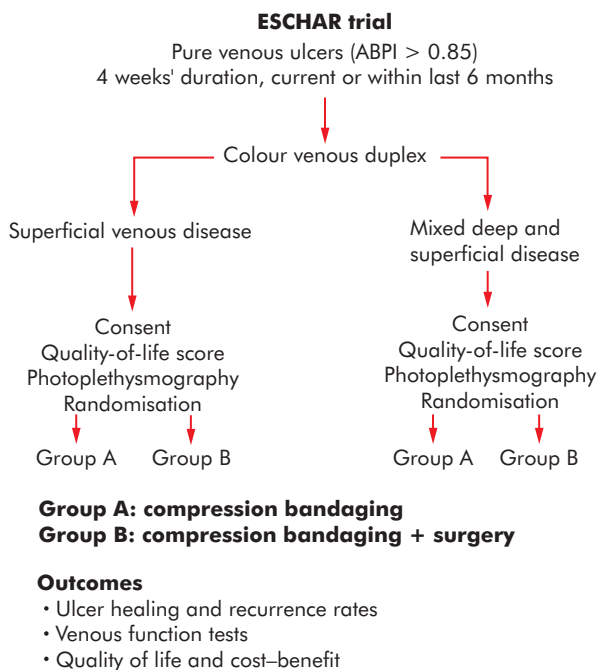

Figure 8.1 ESCHAR trial: completed in Gloucestershire, UK [Gohel, M.S. *et al.* (2005) *British Journal of Surgery* **92**: 291–297. Copyright British Journal of Surgery Society Ltd. Permission is granted by John Wiley & Sons Ltd on behalf of the BJSS Ltd.] ABPI, ankle–brachial pressure index.

(NRES). In addition, all studies should receive hospital trust approval, which ensures that the study complies with the legal framework for research. In the case of clinical trials, the European Union Clinical Trial Directive applies and is regulated by the Medicines and Health Care products Regulatory Agency (MHRA). A clinical trial should be registered with the European Clinical Trials Database (www.eudract.emea.europa.eu) or one of the other free databases (www.clinicaltrials.gov) before applying to NRES. It is then possible to apply to the MHRA for a Clinical Trial Authorisation in parallel to the NRES application. This can be a complicated and trying process, but most hospitals have research support units that will help if any problems are encountered. Editors of the major surgical journals now agree that all clinical trials should have been registered before an article relating to a trial can be published.

Peer review

Once your protocol is finalised, formal peer review is needed. In the UK, you will need to have evidence of peer review before submitting an application to the ethics committee and for hospital trust approval.

- If the research is part of a university course, the university should undertake this review.
- Surgeons working for the NHS can arrange their own peer review by experts who are not connected with the study. Alternatively, most Research and Development Support Units (NHS) will give guidance through the review process.
- Funders of research will usually undertake their own independent peer review. There is usually feedback from this process that often gives valuable advice about the study.

Ethics

In the first instance, common sense is the best guide to whether or not a study is ethical. It is still important to seek advice from an ethics committee whenever research is contemplated.

All studies involving animals require approval from statutory licensing authorities.

In the UK, and also in Australia, new therapeutic procedures and devices were registered and regulated through a body set up by the Surgical Royal Colleges: SERNIP (Safety and Efficacy Register of New Interventional Procedures). This process has now been subsumed by NICE who undertake a similar role.

Ethics committees prefer to see fully developed trial protocols, but it is often possible to get some preliminary advice from the committee chairman. Ethics committee forms may seem long and detailed, and it is important that these are filled in correctly. All dealings with ethics committees should be intelligent and courteous. Do attend the meeting at which your study will be discussed as it provides a forum for direct communication in relation to the study. It can save time as any possible concerns of the ethics committee can be addressed immediately, avoiding lengthy correspondence.

Do not embark on the study until the right approval has been granted. Ensure that a project does not incur hidden expenses to a hospital. The cost of non-routine investigations and extra treatments should be identified and covered by a grant application, or at least underwritten by a hospital finance department.

STATISTICAL ANALYSIS

Both audit and research commonly require statistical analysis. Many surgeons find the statistical analysis of a project the most difficult part. It is also the most commonly criticised part of papers written by other clinicians.

There are many useful books about statistics which can be consulted (see Further reading); if in any doubt, a statistician will be pleased to give assistance. Statisticians like to be consulted before research or audit has been conducted rather than being presented with the data at the end; they often give helpful advice over study design.

The following terms are frequently used when summarising statistical data:

- *Mean*: the result of dividing the total by the number of observations (the average).
- *Median*: the middle value with equal numbers of observations above and below – used for numerical or ranked data.
- *Mode*: the value with the highest frequency observed – used for nominal data collection.
- *Range*: the largest to the smallest value.

The most important decision for analysis is whether the distribution of results is normal, i.e. parametric or non-parametric. Normally distributed results have a symmetrical, bell-shaped curve, and the mean, median and mode all lie at the same value. The type of data collected determines which statistical test should be used.

- 1 Numerical and normally distributed (e.g. blood pressure) – use unpaired *t*-test to compare two groups, or paired *t*-test to assess whether a variable has changed between two time points.

- 2 Numerical but not normally distributed (e.g. tumour size) – use Mann–Whitney *U*-test to compare two groups, or a Wilcoxon signed rank test to assess whether a variable has increased/stayed the same/decreased between two time points.
- 3 Categorical (e.g. admitted to intensive care unit) – can use chi-squared test to compare two groups

(Please note: the use of any other test may benefit from professional advice.)

Confidence intervals are the best guide to the possible range in which the true differences are likely to lie. A confidence interval that includes zero usually implies a lack of statistical significance.

Scientists usually employ *P*-values to describe statistical chance. A *P*-value < 0.05 is commonly taken to imply a true difference. It is important not to forget that *P* = 0.05 simply means there is only a 1:20 chance that the differences between the variables would have happened by chance when there was no real difference. If enough variables are examined in any study, significant differences will occur simply by chance. Trials with multiple endpoints or variables require more sophisticated analysis to determine the significance of individual risk factors. Univariable or multivariable logistic regression analysis techniques may be appropriate.

Statistics simply deal with the chance that observations between populations are different, and should be treated with caution. Clinical results should show clear differences. If statistics are required to demonstrate differences between results, it is possible that they are unlikely to have major clinical significance.

Computer software packages available

Statistical computer packages offer a quick way of analysing descriptive statistics such as mean, median and range, as well as the most commonly used statistical tests such as the chi-squared test. Various packages are available commercially and are useful tools in data analysis.

ANALYSING A SCIENTIFIC ARTICLE

The simplest way to analyse an article from a scientific journal is to look at the check-list of requirements for good scientific research. A group of scientists and editors developed the CONSORT (Consolidated Standards of Reporting Trials) statement to improve the quality of reporting of RCTs. Looking in detail at the study design is often the best way of deciding whether a trial is any good. The CONSORT document includes a check-list for the conduct of good randomised trials (Table 8.4). Often clinicians overlook biases that others find obvious to detect, which can have a profound influence on the outcome of any study. Several scientists have tried to use scoring systems to grade clinical trials, as the label 'randomised clinical trial' does not always guarantee quality.

PRESENTING AND PUBLISHING AN ARTICLE

There is no point in conducting a research or audit project and then leaving the results unreported. Even when results are negative, they are worth distributing; no project is worthless. Most studies do not provide dramatic results, and few surgeons publish seminal articles.

The key to both presentation and publication is to decide on the message, and then aim for an appropriate forum. Big important randomised studies or national audits merit presentation at national meetings and publication in international journals. Small observational studies and audits are more often accepted for presentation at regional or hospital meetings and for publication in smaller specialist journals. Help and advice from clinicians familiar with presentation and publication are invaluable at this stage. The most important piece of advice is to follow accurately the instructions for journal submission. Most international meet-

Table 8.4 Check-list for authors

Heading	Sub-heading	Descriptor
Title		Identify as randomised trial
Abstract		Structured format
Introduction		Prospectively defined hypotheses, clinical objective
Methods	Protocol	Study population

	External validity	
	General interpretation	

From the CONSORT statement: *Journal of the American Medical Association* (1996) **276**: 637–639.

ings will accept presentations eagerly (especially by poster) as this increases the attendance at a conference.

Most surgeons publish research in peer-reviewed journals. The work that is submitted is checked anonymously by other surgeons before publication. If in doubt about whether to submit to a journal, many editors will give advice about the suitability of an article by letter or telephone.

Convention dictates that articles are submitted in IMRAD form – introduction, methods, results and discussion. Increasingly, electronic publication and the Internet may change the face of scientific publication and, in the next decade, these restrictions on style may disappear. For now, the IMRAD format remains inviolable. The length of an article is important: a paper should be as long as the size of the message. Readers of big randomised multicentre trials wish to know as much detail about the study as possible; reports on small negative trials should be brief.

Introduction

This should always be short. A brief background of the study should be presented and then the aims of the trial or audit outlined.

Methods

The methodology and study design should be given in detail. It is important to own up to any biases. Any new techniques or investigations should be detailed in full; if they are common practice or have been described elsewhere, this should be referenced instead of described.

Results

Results are almost always best shown diagrammatically using tables and figures if possible. Results shown in the form of a diagram need not then be duplicated in the text.

Discussion

It is important not to repeat the introduction or reiterate the results in this section. The study should be interpreted intelligently, and any suggestions for future studies or changes in management should be made. It is important not to indulge in flights of fantasy or wild imagination about future possibilities; most journal editors will delete these. Recently, a standard format for the discussion section has been promoted, and journals such as the *British Medical Journal* are keen that authors use it.

References

This section should include all relevant papers recording previous studies on the subject in question. The number should reflect the size of the message and the importance of the work. The reference section does not usually have to be exhaustive, but should include up-to-date articles. Remember to present the references in the style of the journal of submission.

EVIDENCE-BASED SURGERY

Surgical practice has been considered an art: ask 50 surgeons how to manage a patient and one will probably get 50 different answers. There is so much clinical information available that no surgeon can know it all. Evidence-based surgery is a move to find the best ways of managing patients using clinical evidence from collected studies. It was estimated that sufficient evidence to justify routine myocardial thrombolysis for heart attacks was available years before the randomised clinical studies that finally made it clinically accept-

able. No-one had gathered all the available information together. Centres such as the Cochrane Collaboration have been collecting randomised trials and reviews to provide up-to-date information for clinicians. The Cochrane Library presently includes a database of systematic reviews, reviews of surgical effectiveness and a register of controlled trials. The *British Journal of Surgery* has been collecting surgical randomised trials on its website archive for 10 years (www.bjs.co.uk). There are now almost 1000 annotated references that can be a valuable resource for scientific authors. As evidence accumulates, it is expected that this will gradually smooth out the differences between clinicians as the best way of managing patients becomes more obvious. Collecting published evidence together and analysing it often requires reviews of multiple randomised trials. These meta-analyses involve complex statistical analyses designed to interpret multiple findings and synthesise the results of multiple studies. There exist standard formats for the presentation of meta-analyses described in the QUORUM statement (a statement produced after a conference that was convened to address standards for improving the quality of reporting of meta-analysis of clinical RCTs).

Surgical ethics

LEARNING OBJECTIVES

To understand:

- The importance of autonomy in good surgical practice
- The moral and legal boundaries and practical difficulties of informed consent
- Good practice in making decisions about the withdrawal of life-sustaining treatment
- The importance and boundaries of confidentiality in surgical practice
- The importance of appropriate regulation in surgical research
- The importance of rigorous training and maintenance of good practice standards

INTRODUCTION

Ethics and surgical intervention must go hand in hand. In any other arena of public or private life, if someone deliberately cuts another person, draws blood, causes pain, leaves scars and disrupts everyday activity, then the likely result will be a criminal charge. If the person dies as a result, the charge could be manslaughter or even murder. Of course, it will be correctly argued that the difference between the criminal and the surgeon is that the latter causes harm only incidentally. The surgeon's intention is to cure or manage illness, and any bodily invasion that it incurs is only with the permission of the patient.

Patients consent to surgery because they trust their surgeons. Yet what should such consent entail in practice and what should surgeons do when patients need help but are unable or unwilling to agree to it? When patients do consent to treatment, surgeons wield enormous power over them, the power not just to cure, but to maim, disable and kill. How should such power be regulated to reinforce the trust of patients and to ensure that surgeons practise to an acceptable professional standard? Are there circumstances, in the public interest, in which it is acceptable to sacrifice the trust of individual patients through revealing information that was communicated in what patients believed to be conditions of strict privacy?

These questions about what constitutes good professional practice concern ethics rather than surgical technique. Surgeons may be expert in the management of specific diseases but may have little understanding of how much and what sort of information is required for patients to give valid consent to treatment. Surgeons can understand the delicate techniques associated with specific types of procedures without necessarily knowing when these should be administered to patients who are unable to consent at all. Surgeons can recognise their own mistakes and those of colleagues without knowing how much should be said about them to others. And so it goes on.

Traditional surgical training offers little help in the resolution of such ethical dilemmas. This chapter provides guidance which is morally coherent, widely endorsed and legally justifiable. Our focus will be the practice of surgery within the UK, although much of the analysis will also apply to surgical work elsewhere.

RESPECT FOR AUTONOMY

Surgeons have a duty of care towards their human patients which goes beyond just protecting their life and health. Their additional duty of care is to respect the autonomy of their patients and their ability to make choices about their treatments, and to evaluate potential outcomes in light of other life plans. Such respect is particularly important for surgeons because, without it, the trust between them and their patients may be compromised, along with the success of the surgical care provided. We are careful enough at the best of times about whom we allow to touch us and to see us unclothed. It is hardly surprising that many people feel strongly about exercising the same discretion in circumstances in which someone is not only going to do these things but to inflict what may be very serious wounds on them as well.

For all these reasons, there is a wide moral and legal consensus that patients have the right to exercise choice over their surgical care. In this context, a right should be interpreted as a claim that can be made on others and that they believe that they have a strict duty to respect, regardless of their own preferences. Thus, to the degree that patients have a right to make choices about proposed surgical treatment, it then follows that they should be allowed to refuse treatments that they do not want, even when surgeons think that they are wrong. For example, patients can even refuse surgical treatment that will save their lives, either at present or in the future, through the formulation of advance directives specifying the types of life-saving treatments that they do not wish to have if they become incompetent to refuse them.

INFORMED CONSENT

In surgical practice, respect for autonomy translates into the clinical duty to obtain informed consent before the commencement of treatment. The word ‘informed’ is important here. Because of the extremity of their clinical need, patients might agree to surgery on the basis of no information at all. Agreement of this kind, however, does not constitute a form of consent that is morally or legally acceptable. Unless such patients have some understanding of what they are agreeing to, their choices may have nothing to do with planning their lives and thus do not count as expressions of their autonomy. Worse still, if patients are given no information, their subsequent choices may be based on misunderstanding and lead to plans and further decisions that they would not otherwise have made.

For agreement to count as consent to treatment, patients need to be given appropriate and accurate information. Such information should include:

- the condition and the reasons why it warrants surgery;
- the type of surgery proposed and how it might correct the condition;
- the anticipated prognosis and expected side-effects of the proposed surgery;
- the unexpected hazards of the proposed surgery;
- any alternative and potentially successful treatments other than the proposed surgery;
- the consequences of no treatment at all.

With such information, patients can link their clinical prospects with the management of other aspects of their life and the lives of others for whom they may be morally and/or professionally responsible. Good professional practice dictates that obtaining informed consent should occur in circumstances that are designed to maximise the chances of patients understanding what is said about their condition and proposed treatment, as well as giving them an opportunity to ask questions and express anxieties.

Where possible:

- a quiet venue for discussion should be found;
- written material in the patient’s preferred language should be provided to supplement verbal communication;
- patients should be given time and help to come to their own decision;
- the person obtaining the consent should ideally be the surgeon who will carry out the treatment. It should not be – as is sometimes the case – a junior member of staff who has never conducted such a procedure and thus may not have enough understanding to counsel the patient properly.

Good communication skills go hand in hand with properly obtaining informed consent for surgery. It is not good enough just to go through the motions of providing patients with the information required for considered choice. Attention must be paid to:

- whether or not the patient has understood what has been stated;
- avoiding overly technical language in descriptions and explanations;
- the provision of translators for patients whose first language is not English;
- asking patients if they have further questions.

When there is any doubt about their understanding, surgeons should ask patients questions about what has supposedly been communicated to see if they can explain the information in question for themselves.

Surgeons have a legal, as well as a moral, obligation to obtain consent for treatment based on appropriate levels of information. Failure to do so could result in one of two civil proceedings, assuming the absence of criminal intent. First, in law, intentionally to touch another person without their consent is a battery, remembering that we are usually touched by strangers as a consequence of accidental contact. Surgeons have a legal obligation to give the conscious and competent patient sufficient information ‘in broad terms’ about the surgical treatment being proposed and why. If the patient agrees to proceed, no other treatment should ordinarily be administered without further explicit consent.

Negligence is the second legal action that might be brought against a surgeon for not obtaining appropriate consent to treatment. Patients may have been given enough information about what is surgically proposed to agree to be touched in the ways suggested. However, surgeons may still be in breach of their professional duty if they do not provide sufficient information about the risks that patients will encounter through such treatment. Although standards of how much information should be provided about risks vary between nations, as a matter of good practice, surgeons should inform patients of the hazards that in their view any reasonable person in the position of the patient would wish to know. In practice, surgeons should ask themselves what they or a close relative or friend should be entitled to know in similar circumstances.

Finally, surgeons now understand that, when they obtain consent to proceed with treatment, then patients are expected to sign a consent form of some kind. The detail of such forms can differ, but they often contain very little of the information supposedly communicated to the patient who signed it. Partly for this reason, the process of formally obtaining consent can become overly focused on obtaining the signature of patients rather than ensuring that appropriate types and amounts of information have been provided, and have been understood.

Both professionally and legally, it is important for surgeons to understand that a signed consent form is not proof that valid consent has been properly obtained. It is simply a piece of evidence that consent may have been attempted. Even when they have provided their signature, patients can and do deny that appropriate information has been communicated or that the communication was effective. Surgeons are therefore well advised to make brief notes of what they have said to patients about their proposed treatments, especially information about significant risks. These notes should be placed in the patient’s clinical record.

PRACTICAL DIFFICULTIES

Thus far, we have examined the moral and legal reasons why the duty of surgeons to respect the autonomy of patients translates into the specific responsibility to obtain informed consent to treatment. For consent to be valid, patients must:

- be competent to give it – be able to understand, remember and deliberate about whatever information is provided to them about treatment choices, and to communicate those choices;

- not be coerced into decisions that reflect the preferences of others rather than themselves;
- be given sufficient information for these choices to be based on an accurate understanding of reasons for and against proceeding with specific treatments.

Surgeons will face four key practical difficulties in aspiring to these goals.

First, surgical care will grind to a halt if it is always necessary to obtain explicit informed consent every time a patient is touched in the context of their care. Fortunately, such consent is unnecessary because patients will already have given their implied consent to whatever bodily contact is required in order to fulfil the therapeutic goals when they gave their explicit consent to treatment. Yet the fact that this is so underlines the importance of obtaining proper and explicit consent in the first place, along with taking care to note any sign of the patient withdrawing that consent or placing restrictions on it – for example, through verbally refusing or physically resisting specific aspects of care.

Second, some patients will not be able to give consent because of temporary unconsciousness. This might be a by-product of their illness or injury, or it could simply be the result of the administration of general anaesthetic. The moral and legal rules that govern such situations are clear. Patients may be at risk of death or of serious and permanent disability if surgery is not immediately performed. The situation is then one of medical necessity, and intervention can occur in their best interests without consent. The exception is when it is known that patients have made a legally valid advance decision refusing treatment of the specific kind required. In any case, surgery that is not immediately necessary because of such risks should be postponed until patients regain consciousness and are able to give informed consent or refusal for themselves.

Surgeons must take care to respect this distinction between procedures that are therapeutically necessary and those that are done merely out of convenience, even when, in the course of one operation, they discover problems unknown to the patient that they believe to require further surgical work. For example, a surgeon was successfully sued for battery by a female patient for performing a hysterectomy thought to be in her best interests when all that she had explicitly consented to was a dilatation and curettage.

Third, informed consent may be made impossible by incompetence of other kinds. In the case of children, parents or someone with parental responsibility are ordinarily required to give explicit written consent on their behalf. This said, surgeons should:

- take care to explain to children what is being surgically proposed and why;
- always consult with children about their response;
- where possible, take the child's views into account and note that even young children can be competent to consent to treatment provided that they too can understand, remember, deliberate about and believe information relevant to their clinical condition.

When such competence is present, under English law, children can provide their own consent to surgical care, although they cannot unconditionally refuse it until they are 18 years old. With the exception of the latter, these provisions illustrate the importance of respecting as much autonomy as is present among child patients and remembering that, for the purposes of consent to medical treatment, they may be just as autonomous as adults.

If competence is severely compromised by psychiatric illness or mental handicap, other moral and legal provisions hold. If patients lack the autonomy to choose how to protect themselves as regards the consequences of their illness then others charged with protecting them must assume the responsibility. Yet care must be taken not to abuse this duty. Even when such patients have been legally detained for compulsory psychiatric care, it does not follow that such patients are unable to provide consent for surgical care. Their competence should be assumed and consent should be sought. If it is established with the help of their carers that such patients are also incompetent to provide consent for surgery and that they are at risk of death or serious and permanent disability, then therapy can proceed in their best interests. However, if treatment can be postponed, then this should be done until, as a result of their psychiatric care, patients become able either to consent or to refuse. As with children, respect should always be shown for as much autonomy as is present.

If, for whatever clinical reason, adult patients are permanently incompetent to consent to surgery, therapy can again proceed if it is necessary to save life, to prevent serious and permanent injury or, more electively, to alleviate discomfort and optimise care. The only exception is, again, when the patient has already formulated a legally valid advance decision refusing the specific treatments on offer and someone has been appropriately appointed by the patient as having appropriate power of lasting attorney (or possesses such power for any other judicial reason).

Otherwise, it is always a futile exercise to ask the relatives of incompetent patients to sign consent forms for surgery on adults who cannot do so for themselves. Indeed, to make such requests can be a disservice to relatives, who may feel an unjustified sense of responsibility if the surgery fails. This said, relatives should be treated with politeness and consulted about issues that pertain to determining the best interests of patients.

MATTERS OF LIFE AND DEATH

It has been noted that the right of a competent adult to consent to and refuse treatment is unlimited, including the refusal of life-sustaining treatment. Probably the example of this most familiar to surgeons is Jehovah's Witnesses, who refuse blood transfusions at the risk of their own lives. There can be no more dramatic example of the potential tension between the duties of care to protect life and health and to respect autonomy.

The tension does not stop here, however. For there will be some circumstances in which the protection of the life and health of patients is judged to be inappropriate; in which they are no longer able to be consulted; and in which they have not expressed a view about what their wishes would be in such circumstances. Here, if possible after discussion and consensus with the next of kin, a decision may be made to withhold or to withdraw life-sustaining treatment on behalf of the incompetent patient. The fact that such decisions can be seen as omissions to act does not excuse surgeons from morally and legally having to reconcile them with their ordinary duty of care. Ultimately, this can only be done through arguing that such omissions to sustain life are in the patient's best interests.

A Jehovah's Witness is a member of a millenarian fundamentalist Christian sect founded in America in 1884. They have their own translation of the Bible which they interpret literally.

The determination of best interests in these circumstances will rely on one of three objective criteria, over and above the subjective perception by the surgeon that the quality of life of the patient is poor. There is no obligation to provide or to continue life-sustaining treatment:

- If doing so is futile – when clinical consensus dictates that it will not achieve the goal of extending life. Thought of in this way, judgements about futility should not be linked to evaluations of a patient's quality of life and thus can be difficult to justify as long as treatment might stand even a very small chance of success.
- If patients are imminently and irreversibly close to death – in such circumstances, it would not be in the patient's best interests to prolong life slightly (e.g. through the application of intensive care) when, again, there is no hope of any sustained success. Not needlessly interfering with the process of a dignified death can be just as caring as the provision of curative therapy.
- If patients are so permanently and seriously brain damaged that, lacking awareness of themselves or others, they will never be able to engage in any form of self-directed activity. The argument here is backed up by morally and legally reasoning that further treatment other than effective palliation cannot be in the best interests of patients as it will provide them with no benefit.

When any of these principles are employed to justify an omission to provide or to continue life-sustaining treatment, the circumstances should be carefully recorded in the patient's medical record, along with a note of another senior clinician's agreement.

Finally, surgeons will sometimes find themselves in charge of the palliative care of patients whose pain is increasingly difficult to control. There may come a point in the management of such pain when effective palliation is possible at the risk of life because of the respiratory effects of the palliative drugs. In such circumstances, surgeons can with legal justification administer a dose that might be dangerous, although experts in palliative care are sceptical that this is ever necessary with appropriate training. In any case, the argument employed to justify such action refers to its 'double effect': that both the relief of pain and death might follow from such an action. As intentional killing (active euthanasia) is rejected as professional and legal medical practice throughout most of the world, a potentially lethal dose is regarded as appropriate only when it is motivated by palliative intent and this motivation can be documented.

CONFIDENTIALITY

Respect for autonomy does not entail only the right of competent patients to consent to treatment. Their entitlement to exercise control over their life and future corresponds to the duty of surgeons to respect their privacy – not to communicate information revealed in the course of treatment to anyone else without consent. Generally speaking, such respect means that surgeons must not discuss clinical matters with relatives, friends, employers and others unless the patient explicitly agrees. To do otherwise is regarded by all the regulatory bodies of medicine and surgery as a grave offence, incurring harsh penalties. For breaches of confidentiality are not only abuses of human dignity; they again undermine the trust between surgeon and

patient on which successful surgery and the professional reputations of surgeons depend.

Important as respect for confidentiality is, however, it is not absolute. Surgeons are allowed to communicate private information to other professionals who are part of the health-care team – provided that the information has a direct bearing on treatment. Here, the argument is that patients have given their implied consent to such communication when they explicitly consent to a treatment plan. Certainly, patients cannot expect strict adherence to the principle of confidentiality if it poses a serious threat to the health and safety of others. There will be some circumstances in which confidentiality either must or may be breached in the public interest. For example, it must be breached as a result of court orders or in relation to the requirements of public health legislation. It may be ignored in attempts to prevent serious crime or to protect the safety of other known individuals who are at risk of serious harm.

RESEARCH

As part of their duty to protect life and health to an acceptable professional standard, surgeons have a subsidiary responsibility to strive to improve operative techniques through research, to assure themselves and their patients that the care proposed is the best that is currently possible. Yet, there is moral tension between the duty to act in the best interests of individual patients and the duty to improve surgical standards through exposing patients to the unknown risks that any form of research inevitably entails.

The willingness to expose patients to such risks may be further increased by the professional and academic pressures on many surgeons to maintain a high research profile in their work. For this reason, surgeons (and physicians, who face the same dilemmas) now accept that their research must be externally regulated to ensure that patients give their informed consent, that any known risks to patients are far outweighed by the potential benefits, and that other forms of protection for the patient are in place (e.g. proper indemnity) in case they are unexpectedly harmed. The administration of such regulation is through research ethics committees, and surgeons should not participate in research that has not been approved by such bodies. Equally, special provisions will apply to research involving incompetent patients who cannot provide consent to participate and research ethics committees will evaluate specific proposals with great care.

In practice, it is not always clear what is to count as surgical research that should be subjected to regulation and what constitutes a minor innovation dictated by the contingencies of a particular clinical situation. Surgeons must always ask themselves in such circumstances whether or not the innovation in question falls within the boundaries of standard procedures in which they are trained. If so, what may be a new technique for them will count not as research but as an incremental improvement in personal practice.

Yet, if the improvement is to be thought of in this way, no conclusions can be drawn from it to alterations in standard practice or to an evaluation of their efficacy. Equally, there will be no consequences for surgical training, as the innovation in question should only have been attempted against the background of the already existing training and experience of the surgeon in question. If a proposed innovation exceeds these conditions, then it does count as research and should be approved by a research

ethics committee. Such surgical research should also be subject to a clinical trial designed to ensure that findings about outcomes are systematically compared with the best available treatment and that favourable results are not the result of arbitrary factors (e.g. unusual surgical skill among researchers) that cannot be replicated.

MAINTAINING STANDARDS OF EXCELLENCE

To optimise success in protecting life and health to an acceptable standard, surgeons must only offer specialised treatment in which they have been properly trained. To do so will entail sustained further education throughout a surgeon's career in the wake of new surgical procedures. While training, surgery should be practised only under appropriate supervision by someone who has appropriate levels of skill. Such skill can be demonstrated only through appropriate clinical audit, to which all surgeons should regularly submit their results. When these reveal unacceptable levels of success, no further surgical work of that kind should continue unless further training is undergone under the supervision of someone whose success rates are satisfactory. To do otherwise would be to place the interest of the surgeon above that of their patient, an imbalance that is never morally or professionally appropriate.

Surgeons also have a duty to monitor the performance of their colleagues. To know that a fellow surgeon is exposing patients to unacceptable levels of potential harm and to do nothing about it is to incur partial responsibility for such harm when it occurs. Surgical teams and the institutions in which they function should have clear protocols for exposing unacceptable professional performance and helping colleagues to understand the danger to which they may expose patients. If necessary, offending surgeons must be stopped from practising until they can undergo further appropriate training and counselling. Too often, such danger has had to be reported by individuals whose anxieties have not been properly heeded and who have been professionally pilloried rather than congratulated for their pains. Surgeons and anyone else discovered to have been participating in such 'cover up' and ostracism should share the blame and punishment for any resulting harm to patients.

CONCLUSION

The two general duties of surgical care are to protect life and health and to respect autonomy, both to an acceptable profes-

sional standard. The specific duties of surgeons are shown to follow from these: acceptable practice concerning informed consent, confidentiality, decisions not to provide, or to omit, life-sustaining care, surgical research and the maintenance of good professional standards. The final duty of surgical care is to exercise all these general and specific responsibilities with fairness and justice, and without arbitrary prejudice. The conduct of ethical surgery illustrates good citizenship: protecting the vulnerable and respecting human dignity and equality. To the extent that the practice of individual surgeons is a reflection of such sustained conduct, they deserve the civil respect which they often receive. To the extent that it is not, they should not practise the honourable profession of surgery.

**Investigation and
diagnosis**

This page intentionally left blank

Diagnostic imaging

LEARNING OBJECTIVES

To understand:

- The advantages of good working relationships and close collaboration with the imaging department in planning appropriate investigations
- The basic principles of radiation protection and know the law in relation to the use of ionising radiation
- The principles of different imaging techniques and their advantages and disadvantages in different clinical scenarios

INTRODUCTION

Appropriate surgical management of the patient relies on correct diagnosis. While clinical symptoms and signs may provide a firm diagnosis in some cases, other conditions will require the use of supplementary investigations including imaging techniques. The number and scope of imaging techniques available to the surgeon have dramatically increased within a generation from a time when radiographs alone were the mainstay of investigation. The development of ultrasound and colour Doppler, computerised tomography (CT) and magnetic resonance imaging (MRI) has enabled the surgeon to make increasingly confident diagnoses and has reduced the need for diagnostic surgical techniques such as explorative laparotomy. Faced with such a plethora of imaging to choose from, it is important that the patient is not sent on a journey through multiple unnecessary examinations.

As a basic principle, the simplest, cheapest test should be chosen that it is hoped will answer the clinical question. This necessitates knowledge of the potential complications and diagnostic limitations of the various methods. For example, in a patient presenting with the clinical features of biliary colic, an ultrasound examination alone may give enough information to enable appropriate surgical management. In more complex cases, it may be more efficient to opt for a single, more expensive investigation such as CT rather than embarking on multiple simpler and cheaper investigations that may not yield the answer. The choice of technique is often dictated by equipment availability, expertise and cost as well as the clinical presentation. However, it must be emphasised that, not infrequently, the most valuable investigation is a prior radiograph; this not only reduces the cost and the amount of radiation a patient receives but very often improves patient care.

HOW TO REQUEST IMAGING

Best practice depends on close collaboration between the radiologist and the referrer and must take into account local expertise

and access to facilities. The start of this important communication is most often the 'request card' (Summary box 10.1).

Summary box 10.1

Imaging request card

The important details are:

- name
- date of birth
- hospital number or other unique identifier code
- address and post code – the post code is often the key to patient administration system (PAS) databases
- patient's telephone number (enables quick contact)
- weight (obese patients may not be safe in a scanner or the table may not be able to accommodate their weight)
- in the case of female patients, the date of the last menses if the woman has not been sterilised (important for all radiation procedures and MRI to exclude the possibility of pregnancy)
- other relevant past medical history, i.e. diabetes, epilepsy, renal failure, allergies and anticoagulation, all of which can affect which contrast agent can be given safely
- the name of the clinician who is in charge of care and of the requesting clinician, with a legible contact number
- the most recent creatinine result if contrast agents are to be employed

Fortunately, electronic requesting via a radiology information system (RIS) allows the demographic data for a patient to be stored electronically and should make the requesting process easier.

When requesting imaging, consider what it is that you want to know from the investigation. Give a provisional diagnosis or state the clinical problem. For plain film radiography, it is best to allow the radiographer to decide on the best views. For more complex investigations, such as multidetector CT or MRI, the radiologist will protocol the examination in order to optimise the chance of

a useful answer from the test. If you are unsure of the best method to answer the clinical problem, discuss with a radiologist.

INTERPRETING IMAGES

Highly complex imaging should be left to radiologists to interpret, but the clinician should be able to examine radiographs to exclude major abnormalities. The plain radiograph can be systematically examined using the system in Summary box 10.2.

Summary box 10.2

A simple system for checking radiographs

Label	Name of patient
Site	Date of examination Side (check marker) What part is the film centred on? Does the film cover the whole area required? Is there more than one view?
Quality	Is the penetration appropriate?
Compare	How have the appearances changed from previous images?
Conclude	Is the diagnosis clear? Is further imaging needed?

The systematic approach to examining a radiograph varies according to the part of the body being imaged. For instance, for a radiograph of an extremity, the alignment, the cortices and the medullary cavity of the individual bones, the joints and the soft tissues all need to be assessed on each view. You should develop, learn and practise your own method for ensuring that you study all of these in each case. This will take a long time when you start, but speed comes with practice.

Some abnormalities on the radiograph may prompt you to look at other areas of the film or may require an additional view to be taken. This knowledge can only be attained by reading and experience! Do not forget that radiologists are always delighted to help you with interpreting a film; they are not so happy when they have to report that an incorrect conclusion has been drawn.

HAZARDS OF IMAGING

Contrast media

There has been a dramatic increase in the use of contrast agents in recent years, mainly related to the increasing use of CT. Potential problems include allergic reaction and nephrotoxicity. The newer low-osmolality contrast media (LOCM) are 5–10 times safer than the older higher-osmolality agents. Reactions are rare: serious reactions occur in about 1:2500 cases and life-threatening reactions in about 1:25 000 cases. The risk of sudden death, however, has not changed with the new agents. Local policies for dealing with patients at increased risk vary between departments and, indeed, between countries. A recent publication from the Royal College of Radiologists (RCR) in the UK does not recommend routine steroid prophylaxis for patients at increased risk of allergic reaction, but rather the use of a LOCM and observation of the patient for 30 min after injection with the intravenous cannula still *in situ*, as most serious reactions occur

shortly after injection. Guidelines from the European Society of Uroradiology (ESUR), however, continue to advocate the use of steroids.

In patients with diabetes or renal impairment, a recent creatinine level should be available. The radiologist should be informed of any history of renal impairment, as all contrast media are nephrotoxic in patients with impaired renal function. The risks and benefits of contrast administration need to be carefully assessed in these patients and, if contrast is given, the lowest dose of a LOCM should be given. The British RCR does not recommend the routine use of *N*-acetylcysteine for renal protection.

Concerns about lactic acidosis in patients on metformin receiving contrast led to various recommendations for stopping the metformin. The latest RCR recommendations are that it can be continued in patients receiving 100 ml or less of intravenous contrast who are thought to have normal renal function. Other patients, including those who have intra-arterial contrast for angiography, should be discussed with the radiologist.

Allergic reactions to gadolinium diethyltriaminepentaacetic acid (DTPA) injection are rare, and gadolinium DTPA has been used as an alternative contrast agent in patients with iodine allergy. Mild reactions may occur in around 1:200 patients, with severe reactions in around 1:10 000 patients. Gadolinium DTPA has also been found to be nephrotoxic in patients with pre-existing renal failure. In addition, there have been some worrying reports of an association between gadolinium DTPA injection and the development of nephrogenic fibrosing dermopathy in patients with renal impairment.

HAZARDS OF IONISING RADIATION

The majority of ionising radiation comes from natural sources on the earth and cosmic rays, and this makes up the background radiation. However, medical exposure accounts for 12% of the total received by humans. The effects of ionising radiation can be broadly divided into two groups. The first group comprises predictable, dose-dependent (termed deterministic or non-stochastic) effects and includes, for example, the development of cataracts in the lens of the eye. These effects are important for those chronically exposed to radiation, including those using image intensifiers regularly. The second group comprises the all or nothing effects such as the development of cancer (termed stochastic). These effects are not dose dependent, but increase in likelihood with increased radiation dose.

The risk of radiation-induced cancer for plain films of the chest or extremities is very small, of the order of 1:1 000 000. However, that risk rises considerably for high-dose examinations such as CT of the abdomen or pelvis, where the lifetime excess risk of cancer increases to the order of 1:1000. Obviously, the risk of such examinations has to be balanced against the benefit to the patient in terms of increased diagnostic yield, and must also be viewed in the context that the lifetime risk of cancer for people generally is about 1:3. Nevertheless, techniques that do not use ionising radiation, such as ultrasound and MRI, should be carefully considered as alternatives, particularly in children and young people.

CURRENT LEGISLATION

In the UK, the Ionising Radiation (Medical Exposure) Regulations (IRMER) introduced in 2000 impose on the radiologist

the duty to the patient to make sure that all studies involving radiation (plain radiographs, CT and nuclear medicine) are performed appropriately and to the highest standards. Inappropriate use of radiation is a criminal offence, so investigations involving radiation need careful consideration in order to prevent wasteful use of radiology (Summary box 10.3).

Summary box 10.3

Wasteful use of radiology

Results unlikely to affect patient management	
Positive finding unlikely	
Anticipated finding probably irrelevant for management	Do I need it?
Investigating too often	
Before disease could be expected to have progressed or resolved	Do I need it now?
Repeating investigations done previously	
Other hospital (?)	
GP (?)	Has it been done already?
Failing to provide adequate information	
Therefore wrong test performed or essential view omitted	Have I explained the problem?
Requesting wrong investigation	
Discuss with radiologist	Is this the best test?
Overinvestigating	Are too many investigations being performed?

After: *Making the Best Use of a Department of Clinical Radiology*, 5th edn. Royal College of Radiologists, 2003.

Summary box 10.4 gives a summary of the responsibilities of both the radiologist and the referrer.

Summary box 10.4

Responsibilities

- Radiologists have a legal responsibility to keep imaging as safe as possible
- The referrer has a duty to balance risk against benefit
- The referrer must provide adequate clinical details to allow justification of the examination
- Avoid using portable (mobile) X-ray machines whenever practical
- Take all precautions when using an image intensifier
- The gonads, eyes and thyroid are especially vulnerable to radiation and should be protected

The Royal College of Radiologists has published a book, *Making the Best Use of a Department of Clinical Radiology* (5th edition, 2003), which has been adopted in many European countries. Local rules and guidelines are in place to deal with particular circumstances. Table 10.1, showing the radiation doses for common procedures, is taken from this publication.

There are special considerations for portable and fluoroscopy units. The longer an operator keeps the fluoroscopy unit running,

the higher the dose of radiation to all in the vicinity. Portable X-ray machines and fluoroscopic imaging equipment use much more radiation to achieve the same result. The staff, and patients in the next bed, are at risk when portable equipment is used. The result is also of lower quality, so portable X-ray machines should not be used unless absolutely necessary.

When using the image intensifier, lead aprons, thyroid shields, lead glasses and radiation badges should always be worn. Pregnancy in the female patient or staff must be excluded.

DIAGNOSTIC IMAGING

Basic principles of imaging methods

Conventional radiography

Despite the fact that it is over a hundred years since the discovery of X-rays by Roentgen in 1895, conventional radiography continues to play a central role in the diagnostic pathway of many acute surgical problems and particularly in chest disease, trauma and orthopaedics.

X-rays emitted from an X-ray source are absorbed to varying degrees by different materials and tissues and therefore cause different degrees of blackening of radiographic film, resulting in a radiographic image. This differential absorption is dependent partly on the density and the atomic number of different substances. In general, higher-density tissues result in a greater reduction in the number of X-ray photons and reduce the amount of blackening caused by those photons. In terms of conventional radiographs, a large difference in tissue structure and density is required before an appreciable difference is manifested radiographically. The different densities visible consist of air, fat, soft tissue, bone and mineralisation, and metal. Different soft tissues cannot be reliably distinguished as, in broad terms, they possess similar quantities of water (Fig. 10.1). Manipulation of X-ray systems and X-ray energies, as used in circumstances such as

Figure 10.1 Supine abdominal radiograph of a patient with small bowel obstruction demonstrating multiple dilated small bowel loops. The different densities visible are air (within the bowel), bones, soft tissues and fat. The different soft tissues, subcutaneous and intra-abdominal, cannot be differentiated.

Wilhelm Conrad Roentgen, 1845–1923, Professor of Physics, Wurtzburg, (1888–1900), and then at Munich, Germany. He was awarded the Nobel Prize for Physics in 1901 for his work on X-rays.

Table 10.1 Typical effective doses from diagnostic medical exposure in the 2000s

Diagnostic procedure	Typical effective dose (mSv)	Equivalent no. of chest radiographs	Approximately equivalent period of natural background radiation ^a
<i>Radiographic examinations</i>			
Limbs and joints (except hip)	< 0.01	< 0.5	< 1.5 days
Chest (single posteroanterior film)	0.02	1	3 days
Skull	0.07	3.5	11 days
Thoracic spine	0.7	35	4 months
Lumbar spine	1.3	65	7 months
Hip	0.3	15	7 weeks
Pelvis	0.7	35	4 months
Abdomen	1.0	50	6 months
Intravenous urography (IVU)	2.5	125	14 months
Barium swallow	1.5	75	8 months
Barium meal	3	150	16 months
Barium follow-through	3	150	16 months
Barium enema	7	350	3.2 years
CT head	2.3	115	1 year
CT chest	8	400	3.6 years
CT abdomen or pelvis	10	500	4.5 years
<i>Radionuclide studies</i>			
Lung ventilation (¹³³ Xe)	0.3	15	7 weeks
Lung perfusion (^{99m} Tc)	1	50	6 months
Kidney (^{99m} Tc)	1	50	6 months
Thyroid (^{99m} Tc)	1	50	6 months
Bone (^{99m} Tc)	4	200	1.8 years
Dynamic cardiac (^{99m} Tc)	6	300	2.7 years
PET head (18F-FDG)	5	250	2.3 years

^a UK average background radiation = 2.2 mSv per year; regional averages range from 1.5 to 7.5 mSv. 18F-FDG, 18F-2-fluoro-2-deoxy-D-glucose; CT, computerised tomography; ^{99m}Tc, ^{99m}technetium; PET, positron emission tomography. From: *Making the Best Use of a Department of Clinical Radiology*, 5th edn. Royal College of Radiologists, 2003. By kind permission.

mammography, may allow better differentiation between some soft-tissue structures.

Despite this inherent lack of soft-tissue contrast, conventional radiography has many advantages. It is cheap, universally available, easily reproducible and comparable with prior examinations and, in many instances, has a relatively low dose of ionising radiation in contrast to more complex examinations. However, injudicious repeat radiography, particularly of the abdomen, pelvis and spine, can easily result in doses similar to CT.

The lack of soft-tissue contrast allows little assessment of the internal architecture of many abdominal organs. To obviate this problem, techniques employing the administration of contrast material combined with radiography have long been used. These techniques include intravenous urography and barium examinations (Fig. 10.2). In intravenous urography (IVU), intravenous administration of iodinated contrast material initially results in opacification of the renal parenchyma, followed by opacification of the pelvicalyceal system, ureters and bladder, allowing identification of pelvicalyceal morphology and filling defects (Fig. 10.3). Iodinated contrast material may even be instilled retrogradely into the bladder per urethra and combined with radiographs obtained during micturition to allow the assessment of the lower urinary tract.

A further modification of conventional X-rays uses fluorescent screens to allow real-time monitoring of organs and structures as opposed to the 'snapshot' images obtained with radiographs. This

is used to follow the passage of barium through the bowel, obtaining dedicated images at specific points of interest only. Motility of the bowel can also be assessed in this way. Fluoroscopy is used extensively in interventional radiology and, in particular, in vascular intervention by allowing real-time assessment of the passage of intravascular iodinated contrast and the acquisition of multiple images per second to diagnose intravascular lesions and to guide treatment. Naturally, with the more sustained use of

Figure 10.2 Barium examination of the small bowel demonstrates a focal short segment stricture of the distal ileum in a patient with Crohn's disease.

Figure 10.3 Intravenous urogram in a patient with macroscopic haematuria. There are focal irregular filling defects in the left side of the bladder and the right renal pelvis, consistent with multifocal transitional cell carcinomas.

ionising radiation, the cumulative doses tend to be greater than obtaining a conventional radiograph.

Ultrasound

Ultrasound is the second commonest method of imaging. It relies on high-frequency sound waves generated by a transducer containing piezoelectric material. The generated sound waves are reflected by tissue interfaces and, by ascertaining the time taken for a pulse to return and the direction of a pulse, it is possible to form an image. Medical ultrasound uses frequencies in the range 3–20 MHz. The higher the frequency of the ultrasound wave, the greater the resolution of the image, but the less depth of view from the skin. Consequently, abdominal imaging uses transducers with a frequency of 3–7 MHz, while higher-frequency transducers are used for superficial structures, such as musculoskeletal and breast ultrasound. Dedicated transducers have also been developed for endocavitary ultrasound such as transvaginal scan-

Figure 10.4 Longitudinal transvaginal ultrasound scan of the uterus demonstrating thickening of the endometrium in a patient during the secretory phase of the menstrual cycle.

ning and transrectal ultrasound of the prostate, allowing high-frequency scanning of organs by reducing the distance between the probe and the organ of interest (Fig. 10.4). A further application of dedicated probes has been in the field of endoscopic ultrasound, allowing exquisite imaging of the wall of a hollow viscus and the adjacent organs such as the gastric wall and the pancreas.

Reflection of an ultrasound wave from moving objects such as red blood cells causes a change in the frequency of the ultrasound wave. By measuring this frequency change, it is possible to calculate the speed and direction of the movement. This principle forms the basis of Doppler ultrasound, whereby velocities within major vessels as well as smaller vessels in organs such as the liver and the kidneys can be measured. Doppler imaging is widely used in the assessment of arterial and venous disease, in which stenotic lesions cause an alteration in the normal velocity. Furthermore, diffuse parenchymal diseases such as cirrhosis may cause an alteration in the normal Doppler signal of the affected organ.

The advantages of ultrasound are that it is cheap and easily available. It is the first-line investigation of choice for assessment of the liver, the biliary tree and the renal tract (Figs 10.5 and 10.6). Ultrasound is also the imaging method of choice in obstetric assessment and gynaecological disease. High-frequency transducers have made ultrasound the best imaging technique for the evaluation of thyroid and testicular disorders in terms of both diffuse disease and focal mass lesions. It is also an invaluable tool for guiding needle placement in interventional procedures such as biopsies and drainages, allowing direct real-time visualisation of the needle during the procedure.

Ligament, tendon and muscle injuries are also probably best imaged in the first instance by ultrasound (Fig. 10.7). The ability to stress ligaments and to allow tendons to move during the investigation gives an extra dimension, which greatly improves its diagnostic value. The use of 'panoramic' or 'extended field of view' ultrasound (Fig. 10.8) provides images that are more easily interpreted by an observer not performing the examination, and are of particular assistance to surgeons planning a procedure.

Figure 10.5 Transverse ultrasound image of the liver in a patient with colorectal cancer shows a solitary liver metastasis.

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler Principle' in 1842.

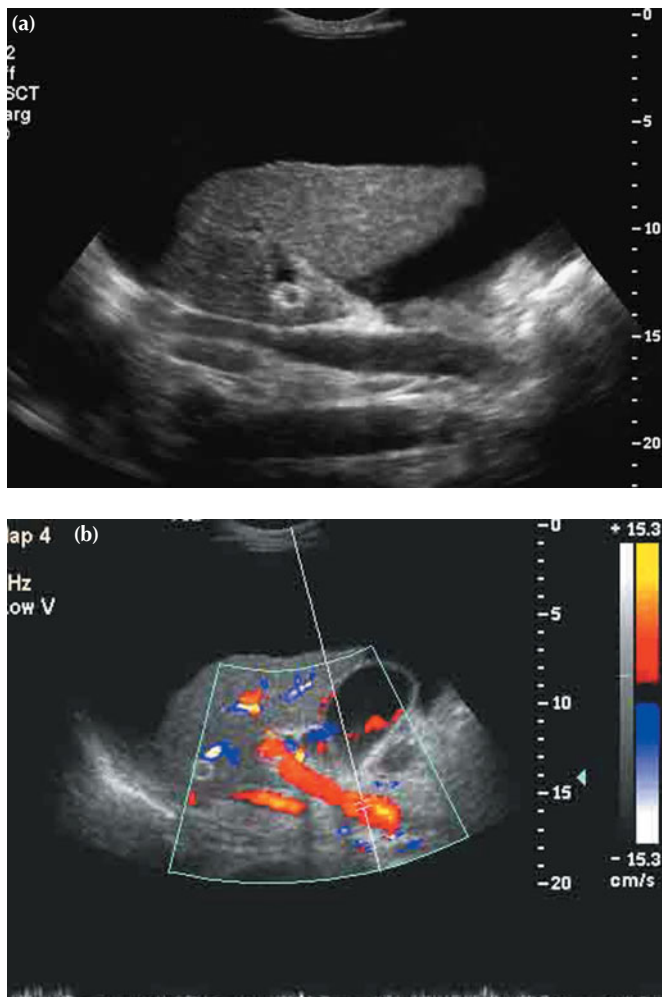

Figure 10.6 Sagittal ultrasound image of the liver (a) in a patient with cirrhosis demonstrates nodularity of the liver surface and extensive ascites. Doppler ultrasound (b) illustrates portal vein flow with a normal direction.

Figure 10.7 Ultrasound of the dorsal surface of the wrist shows the normal fibrillar pattern of the extensor tendons. There is increased fluid within the tendon sheath in this patient with extensor tenosynovitis.

Ultrasound will demonstrate most foreign bodies in soft tissues, including those that are not radio-opaque.

The disadvantages of ultrasound are that it is highly operator dependent, and most of the information is gained during the actual process of scanning as opposed to reviewing the static images. Another drawback is that the ultrasound wave is highly attenuated by air and bone and, thus, little information is gained with regard to tissues beyond bony or air-filled structures; alternative techniques may be required to image these areas (Summary box 10.5).

Summary box 10.5

Ultrasound

Strengths

- No radiation
- Inexpensive
- Allows interaction with patients
- Superb soft-tissue resolution in the near field
- Dynamic studies can be performed
- First-line investigation for hepatic, biliary and renal disease
- Endocavitary ultrasound for gynaecological and prostate disorders
- Excellent resolution for breast, thyroid and testis imaging
- Good for soft tissue, including tendons and ligaments
- Excellent for cysts and foreign bodies
- Doppler studies allow assessment of blood flow

Weaknesses

- Interpretation only possible during the examination
- Long learning curve for some areas of expertise
- Resolution dependent on the machine available
- Images cannot be reliably reviewed away from the patient

Computerised tomography

There has been a great deal of development in CT technology over the last 30 years from the initial conventional CT scanners through to helical or spiral scanners and the current multi-detector machines. CT scanners consist of a gantry containing the X-ray tube, filters and detectors, which revolve around the patient, acquiring information at different angles and projections. This information is then mathematically reconstructed to produce a two-dimensional grey-scale image of a slice through the body. This technique overcomes the problem of superimposition

Figure 10.8 Panoramic ultrasound of the calf. The normal muscle fibres and the fascia can be identified over an area measuring approximately 12 cm.

of different structures, which is inherent in conventional radiography. Improvements in gantry design, advances in detector technology using more sensitive detectors and an increase in the number of detectors have resulted in an increase in spatial resolution as well as the speed at which the images are acquired. In early CT scanners, the table on which the patient was positioned moved in between the gantry revolution to allow imaging of an adjacent slice. Modern scanners allow for continuous movement of the table and the patient during the gantry revolution, thus greatly reducing the scan time. With modern equipment, it is now not only possible to obtain images of the chest, abdomen and pelvis in under 20 s, but these axial images can be reformatted in multiple planes with practically no degradation in image quality.

In addition, CT has a far higher contrast resolution than plain radiographs, allowing the assessment of tissues with similar attenuation characteristics. As with radiographs, the natural contrast of tissues is further augmented by the use of intravenous contrast medium. Rapid scanning of a volume of tissue also allows the scans to be performed at different phases of enhancement, which is advantageous in identifying different diseases. For instance, very early scanning during the arterial phase is ideally suited to the examination of the arterial tree and hypervascular liver lesions, whereas scanning performed after a delay may be better suited to the identification of other solid organ pathology such as renal masses. Furthermore, it is possible to obtain scans during several phases including the arterial and venous phases in the same patient, which may aid in the identification and characterisation of lesions.

CT is widely used in thoracic, abdominal (Fig. 10.9), neurological (Fig. 10.10), musculoskeletal (Fig. 10.11) and trauma imaging. The thinner collimation and improved spatial resolution have also resulted in the development of newer techniques such as CT angiography, virtual colonoscopy and virtual bronchoscopy. Furthermore, three-dimensional images can be reconstructed from the raw data to aid in surgical planning. The disadvantage of CT compared with ultrasound and conventional radiography lies largely in the increased costs and the far higher doses of ionising radiation. For instance, a CT scan of the abdomen and pelvis has a radiation dose equivalent to approximately 500 chest radiographs (Summary box 10.6).

Summary box 10.6

Computerised tomography

Strengths

- High spatial and contrast resolution
- Contrast resolution enhanced by imaging in arterial and/or venous phases
- Rapid acquisition of images in one breath-hold
- Imaging of choice for the detection of pulmonary masses
- Allows global assessment of the abdomen and pelvis
- Excellent for liver, pancreatic, renal and bowel pathology
- Three-dimensional reconstruction allows complex fracture imaging
- Multiplanar reconstruction and three-dimensional imaging, e.g. CT angiography and colonoscopy

Weaknesses

- High radiation dose
- Poor soft-tissue resolution of the peripheries and superficial structures
- Patient needs to be able to lie flat and still

Figure 10.9 Axial computerised tomography scan through the pelvis with oral contrast administration illustrates loops of distal ileum with mural thickening in a patient with Crohn's disease.

Magnetic resonance imaging

Over the last 20 years, MRI has become an integral part of the imaging arsenal with ever-expanding indications. MRI relies on the fact that nuclei containing an odd number of protons or electrons have a characteristic motion in a magnetic field (precession) and produce a magnetic moment as a result of this motion. In a strong uniform magnetic field such as a MRI scanner, these nuclei align themselves with the main magnetic field and result in a net magnetic moment. A brief radiofrequency pulse is then applied to alter the motion of the nuclei. Once the radiofrequency pulse is removed, the nuclei realign themselves with the main magnetic field (relaxation) and in the process emit a radiofrequency signal that can be recorded, spatially encoded and used to construct a grey-scale image. The specific tissue characteristics define the manner and rate at which the nuclei relax. This relaxation is measured in two ways, referred to as the T1 and T2 relaxation times. The relaxation times and the proton density determine the signal from a specific tissue.

Figure 10.10 Axial computerised tomography scan of the head following intravenous contrast demonstrates a large mass lesion in the left frontal region in a patient with a large left frontal meningioma.

Figure 10.11 Coronal computerised tomography (a) and axial reformat (b) of the foot in a patient involved in a road traffic accident demonstrates Lisfranc fracture dislocation with a comminuted fracture of the base of the second metatarsal.

There are a large number of imaging sequences that can be used by applying radiofrequency pulses of different strengths and durations. The image characteristic and signal intensity from different tissues is governed by the pulse sequence employed and whether it is T1 weighted or T2 weighted. For instance, fat, methaemoglobin and mucinous fluid are bright on T1-weighted images, whereas water and thus most pathological processes, which tend to increase tissue water content, are bright on T2-weighted images. Cortical bone, air, haemosiderin and ferromagnetic materials are of very low signal on all pulse sequences. In general, T1-weighted images are superior in the delineation of anatomy, while T2-weighted images tend to highlight pathology better. For added tissue contrast, intravenous gadolinium may be

Jacques Lisfranc de St. Martin, 1790–1847, Professor of Surgery and Operative Medicine, Paris, France.

administered. Other more specific contrast media are also available for liver, bowel and lymph node imaging.

MRI's exquisite contrast resolution, coupled with a lack of ionising radiation, is very attractive in imaging, particularly of tissues that have relatively little natural contrast. MRI also has the advantage of multiplanar imaging, as images can be acquired in any plane prescribed. It has traditionally been used extensively in the assessment of intracranial, spinal and musculoskeletal disorders (Figs 10.12–10.14), allowing a global assessment of bony and soft-tissue structures. More recent developments have resulted in new indications and applications. Today, MRI is commonly used in oncological imaging such as staging of rectal carcinoma and gynaecological malignancies, characterisation and identification of hepatic masses, assessment of the biliary tree [magnetic resonance

Figure 10.12 T2-weighted axial magnetic resonance imaging scan of the head in a patient with a large left-sided oligodendroglioma.

Figure 10.13 Sagittal T2-weighted magnetic resonance imaging scan of the lumbar spine demonstrates disc herniation in a patient with acute back pain.

Figure 10.14 Coronal magnetic resonance imaging scan of the knee demonstrating extensive serpiginous areas of altered signal intensity in the distal femur and proximal tibia in a patient with bone infarcts secondary to oral corticosteroids.

cholangiopancreatography (MRCP) (Fig. 10.15)] and cardiac imaging. Techniques have also been developed which allow non-invasive angiography of the cranial and peripheral circulation (MR angiography) (Fig. 10.16).

However, the availability of MRI is still relatively limited in comparison with other imaging techniques, and it is time-consuming with respect to image acquisition and interpretation. Images are easily degraded by motion, including respiratory and cardiac motion. The use of respiratory and cardiac gating can minimise this, although bowel peristalsis can still be a problem. The long acquisition times require a cooperative patient who can lie very still, which can be difficult especially in claustrophobic individuals or those in pain. Furthermore, because of the use of high-strength magnetic fields, patients with some metallic implants, such as some aneurysm clips and prosthetic heart

Figure 10.15 Magnetic resonance cholangiopancreatography demonstrating dilated central intrahepatic bile ducts and a stricture of the common bile duct in a patient with obstructive jaundice and cholangiocarcinoma.

Figure 10.16 Maximum intensity projection image from a magnetic resonance angiogram demonstrating the abdominal aorta, common and external iliac arteries as well as parts of the pulmonary, mesenteric and renal vasculature.

valves, and those with implanted electronic devices such as pacemakers and defibrillators, cannot be examined. Some newer implants may, however, be MRI compatible, and patients with joint replacements can be studied safely (Summary box 10.7).

Summary box 10.7

Magnetic resonance imaging

Strengths

- No ionising radiation
- Excellent soft-tissue contrast
- Best imaging technique for
 - Intracranial lesions
 - Spine
 - Bone marrow and joint lesions

Evolving use

- Staging
- MRCP
- MR angiography
- Breast malignancy
- Pelvic malignancy
- Cardiac imaging

Weaknesses

- Absolute contraindications
 - Ocular metallic foreign bodies
 - Pacemakers
 - Cochlear implants
 - Cranial aneurysm clips
- Relative contraindications
 - First trimester of pregnancy
 - Claustrophobia

Long scan times so patients may not be able to keep still, especially if in pain

Limited availability

Expensive

Nuclear medicine

In other imaging techniques using ionising radiation such as CT and conventional radiography, the individual is exposed to ionising radiation from an external source and the radiation transmitted through the patient is recorded. In nuclear medicine, however, a radioactive element or radionuclide such as technetium, gallium, thallium or iodine is administered to the patient as part of a radiopharmaceutical agent, and a detector such as a gamma camera is then used to record and localise the emission from the patient, thus forming the image. The radionuclide is chosen and coupled with other compounds such that it is distributed and taken up in the tissues of interest. Therefore, a variety of radionuclides are required for imaging of different tissues. Nuclear medicine also differs from other means of imaging, which are largely anatomically based, as it also provides functional information.

Radionuclide imaging is widely used in bone imaging with very

high sensitivity for assessing metastatic disease, metabolic bone disease, established arthropathies and occult infection and traumatic injuries (Fig. 10.17), although many of these applications are being replaced by MRI. In genitourinary disease, dynamic imaging can be performed to assess renal perfusion and function including obstruction, investigate renovascular hypertension and evaluate renal transplants. Radionuclide imaging is also commonly used in thyroid and parathyroid disorders, ischaemic cardiac disease, detection of pulmonary emboli and assessment of occult infection and inflammatory bowel disease.

Positron emission tomography (PET) is an extension of nuclear medicine, in which a positron-emitting substance such as ^{18}F is tagged and used to assess tissue metabolic characteristics. The most commonly used radiolabelled tracer is ^{18}F -2-fluoro-2-deoxy-D-glucose (FDG), although other tracers can also be used in order to assess metabolic functions such as oxygen and glucose consumption and blood flow. Radioisotope decay

Figure 10.17 Bone scintigraphy in a patient with carcinoma of the breast illustrating bony metastatic deposits involving multiple vertebrae, the skull, pelvis and ribs.

causes the emission of a positron, which subsequently, within a few millimetres, collides with and annihilates an electron to produce a pair of annihilation photons. The drawbacks have been high cost, very limited availability and relatively low spatial resolution. The last of these has been addressed by PET/CT systems combining simultaneous PET imaging and CT, allowing the two sets of images to be registered so that the anatomical location of the abnormality can be localised more precisely (Summary box 10.8).

Summary box 10.8

Radionuclide imaging

Strengths

- Allows functional imaging
- Allows imaging of the whole body
- Bone scan has a high sensitivity for metastatic bone disease, fractures and infection
- PET scanning is valuable in the detection of metastatic cancer

Weaknesses

- Specific agents are required for specific indications
- Often non-specific and an abnormal result may require further imaging
- Generally poor spatial resolution

IMAGING IN ORTHOPAEDIC SURGERY

Introduction

Imaging is an intricate part of musculoskeletal diagnosis, and image-guided, minimally invasive techniques also play a major role in treatment. In broad terms, radiographs are the best method of looking for bony lesions or injuries, MRI shows bone marrow disease, muscle tendon and soft-tissue disorders, and ultrasound has better resolution than MRI for small structures, with the added advantage of showing dynamic changes. CT enables visualisation of the fine detail of bony structures, clarifying abnormalities seen on plain radiographs (Summary box 10.9).

Summary box 10.9

Types of imaging

- Radiographs are the best first-line test for bone lesions and fractures
- MRI is good for diagnosing bone marrow disease, occult fractures and tendon and soft-tissue disorders
- CT enables visualisation of the fine detail of bony structures
- CT gives the best three-dimensional information on fractures
- Ultrasound has better resolution in accessible soft tissues and can be used dynamically
- Ultrasound is the best method of distinguishing solid from cystic lesions
- Ultrasound is the only method for locating non-metallic foreign bodies
- Ultrasound is the best method for detecting muscle hernias

There are occasions when a combination of techniques will be important, and due consideration should be given to reducing the ionising radiation burden to the patient, using ultrasound and MRI as primary investigations whenever appropriate.

Skeletal trauma

Musculoskeletal trauma is best imaged by an initial plain radiograph. All skeletal radiographs should be taken from two different angles, usually at right angles to each other. This is important in trauma because a fracture or dislocation may not be visible on a single view (Fig. 10.18). Occasionally, and in specific locations such as the scaphoid, more than two views are routinely performed. If this fails to make a clear diagnosis, or if there is suspicion of soft-tissue injuries, then cross-sectional studies are indicated.

In the spine, CT is a normal second-line investigation, but this is best performed with reference to good-quality radiographs, including oblique views if necessary (Summary box 10.10).

Figure 10.18 Anteroposterior radiograph of the wrist (a) in a patient following a fall does not show an acute bony injury. It is only on the second view (b) that a fracture of the dorsal cortex of the distal radius is visualised.

Summary box 10.10

Trauma imaging

- Initial imaging is radiography
- At least two views are needed
- Use CT for spine, intra-articular or occult fractures

Axial CT images alone may fail to diagnose some fractures, so three-dimensional reformatting is important to prevent errors. Sections should be thin, but care must be taken not to cover too wide an area, as the radiation burden may be excessive, particularly with multislice CT.

Degenerative disease

Synovitis

Radiographs are usually the first-line imaging investigation performed for the examination of joints. Typical changes of a degenerative or an erosive arthropathy are well known and understood. However, early arthropathy will be missed on radiographs and, with the advent of disease-modifying drugs, it is important to detect early synovitis before it is even apparent on clinical examination. Gadolinium DTPA-enhanced MRI is the most sensitive method for detecting synovial thickening of numerous joints, but ultrasound is also sensitive, albeit more laborious to perform. Ultrasound shows effusions and synovial thickening clearly, and shows the increased blood flow around the affected joints without the use of contrast agents (Figs 10.19 and 10.20).

Articular cartilage damage

Articular surface disease is difficult to detect using non-invasive techniques. MRI is probably the best method, although it is not sensitive to early chondral changes (Fig. 10.21) Higher field strength magnets (3 Tesla and above) with dedicated surface coils provide more precise assessment; however, MR arthrography is currently the imaging 'gold standard'. Saline mixed with a dilute

Figure 10.19 Axial T2-weighted fat-suppressed image of the wrist in a patient with rheumatoid arthritis demonstrating synovitis manifested as increased signal dorsal to the carpal bones.

Figure 10.20 Ultrasound of the wrist (a) shows thickening of tissues on the dorsal aspect of the radiocarpal joint. (b) There is increased flow on power Doppler ultrasound in this patient with wrist synovitis and rheumatoid arthritis.

quantity of gadolinium DTPA is introduced into the joint by needle puncture, which is followed by an MRI examination. Using this technique, more subtle changes in the articular surface can be seen, including thinning, fissuring and ulceration. However, early softening of articular cartilage will not be visible. MR

Figure 10.21 Coronal magnetic resonance imaging of the knee demonstrates a focal osteochondral abnormality of the medial femoral condyle with full-thickness loss of the articular cartilage and abnormality of the subchondral bone.

arthrography is also useful for detecting labral tears in the shoulder or hip (Fig. 10.22), and in the assessment of patients who have undergone a previous meniscectomy. The triangular fibrocartilage of the wrist is also difficult to assess fully without arthrography (Fig. 10.23).

In the shoulder, rotator cuff trauma and degenerative changes can be studied using ultrasound or MRI. In experienced hands, ultrasound has a higher accuracy rate, because image resolution is better and because the mechanical integrity of the cuff can be tested by dynamically stressing it (Fig. 10.24). MRI has the advantage of being able to show abnormalities in the subcortical bone.

In the majority of arthropathies and degenerative disorders, serial imaging is useful. Changes in films taken weeks or months apart are far easier to see and interpret than from a single snapshot study (Summary box 10.11).

Summary box 10.11

Imaging techniques for joint disease

- Radiographs are good for assessing established articular disease
- Synovitis can be detected using ultrasound or contrast-enhanced MRI
- Early damage to articular cartilage is difficult to image by conventional methods
- Rotator cuff lesions are best studied using ultrasound or MRI
- Destructive lesions are best studied first on plain radiographs
- MRI is best for staging tumours
- Biopsy can be guided by fluoroscopy, CT or ultrasound

Aggressive bone disease

The radiograph is the first imaging technique for destructive lesions in bones. There is considerable experience in the interpretation of these films, especially with regard to whether the lesion is benign or malignant (Fig. 10.25).

Figure 10.22 Coronal oblique T1-weighted fat-suppressed image of the right shoulder following intra-articular injection of diluted gadolinium demonstrates imbibition of the gadolinium mixture into the superior labrum in a patient with superior labrum anterior posterior (SLAP) tear.

Figure 10.23 Coronal T1-weighted fat-suppressed image following injection of diluted gadolinium mixture into the radiocarpal joint shows extension of gadolinium into the distal radioulnar joint through a tear in the triangular fibrocartilage.

Figure 10.24 Ultrasound of the supraspinatus tendon identifies a partial tear of the tendon, which is predominantly articular sided but with a component that is nearly full thickness.

Radiographs are also vital in the assessment of soft-tissue calcification in tumours of muscle, tendon and subcutaneous fat. When a lesion is detected, there needs to be an early decision as to whether this is benign or malignant. If there is a suspicion of malignancy on the radiograph, or any uncertainty, then local staging is indicated. This is best performed by MRI for both bone and soft-tissue lesions (Fig. 10.26). At this stage, it is likely that a biopsy will be indicated, and preferably under image guidance. Soft-tissue and bone biopsy needles may be guided by CT, ultrasound or interventional MRI systems. The route of puncture should avoid vital structures and must be agreed with the surgeon, who will perform local excision if the lesion proves to be malignant. Care should be taken to avoid contaminating other compartments. In all circumstances, samples are best sent for both histopathological and microbiological examination. It may be difficult to tell on imaging whether or not a lesion is infected, and histology often provides a clear diagnosis in inflammatory

Figure 10.25 Anteroposterior (a) and lateral (b) radiographs of the left knee in a young patient with knee pain. There is a mixed lucent and sclerotic lesion of the distal femur with breach of the cortex medially and soft-tissue extension seen anteriorly and posteriorly. The location and appearances are consistent with osteosarcoma.

conditions. Bone scintigraphy is useful in detecting whether a lesion is solitary or multiple, although whole-body MRI is becoming available (Summary box 10.12).

Summary box 10.12

Imaging of aggressive lesions in bone

- Plain radiographs are important as a first investigation
- MRI is best for local staging
- Bone scintigraphy or whole-body MRI for solitary or multiple lesion determination
- CT detects lung metastases
- Fluoroscopy, CT, MRI or ultrasound can be used to guide the biopsy

Mass lesions

Mass lesions in muscle and soft tissue are examined by ultrasound, which can be diagnostic in the majority of cases, thereby

Figure 10.26 Coronal T1- (a) and axial T2-weighted fat-suppressed (b) images through the distal femur of the patient in Figure 10.25 illustrates the bony area involved, the soft-tissue extent of the tumour and the relationship of the neurovascular structures to the mass.

avoiding the need for further imaging. This is most often the case when a lesion is purely cystic and, as most soft-tissue masses are cysts, ultrasound is a very effective screening test. There are occasions when no mass lesion is found at the site of concern, and then reassurance can be offered. If the ultrasound examination is normal, this effectively excludes soft-tissue neoplasia. A reasonable protocol is to perform ultrasound on all palpable 'lesions' to exclude cysts, and on patients without any identifiable mass, and to proceed to MRI only when there is a solid or partly solid element to an unidentifiable lesion. Tumour vascularity is best assessed by Doppler ultrasound. It can be studied by intravenous gadolinium DTPA-enhanced MRI; however, this is a more expensive and invasive technique, providing no more information than Doppler ultrasound (Summary box 10.13).

Summary box 10.13

Imaging of soft-tissue lesions

- Ultrasound is the best for screening; it is often the only imaging required
- MRI is best for local staging and follow-up
- Doppler ultrasound can assess vascularity cheaply and effectively
- Ultrasound is useful for biopsy

Infection

In the early stages of joint infection, the plain films may be normal, but they should still be performed to exclude bony erosions, in case a painful joint is the first sign of an arthropathy. Ultrasound examination is the easiest and most accurate method of assessing joint effusions, although, when an effusion is identified, it is not

possible to discriminate between blood and pus. Aspiration guided by ultrasound is the best method of making this distinction. MRI may be required to assess early articular cartilage and bone involvement.

Radiographs should also be used to examine patients with suspected osteomyelitis. Although they may not detect early infection, they will demonstrate or exclude bony destruction, calcification and sequestrum formation. CT may be needed to give a cross-sectional view, in order to assess the extent of bony sequestrum.

MRI is perhaps the most sensitive method for detecting early disease and is the preferred technique to define the activity and extent of infection, as it shows not only the bony involvement but also the extent of oedema and soft-tissue involvement (Fig. 10.27). Abscesses may be detected or excluded, and subperiosteal oedema is readily visible. MRI can be used as a staging procedure to plan treatment, including surgical intervention.

Figure 10.27 (a) The plain films of this 13-year-old are close to normal. On close inspection, there is a fine periosteal reaction on the fibula. (b) The coronal T1-weighted magnetic resonance image shows little more, but (c) the coronal fast STIR (short tau inversion recovery) images and (d) axial T2 fast spin echo with fat suppression show the oedema in bone as white and the extensive periosteal fluid with soft-tissue inflammation. The diagnosis is acute osteomyelitis.

Serial examinations can be used to follow the response to intravenous antibiotics and are very useful in the management of complex osteomyelitis. In cases of negative or equivocal MRI, nuclear medicine techniques such as bone scintigraphy can be very sensitive, and specialised studies using tracers such as gallium citrate or indium-labelled white cells increase specificity (Summary box 10.14).

Summary box 10.14

Imaging of potentially infected bone and joint

- Plain radiographs may be needed to exclude bone erosion
- Ultrasound is sensitive for an effusion, periosteal collections and superficial abscesses and can be used for guided aspiration
- CT is useful in established infection to look for sequestrum
- MRI is useful to define the activity of osteomyelitis, early infection and soft-tissue collections
- Bone scans are sensitive but of low specificity
- Complex nuclear medicine studies are useful in negative MR examinations or equivocal cases

Metabolic bone disease

Plain radiographs should be the first images of patients with metabolic bone disease. They may detect the subperiosteal erosions in hyperparathyroidism or, more commonly, the osteopenia in osteoporosis, but they cannot be used to quantify osteoporosis. The apparent density of the bone on the film is linked to the penetration of the rays, among other variables, as well as to the bone density. If a quantitative method is needed, however, bone mineral density using dual X-ray absorptiometry (DEXA) is the most accurate and practical. However, fractures will cause erroneously high readings, and they tend to occur in the vertebrae used for DEXA measurements. Quantitative CT is an alternative technique, although this is less readily available. Ultrasound transmission measurement in the extremities has its advocates, as it arguably measures factors that better represent the strength of bone rather than its density. Its limitations are that it cannot be used to study the vertebrae or hip, and these are the sites where osteoporotic fractures occur most frequently. MRI may be useful in detecting fractures and is an essential prerequisite to percutaneous vertebroplasty.

IMAGING IN MAJOR TRAUMA

Introduction

Trauma remains a major cause of mortality and morbidity in all age groups. Presented with a multiply injured patient, rapid and effective investigation and treatment are required to maximise the chances of survival and to reduce morbidity. Imaging plays a major role in this assessment and in guiding treatment. As with the clinical assessment, imaging is carried out according to the principles of primary and secondary surveys, identifying major life-threatening injuries of the airway, respiratory system and circulation before a more detailed and typically time-consuming assessment of other injuries. At no point should imaging delay the treatment of immediately life-threatening injuries. As in other settings, the quickest and least invasive examinations should be performed first. A radiologist present in the trauma room at the time of patient assessment is able to rapidly evaluate the

radiographs, relay this information back to the team and guide further imaging, which may include further plain films, CT, ultrasound and MRI.

Plain radiographs

Conventional radiography allows rapid assessment of the major injuries and can be carried out in the trauma room while the patient is clinically assessed and treated. Despite the time constraints, the number of staff involved and the restricted mobility of the patient, high-quality images can be routinely obtained with due care and attention.

There is no routine set of radiographs to be obtained, and the decision is based on the mechanism of injury, the stability of the patient's condition and whether the patient is intubated. The most commonly performed initial radiographs are a chest radiograph, a single anteroposterior view of the pelvis and a cervical spine series.

The supine chest radiograph should encompass an area from the lung apices to the costophrenic recesses and include the ribs laterally. Chest radiographs give valuable information in both blunt and penetrating trauma. Evaluation of the radiograph should be undertaken in a systematic manner to minimise the chances of missing an injury. In the first instance, the position of line and tubes including the endotracheal tube should be assessed followed by assessment of the central airways. Following this, the lungs should be evaluated for abnormal focal areas of opacification, which may represent aspiration, haemorrhage, haematoma or oedema as well as more diffuse opacification reflecting a pleural collection. Alternatively, relative focal or unilateral lucency may reflect a pneumothorax in the supine position. Evaluation of the mediastinum should include its position, which may be altered by tension pneumothoraces or large collections, as well as its contour, an alteration of which may reflect a mediastinal haematoma due to aortic or spinal injury. Finally, the skeleton and the soft tissue should be carefully examined for rib, vertebral, scapular and limb fractures as well as evidence of surgical emphysema and paraspinal haematomas (Fig. 10.28).

Pelvic radiographs are also commonly performed to screen for and assess fractures of the bony pelvis. The image should include the iliac crests in their totality and extend inferiorly to below the lesser trochanters. When assessing the film, the alignment of the sacroiliac joints and the symphysis pubis should be carefully examined, as some fractures, especially those of the sacral arcades, can be very subtle on the pelvic radiograph. The presence of pubic fractures raises the possibility of urethral injury and should alert clinicians to exercise caution with bladder catheterisation (Fig. 10.29).

The utility of cervical spine X-rays depends on the conscious level of the patient and the presence of distracting injuries. In fully conscious patients with an isolated neck injury, clinical assessment can be used to guide the need for X-rays. In patients with distracting injuries and/or altered consciousness, including intubated patients, radiography is required. Typically, in patients who are not intubated, at least three views are performed including an anteroposterior view, an open mouth odontoid peg view and a lateral view extending down to the cervicothoracic junction. These may be supplemented with trauma oblique views in which the tube is rotated rather than the patient. In intubated individuals, open mouth views cannot be performed, and soft-tissue assessment is impaired by the presence of the endotracheal tube, so CT should be used to supplement an initial lateral

Figure 10.28 Supine chest radiograph of a patient involved in a road traffic accident. The patient is intubated. There are multiple left-sided rib fractures and extensive surgical emphysema. Depression of the left hemidiaphragm and mediastinal shift to the right suggest that there is a tension pneumothorax present.

radiograph (Fig. 10.30). When fractures are identified or when the radiographs do not fully examine the cervicothoracic junction, CT is indicated. If the patient is to undergo emergency CT examination for head or chest indications, a good-quality multi-detector CT study using thin sections and both coronal and sagittal reconstructions may be used to replace radiographs. CT may also be indicated when the radiographs appear normal but the nature of the injury or the clinical circumstances strongly suggest that the cervical spine may be injured.

Further radiographs of the thoracic and lumbar spine and the peripheral skeleton may be required depending on the clinical

Figure 10.29 Retrograde urethrogram in a patient who sustained extensive pelvic fractures following a fall. The pelvic injuries have been stabilised using an external fixation device. The urethrogram identifies extensive injury to the urethra with extravasation of contrast.

Figure 10.30 Lateral view of the cervical spine (a) fails to demonstrate the cervicothoracic junction. In addition, there appears to be a break in the posterior arch of C1. Computerised tomography of the cervical spine (b) demonstrated a fracture of the anterior arch as well as the posterior arch of C1.

setting. As with all skeletal radiographs, two perpendicular views are required for adequate assessment. Radiographs of the skull or facial bones have no role in the immediate assessment of the multitrauma individual except for immediate localisation of a penetrating object.

Ultrasound

Ultrasound has an evolving role in the assessment of acutely traumatised patients. The main current roles of ultrasound include the assessment of intraperitoneal fluid and haemopericardium (focused assessment with sonography for trauma, FAST), the evaluation of pneumothoraces in supine patients and in guiding intervention.

FAST ultrasound is a limited examination directed to look for

intra-peritoneal fluid or pericardial injury as a marker of underlying injury. This avoids the invasiveness of diagnostic peritoneal lavage. In the presence of free intra-peritoneal fluid and an unstable patient, the ultrasound allows the trauma surgeon to explore the abdomen as a cause of blood loss. In the presence of fluid and a haemodynamically stable individual, further assessment by way of CT can be performed. However, it is important to realise that ultrasound has limitations in the identification of free fluid. This includes obscuration of fluid by bowel gas or extensive surgical emphysema. More organised haematoma may be more difficult to visualise. It must also be emphasised that the principal role of ultrasound is not to identify the primary solid organ injury, although this may be visualised. Occasionally, a second ultrasound scan may show free fluid in the presence of an initially negative FAST scan.

The detection of a pneumothorax on a supine radiograph can be very difficult. Ultrasound examination may be used to identify a radiographically occult pneumothorax. With a high-resolution linear probe, the pleura can be visualised as an echogenic stripe, and its motion with respiration can also be assessed. In the presence of a pneumothorax, the sliding motion of the pleura is lost. Ultrasound may also be used to detect a haemothorax or haemopericardium.

Finally, ultrasound may be of value in guiding the placement of an intravascular line by direct visualisation of the vessels. This can be especially advantageous in shocked patients.

Computerised tomography

CT is the main imaging method for the investigation of intracranial and intra-abdominal injuries and vertebral fractures. With current multidetector scanners a comprehensive examination of the head, spine, chest, abdomen and pelvis can be completed in less than 5 min. However, much more time is taken up in transferring the patient and the associated monitoring equipment onto the scanner. Therefore, the total time can be in excess of 30 min, and CT should be reserved for individuals whose condition is stable.

CT examination of the head is accurate in identifying treatable intracranial injuries (Figs 10.31 and 10.32) and should not

Figure 10.31 Computerised tomography of the head in a patient with head injury shows bilateral large frontal extradural collections.

Figure 10.32 Computerised tomography of the head following head trauma shows a skull fracture with a large depressed component.

be delayed by radiography of peripheral injuries, as there is declining success in cases of intracranial collection when treated after the initial 3–4 hours. In comparison, identification of more widespread injuries such as diffuse axonal injury is relatively poor. Examination of facial injuries and cervical spine fractures can also be carried out at the same time as this only adds seconds to the examination. There is evidence that CT of the abdomen and pelvis is of benefit in multiple trauma when there is a head injury, as it often shows unexpected abnormalities, and this may affect the immediate management, especially if the patient deteriorates.

Chest CT with intravenous contrast agent is valuable in identifying vascular and lung injuries and is the most accurate way of demonstrating haemothorax and pneumothorax. The position of chest drains can be identified, allowing adjustment of position if necessary. Abdominal and pelvic CT is usually undertaken as an extension to the chest CT. If an abdominal examination is performed, the pelvis should be included to avoid missing pelvic injuries and free pelvic fluid. CT is an excellent means of identifying hepatic, splenic (Fig. 10.33) and renal injuries. Delayed examination after the administration of intravenous contrast agents allows assessment of the pelvicalyceal system in cases of renal trauma. Pancreatic and duodenal injuries may also be identified, but detection of these injuries may be more problematic. Using CT, the accuracy of detection of bowel or mesenteric injuries is less than it is for solid organ injury, and these injuries should be suspected when there is free intra-peritoneal fluid without an identifiable cause (Fig. 10.34).

The image data may be reconstructed into thinner slices for the diagnosis of injuries to the thoracic and lumbar spine and for the better delineation of pelvic and acetabular fractures. Multidetector machines will be optimum for this purpose but, with older CT scanners, additional dedicated thin sections may be required for adequate examination. Complex intra-articular fractures of the peripheral skeleton such as calcaneal and tibial plateau fractures may be usefully examined by dedicated thin-section studies provided this does not delay the treatment of other more serious injuries (Fig. 10.35). CT angiography may be

Figure 10.33 Post-contrast abdominal computerised tomography of a patient following blunt abdominal trauma shows a splenic laceration with herniation of mesenteric fat. A right-sided pleural collection is also evident.

Figure 10.35 Sagittal reformats of computerised tomography of the calcaneus in a patient following a fall illustrate a comminuted calcaneal fracture with intra-articular extension into the posterior facet of the subtalar joint.

Figure 10.34 Post-intravenous contrast computerised tomography examination in a patient with a penetrating abdominal injury and mesenteric tear shows free fluid in the flanks and active extravasation of contrast centrally.

used to demonstrate vascular injuries in the limbs in those with penetrating injuries or complex displaced fractures.

Magnetic resonance imaging

The value of immediate MRI in trauma is relatively limited and is largely confined to the imaging of spinal injuries (Fig. 10.36). Access to urgent MRI is not widely available, and there are major practical problems in imaging patients who require ventilation or monitoring. MRI is therefore only practical in stable patients. All monitoring equipment must be MRI compatible, and ventilation support should be undertaken by staff skilled and experienced in these techniques as applied to the MRI environment. MRI may be used to stage injuries of the spinal cord and associated perispinal haematomas in patients with neurological signs or symptoms. MRI can supplement CT in spinal injuries by imaging soft-tissue injuries to the longitudinal and interspinous ligaments.

MRI is mandatory in patients in whom there is facet dislocation if surgical reduction is being considered to minimise the risk of displacing soft-tissue or disc material into the spinal canal during reduction procedures. Subtle fractures may be difficult to identify, particularly if they are old, but an acute injury is normally identified by the surrounding oedema. Bony abnormalities should be reviewed using CT, as fracture lines are hard to identify with MRI and unstable injuries may be overlooked. In the less acute setting, MRI may also be used to assess diffuse axonal injuries, with an accuracy exceeding CT.

Vascular interventional radiology

Angiography has been used for both the diagnosis and treatment of vascular injuries in the trauma patient. With the development and refinement of CT angiography techniques, the diagnostic role of interventional radiology may become more limited. Already, CT has a diagnostic accuracy similar to that of formal angiograms in patients with suspected aortic injuries, with the latter reserved for cases where CT has been suboptimal, doubt exists about the diagnosis or stent grafting is being considered. At present, peripheral angiograms are still performed, particularly in cases of penetrating injury, but as experience grows with CT peripheral angiography, this will probably become the preferred technique.

Endovascular techniques play an important role in the treatment of acute solid organ injuries, and the interventional radiologist should be consulted early in the decision-making process. Using coaxial catheter systems and a variety of available embolic agents such as soluble gelatine sponge and microcoils, selective embolisation and reduction of blood flow to the injured segment can be achieved without causing infarction. Selective embolisation techniques are also suitable for the treatment of patients with pelvic fractures with ongoing blood loss and volume issues. With penetrating and non-penetrating extremity trauma, balloon occlusion and embolisation may be employed to control haemorrhage, while the application of stent grafts can aid in re-establishing the circulation to the affected extremity.

Figure 10.36 Sagittal T1-weighted (a) and T2-weighted (b) magnetic resonance imaging of the spine demonstrates a burst fracture of L2 causing neural compression.

IMAGING IN ABDOMINAL SURGERY

The acute abdomen

The term 'acute abdomen' encompasses many diverse entities. Imaging tests are selected based on the likely diagnosis, and the use of imaging early in the assessment process is highly desirable (Summary box 10.15).

Summary box 10.15

The investigation of the acute abdomen

Imaging tests	Indications/signs
Chest radiography (erect)	Free gas under the diaphragm
Anterior radiograph (supine)	Dilated bowel/gas pattern Gas inside/outside bowel Obstruction Closed loop Bowel wall oedema
IVU	Renal colic Ureteric obstruction by stone
Ultrasound	Ascites Cholecystitis/biliary colic Renal colic and bladder stones Abscess Obstruction – dilated fluid-filled bowel
Focused high-resolution ultrasound	Diverticulitis Appendicitis Bowel wall thickening/abscess
CT scan	Severe pancreatitis Diverticulitis Abscess Small bowel obstruction (high grade) Bowel infarction
Focused CT scan	Appendicitis Ureteric colic

Erect chest and supine abdomen radiographs remain the investigations of choice when perforation or intestinal obstruction is suspected (Figs 10.37 and 10.38). In many patients, these will provide sufficient information to determine further management. When the diagnosis is less clear, new imaging techniques are challenging the traditional approach. Both ultrasound and CT may contribute valuable information in inflammatory disease within the abdomen, notably in cholecystitis, diverticulitis, appendicitis and inflammatory bowel disease. CT is particularly useful in patients in whom there is a strong clinical suspicion of a collection, but the ultrasound examination is negative, as some collections may be overlooked using ultrasound. In some centres, the use of spiral CT as a first-line investigation is being promoted as a cost-effective alternative to increase the specificity of primary diagnosis.

In acute right upper quadrant pain, ultrasound is the best investigation for the gall bladder and biliary system and the best first-line test for liver disease. The pancreas is often well seen, dependent upon both the assiduousness of the scanning technique and the extent of upper abdominal gas.

Ultrasound can be a good first-line investigation for suspected appendicitis in patients in whom the diagnosis is not clinically obvious. It is especially useful in children and young adults and, in females, it will allow exclusion of a gynaecological cause. Thickened loops of terminal ileum or mesenteric abscess may be

Figure 10.37 Erect chest radiograph showing marked bilateral elevation of the hemidiaphragms with a large volume of subdiaphragmatic free gas.

Figure 10.38 Pneumoperitoneum. The presence of free intraperitoneal air outlines the bowel so that both sides of the bowel wall can be seen (Rigler's sign).

Leo George Rigler, 1896–1979, an American Radiologist, described the double wall sign in pneumoperitoneum.

identified in patients presenting with acute Crohn's disease. If there is remaining clinical doubt, then this may be resolved by a CT scan, which can be limited to the region of interest (Fig. 10.39).

In patients presenting with left iliac fossa pain and point tenderness, ultrasound may identify focal diverticulitis by the demonstration of bowel wall thickening and a paracolic or mesenteric collection. However, in most cases, CT is the best investigation for suspected diverticulitis and will allow staging of the disease to determine management. Barium enema is of limited value in this situation as the disease process is predominantly extraluminal (Fig. 10.40).

Figure 10.39 Computerised tomography (CT) scan. Acute appendicitis. Note the thickening of the caecal wall with a periappendiceal fluid collection indicating an appendix abscess.

Figure 10.40 Computerised tomography scan showing a segment of thickened sigmoid colon with a paracolic abscess (arrow) in a patient with diverticulitis.

Burrill Bernard Crohn, 1884–1983, Gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.

Bowel obstruction

Colonic obstruction is usually evident on the abdominal radiograph and, if this is equivocal, a limited unprepared contrast enema may confirm.

Although the abdominal radiograph is often diagnostic, small bowel obstruction can be more difficult to diagnose with confidence. Both ultrasound and CT are useful in demonstrating the presence of fluid-filled dilated small bowel loops in high-grade obstruction, and can identify the site and often the cause of the obstruction (Fig. 10.41). The use of CT, particularly in small bowel obstruction, has been widely advocated, although caution must be exercised in view of the radiation burden.

In subacute or low-grade obstruction, CT is very much less accurate and, in such cases, a small bowel enema (enteroclysis) is the investigation of choice.

IMAGING IN HEPATOBILIARY SURGERY

The techniques for imaging the liver, spleen, biliary tree and pancreas are discussed in Chapters 61, 62, 63 and 64 respectively.

IMAGING IN UROLOGY (SEE ALSO CHAPTER 70)

Renal colic

An initial abdominal radiograph and ultrasound will detect renal tract calculi in a proportion of patients and may reveal other causes for abdominal pain such as constipation. These techniques do not detect all calculi or causes of obstruction and, when negative, unenhanced helical CT is the most sensitive technique for the detection of ureteric calculi in renal colic and haematuria. Secondary signs of ureteric obstruction may also be appreciated, such as ureteric dilatation and stranding in the perinephric fat.

Figure 10.41 High-grade small bowel obstruction due to adhesions. Computerised tomography scan showing multiple, dilated, fluid-filled loops of small bowel with collapsed distal ileal loops beyond the point of obstruction (arrow).

A limited intravenous urogram remains a satisfactory alternative diagnostic test and has a lower radiation dose. Ultrasound may show a dilated collecting system, and the use of colour Doppler may demonstrate the absence of a ureteric jet into the bladder on the obstructed side or a twinkling artefact at the site of a calculus. However, in acute colic, the intrarenal collecting system may not be dilated and may result in a false-negative examination.

Haematuria

Analysis of the urine, including urine microscopy, will distinguish glomerular causes of haematuria such as immunoglobulin (Ig)A nephropathy from non-glomerular causes. The former will require renal ultrasound and chest radiography and further evaluation by nephrologists. The latter will require investigation of the entire urinary tract. Imaging should be accompanied by direct cystoscopy, as no imaging technique has sufficient sensitivity to exclude small bladder lesions. The initial investigation of haematuria varies between centres, but usually relies on IVU, ultrasound or both. Both have good sensitivity for detecting clinically important abnormalities, and there is little good evidence comparing the techniques upon which to base practice. Each technique has relative blind areas where sensitivity is reduced. Ultrasound is good for the detection of renal mass lesions but relatively less sensitive for urothelial lesions such as transitional cell carcinoma. Small non-obstructing calculi are also difficult to see, and combining ultrasound with plain film radiography improves their detection. Conversely, the IVU is sensitive for urothelial lesions and calculi, but may miss small renal mass lesions, particularly anteriorly or posteriorly projecting exophytic tumours.

CT is an extremely useful tool in the investigation of haematuria, but cost and radiation dose (see Table 10.1, p. 130) need to be considered against clinical benefit. As stated above, unenhanced CT is very sensitive in the detection of renal tract calculi. CT is more sensitive than ultrasound in the detection of renal mass lesions and is valuable in characterising solid tumours and in differentiating complex, potentially malignant cystic tumours from benign cystic lesions. With multidetector helical CT, the standard technique of contrast-enhanced CT may be modified to give reconstructed coronal images, sometimes with the use of abdominal compression. This technique, termed CT urography, can give excellent demonstration of the pelvicalyceal systems and ureters, equal or superior to standard IVU. Similar techniques have been developed for MR urography, with heavily T2-weighted coronal sequences depicting urine as a high signal.

IMAGING IN ONCOLOGY

Modern surgical treatment of cancer requires an understanding of tumour staging systems, as in many instances the tumour stage will define appropriate management. The development of stage-dependent treatment protocols involving neoadjuvant chemotherapy and preoperative radiotherapy relies on the ability of imaging to determine stage accurately before surgical and pathological staging. Once a diagnosis of cancer has been established, often by percutaneous or endoscopic biopsy, new imaging techniques can considerably improve the ability to define the extent of tumour, although the pathological specimen remains the 'gold standard'. Many staging systems are based on the tumour–node–metastasis (TNM) classification.

Tumour

In most published studies, cross-sectional imaging techniques (CT, ultrasound, MRI) are more accurate in staging advanced (T3, T4) than early (T1, T2) diseases, and the staging of early disease remains a challenge. In gut tumours, endoscopic ultrasound is more accurate than CT or MRI in the local staging of early disease (T1 and T2) by virtue of its ability to demonstrate the layered structure of the bowel wall and the depth of tumour penetration (Fig. 10.42). Developments in MRI may also improve the staging accuracy of early disease. MRI is extremely valuable in bone and soft-tissue tumour staging and in intracranial and spinal disease.

Figure 10.42 (a) Echo endoscopy in gastric cancer. The hypoechoic tumour (arrows) is destroying the layered structure of the gastric wall and extending out beyond the serosa. (b) Computerised tomography scan demonstrates thickening and enhancement of the gastric wall in the same area (arrows). The stomach is distended with water to provide low-density contrast.

Nodes

Accurate assessment of nodal involvement remains a challenge for imaging. Most imaging techniques rely purely on size criteria to demonstrate lymph node involvement, with no possibility of identifying micrometastases in normal-sized nodes. A size criterion of 8–10 mm is often adopted, but it is not usually possible to distinguish benign reactive nodes from infiltrated nodes. This is a particular problem in patients with intrathoracic neoplasms, in whom enlarged benign reactive mediastinal nodes are common. The echo characteristics of nodes at endoscopic ultrasound have been used in many centres to increase the accuracy of nodal staging, and nodal sampling is possible via either mediastinoscopy or transoesophageal biopsy under endoscopic ultrasound control. New radioisotope techniques are being developed using radiolabelled monoclonal antibodies against tumour antigens, which may increase the detection of nodal involvement by demonstrating micrometastases in non-enlarged nodes. There are current clinical studies of new MRI contrast agents that can identify tumour-infiltrated nodes.

Metastases

The demonstration of metastatic disease will usually significantly affect surgical management. Modern cross-sectional imaging has greatly improved the detection of metastases, but occult lesions will be overlooked in between 10% and 30% of patients. CT is the most sensitive technique for the detection of lung deposits, although the decision to perform CT will depend on the site of the primary tumour, its likelihood of intrapulmonary spread and the effect on staging and subsequent therapy of the demonstration of intrapulmonary deposits.

Ultrasound and CT are most frequently used to detect liver metastases. Contrast-enhanced CT can detect most lesions greater than 1 cm, although accuracy rates vary with the technique used and range from 70% to 90%. Recent studies suggest that MRI may be more accurate than CT in demonstrating metastatic disease. Although enhanced CT is used in most centres for screening for liver deposits, CT-AP (CT with arterial portography), which requires contrast injection via the superior mesenteric artery, is considered by many to be the most accurate technique for staging liver metastases if surgical resection is being considered. However, thin-section multislice CT with arterial and portal venous phase scanning is likely to replace this. Preoperative identification of the segment of the liver involved can be determined by translation of the segmental surgical anatomy, as defined by Couinaud, to the cross-sectional CT images (Fig. 10.43).

The technique of PET/CT is becoming a powerful tool in oncological imaging. This functional and anatomical imaging technique reflects tumour metabolism and allows the detection of otherwise occult metastases. The most common indications for PET/CT have been staging of lymphoma, lung cancer, particularly non-small cell lung cancer, and preoperative assessment of potentially resectable liver metastases such as colorectal carcinoma metastases.

Intraoperative ultrasound is an additional method of staging that provides superb high-resolution imaging of subcentimetre liver nodules that may not be palpable at surgery. This is often used immediately prior to resection of liver metastases.

Gastrointestinal endoscopy

LEARNING OBJECTIVES

To gain an understanding of:

- The position of endoscopy as a therapeutic and diagnostic tool
- The basic organisation of an endoscopy unit and its equipment
- Consent and safe sedation
- The key points in managing endoscopy in diabetic patients and those on anticoagulants, as well as when to use antibiotic prophylaxis
- The indications for diagnostic and therapeutic endoscopy/colonoscopy/endoscopic retrograde cholangiopancreatography
- The recognition and management of complications
- Novel techniques for endoscoping the small bowel
- Advances in diagnostic ability

INTRODUCTION

The gastrointestinal tract has a myriad of functions such as digestion, absorption and excretion as well as the synthesis of a vast array of hormones, growth factors and cytokines. In addition, a complex enteric nervous system has evolved to control its function and communicate with the central and peripheral nervous systems. Finally, as the gastrointestinal tract contains the largest sources of foreign antigens to which the body is exposed, it houses well-developed arms of both the innate and acquired immune system. Therefore, it is not surprising that malfunction or infection of this complex organ results in a wide spectrum of pathology. However, its importance in disease pathogenesis is matched only by its inaccessibility to traditional examination.

Few discoveries in medicine have contributed more to the practice of gastroenterology than the development of diagnostic and therapeutic endoscopy. Although spectacular advances in radiology have occurred recently with the introduction of spiral computerised tomography (CT) and the increasing use of magnetic resonance imaging (MRI), the ability to take targeted mucosal biopsies remains a unique strength of endoscopy. Historically, radiological techniques were required to image areas of jejunum and ileum inaccessible to the standard endoscope; however the introduction of both capsule endoscopy and single/double-balloon enteroscopy allows both diagnostic and therapeutic access to the entire gastrointestinal tract. Image enhancement with techniques such as chromoendoscopy, magnification endoscopy and narrow band imaging allow increased resolution and near histological accuracy in lesion discrimination. The advances in the diagnostic accuracy of endoscopy lend themselves to disease surveillance for specific patient groups as well as population screening for gastrointestinal malignancy. Likewise there has been a rapid expansion in the therapeutic capability of

endoscopy with both luminal and extraintestinal surgery being performed via endoscopic access.

As in all areas of interventional practice, a competent endoscopist must match a thorough grounding in anatomy and physiology with a clear understanding of the capabilities and limitations of the rapidly advancing techniques available. Perhaps most importantly they must also appreciate all aspects of patient care including pre-procedural management, communication before and during the procedure and the management of endoscopic complications. This chapter aims to guide the reader through these areas in addition to providing an introduction to the breadth of procedures that are currently performed.

HISTORY OF ENDOSCOPY

Over the last 50 years, endoscopy has become a most powerful diagnostic and therapeutic tool. However, its development required two obvious but formidable barriers to be overcome. First, the gastrointestinal tract is rather long and tortuous and, second, no natural light shines through the available orifices! Therefore, successful visualisation of anything beyond the distal extremities requires a flexible instrument with an intrinsic light source that can transmit images to the operator. The illumination issue was solved in 1879 by Thomas Edison, but 25 years elapsed before a light source was incorporated into the primitive rigid endoscopes available at that time. The first approach to gastrointestinal tortuosity was an instrument with articulated lenses and prisms, proposed by Hoffmann in 1911. Again, approximately two decades elapsed before this concept was

Thomas Alva Edison, 1847–1931, American Physicist and Inventor of Menlo Park, New Jersey, NJ, USA produced the first carbon filament electric light bulb in 1879.

incorporated into a semiflexible gastroscope by Wolf, a fabricator of medical instruments, and Schindler, a physician.

The real breakthrough was the discovery that images could be transmitted using flexible quartz fibres. Although this was first described in the late 1920s, it was not until 1954 that Hopkins built a model of a flexible fibre imaging device. The availability of highly transparent optical quality glass led to the development in 1958 of the first flexible fibreoptic gastroscope by Larry Curtiss, a graduate student in physics, and Basil Hirschowitz, a trainee in gastroenterology. Over the next 30 years, the fibrescope evolved to allow examination of the upper gastrointestinal tract, the biliary system and the colon. In parallel with advances in diagnostic ability, a range of therapeutic procedures was developed (Table 11.1). Although the fibreoptic endoscope has been the workhorse of many endoscopy units over the last three decades, its obsolescence was guaranteed by the invention of the charge coupled device (CCD) in the 1960s, which allowed the creation of a digital electronic image, permitting endoscopic images to be processed by a computer and transmitted to television screens. Thus the modern endoscope was born (Fig. 11.1).

History does not sit still, and endoscopic evolution will continue with the replacement of much diagnostic endoscopy with cap-

sule endoscopy and virtual imaging. Traditional endoscopy will therefore become increasingly therapeutic and historical divisions between medicine and surgery will become progressively blurred. As the complexity of the procedures increase, the distinction between specialist and general endoscopists will become more definite. This reinforces the need for all endoscopic practitioners to have a detailed understanding of the units in which they work and the instruments that they use.

THE MODERN ENDOSCOPY UNIT

Organisation

A well-designed endoscopy unit staffed by trained endoscopy nurses and dedicated administrative staff is essential to support good endoscopic practice and training. Clinical governance with regular appraisal and assessment of performance should be a routine process embedded within the unit philosophy. Endoscopist training demands particular attention, with a transparent process of skills- and theory-based education centred on practical experience and dedicated training courses. Experienced supervision of all trainee endoscopists is essential until competency has been obtained and assessed by an appropriately validated technique such as direct observation of practical skills (DOPS) and review of procedure logbooks. However, all endoscopists should keep an on-going log to record diagnostic and therapeutic procedure numbers and markers of competency such as colonoscopy completion rates, polyp detection rates, mean sedation use and complication rates. Central to this is an efficient data management system that provides outcome analysis for all aspects of endoscopy including adherence to guidelines, near misses, patient satisfaction, decontamination processes and scope tracking as well as the more obvious completion and complication rates.

Equipment

A full description of all available endoscopic equipment is beyond the scope of this chapter. However, each unit should have a sufficient range of endoscopes, processors and accessories as dictated by the local case mix and sufficient scope numbers to ensure smooth service provision. These should include both forward- and lateral-viewing gastroscopes, an enteroscope for proximal small bowel visualisation and a range of adult and paediatric colonoscopes to aid examination of both redundant and fixed colons. Dedicated small bowel centres require capsule endoscopy and a single/double-balloon enteroscope for ileojejunal therapeutics. An electrosurgical unit is the cornerstone of many therapeutic procedures and this may be supplemented by an argon plasma coagulation unit and laser units for advanced therapeutics in specialised centres.

Instrument decontamination

Endoscopes will not withstand steam-based autoclaving and therefore require high-level disinfection between cases to prevent transmission of infection. Although accessories may be autoclaved, best practice requires the use of disposable single use items whenever possible. All equipment should be decontaminated to an identical standard whether for use on immunocompromised/infected patients or not. This process involves two equally important stages: first, removal of physical debris from the internal and external surfaces of the instrument and, second, chemical neutralisation of all microbiological agents. A variety of

agents are available and endoscopists should familiarise themselves with the agent in use in their department. Key points in endoscope decontamination are shown in Summary box 11.1.

Summary box 11.1

Disinfection of endoscopes

- All channels must be brushed and irrigated throughout the disinfection process
- All instruments and accessories should be traceable to each use, patient and cleaning cycle
- All staff should be trained and protected (particularly if glutaraldehyde is used in view of its immune-sensitising properties)
- Regular monitoring of disinfectant power and microbiological contamination should be performed

There are currently no reliable means of decontaminating scopes from contact with prion-associated conditions such as new variant Creutzfeldt–Jakob disease (nvCJD). Endoscopy should be avoided in patients thought to be at risk of this condition, as instruments require quarantine until the diagnosis can be excluded (which is often only possible post mortem). In many countries, previously exposed endoscopes are available if a patient with suspected nvCJD requires endoscopy.

CONSENT IN ENDOSCOPY

Approximately 1% of medical negligence claims in the USA relate to the practice of endoscopy. Many of these could have been avoided by a careful explanation of the procedure including an honest discussion of the risks and benefits. Therefore, obtaining informed consent is a cornerstone of good endoscopic practice. It preserves a patient's autonomy, facilitates communication and acts as a shield against future complaints and claims of malpractice.

The most important aspect of the consent procedure is that a patient understands the nature, purpose and risk of a particular procedure. Current guidelines would suggest that a patient should be informed of minor adverse events with a risk of more than 10% and serious events with an incidence of more than 0.5%. The key risks of endoscopy are summarised in Summary box 11.2.

Summary box 11.2

The risks of endoscopy

- Sedation
- Damage to dentition
- Aspiration
- Perforation or haemorrhage after endoscopic dilatation
- Perforation, infection and aspiration after percutaneous endoscopic gastrostomy insertion
- Perforation or haemorrhage after flexible sigmoidoscopy/colonoscopy with polypectomy
- Pancreatitis, cholangitis, perforation or bleeding after endoscopic retrograde cholangiopancreatography

Hans Gerhard Creutzfeldt, 1885–1964, a Neurologist, of Kiel, Germany.
Alfons Marie Jakob, 1884–1931, a Neurologist of Hamburg, Germany.

SAFE SEDATION

If performed competently the majority of diagnostic endoscopy and colonoscopy can be performed without sedation or with pharyngeal anaesthesia alone. However, therapeutic procedures may cause pain and patients are often anxious; thus in most countries sedation and analgesia are offered to achieve a state of conscious sedation (*not* anaesthesia). Medication-induced respiratory depression in elderly patients or those with comorbidities is the greatest cause of endoscopy-related mortality and, therefore, safe sedation practices are essential. The involvement of anaesthetists to advise on appropriate protocols is recommended (Summary box 11.3).

Summary box 11.3

Sedation in endoscopy

- Pharyngeal anaesthesia may increase the risk of aspiration in sedated patients
- Comorbidities must be identified so that sedation can be individualised
- All sedated patients require secure intravenous access
- Benzodiazepines reach their maximum effect 15–20 min after administration – doses should be titrated carefully, particularly in the elderly or those with comorbidities
- Co-administration of opiates and benzodiazepines has a synergistic effect – opiates should be given first and doses need to be reduced
- The use of supplementary oxygen is essential in all sedated patients
- Sedated patients require pulse oximetry to monitor oxygen saturation; high-risk patients or those undergoing high-risk procedures also require electrocardiogram monitoring
- A trained assistant should be responsible for patient monitoring throughout the procedure
- Resuscitation equipment and sedation reversal agents must be readily available
- The use of anaesthetic agents such as propofol for complex procedures requires specialist training
- The half-life of benzodiazepines is 4–24 hours – appropriate recovery and monitoring is essential. Post-procedural consultations may not be remembered, and patients must be advised not to drink alcohol or drive for 24 hours

ENDOSCOPY IN DIABETIC PATIENTS

As approximately 2% of the population is diabetic, managing glycaemic control before and after endoscopy is an essential aspect of endoscopic practice. Factors influencing management include the type of diabetes, the procedure that is planned, the preparation and recovery time, and the history of diabetic control in the individual patient. Thus, a poorly controlled insulin-dependant diabetic undergoing colonoscopy will require more input than a type 2 diabetic on oral hypoglycaemic medication undergoing upper gastrointestinal endoscopy. All patients should bring their own medication to the unit and should be advised not to drive in case there is an alteration in their glycaemic control. The majority of patients can be managed using clear protocols on an outpatient basis; however, elderly patients and those with brittle control should be admitted. In general, diabetic patients should

be endoscoped first on the morning list. In complex cases the diabetic team should be involved.

ANTIBIOTIC PROPHYLAXIS

The majority of endoscopy can be performed safely without the need for routine antibiotic prophylaxis. However, given that certain endoscopic procedures are associated with a significant bacteraemia (Table 11.2), there are several specific situations where antibiotic cover is essential to prevent either bacterial endocarditis or infection of surgical prostheses. In general, the risk of infection relates to the level of bacteraemia and the risk of the underlying medical condition. Thus, patients with high-risk conditions such as prosthetic heart valves or a previous history of infective endocarditis should have prophylaxis for all endoscopic procedures, whereas those with moderate-risk conditions such as mitral valve prolapse with leaflet pathology or regurgitation only require antibiotics for procedures resulting in significant bacteraemia. Individual endoscopy societies have their own guidelines, which are widely available on the internet (e.g. the British Society of Gastroenterology guidelines are shown in Table 11.3; http://www.bsg.org.uk/pdf_word_docs/prophylaxis2001.pdf). Patients with severe neutropenia may also require antibiotic prophylaxis for endoscopy. The antibiotic regime used will depend on local guidelines. A standard protocol to prevent infective endocarditis is 1 g of amoxicillin and 120 mg of gentamicin intravenously 5–10 min before the procedure. Teicoplanin 400 mg intravenously can be used in patients who are allergic to penicillin.

In addition, procedures such as endoscopic percutaneous gastrostomy are associated with a significant incidence of wound or stoma infection, particularly if inserted for malignant disease. There is excellent evidence that antibiotic prophylaxis reduces this complication and a single intravenous injection of co-amoxiclav should be administered before the procedure. Ciprofloxacin is routinely used before endoscopic manipulation of an obstructed biliary tree to prevent sepsis. Finally, patients with

Table 11.2 Approximate incidence of bacteraemia in immunocompetent individuals following various procedures involving the gastrointestinal tract

Procedure	Incidence of bacteraemia (%) ^a

ERCP, endoscopic retrograde cholangiopancreatography; OGD, oesophagogastroduodenoscopy.

chronic liver disease and ascites undergoing variceal sclerotherapy should receive antibiotic prophylaxis to prevent bacterial peritonitis.

ANTICOAGULATION IN PATIENTS UNDERGOING ENDOSCOPY

Many patients undergoing endoscopy may be taking medication that interferes with normal haemostasis, such as warfarin, heparin, clopidogrel or aspirin. The key points to remember when managing anticoagulants in patients undergoing endoscopy are given in Summary box 11.4.

Summary box 11.4

Managing anticoagulants in patients undergoing endoscopy

It is important to recognise and understand:

- The risk of complications related to the underlying gastrointestinal disease from anticoagulant therapy
- The risk of haemorrhage related to an endoscopic procedure in the setting of anticoagulant therapy
- The risk of a thromboembolic/ischaeamic event related to interruptions of anticoagulant therapy

Gastrointestinal bleeding in the anticoagulated patient

The risk of clinically significant gastrointestinal bleeding in patients on warfarin is increased, particularly in patients with a past history of similar events, if the international normalised ratio (INR) is above the therapeutic range or if they are taking concomitant aspirin/non-steroidal anti-inflammatory drugs (NSAIDs). In this situation the risk of reversing the anticoagulation must be weighed against the risk of on-going haemorrhage. If complete reversal is not appropriate, correction of the INR to

approximately 1.5 is usually sufficient to allow endoscopic diagnosis and therapy. Anticoagulation can be resumed 24 hours after successful endoscopic therapy. If rapid resumption of anticoagulation is required, intravenous heparin should be used.

Elective endoscopy in the anticoagulated patient

Endoscopic procedures vary in their potential to produce significant or uncontrolled bleeding. Diagnostic oesophagogastroduodenoscopy (OGD), colonoscopy, enteroscopy and endoscopic retrograde cholangiopancreatography (ERCP) without sphincterotomy are considered low risk, as is mucosal biopsy. High-risk procedures include colonoscopic polypectomy (1–2.5%), gastric polypectomy (4%), laser ablation of tumour (6%), endoscopic sphincterotomy (2.5–5%) and procedures with the potential to produce bleeding that is inaccessible or uncontrollable by endoscopic means, such as dilatation of benign or malignant strictures, percutaneous gastrostomy insertion and endoscopic ultrasound (EUS)-guided fine-needle aspiration. Likewise, the probability of a thromboembolic complication during temporary cessation of anticoagulant therapy depends on the underlying medical condition (see Table 11.4) (Summary box 11.5).

Summary box 11.5

Recommendations concerning anticoagulant management

Low-risk procedures

- No adjustment to anticoagulation required
- Avoid elective procedures when anticoagulation is above the therapeutic range

High-risk procedure in a patient with a low-risk condition

- Discontinue warfarin 3–5 days before the procedure
- Consider checking the international normalised ratio on the day of the procedure

High-risk procedure in a patient with a high-risk condition

- Discontinue warfarin 3–5 days before the procedure
- Warfarin may be resumed the night of the procedure
- The decision to administer intravenous heparin should be individualised
- Intravenous heparin should be discontinued 4–6 hours before the procedure and may be resumed 2–6 hours after the procedure
- Heparin and warfarin should overlap until the international normalised ratio has stabilised within the therapeutic range
- The use of ambulatory low molecular weight heparin should be considered

Table 11.4 The risk of a thromboembolic event varies according to the underlying medical condition

Condition	Risk
Atrial fibrillation with valvular heart disease	High
Mechanical mitral valve	High
Mechanical valve and previous thromboembolic event	High
Deep vein thrombosis	Low
Uncomplicated atrial fibrillation	Low
Bioprosthetic valve	Low
Mechanical aortic valve	Low

Aspirin, non-steroidal anti-inflammatory drugs and anti-platelet therapies

Aspirin and NSAIDs inhibit platelet cyclo-oxygenase resulting in suppression of thromboxane A₂-induced platelet aggregation. Limited published data do not suggest an increased bleeding risk in patients taking standard doses and, therefore, there is no need to discontinue therapy before endoscopic procedures. Anecdotal evidence suggests an increased risk of bleeding after high-risk endoscopic procedures in patients taking clopidogrel and ticlopidine, although there are no clear data on which to base recommendations. Decisions to withhold therapy to prevent post-endoscopy haemorrhage must be weighed against the risk of an adverse coronary event. It would seem prudent to withhold therapy for 1 week before high-risk endoscopic therapy, particularly in patients taking concomitant aspirin.

UPPER GASTROINTESTINAL ENDOSCOPY

OGD is the most commonly performed endoscopic procedure in the world. Excellent visualisation of the oesophagus, gastro-oesophageal junction, stomach, duodenal bulb and second part of the duodenum can be obtained (Fig. 11.2). Retroversion of the gastroscope in the stomach is essential to obtain complete views of the gastric cardia and fundus (Fig. 11.2). Traditional forward-viewing endoscopes do not adequately visualise the ampulla, and a side-viewing scope should be used if this is essential. Likewise, although it is possible to reach the third part of the duodenum with a standard 120 cm instrument, a longer enteroscopy is required if views beyond the ligament of Treitz are required. In addition to clear mucosal views, diagnostic endoscopy allows mucosal biopsies to be taken, which may either undergo processing for histological examination or be used for near-patient detection of *Helicobacter pylori* infection using a commercial urease-based kit. In addition, brushings may be taken for cytology and aspirates for microbiological culture.

Indications for oesophagogastroduodenoscopy

A full assessment of the role of OGD is outside the scope of this chapter. It will vary with local circumstances and the availability of alternative diagnostic techniques. OGD is usually appropriate when a patient's symptoms are persistent despite appropriate empirical therapy or are associated with warning signs such as intractable vomiting, anaemia, weight loss, dysphagia or bleeding. It is also part of the diagnostic work-up for patients with symptoms of malabsorption and chronic diarrhoea. However, increasing ease of access to OGD with the availability of 'open access' endoscopy has resulted in a significant number of unnecessary procedures being performed in young patients with dyspepsia or gastro-oesophageal reflux disease (GORD). This has led to a number of international gastroenterology societies proposing guidelines for the management of dyspepsia/GORD, including the empirical use of acid suppression and non-invasive *H. pylori* tests, such as urease breath tests and serology (e.g. the National Institute for Health and Clinical Excellence guidelines on dyspepsia; <http://guidance.nice.org.uk/CG17/guidance/pdf/English/download.dsp>). In addition to the role of OGD in diagnosis, it is also commonly used in the surveillance of neoplasia

Wenzel Treitz, 1819–1872, Professor of Pathology, Prague, The Czech Republic.

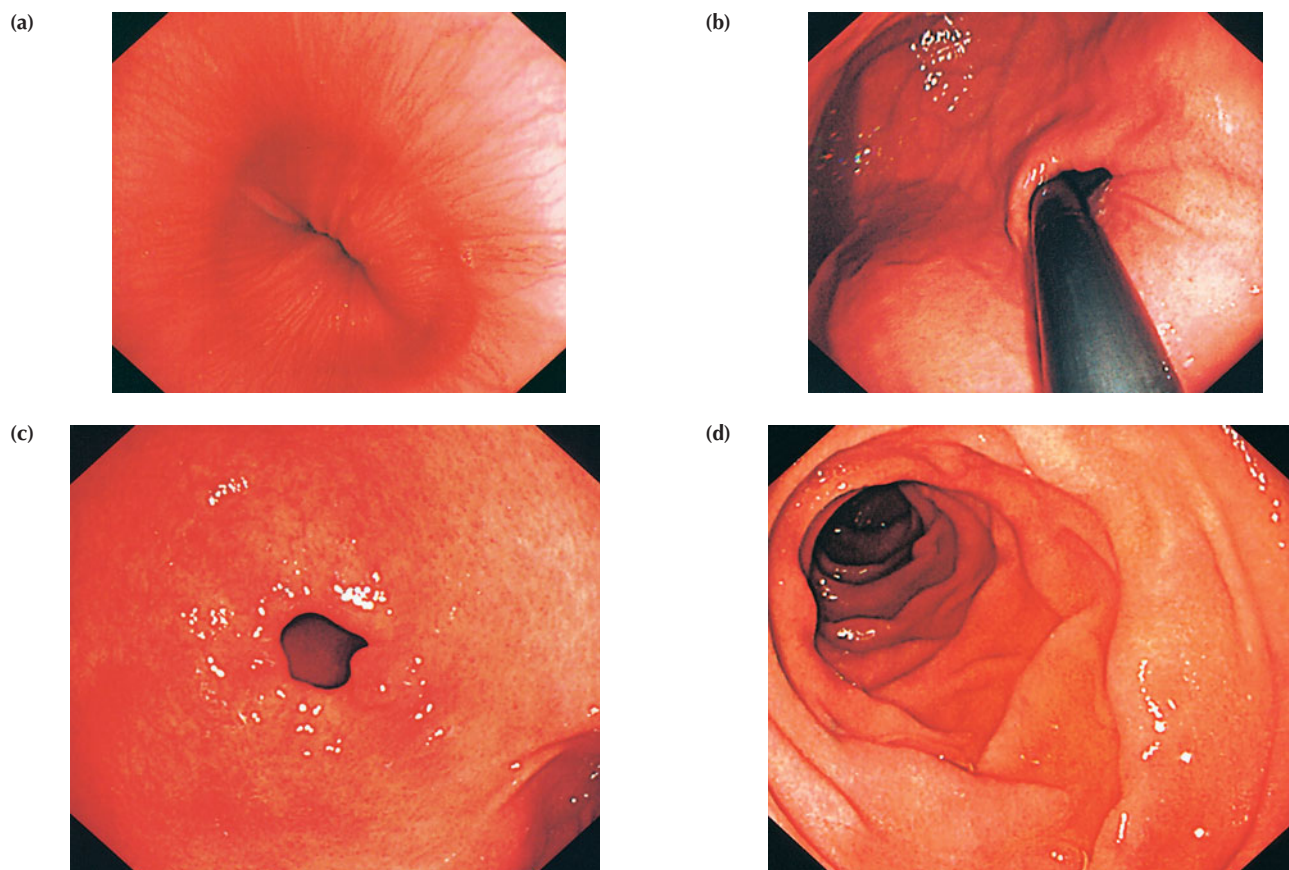

Figure 11.2 A normal upper gastrointestinal endoscopy showing the gastro-oesophageal junction (a), the gastric fundus in the 'J' position (b), the gastric antrum (c) and the second part of the duodenum (d).

development in high-risk patient groups. Whereas there is consensus about its role in genetic conditions such as familial adenomatous polyposis and Peutz–Jegher syndrome, controversy remains about the role and frequency of endoscopic surveillance in pre-malignant conditions such as Barrett's oesophagus and gastric intestinal metaplasia.

Therapeutic oesophagogastrroduodenoscopy

Increasing technological advances have revolutionised the therapeutic applications of upper gastrointestinal endoscopy. However, appropriate patient selection and monitoring is essential to minimise complications. The most common therapeutic endoscopic procedure performed as an emergency is the control of upper gastrointestinal haemorrhage of any aetiology. Band ligation has replaced sclerotherapy in the management of oesophageal varices (Fig. 11.3) whereas sclerotherapy using thrombin-based glues can be used to control blood loss from gastric varices. Injection sclerotherapy with adrenaline coupled with a second haemostatic technique such as heater probe vessel obliteration or haemoclip application remains the technique of choice for a peptic ulcer

with an active arterial spurt or stigmata of recent haemorrhage (Fig. 11.4). This should be followed by 72 hours of intravenous proton pump inhibition in all cases. Chronic blood loss from angioectasia is most safely treated with argon plasma coagulation because of the controlled depth of burn compared with alternative thermal techniques (Fig. 11.5).

Therapeutic OGD is a cornerstone in the management of both benign and malignant upper gastrointestinal disease. Benign oesophageal and pyloric strictures may be dilated under direct vision with 'through the scope' (TTS) balloon dilators or the more traditional guidewire-based systems such as Savary–Guillard bougie dilators (Fig. 11.6). Intractable disease can be treated by the insertion of a removable stent. Likewise, the lower oesophageal sphincter hypertension associated with achalasia can be reduced by pneumatic balloon dilatation, although the procedure may need to be repeated every few years and the large (2–3 cm) balloons required are associated with a significantly increased risk of perforation. An alternative is the injection of botulinum toxin, which has a considerably more favourable side-effect profile but a shorter duration of benefit.

There are an increasing number of endoscopic techniques available to reduce gastro-oesophageal reflux, which rely on tightening the loose gastro-oesophageal junction by plication, the application of radial thermal energy or injection of a bulking agent. Although many of these techniques deliver short-term clinical benefits and a reduction in 24-hour oesophageal acid exposure, none has demonstrated long-term benefits in a group of

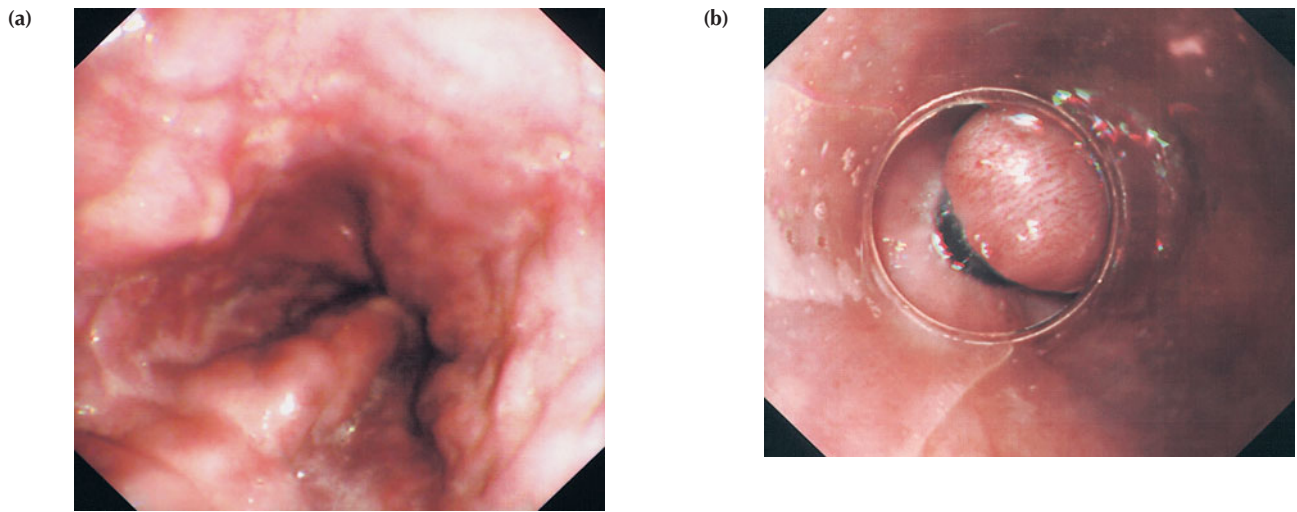

Figure 11.3 Grade 2 oesophageal varices (a), which can be treated by the application of bands to ligate the vessel and reduce blood flow (b).

patients resistant to proton pump inhibitors. Likewise, endoscopic techniques to tackle obesity, such as gastric balloon insertion, have not been associated with evidence of long-lasting benefit. In contrast, there is clear evidence that the insertion of a percutaneous endoscopic gastrostomy (PEG) tube enhances nutritional and functional outcome in patients unable to maintain oral nutritional intake (Fig. 11.7). PEG insertion is often a prelude to treatment of complex orofacial malignancy, and may be used to support nutrition in patients with alternative malignant, degenerative or inflammatory diseases.

The deployment of ‘memory metal’ self-expanding stents with or without a covering sheath inserted over a stiff guidewire leads to a significant improvement in symptomatic dysphagia and quality of life in patients with malignant oesophageal and gastric outlet obstruction (Fig. 11.8). Covered stents are the mainstay of treatment for benign or malignant tracheo-oesophageal fistulae. However, the area of greatest progress over the last few years has been in the endoscopic management of early oesophageal and gastric neoplasia with endoscopic mucosal resection (EMR) and the destruction of areas of high-grade dysplasia (HGD) using

Figure 11.4 A gastric ulcer with active bleeding (a) is initially treated with adrenaline injection to achieve haemostasis (b). Two haemoclips are then applied to prevent rebleeding (c and d).

Figure 11.5 The classic appearance of gastric antral vascular ectasia (GAVE), which is often treated with argon plasma coagulation.

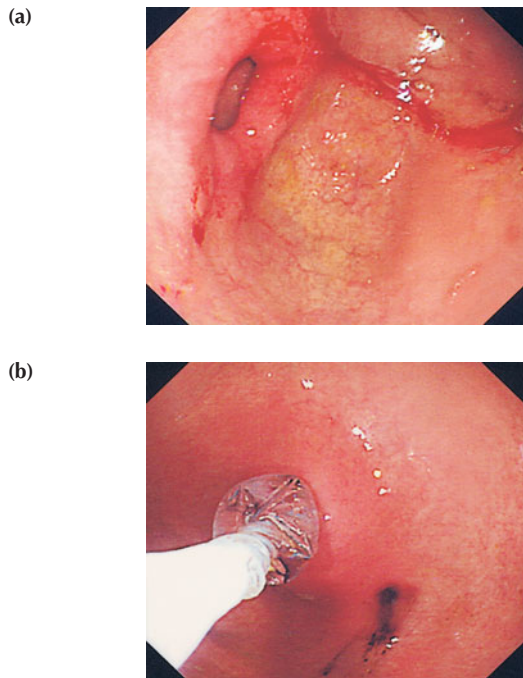

Figure 11.6 A pyloric stricture (a) can be dilated using a 'through the scope' balloon under direct vision to minimise complications (b).

either EMR (Fig. 11.9) or photodynamic therapy. However, long-term follow-up studies are required to ensure that the endoscopic ablation of areas of HGD has an impact on the progression to cancer.

Complications of diagnostic and therapeutic oesophagogastroduodenoscopy

Diagnostic upper gastrointestinal endoscopy is a safe procedure with minimal morbidity as long as appropriate patient selection and safe sedation practices are embedded in the unit policy. The mortality rate is estimated to be less than 1:10 000, with a complication rate of approximately 1:1000. As mentioned above, the

majority of adverse events relate to sedation and patient comorbidity. Particular caution should be exercised in patients with recent unstable cardiac ischaemia and respiratory compromise. Perforation can occur at any point in the upper gastrointestinal tract including the oropharynx. It is rare during diagnostic procedures and is often associated with inexperience. Perforation is more common in therapeutic endoscopy, particularly oesophageal dilatation and EMR for early malignancy. Early diagnosis significantly improves outcome and thus all staff must be alert to the symptoms (Summary box 11.6).

Summary box 11.6

Symptoms of endoscopic oesophageal perforation

- Neck/chest pain
- Abdominal pain
- Increasing tachycardia
- Hypotension
- Surgical emphysema

Prompt management includes radiological assessment using CT/water-soluble contrast studies, strict nil by mouth, intravenous fluids and antibiotics, and early review by an experienced upper gastrointestinal surgeon.

ENDOSCOPIC ASSESSMENT OF THE SMALL BOWEL

Introduction and indications

The requirement to visualise, biopsy and treat the small bowel is far less than in the stomach, biliary tree or colon, which has resulted in a time lag in technological advances. The most frequent indication is the investigation of gastrointestinal blood loss, which may present with either recurrent iron deficiency anaemia (occult haemorrhage) or recurrent overt blood loss per rectum (cryptic haemorrhage) in a patient with normal OGD (with duodenal biopsies) and colonoscopy. Other indications include the investigation of malabsorption; the exclusion of cryptic small bowel inflammation such as Crohn's disease in patients with diarrhoea/abdominal pain and evidence of an inflammatory response; targeting lesions seen on radiological images; and surveillance for neoplasia in patients with inherited polyposis syndromes.

A standard enteroscope is able to reach and biopsy lesions detected in the proximal small bowel; however, even in the most experienced hands this is limited to approximately 100 cm distal to the pylorus, although the use of a stiffening overtube may increase this somewhat. The procedure takes approximately 45 min and may be exceedingly uncomfortable, requiring high doses of sedation with the attendant increased risk of perforation and sedation-related morbidity. Sonde endoscopy, in theory, has the potential to examine the entire small bowel. In this procedure a long thin endoscope is inserted transnasally into the stomach and pushed through the pylorus with a gastroscope passed through the mouth. It is carried distally by peristalsis, which propels a balloon inflated at the tip. The technique has several limitations including a long examination time (6–8 hours), patient

Burrill Bernard Crohn, 1884–1983, Gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.

Figure 11.7 A schematic diagram of percutaneous endoscopic gastrostomy insertion. A standard endoscopy is performed to ensure that there are no contraindications to gastrostomy insertion. The stomach is insufflated with air and a direct percutaneous needle puncture made at a point where the stomach abuts the abdominal wall. Lignocaine is infused on withdrawal (a). A trochar is inserted and a wire passed into the stomach, which can be caught with a snare (b). The scope is withdrawn, pulling the wire out through the mouth, at which point it is attached to the gastrostomy tube (c). The gastrostomy is pulled through into the stomach and out through the track created by the trochar insertion (d).

discomfort, the danger of perforation and the inability to perform therapeutic procedures. For these reasons it is not widely performed and will soon become obsolete.

Therefore, until recently, barium follow-through or enteroclysis were the most effective imaging modalities to visualise the distal duodenum, jejunum and ileum. Obviously these techniques do not give true mucosal views, and outside specialist centres their decreasing use has led to diminished expertise and a

Figure 11.8 A self-expanding metal stent may be used to alleviate symptoms relating to malignant oesophageal strictures.

Figure 11.9 Novel upper gastrointestinal therapeutic uses of oesophagogastrroduodenoscopy include the use of endoscopic mucosal resection to remove early gastric cancer leaving a clean base.

reduced diagnostic yield. There have been rapid advances in axial radiological techniques such as MRI and CT enteroclysis, which demonstrate excellent diagnostic accuracy in this area (see Chapter 10). However, although these techniques may yield information about vascularity and bowel wall thickening, they do not allow direct mucosal views, have no biopsy capability and have limited scope in terms of therapeutics. Until recently, if an area of interest was outside the reach of a standard enteroscope, direct access via enterotomy under either laparoscopic or open surgery was required. Two major clinical advances over the last 2–3 years have revolutionised small bowel diagnosis and therapeutics. First, the development of the capsule endoscope allows diagnostic mucosal views of the entire small bowel to be obtained with minimal discomfort in unsedated patients. Second, the novel technique of single/double-balloon enteroscopy allows endoscopic access to the entire small bowel for biopsy and therapeutics (Table 11.5).

Capsule endoscopy

The prototype capsule endoscope was developed at the Royal London Hospital in the UK by Professor Paul Swain. Several companies have developed different systems for routine clinical use, but the basic principles remain identical. The technique requires three main components: an ingestible capsule, a portable data recorder and a workstation equipped with image-processing software. The capsule consists of an optical dome and lens, two light-emitting diodes, a processor, a battery, a transmitter and an antenna encased in a resistant coat the size of a large vitamin pill (Fig. 11.10). It acquires video images during natural propulsion through the digestive system that it transmits via a digital radio-frequency communication channel to the recorder unit worn outside the body; this also contains sensors which allow basic localisation of the site of image capture within the abdomen. Upon completion of the examination, the physician transfers the accumulated data to the workstation for interpretation via a high-capacity digital link. The workstation is a modified personal computer required for off-line data storage, interpretation and analysis of the acquired images, and report generation.

Clinical trials have been performed to evaluate the safety and efficacy of the system as a tool in the detection of small bowel diseases. Preliminary results show that the small bowel capsule provides good visualisation from mouth to colon with a high diagnostic yield. It compares favourably with the 'gold standard' techniques for the localisation of cryptic and occult gastrointestinal bleeding and the diagnosis of small bowel Crohn's disease. Use of the capsule endoscope is contraindicated in patients with known small bowel strictures in which it may impact, resulting in acute obstruction requiring retrieval at laparotomy or via laparoscopy. Severe gastroparesis and pseudo-obstruction are also relative contraindications to its use. Some units advocate a barium follow-through to exclude stricturing disease in all patients before capsule endoscopy. An alternative is to use a 'dummy' patency capsule that can be tracked via a hand-held device or conventional radiology as it passes through the intestine; it dissolves after 40 hours if it becomes impacted. Technology in this field is rapidly advancing with capsule systems designed to image the oesophagus and colon nearing the market. Prototype capsules that can be directed and deliver thermal therapy to angioectasia are in development.

Single/double-balloon enteroscopy

This technique allows the direct visualisation of and therapeutic intervention for the entire small bowel and may be attempted via either the oral or rectal route. Double-balloon enteroscopy was developed in 2001 in Japan; it involves the use of a thin enteroscope and an overtube, which are both fitted with a balloon. The procedure is usually carried out under general anaesthesia, but may be carried out with the use of conscious sedation. The enteroscope and overtube are inserted through either the mouth or anus and steered to the proximal duodenum/terminal ileum in the conventional manner. Following this the endoscope is advanced a small distance in front of the overtube and the balloon at the end is inflated. Using the assistance of friction at the interface between the enteroscope and intestinal wall, the small bowel is accorded back to the overtube. The overtube balloon is then deployed and the enteroscope balloon is deflated.

Table 11.5 Comparison of the advantages and disadvantages of the currently available modalities to endoscope the small intestine

Technique	Advantages	Disadvantages
Traditional enteroscopy	Simple technique with wide availability Full range of therapeutics available Performed under sedation	Some discomfort Can only access proximal small bowel
Capsule endoscopy	Able to visualise the entire small bowel Preferable for patients No sedation Painless	No biopsies Not controllable and no accurate localisation Variable transit Incomplete studies due to battery life Not suitable for patients with strictures Large capsule to swallow
Double/single-balloon enteroscopy	Able to visualise the entire small bowel Full range of therapeutics	Requires sedation/general anaesthesia Patient discomfort May take 3–4 hours; may require admission Specialist centres only Complications include perforation

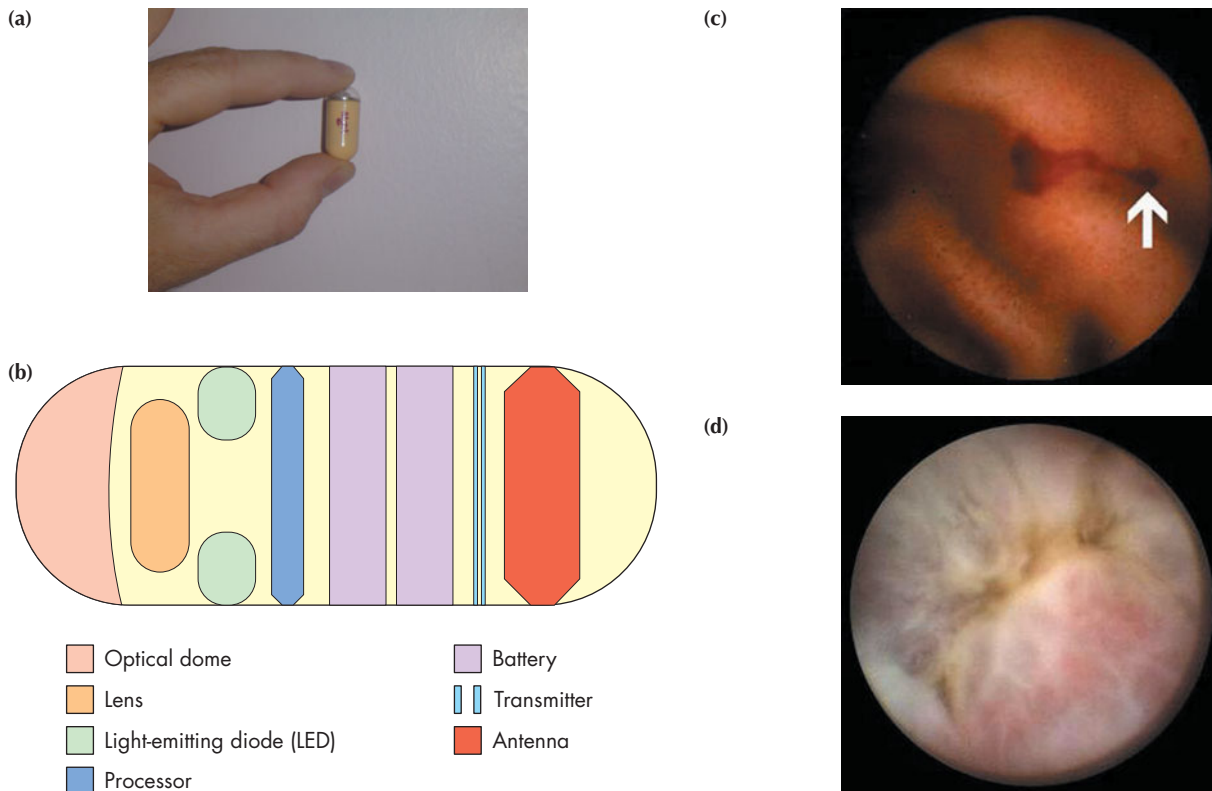

Figure 11.10 Complete diagnostic visualisation of the small bowel can be achieved with capsule endoscopy (a). The structure of the capsule is shown in (b). Clear mucosal pictures can be achieved here showing angioectasias (arrow) (c) and small bowel Crohn's disease (d).

The process is then continued until the entire small bowel is visualised (Fig. 11.11). In single-balloon enteroscopy, developed more recently, an enteroscope and overtube are used, but only the overtube has a balloon attached. A full range of therapeutics including diagnostic biopsy, polypectomy, argon plasma coagulation and stent insertion are available for balloon enteroscopy. Some experts advocate routine capsule endoscopy before balloon enteroscopy in an attempt to localise any lesions and plan whether oral or rectal access is more appropriate. The indications for single/double-balloon enteroscopy are given in Summary box 11.7.

Summary box 11.7

Current established indications for single/double-balloon enteroscopy

- Bleeding from the gastrointestinal tract of obscure cause
- Iron deficiency anaemia with normal colonoscopy and gastroscopy
- Visualisation of and therapeutic intervention for abnormalities seen on traditional small bowel imaging/capsule endoscopy

Figure 11.11 The technique of double-balloon enteroscopy is performed with an adapted enteroscope and overtube, both of which have inflatable balloons at their tip.

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

This procedure involves the use of a side-viewing duodenoscope, which is passed through the pylorus and into the second part of the duodenum to visualise the papilla. This is then cannulated, either directly with a catheter or with the help of a guidewire (Fig. 11.12). Occasionally a small pre-cut is required to gain access. By altering the angle of approach one can selectively cannulate the pancreatic duct or biliary tree, which is then visualised under fluoroscopy after contrast injection. The significant range of complications associated with this procedure and improvements in radiological imaging using magnetic resonance cholangiopancreatography (MRCP) have rendered much diagnostic ERCP obsolete, and thus most procedures are currently performed for therapeutic purposes. There is still a role for accessing cytology/biopsy specimens.

Therapeutic endoscopic retrograde cholangiopancreatography

It is essential to ensure that patients have appropriate assessment prior to therapeutic ERCP, which is associated with a significant morbidity and occasional mortality. All patients require routine blood screening including a clotting screen. Assessment of respiratory and cardiovascular comorbidity is essential. Patients with an obstructed biliary system require antibiotic prophylaxis. The use of supplementary oxygen and both cardiac and oxygen saturation monitoring during the procedure are essential because of the high levels of sedation that are often required. The most common indication for therapeutic ERCP is the relief of biliary obstruction due to gallstone disease and benign or malignant biliary strictures. The pre-procedural diagnosis can be confirmed by contrast injection, which will clearly differentiate the filling defects associated with gallstones and the luminal narrowing of a stricture. If there is likely to be a delay in relieving an obstructed system, percutaneous drainage may be required.

The cornerstone of gallstone retrieval is an adequate biliary sphincterotomy, which is normally performed over a well-positioned guidewire using a sphincterotome connected to an electrosurgical unit. Most gallstones less than 1 cm in diameter will pass spontaneously in the days and weeks following a sphincterotomy, but most endoscopists prefer to ensure duct clearance

at the initial procedure to reduce the risk of impaction, cholangitis or pancreatitis. This can be achieved by trawling the duct using a balloon catheter or by extraction using a wire basket. If standard techniques fail, large or awkwardly placed stones can be crushed using mechanical lithotripsy. If adequate stone extraction cannot be achieved at the initial ERCP it is imperative to ensure biliary drainage with the placement of a removable plastic stent while alternative options are considered. These include surgery, endoscopically directed shockwaves under direct choledochoscopic vision using a mother and baby scope, and extracorporeal shockwave lithotripsy with subsequent ERCP to remove stone fragments.

Dilation of benign biliary strictures uses balloon catheters similar to those used in angioplasty inserted over a guidewire under fluoroscopic control. It is traditional to insert a temporary plastic stent to maintain drainage as several attempts at dilatation may be required. Self-expanding metal stents are most commonly used for the palliation of malignant biliary obstruction and are also normally inserted after a modest sphincterotomy. Correct stent placement can normally be confirmed by a flow of bile after release and by the presence of air in the biliary tree on follow-up plain abdominal radiographs. Stent malfunction, associated with recurrent or persistent biochemical cholestasis, may be due to poor initial stent position, stent migration, blockage with blood clot or debris, or tumour ingrowth. A repeat procedure is required to assess the cause, which can usually be remedied by the insertion of a second stent through the original one.

In addition to the standard techniques discussed above, ERCP is also used for pancreatic disease and the assessment of biliary dysmotility (sphincter of Oddi dysfunction) using manometry in specialist centres. Indications include pancreatic stone extraction, the dilatation of pancreatic duct strictures and the trans-gastric drainage of pancreatic pseudocysts. To minimise the risks of subsequent pancreatitis, pancreatic sphincterotomy is most safely performed after the placement of a temporary pancreatic stent to prevent stasis within the pancreatic duct.

Complications associated with endoscopic retrograde cholangiopancreatography

The same risks associated with other endoscopic procedures also apply to patients undergoing ERCP, but risks may be increased because of the increased patient frailty and high sedation levels

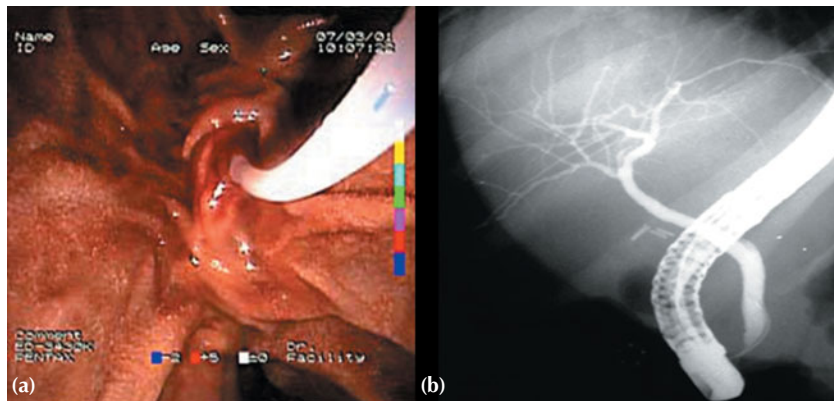

Figure 11.12 During endoscopic retrograde cholangiopancreatography a side-viewing duodenoscope is positioned opposite the papilla, which can then be cannulated using either a catheter or a guidewire (a). Contrast is injected to achieve a cholangiogram (b).

required. Complications specific to ERCP include duodenal perforation (1.3%)/haemorrhage (1.4%) after scope insertion or sphincterotomy, pancreatitis (4.3%) and sepsis (3–30%); the mortality rate approaches 1%. It is important to remember that post-sphincterotomy complications may be retroperitoneal and, therefore, CT scanning is essential in patients with pain, tachycardia or hypotension post-procedure. Although normally mild, post-ERCP pancreatitis can be severe with extensive pancreatic necrosis and a significant mortality rate. Many trials have assessed pharmacological strategies to reduce the incidence of pancreatitis, particularly in high-risk patients (Table 11.6). There is some evidence for the use of periprocedural nitroglycerine or rectal NSAIDs after a high-risk procedure.

COLONOSCOPY

Early attempts at colonoscopy were hindered by poor technique and the limitations of the available instruments. The ability to steer an endoscope around the entire colon and into the terminal ileum was made possible by the development of fully flexible colonoscopes with greater than 90° angulation of the tip. Advances in bowel preparation have enhanced mucosal visualisation during the examination. Two key revelations about the practical performance of colonoscopy have allowed skilled operatives to achieve a greater than 95% caecal intubation rate and frequent ileal intubation with minimal discomfort using light sedation. The first is that continued inward pressure of the endoscope results in the formation of loops within the mobile sigmoid and transverse colon, decreasing angulation control at the tip and removing the beneficial effect of shaft torque to aid steering around acute bends. The second is that pulling back the scope regularly with appropriate torque to ensure a straight passage through the sigmoid colon and around the splenic flexure greatly aids the completion of right-sided examination. Targeted abdominal hand pressure to prevent loops in a mobile colon and regular patient position change to enhance mucosal views and remove residual bowel content are also important aids to successful colonoscopy. It is essential that caecal intubation is confirmed to avoid missing pathology by incorrectly assuming that the caecal pole has been reached. The landmarks may not be clear and, therefore, visualisation of the appendix orifice or preferably terminal ileal intubation is necessary to confirm a complete colonoscopy (Fig. 11.13).

Mucosal biopsies may either be targeted to areas of abnormality

Table 11.6 Risk factors for post-ERCP pancreatitis

Definite	Suspected SOD
	Young age
	Normal bilirubin
	Prior ERCP-related pancreatitis
	Difficult cannulation
	Pancreatic duct contrast injection
	Pancreatic sphincterotomy
Possible	Balloon dilatation of biliary sphincter
	Female sex
	Low volume of ERCPs performed
	Absent CBD stone

CBD, common bile duct; ERCP, endoscopic retrograde cholangiopancreatography; SOD, sphincter of Oddi dysfunction.

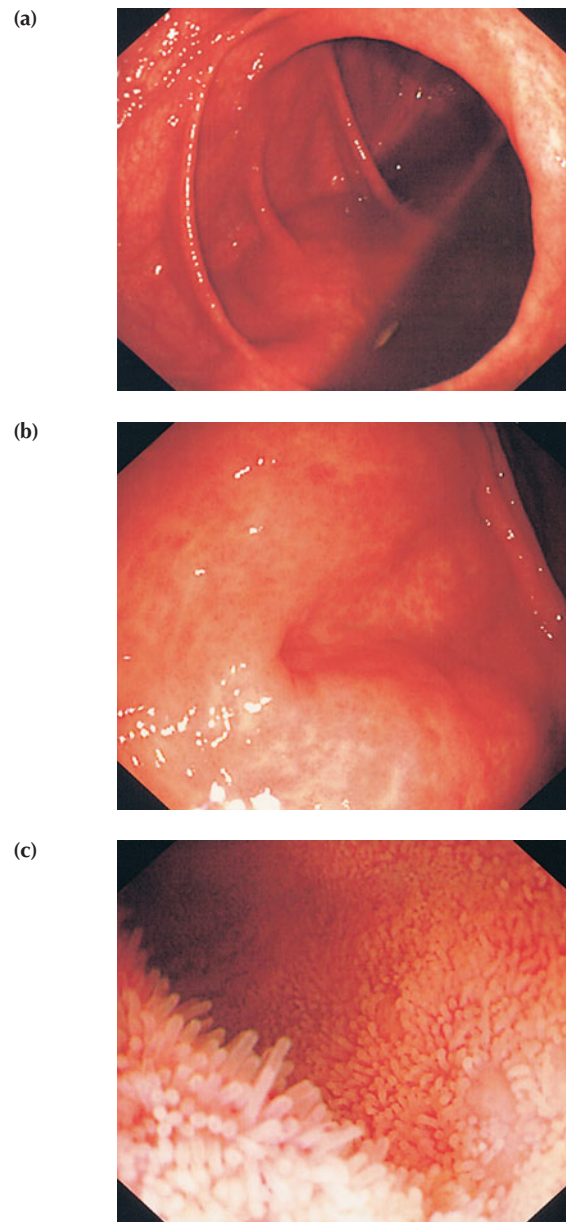

Figure 11.13 The caecal pole may not be easy to identify (a) and, therefore, the endoscopist should confirm complete colonoscopy by visualising the appendix orifice (b) or preferably intubating the terminal ileum (c), which demonstrates villi and Peyer's patches.

or random to exclude microscopic colitis in a patient with chronic diarrhoea but a macroscopically normal mucosa. Despite the increasing sophistication of radiological techniques to assess the colon such as CT colonography, the ability to biopsy areas of abnormality and resect polyps will ensure that colonoscopy remains the most appropriate investigation for the majority of patients (Summary box 11.8). Several countries including the USA and the UK have recently introduced colorectal cancer (CRC) screening programmes in the asymptomatic population once they reach a

Johann Conrad Peyer, 1653–1712, Professor of Logic, Rhetoric and Medicine, Schaffhausen, Switzerland, described the lymph follicles in the intestine in 1677.

predetermined age. The goal is to increase the number of early-stage CRCs detected and hence decrease mortality, as well as to identify and remove adenomatous polyps and prevent the onset of disease. There is on-going debate about the relevant benefits of different screening modalities including colonoscopy, CT colonography, flexible sigmoidoscopy and biannual/one-off faecal occult blood testing with colonoscopy only in positive patients. Whichever modality is used, colonoscopy is essential to resect any polyps identified and biopsy unresectable lesions.

Summary box 11.8

Indications for colonoscopy

- Rectal bleeding with looser or more frequent stools +/- abdominal pain related to bowel actions
- Iron deficiency anaemia (after biochemical confirmation +/- negative coeliac serology): oesophagogastroduodenoscopy and colonoscopy together
- Right iliac fossa mass if ultrasound is suggestive of colonic origin
- Change in bowel habit associated with fever/elevated inflammatory response
- Chronic diarrhoea (> 6 weeks) after sigmoidoscopy/rectal biopsy and negative coeliac serology
- Follow-up of colorectal cancer and polyps
- Screening of patients with a family history of colorectal cancer
- Assessment/removal of a lesion seen on radiological examination
- Assessment of ulcerative colitis/Crohn's extent and activity
- Surveillance of inflammatory bowel disease
- Surveillance of acromegaly/ureterosigmoidostomy

Therapeutic colonoscopy

The most common therapeutic procedure performed at colonoscopy is the resection of colonic polyps (Fig. 11.14). Retrieved specimens can be assessed for risk factors for neoplastic progression and an appropriate surveillance strategy determined. Small polyps up to 5 mm are removed by either cheese-wiring with a 'cold' snare or hot biopsy, during which the tip of a pedunculated polyp is grasped between biopsy forceps and tented away from the bowel wall. A brief burst of monopolar current is used to coagulate the stalk, allowing the polyp to be removed. Larger polyps with a defined stalk can be resected via snare polypectomy using coagulating current either *en bloc* or piecemeal depending on their size (Fig. 11.14). Post-polypectomy bleeding can be prevented by the application of haemoclips or an endoloop to the polyp stalk. Sessile polyps extending over several centimetres can be removed by endoscopic mucosal resection, which involves lifting the polyp away from the muscularis propria with a submucosal injection of saline to prevent iatrogenic perforation (Fig. 11.15). Any residual polyp is obliterated with argon plasma coagulation. Care should be taken with all polypectomies in the right colon where the wall may only be 2–3 mm thick.

APC and alternative thermal therapies such as heater probes are also used in the treatment of symptomatic angioectasias of the colon (Fig. 11.16). Laser photocoagulation may be used to debulk colonic tumours not suitable for resection. As with benign oesophageal strictures TTS balloons can be used to dilate short (less than 5 cm) colonic strictures. The dilatation of surgical anastomoses gives the most durable benefit as inflammatory strictures tend to recur even if intramucosal steroids are injected at the time of the dilatation. Finally, the colonoscopic placement of self-expanding metal stents may provide excellent palliation of inoperable malignant strictures (Fig. 11.17) and may also play an

Figure 11.14 Colonoscopy is the most appropriate investigation to detect colonic polyps (a), which can be removed by snare polypectomy during the same procedure leaving a clean polyp base (b).

en bloc is French for 'in a block'.

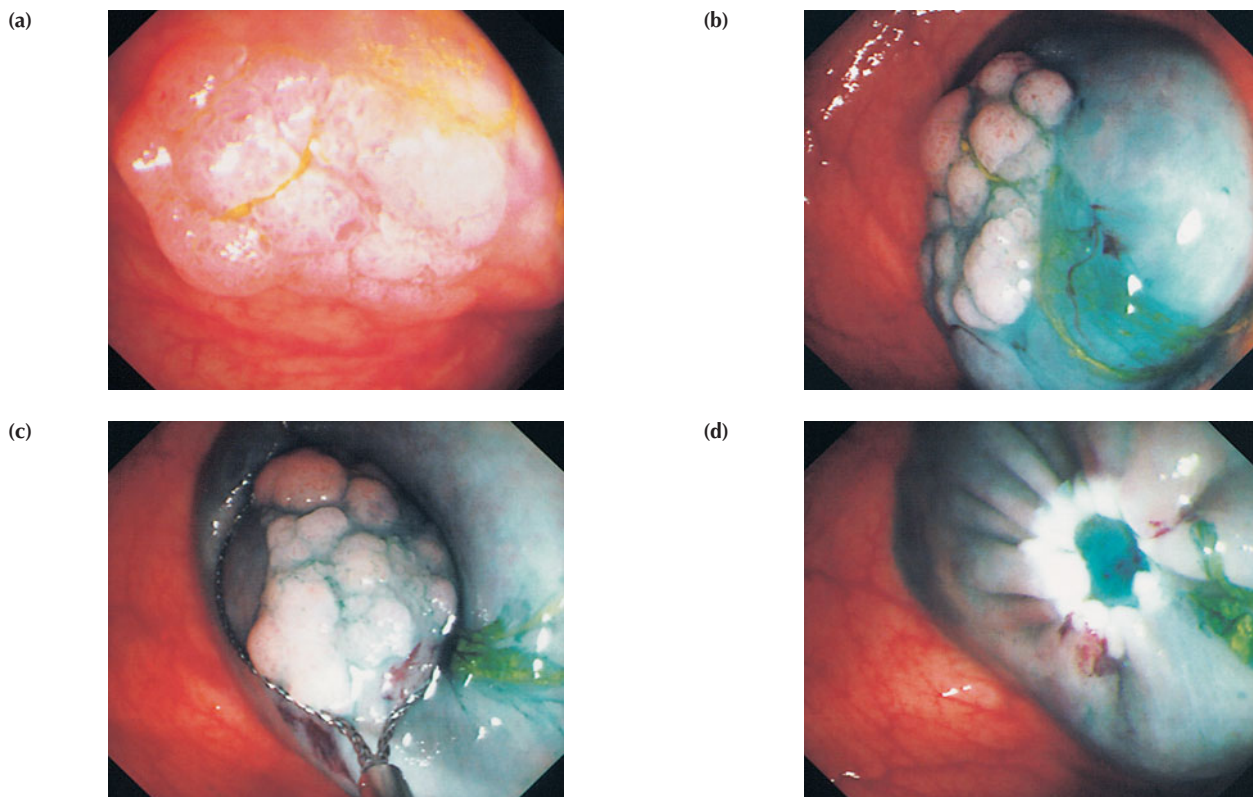

Figure 11.15 Large sessile polyps (a) can be removed by endoscopic mucosal resection. First the polyp is raised on a bed of injected saline containing dye (b). This ensures that there is no submucosal invasion and protects from transmural perforation. A snare is closed around the polyp (c), which is then resected leaving a clean excision base (d).

invaluable role in decompressing an obstructed colon to allow planned as opposed to emergency surgery.

Complications of colonoscopy

A competent endoscopist should cause few complications during routine diagnostic colonoscopy, although perforations have been reported as a result of excessive shaft tip pressure and with excessive air insufflation in severe diverticular disease. Total colonoscopy is contraindicated in the presence of severe colitis; a limited examination and careful mucosal biopsy only should be performed. Polypectomy is associated with a well-documented

rate of perforation (approximately 1%) and haemorrhage (1–2%). Immediate haemorrhage should be managed by re-snaring the polyp stalk where possible and applying tamponade for several minutes followed by careful coagulation if this is unsuccessful. Submucosal adrenaline injection and the deployment of haemoclips are alternatives if this is not possible. Delayed haemorrhage

Figure 11.16 A large angioectasia of the colon. If this results in symptomatic anaemia, it should be obliterated with argon plasma coagulation.

Figure 11.17 Malignant colonic obstruction can be palliated or temporarily relieved by insertion of a self-expanding metal stent.

may occur 1–14 days post-polypectomy and can normally be managed by conservative observation. Transfusion may occasionally be required, but repeat colonoscopy is rarely necessary. If recognised at the time of polypectomy small perforations should be closed using clips and the patient admitted for observation. Symptoms of abdominal pain and cardiovascular compromise after a polypectomy should alert one to the risk of delayed perforation. Patients should be kept nil by mouth and receive intravenous resuscitation and antibiotics. Prompt assessment with plain radiography and a CT scan will often distinguish between a frank perforation and a transmural burn with associated localised peritonitis (the post-polypectomy syndrome). Assessment by an experienced colorectal surgeon is essential, as surgery is often the most appropriate course of action.

FUTURE DIRECTIONS IN ENDOSCOPY

Chromoendoscopy, narrow band imaging and high resolution magnification endoscopy

The ability to enhance lesion detection and achieve near-patient discrimination of pathology without the need for histology is a common theme of several active areas of endoscopic development. The goal is to allow accurate discrimination of dysplasia grade in areas of Barrett's oesophagus or quiescent ulcerative colitis and to aid polyp detection and the recognition of early gastric and colorectal cancer. The most widely available technique is chromoendoscopy, which involves the topical application of stains or pigments to improve tissue localisation, characterisation or diagnosis. Several agents have been described, which can broadly be categorised as absorptive (vital) stains such as methylene blue, contrast (reactive) stains such as indigo carmine, and those used for tattooing such as India ink. Narrow band imaging (NBI) relies on an optical filter technology that radically improves the visibility of capillaries, veins and other subtle tissue structures by optimising the absorbance and scattering characteristics of light. NBI uses two discrete bands of light: one blue at 415 nm and one green at 540 nm. Narrow band blue light displays superficial capillary networks whereas green light displays subepithelial vessels; when combined they offer an extremely high contrast image of the tissue surface. Finally, high-resolution magnifying endoscopy may be used alone or in combination with one of the above techniques to achieve near-cellular definition of the mucosa (Fig. 11.18).

CONCLUSIONS

Over the last 30 years endoscopy has become an integral part of the diagnostic work-up of patients with gastrointestinal disease. Whereas advances in radiology may obviate the need for some diagnostic procedures (routine OGD and ERCP), the ability to take mucosal biopsies will ensure that it retains a vital role. Moreover, on-going advances in technology such as magnifying endoscopy and chromoendoscopy are able to give near-histological quality definition to allow near-patient diagnosis. There have also been major advances in the range of conditions that are amenable to endoscopic therapy; such therapy may have substantially lower associated morbidity rates than traditional surgical approaches. However, as the scope of procedures widens and the age range/comorbidities of the patients increases it is beholden to the endoscopist to ensure that he or she adheres to

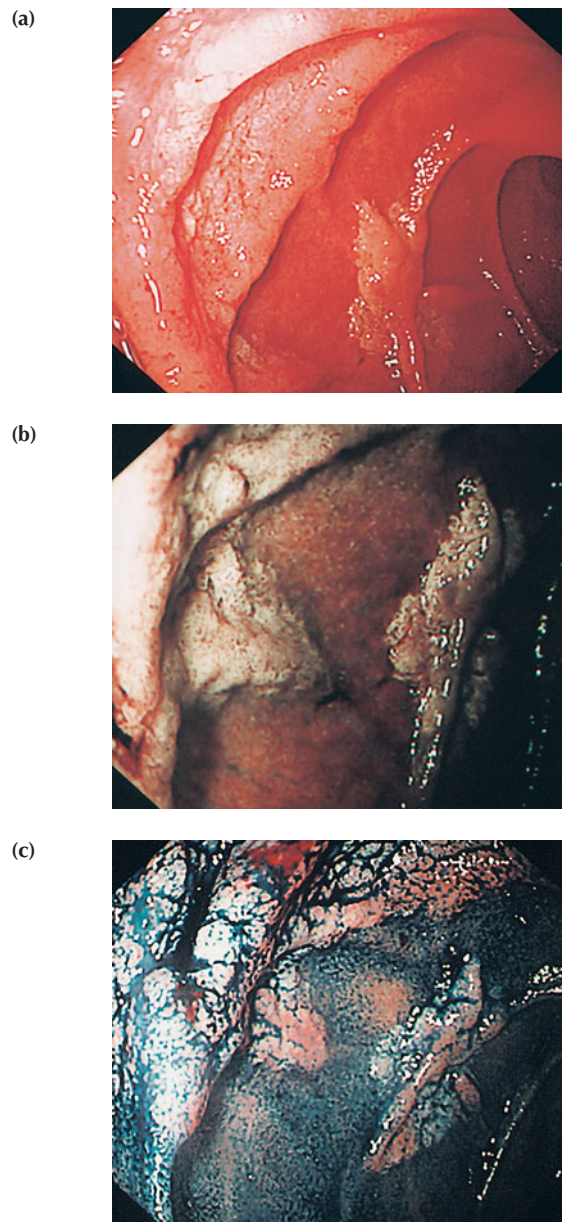

Figure 11.18 Endoscopic diagnostic accuracy can be improved by novel endoscopic techniques. This duodenal adenoma can be seen with conventional white light (a), but its full extent is more clearly delineated using narrow band imaging (b) or chromoendoscopy with indigo carmine (c).

appropriate governance/consent and sedation practice to minimise complications.

Tissue diagnosis

LEARNING OBJECTIVES

To understand:

- The value and limitations of tissue diagnosis
- How tissue samples are processed
- The role of histology, cytology and the autopsy

To be aware of:

- The role of additional techniques used in clinical practice, including special stains, immunohistochemistry and molecular methods

- The principles of microscopic diagnosis, particularly of neoplasia
- The importance of clinicopathological correlation
- Relevant management issues

INTRODUCTION

For centuries, macroscopic examination of autopsy material was the main form of tissue diagnosis. Microscopic examination of human tissue from autopsies and surgical procedures was introduced in the nineteenth century. Analysis of tissue samples is now an integral part of clinical management. Most tissue diagnosis is the responsibility of a histopathologist (or 'pathologist'), a medically qualified practitioner. The specialty now known as histopathology encompasses histopathology, cytopathology and autopsy (post-mortem) work, and is heavily dependent on microscopy.

In the UK, the nature of the histopathologist's work has changed since the 1960s. There has been a steady increase in biopsy numbers, partly as a result of flexible endoscopy. Many resection specimens are assessed with management and prognosis in mind, the diagnosis having been made preoperatively. Screening programmes have had a major impact. New techniques have improved the quality and value of histopathological assessment, while autopsies have steadily decreased in number.

A modern histopathology department is usually located in a large hospital. Typically, more than 80% of specimens are from the gastrointestinal tract, gynaecological tract or skin. Highly specialised work, e.g. neuropathology, is confined to regional centres.

REASONS FOR ASSESSMENT OF TISSUE

There are several reasons for tissue analysis (Summary box 12.1). A new diagnosis may be made, e.g. squamous cell carcinoma, or a known diagnosis confirmed. Clues to a diagnosis may be found, e.g. granulomatous inflammation. Additional diagnoses may be excluded. For example, biopsies from Barrett's oesophagus may

confirm the diagnosis and also exclude pre-malignant change. Tissue analysis also helps to determine treatment and prognosis. For example, a liver biopsy from a patient with chronic hepatitis helps to determine therapy, exclude other diseases (e.g. steatohepatitis) and exclude complications (e.g. neoplasia). Tissue analysis, particularly assessment of resections, also helps surgeons to audit their performance.

A tissue sample does not always represent the entire patient. The interpretation of microscopic changes is enhanced by correlation with the macroscopic findings and the clinical picture. Accordingly, a request form with adequate clinical details should accompany all specimens. Useful details include site of biopsy, date of birth, gender, ethnicity, medications, relevant risk factors and past medical history.

Summary box 12.1

Reasons for tissue analysis

- To make new diagnoses
- To confirm suspected clinical diagnoses
- To exclude other diagnoses
- To assist with prognosis
- To help plan treatment
- Audit

TISSUE SPECIMENS

Routine tissue specimens received by a histopathology department include those intended for histopathological and cytopathological assessment (Summary box 12.2). Sometimes these two areas overlap.

Summary box 12.2

Common types of tissue sample

■ Histology

Formalin-fixed tissue

Biopsy

Mucosal

Punch

Needle

Excision

Resection

Fresh tissue (usually for frozen section)

■ Cytology

Cervical

Washings, brushings

Fine-needle aspirate (FNA)

Fluids

Histology

Specimens for histology are arbitrarily classified as biopsies and resections, although the word 'biopsy' means any tissue sample. Types of biopsy include punch biopsy, needle core biopsy and mucosal biopsy. An excision biopsy serves as both a diagnostic biopsy and a small resection. Samples for routine histology are placed in a fixative, almost always formalin (10% formaldehyde), so as to preserve morphology.

Cytology

Cytological specimens can be obtained from many sites using a variety of approaches. Some are easy to obtain, e.g. urine and sputum, whereas others require more intervention.

A conventional cervical smear is obtained by sampling the ectocervix with a spatula. Bronchial aspirates, washings and brushings, and gastrointestinal and biliary brushings sample a relatively wide area and may therefore be useful for the diagnosis of neoplasia. Fine-needle aspiration (FNA) cytology may be of accessible sites such as the breast, thyroid and superficial lymph nodes, while FNA from deeper structures, e.g. liver, pancreas, kidney and lung, is usually assisted by ultrasound or computerised tomography (CT) guidance. Transbronchial FNA may be used for mediastinal masses and transmucosal FNA for submucosal gastrointestinal lesions. Fluids may be submitted directly to the laboratory for cytological assessment.

Fresh tissue

The most common indication for submission of a fresh tissue sample (i.e. without fixative) is rapid frozen section diagnosis, but other indications are microbiological assessment, electron microscopy and various types of molecular pathological analysis. Before fixing a histology or cytology specimen, the operator should ask whether any of these investigations might be useful, e.g. microbiology if tuberculosis is suspected.

Risk management

Safety and risk management are priorities in the laboratory. Any risk of transmissible infection, e.g. hepatitis B, must be minimised

by the use of warning labels, especially when fresh tissue is being submitted. Formalin kills most micro-organisms, but any risk of infection should still be notified. Formalin itself is toxic to the eyes and skin. Accordingly, leaking or faulty specimen containers should be discarded. Containers must be labelled with the patient's details and the sample site to minimise errors of identity (Fig. 12.1).

SPECIMEN PROCESSING

Histology specimen

On arrival in the histopathology department, specimens are given a unique number and submitted for macroscopic assessment and sampling ('cut up'). The largest specimens are opened (e.g. bowel) or sliced (e.g. uterus) and left to fix in formalin for at least 1 day (Fig. 12.2a–c). A written description is made. Representative samples ('blocks') are taken from any specimen too large to be processed whole (Fig. 12.3). This is usually done by a pathologist, especially if a case is complex. A local or national protocol is often followed. Samples from a cancer will include resection margins, tumour, lymph nodes, non-neoplastic tissue and other abnormal areas. Coloured inks may be used to identify resection margins and surfaces (Fig. 12.4a and b, page 170).

Specimens, or samples from specimens, are placed in plastic cassettes (Fig. 12.5, page 170), and then embedded in paraffin wax to make a block (Fig. 12.6, page 170). Sections with a thickness of 5 μm (microns) are cut from the block using a microtome (Fig. 12.7, page 171). The sections are placed on a glass slide and stained with haematoxylin and eosin (H&E) (Fig. 12.1). This work is done by trained staff, known in the UK as biomedical scientists (BMSs). High standards are necessary because a poorly cut section may have various artefacts, such as lines and folds, which impede accurate assessment. H&E staining has stood the test of time, probably because it is inexpensive, safe, fast, reliable and informative.

The stained sections are examined with a microscope (Fig. 12.8, page 171) by a histopathologist, who correlates the histological features with the clinical details and with the macroscopic description. After any appropriate further studies, the pathologist writes a report, which may be entered onto a computer system (Summary box 12.3).

Figure 12.1 Sections on glass slides stained with haematoxylin and eosin (H&E). Each slide has a unique specimen identifying number (06S022081), a letter corresponding to the biopsy site (A1–F1) and a site label (e.g. DUOBX for duodenal biopsy).

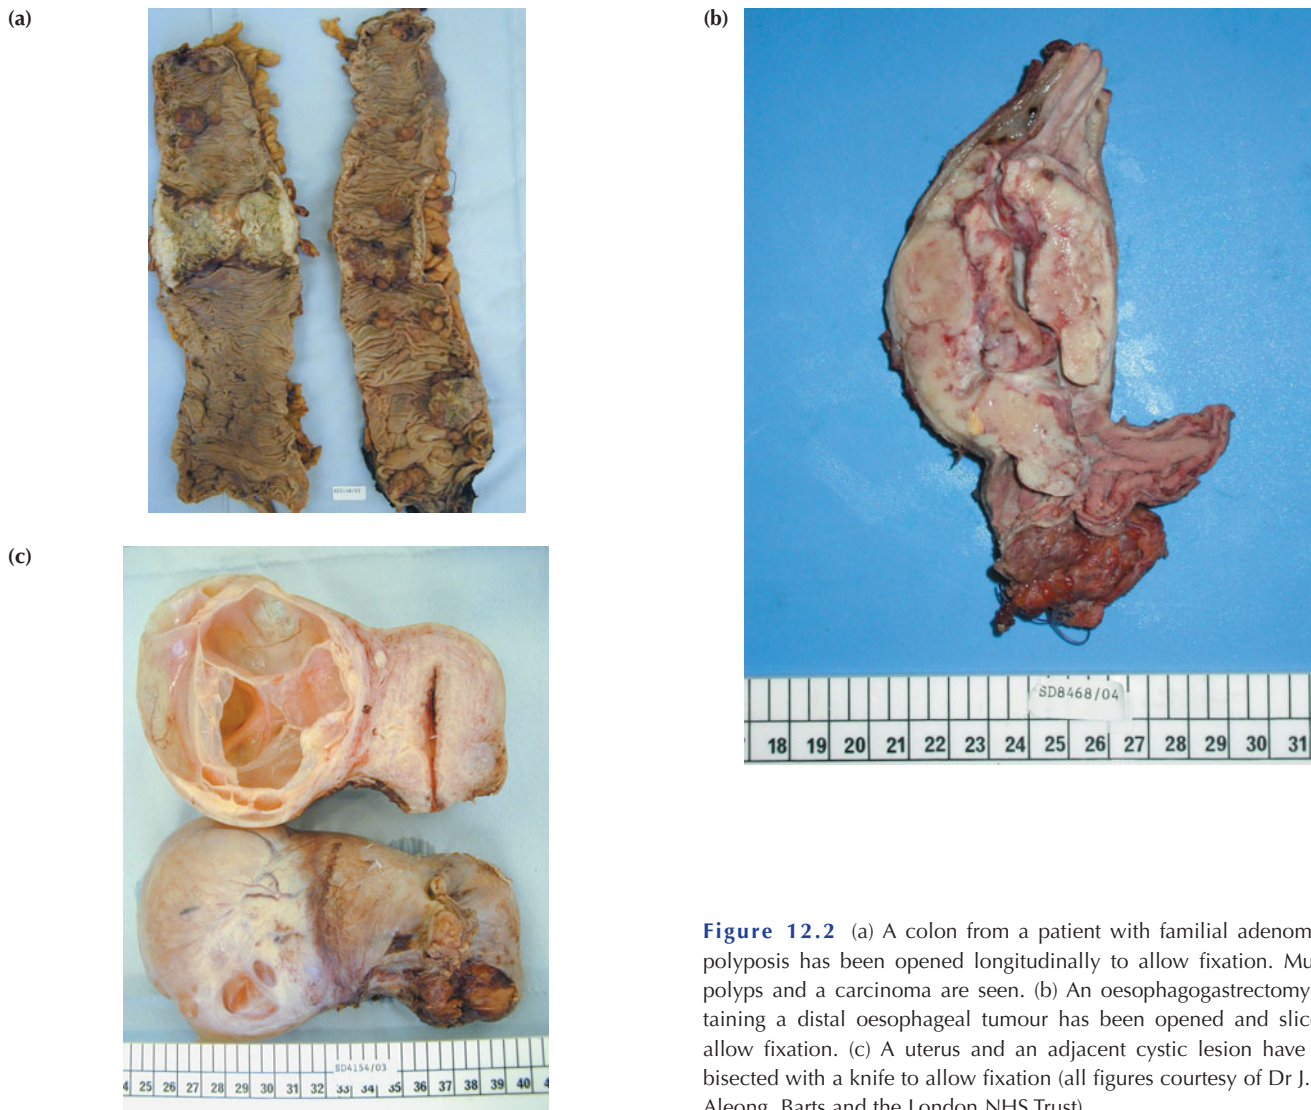

Figure 12.2 (a) A colon from a patient with familial adenomatous polyposis has been opened longitudinally to allow fixation. Multiple polyps and a carcinoma are seen. (b) An oesophagogastrectomy containing a distal oesophageal tumour has been opened and sliced to allow fixation. (c) A uterus and an adjacent cystic lesion have been bisected with a knife to allow fixation (all figures courtesy of Dr J. Chin Aleong, Barts and the London NHS Trust).

Summary box 12.3

Histological processing: sequence of events

- Biopsy or resection specimen received
- Description made
- Specimen sampled (if necessary)
- Specimen or samples from specimen placed in cassette(s)
- Paraffin wax block(s) made
- 5- μ m sections cut
- Sections put on glass slides
- Sections stained with H&E
- Histopathologist examines slides
- Histology compared with clinical and macroscopic findings
- Further studies if necessary
- Report entered onto computer system

FROZEN SECTION SPECIMEN

Frozen section diagnosis is useful when a rapid answer is necessary. Surgeons are the main users of this service. A fresh (unfixed) tissue sample is frozen on a metal chuck, and sections are cut and

stained within a few minutes. There are several disadvantages (Summary box 12.4). Fresh tissue carries a higher risk of infection than fixed tissue. The quality of a frozen section slide is inferior to that of routinely processed material, reducing the accuracy and precision of diagnosis. Small samples are required. Also, certain

Figure 12.3 A sample is taken from a resection specimen with a scalpel.

Figure 12.4 (a) An unopened pancreatoduodenectomy specimen (posterior view). Four inks of different colours have been painted onto various resection margins and external surfaces. (b) Yellow ink on the edge of a histology section (thick arrow). Tumour (thin arrow) lies close to the surface. The distance between the tumour and a surface or a resection margin can be measured (double-headed arrow).

types of tissue, e.g. fat, are difficult to process. Importantly, frozen sections are very time-consuming and disruptive for the histopathology department.

Summary box 12.4

Frozen section: advantages and disadvantages

Advantages:

- Quick diagnosis

Disadvantages:

- Labour intensive
- Disruptive
- Risk of infection
- Poorer quality sections
- Small sample required
- Some tissue types difficult to process

Figure 12.5 A sample from a resection specimen is placed in a cassette.

Figure 12.6 Paraffin wax blocks. Cassettes of different colours allow specimens to be organised into groups.

Cytology specimen

Many samples can be smeared immediately onto glass slides, fixed (usually in alcohol) or air dried, and stained immediately or later. Several slides are usually produced, some of which are stained with a Papanicolaou (Pap) stain and some with another method such as May–Grünwald–Giemsa (MGG) or Romanowsky. Cervical smears are usually stained with a Pap stain only (Fig. 12.9). For liquid-based cytology, the brushes used to obtain the sample are processed in the laboratory using purpose-built equipment.

Storage

Resection specimens are generally stored for about 4–6 weeks. Tissue blocks are retained for as long as space permits, typically for at least 30 years, while glass slides are typically retained for at least 10 years. Fresh tissue can be frozen and stored.

George Nicholas Papanicolaou, 1883–1962, Professor of Anatomy, Cornell University, New York, NY, USA, reported on the value of cervical smears in the diagnosis of carcinoma of the uterus in 1941.

Richard May, B. 1863, a Physician of Munich, Germany.

Ludwig Grunwald, B. 1863, an Otolaryngologist of Munich, Germany.

Gustav Giemsa, 1867–1948, a Bacteriologist who became Privatdozent in Chemotherapy, at The University of Hamburg, Hamburg, Germany.

Dimitri Leonidovich Romanovsky, 1861–1921, Professor of Medicine, St. Petersburg, Russia.

Figure 12.9 A cervical smear stained with a Papanicolaou stain. Numerous cells are present.

PRINCIPLES OF MICROSCOPIC DIAGNOSIS

Diagnosis of malignancy

The main histological criteria for malignancy are metastasis, invasion, architectural changes and cytological features (Summary box 12.5).

Summary box 12.5

Microscopic features of malignancy

- Metastasis
- Invasion
 - Of surrounding tissue
 - Vascular
 - Perineurial
- Architectural abnormalities
- Necrosis
- Numerous mitotic figures
- Atypical mitotic figures
- Nuclear abnormalities
 - Pleomorphism
 - Enlargement
 - Hyperchromaticity
 - Chromatin clumping
- Nucleolar enlargement and multiplicity

Metastasis is diagnostic of malignancy. Invasion of surrounding structures suggests malignancy, while perineurial (Fig. 12.10) and vascular invasion (Fig. 12.11) strongly suggest malignancy. Other microscopic features of malignancy include architectural derangement, an increased number of mitotic figures, atypical mitoses and necrosis (tissue death) (Fig. 12.12). Cytological changes include nuclear enlargement, an increased nuclear:cytoplasmic ratio, nuclear pleomorphism (variation in shape) and nuclear hyperchromasia (dark colour) (Fig. 12.13). Multiplicity, irregularity and enlargement of nucleoli may also be seen (Fig. 12.13).

The diagnosis of malignancy depends on the site and type of tissue. In general, epithelial cells must invade beyond

Figure 12.10 Perineurial invasion. A nerve is largely surrounded by tumour.

Figure 12.11 Vascular invasion. Aggregates of carcinoma cells are present within vessels.

Figure 12.12 A poorly differentiated carcinoma. There is an area of necrosis.

Figure 12.13 (a) A lymphoma showing cytological features of malignancy. There is nuclear pleomorphism (variation in appearance). Mitotic figures (thick arrow) are frequent. Many nuclei contain a prominent nucleolus (thin arrow). (b) A malignant melanoma showing nuclear pleomorphism and prominent nucleoli (arrow) (courtesy of Dr E. Husain, Barts and the London NHS Trust).

normal boundaries for malignancy to be diagnosed. The term 'dysplasia' indicates that microscopic features of carcinoma are present, but invasion has not occurred, e.g. cervical intraepithelial neoplasia (CIN), colorectal dysplasia (Fig. 12.14). However, in many types of non-epithelial tumour, the cytoarchitectural features, rather than invasiveness, are used to diagnose malignancy. In some cases, e.g. endocrine tumours, histological distinction between benign and malignant is impossible.

There are various causes of a false-positive diagnosis of malignancy. These include contamination of a specimen with tumour from elsewhere and interchanging of specimens. There are also numerous potential interpretative pitfalls for the histopathologist, the risk of which is reduced by thorough training, regular updating, discussion of difficult cases and avoidance of excessive workloads. The surgeon can also help to minimise interpretative errors by supplying adequate clinical details. For example, a history of radiotherapy is essential because radiation effects can mimic neoplasia. The histological changes in regenerating tissue, e.g. next to an ulcer, may also resemble malignancy (Summary box 12.6).

Figure 12.14 A colonic biopsy from a tubular adenoma with low-grade dysplasia. There is one non-dysplastic crypt (lower right corner). The remaining crypts show features of dysplasia, including nuclear stratification (multilayering) and nuclear hyperchromaticity (dark colour).

Summary box 12.6

Causes of false-positive diagnoses of malignancy

- Interchanged samples
- Contamination
- Interpretative error
- Treatment-induced change
- Ulceration

Histological types of malignancy

A malignant tumour showing features of epithelial differentiation, and typically arising in an epithelial layer, is a carcinoma. Other major types of malignancy include malignant melanoma (melanocytes), lymphoma (lymphoid cells) (Fig. 12.13a) and sarcoma (mesenchymal cells). In most cases, further subclassification is possible. For example, a carcinoma can be classified as squamous cell carcinoma (keratinisation) (Fig. 12.15), adenocarcinoma (tubule formation and mucin production) (Fig. 12.16), neuroendocrine carcinoma/small cell carcinoma (usually requiring immunohistochemical confirmation), clear cell carcinoma (Fig. 12.17), hepatocellular carcinoma or one of many other types.

Figure 12.15 A squamous cell carcinoma. There are foci of keratinisation (arrows).

Figure 12.16 A well-differentiated adenocarcinoma. Gland formation (arrow) is obvious.

Figure 12.17 A metastatic clear cell carcinoma, composed of sheets of cells with clear cytoplasm. This is most likely to be of renal origin.

Prognostic factors for tumours

Tissue assessment is important for prognosis. Stage is the most important prognostic factor for most carcinomas, and the commonly used UICC (Union internationale contre le cancer) staging scheme depends heavily on the histopathological TNM category (pT_pN_pM), although the M(etastases) category is usually evaluated clinically. Grade may also be prognostic and is usually determined microscopically. Low-grade/well-differentiated tumours resemble their normal tissue counterparts (Fig. 12.16), whereas high-grade/poorly differentiated tumours do not (Figs 12.11 and 12.12). Other histological features associated with a poor prognosis include vascular invasion (Fig. 12.11), perineurial invasion (Fig. 12.10) and positive resection margins.

Inflammatory conditions

Acute inflammation is characterised by neutrophils (polymorphonuclear leucocytes) (Fig. 12.18), and chronic inflammation by lymphocytes and plasma cells. Other inflammatory cells include eosinophils (Fig. 12.19), mast cells and histiocytes. Granulomas (i.e. collections of epithelioid histiocytes) (Fig. 12.20a and b) raise the possibility of mycobacterial infection, fungal infection and a

Figure 12.18 An acute inflammatory process characterised by neutrophils. Each arrow points to a neutrophil. Note the multilobated nuclei.

Figure 12.19 An inflammatory lesion in which eosinophils, characterised by bright red cytoplasm, are predominant.

Figure 12.20 (a) A granuloma with central necrosis, suggesting tuberculosis. (b) A Ziehl-Neelsen stain (different case) shows numerous acid-fast bacilli.

reaction to foreign material, among numerous possible causes. Eosinophils in large numbers may reflect parasitic infection or allergy. Interpretation depends heavily on the site and clinical setting.

ASSESSMENT

Microscopy

Most tissue assessment depends on conventional light microscopy. Microscopes have several lenses with various powers of magnification, typically ranging from $\times 20$ to $\times 400$ or more. A low-power lens allows a sample to be scanned, and overall architecture to be assessed, while a high-power lens allows a closer more detailed view (Fig. 12.21a and b). A teaching arm and a digital camera can be attached to most microscopes (Fig. 12.8). Polarisation can be used to detect foreign material or to assess a special stain, e.g. Congo red.

Histological assessment

In a histological preparation, the microscopic structure of the tissue is preserved, allowing direct visualisation of architecture. Accordingly, the pathologist can see not only the characteristics of the cells that form the tissue, but also the way in which these cells are related to one another and the way in which different tissue compartments are arranged.

Cytological assessment

A cytological preparation consists of a sample of cells. Architecture cannot be determined, because intact tissue is absent or sparse (Figs 12.9 and 12.22a and b). Therefore, assess-

Figure 12.21 (a) Low-power view of an umbilical nodule. Glands are distributed irregularly through the stroma. (b) High-power view shows benign columnar epithelium lining the glands, favouring endometriosis over carcinoma.

Figure 12.22 (a) A cytology preparation of a pleural effusion. Numerous cells with atypical features are present. (b) Immunohistochemistry shows positive staining for carcinoembryonic antigen (CEA), favouring carcinoma over mesothelioma

ment relies mainly on the characteristics of the cells themselves. Accordingly, it may be difficult to diagnose malignancy, because many of the criteria, particularly invasiveness, cannot be assessed. However, cytology has several potential advantages over histology (Summary box 12.7). A wider area may be sampled, and obtaining a specimen may be easier and less traumatic. Processing times are usually shorter and costs lower. Also, non-medical staff can be trained to report, particularly cervical smears (Fig. 12.9).

Summary box 12.7

Cytology compared with histology

Advantages:

- Wider area may be sampled
- Sampling may be less invasive
- Fast
- Cheap
- Can be interpreted by non-medical staff

Disadvantages:

- Cannot assess tissue architecture
- Less amenable to further studies

Screening

Screening programmes aim to detect and treat pre-malignant tissue changes. They may rely on cytology, histology or both. The

largest is the cervical cancer programme, which uses cytology initially, with biopsy and histology follow-up if appropriate. The breast cancer screening programme uses cytology and histology, while screening for cancer in ulcerative colitis relies entirely on histology.

Specimen adequacy

There are several possible reasons for an inadequate specimen (Summary box 12.8). The operator may fail to sample the intended organ or lesion, or may take too few samples to detect a heterogeneous abnormality. A sample from the centre of a necrotic or ulcerated lesion may not include viable tissue. Superficial biopsies from a carcinoma may fail to distinguish dysplasia (Fig. 12.14) from invasive carcinoma. Cautery and crush artefact may be severe enough to impede assessment. Cytology samples which have been spread too thickly may not be interpretable.

Summary box 12.8

Reasons for an inadequate sample

Histology and cytology:

- Failure to sample the intended organ or lesion
- Sample too limited
- Non-viable tissue

Histology:

- Sample too superficial
- Cautery artefact
- Crush artefact

Cytology:

- Thick smear

Further work

Further work is performed on a minority of histology specimens, and includes deeper levels, extra blocks, special stains and immunohistochemistry. *In situ* hybridisation, electron microscopy and polymerase chain reaction (PCR)-based methods may also be used. Some techniques can also be applied to cytology specimens (Summary box 12.9, Fig. 12.22a and b).

Summary box 12.9

Additional techniques

- Deeper levels
- Extra blocks
- Special stains
- Immunohistochemistry
- *In situ* hybridisation
- Electron microscopy
- PCR-based techniques
- Fluorescence *in situ* hybridisation (FISH)

DEEPER LEVELS AND EXTRA BLOCKS

The pathologist may request 'deeper levels', whereby the BMS cuts further into the paraffin block to obtain further sections. For example, deeper levels of an atypical but non-invasive epithelial lesion might show foci of invasion, allowing carcinoma to be

diagnosed. Extra samples may be taken if a specimen has been sampled inadequately, e.g. if insufficient lymph nodes have been retrieved from a resection specimen.

SPECIAL STAINS

A 'special stain' is a stain that is not routine. Immunohistochemical stains are conventionally excluded from this category. Some special stains demonstrate normal substances in increased quantities or abnormal locations. The periodic acid–Schiff (PAS) stain demonstrates both glycogen and mucin, whereas a diastase PAS (D-PAS) stain demonstrates mucin, e.g. in an adenocarcinoma. Perls Prussian blue stain demonstrates iron accumulation (Fig. 12.23a and b), e.g. in haemochromatosis. A reticulin stain helps to demonstrate fibrosis (Fig. 12.24a and b). Elastic stains also show fibrosis and can highlight blood vessels by outlining their elastic laminae. Special stains can also reveal the accumulation of abnormal substances, e.g. a Congo red stain for amyloid (Summary box 12.10).

Figure 12.23 (a) Brown pigment in a biopsy. (b) A Perls stain is positive, indicating that the pigment is iron.

Hugo Schiff, 1834–1915, a German Biochemist who worked at Florence, Italy.
Max Perls, 1843–1881, A Pathologist of Giesen, Germany.
Congo Red is Sodium diphenylbisazobisnaphthylamine sulphonate.

Figure 12.24 (a) A liver biopsy stained with haematoxylin and eosin (H&E) in which the severity of fibrosis cannot be determined. (b) A reticulin stain demonstrates fibrous bridges (arrows).

Summary box 12.10

Common special stains

- PAS: glycogen, fungi
- D-PAS: mucin
- Perls Prussian blue: iron
- Reticulin: reticulin fibres
- van Gieson: collagen
- Congo red: amyloid
- Ziehl–Neelsen: mycobacteria

Special stains are also useful for the diagnosis of infection. For example, a Ziehl–Neelsen stain demonstrates acid-fast bacilli, particularly mycobacteria, by staining them bright red in a blue background (Fig. 12.20a and b). Mycobacteria cannot be seen on H&E slides. Other micro-organisms that may be detectable on H&E but are easier to see with a special stain include fungi (PAS or Grocott stain), protozoa (Giemsa stain) and spirochaetes (Warthin–Starry stain).

Ira Thompson van Gieson, 1866–1913, an American Neuropathologist, described this stain in 1889.

Franz Heinrich Paul Ziehl, 1859–1926, Neurologist, Lübeck, Germany.

Friedrich Carl Adolf Neelsen, 1854–1894, Pathologist, Prosector, the Stadt-Krankenhaus, Dresden, Germany.

Aldred Scott Warthin, 1866–1931, Professor of Pathology, The University of Michigan, Ann Arbor, MI, USA.

IMMUNOHISTOCHEMISTRY

Immunohistochemistry, which was introduced in the 1970s, has had a major impact on histopathological diagnosis. This technique detects a specific antigen using an antibody. Numerous antibodies are now commercially available. The antibody is labelled with a dye and, when bound to its target antigen, is seen in the tissue section as a coloured stain, often brown (Fig. 12.25), allowing the presence of an antigen and its tissue distribution to be determined. Immunohistochemistry can be applied to fixed, fresh and frozen tissue and to cytological preparations (Fig. 12.22b). It is specific, safe, quick and relatively inexpensive. False-positive results can result from non-specific staining or cross-reaction with similar antigens.

Immunohistochemistry: tumour pathology

Immunohistochemistry has numerous applications in tumour pathology, including determination of cell type/direction of differentiation and elucidation of site of origin. Immunohistochemistry may also help to confirm neoplasia, determine the selection of treatment and refine prognostic predictions (Summary box 12.11).

Summary box 12.11

Some immunohistochemical stains used for tumours

- Cell type/site of origin:
 - Epithelial (carcinoma): cytokeratins
 - Lymphoid (lymphoma): CD3, CD20
 - Melanocytic (melanoma): S100
 - Neuroendocrine: CD56, chromogranin
 - Vascular: CD31, CD34
 - Myoid: desmin, actin
- Site of origin/cell type:
 - Prostate: prostate-specific antigen (PSA)
 - Lung: thyroid transcription factor-1 (TTF-1)
 - Thyroid: thyroglobulin
 - Colorectum: cytokeratin 20 (CK20)
 - Stomach, gynaecological, lung: cytokeratin 7 (CK7)
 - Liver: HepPar
 - Ovary: CA125
- Prognosis and treatment:
 - Breast carcinoma: receptors (ER, PR, HER2)
 - Endocrine tumours: Ki67 proliferative index
 - GIST: CD117

Various immunohistochemical stains are used to detect cell type. Cytokeratins are expressed by epithelial cells. Cytokeratin positivity suggests carcinoma (Fig. 12.25), but can also occur in other malignancies. Endothelial cell markers include CD31 and CD34, which may highlight vascular invasion or confirm a diagnosis of vascular neoplasia. Lymphoid markers include the pan-lymphoid marker CD45, the T-cell marker CD3 and the B-cell marker CD20. Markers of melanocytic differentiation include S100 and HMB45. Neuroendocrine/endocrine markers such as chromogranin and CD56 stain all neuroendocrine tumours including carcinoid, neuroendocrine carcinoma and small cell carcinoma.

Figure 12.25 Diffuse immunohistochemical staining (brown) for a pancytokeratin marker in a malignancy, suggesting carcinoma.

The site of origin of a metastatic tumour may be suggested by H&E appearances. For example, a clear cell carcinoma (Fig. 12.17) is most likely to be of renal origin. In more difficult cases, markers of cell type (see above) provide clues. Other immunostains may provide further information. Some are highly specific, e.g. prostate-specific antigen (PSA) and thyroglobulin. Others are slightly less specific, e.g. thyroid transcription factor-1 (TTF-1), which favours bronchogenic origin, and HepPar, which favours hepatocellular origin. Individual cytokeratins include cytokeratin 7 (CK7), expressed by upper gastrointestinal, breast, lung and gynaecological malignancies, and CK20, expressed by colorectal carcinoma. Carcinoembryonic antigen (CEA) is seen in gastrointestinal and lung carcinomas (Fig. 12.22a and b), while CA125 is a marker for ovarian and other gynaecological tumours. However, a significant minority of tumours, especially if poorly differentiated, do not conform to these typical patterns. Therefore, the clinical picture, imaging results and H&E appearances must always be taken into account.

Immunohistochemistry may help to confirm malignancy. In lymphoid proliferations, light chain restriction (expression of only one immunoglobulin light chain) suggests clonality and favours neoplasia. S100 and actin stains can be used to identify the myoepithelial cell layer in a duct or gland; the absence of this layer around a neoplastic proliferation suggests invasiveness and favours malignancy.

Immunohistochemistry may play a role in the selection of treatment and prognostic predictions. Carcinomas of the breast are assessed for oestrogen receptor, progesterone receptor and HER2 status, while lymphomas are subjected to a comprehensive array of stains. Metastases from gastrointestinal stromal tumours (GIST) can be treated with the chemotherapeutic agent imatinib if they express CD117 (Fig. 12.26a and b). The management of endocrine tumours is influenced by the Ki67 proliferative index (Fig. 12.27).

Immunohistochemistry: infections

There are antibodies to many infective agents, including cytomegalovirus (CMV), Epstein–Barr virus (EBV), herpes simplex

Michael Anthony Epstein, B. 1921, formerly Professor of Pathology, The University of Bristol, Bristol, England.
Yvonne Barr, B. 1931, a Virologist who emigrated to Australia. Epstein and Barr discovered this virus in 1964.

Figure 12.26 (a) A metastatic tumour composed of spindle cells. Gastrointestinal stromal tumour (GIST) was suspected. (b) Positive immunohistochemistry for CD117, confirming GIST, and indicating suitability for imatinib treatment.

Figure 12.27 Immunohistochemistry for Ki67. The proliferative index is approximately 10%.

virus, human herpes virus 8 (HHV8) and hepatitis B. Some of these, e.g. EBV and HHV8, cannot be demonstrated by H&E and require immunohistochemistry or other techniques for their detection.

Immunohistochemistry: other applications

Immunoglobulin expression can be studied, and the abnormal accumulation of various proteins such as alpha-1-antitrypsin (A1AT) can be assessed. Amyloid can be characterised. Screening for mutations is another application (Summary box 12.12, see below).

Summary box 12.12

Uses of immunohistochemistry

- Cell type
- Neoplasia:
 - Differentiation
 - Metastasis: site of origin
 - Confirmation of neoplasia
 - Selection of treatment
 - Prognosis
- Micro-organisms
- Other:
 - Amyloid
 - Immunoglobulins
 - Other proteins

IN SITU HYBRIDISATION

This technique uses an oligonucleotide probe targeted at a specific RNA or DNA sequence and can be performed on fixed or fresh tissue sections. The presence or absence of a particular gene, and also its location, can be determined. Micro-organisms, including EBV (Fig. 12.28), CMV and human papillomavirus, can be detected.

ELECTRON MICROSCOPY

Electron microscopy allows tissue to be visualised at very high magnification, e.g. $\times 1000$ to $\times 500\,000$. It may help to decide the lineage of a non-neoplastic or neoplastic cell in difficult cases, and may help to determine the nature of abnormal deposits, e.g. in renal disease. Unfortunately, it is time-consuming, labour intensive and expensive, and is now used selectively.

Figure 12.28 *In situ* hybridisation for Epstein-Barr virus (EBV) showing extensive nuclear positivity (black nuclei) in a gastric adenocarcinoma.

POLYMERASE CHAIN REACTION-BASED AND RELATED TECHNIQUES

The PCR amplifies DNA, yielding millions of copies from a single copy of a selected target. The amplified DNA is detected using various techniques, e.g. electrophoresis. RNA can also be amplified, using the technique of reverse transcriptase PCR (RT PCR). PCR is highly sensitive, fast and safe. However, it is expensive and has a high risk of contamination with DNA from outside sources. PCR can be performed on non-tissue samples (e.g. peripheral blood) and on homogenised tissue. PCR has an increasing number of clinical applications, including detection of mutations, confirmation of clonality and detection of infective agents (Summary box 12.13).

Summary box 12.13

Clinical applications of PCR to tissue samples

- Mutational analysis
- Clonality
- Loss of heterozygosity
- Chromosomal abnormalities
- Detection of micro-organisms

Detection of mutations

Mutational analysis comprises screening methods and direct sequencing. A germline mutation may predispose a patient to a specific disease or tumour. If the mutation is known, a sample of blood or tissue can be used to test patients and screen their families. For example, most patients with hereditary haemochromatosis are homozygous for a mutation of the *HFE* gene, while von Hippel–Lindau disease is caused by a mutation in the *vHL* gene. Mutations in colorectal carcinoma, whether sporadic or familial, include *APC* gene mutations (Fig. 12.29) and DNA

Figure 12.29 Mutation analysis of the *APC* gene. A variety of different tumours have been tested for mutation of the *APC* gene by polymerase chain reaction (PCR). Samples 1 and 2 (colorectal cancers) show loss of part of the *APC* gene resulting in smaller sized PCR products. All samples underwent sequence analysis, and point mutations (resulting in sequence change without loss of DNA) were identified in samples 5 and 7 (also colorectal cancers) (courtesy of Professor M. Ilyas, Nottingham University).

Eugen von Hippel, 1867–1939, Professor of Ophthalmology, Göttingen, Germany.
Arvid Lindau, 1892–1958, Professor of Pathology, Lund, Sweden.

mismatch repair gene abnormalities with associated microsatellite instability (MSI). Screening methods for the latter include immunohistochemistry (Fig. 12.30) and DNA amplification of specific microsatellites. Screening results indicate whether direct sequencing for mutations is justified.

Clonality

Clonal immunoglobulin heavy chain (IgH) gene rearrangements in B-cell proliferations and clonal T-cell receptor gene rearrangements in T-cell proliferations favour neoplasia over reactive proliferations. These rearrangements can be detected using PCR and specific primers.

Loss of heterozygosity

In some centres, loss of heterozygosity (LOH) assessment is performed routinely on certain tumours, e.g. resected oligodendrogliomas (for which LOH at 1p and 19q is prognostic). PCR-based methods are the most reliable, but FISH has the potential to yield similar information and is quicker and cheaper.

Figure 12.30 Immunohistochemical screening for microsatellite instability in a carcinoma. (a) Nuclear MLH1 expression is retained (arrows showing positively staining brown neoplastic nuclei). (b) In contrast, MSH2 expression is lost, suggesting microsatellite instability and mismatch repair gene abnormality.

Micro-organisms

Conventional diagnosis of infection relies on microscopy, culture or serology. PCR can be used to amplify DNA from micro-organisms. This is often done on peripheral blood and other fluids, but can be performed on tissue.

CYTOGENETICS AND FISH

Cytogenetics is the study of chromosomes. Chromosomal abnormalities may be numerical, structural (e.g. translocations) or of other types. Conventional cytogenetics is time-consuming and requires fresh tissue. Interphase cytogenetics relies on the FISH technique, which is safe and fast and can be applied to fresh or fixed tissue. Interphase FISH is used for the analysis of chromosomal abnormalities, e.g. in haematological malignancies and genetic conditions such as trisomy 23. Immunohistochemistry and FISH are used to assess HER2 amplification in breast cancer. Translocations, amplifications and other changes can also be detected using PCR.

AUTOPSY

In the past, major advances in medical knowledge were sometimes based on autopsy findings. Autopsies remain very useful for medical education and audit. In the UK, there are two types of autopsy. The first is the coroner's post-mortem, where there is a legal need to establish the cause of death. The second is the hospital autopsy, which requires relatives' consent. In most cases, all organs are examined. Tissue may be retained for further examination if appropriate.

Preoperative preparation

LEARNING OBJECTIVES

To understand:

- The tasks involved in preparing a patient for theatre
- The common problems affecting a patient's fitness for operation
- How to optimise a patient's medical state prior to anaesthesia/surgery
- How to take informed consent
- The organisation of an operating list

INTRODUCTION

A consultant surgeon leads a large team of people involved in safely seeing a patient through their individual operative experience. Even at an early stage in surgical training a trainee is a key member of that team.

Important aspects of the trainee's role in this process are:

- 1 *Gathering and recording* concisely all relevant information. Notes on the history, examination, investigation, conclusions and treatment plan should be clearly written, concise and yet comprehensive. The same applies to subsequent notes. They should allow other members of the team to familiarise themselves rapidly with the management plan and its rationale. It should be easy to check objective observations for any change in the patient's condition. If the notes are needed in court they should be a credit to the team, recording accurately the high level of care that has been given.
- 2 *Planning* to minimise risk and maximise benefit for the patient. Patients do not have to be medically fit before surgery is undertaken. This is simply not possible in many cases, especially when surgery is being undertaken as an emergency or when elective surgery is undertaken in the elderly. However, every effort should be made to find out what medical problems the patient has and how bad these are. Any problems should be treated if possible so that the risk to the patient is minimised. This will also involve balancing the potential harm caused by the delays involved in diagnosing and treating comorbidity with the benefits of taking time to bring problems under control. Elective patients should have all medical problems identified, assessed and addressed before being put onto an operative list; however, critically ill patients may only be able to receive rapid, continuous resuscitation on the way to theatre if they are to be treated in a timely manner.
- 3 *Being prepared* for adverse events and how to deal with them. Anticipating possible adverse events allows many of them to be avoided (e.g. making sure that the appropriate implant is available). Inevitably, things sometimes do not turn out as expected; comprehensive planning will have allowed contingency plans to

be made, ready for immediate implementation. One characteristic of an experienced surgeon is that there are rarely any surprises.

- 4 *Communicating* with the patient and all other members of the team. Communication errors are the source of many problems in patient care. Everyone, including the patient, should understand the surgical plan (Summary box 13.1).

Summary box 13.1

Preoperative patient preparation

- Gather and record concisely all relevant information
- Devise a plan to minimise risk and maximise benefit for the patient
- Consider possible adverse events and plan how to deal with them
- Communicate to ensure that everyone (including the patient) understands the surgical plan

PATIENT ASSESSMENT

Introduction

In the last 10 years there has been a major shift from in-patient to out-patient surgery. Alongside this, many patients requiring major in-patient elective surgery now arrive in hospital on the day of surgery. Preoperative assessment and optimisation have therefore become an increasingly important part of modern surgical practice.

At the start of each consultation the surgeon should introduce him/herself to the patient, explaining who he/she is. Patient details should be confirmed.

History

Do not assume that the history has already been adequately covered previously. Important points may have been overlooked in a busy out-patient clinic. In addition, there may have been a substantial delay between the clinic appointment and the admission for surgery, during which time symptoms and signs may have changed considerably.

There are a number of useful principles to adhere to when taking a history:

- *Listen*. What does the patient see as the problem? (Open questions.) Patients are allowed to describe their symptoms in their own words (try not to interrupt at this stage).
- *Clarify*. What does the patient expect? (Closed questions.) Clarify details in the history and explore the patient's hopes, fears and expectations of surgery. What outcome is the patient looking for?
- *Narrow the differential diagnosis*. (Focused questions.) Formulate a list of differential diagnoses as the story unfolds, with the most likely first. The order may change as the history progresses. Focused questions may help to exclude any outstanding differential diagnoses or highlight any ancillary problems that may need addressing.
- *Fitness*. What other comorbidities exist? (Fixed questions.) Some aspects of the history are not directly relevant to the diagnosis in hand but will be vital if anaesthesia and surgery are eventually necessary. Other conditions could alter the surgical plan or adversely affect the outcome unless they are identified and optimised. These factors all need to be considered before formulating the definitive management plan. Important negative findings must also be noted when they are important for the care plan, e.g. 'no problems with previous anaesthetics' (Summary box 13.2).

Summary box 13.2

Principles of history-taking

- *Listen*: what does the patient see as the problem? (Open questions)
- *Clarify*: what does the patient expect? (Closed questions)
- *Narrow the differential diagnosis*. (Focused questions)
- *Fitness*: what other comorbidities exist? (Fixed questions)

Layout of a standard history

Presenting complaint

The first few lines of the history should include the age and sex of the patient and, ideally, one sentence summarising the immediate problem(s) that the patient wants to resolve.

History of the presenting complaint

This section should describe the time course and severity of the patient's symptoms. Some assessment of the extent to which the problem is interfering with the patient's life should be made. What has the patient already tried to relieve the symptoms and what does the patient hope to achieve from any possible surgery? A useful mnemonic to help remember which of the basic features of the presenting complaint to explore is SORE POPE (Summary box 13.3).

Summary box 13.3

Features of the history of the presenting complaint to explore

- Symptoms, including features *not* present
- Onset
- Relieving factors
- Exacerbating factors
- Pain, nature of the pain, any radiation, etc.
- Other therapies
- Planned surgery
- Expectations

Past medical history

There will frequently be many negative responses in this section but any positive findings need to be recorded in some detail, including dates, causes, treatment and subsequent control of symptoms (Summary box 13.4).

Summary box 13.4

Key topics to review when taking the past medical history

Cardiovascular

- Ischaemic heart disease – angina, myocardial infarction^a
- Hypertension^a
- Heart failure
- Dysrhythmias
- Peripheral vascular disease
- Deep vein thrombosis and pulmonary embolism^a
- Anaemia

Respiratory

- Chronic obstructive pulmonary disease
- Asthma^a
- Fibrotic lung conditions
- Respiratory infections
- Malignancy

Gastrointestinal

- Peptic ulcer disease and gastro-oesophageal reflux
- Bowel habit – bleeding per rectum, obstruction
- Malignancy
- Liver disease – jaundice, alcohol, coagulopathy

Genitourinary tract

- Urinary tract infection
- Prostatism^a
- Renal dysfunction

Neurological

- Epilepsy
- Cerebrovascular accidents and transient ischaemic attacks
- Psychiatric disorders
- Cognitive function

Endocrine/metabolic

- Diabetes
- Thyroid dysfunction
- Pheochromocytoma
- Porphyria

Locomotor system

- Osteoarthritis
- Inflammatory arthropathy such as rheumatoid arthritis, including neck instability

Infectious diseases

- Human immunodeficiency virus
- Hepatitis
- Tuberculosis

Previous surgery

- Types of anaesthetic and any problems encountered^a
- Have any members of the patient's family had particular problems with anaesthesia?

^a These probably need recording even when negative as they are so important.

Drug history

Many patients also take alternative therapies such as herbal remedies or Chinese traditional medicine. It is important to list these as some therapies can interfere with the action of drugs such as warfarin. Enquiries should also be made about illegal drug use and any rehabilitation programme being followed. Ask about any allergic reactions, including their severity.

Social history

This should include a smoking and alcohol history as well as the patient's occupation and social circumstances. Social support is particularly important for the frail, elderly and disabled. Homeless patients and intravenous drug abusers present different challenges, as do those who are sole carers for disabled relatives. Identify problems early to formulate a sensible postoperative plan and prevent delays in discharge.

Examination

Keep patients warm and comfortable while they are being examined and always treat them with respect. Only expose parts of the body as they are required. Ideally a chaperone should always be present but this should certainly be the case for intimate examinations such as a vaginal or rectal examination. A full explanation of what is being done and why should be provided throughout. Painful areas should be approached with special caution and the patient's face watched throughout to check for signs of discomfort.

First, possible differential diagnoses should be actively excluded and any new complications that might make surgery more difficult highlighted, e.g. an inguinal hernia developing signs of bowel obstruction. Second, a general medical examination should be performed to identify the presence and severity of any comorbidities. If an operation has known complications (e.g. sciatic nerve damage in a patient receiving a total hip replacement) it is important to record the situation preoperatively, in case the problem pre-dates the surgery.

Summary box 13.5 highlights some important points to be noted in a general medical examination. The patient's nutritional status deserves special mention. This is an important determinant of surgical outcome. Patients with pre-existing nutritional impairment who are likely to be denied nutrition for a significant length of time because of the nature of their surgery or who have been septic or significantly injured are all at special risk. The body mass index (BMI) should be estimated for all patients if possible (body weight in kilograms divided by height in metres squared). A BMI of less than 18.5 indicates nutritional impairment and a BMI of less than 15 is associated with significant hospital mortality. Ask about recent weight loss and look for muscle wasting, loss of subcutaneous fat (the skin hanging in loose folds), oedema and alopecia (see Fig. 13.1) (Summary box 13.5).

Summary box 13.5

Key topics in the general medical examination

General

- Anaemia, jaundice, cyanosis, nutritional status, teeth, feet, leg ulcers (sources of infection)

Cardiovascular

- Pulse, blood pressure, heart sounds, bruits, peripheral pulses, peripheral oedema

Respiratory

- Respiratory rate and effort, chest expansion and percussion note, breath sounds, oxygen saturation

Gastrointestinal

- Abdominal masses, ascites, bowel sounds, bruits, herniae, genitalia

Neurological

- Conscious level, any pre-existing cognitive impairment or confusion, deafness, neurological status of limbs

Explaining to the patient

When the examination is complete the patient should be covered and made comfortable before discussing the proposed management plan. Allow the patient to ask questions.

Investigations

These should be ordered only when clinically indicated. Most hospitals have protocols to guide preoperative investigation requests. These are helpful but should not be followed blindly, as supplementary investigations are often required to aid surgical or anaesthetic planning. Request forms should be filled in clearly, including an explanation for why the request has been made. Record test results clearly in the notes, as well as the action taken to resolve any problems identified. Investigations that are commonly needed are described in the following sections.

Full blood count

This will be necessary in young women with menorrhagia or in any patient whose surgery may involve significant blood loss. It is usually necessary in older patients who may have undiagnosed

Figure 13.1 Cachectic male patient – mesothelioma of the left posterior chest wall.

anaemia. An abnormal white cell count will need further investigation to discover its cause.

Urea and electrolytes

This is normally necessary in patients over the age of 65, in patients who may lose a significant amount of blood in theatre or those with a history of cardiovascular, pulmonary or renal problems. It is also helpful in those taking regular diuretics.

Liver function tests

These are indicated in patients with jaundice, known or suspected hepatitis, cirrhosis, malignancy, portal hypertension, poor nutritional reserves or clotting problems.

Clotting screen

This is indicated for any patient on anticoagulants, with compromised liver function tests or evidence of a bleeding diathesis. It may also be advisable if the surgery may involve heavy blood loss.

Arterial blood gases

These are occasionally required for detailed assessment of some respiratory conditions, particularly if improvements might be achievable preoperatively. They are also useful if a significant acid–base disturbance is anticipated.

Electrocardiography

All departments will have guidelines on who should undergo electrocardiography (ECG). It is usually required in anyone over the age of 65, in all patients in whom significant blood loss is possible and in all those with a history of cardiovascular, pulmonary or anaesthetic problems.

Chest radiography

This is not usually required unless the patient has a significant cardiac history (including hypertension) or respiratory problems.

Further cardiac evaluation

Previous discussion with the anaesthetist and/or a cardiologist is advisable if there are cardiac problems. A resting ECG does not reliably predict ischaemic perioperative events. A ventricular ejection fraction of less than 35%, however, indicates a high risk of cardiac complications.

Further respiratory evaluation

Thoracic surgery usually requires a thorough respiratory work-up preoperatively. Otherwise, this is only indicated in patients with severe chronic obstructive airways disease [forced expiratory volume in 1 s (FEV₁) of < 40%] or poorly controlled asthma in which preoperative optimisation might be possible.

Temperature

Patients with a pyrexia should not be operated on until the cause has been identified and corrected if possible.

Urinalysis

Dipstick testing of urine is usually carried out preoperatively. It can detect urinary infection, biliuria, glycosuria and inappropriate osmolality. More detailed microscopic or biochemical analysis is indicated if the patient has a history of urinary tract problems or the urinalysis tests are abnormal.

β -Human chorionic gonadotrophin

This may be tested in blood or urine and used to confirm pregnancy. It is essential in all female patients of childbearing age with abdominal pain to exclude an ectopic pregnancy and in any unconscious female patient of childbearing age.

Sickle cell test

Usually the patient with sickle cell disease will know that they have this and inform the surgical team but it is important to exclude it in any unconscious patient from an affected part of the world. Sickle cell trait is less serious but should be tested for if a prolonged tourniquet time is anticipated.

Hepatitis/human immunodeficiency virus serology

Testing should be undertaken in any patient with a past history of high-risk exposure to infected body fluids, hepatitis or disorders associated with acquired immunodeficiency syndrome. Patient consent must usually be obtained before undertaking these tests, unless it is deemed that the patient lacks competence (see Obtaining consent, p. 192). In this situation the doctor must act in the patient's best interests.

Other radiological investigations

Patients with rheumatoid arthritis may have an unstable cervical spine, in which case the spinal cord can be injured during intubation. Flexion and extension lateral cervical spine radiographs should be obtained preoperatively to check for instability.

Orthopaedic surgery often requires careful planning on the basis of recent radiographs. Specialist views and imaging are sometimes required. It is important to check the requirements of the consultant concerned and make sure that the imaging (and not just the reports) is available at the time of surgery.

MANAGEMENT

Once the assessment process is completed a management plan can be drawn up in discussion with the patient. This should be carried out using language that the patient will understand. Often there will be two interdependent parts to this discussion.

First, the specific surgical diagnosis or diagnoses should be discussed. This discussion should include a systematic and logical presentation of any further investigations planned and treatment proposed. The possibility of not intervening should always be offered and the patient should be given ample time to voice their own concerns.

Second, confounding issues, such as medical comorbidities, may have been identified that will complicate the management plan. The risk of even a simple surgical procedure can be significantly increased by such comorbidities and this needs to be frankly discussed with the patient to allow truly informed consent to be given. It is not unusual for a patient in this situation to want time to think things over. If the patient is unsure it may be best to defer a final decision. Invite the patient to come back on another day with a prepared list of questions and suggest that they may wish to bring along a 'best friend' to help them at this important meeting. Inform the surgeon, the anaesthetist and any other relevant member of the team if you feel that you have identified a patient whose care may need to be out of the ordinary (Summary box 13.6).

Summary box 13.6

Key points in the management plan discussion

- Provide all of the information necessary for the patient to make an informed decision
- Use language that the patient will understand
- Discuss the options rather than telling the patient what will be done
- Give the patient time to think things over
- Encourage the patient to discuss things with a trusted friend/partner
- Suggest that the patient write down a list of points that he or she wishes to discuss

SPECIFIC PREOPERATIVE PROBLEMS

Cardiovascular disease

Hypertension

The number of operations cancelled because of uncontrolled hypertension has been substantially reduced by preoperative assessment clinics. Patients with systolic pressures of 160 mmHg or above and diastolic pressures of 95 mmHg or above should have elective surgery deferred until their blood pressure is under control. Newly diagnosed hypertension may need further investigation to look for an underlying cause; the medical team may need to be involved.

For an acute admission requiring urgent surgery the blood pressure may need to be controlled more rapidly. It can be dangerous for a patient's blood pressure to drop precipitously and this should be carried out with the assistance of the medical team.

Ischaemic heart disease, including recent myocardial infarction

Recent myocardial infarction is a strong contraindication to elective anaesthesia. There is a significant mortality rate from anaesthesia within 3 months of infarction and elective procedures should ideally be delayed until at least 6 months have elapsed.

Significant or worsening angina needs investigation by a cardiologist before elective surgery (Fig. 13.2). If urgent surgery is required, aggressive medical therapy is indicated and meticulous optimisation of oxygenation and fluid balance throughout the perioperative period must be obtained.

Dysrhythmias

Fast atrial fibrillation must be controlled before surgery. The intervention necessary depends on the physiological state of the patient and the urgency of the surgery required. Regular measurement of serum potassium is essential, particularly if digoxin is being used.

Some conduction disorders may require pacing preoperatively, in particular second- or third-degree heart block. If a pacemaker is already fitted it is important to check whether it is programmable, as it will need to be switched to 'rate' or 'demand' mode preoperatively; expert cardiologist support should be obtained for this. Most standard pacemakers are stable during anaesthesia but only bipolar diathermy should be used whenever possible. Figures 13.3 and 13.4 illustrate two cases requiring preoperative optimisation.

Figure 13.2 Preoperative electrocardiogram of a patient who complained of chest pain the previous day showing recent transmural anterior myocardial infarction with Q waves and ST elevation.

Cardiac failure

This needs careful work-up preoperatively and will require specialist medical input. Oxygenation and fluid balance are of critical importance in these patients and must be meticulously monitored and documented.

Anaemia and blood transfusion

Preoperative anaemia may result from bleeding or as a result of a chronic disease state. Preoperative transfusion should be considered if the preoperative haemoglobin concentration is below 8 g dl⁻¹ or if the patient is symptomatic or actively losing blood.

In stable patients a small dose of a loop diuretic should be given with each alternate bag of blood. Each unit should be given over a sensible time period (usually 4 hours) and transfusion at night should be avoided. If possible, the transfusion should be given a day or so before the surgery to allow time for the

Figure 13.3 Routine preoperative electrocardiogram in an 83-year-old patient with no symptoms other than lethargy for the last 3 months. This shows complete heart block with dissociated P waves and QRS complexes, requiring preoperative pacing.

Figure 13.4 Atrial flutter with 2:1 block. Note the characteristic 'sawtooth' baseline, best seen in lead II. The cause should be treated and the rate controlled.

2,3-diphosphoglycerate levels to recover, so improving the oxygen-carrying capability of the cells. It is important to avoid rapidly transfusing patients with chronic macrocytic anaemia as heart failure can result. Other blood products such as platelets may also be required and may need to be requested well in advance if they are to be available on time.

Requests for blood must be carefully and clearly written to avoid the catastrophic complication of mis-transfusion. Mild febrile and allergic reactions are common with transfusion but high fevers and rigors require immediate cessation of the infusion and aggressive treatment for possible septic shock (Summary box 13.7).

Summary box 13.7

Preoperative transfusions

- Consider transfusion if haemoglobin level is less than 8 g dl^{-1}
- Consider carefully which products to use
- Order and write up blood products clearly
- Give the blood at a sensible time of day
- Consider co-administration of a loop diuretic
- Be prepared to treat any reactions rapidly

For major procedures a preoperative 'group and save' should be performed and blood cross-matched if necessary. Some units now use blood recycling systems in theatre, although paradoxically this does not seem to reduce the need for cross-matched blood.

Some patients will refuse blood transfusion (e.g. Jehovah's Witnesses). They should be asked to sign an extra consent form preoperatively making this explicit and accepting the consequences.

Prosthetic or leaking cardiac valves

Prophylactic antibiotic cover is usually necessary in these patients, especially if turbulent flow is likely to occur or the surgery may produce a bacteraemia.

A Jehovah's Witness is a member of a millenarian fundamentalist Christian sect founded in America in 1884. They have their own translation of the Bible which they interpret literally.

Respiratory disease

Infection

Significant lower respiratory tract infections should be treated before surgery except when the surgery is life-saving. Hospital protocols should be followed. The initial choice of antibiotic will depend on whether the infection was acquired at home or from hospital, and on the severity of the infection.

Patients with bronchiectasis and chronically infected sputum may need appropriate antibiotics combined with intensive physiotherapy. This may best be organised by admission to hospital several days before the surgery.

Asthma

The patient's usual inhalers should be continued. Brittle asthmatics may need oral steroid cover. The care plan will need to be discussed with the anaesthetist.

Chronic obstructive pulmonary disease

The anaesthetist must be informed if the chronic obstructive pulmonary disease (COPD) is significant, as regional anaesthetic techniques may need to be considered. Appropriate postoperative care will also need to be arranged and discussed with the patient and other members of the team. This may include booking an intensive therapy unit (ITU) bed.

Pulmonary fibrosis

There is no evidence that any treatment alters the course of this group of diseases but the anaesthetist will appreciate being warned about any cases in which gaseous exchange is significantly impaired.

Most respiratory conditions significantly increase postoperative morbidity and this should be made clear to the patient and mentioned in the consent. If the patient smokes they should be asked to stop at least 4 weeks before the surgery and the reasons be explained.

Gastrointestinal disease

Malnutrition

In the malnourished patient, treatment with nutritional support for a minimum of 2 weeks before surgery is required to have any impact on subsequent morbidity. If it is clear that the patient will not be able to eat for a significant time postoperatively, arrangements should be made to start nutritional support in the immediate postoperative phase. Chapter 17 covers this important topic in detail.

Obesity

Obesity is defined as a BMI of more than 30. These patients are at an increased risk of a number of postoperative complications. In some cases it might be better for the patient to delay surgery until they have lost weight. In others, extra prophylactic measures may need to be taken and the risks incorporated into the consent form (Summary box 13.8).

Summary box 13.8

Problems of surgery in the obese

Increased risk of:

- Difficulty intubating
- Aspiration
- Myocardial infarction
- Cerebrovascular accident
- Deep vein thrombosis and pulmonary embolism
- Respiratory compromise
- Poor wound healing/infection
- Pressure sores
- Mechanical problems – lifting, transferring, operating table weight limits

Regurgitation risk

Pulmonary aspiration can lead to acid pneumonitis, severe bronchospasm, pneumonia and death. Patients with a hiatus hernia, bowel obstruction or paralytic ileus, as well as emergency patients, are at a particularly high risk, even if they have been nil by mouth for an appropriate period.

A frequently used regime is 'no solids for 6 hours' and 'no clear fluids for 4 hours' before surgery. Some units now allow clear fluids up to 2 hours before surgery and the rules may be different again for infants.

Other management strategies may include the preoperative use of H₂-receptor blockade, a nasogastric tube to empty a significantly distended stomach and specific anaesthetic techniques.

Jaundice

If the cause of jaundice is obstruction to the biliary tree it is important to ascertain whether there is associated sepsis (cholangitis). Infective causes may represent an increased risk to members of staff potentially exposed to body fluids and this should be highlighted to those concerned.

Jaundiced patients are also at risk of significant secondary complications. Impaired clotting occurs because of vitamin K deficiency and this should be corrected. There is also an increased risk of renal failure (hepatorenal syndrome) and so patients must be kept well hydrated, as well as a risk of other infections, so that prophylactic antibiotics will also be needed (Summary box 13.9).

Summary box 13.9

Surgery in the jaundiced patient

Causes of jaundice:

- Pre-hepatic – haemolysis
- Hepatic – hepatitis, cholangitis, alcohol
- Post-hepatic – biliary obstruction, drugs

Secondary complications of surgery:

- Clotting disorders
- Hepatorenal syndrome
- Infection

Genitourinary disease**Renal impairment****Prerenal**

If the renal impairment appears to be a new finding, suspect a prerenal cause such as volume depletion. If previous tests of renal

function are available for comparison, a disproportionate rise in urea concentrations compared with those of creatinine is diagnostic. Consider other causes of poor perfusion, particularly impairment of cardiac output.

Renal

A 'renal' cause for low urine output may arise following prolonged dehydration or the administration of certain nephrotoxic drugs [non-steroidal anti-inflammatory drugs (NSAIDs) and aminoglycoside antibiotics] or in the presence of several medical conditions. The cause of the problem should be removed and the advice of a physician sought. Prolonged dehydration may also affect platelet function and cause immunosuppression. Patients with chronic renal failure who do not require dialysis may easily be precipitated into end-stage failure by an episode of intraoperative hypotension or inadequate fluid management. Those already receiving dialysis will need to be treated 24 hours before surgery to ensure optimal fluid balance and electrolyte correction and to allow the necessary heparinisation to wear off. Further dialysis should be delayed for 24 hours after surgery if possible. Transplant patients should continue their immunosuppression and be covered with prophylactic antibiotics if necessary.

Postrenal

'Postrenal' causes of renal impairment include obstruction from any cause, e.g. renal calculi and prostate enlargement, or even a blocked catheter (Summary box 13.10).

Summary box 13.10

Renal impairment

- Prerenal:
 - Dehydration
 - Poor perfusion
- Renal:
 - Acute – volume depletion, platelet function, immunosuppression
 - Chronic – fluid balance, ?dialysis, ?transplantation
- Postrenal:
 - Obstruction – calculi, prostate, blocked catheter

Urinary tract infection

Uncomplicated urine infections are seen most commonly, but not exclusively, in female patients. A male patient with outflow uropathy will almost invariably have chronically infected urine. Most centres treat such infections before high-risk elective surgery (such as joint replacement surgery) and wait for a negative result before proceeding. Urgent procedures rarely need delaying because of a urinary tract infection but antibiotics should be started and care taken to ensure that the patient maintains a good urine output.

In the systemically compromised patient, renal tract obstruction and pyelonephritis should be excluded.

Metabolic disorders**Diabetes**

These patients are at high risk of complications. A careful preoperative assessment of their cardiovascular, peripheral vascular and neurological status should always be made. Possible preoperative risk-reduction strategies may include (but are not limited

to) introducing lipid-lowering medication, improving diabetic control and treating significant vascular stenoses (Summary box 13.11).

Summary box 13.11

Surgical risks for the diabetic patient

- Increased risk of sepsis – local and general
- Neuropathic complications – pressure care
- Vascular complications – cardiovascular, cerebrovascular, peripheral
- Renal complications
- Fluid and electrolyte disturbances

Minor surgery in the non-insulin-dependent diabetic can be managed by simply omitting their morning dose of medication, listing them for early surgery and restarting treatment when they start eating postoperatively. For more significant surgery, and in the insulin-dependent diabetic, an intravenous insulin infusion will be required. This should be started when the patient first omits a meal and continued until they have recovered from the surgery. The plasma potassium level must be closely monitored.

There is a risk of life-threatening lactic acidosis in patients taking metformin who are to have contrast angiography. This drug should be discontinued 24 hours before the test and restarted 24–48 hours afterwards.

Adrenocortical suppression

Patients receiving oral adrenocortical steroids regularly (including up to 2 months before surgery) will have a degree of adrenocortical suppression. They will require extra doses of steroids around the time of surgery to avoid an Addisonian crisis.

Other (rare) metabolic disorders

Familial porphyria, malignant hyperpyrexia and pheochromocytoma are all rare conditions with specific, significant anaesthetic risks. The anaesthetist should be informed if these conditions are identified.

Coagulation disorders

Patients taking drugs that interfere with the clotting cascades

Warfarin is the commonest drug in this category. The reasons for the therapy should be established and the associated risks of stopping the treatment assessed.

For simple atrial fibrillation, warfarin can usually be stopped 3–4 days before surgery and then restarted at the normal dosage level on the evening after surgery. Check that the international normalised ratio (INR) has dropped to 1.5 or lower before surgery. Alternative perioperative anticoagulation is not required.

When the risk of thrombosis is significant, for instance with a mechanical heart valve, the warfarin should be replaced with an infusion of heparin, which is stopped 2 hours before surgery and restarted immediately afterwards. This will need close monitoring with sequential blood tests of the activated partial thromboplastin time (APTT).

Thomas Addison, 1795–1860, Physician, Guy's Hospital, London, England, described the effects of disease of the suprarenal capsules in 1849.

For intermediate risk patients, a low molecular weight heparin may provide sufficient cover.

In some centres warfarin is not stopped for minor surgery, such as carpal tunnel release, and, if necessary, the effects of warfarin can be reversed using blood products and/or vitamin K. Vitamin K administration may cause prolonged resistance to warfarin and so should be used judiciously. The administration of low molecular weight heparin for any cause may preclude certain regional anaesthetic techniques, especially an epidural (because of the risk of a bleed in the spinal canal).

Anti-platelet agents such as aspirin and clopidogrel do not affect the INR or APTT but may affect bleeding times. The effects of these drugs cannot easily be acutely reversed, except with an infusion of new platelets. After these drugs are discontinued the effects are not reversed until the body manufactures new platelets; this commonly takes about a week. Most minor surgery can be safely undertaken without waiting this length of time but some anaesthetists are reluctant to use certain regional techniques if clopidogrel has been recently taken. For extensive surgery, or when considerable bleeding is anticipated, the safest policy is to wait if possible.

Acquired coagulopathy

For complex disorders, such as disseminated intravascular coagulation (DIC) and haemophilia, the treatment should be discussed with the haematologist.

Hypothermic patients bleed more than normal and they should be actively warmed before surgery. All patients should be kept warm in theatre, particularly during prolonged procedures.

Thrombophilia

An increased tendency to thrombosis is associated with a number of risk factors. Patients with a strong family history or previous personal history of thrombosis may have one of a number of genetic mutations. These include deficiencies in antithrombin III, protein S and C and anticardiolipin antibodies. Routine screening for these conditions is not recommended but if they are identified preoperatively management should be discussed with the haematology team (Summary box 13.12).

Summary box 13.12

Risk factors for thrombosis

- Increasing age
- Significant medical comorbidities (particularly malignancy)
- Trauma or surgery (especially of the abdomen, pelvis and lower limbs)
- Pregnancy/puerperium
- Immobility (including a lower limb plaster)
- Obesity
- Family/personal history of thrombosis
- Drugs, e.g. oestrogen, smoking

Reversible risk factors for thrombosis should be addressed before elective surgery if possible. After this has been carried out, individual risk factors should be taken into account to allow patients to be stratified into low-, moderate- or high-risk groups (Summary box 13.13).

Summary box 13.13

Risk groups for thrombosis*Low risk*

- Minor surgery (less than 30 min), no risk factors, any age
- Major surgery (more than 30 min), no risk factors, less than age 40
- Minor trauma or medical illness

Moderate risk

- Major surgery (not orthopaedic or abdominal cancer), age 40+ or other risk factor
- Major medical illness, trauma or burns
- Minor surgery, trauma or illness in patient with a family/personal history

High risk

- Major surgery (elective or trauma orthopaedic, cancer) of the pelvis, hip or lower limb
- Major surgery, trauma or illness in a patient with a family/personal history
- Lower limb paralysis/amputation

Some routine prophylaxis is recommended for moderate- and high-risk groups but the exact regime will be dictated by the risk–benefit ratio in each patient. Mechanical and/or pharmacological prophylaxis may be used. Pharmacological prophylaxis carries a variable risk of undesirable bleeding (gastrointestinal, intracranial, intraoperative and postoperative haematoma) (Summary box 13.14).

Summary box 13.14

Prophylaxis against thrombosis*Mechanical*

- Early mobilisation
- Neuraxial anaesthesia
- Leg compression stockings
- Calf and foot pumps

Pharmacological

- Heparin and low molecular weight heparin
- Warfarin
- Aspirin
- Pentasaccharides (e.g. fondaparinux – inhibits activated factor X)
- Direct thrombin inhibitors (e.g. melagatran and ximelagatran)

Neurological and psychiatric disorders

Peripheral neuropathies and myopathies may require prolonged ventilation postoperatively and this should be anticipated.

Anticonvulsants need to be continued perioperatively and may need to be changed to intravenous forms if starvation is prolonged.

Psychiatrically disturbed patients may require general rather than regional anaesthesia.

Certain psychiatric medications (particularly tricyclic antidepressants and monoamine oxidase inhibitors) may have unwanted interactions with anaesthetic and narcotic drugs. Ideally, monoamine oxidase inhibitors should be discontinued preoperatively.

Locomotor disorders

Specific complications of the inflammatory arthropathies should be identified preoperatively. The commonest, and potentially most catastrophic, of these is the unstable cervical spine in the patient with rheumatoid arthritis (Figs 13.5 and 13.6). If not handled carefully during intubation these patients can sustain significant spinal cord damage.

Most centres no longer stop disease-modifying drugs before surgery as this results in a flare-up of the disease that can take months to control and delays rehabilitation. Many of the disease-modifying drugs do increase the risk of wound-healing difficulties and infection but these effects are often longstanding and cannot be simply reversed by stopping the medication for a few weeks in isolation.

Figure 13.5 Extension view of cervical spine in patient with rheumatoid arthritis.

Figure 13.6 Flexion view in the same patient as in Figure 13.5. Note the huge increase in the atlantodens interval, implying significant instability at this level.

Remote site infection

Sources of potential bacteraemia, other than those already discussed, can compromise surgical results. Particularly significant is the risk of colonisation of any artificial material implanted at the time of surgery, such as in joint replacement surgery or arterial grafting. Sources of infection include infected toes and teeth. These should be treated preoperatively if possible. Appropriate antibiotic prophylaxis should be given if time does not permit complete eradication of the source of infection.

DOCUMENTATION

Clinical notes should be presented in a logical and economical manner. Investigations and a management plan should be clearly listed for action.

A drug chart should be completed including all of the patient's routine medication. Extra medications required perioperatively should be included, such as increased doses of corticosteroids, analgesia, antiemetics and thrombosis prophylaxis. Although the mainstay of infection prevention in the surgical patient is meticulous surgical technique, there is good evidence that prophylactic antibiotics can help reduce the incidence of this complication. The antibiotics prescribed should reflect the likely organisms involved. Most hospitals follow specific protocols for this. The drugs should be prescribed to allow peak serum concentrations to occur as the surgery starts. Only three doses (8-hourly) of prophylactic antibiotics should be given. Continuing antibiotics beyond the first 24 hours carries the risk that antibiotic resistance may develop, and there is no evidence of any benefit to the patient.

Certain procedures require bowel preparation to be given in advance and this should also be prescribed. Fluid charts and infusion pumps may also need to be organised.

OBTAINING CONSENT

The person obtaining consent should be fully conversant with the planned surgery, including all of the possible complications and alternatives.

Competence

To give informed consent adults (over 16 years) must be deemed competent. This requires that they can comprehend and retain the information discussed with them, believe it, and weigh up and choose from an array of treatment options. Children under 16 years of age can only give consent if they truly understand the nature, purpose and hazards of the relative treatment options. Although it is common to allow children to countersign the consent as they get older, it is still usually a parent who gives formal consent. A social worker can give consent for treatment for a child under a care order but if the child is in voluntary care the parent must still sign. For adults who are not deemed competent to give consent, treatment can still proceed if it is believed that it is in their best interests. It is usual to obtain two consultants' signatures in such cases and the reasons for the actions taken must be fully documented.

Stages in the consent process

The sections of most consent forms allow a structured approach to obtaining consent.

First, the patient's demographic details should be checked with the patient and the person obtaining consent should make it clear who they are and what their role is in the planned surgical episode.

Second, the planned operation should be outlined and confirmed with the patient. Alternatives to the proposed plan and the likely complications/outcomes of each choice (including doing nothing) should be discussed. All life- or limb-threatening complications and all minor complications with an incidence of 1% or more should be discussed. At this stage any risks specific to the patient should be discussed and recorded on the consent form (e.g. the extra risks arising from obesity). Steps that will be taken to minimise the risks and what will happen if complications do occur will also need to be discussed. Finally, it is important to check that the patient has understood what has been discussed and has no more questions.

If the preoperative preparation has been adequate the patient will be clear about the proposed plan and be happy to consent. Occasionally, new information may have been presented or the situation may have changed. The final decision is entirely the patient's and they must be given time and space to be completely comfortable with their choice (Summary box 13.15).

Summary box 13.15

Stages in the consent process

- Ensure competence (ensure that the patient can take in, analyse and express their view)
- Check details (correct patient)
- Make sure that the patient understands who you are and what your role is
- Discuss the treatment plan and sensible alternatives
- Discuss possible risks and complications (especially those specific to the patient)
- Discuss the type of anaesthetic proposed
- Give the patient time and space to make the final decision
- Check that the patient understands and has no more questions
- Record clearly and comprehensively what has been agreed

Marking

If the patient is to proceed directly to surgery this is a good time to mark the relevant side/limb if necessary.

MULTIPROFESSIONAL TEAM INVOLVEMENT

Organising an episode of surgical patient care involves a huge number of people and good communication is vital at all stages. The surgeon plays a key role in this team. A list of other people who may need to be involved is provided in Summary box 13.16.

Summary box 13.16

Multiprofessional team members**For theatre**

- Ward staff
- List organiser and circulator
- Theatre nursing staff
- Anaesthetic staff, including operating department practitioners (ODPs)
- Other members of the surgical team
- Radiology department
- Pathology department

For postoperative recovery

- Rehabilitation staff
- Social care workers
- Children's ward staff
- ITU/high-dependency unit staff
- Specialist nurse counsellor (stoma/amputation)

The person responsible for organising the order and circulation of the operating list must be provided with essential information such as who has diabetes (to list them early) and which cases are 'dirty' (to list them last/late). High-risk cases, such as patients

infected with human immunodeficiency virus or those with a latex allergy, must also be clearly documented.

Theatre scrub staff will need to be informed if any special equipment is required.

Postoperative recovery and discharge may be hastened by preoperative planning with rehabilitation staff.

Children and parents may value a visit to the ward where they will be staying and a chance to meet staff there, including the play specialist if available. Patients who may spend some time on the intensive care ward or a similar unit may appreciate familiarising themselves with this daunting environment before they are admitted as a completely dependent patient.

Preoperative counselling with a specialist nurse can lessen the psychological impact of some types of surgery (e.g. limb amputation surgery or stoma formation).

Anaesthesia and pain relief

CHAPTER 14

LEARNING OBJECTIVES

To gain an understanding of:

- Anaesthetic duties preoperatively, peroperatively and postoperatively
- The techniques for maintaining an airway
- The special problems of day surgery
- The methods of providing pain relief – advantages and dangers
- The principles underlying the provision of postoperative analgesia
- The management of chronic pain and pain arising from malignant disease

HISTORY

The first successful demonstration of general anaesthesia took place at the Massachusetts General Hospital in Boston, USA on 16 October 1846 when Morton, a local dentist, administered ether to Gilbert Abbot so that John Collins Warren could operate upon a vascular tumour on the patient's neck. News of the operation reached England later that year and on the 21 December Liston, at University College Hospital, London, amputated a leg through the thigh under ether anaesthesia. In 1847, Simpson of Edinburgh introduced chloroform as an alternative to ether, and this was used extensively for general surgery, and also to relieve the pain of labour. This latter use was opposed by some members of the public who felt that relieving labour pains was contrary to the teaching of the Bible. Public recognition of the benefits of anaesthesia for childbirth was attained when Queen Victoria accepted chloroform from John Snow during the birth of Prince Leopold, in April 1853 (chloroform a la reine).

PRINCIPLES

Many advances in anaesthesia have facilitated or been driven by changes in surgical practice. Optimal patient care is dependent

on good anaesthetic and surgical teamwork, with a joint approach to risk benefit assessment and preoperative optimisation of the patient's medical condition.

The importance of multidisciplinary collaborations at national level has been clearly demonstrated by the Confidential Enquiries into Maternal Deaths (triennial reports) and into Perioperative Deaths (CEPOD). These audits have enabled UK surgical and anaesthetic joint working parties to produce practice recommendations, which have resulted in influential documents such as *Pain after Surgery*.

Throughout, the anaesthetist's prime duty is to maintain the patient's safety and welfare, but it is also important to optimise the operative conditions. A collective duty of care exists to prevent injuries such as cutaneous burns or those to vulnerable structures such as nerves and eyes.

An anaesthetist's care extends into the postoperative period, at least until it has been clearly delegated to another person on the surgical ward or intensive care unit. Indeed, the modern anaesthetist is developing a more defined role as 'perioperative physician', with recognition of the continuing care beyond the immediate recovery period (Summary box 14.1).

William Thomas Green Morton, 1819–1868, a dentist who practised in Boston, MA, USA.

John Collins Warren, 1778–1856, Professor of Anatomy and Surgery, The Harvard Medical School, Boston, MA, USA.

Robert Liston, 1794–1847, Surgeon, University College Hospital, London, England.

Sir James Young Simpson, 1811–1870, Professor of Midwifery, Edinburgh, Scotland.

Alexandrina Victoria, 1819–1901, Queen of the United Kingdom of Great Britain and Ireland, (1837–1901).

John Snow, 1813–1858, a General Practitioner of London, England, who was one of the pioneers of anaesthesia.

Prince Leopold, 1853–1884, who later became Duke of the Albany, was the eighth of Queen Victoria's nine children, and her fourth son.

Summary box 14.1

Responsibilities of an anaesthetist: patient's safety and welfare

- Make sure the patient's condition is optimal before surgery
- Ensure that the patient knows what is going to happen
- Coordinate the team during surgery
- Participate in the collective duty of the team to protect the patient from harm
- Supervise the safe recovery of the patient from anaesthesia and into the recovery period

PREPARATION FOR ANAESTHESIA

Recognition of general medical and specific anaesthetic risk factors facilitates the implementation of pre-emptive measures and improves patient safety. Early assessment, liaison with the anaesthetist and appropriate investigations avoid unnecessary delays. The anaesthetist who is to administer the anaesthetic during the operation should assess the patient preoperatively and participate in the preparation for surgery. The various aspects of postoperative pain relief, nutrition and rehabilitation should all be discussed with the patient preoperatively to make sure that they understand and can help with what is happening.

GENERAL ANAESTHESIA

Intraoperatively, the anaesthetist should provide the general anaesthetic triad of unconsciousness, pain relief and muscular relaxation, while ensuring maintenance of tissue perfusion and oxygenation.

General anaesthesia is most frequently induced intravenously and maintained by inhaled vapour such as halothane, enflurane or the more recent desflurane or sevoflurane. Propofol has replaced thiopentone as the commonest intravenous agent. It can also be used for maintenance in total intravenous anaesthesia (TIVA), by choice or when inhalational anaesthesia may be impractical such as during airway laser surgery, endoscopy or cardiopulmonary bypass. TIVA usually comprises propofol, combined with a short-acting opioid analgesic agent such as alfentanil or ultra-short-acting remifentanyl, and neuromuscular blockade and pulmonary ventilation with a mixture of air and oxygen. The introduction of non-pungent sevoflurane has led to the renewed use of inhalational induction, particularly for children or 'needle-phobic' adults. It may also be used in patients who are at higher risk of developing airway obstruction.

Analgesic agents are also frequently injected at the time of anaesthetic induction, to reduce the cardiovascular response to tracheal intubation and to be effective by the time of surgical incision.

Although the use of nitrous oxide contributes analgesic and weak anaesthetic effects, its use is slowly declining as oxygen-enriched air mixtures become more popular, especially for longer cases. To provide a safety margin, at least 30% oxygen is added to the inspired mixture. Although still employed in some parts of the world, ether has generally been replaced by halothane, enflurane and isoflurane. The most recently introduced agents desflurane and sevoflurane have the advantages of fewer side-effects and more rapid recovery.

If compressed sources of oxygen, nitrous oxide or air are scarce, then air may be drawn into the anaesthetic circuit either by the (unparalysed) patient's own respiratory effort or by a mechanical ventilator (Fig. 14.1) (Summary box 14.2).

Summary box 14.2

The general anaesthetic triad

- Unconsciousness
- Pain relief
- Muscle relaxation

Figure 14.1 A continuous flow anaesthetic machine.

Management of the airway during anaesthesia

Loss of muscle tone as a result of general anaesthesia jeopardises airway patency and, hence, there is a requirement for methods to maintain the airway. These include manual techniques (e.g. jaw thrust) or the use of devices such as the Guedel or laryngeal mask airway or an endotracheal tube.

Sir Ivan Magill developed the endotracheal tube during the First World War to facilitate plastic surgery around the mouth without a face mask. The addition of a cuff to the tube allowed a seal of the trachea to protect the lungs from aspiration of blood or secretions and, later, to facilitate mechanical positive-pressure pulmonary ventilation.

The following means of airway control in the anaesthetised or unconscious patient are used:

- *Positioning of the tongue and jaw.* During a short procedure or before a definitive airway is inserted the anaesthetist thrusts the jaw forward from behind the temporomandibular joints, thereby lifting the tongue off the posterior pharyngeal wall. This may also be achieved by inserting an artificial oropharyngeal airway such as the Guedel airway. In these cases the anaesthetic gases are given through a face mask.
- *Laryngeal mask airway (LMA).* This was developed in the 1980s by Archie Brain, a UK anaesthetist. It is also inserted via the mouth and is positioned so that the mask covers the laryngeal inlet, which is sealed by an inflatable cuff. It provides a reliable means of maintaining the airway and frees the anaesthetist's hands from holding the patient's jaw or face mask. Its placement is less irritating to the patient's airway than

Arthur Ernest Guedel, 1883–1956, Clinical Professor of Anesthesiology, The University of Southern California, Los Angeles, CA, USA.

Sir Ivan Whiteside Magill, 1888–1986, Anaesthetist, The Westminster Hospital, London, England.

Archibald Ian Jeremy Brain, Formerly Anaesthetist, The Royal Berkshire Hospital, Reading, Berkshire, England.

endotracheal intubation. The technique is readily taught to non-anaesthetists for emergency airway management before endotracheal intubation (Fig. 14.2).

- **Endotracheal tube.** This may be passed into the trachea via either the mouth or the nose and is usually placed by direct laryngoscopy using a laryngoscope. Occasionally it is impossible to visualise the larynx in this way and a fiberoptic technique may be employed in which the tracheal tube is 'railroaded' over the flexible laryngoscope once the tip has been steered into the trachea (Figs 14.3–14.5).

Both the LMA and cuffed endotracheal tube facilitate artificial ventilation, but the cuffed endotracheal tube more reliably protects the lungs if there is a risk of pulmonary aspiration. If fluid or debris is likely to collect in the mouth from above (as in nasal surgery), an absorbent throat pack is placed in the oropharynx.

Endotracheal intubation is possible on most patients even in an emergency. However, on occasions it is impossible or airway control may be lost. There may even be accidental intubation of the oesophagus, which may initially go unrecognised.

Figure 14.2 The laryngeal mask airway. The laryngeal mask airway (left), I-gel airway (centre) and reinforced laryngeal mask airway (right).

Figure 14.3 The Macintosh laryngoscope with a standard blade (left) and McCoy's modification of the Macintosh blade (right).

Figure 14.4 Endotracheal devices. From left to right: an uncut orotracheal tube; reinforced orotracheal tube; oral version of an RAE (Ring, Adair and Elwyn) preformed tube; nasal version of an RAE preformed tube; tracheostomy tube.

Figure 14.5 A fiberoptic intubating laryngoscope.

Other complications include:

- accidental intubation of a main bronchus;
- trauma to the larynx, trachea or teeth;
- aspiration of vomitus during neuromuscular blockade for intubation;
- disconnection or blockage of the tube;
- delayed tracheal stenosis – in children or after prolonged intubation.

Careful technique, vigilance and patient monitoring minimise these risks.

There are many modified tracheal tube designs including armouring to avoid kinking and the use of non-combustible materials (metal or Teflon) for laser surgery in the airway to avoid potentially fatal fires in the patient's airway.

The RAE tube takes its name from the initials of the surnames of the people who introduced it, Wallace Harold Ring, John Adair and Richard Elwyn.

- *Tracheostomy tube.* Anaesthesia and pulmonary ventilation can be safely conducted through a tracheostomy tube using an inflatable cuff for airway control in place of an indwelling silver or fenestrated tracheostomy.
- *Endobronchial tube.* In open thoracic procedures such as pulmonary and oesophageal surgery, selective intubation of a main bronchus facilitates deflation of the lung on the operated side. Its use is also essential to protect the normal lung in the presence of a bronchopleural fistula.
- *Ventilation through a bronchoscope or endotracheal catheter.* The lungs can be ventilated during laryngotracheal surgery or bronchoscopy by intermittent jets of oxygen, which entrain air by the Venturi effect to generate enough pressure and flow to inflate the lungs (Summary box 14.3).

Summary box 14.3

Techniques for maintaining an airway

- Jaw thrust – only suitable for short term
- Guedel airway – holds tongue forwards but does not prevent aspiration
- Laryngeal mask – simple to insert, allows ventilation
- Endotracheal intubation – very secure protection of the airway
- Tracheostomy – used when airway needs protecting for prolonged periods

Neuromuscular blockade during surgery

The advent of neuromuscular blockade in the 1940s facilitated many advances in abdominal and thoracic surgery. Pharmacological blockade of neuromuscular transmission provides relaxation of muscles to facilitate surgery and mechanical positive pressure ventilation.

The depolarising muscle relaxant suxamethonium rapidly provides excellent intubating conditions of brief duration; however, it commonly causes postoperative diffuse muscle pains and, rarely, may cause a prolonged muscular block if the patient is deficient in plasma pseudocholinesterase.

The competitive neuromuscular blocking agents such as curare and its modern successors atracurium, cisatracurium, vecuronium and rocuronium share more predictable activity profiles and are less dependent on hepatorenal function for termination of action; however, they produce prolonged effects and, hence, require careful timing of doses so that the patient's muscle power is restored by the end of surgery. A peripheral nerve stimulator is also used to check for adequate depth of blockade during surgery and to confirm satisfactory recovery of neuromuscular function before resumption of spontaneous respiration and extubation of the trachea. It is essential to understand that these drugs are not hypnotic agents and are used as an adjunct to general anaesthesia, which is maintained by intravenous or inhalational anaesthetic agents to avoid any risk of accidental patient awareness.

Haemostasis and blood pressure control

Although the dangers of profound hypotension are well known nowadays, a 20–30% reduction of mean arterial blood pressure

Giovanni Battista Venturi, 1746–1822, Professor of Physics, The University of Modena, Modena, Italy.

from the awake preoperative level in fit patients is still deemed acceptable, greatly improving the quality of the operative field and reducing total blood loss. Reduction of venous pressure at the wound by correct patient positioning and avoidance of any causes of venous obstruction will prevent excessive bleeding, as will maintenance of satisfactorily deep anaesthesia with slightly reduced arterial carbon dioxide tension.

Hypotensive drugs may be used to produce deliberate controlled hypotension if there is a clear surgical benefit to be obtained. However, preservation of cerebral perfusion and oxygenation must take priority over any other considerations.

Management of temperature during anaesthesia

Vasodilatation, cold infusions of fluid and loss of body heat by radiation and fluid evaporation from open body cavities results in hypothermia under anaesthesia. It is a particular hazard in children because of the high ratio of body surface area to body mass. The elderly are also at particular risk as hypothermia and shivering increase oxygen consumption and vascular resistance, predisposing to myocardial infarction. Careful intraoperative temperature control using warm air blowers and warming blankets and maintenance of fluids for intravenous infusion or irrigation of body cavities or organs (such as the bladder and renal pelvis) to body temperature greatly reduce postoperative morbidity.

Monitoring during anaesthesia

Safety is optimised by the mandatory continuous presence of an adequately trained anaesthetist and equipment for patient monitoring during anaesthesia and cardiopulmonary resuscitation. The basic parameters monitored are inspiratory oxygen concentration, oxygen saturation by pulse oximetry, expiratory carbon dioxide tension, blood pressure and the electrocardiogram. For major surgery, hourly urine volumes and invasive, direct monitoring of the circulation are also used. Ventilators and breathing circuits should all have airway pressure monitors, disconnection alarms and continuous analysis of the oxygen content (with oxygen supply failure alarms). There should also be a measure of anaesthetic concentration in the inspiratory gas mixture (Summary box 14.4).

Summary box 14.4

Tasks of the anaesthetist during anaesthesia

- Muscle relaxation – to allow ventilation and opening of wounds
- Pain control and unconsciousness – to minimise distress to patient
- Minimise blood loss – careful control of blood pressure
- Temperature – avoid hypothermia
- Monitoring – patient safety

Recovery from general anaesthesia

Recovery from general anaesthesia should be closely supervised by trained nursing staff skilled in airway management in an area equipped with the means for resuscitation and adequate monitoring devices. Inadequate breathing after general anaesthesia may result from:

- obstruction of the airway;
- central sedation from opioid drugs or anaesthetic agents;

- hypoxia or hypercarbia of any cause;
- hypocarbia from mechanical overventilation;
- persistent neuromuscular blockade.

An anaesthetist should be readily available to respond to any problem. For the seriously ill patient, a high-dependency unit or intensive care unit may be necessary until the patient's condition is satisfactory and stable.

General anaesthesia for day-case surgery

Driven by financial need and patient preference, day-case management is increasing worldwide, accounting for 70% of procedures in some countries. Although the principles remain the same, day-case patients have to recover rapidly from general anaesthesia and mobilise with the minimum of side-effects. Both longer and more complex operations are now conducted as day cases. Careful selection of patients is important. Coexisting diseases, the nature of the proposed surgery, the availability of a suitable escort and transport home, and domiciliary care all influence the decision as to whether day surgery is appropriate. Well-controlled non-debilitating chronic diseases do not preclude day care. Anaesthetics that promote rapid recovery such as propofol, sevoflurane and desflurane are preferred. Drugs with prolonged depressant central action, including pre-medicant drugs, are avoided. When possible, patients are managed with a laryngeal mask or face mask.

Postoperative analgesia must be given regularly to prevent breakthrough pain and should be strong enough to cope with the pain once the local anaesthetic has worn off. This is especially true in painful procedures such as hernia repair, haemorrhoidectomy, tubal surgery and meniscectomy (Summary box 14.5).

Summary box 14.5

Day or ambulatory surgery

- Being used more and more commonly even for major operations
- Preoperative assessment of social, medical and surgical needs is important
- Anaesthesia needs to be modified for rapid recovery
- Appropriate and regular postoperative analgesia will prevent breakthrough

General anaesthesia and cardiopulmonary bypass

The technique is discussed in Chapter 52.

Table 14.1 Summary of drugs used for local anaesthesia

Name	Dose limit	Concentration	Comments
Lignocaine	3 mg kg ⁻¹ 7 mg kg ^{-1a}	1%, 2%	Early onset, short acting, good for sensory blocks
Bupivacaine	2 mg kg ⁻¹	0.25%, 0.5%	Longer lasting than lignocaine but more cardiotoxic; must never be injected into a vein
Ropivacaine	225 mg	0.2%, 1%	Less cardiotoxic; greater sensory than motor block
Prilocaine	400 mg	1%	Blue-brown skin colour indicates methaemoglobin toxicity
Levobupivacaine	150 mg	0.25%, 0.5%, 0.75%	An isomer of bupivacaine, less cardiotoxic

^a With adrenaline. Adrenaline enhances the effect of the local anaesthetic, prolongs its effect and allows larger doses to be used, but must not be given near end-arteries.

LOCAL ANAESTHESIA

Local anaesthetic drugs may be used to provide anaesthesia on their own by local infiltration, by the use of regional anaesthetic techniques or by providing neuraxial blockade (intrathecal or epidural anaesthesia), or as an adjunct to general anaesthesia by providing pain relief extending to the postoperative period. The choice of local anaesthetic technique depends upon its feasibility for a particular procedure and the patient's willingness and ability to cooperate, as well the surgeon's and anaesthetist's preference. Local anaesthesia may be the reliable and traditional method for some minor surgical procedures but it is not infallible and may be contraindicated by allergy or local infection. Epidural and intrathecal (spinal) anaesthesia are ideal for some operations but may cause vasodilatation and systemic hypotension because they also block the sympathetic nerves.

Complications may be local, such as infection or haematoma, or systemic, if overdosage or accidental intravascular injection leads to toxic blood levels. The latter may manifest as depressed conscious level, convulsions and/or cardiac arrest (particularly bupivacaine), and may be heralded by circumoral paraesthesia and light-headedness. Prilocaine overdosage causes methaemoglobinaemia. Recently introduced local anaesthetics such as ropivacaine and levobupivacaine are claimed to have enhanced cardiovascular safety profiles.

The addition of adrenaline (commonly at a concentration of 1:200 000–1:125 000) to the local anaesthetic solution hastens the onset and prolongs the duration of action and permits a higher dose of drug to be used as it is more slowly absorbed into the circulation. Adrenaline should not be used in hypertensive patients or for patients taking either monoamine oxidase inhibitors or tricyclic antidepressant drugs, as its cardiovascular effects may be potentiated. It is contraindicated in end-arterial locations where there is no collateral circulation, such as fingers and toes or around the retinal artery.

Appropriately skilled personnel and resuscitation and oxygen equipment should always be available when local anaesthetic is being used because of the potential risk of life-threatening complications.

The sensible upper dose limits for the common local anaesthetic agents are given below (Table 14.1):

- *Lignocaine* 3 mg kg⁻¹ or lignocaine with adrenaline (1:200 000) 7 mg kg⁻¹. Lignocaine 1% is effective for most sensory blocks. Thus, around 50 ml of lignocaine 1% (10 mg ml⁻¹) with adrenaline can be infiltrated into the tissues of a 70 kg patient.
- *Bupivacaine* 2 mg kg⁻¹ (30 ml of 0.5% bupivacaine is more cardiotoxic than lignocaine but has a longer-lasting effect).

Bupivacaine 0.25% is effective for sensory block against a moderate stimulus. Bupivacaine must never be injected into a vein and is absolutely contraindicated for use in intravenous regional anaesthesia or Bier's block.

- *Ropivacaine* 225 mg. A recent addition, it is claimed to have an improved cardiovascular safety profile while providing relatively greater sensory than motor blockade.
- *Prilocaine* 400 mg. The presence of a blue-brown skin colour indicates methaemoglobin toxicity.
- *Levobupivacaine*. Recently introduced, the levobupivacaine stereoisomer potentially has an improved cardiovascular safety profile while maintaining equivalent potency (Summary box 14.6).

Summary box 14.6

Types of anaesthesia

- Local anaesthetic – suitable for day cases; contraindicated in infection
- Regional block – useful in an emergency when the patient is not starved; gives good postoperative pain relief
- Spinal and epidural anaesthetic – only to be used by an anaesthetist under full sterile conditions; allows on-going postoperative pain relief
- General anaesthetics are now safer and more controllable so still have an important role to play

Topical anaesthesia

Topical anaesthetic agents are used on the skin, the urethral mucosa, the nasal mucosa and the cornea. These agents include amethocaine, because it is well absorbed by mucosa; cocaine, for its vasoconstrictive properties; lignocaine; and prilocaine. A lignocaine and prilocaine eutectic mixture (EMLA cream) is commonly used on the skin of children before venepuncture.

Local infiltration

Infiltration of a local anaesthetic drug may be into or around a wound, ideally paying particular attention to neuroanatomical territories and boundaries. It is not necessary to starve the patient preoperatively unless the procedure carries a high risk of intravascular or intrathecal injection. Local infiltration is contraindicated near infection because it not only spreads the infection but is also ineffective, as the acidity produced by infection blocks the action of the drugs. It is also contraindicated in the presence of a clotting disorder as it may result in haemorrhage.

Regional anaesthesia

Regional anaesthesia involves the blockade of major nerve trunks innervating the site of surgery. It is most commonly used for limb, abdominal and thoracic surgery and obstetric analgesia and surgery. It may also be safer to use regional anaesthesia in an emergency when a patient has not been starved as the risk of aspiration of gastric contents is marginally reduced.

Spinal and epidural anaesthesia should only be conducted by anaesthetists using full aseptic techniques in a safe environment. Preoperative patient preparation for elective regional anaesthesia includes that required for general anaesthesia, with

explanation of the local anaesthetic procedure. The recently introduced subcutaneous low molecular weight heparins (LMWH) for prophylaxis for deep venous thrombosis are longer acting than heparin and appear to have increased the risk of intraspinal haematoma. Epidural and spinal injections (and catheter insertion or removal) should only be performed at least 12 hours after a LMWH dose, and the next LMWH dose should be delayed by at least 2 hours. As with many perioperative management issues, optimal care depends upon close liaison between anaesthetist and surgeon.

Electrocardiogram, pulse oximetry and blood pressure measurements should be performed during regional anaesthesia. Oxygen by face mask should be given to frail or sedated patients during surgery.

If regional anaesthesia fails, general anaesthesia may be necessary. Compensation for an inadequate regional block by heavy sedation carries great dangers including airway obstruction and pulmonary aspiration of gastric contents. These may easily go unrecognised by a single operator; hence it is essential that a doctor other than the operator is present to continuously monitor and resuscitate the patient as necessary. In emergency surgery, regional anaesthesia carries the advantage of preserving the protective laryngeal reflexes, particularly in emergency obstetric anaesthesia, for which epidural or spinal regional anaesthesia is commonly the method of choice. The reduction in blood pressure with spinal and epidural anaesthesia can be advantageous in reducing intraoperative blood loss; however, it is essential to achieve haemostasis before wound closure and restoration of normal blood pressure.

Regional anaesthesia had very clear advantages over general anaesthesia when general anaesthetic agents carried high morbidity and mortality rates. In contemporary practice this advantage is less pronounced or even reversed. Regional anaesthesia does provide excellent analgesia into the postoperative period, reducing the need for centrally acting analgesic agents. In cardiovascular disease, although general anaesthesia with support of the circulation and pulmonary ventilation may confer less hypotension and tachyarrhythmias, exacerbating ischaemic heart disease and resultant angina. However, regional anaesthesia still remains advantageous for patients who have debilitating respiratory disease. The most clear indications for spinal and epidural anaesthesia are in obstetric practice to spare the mother from the risk of pulmonary aspiration because of the full stomach usually present in labour, and also to spare the newborn from the depressant action of the general anaesthetic and analgesic drugs.

Common local anaesthetic techniques

In awake patients the nerve blocks must provide comprehensive numbness throughout the surgical field. The following field blocks are commonly used:

- *Brachial plexus* block for surgery on the upper limb.
- *Field block* for inguinal hernia repair. The iliohypogastric and ilioinguinal nerves are blocked immediately inferomedial to the anterior superior iliac spine. The genitofemoral nerve is infiltrated at the mid-inguinal point and at the pubic tubercle. If a large volume of local anaesthetic is used, the peritoneal sac can be anaesthetised before the incision, but care must be taken to avoid drug toxicity. The line of the skin incision should also be infiltrated with the mixture.
- *Regional block* of the ankle. This can be used for surgery on the toes and minor surgery of the foot.

August Karl Gustav Bier, 1861–1949, Professor of Surgery, Bonn, (1903–1907), and Berlin, Germany (1907–1932).

Intravenous regional anaesthesia (Bier's block)

The arm to be operated on is exsanguinated by elevation and/or compression, and then isolated from the general circulation by the application of a tourniquet inflated to a pressure well in excess of the systolic arterial pressure. The venous system is then filled with local anaesthetic agent, injected via a previously placed indwelling venous cannula. The drug diffuses from the bloodstream into the nerves to produce an effective block. The arm is more suitable for this procedure than the leg because the large volume of drug required for the latter can easily lead to toxicity. The tourniquet must only be deflated after adequate time has elapsed (at least 20 min) to allow for the residual venous drug load to fall to a safe level before it is washed back into the general circulation. Cardiac arrest or convulsions may well occur if the tourniquet is accidentally released before the drug is fixed. This is a particular risk with bupivacaine, which has been banned from use in this procedure. Up to 50 ml of prilocaine 0.5% is recommended as the safest agent to use. A separate medical practitioner should supervise the block and monitor the patient while the surgeon operates (Summary box 14.7).

Summary box 14.7

Bier's block

- Only safe in the upper limb
- Prilocaine is best – bupivacaine must *not* be used
- A second practitioner must be present to oversee the block
- The cuff must not be deflated for 20 min to prevent systemic toxicity

Spinal anaesthesia

Spinal anaesthesia in the awake patient is useful for some forms of surgery in the pelvis or lower limbs. Hyperbaric solutions of bupivacaine are injected as a 'single shot' into the cerebrospinal fluid to rapidly produce an intense blockade, usually within 5 min. Autonomic sympathetic blockade results in hypotension, so the patient should be preloaded with intravenous fluids and vasoconstrictor drugs may need to be given. If the hyperbaric solution is allowed to ascend too high, severe hypotension and ventilatory failure occur. This factor limits the use of spinal anaesthesia to surgery below the segmental level of T10. Intrathecal opioid drugs used in combination with local anaesthetics provide better postoperative analgesia but carry a significant risk of respiratory depression.

The incidence of postoperative headache as a result of cerebrospinal fluid leakage through the dural perforation is decreasing with the increasing use of modern needles (very fine with a round or pencil point tip and side aperture) designed to split rather than cut the dural fibres.

Epidural anaesthesia

Epidural anaesthesia is slower in onset than spinal anaesthesia but has the advantage of multiple dosing and prolonged use in the postoperative period as an indwelling catheter may be threaded into the epidural space. Urinary retention is common, necessitating catheterisation of the bladder. Epidural anaesthesia also includes sympathetic blockade but, being slower in onset, the resulting hypotension may be easier to control and can be advantageous for the surgery by reducing blood loss. Epidural anaesthesia used alone

does not produce adequate analgesia for surgical intervention but, using a weak solution of bupivacaine or the newer ropivacaine, this technique produces a predominantly sensory block for analgesia after upper abdominal or thoracic surgery. The contemporary trend is to combine weak solutions of local anaesthetic with opioid agents such as the lipid-soluble diamorphine or fentanyl, the latter producing analgesia by their action on the opioid receptors in the spinal cord. However, the potential complication of epidural opioid analgesia is delayed respiratory arrest from rostral spread and central depression, as late as 24 hours after the last dose. Hence, regular monitoring of conscious level and respiratory rate, as well as the facility to immediately reverse the opioid with intravenous naloxone or to resuscitate, are essential prerequisites.

Caudal epidural anaesthesia is produced by injection of the local anaesthetic agent through the sacrococcygeal membrane. Used to supplement general anaesthesia, it provides very effective postoperative pain relief. This analgesic technique is much used in paediatric surgery (Fig. 14.6) (Summary box 14.8).

Summary box 14.8

Epidural block

- Slower action than spinal
- Blood loss in surgery is less
- Allows top-ups and is ideal for postoperative pain
- Epidurals containing opioids need careful monitoring for 24 hours

PERIOPERATIVE PAIN RELIEF (ACUTE PAIN MANAGEMENT)

Optimal management of acute postoperative pain requires planning, patient and staff education and tailoring of the regimen to the type of surgery and the needs of the individual patient. Of

Figure 14.6 Equipment for epidural/spinal anaesthesia. A Touhy needle (curved tip Huber point) for epidural anaesthesia (left), an epidural catheter through a Touhy needle attached to a filter system (centre) and a spinal needle (right).

Edward Boyce Tuohy, 1908–1959, Professor of Anesthesiology, Georgetown Medical Center, Washington, DC (1947–1952), and later at the University of Southern California Medical School, Los Angeles, CA, USA.
Ralph L. Huber, 1890–1953, a Dentist of Seattle, WA, USA.

late, pain management has had to adapt to newer less invasive or destructive surgical techniques.

Patients vary greatly (up to eightfold) in their requirement for analgesia, even after identical surgical procedures. Undertreatment results in unacceptable levels of pain with tachycardia, hypertension, vasoconstriction and 'splinting' of the affected part. Painful abdominal and thoracic wounds restrict inspiration, leading to tachypnoea, small tidal volumes and inhibition of effective coughing and mobilisation. This predisposes to chest infection, delayed mobilisation, deep venous thrombosis, muscle wasting and pressure sores.

However, too much analgesic drug increases the risks of side-effects such as nausea, vomiting, somnolence and dizziness or, if greatly in excess, severe central effects including depressed consciousness and respiration. This can be avoided by sensible initial dosing, followed by titration until the patient is comfortable. Exaggerated fears of opioid-induced central depression and addiction have led all too commonly to the reluctance of staff to prescribe and administer adequate doses of opioids. Intermittent intramuscular dosing also leads to delays in administration of the 'controlled' opioids. The failure of pain relief is compounded by the slow time to onset of action.

A joint working party report of the Royal Colleges of Anaesthetists and Surgeons, *Pain after Surgery*, recommended the establishment of acute pain services comprising medical and nursing specialists to oversee the implementation of guidelines for practice, including the routine recording of pain levels and the education of both staff and patients. In hospital practice in the USA, a recent national initiative called 'Pain, the fifth vital sign' requires regular pain measurement, with staff to be alerted in the event of high scores. The joint working party report also encouraged the use of combined 'multimodal' analgesia comprising local anaesthesia and simple analgesics such as paracetamol (acetaminophen) and non-steroidal anti-inflammatory drugs (NSAIDs) with opioid drugs (Summary box 14.9).

Summary box 14.9

Acute postoperative pain relief

- Requires an expert team approach
- Pain levels must be measured regularly
- Analgesia is best given before pain breaks through
- A combination of analgesics gives best results
- Opioids should not be withheld
- The dose of analgesia used must be adequate to control the pain

Simple analgesic agents

In minor surgery and when the patient is able to eat after surgery, NSAIDs and paracetamol may be sufficient. Reye's syndrome, metabolic acidosis and hepatotoxicity in children have made paracetamol a preferable drug to aspirin in the younger age group. Within its dose recommendations paracetamol is a very safe and effective analgesic and is now widely available in intravenous formulation. Codeine phosphate is commonly favoured after intracranial surgery because of its intermediate respiratory depressant effect; however, it should not be given intravenously as it can then cause profound hypotension. Constipation is also not uncommon with codeine.

Ralph Douglas Kenneth Reye, 1912–1977, Director of Pathology, The Royal Alexandra Hospital for Children, Sydney, NSW, Australia, described this syndrome in 1963.

NSAIDs are useful as the main analgesic for moderate pain or as adjuvant therapy with opioids for severe pain. They cause non-specific cyclo-oxygenase (COX) inhibition, which results in side-effects including loss of gastric cytoprotection, renal homeostasis and platelet function. Rectal and intravenous diclofenac or intravenous ketorolac are commonly used NSAIDs in the perioperative period. Patients with a tendency towards peptic ulceration may need cover with proton pump inhibitors or misoprostol during analgesic treatment with anti-inflammatory agents.

Specific COX-2 inhibitor anti-inflammatory analgesics have the particular advantage in perioperative use of maintained platelet function but they may be contraindicated in some conditions such as ischaemic heart disease.

Stronger analgesic agents

With adjuvant analgesics in combination, regular intramuscular morphine injection can provide effective treatment for the majority of surgical patients. However, there are more sophisticated methods of pain management:

- *Patient-controlled analgesia (PCA)*. Opioid analgesia is injected intravenously or through an epidural cannula. The patient is trained to give a bolus dose of drug by pressing a button on a machine. The medical staff preset the strength, frequency and total dose of drug, which can be administered by the PCA machine over a given time. This method is popular with patients as they have control over their pain, while delays in administration of doses are avoided.
- *Local anaesthetic blocks*. These give excellent short-term analgesia but they require skill and have a small failure rate. Continuous catheter techniques provide prolonged pain relief but are generally only appropriate for in-patients.

Special methods of pain relief used under close supervision are:

- continuous epidural anaesthesia with opiate or local anaesthetic drugs;
- spinal opioids – generally very useful for appropriate types of surgery but again they require skill and are limited by concerns over severe respiratory depression.

Continuous intravenous or subcutaneous infusions of opioid analgesia carry the risk of overdose in the more sensitive patient but are safe in the context of a continuously monitored high-dependency environment and careful dose titration.

Effective postoperative pain relief encourages early mobilisation and hospital discharge.

The methods described above can also be used for managing the pain of acute trauma (Summary box 14.10).

Summary box 14.10

Techniques for postoperative pain relief

- Regular intramuscular injections – may get pain breakthrough
- Local anaesthetic block – ideal if it works
- Indwelling epidural – good pain control; opioids may depress respiration
- Continuous infusions – reduce oscillations in pain relief but risk overdose
- Patient-controlled analgesia – pain relief titrated to patient's needs

Chronic pain management

In surgical practice, the patient with chronic pain may present for treatment of the cause (e.g. pancreatitis) or have concomitant pathology. Surgery itself may have been the cause of the now chronic symptom, as acute pain may progress to chronic pain. There is a developing belief that inadequate treatment of acute pain may make this situation more likely.

Chronic, intractable pain may be of malignant or non-malignant origin and of several types:

- **Nociceptive pain.** Pain may result from musculoskeletal disorders or cancer activating cutaneous nociceptors. Prolonged ischaemic or inflammatory processes result in sensitisation of peripheral nociceptors and altered activity in the central nervous system leading to exaggerated responses in the dorsal horn of the spinal cord. The widened area of hyperalgesia and increased sensitivity (allodynia) has been attributed to increased transmission of afferent pain impulses consequent upon this spinal cord dynamic plasticity.
- **Neuropathic (or neurogenic) pain.** Pain is caused by the dysfunction of peripheral or central nerves (excluding the 'physiological' pain due to noxious stimulation of the nerve terminals). Neuropathic pain is classically 'burning', 'shooting' or 'stabbing' and may be associated with allodynia, numbness and diminished thermal sensation. It is poorly responsive to opioids. Examples include trigeminal neuralgia, metatarsalgia and postherpetic and diabetic neuropathy. Monoaminergic, tricyclic and anticonvulsant drugs are the mainstay of treatment.
- **Psychogenic pain.** Psychological factors play a greater or lesser role in many chronic pain syndromes. Whatever the primary cause may have been, depressive illness and chronic pain may exacerbate each other.

The treatment of pain of malignant origin differs from that of pain of a benign cause, which may be the more difficult to overcome. Drugs should preferably be taken by mouth, but the patient must be regularly reassessed to ensure that analgesia remains adequate as the disease process changes (Summary box 14.11).

Summary box 14.11

Chronic pain

- Inadequate control of acute pain may lead to chronic pain
- Chronic stimulation of nociceptors appears to produce sensitisation
- Dysfunction in nerves produces neuropathic pain
- Psychogenic pain – depression causes and is caused by chronic pain

Pain control in malignant disease

In intractable pain, the underlying principle of treatment is to encourage independence of the patient and an active life in spite of the symptom. The main guide to the management of cancer pain is provided by the World Health Organization, which portrays three levels of treatment – the 'pain stepladder':

- first rung: *simple analgesics* – aspirin, paracetamol, NSAIDs, tricyclic drugs or anticonvulsant drugs;

- second rung: *intermediate strength opioids* – codeine, tramadol or dextropropoxyphene;
- third rung: *strong opioids* – morphine (pethidine has been withdrawn from the second edition of the World Health Organization guide).

Oral opiate analgesia is necessary when the less powerful analgesic agents no longer control pain on movement or prevent the patient from sleeping. Fear that the patient may develop an addiction to opiates is usually not justified in malignant disease.

Oral morphine can be prescribed in short-acting liquid or tablet form and should be administered regularly every 4 hours until an adequate dose of drug has been titrated to control the pain over 24 hours. Once this is established, the daily dose can be divided into two separate administrations of enteric-coated, slow-release morphine tablets (MST morphine) every 12 hours. Additional short-acting morphine can then be used to cover episodes of 'breakthrough pain'. Nausea is a problem that is encountered early in the use of morphine treatment and it may need to be controlled with antiemetic agents, e.g. haloperidol, methotrimeprazine, metoclopramide or ondansetron. Nausea does not usually persist, but constipation is frequently a persistent complication requiring regular prevention by laxatives.

The infusion of *subcutaneous, intravenous, intrathecal or epidural opiate drugs* is necessary if a patient is unable to take oral drugs. Subcutaneous infusion of diamorphine is simple and effective to administer. Epidural infusions of diamorphine can be used in mobile patients with the aid of an external pump. Intrathecal infusions are prone to infection, but implantable reservoirs with pumps programmed by external computers are being used for long-term intrathecal analgesia. Intravenous narcotic agents may then be reserved for acute crises, such as pathological fractures.

Neurolytic techniques in cancer pain should only be used if the life expectancy is limited and the diagnosis is certain. The useful procedures are:

- subcostal phenol injection for a rib metastasis;
- coeliac plexus neurolytic block with alcohol for pain of pancreatic, gastric or hepatic cancer – image intensifier control is essential;
- intrathecal neurolytic injection of hyperbaric phenol – this technique is useful only if facilities for percutaneous cordotomy are not available because it can damage motor pathways;
- percutaneous anterolateral cordotomy to divide the spinothalamic ascending pain pathway – it is a highly effective technique in experienced hands, selectively eliminating pain and temperature sensation in a specific limited area.

Alternative strategies include:

- the use of anti-pituitary hormone drugs such as tamoxifen and cyproterone, which enables effective pharmacological therapy for the pain of widespread metastases instead of pituitary ablation surgery;
- palliative radiotherapy, which can be most beneficial for the relief of pain in metastatic disease;
- adjuvant drugs such as corticosteroids, which reduce cerebral oedema or inflammation around a tumour and may be useful in symptom control; tricyclic antidepressants, anticonvulsants and occasionally flecainide are also used to reduce the pain of nerve injury (Summary box 14.12).

Summary box 14.12

Techniques for managing chronic pain

- Oral opioids – initial nausea, long-term constipation
- Opioid infusions – useful if the patient cannot take drugs orally
- Neurolysis – only in limited life expectancy

Pain control in benign disease

Surgical patients may have persistent pain from a variety of disorders including chronic inflammatory disease, recurrent infection, degenerative bone or joint disease, nerve injury and sympathetic dystrophy. Chronic pain may result from persistent excitation of the nociceptive pathways in the central nervous system, invoking mechanisms such as spontaneous firing of pain signals at *N*-methyl-D-aspartate receptors in the ascending pathways. Such activity responds poorly to opiates; neuroablative surgery is unlikely to produce prolonged benefit and may make the pain worse.

As is well known, amputation of limbs may result in phantom limb pain, the likelihood being further increased if the limb was painful before surgery. Continuous regional local anaesthetic blockade (epidural or brachial plexus), established before operation and continued postoperatively for a few days, is believed to effectively reduce the establishment of phantom pain.

The following are treatments for chronic pain of benign origin:

- *Local anaesthetic and steroid injections.* These can be effective around an inflamed nerve and they reduce the cycle of constant pain transmission with consequent muscle spasm. Epidural injections are used for the pain of nerve root irritation associated with minor disc prolapse. This treatment should be in association with active physiotherapy to promote mobility.
- *Nerve stimulation procedures.* Acupuncture, transcutaneous nerve stimulation and the neurosurgical implantation of dorsal column electrodes aim to increase endorphin production in the central nervous system altering pain transmission.
- *Nerve decompression.* In patients who are fit for craniotomy, decompression of the trigeminal nerve at craniotomy is now performed for trigeminal neuralgia rather than percutaneous coagulation of the trigeminal ganglion.
- *Treatment of pain dependent on sympathetic nervous system activity.* Even minor trauma and surgery (often of a limb) can provoke chronic burning pain, allodynia, trophic changes and resultant disuse. The syndrome has been attributed to excessive sympathetic adrenergic activity inducing vasoconstriction and abnormal nociceptive transmission. Management may include:
 - a test response to systemic α -adrenergic blockade using intravenous phentolamine;
 - local anaesthetic injection of the stellate ganglion or lumbar sympathetic chain;
 - intravenous regional sympathetic blockade using guanethidine under tourniquet – this is now controversial as consistent evidence to confirm efficacy has not emerged, and some centres have abandoned this method.

- *Percutaneous chemical lumbar sympathectomy with phenol under radiographic control.* This is practised by both surgeons and anaesthetists for relief of rest pain in advanced ischaemic disease of the legs. It can also promote the healing of ischaemic ulcers by improving peripheral blood flow.
- *Drugs in chronic non-malignant pain.* Paracetamol and NSAIDs are the mainstay of musculoskeletal pain treatment, but NSAIDs are handicapped by gastrointestinal intolerance and peptic ulceration. These carry significant levels of non-compliance, contraindication and morbidity. Specific COX-2 inhibition, with preservation of protective COX-1 activity, promises to improve tolerability and safety in NSAID treatment. The tricyclic antidepressant drugs and anticonvulsant agents are often useful for diminishing the pain of nerve injury, although side-effects can prove troublesome and reduce compliance. Opioid analgesic drugs have been more commonly prescribed in more severe and debilitating non-malignant chronic pain with the advent of slow-release oral preparations of morphine and oxycodone and the development of transcutaneous patches delivering fentanyl and buprenorphine. Combinations of drugs often prove useful to achieve the optimum efficacy with minimal side-effects.

In the management of chronic pain of benign cause, a multidisciplinary approach by a team of medical and nursing staff working with pain specialists, psychologists, physiotherapists and occupational therapists can often achieve much more benefit than the use of powerful drugs. Multidisciplinary pain management programmes have been devised to help the chronic benign pain patients who do not respond to conventional means. They can help a number of patients to cope with the pain and maintain a higher quality of life (Summary box 14.13).

Summary box 14.13

Techniques for managing chronic pain in benign disease

- Local blocks
- Transcutaneous nerve stimulators
- Nerve decompression
- Amputation – only with good pain control before and after surgery
- Encourage activity
- Antidepressants
- A team approach is important

Care in the operating room

CHAPTER 15

LEARNING OBJECTIVES

To understand:

- How to prepare a patient for theatre
- The process of gloving and gowning
- The process of preparation and draping the patient
- Behaviour in the operating room
- The process of writing an operative note

First do no harm

Hippocrates

PREOPERATIVE PREPARATION IMMEDIATELY BEFORE SURGERY

The patient should be seen by both the surgeon and the anaesthetist before any pre-medication is given.

- 1 The patient's identity should be confirmed and the patient should be asked to confirm what surgery is being carried out. The case notes should agree with this and with what is written on the operating schedule.
- 2 A check should be made that there has been no change in the patient's condition since they were last seen and, if the patient's condition has changed, this needs to be recorded.
- 3 Consent. The patient should be asked if they want the consent process to be repeated and, even if not, they should be asked whether they have any questions and whether they are happy to proceed with surgery. This should be recorded in the notes.
- 4 All relevant results, investigations and imaging must be available.
- 5 Adequate preoperative planning should have been undertaken and preferably recorded in the notes.
- 6 A check should be made for any sepsis (skin, teeth, urine and chest).
- 7 If there is the possibility of any neurovascular complications, the neurovascular status should also be recorded at this stage.
- 8 The side to be operated on should be marked with indelible pen.
- 9 The surgical area should be shaved either at this time or immediately before the incision is made (Summary box 15.1).

Hippocrates, c460–c375 BC, was a Greek Physician and Surgeon who is regarded by common consent to be 'The Father of Medicine'. He was born on the island of Cos off Turkey, and probably died about 375 BC.

Summary box 15.1

Preoperative checks with the patient

- Patient's name
- Condition
- Consent – mark side
- All investigations available
- Sepsis
- Pre-existing complications

Surgeon's preparation for the operation

All surgeons will have an envelope or ceiling to their surgical abilities, which is unique to them. A surgeon should only operate if he/she is capable of performing the surgery safely in the circumstances.

The surgeon must aim to optimise the patient's procedure by adequate preparation. This is highlighted in the traditional military saying: 'the seven "Ps" – prior preparation and planning prevents profoundly poor performance'. A simple measure of how well the preparation has been for an operation is the number of times that a runner needs to be sent out of the operating room to fetch another implant or piece of equipment during the actual operation.

Preoperative planning

Preoperative planning should cover all of the aspects of the surgical process. The preoperative planning process may be very brief and require minimal time in the case of routine, frequently undertaken and minor procedures, or it can be complex and prolonged with templating of radiographs and a pre-written surgical contingency plan for each phase of the surgical process.

Theatre team's preparation for the operation

The theatre team should be given as much notice as possible for the proposed operation. Every hospital and operating department will have a policy for the booking and scheduling of theatre cases, both for elective and emergency cases. Clearly, elective cases will be relatively easier to prepare for because the theatre team have

more notice. Children are usually put first on operating lists to reduce the anxiety created by waiting. Diabetics and other patients whose conditions are potentially labile should also be put early on the list. Otherwise, the order of the list needs to be balanced carefully between the wishes of the surgeon, the anaesthetist and the operating and ward staff, as well as the patient.

Pre- and perioperative communication

Communication is one of the keys to good leadership and teamwork. The whole surgical team should be aware of the surgical plan on a 'need to know basis'. This includes the patient, ward staff, porters and the anaesthetic, surgical and recovery teams.

The theatre list

The theatre list should have as a header the date and the details of the theatre, surgeon and anaesthetist. For each operation the patient's name and number, the ward that they will be coming from, the operation title and the side of surgery, if appropriate, should be given. If a specific implant or equipment is required this must be specified. The need for other special equipment such as image intensification, a cell saver or a specific operating table should also be recorded. It is also helpful to note whether blood is available. It is a good idea to go over the list face-to-face with the theatre staff at least a day before surgery to make sure that nothing has been forgotten and that there are no further questions. This will be especially important for a complex or rare procedure, in which there may need to be a great deal of verbal communication of every aspect of the procedure, for example patient positioning, the position of the table in the room, which instrument sets are required and what type of dressing will be applied.

The anaesthetist should be aware of the operative procedure to estimate the effect on the physiology of the patient. This may affect the type of anaesthetic chosen. The need for preoperative prophylactic antibiotics should be discussed well in advance so that any antibiotic can be administered at an appropriate time. Any other possible requirements such as blood transfusion, platelet infusion or anti-haemophilic fraction administration should be discussed with the anaesthetist before starting the operative procedure.

Supporting services, such as pathology for frozen sections or radiology for intraoperative imaging, will all appreciate as much notice as possible so that they can respond without delay (Summary box 15.2).

Summary box 15.2

Theatre staff preparation

- Operating list (order of patients)
- Special needs (implants and equipment)
- Cross-matched blood, imaging and investigations
- Extra staff (radiology, pathology)

Induction of anaesthesia

Before the patient is anaesthetised it is important that the patient is once again checked with regard to the following:

- the patient's name and identity label should be checked and confirmed;
- the nature of the operation should be confirmed with the patient;
- any dentures should be removed and any rings taped;

- the marking on the limb to be operated on should be confirmed;
- the appropriate consent form should be checked;
- preoperative antibiotics should be given.

Once the patient is anaesthetised the following can be undertaken:

- the patient is catheterised if indicated;
- the surgical site and monopolar diathermy site may require shaving in the hirsute patient; this is best carried out at this time rather than hours or the day before to prevent skin colonisation;
- a monopolar diathermy pad is applied if necessary (see below);
- a tourniquet is applied if appropriate (see Tourniquets);
- in some operating departments a 'pre-prep' or 'pre-scrub' using either soapy disinfectant or standard surgical skin preparation fluid may be undertaken.

The following general measures should be taken for the safe and effective use of diathermy:

- shave excess hair before applying the diathermy plate;
- make sure that the patient is not touching any earthed metal objects;
- ensure good contact between the patient and the plate, over an area of good muscle mass;
- check the plate if the patient is moved during surgery;
- place the plate as close as possible to the operative site;
- ensure that all connections to the generator are made before switching it on; always check the patient's skin at the site of the return electrode for signs of damage (Summary box 15.3).

Summary box 15.3

Positioning on the table

- The diathermy plate must be secure and well positioned
- The patient must be securely held on the table in the correct position
- There should be no contact between the patient and any metal surface
- All pressure areas should be protected

Tourniquets

The majority of limb tourniquets in use in contemporary practice are pneumatic tourniquets.

A tourniquet can and should be sized for the surgery to be undertaken. Small tourniquets can be used for digits, the simplest being either a rubber Penrose drain or the finger of a surgical glove with a small cut made in the tip; the finger of the glove is rolled down to exsanguinate the digit and then act as the tourniquet.

The skin underlying the tourniquet should be protected by either a specific tourniquet protector or some form of wool bandage as shown in Fig. 15.1a–c.

Most limb tourniquets are non-sterile, but sterile limb tourniquets are available and the smaller digit tourniquets are applied in the sterile field.

Charles Bingham Penrose, 1862–1925, Professor of Gynaecology, The University of Pennsylvania, Philadelphia, PA, USA, described this type of drain in 1890.

Tourniquet application

An appropriately applied tourniquet, as shown in Fig. 15.1b, will minimise complications.

- Distal neurovascular status must be checked before inflation. If there is any sign of distal neuropathy or peripheral vascular disease (especially calcification of arteries) a tourniquet must not be used.
- The tourniquet must be placed as proximally as possible.
- The underbandaging or cover should be applied to the skin without creases.
- The tourniquet must be placed snugly enough so as not to slide down the limb but not so tight that it impedes exsanguination.
- An additional broad tape can be used to prevent surgical preparation solution from running under the tourniquet and causing skin damage.
- The distal limb can be exsanguinated before inflating the tourniquet if a completely blood-free field is needed (Fig. 15.1c). Care should be taken not to damage the skin with an Esmarch bandage wound on too tightly.

- As soon as the tourniquet is inflated then the time should be noted and arrangements made for a warning to be given to the surgeon as soon as that time exceeds 1 hour.
- Application of a safe tourniquet is a skilled process and is ultimately the surgeon's responsibility.
- It is also the responsibility of the surgeon to ensure that the tourniquet has been removed and that distal sensation and circulation has returned. This must be recorded in the notes (Summary box 15.4).

Summary box 15.4

Tourniquet

- Note the distal neurovascular status before application
- Care with position and padding
- Exsanguinate the limb before inflation
- Note the time of inflation
- Deflate after 1 hour
- Check return of circulation and sensation after deflation

Figure 15.1 Tourniquet and tourniquet dressing. (a) Poor placement, too low – interfering with operative field. (b) Optimal placement of the tourniquet using a single-use tourniquet cover, which protects the skin under the tourniquet and has an adhesive strip to prevent ingress of preparation solution (arrow). This tourniquet is less likely to slip and provides a much larger skin preparation field, important as the patient is undergoing knee surgery. (c) Rhys-Davies exsanguinator.

Johann Friedrich August von Esmarch, 1823–1908, Professor of Clinical Surgery, Kiel, Germany, devised this type of bandage whilst working as a military surgeon during the Franco–Prussian war (1870–71), and described its use in 1873.

Tourniquet complications

- Excessive tourniquet time causes both local pressure and distal ischaemic effects, with nerve damage and even compartment syndrome. Tourniquets should usually be let down after 1 hour unless close to the end of a procedure. They can then be reinflated after 5–10 min for a further hour.
- If the tourniquet pressure is inadvertently set too high, nerve and muscle damage beneath the cuff itself will occur. The generally recommended pressure level in adults is 200–250 mmHg for the upper limb (or 100 over systolic blood pressure) and 300–350 mmHg for the lower limb (or 150–200 over systolic blood pressure).
- Chemical burn or blistering from skin preparation leaking under the tourniquet.
- Tourniquet failure. This is generally the result of inadequate application of the tourniquet itself and is rarely caused by failure of the cuff or machine (which should be checked regularly). Failure may lead to some arterial inflow but with blocked venous outflow; this causes venous engorgement of the surgical field. The cuff will need removing at once and then reapplying if necessary.

THE OPERATION

Transfer and patient set-up

Transfer of patient from bed to operating table should be slow and smooth, ideally under the joint supervision of the anaesthetist and the surgeon as shown in Fig. 15.2. Protective gloves should be worn throughout the handling of the patient. This process can be assisted by the use of sliding boards or rollers carefully placed under the patient at the time of transfer, which are then removed until the end of surgery.

The patient should be firmly held on the table especially if the lateral position is needed for the operative procedure. All of the pressure areas should be well covered and protected, and limbs should be positioned to ensure that no bony prominence, vessels

or nerves are compressed. Extra precautions should be taken with high-risk patients such as the elderly, as well as with excessively thin and obese patients.

No part of the skin surface should be in contact with any metal if diathermy is to be used.

Patients and theatre staff will need gonad and thyroid protection with lead shields if imaging is to be performed during the surgery.

Extensions of the operating table, e.g. arm board or leg holder, should be positioned either by the surgeon or by one of the team under appropriate supervision (see Fig. 15.3). The patient is then 'hooked-up' to the monitoring, intravenous infusion, diathermy and tourniquet apparatus as appropriate prior to skin preparation and draping of the operation site. A final check should now be made to ensure that the patient is safe on the table, as he/she will need to keep still for a given time period and may not be able to communicate or even feel developing problems because of the anaesthesia. This protection relates to the following:

- *Skin.* The operating table will be padded but additional soft padding under the back, buttocks, elbows and heels may be required, dependent on the patient's position for surgery.
- *Limbs* that are uninvolved in surgery, e.g. the arms, should be protected by arm boards with padding to further protect the ulnar nerve at the elbow. Legs in the lithotomy holders may need additional padding and bandaging to prevent movement of the limbs or pressure effects, both of which may cause tissue damage.
- *Side supports* may be needed to stop the patient sliding off the table if the patient is to be placed into a semi-decubitus lateral position.
- *Eyelids* may be taped to protect the corneas.

Asepsis

No operating room can be kept completely free of bacteria and, therefore, the risk of a wound becoming infected from contamination is always present. However, the risk can be minimised by strict theatre discipline.

Figure 15.2 Patient transfer. Enough personnel are available to undertake the transfer. The anaesthetist supervises and protects the head, neck and airway. The patient is rolled and a sliding board (arrow) is placed under the patient and undersheet or canvas, which will allow the patient to slide across to the bed in a controlled fashion. Care is being taken by all of the team members to protect the whole patient.

Figure 15.3 An example of an additional table attachment. The patient on an operating table with an arm board attached (arrow).

Scrubbing

'Scrubbing up' is the process of washing the hands and arms prior to donning a gown and gloves, to minimise the microbial loads on parts of the surgical staff that might come into contact with the patient. Time spent scrubbing varies from unit to unit but as a general rule surgeons in training should usually start scrubbing before, and finish after, the senior surgeon. The commonest solutions used for hand-washing in the UK are 2% chlorhexidine gluconate or 7.5% povidone-iodine.

Excessive time or vigour in scrubbing may cause breakdown of the skin with an increased risk of infection. As a result, some centres are now adopting the use of water-free, spirit-based anti-septic solutions.

Scrub technique

- Preparation before scrubbing:
 - You should not scrub if you have an open wound or an infection. (Uninfected cuts or abrasions can be covered after a routine scrub-up process by applying a sterile clear dressing before gloving.)
 - All jewellery on the hands should be removed.
- A theatre hat, mask and eye protection should be fitted so that no hair is exposed and you are protected from splashback.
- A sterile scrubbing brush and nail cleaner are used for 1–2 min to remove dirt from under the nails and from deep creases in the skin.
- The hands are then washed systematically, paying special attention to the clefts between the fingers. This should be carried out on at least two further occasions, extending up the forearms to just below the elbows (see Fig. 15.4a). After applying disinfectant, the arms are washed from distal to proximal, with hands up and elbows flexed to avoid/minimise any contamination from the more proximal 'unclean' areas. The scrubbing surgeon in Fig. 15.4 demonstrates the correct position for scrubbing.
- Following the final rinse the hands and arms should be raised to face level, away from the body. This allows water to drop from the elbows.
- The hands and arms should be dried using a sterile towel for each side. Drying with each towel should start with the fingers and work across the hand and up the arm. The towel should then be discarded (see Fig. 15.4b).
- The first scrub up of the day, therefore, should take about 5 min from start to drying.
- If the surgeon stays within the theatre suite and there are no significant external contacts or contamination, subsequent scrub up will be shorter, with no need for the use of the nail cleaner or brush.

If the scrubbing procedure is interrupted, e.g. by touching the tap, the scrubbing procedure should be restarted. This is a common problem, particularly for those unused to the technique (Summary box 15.5).

Summary box 15.5

Scrubbing

- Do not scrub if you have an infection
- Make sure all hair is covered and that you are protected from splashes
- Start scrubbing before, and finish after, the senior surgeon
- Dry hands from distal to proximal

Figure 15.4 (a and b) Scrubbing up.

Types of scrub disinfectant solutions

Chlorhexidine gluconate has a residual effect and is effective for more than 4 hours. It has potent antiseptic activity against Gram-positive and Gram-negative organisms and some viruses but only moderate activity against the tubercle bacillus.

Iodine has some residual effects but these are not sustained for more than 4 hours. It is highly bactericidal, fungicidal and viricidal. There is some activity against bacterial spores and good activity against the tubercle bacillus. The iodine agents penetrate cell walls to produce anti-microbial effects. They may be irritating to the skin or cause allergic reactions.

The alcohols are highly effective, rapidly acting anti-microbial agents with broad-spectrum activity. They are effective in destroying Gram-positive and Gram-negative bacteria, fungi, viruses and tubercle bacilli, but are not sporicidal. Alcohol is an

Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology (1891–1900) and of Medicine (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.

inexpensive anti-microbial agent and one of the most widely used skin antiseptics, especially preceding subcutaneous and intramuscular injections and venepunctures; a 10-s drying after application enhances its effectiveness. Some alcohol scrub preparations will therefore avoid the use of water washing altogether, using a similar sequence of repeated hand and forearm washes.

Gowning

- The folded gown is lifted away from the surrounding wrapping and kept away from the trolley.
- The gown is grasped firmly at the neckline and allowed to unfold completely, with the inside facing the wearer.
- The arms are inserted into the armholes simultaneously (the front of the gown is not to be touched with ungloved hands).
- Hands should stay inside the cuffs while gloving.
- The circulating theatre nurse should secure the gown at the neck and waist.
- If a wrap-around type of gown is worn, these ties are secured with the help of the circulating nurse once gloves are on.

Gloving

Gloves have two important functions. They prevent contamination of the surgical wound and they also protect the scrub team from the blood and body fluids of the patient. Double gloving

reduces the chance of a breach in this protection and allows the outer gloves to be changed if damaged. Double gloving is now a standard part of 'universal precautions' for minimising the transmission of human immunodeficiency virus (HIV) and hepatitis B and C (Fig. 15.5).

Once gowned and gloved, the hands must remain above waist level at all times, and when not involved in a sterile procedure the hands should be held together at chest height (do not tuck them into the armpits or dangle them!). Gloves are frequently perforated during surgical procedures, thus increasing the risk for surgical site infections. They should be changed if there is any suspicion of perforation (Summary box 15.6).

Summary box 15.6

Precautions when gloving/degloving

- Do not allow your skin to touch the outer surface of the glove
- Keep your fingers inside the sleeve of the gown until the glove is on
- If contamination occurs, both gown and gloves must be replaced
- Gloves are removed after the gown using a glove-to-glove, then skin-to-skin technique

Figure 15.5 Gloving techniques. (a) The initial gloving occurs with the hands covered by the gown. The first glove is then placed onto the palmar surface and pulled into position. (b) The double gloving technique, with minimal touch technique. (c) The closed two-person gloving technique; the glove being held open by one person for the second to insert their hand into the glove.

The operating room/theatre

Temperature and humidity

Patients are at risk of becoming hypothermic during prolonged operations. Paralysis, cool intravenous fluid and large exposed wounds all add to this potential problem. To prevent such hypothermia ambient temperatures of between 24 and 26°C are recommended. However, most surgeons find such temperatures uncomfortable and fatigue quickly. Ideal working temperatures for surgeons are between 19 and 20°C. For prolonged operations a compromise often has to be made or a patient-warming blanket should be used. This is especially important in small children.

Relative humidity in theatres should be capable of adjustment in the range 40–60%.

Illumination

The light source in theatre should not produce shadow. It should be capable of producing a minimum of 40 000 lux at the incision site. Satellite lights can be employed; however, these create heat and subsequent convection currents and may therefore alter local airflow patterns, increasing the risk of wound contamination from airborne bacteria.

Ventilatory system

The aim of the airflow system is to keep air fresh, and this is measured by air changes per hour. The minimum standard number of airflow changes allowed in operating rooms in the UK is 17 per hour. Laminar flow will generally provide 100–300 air changes per hour and is used in operations in which airborne infection must be avoided at all costs (operations involving implants).

Movement

All staff should enter the theatre through the entry zone, which is used for scrubbing and gowning. The amount of movement in and around the operating room and table itself should be kept to a minimum. There should be doors clearly marked for entry and exit, as one-way traffic will minimise the risk of contamination.

Airborne contamination

Airborne bacteria in the theatre originate almost exclusively from personnel within the theatre. It has been shown that a person may shed from 3000 to 50 000 micro-organisms per minute depending on activity and clothing. The major source of these bacteria is the skin, which is often contaminated with *Staphylococcus aureus* and other benign coagulase-negative staphylococcal species. Bacteria also disperse from the upper respiratory tract.

Excessive or unnecessary movements, operating room/theatre overcrowding, poor scrubbing up, gowning and gloving technique, poor airflow and inappropriate temperatures and humidity can all conspire to increase the bacterial load within an operating room and the operating table zone, with potentially catastrophic infective sequelae (Summary box 15.7).

Summary box 15.7

External sources of contamination in the operating theatre

- Poor scrubbing up, gowning and gloving technique
- Excessive inappropriate movement into and out of the operating room
- Too many people in the operating room – excessive movement
- Unnoticed perforation of a glove
- Contamination of instruments by an unscrubbed person

THE PATIENT ON THE OPERATING TABLE

Hypothermia

Heat loss generally occurs through four main mechanisms:

- conduction – the transfer of body heat directly to colder objects;
- convection – through moving air currents;
- radiation – the transfer of heat to colder objects nearby;
- evaporation – the heat utilised during conversion of water to vapour.

Factors that predispose a patient to hypothermia include:

- long preoperative fasting (lowered patient metabolism);
- prolonged immobility on the operating table;
- the effects of anaesthetic agents, e.g. peripheral vasodilatation;
- evaporative heat loss from exposed viscera;
- emergency surgery on shocked patients who are already hypothermic;
- in children, the large surface area-to-weight ratio means that they lose heat quickly.

Hypothermia is associated with poor clotting (disseminated intravascular coagulation), cardiac arrhythmias, respiratory failure, sepsis and ultimately death. Warming blankets and warmed intravenous fluids can reduce the risk of hypothermia.

Accidental injury to the patient

- Tired assistants may lean on the patient. This may compromise the patient's ability to breathe.
- Retractors must be placed carefully, and then minimum pressure applied to avoid damaging soft tissues, especially nerves.
- Diathermy should be used sparingly to avoid excessive burning.
- Clips should not be applied blind when trying to control bleeding in case nerves are crushed too.

SKIN PREPARATION – 'PREPPING' AND DRAPING

The aim of skin preparation before surgery (often shortened to 'prepping') is to reduce the microbial count on the patient's skin to the minimal level possible, to inhibit microbial regrowth and contamination of the wound itself during surgery.

Cleaning removes all debris and the material on which micro-organisms exist. It is achieved with soaps or detergents and water in the 'pre-prep' phase.

Disinfection destroys micro-organisms provided that it comes into contact with them for long enough.

Sterilisation brings about the complete destruction of pathogenic micro-organisms and their spores. This process is used to ensure that drapes, instruments and implants are completely free of infective organisms.

Skin preparation

‘Pre-prep’

The skin of the patient must be prepared before formal surgical skin preparation to remove soil and debris. If a plaster of Paris cast has just been removed, the skin should be washed with soapy disinfectant and then washed down with water or saline followed by application of surgical disinfectant (‘prep’) prior to the main prep. This pre-prep process is therefore not used for all patients and can be undertaken in the anaesthetic room. For patients undergoing elective surgery, a shower on the day of surgery with a soapy disinfectant should suffice.

Skin preparation solution – ‘prep’

The solution used may have an aqueous or alcohol base. The agents commonly used are similar to those used in the surgical scrub solutions described in the section above. Care must be taken that the solution does not pool under the patient, as pooling can cause a chemical burn. In general, alcohol or spirit-based solutions are used when the skin is intact and aqueous solutions when there is an open wound.

Method of preparing the skin

The prep area should include the surgical site and a substantial area surrounding it, to minimise the possibility of micro-organism migration from unclean to clean areas during the surgical procedure. When the surgical site is part of a limb, it may be best practice to prep the entire limb. The cleansing of the skin should start at the incision site, working outwards in continually expanding circles away from the surgical site. The prep sponge/swab on a stick should then be discarded and a new clean swab taken.

Contaminated areas, e.g. axilla, groin or perineum, must be prepped last, and once the prep sponge has been used in this area it must be again be discarded. Two separate coats of prep are generally used, and some surgeons will then remove excess prep solution with a dry swab (see Fig. 15.6) (Summary box 15.8).

Summary box 15.8

Preparing the patient’s skin (‘prepping’)

- Performed by staff who are scrubbed up
- Use aqueous solutions for open wounds, alcohol for intact skin
- Work from the incision site outwards
- Repeat at least twice
- Clean heavily contaminated areas last and then discard the prep sponge
- Remove excessive prep solution with a dry swab

Plaster of Paris is a white powder, calcium sulphate hemi-hydrate ($\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$) which sets hard when water is added to it.

Figure 15.6 Prepping (skin preparation) and draping. Application of skin disinfectant solution to skin. Note that this is the second coat being applied to the posterior aspect of the leg. The leg holder is standing away from the scrub nurse and should be gloved. For this operation the foot is not being prepped.

Draping of the operative area

Surgical draping involves covering with sterile barrier material, ‘drapes’, the area immediately surrounding the operative site. Drape materials should resist penetration of microscopic particles and moisture, limiting the migration of micro-organisms into the surgical wound.

The purpose of surgical draping is to create and maintain a protective zone of asepsis, called a ‘sterile field’, so that all sterile items for the surgical procedure avoid touching any unclean surface (see Fig. 15.7a–c). Drapes should be handled only by personnel wearing sterile gloves and should be placed carefully and not disturbed once placed.

Both re-usable and disposable drapes and gowns are in use today. Disposable drapes are a more effective barrier to fluid penetration (‘strike-through’) and therefore prevent secondary ingress of micro-organisms. Re-usable drapes will lose their barrier quality if not properly laundered and must be routinely inspected for holes and tears.

Draping should allow access to the whole surgical incision and allow for extensile exposure if this is possibly going to be needed. The drapes should also be applied to allow the free movement of a limb if this is going to be necessary during the operation. When possible the edge of the drape nearest the incision should be stuck down onto the patient’s skin, while the outer edge should be allowed to drop away off the edge of the operating table. The exposed skin around the incision area itself may be covered with a self-adhesive transparent drape, which should reduce wound contamination from the skin at the edge of the wound. The diathermy and sucker must be firmly attached to the drapes with enough slack to allow free movement. The outer ends of each are then passed off the operating table and from this point are regarded as unsterile.

Figure 15.7 (a) A waterproof underdrape is applied with adhesive edges. A sterile waterproof stockingette is about to be applied by the scrub nurse, initially onto the forefoot with the unscrubbed assistant supporting the heel. The unsterile assistant will then move away carefully from the operating table. All of these drapes are disposable. (b) The stockingettes applied. (c) The final drapes are placed over the stockingettes, the operation sites are covered with clear adhesive and a sterile bandage is used to secure the stockingettes. In our department some of the surgeons will prep the feet entirely before draping. Note also the hand position of the surgeon.

GENERAL PRECAUTIONS FOR ESTABLISHING AND MAINTAINING ASEPTIC TECHNIQUE

Scrubbed personnel movements

Once the patient is draped the surgeon and assistant should keep their hands and arms on the table within the sterile field whenever possible. Their hands should not come near to their faces and should remain still when not actively involved in the surgery. Surgeons should only sit down if this is to be for the entire procedure. The seat should be covered with a sterile drape so that the surgeon's back stays sterile. Only sterile equipment can be used within the sterile field.

Instrument tables and/or trolleys and instruments

These are sterile only at table level. Anything extending over the edge of the table must be considered unsterile unless the sterile end is clipped to the drapes.

Behaviour of theatre personnel

Staff who are 'scrubbed up' only touch sterile items or areas. Staff who are not 'scrubbed up' only touch unsterile items or areas.

- Supplies are brought to the sterile team members by the circulator, who opens the outside wrappers on sterile packages. They pass the sterile contents to the scrub nurse by holding onto the object by the outer wrapper. The circulator ensures a sterile transfer to the sterile field.
- Staff who are not scrubbed avoid reaching over the sterile field. Staff who are scrubbed avoid leaning over the unsterile area.

Staff who are scrubbed up always:

- watch the sterile fields to guard against contamination;
- pass each other back to back or front to front;
- stay within the sterile field, facing the sterile area; they do not walk around or go outside the room;
- keep movement to a minimum to avoid contamination of sterile items or persons.

Staff who are not scrubbed up always:

- maintain a distance of at least 50 cm from the sterile field;
- face and observe a sterile area when passing it to be sure that they do not touch it;
- avoid walking through a sterile field (i.e. between the patient and the trays);
- keep all activity near the sterile field to a minimum.

Surgical assistants

Surgical assistants are frequently surgeons in training. They are therefore in theatre to help the senior surgeon and to learn as much as possible.

- *Preparation.* Assistants should review the anatomy before surgery and read up on the operation so that they can anticipate the actions of the senior surgeon and understand what she/he is trying to achieve. They should arrive at the operating theatre before the operating surgeon and should start scrubbing first, having first checked that the patient is ready for theatre.
- *At surgery.* The assistant should at all times try to provide the surgeon with the best access possible by placing and holding retractors and showing the surgeon the field where she/he will next be working, hence the need to know the anatomy and the operation in advance. Instruments and retractors should always be asked for by name.
- *After surgery.* The assistant should help transfer the patient safely off the table and may be allowed to write the operative note. Assistants should always keep an audit of all operations attended and what they have learnt from each case.

Universal precautions

Universal precautions are based on the concept that blood, blood products and body fluids of all persons are potential sources of infection, independent of diagnosis or perceived risk. Therefore, all staff must adhere rigorously to protective measures, which minimise exposure to these agents. The use of universal precautions involves placing barriers between staff and all blood and body fluids. The use and uptake of universal precautions has been patchy.

Universal precautions include:

- wearing of protective gloves, ideally with double layers;
- wearing of protective eyewear and mask;
- wearing of protective apron and gown;
- using safe sharp instrument handling techniques (as described below);
- undertaking hepatitis B vaccination for staff;
- covering open wounds that are clean;
- staff with infected wounds or active dermatitis should stay off work.

The following rules are important when handling sharp instruments:

- Sharp instruments should not be passed between surgeons and their assistants;
- Surgeons should be responsible for the safe placement of sharp instruments, usually into a bowl or tray, which can then be used to transfer them;
- Only one sharp instrument should be placed in the dish at a time;

- When two surgeons are operating simultaneously, each must have their own sharps dish;
- Used needles and other disposable sharp instruments must be discarded into an approved sharps container as soon as practicable.

POSTOPERATIVE CARE OF THE PATIENT

After the operation the patient should be safely transferred to the bed from the operating table, under the supervision of the anaesthetist and surgeon.

A clear operative note should be written immediately. This should include instructions on the postoperative care, including the thresholds for calling back the surgeon.

The following details should be included in the operative note:

- 1 Patient's details – full name, date of birth, hospital number, address, ward.
- 2 Date (and start/finish time) of operation.
- 3 Operating room.
- 4 Name of operation.
- 5 Surgeon, assistant, anaesthetist.
- 6 Anaesthetic type.
- 7 Patient positioning and set-up.
- 8 Was a tourniquet used, were antibiotics given, was the patient catheterised, type of skin preparation, method of draping.
- 9 Tourniquet time, if applicable.
- 10 Operative details including:
 - incision;
 - approach;
 - findings;
 - procedure (appropriate illustration, if appropriate);
 - complications, untoward events;
 - implants used;
 - closure, including suture material used;
 - dressing;
 - postoperative state (e.g. distal neurovascular status);
 - type of dressing used.
- 11 Postoperative instructions relevant to surgery:
 - observations required and frequency, e.g. 4-hourly pulse and blood pressure measurements for 24 hours;
 - possible complications and action to be taken if complications occur, e.g. if blood loss exceeds 500 ml in a drain call the surgeon;
 - treatment, e.g. intravenous fluids;
 - time lines for patient recovery, e.g. when to mobilise, when to resume normal oral intake, the need for physiotherapy, allowable movements, dressing changes.
- 12 Discharge and follow-up details; instruction for sutures, splints, casts, etc.

Perioperative management of the high-risk surgical patient

LEARNING OBJECTIVES

To understand:

- The factors that put a patient at high risk from surgery and anaesthesia
- The problems of patients being treated as an emergency
- Classification and optimisation of high-risk patients
- The value of the critical care unit in the perioperative period

INTRODUCTION

Every surgical procedure involves some risk of significant post-operative complications or death. Whereas in most cases, this risk is well below 1%, a surgical population can easily be identified in which serious complications and death are much more frequent. Between 10% and 15% of in-patient surgical procedures appear to fall into this high-risk category and therefore represent an important cause of death and disability (Fig. 16.1). In the UK, 1.3 million hospital in-patients undergo general surgical procedures each year, of whom 166 000 can be identified as being at high risk of complications or death. The high-risk surgical population accounts for over 80% of surgical deaths but less than 15% of in-patient surgical procedures (Fig. 16.2). Of these high-risk surgical patients in the UK, 25 000 die postoperatively each year in hospital, and a further 115 000 patients who suffered complications will not survive in the long term.

The high-risk surgical population typically consists of elderly patients with coexisting medical conditions undergoing complex or major surgery, often as an emergency. Early identification and

Figure 16.2 Size and mortality rates for different populations of surgical patients.

optimal care of the high-risk surgical patient will result in a substantial reduction in risk. The aim of this chapter is to describe the basic approach to the perioperative care of such patients (Summary box 16.1).

Summary box 16.1

Characteristics of the high-risk population

- Elderly
- Comorbid conditions
- Needing emergency surgery (no time for optimisation)

Figure 16.1 Distribution of postoperative deaths within the surgical population.

WHY ARE COMPLICATIONS SO FREQUENT IN THIS POPULATION?

Technical complications relating to specific anaesthetic and surgical procedures are well recognised and discussed elsewhere in this book. In this chapter, we are concerned with a range of more general factors which place the surgical patient at additional risk. The nature of risk varies widely with different surgical procedures and does not bear a simple relationship to the extent of tissue

injury during surgery. In most cases, the overall risk of complications and death is a function of a range of patient- and surgery-related factors.

- Patient factors:
 - ischaemic heart disease;
 - chronic obstructive pulmonary disease;
 - diabetes;
 - advanced age;
 - poor exercise tolerance;
 - poor nutritional status.
- Surgical factors:
 - emergency surgery;
 - major or complex surgery;
 - body cavity surgery;
 - large anticipated blood loss;
 - large insensible fluid loss;
 - prolonged duration of surgery.
- Perioperative care factors:
 - inadequate critical care facilities;
 - insufficient patient monitoring;
 - lack of early intervention as complications develop.

Patient-related factors

In most cases, the underlying condition indicating surgical intervention will itself be associated with an increased risk of complications. For example, a patient who has developed severe peripheral vascular disease as a result of heavy smoking can be expected to suffer from significant ischaemic heart disease as well as chronic obstructive pulmonary disease. Other examples include poor nutritional status in a patient requiring cancer surgery and poor mobility in a patient requiring a major joint replacement. Comorbid diseases unrelated to the indication for surgery are also commonplace, with those affecting the respiratory and cardiovascular systems being most important.

The need for emergency treatment is perhaps the single most important factor raising the level of perioperative risk. This results from more serious and deteriorating acute pathology, the lack of opportunity to optimise medical management of comorbid illnesses, the presence of hypovolaemia which may be severe and dependence on junior medical staff often working outside office hours with minimal support or supervision.

Surgery- and anaesthesia-related factors

Tissue injury may result in a systemic inflammatory reaction leading to increased capillary permeability and insensible water losses from the intravascular compartment into the extracellular space. These 'third space' fluid losses tend to be most severe during and after procedures involving bowel resection. They may also be compounded by other forms of fluid loss such as prolonged preoperative fasting and insensible losses during surgery. Accurate estimation of these additional fluid requirements is a challenging but necessary aspect of perioperative care, as either inadequate or excessive perioperative replacement fluid may result in serious complications. Impaired coagulation may also increase the likelihood of haemorrhage.

Quite aside from psychological distress, pain is an important cause of postoperative complications. Excessive pain will result in poor mobility, deteriorating respiratory function (particularly following abdominal surgery), increased arterial pressure and myocardial work. Pain will therefore exacerbate the deteriorations in

both cardiac and respiratory function that occur following major surgery. Optimal postoperative analgesia is therefore essential to ensure that the risk of cardiorespiratory complications is minimised.

Postoperative hypothermia is common in high-risk patients, particularly following prolonged or complex procedures, especially body cavity surgery. Hypothermia may result in shivering, confusion and delayed recovery from anaesthesia. These in turn lead to increased oxygen consumption, poor respiratory function and more frequent cardiorespiratory complications. High-risk patients have a higher likelihood of poor nutritional status as a result of their underlying pathology, compounded by ileus/being denied postoperative nutritional intake, poor appetite or simply experiencing difficulty feeding themselves (Summary box 16.2).

Summary box 16.2

Surgical and anaesthetic factors creating high risk

- Dehydration (shock before surgery, loss of fluids during surgery, inability to tolerate fluids postoperatively)
- Pain (reduces mobility, affects breathing and ability to take food and fluids)
- Hypothermia

IDENTIFICATION OF THE HIGH-RISK PATIENT

The previous section lists the common risk factors leading to a patient being high risk.

For example, an elderly patient with severe heart disease undergoing emergency surgery for a perforation of the large bowel will have a risk of complications in excess of 95%, and the risk of death may be higher than 50%. However, the difficulty with this approach is that perioperative risk is cumulative and depends on a complex interplay between different factors. Experience suggests that many high-risk patients are not identified, despite awareness of those factors that increase the incidence of postoperative complications and death. Consequently, there is continued interest in improving our methods of screening surgical patients and stratifying risk, in order to select the patients who require additional perioperative care. In some cases, this process may indicate a patient in whom the risks of surgery are not justified by the potential benefits.

One approach to this problem is the use of risk scoring systems to classify patients. The simplest and most commonly used system is the American Society of Anesthesiologists (ASA) score, which provides a basic classification according to subjective perception of risk (Table 16.1). Although simple to use, clinicians frequently classify patients incorrectly using the ASA score, and the system does not provide any objective estimate of the risk of death. An alternative approach is to use physiological and surgical variables to estimate predicted mortality. Examples include the POSSUM scoring system (Physiologic and Operative Severity Score for the enUmeration of Mortality and Morbidity) for general surgery and the Parsonnet score for

PARSONNET was developed by V. Parsonnet, and others, at the Newark Beth Israel Medical Center, New Jersey, NJ, USA, and is based on the publication 'A Method of Uniform Stratification of Risk for Evaluating the Results of Surgery in Acquired Adult Heart Disease' (1989).

Table 16.1 American Society of Anesthesiologists (ASA) score

ASA class	Description
Class I	A normal healthy patient
Class II	A patient with mild systemic disease that does not limit functional activity
Class III	A patient with severe systemic disease that limits functional activity
Class IV	A patient with severe systemic disease that poses a constant threat to life
Class V	A moribund patient who is not expected to survive for longer than 24 h, either with or without surgery

The addition of an 'E' denotes emergency surgery.

cardiac surgery. However, these systems were designed to describe populations of patients and are much less reliable when used to assess the individual. Consequently, scoring systems should not be used in isolation to assess perioperative risk.

The American College of Cardiology/American Heart Association (ACA/AHA) Task Force have issued detailed guidelines which help to stratify patients according to metabolic reserve. An important aspect of these guidelines is the use of metabolic equivalents (METs) to help to standardise the assessment of exercise tolerance based on activities of daily living. By stratifying patients in this way, it is possible to focus the use of preoperative investigations on those patients most in need. Although the MET is a useful concept, these guidelines are intended only for the identification and management of cardiac disease in patients undergoing elective surgery, and are not designed for the multifactorial situation of the high-risk surgical patient.

In contrast, anaerobic threshold testing is an increasingly popular method of preoperative assessment for elective surgery, although it requires resources and is still of limited availability. This technique involves the use of an exercise bike and continuous measurement of oxygen consumption to identify the threshold at which anaerobic respiration commences. A low anaerobic threshold appears to be associated with increased postoperative mortality rates and assists in determining appropriate levels of postoperative care. The difficulty with this approach is that the assessment is time-consuming and must be performed several days before surgery. Thus, we still need methods of evaluation to identify those patients in need of detailed risk assessment, and that are feasible for the emergency situation (Summary box 16.3).

Summary box 16.3

Surgical and anaesthetic risk scores

- ASA is frequently incorrectly applied
- POSSUM works best for populations not individuals
- MET measures exercise tolerance
- Anaerobic threshold needs measuring in advance of surgery
- No risk score is reliable in isolation

GENERAL ASPECTS OF PERIOPERATIVE CARE

Preoperative assessment

In addition to identifying the patient at increased risk, preoperative assessment should identify potentially reversible comorbid illness so that every effort can be made to optimise the patient's condition.

Preoperative assessment should be performed by both the anaesthetist and the surgeon and, when appropriate, by specialist physicians. A general assessment should always include an evaluation of respiratory and cardiac function. Other important factors to consider include age, weight (ideally body mass index and girth measurements), smoking and alcohol intake, and general medical history and status (e.g. diabetes).

Careful evaluation of exercise tolerance will provide an indication of cardiorespiratory reserve. This is usually possible by asking the patient about common activities of daily living, for example the ability to climb a flight of stairs and the symptoms this provokes. Poor exercise tolerance generally reflects limitation in cardiorespiratory reserve. Objective assessments such as anaerobic threshold testing and METs help to identify the need for additional intraoperative monitoring and support and postoperative critical care admission. It may prove difficult to assess exercise tolerance in patients with poor mobility. Clinical examination should focus on the cardiac and respiratory systems (Summary box 16.4).

Summary box 16.4

Preoperative assessment for risk

- The history should focus on cardiac and respiratory problems
- Exercise tolerance gives a good guide to cardiac reserve
- Age and body mass index are useful indicators
- Check alcohol and tobacco intake
- Check medications

Preoperative medical therapy

Where significant comorbid disease has been identified, medical management should be reviewed according to current standards particularly for cardiorespiratory disease. The ACA/AHA Task Force guidelines discussed above form the basis of cardiac assessment in many centres. In some cases, patients may require percutaneous coronary intervention (angioplasty or stenting) or coronary artery bypass grafting prior to surgery. Preoperative bronchodilator therapy will be required in patients with reversible airflow limitation [e.g. asthma or chronic obstructive airways disease (COAD)]. A course of oral corticosteroids prior to surgery may also be necessary in such patients. The use of antibiotic therapy in patients with significant sputum production is tempting, but should be given careful consideration. Indiscriminate antibiotic use may simply result in the selection of resistant bacteria without any therapeutic benefit and, worse still, may greatly complicate the treatment of subsequent postoperative pneumonia. Preoperative physiotherapy is helpful for patients with chronic sputum production. Smoking cessation should be encouraged wherever possible with the offer of counselling and other practical support where available. In patients with chronic

or end-stage renal failure, careful discussion with a nephrologist is needed to ensure optimal perioperative care and/or timing of haemodialysis prior to surgery (Summary box 16.5).

Summary box 16.5

Review medical treatment before surgery

- Coronary angiography may be indicated for patients with ischaemic heart disease
- Asthma and COAD may require bronchodilators and steroids
- Antibiotic therapy is not necessarily indicated for patients with chronic sputum production
- Patients should stop smoking
- Patients with renal failure need their surgery planned around dialysis
- Oral medication can be given with water even when a patient is 'nil by mouth'
- When possible, postpone surgery until the patient is optimised

Regular cardiovascular medications should usually be continued in the perioperative period, as omission of such medicines will increase the risk of perioperative hypertension and myocardial ischaemia. Oral medications may be administered prior to surgery with a small volume of water (perhaps 10 ml) without any increased risk of pulmonary aspiration. On a similar basis, most patients may be allowed oral medications after surgery, provided a common sense evaluation is performed.

Clinical management will often be influenced by the nature, indication and urgency of surgery. Ideally, surgery will be postponed until medical management has been optimised and a robust plan for perioperative care put in place. In practice, it is often not possible to achieve this and, clearly, this will not be possible where emergency surgery is required. In this situation, fluid resuscitation should be initiated and other aspects of care addressed as early as possible. Regardless of urgency, the early input of experienced colleagues should be considered, including the physicians, surgeons, anaesthetists and critical care specialists.

Critical care

The high-risk surgical patient may require admission to a critical care unit either before or after surgery.

Assessment of the surgical patient in critical care

Basic clinical assessment

Perioperative critical illness often conforms to a pattern. Simple and versatile clinical parameters may be used to establish the status of the patient. These generally include pulse rate, respiratory rate, arterial pressure, urine output, conscious level (Glasgow Coma Score), capillary refill time and the presence of peripheral cyanosis. The primary aim of perioperative critical care is to ensure adequate tissue perfusion and oxygenation. Measures of end-organ function and tissue perfusion such as urine output and Glasgow Coma Score should therefore be carefully assessed. Core-peripheral temperature gradient may also provide an

Glasgow Coma Score was introduced in 1977 by William Bryan Jennet, Professor of Neurosurgery and Graham Michael Teasdale, a Neurosurgeon of the University Department of Neurosurgery, at the Institute of Neurological Sciences, Southern General Hospital, Glasgow, Scotland.

indication of reduced tissue perfusion in circulatory shock. Basic non-invasive monitoring will include continuous electrocardiography (ECG) and pulse oximetry (SaO₂). Combined with close observation by specially trained medical and nursing staff, these simple techniques allow the prompt identification of any deterioration in clinical status (Summary box 16.6).

Summary box 16.6

Value of admission to critical care unit for perioperative care

- Enables optimal maintenance of tissue perfusion and oxygenation
- Allows close monitoring and rapid response to any instability

Invasive arterial pressure monitoring

Invasive arterial pressure monitoring is used to facilitate the immediate recognition of haemodynamic changes, especially in an unstable patient, as well as enabling repeated blood sampling for arterial blood gas analysis. Despite the benefits perceived for this form of monitoring, arterial blood pressure does not actually have a linear relationship with cardiac output or tissue perfusion and should be interpreted with caution. Nevertheless, invasive arterial pressure monitoring generally provides accurate and reliable data, although a damped waveform may occur with kinking of the cannula or thrombus formation.

Central venous pressure monitoring (CVP)

CVP is usually measured in the superior vena cava with a catheter inserted from either the internal jugular or the subclavian veins. The placement of these catheters may be extremely difficult in the hypovolaemic patient, and the inexperienced practitioner should seek advice and supervision. CVP is determined either through the use of a water manometer or, nowadays more commonly, via an electronic transducer attached to a monitor to give a continuous graphical display. The purpose of CVP measurement is to provide an estimate of intravascular volume status, sometimes termed pre-load. Invasive pressure measurement is frequently relied upon to assess volume status in the critically ill. However, venous pressure has a complex relationship with intravascular volume and may not provide a reliable indication of the need for intravenous fluid administration. The CVP *trend* in response to a fluid challenge (e.g. 200–500 ml given over 30 min) is considered to be more helpful than the absolute value when attempting to identify the hypovolaemic patient.

Arterial blood gas analysis

Arterial blood gas analysis will allow detailed assessment of both respiratory and metabolic status. Interpretation of blood gas data is straightforward and should be regarded as an essential skill for clinical staff involved in the care of the high-risk surgical patient. Reliable interpretation of blood gas data is dependent on a clear understanding of the recent clinical history, and it is vital to know the inspired (and hence alveolar) oxygen concentration when evaluating the arterial oxygen tension and saturation. Subsequent clinical decisions should be based on all the data available and not individual variables. This is particularly true when considering the administration of intravenous fluids to a patient with a significant base deficit or elevated serum lactate.

Cardiac output monitoring

Cardiac output monitoring may be desirable in critically ill patients who require intravenous fluid replacement or vasoactive infusions to stabilise their circulatory status. There are now a variety of commercially available invasive or non-invasive monitors that allow cardiac output measurement.

The pulmonary artery (or 'Swan-Ganz') catheter (PAC) is traditionally regarded as the gold standard method of cardiac output measurement at the bedside. The PAC is a balloon-tipped catheter, which is 'floated' through the great veins, right atrium and right ventricle until the tip lies in the pulmonary artery. Cardiac output is measured intermittently by the thermal indicator dilution technique, in which a bolus of cold fluid is injected proximal to the temperature sensor. Direct measurements include cardiac output, pulmonary artery pressure, central venous pressure, pulmonary artery occlusion pressure and mixed venous oxygen saturation. Derived data include systemic vascular resistance, oxygen delivery and oxygen consumption.

In recent years, the PAC has become less popular because it is perceived to be associated with an excessive complication rate. Although large trials refute this, the use of less invasive cardiac output monitoring is increasingly popular. The oesophageal Doppler technique involves the use of a probe placed in the oesophagus to measure blood velocity in the descending aorta by applying the Doppler shift principle. Aortic cross-sectional area is either estimated with a nomogram or measured directly, thus allowing the estimation of cardiac output. For the experienced operator, this is a quick and simple device to use. The probe is not well tolerated by conscious subjects, and use is therefore confined to the sedated or anaesthetised patient. The principal complication of its use is trauma to the pharynx and oesophagus, and this technique is contraindicated during or after pharyngeal and oesophageal surgery.

Transpulmonary lithium indicator dilution and arterial waveform analysis involves the use of an initial cardiac output measurement by the indicator dilution technique to calibrate arterial waveform analysis software and provide a continuous measurement of cardiac output. Lithium chloride indicator is injected as a bolus into a central vein; a lithium ion-sensitive electrode measures the indicator concentration in blood drawn from an arterial line by a small pump. This provides a calibration factor for continuous analysis of the arterial pressure waveform. Transpulmonary thermal indicator dilution and arterial waveform analysis is a very similar technique. In this case, cold saline is injected into a central vein, and the temperature change is measured using a thermistor-tipped arterial catheter sited in either the femoral or the axillary artery. Once calibrated, pulse contour analysis software is used to provide a continuous measurement of cardiac output (Summary box 16.7).

William Ganz, b. 1919, Cardiologist, Cedars Sinai Medical Center, Los Angeles, CA, USA. Swan and Ganz published the results of the use of their catheter in 1970.

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler Principle' in 1842.

Summary box 16.7

Special monitoring techniques available in the critical care unit

- Oxygenation – invasive arterial gas with inspired oxygen monitoring
- Perfusion – cardiac output monitors – Swan-Ganz catheter, oesophageal Doppler probe, transpulmonary lithium and thermal sensors

General aspects of critical care

It is now routine practice in critical care to employ a 'bundle' of therapeutic strategies in all patients. Tight control of the patient's blood sugar involves the use of a sliding scale insulin infusion to achieve a blood glucose concentration between 4 and 8 mmol l⁻¹. This approach appears to be of particular benefit to patients who require prolonged postoperative critical care support. With the transfusion of stored red blood cells being associated with various complications including transfusion mismatch, infection and transfusion-related acute lung injury, the use of a more cautious haemoglobin concentration of 8 g dl⁻¹ to trigger the transfusion of red blood cells may result in an improvement in outcome. Acquired adrenocortical depression is common in patients who develop septic shock. In such cases, the use of low-dose corticosteroids may reduce vasopressor requirements and improve mortality rates.

It has been traditional to withhold enteral nutrition from patients for several days following surgery, as a result of concerns that early enteral diet may jeopardise bowel anastomoses, exacerbate postoperative ileus and delay recovery. Some authorities have suggested that this approach may in itself be harmful as enterocytes may extract nutritional substrate directly from the gut lumen. Prolonged fasting could therefore result in atrophy of the intestinal mucosa with consequent translocation of bacteria across the bowel wall and an increase in infective complications. While this theory is unproven, it is, in carefully selected cases, usually possible to commence a liquid enteral feed immediately after surgery without any adverse effects. The increasing use of jejunostomy feeding tubes has facilitated this approach.

The importance of deep vein thrombosis prophylaxis should be emphasised as a vital aspect of the care of any surgical patient. The high-risk patient may present with a number of predisposing factors for thromboembolism, including smoking, obesity, malignancy and immobility (Summary box 16.8).

Summary box 16.8

General critical care

- Blood glucose – tight control using an insulin sliding scale
- Blood transfusion reaction – harden threshold for transfusion to 8 g dl⁻¹
- Steroids if there are signs of adrenocortical depression
- Start enteral feeding early (jejunal feeding tubes)
- Protect against deep vein thrombosis

Postoperative respiratory management

Major surgery under general anaesthesia will result in a number of physiological changes to the respiratory system, perhaps the most important of which is a reduction in functional residual

capacity (FRC). These changes will be further compounded by postoperative pain and the residual effects of anaesthesia to cause pulmonary atelectasis predisposing the patient to respiratory infection. Meanwhile, agitation, pain and shivering as a result of hypothermia may all result in an increase in oxygen consumption. The reduction in oxygen delivery at a time of increased demand in part explains the high incidence of postoperative respiratory failure among high-risk surgical patients with reduced respiratory reserve.

It is not necessarily advisable for the high-risk surgical patient to follow the routine of abrupt cessation of anaesthesia at the end of surgery, removal of the tracheal tube and a brief period of care in a postoperative recovery unit before discharge to a standard ward. Although this course of treatment will not necessarily result in complications, inadequate respiratory support in the hours immediately following surgery may lead to hypoxaemia, carbon dioxide retention, acidosis and deterioration in clinical status, precipitating the need for reintubation and ventilation.

Where available, the use of postoperative invasive ventilation will allow staff to discontinue sedation once the patient is cardiovascularly stable, normothermic and well hydrated with optimal analgesia. The amount of time required to achieve this may vary widely. Consequently, it may be necessary to continue invasive ventilation overnight and extubate the patient on the first postoperative day. In some institutions, the provision of extended postoperative recovery facilities or high-dependency units allows overnight invasive ventilation without the expense and complexity of full-scale intensive care (Summary box 16.9).

Summary box 16.9

Potential problems of early extubation vs. extended ventilation overnight

- Sudden extubation may lead to hypoxia from poor respiratory effort
- Atelectasis may prejudice oxygen transfer
- Carbon dioxide levels may rise, leading to acidosis
- Shivering, pain and shock lead to high oxygen demand

Mechanical (invasive) ventilation

The underlying management principles of postoperative mechanical (invasive) ventilation are the same for all critically ill patients. Recent research has emphasised the potential complications of excessive tidal volumes causing overdistension of alveoli termed *volutrauma*, while excessive airways pressure may result in *barotrauma*. It has now emerged that many cases of postoperative acute respiratory distress syndrome arise not as a result of surgery or associated sepsis, but from overly 'aggressive' postoperative invasive ventilation. Evidence suggests that tidal volumes should be maintained between 5 and 7 ml kg⁻¹ wherever possible with a plateau pressure of 30 cmH₂O or less. In many patients, the resulting respiratory minute volume (MV) will be insufficient to maintain PaCO₂ at normal values. However, the mild degree of 'permissive' hypercapnia that results does not appear to be harmful as long as the arterial pH is maintained above 7.20. In practice, this is easily achieved in the absence of severe metabolic acidosis. This approach to ventilation is now often used during surgery as well.

Non-invasive ventilation (NIV)

Non-invasive ventilation via a tight-fitting face mask may prove a useful approach to postoperative respiratory management. This equipment is similar to that used for invasive ventilation (via a tracheal tube), and some modern ventilators may be used for both NIV and invasive ventilation. The chief benefit of NIV is that short periods of respiratory support may be provided without the need for general anaesthesia and tracheal intubation. Continuous positive airways pressure (CPAP) is a similar technique, which involves the application of a constant airways pressure (usually between 5 and 10 cmH₂O) via a tight-fitting face mask without cycling to a higher airways pressure during inspiration. The use of CPAP or NIV according to standardised protocols may facilitate early intervention for patients at risk, with subsequent reduction in the incidence of complications and a more rapid postoperative recovery. These non-invasive techniques of ventilation have also been shown to improve outcome in patients who develop postoperative respiratory failure unexpectedly. These techniques may obviate the need for initial invasive ventilation, or avoid respiratory deterioration and reintubation which risks significant morbidity for the patient.

Postoperative cardiovascular management

Most high-risk surgical patients will develop a degree of postoperative circulatory dysfunction. This may result from hypovolaemia, cardiac failure, haemorrhage, sepsis or a combination of these factors. In severe cases, these may result in circulatory shock, a state in which the perfusion of the tissues is insufficient to meet metabolic requirements.

General approach to treatment of circulatory shock

The Airway, Breathing, Circulation approach to assessment and management should be applied in every acutely ill patient. The purpose of this pragmatic approach to resuscitation is to ensure appropriate prioritisation, assessment and management of life-threatening disease. Circulatory shock is frequently associated with an inadequate airway due to reduced conscious level as well as impaired respiratory function. The resulting hypoxaemia will accelerate the deterioration in cardiac function. Airway and respiratory management should not be delayed to allow haemodynamic resuscitation, although such measures may be instituted simultaneously.

Hypovolaemia is commonplace following major surgery. Even a comparatively stable patient may have a degree of fluid depletion resulting from inadequate intake, haemorrhage and insensible losses. When a high-risk surgical patient develops signs of circulatory shock, it is, regardless of cause, appropriate to administer a 'fluid challenge'. Assessment of any response to fluid administration may provide more reliable evidence of hypovolaemia. This approach is unlikely to cause harm provided small volumes of fluid are administered and followed by careful and regular assessment. A 250-ml bolus of either intravenous crystalloid or colloid solution is generally considered appropriate. Where significant haemorrhage has occurred, the administration of packed red blood cells and other blood products will also be required. Improvement in pulse rate, urine output and conscious level are the most helpful indicators of fluid responsiveness. Arterial pressure may be misleading in the presence of circulatory shock and should be interpreted with caution (Summary box 16.10).

Summary box 16.10

Diagnosis of perioperative hypovolaemia

- Many patients are hypovolaemic at or after surgery
- A small fluid challenge will improve blood pressure, conscious state and urine output in a hypovolaemic patient
- Vasopressor drugs and inotropics may be needed to improve tissue perfusion

Replacement of intravascular volume may not in itself be sufficient to restore haemodynamic stability. Vasopressor drugs may be required to increase systemic vascular resistance (i.e. by vasoconstriction), and inotropic support may be required to increase cardiac output. Once these interventions are required, admission to a critical care unit is usually required. This will also allow the use of cardiac output monitoring. In selecting an inotrope or adjusting existing therapy, the two most important variables are the mean arterial pressure and the cardiac output. Various inotropic drugs are available, each with a specific pattern of cardiac and peripheral vascular effects. The input of an experienced critical care specialist is necessary to ensure the appropriate management of such patients.

Specific measures in the treatment of circulatory shock

While the approach described above may be sufficient to restore circulatory status, in some situations, more specific interventions may be required. These may include surgery in a patient with sepsis, radiological drainage of a collection, surgery to control haemorrhage, and percutaneous coronary intervention. The use of these approaches in the critically ill patient is self-evident and emphasises the importance of the involvement of all appropriate senior specialists at an early stage.

Critical care outreach

In recent years, the role of critical care has been expanded to the concept of 'critical care without walls'. This term describes the delivery of critical care to the patient, regardless of location within the hospital, ensuring high standards of care and optimal outcome. Frequent reports of persistent failures in the care of critically ill patients on standard wards have resulted in the widespread introduction of mainly nurse-led critical care outreach teams to achieve this aim. It would seem obvious that a service that allows early assessment and intervention by experienced critical care practitioners would improve clinical outcomes. However, there is at present no convincing evidence of improved patient outcomes associated with the introduction of critical care outreach teams.

SPECIFIC MANAGEMENT STRATEGIES FOR THE HIGH-RISK SURGICAL PATIENT**Prophylactic perioperative β -blockade**

Where significant cardiac disease is identified prior to surgery, medical management should be optimised in consultation with a cardiologist. The high mortality rates associated with postoperative myocardial infarction have led to the prophylactic use of nitrates, calcium channel antagonists and β -receptor antagonists in patients considered to be at risk of perioperative myocardial ischaemia. With the exception of β -receptor antagonists, none of

these therapies has resulted in documented improvement in outcome.

The considerable metabolic and physiological demands of surgery may result in increased myocardial work and inadequate myocardial oxygen supply. The successful use of β -receptor antagonists in the management of ischaemic heart disease has suggested an indication for the use of these agents in perioperative care. A number of studies suggest that the prophylactic use of atenolol or bisoprolol may result in significant reductions in the incidence of perioperative myocardial ischaemic events. The results of an ongoing, large, multicentre trial may further confirm the value of this approach.

Goal-directed therapy

Perioperative management of the cardiovascular system will always involve predefined treatment limits or targets. These targets may be very basic, such as heart rate and blood pressure, or more sophisticated. Goal-directed therapy (GDT) is a term used to describe the perioperative administration of intravenous fluids and inotropic agents to achieve a predefined 'optimal' goal for oxygen delivery to the tissues. Oxygen delivery is a parameter that is calculated from measurements of cardiac output, haemoglobin concentration, SaO_2 and PaO_2 . This approach was developed following the observation that, when routine parameters such as blood pressure and urine output were stabilised in all surgical patients, survivors had consistently higher cardiac output, oxygen delivery and oxygen consumption than those who subsequently died. The median values attained by the surviving patients in these observational studies were subsequently incorporated into GDT protocols as haemodynamic goals (Summary box 16.11).

Summary box 16.11

Goal-directed therapy

- Treatment aimed at achieving predefined levels of oxygen delivery to tissues
- Uses a multitude of treatment modalities depending on the patient's problem
- Improves cardiac output, renal output, complication rates and patient survival

A number of studies have suggested that GDT may significantly reduce postoperative complication rates. Originally, GDT required the insertion of a pulmonary artery catheter and was continued throughout the perioperative period. However, more recent evidence suggests that this technique is most beneficial when applied for short periods during and after surgery. Significant reductions in complication rates may be achieved with up to 8 hours of postoperative GDT using a minimally invasive cardiac output monitoring technique. It is important to note that the sustained use of GDT in patients with established critical illness is not beneficial and may in fact be harmful.

The simultaneous recommendations for the use of perioperative GDT and β -receptor antagonists in the high-risk population have caused some confusion. While indications for the two therapeutic approaches may seem to be mutually exclusive, this is not the case. The use of prophylactic β -blockade in patients considered at high risk of perioperative myocardial ischaemia will not negate the benefits of goal-directed resuscitation during periods of hypovolaemia.

Intraoperative oesophageal Doppler-guided fluid therapy

The use of oesophageal Doppler cardiac output measurement to guide intravenous fluid therapy is related to the technique of GDT described above. This use of this monitor has proved popular, in part because of the simplicity of the technique, but also because the anaesthetist will generally be able to gain access to the head during surgery. On average, the use of oesophageal Doppler-derived cardiac output measurement does seem to be associated with a larger volume of fluid administration. However, it is important to note the wide variation in the volume of fluid required. This variability in estimated fluid requirements would suggest that the benefit of this approach does not relate to the administration of extra fluid but to the use of an accurate estimate of fluid volume requirements in each individual patient (Summary box 16.12).

Summary box 16.12

Oesophageal Doppler-guided fluid therapy

- Appears to allow more accurate estimation of a patient's fluid needs
- Improves outcome following major surgery
- Reduces the incidence and length of ileus

Oesophageal Doppler-guided fluid management has been shown to improve outcome following cardiac, orthopaedic and abdominal surgery. There is some evidence to believe that this approach to fluid management results in improved mesenteric perfusion and therefore less postoperative ileus. Three separate studies

have shown an earlier return to enteral feeding and an associated reduction in duration of hospital stay.

SUMMARY

The majority of postoperative complications and deaths arise in a high-risk population of surgical patients. Increased awareness of this population with improved systems for the identification and treatment of the high-risk surgical patient is now increasingly important, as novel treatment strategies offer the prospect of significant improvements in outcome. However, a detailed multidisciplinary approach to perioperative care remains essential if the potential of these new approaches is to be realised.

Nutrition and fluid therapy

LEARNING OBJECTIVES

To understand:

- The causes and consequences of malnutrition in the surgical patient
- Fluid and electrolyte requirements in the pre- and postoperative patient
- The nutritional requirements of surgical patients and the nutritional consequences of intestinal resection
- The different methods of providing nutritional support and their complications

INTRODUCTION

Malnutrition is common. It occurs in about 30% of surgical patients with gastrointestinal disease and in up to 60% of those in whom hospital stay has been prolonged because of postoperative complications. It is frequently unrecognised and consequently patients often do not receive appropriate support. There is a substantial body of evidence to show that patients who suffer starvation or have signs of malnutrition have a higher risk of complications and an increased risk of death in comparison with patients who have adequate nutritional reserves.

Long-standing protein-calorie malnutrition is easy to recognise (Fig. 17.1). Short-term undernutrition, which has similar adverse consequences, is an inevitable outcome of critical illness, major trauma, burns or surgery and impacts on patient recovery.

The aim of nutritional support is to identify those patients at risk of malnutrition and to ensure that their nutritional requirements are met by the most appropriate route and in a way that minimises complications.

PHYSIOLOGY

Metabolic response to starvation

After a short fast lasting 12 hours or less, most food from the last meal will have been absorbed. Plasma insulin levels fall and glucagon levels rise, which facilitates the conversion of 200 g of liver glycogen into glucose. The liver, therefore, becomes an organ of glucose production under fasting conditions. Many organs, including brain tissue, red and white blood cells and the renal medulla, can initially utilise only glucose for their metabolic needs. Additional stores of glycogen exist in muscle (500 g) but these cannot be utilised directly. Muscle glycogen is broken down

(glycogenolysis) and converted to lactate, which is then exported to the liver where it is converted to glucose (Cori cycle). With increasing duration of fasting (> 24 hours), glycogen stores are depleted and *de novo* glucose production from non-carbohydrate

Figure 17.1 Severely malnourished patient with wasting of fat and muscle.

Carl Ferdinand Cori, 1896–1984, Professor of Pharmacology, and later of Biochemistry, Washington University Medical School, St. Louis, MO, USA, and his wife Gerty Theresa Cori, 1896–1957 who was also Professor of Biochemistry at the Washington University Medical School. In 1947 the Coris shared the Nobel Prize for Physiology or Medicine with Bernado Alberto Houssay, 'For their discovery of how glycogen is catalytically converted'. *de novo* is Latin for 'from the beginning'.

precursors (gluconeogenesis) takes place, predominantly in the liver. Most of this glucose is derived from the breakdown of amino acids, particularly glutamine and alanine as a result of catabolism of skeletal muscle (up to 75 g per day). This protein catabolism in simple starvation is readily reversed with the provision of exogenous glucose (Fig. 17.2).

With more prolonged fasting there is an increased reliance on fat oxidation to meet energy requirements. Increased breakdown of fat stores occurs, providing glycerol, which can be converted to glucose, and fatty acids, which can be used as a tissue fuel by almost all of the body's tissues. Hepatic production of ketones from fatty acids is facilitated by low insulin levels and after 2–3 weeks of fasting the central nervous system may adapt to using ketone bodies as their primary fuel source. This conversion to a 'fat fuel economy' reduces the need for muscle breakdown by up to 55 g per day. Another important adaptive response to starvation is a significant reduction in the resting energy expenditure, possibly mediated by a decline in the conversion of inactive thyroxine (T_4) to active tri-iodothyronine (T_3). Despite these adaptive responses there remains an obligatory glucose requirement of about 200 g per day, even under conditions of prolonged fasting (Summary box 17.1).

Summary box 17.1

Metabolic response to starvation

- Low plasma insulin
- High plasma glucagon
- Hepatic glycogenolysis
- Protein catabolism
- Hepatic gluconeogenesis
- Lipolysis: mobilisation of fat stores
- Adaptive ketogenesis
- Reduction in resting energy expenditure ($15\text{--}20 \text{ kcal kg}^{-1} \text{ day}^{-1}$)

Metabolic response to trauma and sepsis

This is described in full in Chapter 1 and summarised in Summary box 17.2.

Summary box 17.2

Metabolic response to trauma and sepsis

- Increased counter-regulatory hormones: adrenaline, noradrenaline, cortisol, glucagon and growth hormone
- Increased energy requirements (up to $40 \text{ kcal kg}^{-1} \text{ day}^{-1}$)
- Increased nitrogen requirements
- Insulin resistance and glucose intolerance
- Preferential oxidation of lipids
- Increased gluconeogenesis and protein catabolism
- Loss of adaptive ketogenesis
- Fluid retention with associated hypoalbuminaemia

From a nutritional point of view two factors deserve emphasis. First, in contrast to simple starvation, patients with trauma have impaired formation of ketones and the breakdown of protein cannot be prevented by the administration of glucose (Fig. 17.3). Second, although it is generally accepted that the metabolic response to trauma and sepsis is always associated with 'hypermetabolism' or

Figure 17.2 Schematic diagram to show metabolic response to fasting. L, lactate; P, pyruvate; RBC, red blood cells; WBC, white blood cells.

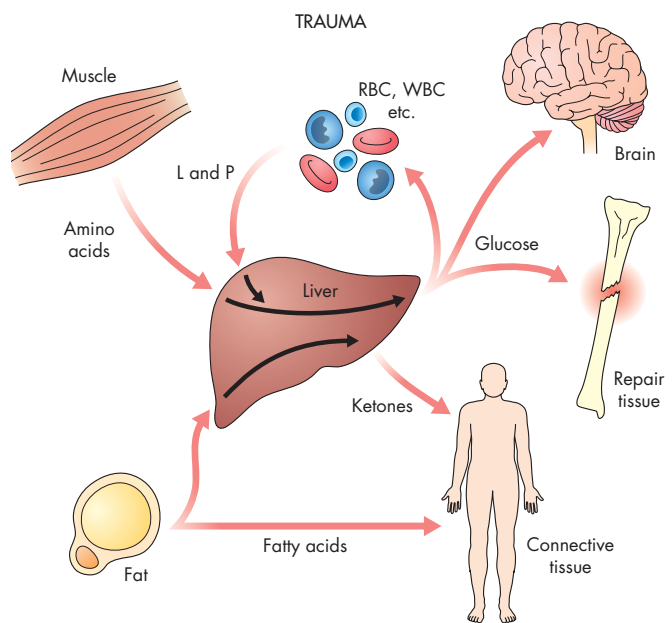

Figure 17.3 Schematic diagram showing metabolic response to trauma or sepsis. For abbreviations, see Fig. 17.2.

'hypercatabolism', these terms are ill defined and do not indicate the need for very high-energy intakes. There is no evidence to show that the provision of high-energy intakes is associated with an amelioration of the catabolic process and it may indeed be harmful.

NUTRITIONAL ASSESSMENT

Laboratory techniques

There is no single biochemical measurement that reliably identifies malnutrition. Albumin is not a measure of nutritional status. Although a low serum albumin level ($< 30 \text{ g l}^{-1}$) is an indicator of

poor prognosis, hypoalbuminaemia invariably occurs because of alterations in body fluid composition and because of increased capillary permeability related to on-going sepsis. Malnutrition is associated with defective immune function, and measurement of lymphocyte count and skin testing for delayed hypersensitivity frequently reveal abnormalities in malnourished patients. Immunity is not, however, a precise or reliable indicator of nutritional status, nor is it a practical method in routine clinical practice.

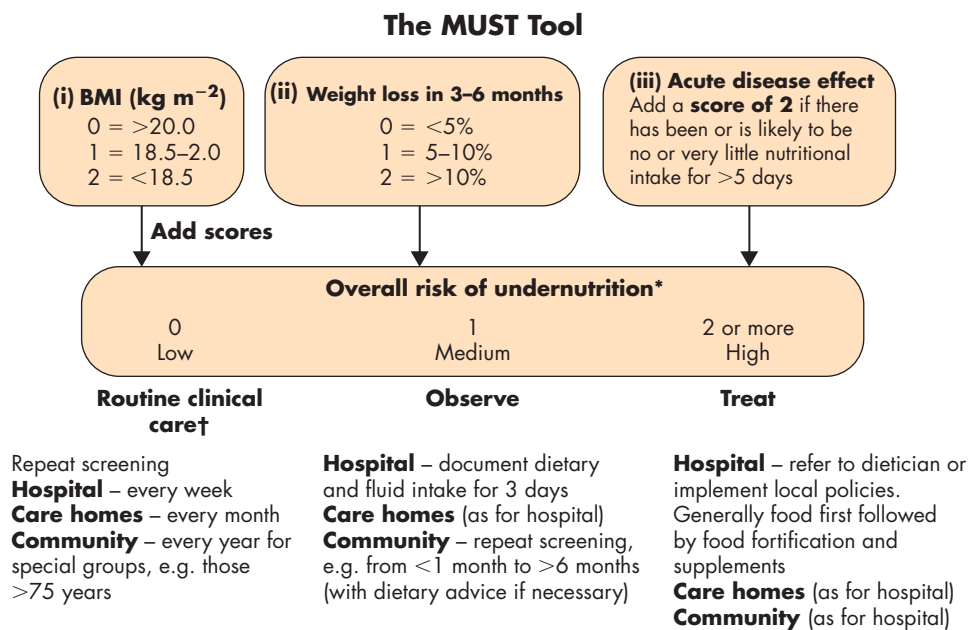

Body weight and anthropometry

A simple method of assessing nutritional status is to estimate weight loss. Measured body weight is compared with ideal body weight obtained from tables or from the patient's usual or pre-morbid weight. Unintentional weight loss of more than 10% of a patient's weight in the preceding 6 months is a good prognostic indicator of poor outcome. Body weight is frequently corrected for height, allowing calculation of the body mass index (BMI – defined as body weight in kilograms divided by height in metres squared). A BMI of less than 18.5 indicates nutritional impairment and a BMI below 15 is associated with significant hospital mortality. Major changes in fluid balance, which are common in critically ill patients, may make body weight and BMI unreliable indicators of nutritional status.

Anthropometric techniques incorporating measurements of skinfold thicknesses and mid-arm circumference permit estimations of body fat and muscle mass, and these are indirect measures of energy and protein stores. These measurements are, however, insufficiently accurate in individual patients to permit planning of nutritional support regimens. Similarly, use of bioelectrical impedance analysis (BIA) permits estimation of intra- and extracellular fluid volumes. These techniques are only useful if performed frequently on a sequential basis in individual patients. All of these techniques are significantly impaired by the presence of oedema.

Clinical

The possibility of malnutrition should form part of the work-up of all patients. A clinical assessment of nutritional status involves a focused history and physical examination, an assessment of risk of malabsorption or inadequate dietary intake and selected laboratory tests aimed at detecting specific nutrient deficiencies. This is termed 'subjective global assessment' and encompasses historical, symptomatic and physical parameters. Recently, the British Association of Parenteral and Enteral Nutrition introduced a Malnutrition Universal Screening Tool (MUST), which is a five-step screening tool to identify adults who are malnourished or at risk of undernutrition (Fig. 17.4).

*If height, weight or weight loss cannot be established, use documented or recalled values (if considered reliable). When measured or recalled height cannot be obtained, use knee height as surrogate measure.

If neither can be calculated, obtain an overall impression of malnutrition risk (low, medium, high) using the following:

- (i) Clinical impression (very thin, thin, average, overweight);
- (iia) Clothes and/or jewellery have become loose fitting;
- (iib) History of decreased food intake, loss of appetite or dysphagia up to 3-6 months;
- (iic) Disease (underlying cause) and psychosocial/physical disabilities likely to cause weight loss.

† Involves treatment of underlying condition, and help with food choice and eating when necessary (also applies to other categories).

Figure 17.4 The Malnutrition Universal Screening Tool (MUST) for adults [adapted from Elia, M. (ed.) (2003) *The MUST Report. Development and Use of the 'Malnutrition Universal Screening Tool' (MUST) for Adults*. A report by the Malnutrition Advisory Group of the British Association for Parenteral and Enteral Nutrition. FLUID AND ELECTROLYTES

Fluid intake is derived from both exogenous (consumed liquids) and endogenous (released during oxidation of solid foodstuffs) fluids. The average daily water balance of a healthy adult is shown in Table 17.1.

Fluid losses occur by four routes:

- **Lungs.** About 400 ml of water is lost in expired air each 24 hours. This is increased in dry atmospheres or in patients with a tracheostomy, emphasising the importance of humidification of inspired air.
- **Skin.** In a temperate climate, skin (i.e. sweat) losses are between 600 and 1000 ml day⁻¹.
- **Faeces.** Between 60 and 150 ml of water are lost daily in patients with normal bowel function.
- **Urine.** The normal urine output is approximately 1500 ml day⁻¹ and, provided that the kidneys are healthy, the specific gravity of urine bears a direct relationship to volume. A minimum urine output of 400 ml day⁻¹ is required to excrete the end products of protein metabolism.

Maintenance fluid requirements are calculated approximately from an estimation of insensible and obligatory losses. Various formulae are available for calculating fluid replacement based on a patient's weight or surface area. For example, 30–40 ml kg⁻¹ gives an estimate of daily requirements.

The following are the approximate daily requirements of some electrolytes in adults:

- sodium: 50–90 mM day⁻¹;
- potassium: 50 mM day⁻¹;
- calcium: 5 mM day⁻¹;
- magnesium: 1 mM day⁻¹.

The nature and type of fluid replacement therapy will be determined by individual patient needs. The composition of some commonly used solutions is shown in Table 17.2.

Note that Hartmann's solution also contains lactate

Table 17.1 Average daily water balance of a healthy adult in a temperate climate (70 kg)

Output	Volume (ml)	Intake	Volume (ml)
Urine	1500	Water from beverage	200
Insensible losses	900	Water from food	1000
Faeces	100	Water from oxidation	300

Table 17.2 Composition of crystalloid and colloid solutions (mM l⁻¹)

Solution	Na	K	Ca	Cl	Lactate	Colloid
Hartmann's	130	4	2.7	109	28

(28 mM l⁻¹). Dextrose solutions are also commonly employed. These provide water replacement without any electrolytes and with modest calorie supplements (1 litre of 5% dextrose contains 400 kcal). A typical daily maintenance fluid regimen would consist of a combination of 5% dextrose with either Hartmann's or normal saline to a volume of 2 litres.

There has been much controversy in the literature regarding the respective merits of crystalloid versus colloid replacement. There is no consensus on this topic and the usual advice is to replace like with like. If the haematocrit is below 30%, blood transfusion may be required. There is increasing recognition, however, that albumin infusions are of little value.

In addition to maintenance requirements, 'replacement' fluids are required to correct pre-existing deficiencies and 'supplemental' fluids are required to compensate for anticipated additional intestinal or other losses. The nature and volumes of these fluids are determined by:

- A careful assessment of the patient including pulse, blood pressure and central venous pressure if available. Clinical examination to assess hydration status (peripheries, skin turgor, urine output and specific gravity of urine), urine and serum electrolytes and haematocrit.
- Estimation of losses already incurred and their nature: for example, vomiting, ileus, diarrhoea, excessive sweating or fluid losses from burns or other serious inflammatory conditions.
- Estimation of supplemental fluids likely to be required in view of anticipated future losses from drains, fistulae, nasogastric tubes or abnormal urine or faecal losses.
- When an estimate of the volumes required has been made, the appropriate replacement fluid can be determined from a consideration of the electrolyte composition of gastrointestinal secretions. Most intestinal losses are adequately replaced with normal saline containing supplemental potassium (Table 17.3).

NUTRITIONAL REQUIREMENTS

Total enteral or parenteral nutrition necessitates the provision of the macronutrients, carbohydrate, fat and protein, together with vitamins, trace elements, electrolytes and water. When planning a feeding regimen the patient should be weighed and an assessment made of daily energy and protein requirements. Standard tables are available to permit these calculations.

Daily needs may change depending on the patient's condition. Overfeeding is the most common cause of complications, regardless of whether nutrition is provided enterally or parenterally. It is

Table 17.3 Composition of gastrointestinal secretions (mM l⁻¹)

	Na	K	Cl	HCO ₃
Saliva	10	25	10	30
Stomach	50	15	110	–
Duodenum	140	5	100	–
Ileum	140	5	100	30
Pancreas	140	5	75	115
Bile	140	5	100	35

essential to monitor daily intake to provide an assessment of tolerance. Failure to do so is the most common reason for inadequate nutrition. In addition, regular biochemical monitoring is mandatory (Table 17.4).

Macronutrient requirements

Energy

The total energy requirement of a stable patient with a normal or moderately increased need is approximately 20–30 kcal kg⁻¹ day⁻¹. Very few patients require energy intakes in excess of 2000 kcal day⁻¹. Thus, in the majority of hospitalised patients in whom energy demands from activity are minimal, total energy requirements are approximately 1300–1800 kcal day⁻¹.

Carbohydrate

There is an obligatory glucose requirement to meet the needs of the central nervous system and certain haematopoietic cells, which is equivalent to about 2 g kg⁻¹ day⁻¹. In addition, there is a physiological maximum amount of glucose that can be oxidised, which is approximately 4 mg kg⁻¹ min, with the non-oxidised glucose being primarily converted to fat. Optimal utilisation of energy during nutritional support is ensured by avoiding the infusion of glucose at rates approximating physiological maximums and providing energy as a mixture of glucose and fat. Glucose is the preferred carbohydrate source.

Table 17.4 Monitoring feeding regimens

Daily	Body weight Fluid balance Full blood count, urea and electrolytes Blood glucose Electrolyte content and volume of urine and/or urine and intestinal losses Temperature
Weekly (or more frequently if clinically indicated)	Urine and plasma osmolality Calcium, magnesium, zinc and phosphate Plasma proteins including albumin Liver function tests including clotting factors Thiamine Acid–base status Triglycerides
Fortnightly	Serum vitamin B12 Folate Iron Lactate Trace elements (zinc, copper, manganese)

in vivo is Latin for ‘in a living thing’.

Fat

Dietary fat is composed of triglycerides of predominantly four long-chain fatty acids. There are two saturated fatty acids – palmitic (C16) and stearic (C18) – and two unsaturated fatty acids – oleic (C18 with one double bond) and linoleic (C18 with two double bonds). In addition, smaller amounts of linolenic acid (C18 with three double bonds) and medium-chain fatty acids (C6–C10) are contained in the diet.

The unsaturated fatty acids linoleic and linolenic acid are considered essential because they cannot be synthesised *in vivo* from non-dietary sources. Both soybean and sunflower oil emulsions are rich sources of linoleic acid and provision of only 1 litre of emulsion per week avoids deficiency. Soybean emulsions contain approximately 7% alpha-linolenic acid (an omega-3 fatty acid). The provision of fat as a soybean oil-based emulsion on a regular basis will obviate the risk of essential fatty acid deficiency.

Safe and non-toxic fat emulsions based upon long-chain triglycerides (LCTs) have been commercially available for over 30 years. These emulsions provide a calorically dense product (9 kcal g⁻¹) and are now routinely used to supplement the provision of non-protein calories during parenteral nutrition. Energy during parenteral nutrition should be given as a mixture of fat together with glucose. There is no evidence to suggest that any particular ratio of glucose to fat is optimal as long as under all conditions the basal requirements for glucose (100–200 g day⁻¹) and essential fatty acids (100–200 g week⁻¹) are met. This ‘dual energy’ supply minimises metabolic complications during parenteral nutrition, reduces fluid retention, enhances substrate utilisation, particularly in the septic patient, and is associated with reduced carbon dioxide production.

Concerns have been expressed about the possible immunosuppressive effects of LCT emulsions. These are more likely to occur if the recommended infusion rates (0.15 g kg⁻¹ hour⁻¹) are exceeded. Nonetheless, these concerns have prompted the development of newer emulsions based upon medium-chain triglycerides, omega-3 fatty acids and, most recently, structured

triglycerides, which combine long- and medium-chain triglycerides in the same emulsion. The evidence of clinical benefit for these emulsions compared with conventional LCTs is tenuous, particularly if infusion rates are appropriate and hypertriglyceridaemia is avoided.

Protein

The basic requirement for nitrogen in patients without pre-existing malnutrition and without metabolic stress is 0.10–0.15 g kg⁻¹ day⁻¹. In hypermetabolic patients the nitrogen requirements increase to 0.20–0.25 g kg⁻¹ day⁻¹. Although there may be a minority of patients in whom the requirements are higher, such as after acute weight loss when the objective of therapy is long-term repletion of lean body mass, there is little evidence that the provision of nitrogen in excess of 14 g day⁻¹ is beneficial.

Vitamins, minerals and trace elements

Whatever the method of feeding these are all essential components of nutritional regimens. The water-soluble vitamins B and C act as coenzymes in collagen formation and wound healing. Postoperatively, the vitamin C requirement increases to 60–80 mg day⁻¹. Supplemental vitamin B12 is often indicated in patients who have undergone intestinal resection or gastric surgery and in those with a history of alcohol dependence. Absorption of the fat-soluble vitamins A, D, E and K is reduced in steatorrhea and the absence of bile.

Sodium, potassium and phosphate are all subject to significant losses, particularly in patients with diarrhoeal illness. Their levels need daily monitoring and appropriate replacement.

Trace elements may also act as cofactors for metabolic processes. Normally, trace element requirements are met by the delivery of food to the gut and so patients on long-term parenteral nutrition are at particular risk of depletion. Magnesium, zinc and iron levels may all be decreased as part of the inflammatory response. Supplementation is necessary to optimise the utilisation of amino acids and to avoid refeeding syndrome.

FLUID AND NUTRITIONAL CONSEQUENCES OF INTESTINAL RESECTION

Up to 50% of the small intestine can be surgically removed or bypassed without permanent deleterious effects. With extensive resection (< 150 cm of remaining small intestine) metabolic and nutritional consequences arise, resulting in the disease entity known as short bowel syndrome. The clinical presentation of patients with short bowel syndrome is dependent upon the nature and extent of intestinal resection.

Small bowel motility

Small bowel motility is three times slower in the ileum than in the jejunum. In addition, the ileocaecal valve may slow transit. The adult small bowel receives 5–6 litres of endogenous secretions and 2–3 litres of exogenous fluids per day. Most of this is reabsorbed in the small bowel. In the jejunum the cellular junctions are leaky and jejunal contents are always isotonic. Fluid absorption in this region of bowel is inefficient compared with the ileum. It has been estimated that the efficiency of water absorption is 44% and 70% of the ingested load in the jejunum and ileum respectively. The corresponding figures for sodium are 13%

and 72% respectively. It can be seen, therefore, that the ileum is critical in the conservation of fluid and electrolytes (Table 17.5).

Ileum

The ileum is the only site of absorption of vitamin B12 and bile salts. Bile salts are essential for the absorption of fats and fat-soluble vitamins. The enterohepatic circulation of bile salts is critical to maintain the bile salt pool. Following resection of the ileum the loss of bile salts increases and is not met by an increase in synthesis. Depletion of the bile salt pool results in fat malabsorption. In addition, loss of bile salts into the colon affects colonic mucosa, causing a reduction in salt and water absorption, which increases stool losses.

Colon

Transit times in the colon vary between 24 and 150 hours. The efficiency of water and salt absorption in the colon exceeds 90%. Another important colonic function is the fermentation of carbohydrates to produce short-chain fatty acids. These have two important functions: first, they enhance water and salt absorption from the colon and, second, they are trophic to the colonocyte.

Effects of resection

Resection of proximal jejunum results in no significant alterations in fluid and electrolyte levels as the ileum and colon can adapt to absorb the increased fluid and electrolyte load. Absorption of nutrients occurs throughout the small bowel and resection of jejunum alone results in the ileum taking over this lost function. In this situation there is no malabsorption.

Resection of ileum results in a significant enhancement of gastric motility and acceleration of intestinal transit. Following ileal resection the colon receives a much larger volume of fluid and electrolytes and it also receives bile salts, which reduce its ability to absorb salt and water, resulting in diarrhoea. Even the loss of 100 cm of ileum causes steatorrhea, which may necessitate the administration of oral cholestyramine to bind bile salts. With larger resections (> 100 cm) dietary fat restriction may be necessary. Regular parenteral vitamin B12 is required.

The most challenging patients are those with short bowel syndrome who have had in excess of 200 cm of small bowel resected together with colectomy. These patients will usually have a jejunostomy. They are conveniently divided into two groups termed 'net absorbers' and 'net secretors'. Absorbers characteristically have more than 100 cm of residual jejunum and they absorb more water and sodium from the diet than passes through the stoma. These patients can be managed without parenteral fluids.

Secretors usually have less than 100 cm of residual jejunum

Table 17.5 Intestinal luminal volume and absorption

	Volume (ml 24 h ⁻¹)	Sodium (mmol l ⁻¹)	Efficiency of water absorption (%)	Efficiency of sodium absorption (%)
Duodenum	9000	800	–	–
Jejunum	5000	700	44	13
Ileum	1500	200	70	72
Colon	100	3	93	99

and lose more water and sodium from their stoma than they take by mouth. These patients require supplements. Their usual daily jejunostomy output may exceed 4 kg per 24 hours. The sodium content of jejunostomy losses or other high-output fistulas is about 90 mmol l^{-1} . Jejunal mucosa is leaky and rapid sodium fluxes occur across it. If water or any solution with a sodium concentration of less than 90 mmol l^{-1} is consumed there is a net efflux of sodium from the plasma into the bowel lumen. It is therefore inappropriate to encourage patients with high-output jejunostomies (secretors) to drink large amounts of oral hypotonic solutions. Treatment begins with restricting the total amount of hypotonic fluids (water, tea, juices, etc.) consumed to less than a litre a day. Patients should be encouraged to take glucose and saline replacement solutions, which have a sodium concentration of at least 90 mmol l^{-1} . The World Health Organization (WHO) cholera solution has a sodium concentration of 90 mmol l^{-1} and is commonly used.

Complications of short bowel syndrome include peptic ulceration related to gastric hypersecretion, cholelithiasis because of interruption of the enterohepatic cycle of bile salts, and hyperoxaluria as a result of the increased absorption of oxalate in the colon predisposing to renal stones. Some patients with short bowel syndrome develop a syndrome of slurred speech, ataxia and altered affect. The cause of this syndrome is fermentation of malabsorbed carbohydrates in the colon to D-lactate and absorption of this metabolite. Treatment necessitates the use of a low carbohydrate diet.

Anti-secretory drugs reduce the amount of fluid secreted from the stomach, liver and pancreas. These include H₂-receptor antagonists, proton pump inhibitors and the somatostatin analogue octreotide. Octreotide also reduces gastrointestinal motility. Anti-motility drugs include loperamide and codeine phosphate, which also decrease water and sodium output from the stoma by about 20%.

ARTIFICIAL NUTRITIONAL SUPPORT

The indications for nutritional support are simple (Fig. 17.5). Any patient who has sustained 5–7 days of inadequate intake or who is anticipated to have no intake for this period should be considered for nutritional support. The periods may be less in patients with pre-existing malnutrition. This concept is important because it emphasises that the provision of nutritional support is not specific to certain conditions or diseases. Although patients with Crohn's disease or pancreatitis, or those who have undergone gastrointestinal resections, may frequently require nutritional support, it is the fact that they have had inadequate intakes for defined periods that is the indication rather than the specific disease process.

Enteral nutrition

The term 'enteral feeding' means delivery of nutrients into the gastrointestinal tract. The alimentary tract should be used whenever possible. This can be achieved with oral supplements (sip feeding) or with a variety of tube-feeding techniques delivering food into the stomach, duodenum or jejunum.

A variety of nutrient formulations are available for enteral

Figure 17.5 Techniques used for adjuvant nutritional support. PPN, partial parenteral nutrition; TPN, total parenteral nutrition. Redrawn with permission from Rick Tharp, rxkinetics.com.

feeding. These vary with respect to energy content, osmolarity, fat and nitrogen content and nutrient complexity. Most contain up to $1\text{--}2 \text{ kcal ml}^{-1}$ and up to 0.6 g ml^{-1} of protein. Polymeric feeds contain intact protein and hence require digestion whereas monomeric/elemental feeds contain nitrogen in the form of either free amino acids or, in some cases, peptides. These are less palatable and are used much less frequently than in previous years. Newer feeding formulations are available that include glutamine and fibre to optimise intestinal nutrition or immunonutrients such as arginine and fish oils but these are expensive and their use is controversial.

Sip feeding

Commercially available supplementary sip feeds are used in patients who can drink but whose appetites are impaired or in whom adequate intakes cannot be maintained with *ad libitum* intakes. These feeds typically provide 200 kcal and 2 g of nitrogen per 200 ml carton. There is good evidence to demonstrate that these sip-feeding techniques are associated with a significant overall increase in calorie and nitrogen intakes without detriment to spontaneous nutrition. The evidence that these techniques improve patient outcomes is less convincing.

Tube-feeding techniques

Enteral nutrition can be achieved using conventional nasogastric tubes (Ryle's), fine-bore feeding tubes inserted into the stomach, surgical or percutaneous endoscopic gastrostomy (PEG) or, finally, post-pyloric feeding utilising nasojejunal tubes or various types of jejunostomy. The choice of method will be determined by local

Burrill Bernard Crohn, 1884–1983, Gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.

ad libitum is Latin for 'at pleasure'.

John Alfred Ryle, 1889–1950, Regius Professor of Medicine, Cambridge University, and later Professor of Social Medicine, Oxford University, Oxford, England, introduced the Ryle's tube in 1921.

circumstances and preference in many patients. Whichever method is adopted it is important that tube feeding is supervised by an experienced dietician who will calculate the patient's requirements and aim to achieve these within 2–3 days of the instigation of feeds. Conventionally, 20–30 ml are administered per hour initially, gradually increasing to goal rates within 48–72 hours. In most units feeding is discontinued for 4–5 hours overnight to allow gastric pH to return to normal. There is some evidence that this might reduce the incidence of nosocomial pneumonia and aspiration. There is good evidence to confirm that feeding protocols optimise the tolerance of enteral nutrition. In these, aspirates are performed on a regular basis and if they exceed 200 ml in any 2-hour period then feeding is temporarily discontinued.

Tube blockage is common. All tubes should be flushed with water at least twice daily. If a build-up of solidified diet occurs, instillation into the tube of agents such as chymotrypsin or papain may salvage a partially obstructed tube. Guidewires should not be used to clear blockages as these may perforate the tube and cause contiguous damage.

Nasogastric tubes are appropriate in a majority of patients. If feeding is maintained for more than a week or so a fine-bore feeding tube is preferable and is likely to cause fewer gastric and oesophageal erosions. These are usually made from soft polyurethane or silicone elastomer and have an internal diameter of < 3 mm.

Fine-bore tube insertion

The patient should be semirecumbent. The introducer wire is lubricated and inserted into the fine-bore tube (Fig. 17.6). The tube is passed through the nose and into the stomach via the nasopharynx and oesophagus. The wire is withdrawn and the tube is taped to the patient. There is a small risk of malposition into a bronchus or of causing pneumothorax. The position of the tube should be checked using plain abdominal radiography (Fig. 17.7). Alternatively, 5 ml of air can be injected and a stethoscope used to confirm bubbling from the stomach. Confirmation of position by pH testing is possible but limited by the difficulty of obtaining a fluid aspirate with narrow lumen tubes.

Figure 17.6 A fine-bore feeding tube with its guidewire.

Figure 17.7 Radiograph of a tube similar to that in Figure 17.6 inserted beyond the duodenojejunal flexure.

Gastrostomy

The placement of a tube through the abdominal wall directly into the stomach is termed 'gastrostomy'. Historically, these were created surgically at the time of laparotomy. Today, the majority are performed by percutaneous insertion under endoscopic control using local anaesthesia (PEG) (Fig. 17.8).

Two methods of PEG are commonly used. The first is called the 'direct-stab' technique in which the endoscope is passed and the stomach filled with air. The endoscopist then watches a cannula entering the stomach having been inserted directly through the anterior abdominal wall. A guidewire is then passed through the cannula into the stomach. A gastrostomy tube (commercially available) may then be introduced into the stomach through a 'peel away' sheath. The alternative technique is the transoral or push-through technique whereby a guidewire or

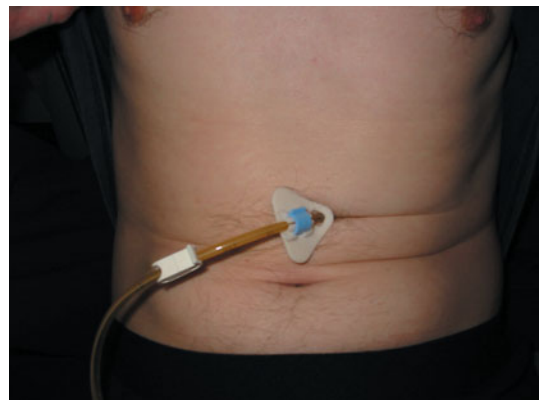

Figure 17.8 Percutaneous endoscopic gastrostomy tube.

suture is brought out of the stomach by the endoscope after trans-abdominal percutaneous insertion and is either attached to a gastrostomy tube or the tube is pushed over a guidewire. The abdominal end of the wire is then pulled, advancing the gastrostomy tube through the oesophagus and into the stomach. Continued pulling abuts it up against the abdominal wall.

If patients require enteral nutrition for prolonged periods (4–6 weeks) then PEG is preferable to an indwelling nasogastric tube; this minimises the traumatic complications related to indwelling tubes. PEG does have procedure-specific complications although these are uncommon. Necrotising fasciitis and intra-abdominal wall abscesses have been recorded. Sepsis around the PEG site is more common and may necessitate systemic antibiotics or repositioning. A persistent gastric fistula can occur on removal of a PEG if it has been in place for prolonged periods and epithelialisation of the tract has occurred. This necessitates surgical closure.

Jejunostomy

In recent years the use of jejunal feeding has become increasingly popular. This can be achieved using nasojejunal tubes or by placement of needle jejunostomy at the time of laparotomy. Some authorities advocate the use of jejunostomies on the basis that post-pyloric feeding may be associated with a reduction in aspiration or enhanced tolerance of enteral nutrition. In particular, there are many advocates of jejunostomies in patients with severe pancreatitis, in whom a degree of gastric outlet obstruction may be present, related to the oedematous head of pancreas. In most patients it is appropriate to commence with conventional nasogastric feeding and progress to post-pyloric feeding if the former is unsuccessful.

Nasojejunal tubes often necessitate the use of fluoroscopy or endoscopy to achieve placement, which may delay commencement of feeding. Surgical jejunostomies, even using commercially available needle-insertion techniques, do involve creating a defect in the jejunum, which can leak or be associated with tube displacement; both of these complications result in peritonitis.

Complications

Most complications of enteral nutrition can be avoided with careful attention to detail and appropriate infusion rates. Patients should be nursed semirecumbent to reduce the possibility of aspiration. Complications can be divided into those resulting from intubation of the gastrointestinal tract and those related to nutrient delivery. The former are more frequent with more invasive means of gaining access to the intestinal tract (see above). The latter include diarrhoea, bloating and vomiting. Diarrhoea occurs in more than 30% of patients receiving enteral nutrition and is particularly common in the critically ill. Up to 60% of patients in intensive care units may fail to receive their targeted intakes. There is no evidence that the incidence of diarrhoea and bloating is reduced by the use of half-strength feeds. It is important to introduce normal feeds at a reduced rate according to patient tolerance. Metabolic complications associated with excessive feeding are uncommon in enterally fed patients. There have been reports of nosocomial enteric infections associated with contamination of feeds, which should be kept in sealed containers at 4°C and discarded once opened.

In all patients it is essential to monitor intakes accurately as target intakes are often not achieved with enteral nutrition.

The complications of enteral nutrition are summarised in Summary box 17.3.

Summary box 17.3

Complications of enteral nutrition

Tube-related

- Malposition
- Displacement
- Blockage
- Breakage/leakage
- Local complications (e.g. erosion of skin/mucosa)

Gastrointestinal

- Diarrhoea
- Bloating, nausea, vomiting
- Abdominal cramps
- Aspiration
- Constipation

Metabolic/biochemical

- Electrolyte disorders
- Vitamin, mineral, trace element deficiencies
- Drug interactions

Infective

- Exogenous (handling contamination)
- Endogenous (patient)

Parenteral nutrition

Total parenteral nutrition (TPN) is defined as the provision of all nutritional requirements by means of the intravenous route and without the use of the gastrointestinal tract.

Parenteral nutrition is indicated when energy and protein needs cannot be met by the enteral administration of these substrates. The most frequent clinical indications relate to those patients who have undergone massive resection of the small intestine, who have intestinal fistula or who have prolonged intestinal failure for other reasons.

Route of delivery: peripheral or central venous access

TPN can be administered either by a catheter inserted in the central vein or via a peripheral line. In the early days of parenteral nutrition the only energy source available was hypertonic glucose, which, being hypertonic, had to be given into a central vein to avoid thrombophlebitis. In the second half of the last century there were a number of important developments that have influenced the administration of parenteral nutrition. These include the identification of safe and non-toxic fat emulsions that are isotonic; pharmaceutical developments that permit carbohydrates, fats and amino acids to be mixed in single containers; and a recognition that the provision of energy during parenteral nutrition should be a mixture of glucose and fat and that energy requirements are rarely in excess of 2000 kcal day⁻¹ (25–30 kcal kg⁻¹ day⁻¹). These changes enabled the development of peripheral parenteral nutrition.

Peripheral

Peripheral feeding is appropriate for short-term feeding of up to 2 weeks. Access can be achieved either by means of a dedicated catheter inserted into a peripheral vein and manoeuvred into the central venous system [peripherally inserted central venous catheter (PICC) line] or by using a conventional short cannula in the wrist veins. The former method has the advantage of minimising inconvenience to the patient and clinician. These PICC

lines have a mean duration of survival of 7 days. Their disadvantage is that when thrombophlebitis occurs the vein is irrevocably destroyed. In the alternative approach, intravenous nutrients are administered through a short cannula in wrist veins, infusing the patient's nutritional requirements on a cyclical basis over 12 hours. The cannula is then removed and re-sited in the contralateral arm. Peripheral parenteral nutrition has the advantage that it avoids the complications associated with central venous administration but suffers the disadvantage that it is limited by the development of thrombophlebitis (Fig. 17.9) Peripheral feeding is not indicated if patients already have an indwelling central venous line or in those in whom long-term feeding is anticipated.

Central

When the central venous route is chosen, the catheter can be inserted via the subclavian or internal or external jugular vein. There is good evidence to show that the safest means of establishing central venous access is by insertion of lines under ultrasound guidance; however, this will not be practicable for all cases. Most intensive care physicians and anaesthetists favour cannulation of internal or external jugular veins as these vessels are easily accessible. They suffer the disadvantage that the exit site is situated inconveniently on the side of the neck, where repeated movements result in disruption of the dressing with the attendant risk of sepsis. The infraclavicular subclavian approach is more suitable for feeding as the catheter then lies flat on the chest wall, which optimises nursing care (Fig. 17.10). For longer term parenteral nutrition Hickman lines are preferable. These are often inserted by a radiologist with fluoroscopic guidance or ultrasound. They incorporate a small cuff, which sits at the exit site of a subcutaneous tunnel. This is

Figure 17.10 Infraclavicular subclavian line.

thought to minimise the possibility of line dislodgement and reduce the possibility of line sepsis. Whichever technique is employed, a post-insertion chest radiograph is essential before feeding is commenced to confirm the absence of pneumothorax and that the catheter tip lies in the distal superior vena cava to minimise the risk of central venous or cardiac thrombosis. Multilumen catheters can be used for the administration of TPN; one port should be employed for that sole purpose and strict protocols of care employed.

Complications of parenteral nutrition

The commencement of TPN may precipitate or accentuate underlying nutrient deficiency by encouraging anabolism. Common metabolic complications include fluid overload, hyperglycaemia, abnormalities of liver function and vitamin deficiencies. Fluid overload can be avoided by daily weighing of the patient. A weight change of $> 1 \text{ kg day}^{-1}$ normally indicates fluid retention. Hyperglycaemia is common because of insulin resistance in critically ill patients. Even modest rates of glucose administration may be associated with hyperglycaemia. Hyperglycaemic patients undergoing surgery are known to run a substantially higher risk of infectious complications.

Abnormalities of liver enzymes are common in patients receiving TPN. Although the precise mechanisms are unclear, intrahepatic cholestasis may occur and hepatic steatosis and hepatomegaly have been reported. Reducing the fat content or infusion of fat-free TPN may be required. If liver enzymes continue to deteriorate TPN should be temporarily discontinued. In addition, overfeeding is a major factor in hepatic and other metabolic complications associated with TPN. Supplemental parenteral glutamine during parental nutrition should be considered, particularly in the critically ill patient.

Catheter-related sepsis occurs in 3–14% of patients. It may occur at the time of line insertion or afterwards by migration of skin bacteria along the external catheter surface. Some studies suggest that manoeuvring of the catheter hub due to frequent manipulations is a common cause. Contamination of the infusate is rare. Seeding on the catheter at the time of bacteraemia from a remote source may also cause catheter infection.

Diagnosis of catheter-related sepsis requires that the same organism is grown from the catheter tip as is recovered from blood and that the clinical features of infection resolve on removal of the catheter. Traditional methods of confirming line

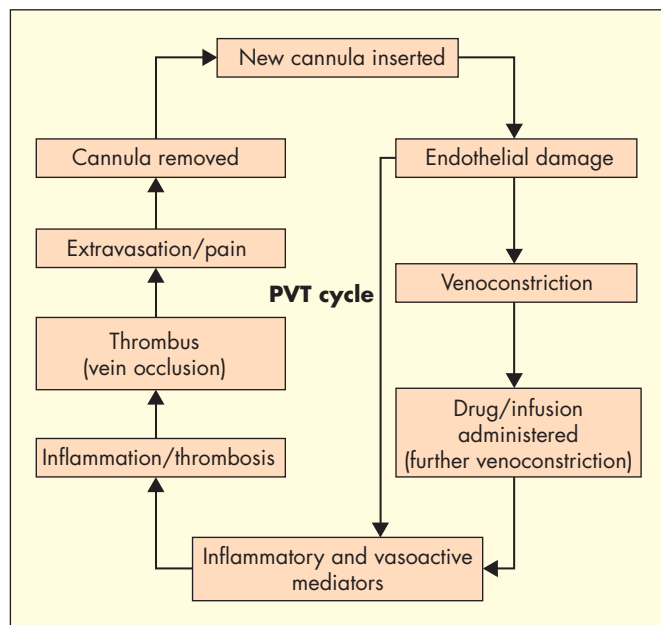

Figure 17.9 Cycle of causes of peripheral vein thrombophlebitis (PVT) [after Payne-James *et al.* (2001).

sepsis have necessitated removal of the line with subsequent bacteriological assessment. An alternative approach is to use an endoluminal brush passed down the catheter and withdrawn into a polythene sheath. The brush tip is cultured at the same time as performing blood cultures. Catheter sepsis is confirmed if identical organisms are cultured from brush and blood. A second alternative is to culture blood withdrawn through the catheter and compare this with peripheral blood cultures. If the colony count from the catheter sample is five or more times higher than that from peripheral blood then line sepsis is probable.

The complications of parenteral nutrition are summarised in Summary box 17.4.

Summary box 17.4

Complications of parenteral nutrition

Related to nutrient deficiency

- Hypoglycaemia/hypocalcaemia/hypophosphataemia/hypomagnesaemia (refeeding syndrome)
- Chronic deficiency syndromes (essential fatty acids, zinc, mineral and trace elements)

Related to overfeeding

- Excess glucose: hyperglycaemia, hyperosmolar dehydration, hepatic steatosis, hypercapnia, increased sympathetic activity, fluid retention, electrolyte abnormalities
- Excess fat: hypercholesterolaemia and formation of lipoprotein X, hypertriglyceridaemia, hypersensitivity reactions
- Excess amino acids: hyperchloraemic metabolic acidosis, hypercalcaemia, aminoacidaemia, uraemia

Related to sepsis

- Catheter-related sepsis
- Possible increased predisposition to systemic sepsis

Related to line

- On insertion: pneumothorax, damage to adjacent artery, air embolism, thoracic duct damage, cardiac perforation or tamponade, pleural effusion, hydromediastinum
- Long-term use: occlusion, venous thrombosis

Refeeding syndrome

This syndrome is characterised by severe fluid and electrolyte shifts in malnourished patients undergoing refeeding. It can occur with either enteral or parenteral nutrition but is more common with the latter. It results in hypophosphataemia, hypocalcaemia and hypomagnesaemia. These electrolyte disorders can result in altered myocardial function, arrhythmias, deteriorating respiratory function, liver dysfunction, seizures, confusion, coma, tetany and death. Patients at risk include those with alcohol dependency,

those suffering severe malnutrition, anorexics and those who have undergone prolonged periods of fasting. Treatment involves matching intakes with requirements and assiduously avoiding overfeeding. Calorie delivery should be increased slowly and vitamins administered regularly. Hypophosphataemia and hypomagnesaemia require treatment.

Nutrition support teams

Multidisciplinary nutrition teams ensure cost-effective and safe nutritional support, irrespective of how this is administered. The incidence of catheter-related sepsis is significantly reduced.

SUMMARY

Fluid therapy and nutritional support are fundamental to good surgical practice. Accurate fluid administration demands an understanding of maintenance requirements and an appreciation of the consequences of surgical disease on fluid losses. This requires knowledge of the consequences of surgical intervention and, in particular, intestinal resection.

Malnutrition is common in hospital patients. All patients who have sustained or who are likely to sustain 7 days of inadequate oral intake should be considered for nutritional support. This may be dietetic advice alone, sip feeding or enteral or parenteral nutrition. These are not mutually exclusive. The success or otherwise of nutritional support should be determined by tolerance to nutrients provided and nutritional endpoints such as weight. It is unrealistic to expect nutritional support to alter the natural history of disease. It is imperative that nutrition-related morbidity is kept to a minimum. This necessitates the appropriate selection of feeding method, careful assessment of fluid, energy and protein requirements, which are regularly monitored, and the avoidance of overfeeding.

To be aware of:

- The whole operative surgical team and the responsibility of each member in the care of sharps and perioperative care of instruments

INCISION OF SKIN

Skin and tissue incisions are usually made using scalpels with disposable blades. All sharp instruments, including needles, pose a risk of 'needle-stick' type injury and need to be passed within the operative team with great care using a kidney dish or similar. Attaching a blade to a scalpel handle, and its subsequent removal, is another simple skill that nevertheless needs to be learnt. This should be done using another instrument, such as a haemostat, and never using fingers. The blade shape and size is chosen for its purpose (Fig. 18.1). Blades for skin incisions usually have a curved margin; those used to make a passage for a drain through the skin or abdominal wall, or for an arteriotomy (which can be enlarged using arteriotomy scissors), have a sharp tip. When making an incision through skin and deeper layers for access, the knife should be pressed down firmly at right angles to the skin and then drawn across it. At the same time, tension should be applied across the line of the incision so that the skin springs apart cleanly (Fig. 18.2). It is important that the skin is not incised obliquely, as necrosis of the 'undercut' edge (not made at 90°) may occur. In long incisions of the lower limb, for vascular access, ischaemia of a skin edge risks infection, which can be disastrous because of the added risk of secondary haemorrhage from the anastomotic suture line. Diathermy, laser and harmonic scalpels can be used instead of blades when opening deeper tissues, as it is felt that they can reduce blood loss and save operating time, and may reduce postoperative pain.

SUTURE OF SKIN

Wounds should be closed with a minimum of tension. The edges of skin should gape slightly to allow swelling as the inflammation of healing occurs over the following few days. If a wound is closed tightly, swelling may cause wound edge necrosis and add to the risk of exogenous infection (Summary box 18.1).

Summary box 18.1

Closure of wounds

- Wound edges should be left slightly gaping to allow swelling
- Edges should be everted
- The knot should be placed to one side of the wound
- Knots must be secure, with the ends long enough to grasp when removing the suture

Figure 18.1 Scalpel blade sizes and shapes. The 11 blade is useful for arteriotomy, the 15 for minor operations and the rest for general use in incisions.

Figure 18.2 Skin incision. The skin is held taut between finger and thumb, and the incision is made with a clean sweep of the knife.

Needles are inserted at right angles to the skin for simple suture, using a supination/pronation movement of the wrist ('forehand' or 'backhand' suturing). Entry and exit points should be approximately the same distance from the wound edge as the thickness of the skin being closed. If the edge of the wound is gently everted with toothed forceps (the teeth can be used as a hook without grasping and injuring tissue) while the needle is inserted, a wider bite of the deeper tissue can be taken than the skin. The same can be done as the needle exits from the other side of the wound, ensuring that the suture takes a deep oval course through the tissues. When the suture is tightened, the wound edges should evert slightly (the best conditions for primary healing). If the suture enters and exits from the skin at an acute angle, the wound may become inverted with poor healing, and a poor cosmetic result needing revision.

As the suture is tightened, the knot should be drawn to one side to facilitate suture removal. When a non-absorbable suture is later removed, it needs to be cut immediately beneath the knot, and pulled out by the knot. The result is that the suture material contaminated by lying on the skin is lifted away without being drawn through the wound.

The final throw of the knot should be 'snugged' down, so that the knot cannot slip. The ends of the knot should be left long enough to be easy to grasp when they are being removed later, but not so long that they are tangled in adjacent sutures, or hair if the operative area has not been shaved.

As a general rule, each suture should be separated by a gap that is twice the thickness of the skin. If a wound is difficult to close, particularly after a large ellipse of skin has been removed, sutures can be placed alternately at each end of the wound, working towards the centre. If the wound has curves or zigzags, then 'stay sutures' at the tip of each corner make sure that the wound edges come together in the correct orientation, to avoid 'dog-ears' (Fig. 18.3). If a skin lesion is excised with overlying or surrounding skin, the wound length should be approximately three times the maximum width of the skin excised to allow closure with minimum distortion. If a wound is too short for the width of the excision, subcutaneous tissue can be excised under each end to prevent dog-ears. When a defect is large, and this technique cannot be used, several layers of side-to-side, from deep to superficial, continuous sutures can be placed in line with the incision.

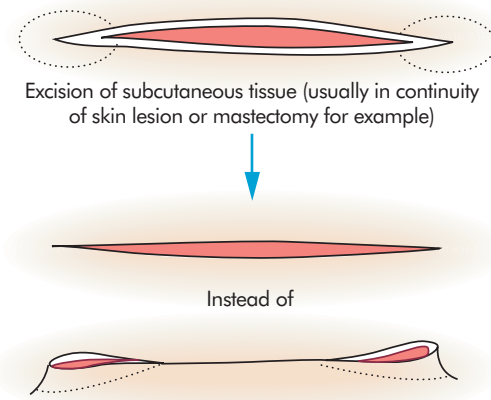

Figure 18.3 Avoidance of lateral incisional 'dog-ears'. The excision of subcutaneous tissue at the ends of a long incision can prevent 'dog-ears' at closure.

The suture ends of each layer are brought out at the wound ends with the deepest layer the most distant from the wound end and the most superficial, in effect, being a subcuticular closure (see later). When the several strands are pulled, the wound comes together with no tension in any of the layers and leaving no dead space.

TYPES OF SKIN CLOSURE

Skin closure may be interrupted or continuous; or simple (Fig. 18.4a), mattress (Fig. 18.4b) or subcuticular (Fig. 18.4c). Interrupted sutures have the advantage that they can be removed individually, if a haematoma or infection forms locally, to help drain blood, or pus if a wound abscess develops later, without disruption of the whole suture line. They are disadvantaged by being slower to insert than continuous sutures. Mattress sutures appose skin edges tidily, ensure eversion and help to close the dead space in the subcutaneous fat layer. They are slower to insert than simple sutures but may avoid the need for a 'fat stitch' before closing skin. This 'fat stitch' may leave a poor cosmetic result; for example, after excision of a breast lump (when placed to close dead space and theoretically reduce the risk of haematoma), it may, through attachment to a breast compartment ligament, cause a permanent dimpling effect in the skin. Subcuticular sutures are cosmetically appealing but are more difficult to place in a wound that is curved. Any dead space in the subcutaneous fat layer may also need to be closed separately (but see the caution above in breast skin closure). Nevertheless, subcuticular closure is the most widely practised skin closure in virtually all specialties, although skin clips have their advocates.

Non-absorbable skin sutures are removed when the wound has healed to avoid scarring, infection and irritation. As a general rule, they are removed from the face in 2–3 days, the scalp in 5 days, the upper limb and groin in 7 days, the abdomen in 10 days, and the dorsum and lower trunk within 10–14 days. Although these timings are conventional, there is evidence that early removal may be followed by the 'spreading' of skin scars, particularly when there is tension. Prolonged wound support using adhesive paper strips (Steristrips), or the potential use of anti-scarring agents, may help to prevent this.

Figure 18.4 Types of skin closure. (a) Simple. (b) Mattress. (c) Subcuticular. Ends can be buried (absorbable) or left open (non-absorbable), with or without being secured by beads, until removal. Beads should be avoided in easily irritated areas such as the axilla.

No-touch technique

Suturing should be undertaken using a no-touch technique to reduce the risk of a needle-stick injury. Obviously, this is not possible when performing a subcuticular closure using a straight needle, still used by many for this type of closure (Summary box 18.2).

Summary box 18.2

No-touch technique

- Used whenever possible
- Needle holders should be suitable for the needle
- Avoids the risk of needle-stick injury

Needle holders should be appropriate for the job. Short-handled holders are used for skin closure, but long-handled holders are needed for sutures placed deep inside the body. They have hardened jaws, usually made of titanium, to hold needles securely, but they can damage or weaken suture material if used for making knots, or placed on the swage that holds the suture in the hollow needle. Needle holders are precision instruments that should be

checked pre- and postoperatively. Experienced surgeons know which type suits them best for different functions. Suturing deep in the pelvis needs a long needle holder and requires practice. The shorter needle holders used in skin closure can be mastered more quickly. Tissue forceps also have many styles, which need to be explored during operative surgical training. Atraumatic forceps are used for delicate tissues, but a toothed forceps can be used as a hook and can be helpful in skin closure without having to grasp tissue.

The needle should be held in the tip of the holder and placed about two-thirds of the way back from its tip, where there is usually a designed, flattened part to allow a secure grip that prevents rotation. If the needle is held too far back, the swage may be crushed and the needle could break or come apart from the suture material. If the needle is grasped by its tip it may bend or break and be lost in the incision, which will disconcert the 'scrub nurse'. Needles can be placed in their holders to be used forehand or backhand. This depends on the most convenient way that a suture line can be performed. Surgeons in training should become adept at both.

Suture materials (Tables 18.1 and 18.2)

There is evidence that traumatic and surgical wounds were closed in 3000 BC by the Egyptians using thorns and needles. They also used adhesive linen strips, similar to modern-day Steristrips. By 1000 BC, Indian surgeons were using horsehair, cotton and leather sutures. In Roman times, linen and silk and metal clips called fibulae were commonly used to close gladiatorial wounds. By the end of the nineteenth century, developments in the textile industry led to major advances, and both silk and catgut became popular as suture materials. Lister believed that catgut soaked in chromic acid (a form of tanning) prevented early dissolution in body fluids and tissues. Moynihan felt that chromic catgut was ideal as it could be sterilised, was non-irritant to tissues, kept its strength until its work was done and then disappeared. How wrong he turned out to be. Catgut does not have any of these desirable properties, apart from being sterilisable, and it certainly causes an inflammatory cellular reaction with release of proteases. It may also carry the risk of prion transmission if of bovine origin.

All the natural sutures, silk, cotton, linen and catgut, are being replaced by polymeric synthetic materials that cause minimal inflammatory reactions, are of predictable strength and absorb at an appropriate rate. They can be manufactured as monofilaments or braids, and can be coated with wax, silicone or polybutyrate to allow them to run smoothly through tissues and to knot securely. The absorbables cause a minimal tissue reaction as they are resorbed. To aid in the prevention of postoperative infection, particularly after prosthetic surgery, absorbable synthetic sutures may be impregnated with an antiseptic (Vicryl Plus, a polyglactin, is impregnated with triclosan). The integrity of some synthetic non-absorbables in holding healing tissues

Gladiators were so called because they fought with a Roman sword called a Gladius.

Joseph Lister (Lord Lister), 1827–1912, Professor of Surgery, Glasgow, Scotland (1860–1869), Edinburgh, Scotland (1869–1877) and King's College Hospital, London, England (1877–1892).

Berkeley George Andrew Moynihan, (Lord Moynihan of Leeds), 1865–1936, Professor of Clinical Surgery, The University of Leeds, Leeds, England.

Table 18.1 Suture materials in common use in surgery: non-absorbable

Suture	Types	Raw material	Tensile strength	Absorption rate	Tissue reaction	Contraindications	Frequent uses	How supplied
Silk	Braided or twisted multifilament. Dyed or undyed. Coated (with wax or silicone) or uncoated	Natural protein Raw silk from silkworm	Loses 20% when wet; 80–100% lost by 6 months. Because of tissue reactions and unpredictability, silk is increasingly not recommended	Fibrous encapsulation in body at 2–3 weeks Absorbed slowly over 1–2 years	Moderate to high Not recommended Consider suitable absorbable or non-absorbable	Not for use with vascular prostheses or in tissues requiring prolonged approximation under stress Risk of infection and tissue reaction makes silk unsuitable for routine skin closure	Ligation and suturing when long-term tissue support is necessary	10/0–2 with needles, 4/0–1 without needles
Linen	Twisted	Long staple flax fibres	Stronger when wet Loses 50% at 6 months; 30% remains at 2 years	Non-absorbable Remains encapsulated in body tissues	Moderate	Not advised for use with vascular prostheses	Ligation and suturing in gastrointestinal surgery. No longer in common use in most centres	3/0–1 with needles, 3/0–1 without needles
Surgical steel	Monofilament or multifilament	An alloy of iron, nickel and chromium	Infinite (> 1 year)	Non-absorbable Remains encapsulated in body tissues	Minimal	Should not be used in conjunction with prosthesis of different metal	Closure of sternotomy wounds Previously found favour for tendon and hernia repairs	Monofilament: 5/0–5 with needles; multifilament: 5/0–3/0 with needles
Nylon	Monofilament or braided multifilament Dyed or undyed	Polyamide polymer	Loses 15–20% per year	Degrades at approximately 15–20% per year	Low	None	General surgical use, e.g. skin closure, abdominal wall mass closure, hernia repair, plastic surgery, neurosurgery, microsurgery, ophthalmic surgery	Monofilament: 11/0–2 with needles (including loops in some sizes), 4/0–2 without needles; multifilament: 6/0–2 with needles, 3/0–1 without needles
Polyester	Monofilament or braided multifilament Dyed or undyed Coated (polybutylate or silicone) or uncoated	Polyester (polyethylene terephthalate)	Infinite (> 1 year)	Non-absorbable: remains encapsulated in body tissues	Low	None	Cardiovascular, ophthalmic, plastic and general surgery	Monofilament: (ophthalmic) 11/10; 10/0 with needles; multifilament: 5/0–1 with needles Ethibond 7/0–5 with needles
Polybutester	Monofilament. Dyed or undyed	Polybutylene terephthalate and polytetramethylene ether glycol	Infinite (> 1 year)	Non-absorbable: remains encapsulated in body tissues	Low	None	Exhibits a degree of elasticity. Particularly favoured for use in plastic surgery	7/0–1 with needles
Polypropylene	Monofilament. Dyed or undyed	Polymer of propylene	Infinite (> 1 year)	Non-absorbable: remains encapsulated in body tissues	Low	None	Cardiovascular surgery, plastic surgery, ophthalmic surgery, general surgical subcuticular skin closure	10/0–1 with needles

Table 18.2 Suture materials in common use in surgery: absorbable

Suture	Types	Raw material	Tensile strength retention <i>in vivo</i>	Absorption rate	Tissue reaction	Contraindications	Frequent uses	How supplied
Catgut	Plain	Collagen derived from healthy sheep or cattle	Lost within 7–10 days Marked patient variability Unpredictable and not recommended	Phagocytosis and enzymatic degradation within 7–10 days	High	Not for use in tissues which heal slowly and require prolonged support Synthetic absorbables are superior	Ligate superficial vessels, suture subcutaneous tissues Stomas and other tissues that heal rapidly	6/0–1 with needles; 4/0–3 without needles
Catgut	Chromic	Collagen derived from healthy sheep or cattle Tanned with chromium salts to improve handling and to resist degradation in tissue	Lost within 21–28 days Marked patient variability Unpredictable and not recommended	Phagocytosis and enzymatic degradation within 90 days	Moderate	As for plain catgut Synthetic absorbables superior	As for plain catgut	6/0–3 with needles; 5/0–3 without needles
Polyglactin	Braided multifilament	Copolymer of lactide and glycolide in a ratio of 90:10, coated with polyglactin and calcium stearate	Approximately 60% remains at 2 weeks Approximately 30% remains at 3 weeks	Hydrolysis minimal until 5–6 weeks. Complete absorption 60–90 days	Mild	Not advised for use in tissues which require prolonged approximation under stress	General surgical use where absorbable sutures required, e.g. gut anastomoses, vascular ligatures. Has become the ‘workhorse’ suture for many applications in most general surgical practices, including undyed for subcuticular wound closures. Ophthalmic surgery	8/0–2 with needles; 5/0–2 without needles
Polyglyconate	Monofilament Dyed or undyed	Copolymer of glycolic acid and trimethylene carbonate	Approximately 70% remains at 2 weeks Approximately 55% remains at 3 weeks	Hydrolysis minimal until 8–9 weeks. Complete absorption by 180 days	Mild	Not advised for use in tissues which require prolonged approximation under stress	Popular in some centres as an alternative to Vicryl and PDS	7/0–2 with needles
Polyglycolic acid	Braided multifilament Dyed or undyed Coated or uncoated	Polymer of polyglycolic acid. Available with coating of inert, absorbable surfactant poloxamer 188 to enhance surface smoothness 87% excreted in urine within 3 days	Approximately 40% remains at 1 week Approximately 20% remains at 3 weeks	Hydrolysis minimal at 2 weeks, significant at 4 weeks. Complete absorption 60–90 days	Minimal	Not advised for use in tissues which require prolonged approximation under stress	Uses as for other absorbable sutures, in particular where slightly longer wound support is required	9/0–2 with needles; 9/0–2 without needles
Polydioxanone (PDS)	Monofilament Dyed or undyed	Polyester polymer	Approximately 70% remains at 2 weeks Approximately 50% remains at 4 weeks Approximately 14% remains at 8 weeks	Hydrolysis minimal at 90 days Complete absorption at 180 days	Mild	Not for use in association with heart valves or synthetic grafts, or in situations in which prolonged tissue approximation under stress is required	Uses as for other absorbable sutures, in particular where slightly longer wound support is required	Polydioxanone suture (PDS) 10/0–2 with needles
Polyglycaprone	Monofilament	Copolymer of glycolite and caprolactone	21 days maximum	90–120 days		No use for extended support	Subcuticular in skin, ligation, gastrointestinal and muscle surgery	8/0–2 with needles

together can last indefinitely, such as the use of polypropylene in arterial anastomosis. Polyamide (nylon) is slowly biodegradable and therefore not suitable for this purpose. Many non-absorbables are presented as monofilaments, which eliminates interstices in the thread and makes knots less likely to be a nidus for infection by reducing the risk of bacterial biofilms and adherence, but requires more skill in tying secure knots (Summary box 18.3).

Summary box 18.3

Modern synthetic polymeric suture materials

- Inflammatory reaction is reduced
- Strength predictable (particularly with non-absorbables)
- Absorption more complete and predictable (with absorbables)
- Synthetic polymers can be monofilament or braided

Suture diameters vary from 0.02 to 0.8 mm. This corresponds to 0.2 to 8 on the metric system (millimetres times 10) and 10/0 to 5 on the British Pharmacopoeia (BP) system. The finest suture that will hold the wound secure, without it breaking or 'cheese-wiring' through the tissues, should be chosen. The amount of suture material used should be kept to a minimum, particularly when braided, to reduce bacterial colonisation. Suture material can be a nidus for infection, and knots can be the focus of a persistent and chronic inflammatory reaction (suture knot sinus).

Metal sutures, clips and staples

Mechanical stapling devices were first used successfully by Hümer Hürtl, in Hungary, to close the stomach after resection. There is now a wide choice of linear, side-by-side and end-to-end stapling devices that give strong predictable suture lines, with minimal tissue necrosis. The staplers also allow access to difficult areas. For example, an oesophagogastric anastomosis can be performed without opening the chest. In an anterior resection, a staple gun may allow a low anastomosis to be performed quickly and without a colostomy, although a temporary loop ileostomy needs to be considered. The specific uses of stapling devices in surgery are described in the appropriate sections of this book. Most stapling devices are entirely disposable, relatively expensive, and now also available for minimally invasive surgery. Their cost is offset by the saving of operative time and increased range of surgery made possible. There are three basic types of gastrointestinal stapling device:

- 1 *Linear stapler* (Fig. 18.5a). A linear everting staple line is fashioned: used for closure of a viscus (e.g. duodenal stump closure after Pólya gastrectomy).
- 2 *Side-to-side stapler*, with or without a knife blade, for transection of a viscus between staple rows (Fig. 18.5b):
 - a linear inverting anastomosis with transection: used for side-to-side intestinal anastomoses (e.g. gastroenterostomy);

- b linear staple line without transection: used for fashioning enteric reservoirs (e.g. ileal pouch);
 - c linear staple line with transection: used for closure of a viscus (e.g. small bowel resection).
- 3 *End-to-end stapler* (Fig. 18.5c). Circular inverting anastomosis: used for end-to-end gastrointestinal anastomoses (e.g. closure of colostomy following Hartmann's procedure). These incorporate a circular knife blade.

Advances in laparoscopic surgery in recent years also owe much to the continuous refinement of clip and stapling devices designed to be used as laparoscopic instruments.

Metal clips for skin allow quick, accurate closure. Disposable units are more expensive than resterilisable Michel clips but save operating time. Skin clips are easy to remove with an appropriate, supplied device and give acceptable scars with a low infection rate. Inexpert placement can cause clips to drop out early, and cause skin edge overlap with a poor cosmetic result.

Stainless steel wire sutures have their place for the closure of the sternum after cardiac operations and in orthopaedic surgery. Their use in laparotomy closure has been superseded by modern synthetic non-absorbables.

Steristrips can be used to buttress a skin closure and can prevent 'spreading' of a scar. This can be useful, for example after a wide lump excision of the breast. Adhesive polyurethane films, such as Opsite, Tegaderm or Bioclusive, may have a similar property. Transparent dressings also allow wound inspection and may protect against cross-infection.

Needles

The choice of surgical needle (Fig. 18.6) is as important as the choice of suture. The needle holder chosen also needs to be appropriate; a large needle holder damages a small needle, and a large needle is unmanageable in a small needle holder. The passage of a needle through tissue should follow its curvature. This minimises tissue damage. The appropriate size and shape of cutting, or round-bodied atraumatic needle, needs to be chosen for the least traumatic passage through tissue. Shaped needles allow easier access for suturing. Examples are the J-shaped needle useful in low-approach femoral hernia repair, or the compound curve needle used in ophthalmic surgery. Hand needles should be avoided because of the risk of needle-stick injury. The tips of laparotomy closure needles are deliberately blunted by some of the manufacturers to reduce the risk of needle-stick injury. Needles may come with a loop suture (to avoid a knot at the end of a laparotomy) or as double-ended sutures (to facilitate arterial closure: see anastomoses).

Tissue glues

Cyanoacrylates

The use of tissue glues is not widespread despite much published work. The cyanoacrylates have been used for skin closure but require near perfect haemostasis if they are to work well. Some specific uses have been described such as the use in closure of a laceration on the forehead of a fractious child in Accident and Emergency (thereby dispensing with local anaesthetic and

sutures). They are relatively expensive but quick to use, do not delay wound healing and are associated with an allegedly low infection rate.

Fibrin tissue glues

Tissue glues, involving fibrin, work on the conversion of fibrinogen by thrombin to fibrin with cross-linking by factor XIII; the addition of aprotinin retards break-up of the fibrin network by plasmin. The fibrinous network produced has good adhesive properties and has been used for haemostasis in the liver and spleen. It has also been used in neurosurgery for dural tears; in ear, nose and throat (ENT) and ophthalmic surgery; to attach skin grafts and prevent haemoserous collections under flaps; and in cardiac and general surgery for the prevention of postoperative adhesions in the pericardium and the peritoneum. Fibrin glues have been used to control gastrointestinal haemorrhage, using endoscopic injection, but do not work when bleeding is brisk. They are more effective in haemostasis when combined with collagen.

Knot tying

Secure knots are crucial in operative surgery. Most should be performed using an instrument such as a needle holder, with care being taken not to crush or damage the suture material incorporated into the knot.

Tying knots with the fingertips is useful when ligating at depth. Surgeons in training should practise these on the jigs devised for use in basic skill courses.

All knots should be square, but the two-throw reef (surgeon's) knot does not slip (Fig. 18.7). A granny knot is a two-throw knot using the same type of throw; its ability to slip is useful in produc-

ing the right tension (Fig. 18.7) prior to ensuring security with a third, double-throw knot (Fig. 18.7). In vascular surgery, some surgeons prefer the security of five or six throws, but a three-throw reef knot is probably as secure as the integrity of the suture being used. The Aberdeen knot can be used with a continuous suture to make a final knot. The free end of the suture is pulled through the final loop several times before being pulled through a final time prior to cutting. It gives a less bulky knot, useful at the end of closure of the deep layers of a laparotomy incision.

When knots are cut short, the free ends or 'ears' should be left at least 1–2 mm long. This is particularly important with monofilament non-absorbables. However, if the ends are left too long, they can cause wound irritation and add to the complications of wound pain and wound sinuses. If knots are not 'snugged down' tightly, a suture cut too short may slide and become undone. When tying, the throw should be taken to the tissue using an instrument or an index fingertip. If this is not done, the vessel being ligated bows, and the ligature may dislodge or cut out; this is important for example when ligating the saphenofemoral junction during varicose vein surgery.

Ligatures can be tied using instruments or by hand when tissues are divided between forceps. The security of a ligature depends on good communication between surgeon and assistant as the tissue forceps is released and tissue tied without slippage. This needs practice.

Secure wound closure is crucial. Technical wound failure follows knots slipping, tissues tearing or breakage of sutures. When this occurs after laparotomy closure, the result is a burst abdomen, a disaster for the patient and a technical failure for the surgeon. This complication is avoided by the use of an appropriate material, polypropylene (Prolene) or polydioxanone suture (PDS), secure knots and appropriate tissue bites. It has been suggested by Jenkins that a suture length to wound length ratio of 4:1 indicates the optimum size of tissue bites and of suture spacing. The use of looped sutures, one starting from each end of the wound, requires only one knot, which also minimises the risk of a knot sinus or of wound pain (Summary box 18.4).

Figure 18.7 Types of knot used in surgery.

Summary box 18.4

Secure wound closure

- Correct suture material
- Appropriate bites of tissue and suture spacing
- Secure knots

ANASTOMOSIS

The word anastomosis comes from the Greek 'ανω', without, and 'στομα', a mouth, i.e. when a tubular viscus (bowel) or vessel (mostly arteries) is joined after resection or bypass without exteriorisation with a stoma. Anastomoses in the bowel were not undertaken successfully until the nineteenth century. Before that, experience was limited to exteriorisation or closure of simple lacerations. Lembert described his seromuscular suture technique for bowel anastomosis in 1826. Senn advocated a two-layer

Antoine Lembert, 1802–1851, Surgeon, Hôtel Dieu, Paris, France.
Nicolas Senn, 1844–1908, Professor of Surgery, Rush Medical College, Chicago, IL, USA.

technique for closure; Halsted favoured a one-layer extramucosal closure. Connell used a single layer of interrupted sutures incorporating all layers of the bowel. Kocher's method, a two-layer anastomosis, first a continuous all-layer suture using catgut, then an inverting continuous (or interrupted) seromuscular layer suture using silk, became the standard. There is evidence that inversion is safest in bowel (least likely to leak), although end-to-end staplers give an everted anastomosis without complication.

The single-layer extramucosal anastomosis, advocated by Matheson, causes the least tissue necrosis or luminal narrowing. There is probably little to choose between these techniques, provided basic essentials are observed. However, catgut and silk have been replaced by synthetic, usually absorbable, polymers.

Anastomosis of vessels was pioneered by Carrel. He advocated an everting anastomosis, with accurate opposition, to provide an intact endothelium that prevented platelet and thrombus deposition. The technique involved three stay sutures, which could be used to rotate the vessels and facilitate a continuous suture. The development of polymers, such as polypropylene which is not biodegradable, has made vascular anastomoses both safe and enduring.

Anastomosis of bowel

With good bowel preparation or an empty bowel, it is probably not necessary to apply clamps (even of the soft occlusion type), which are likely to cause some degree of tissue damage. If there is any risk of intestinal spillage during anastomosis, when bowel is unprepared or obstructed for example, atraumatic intestinal clamps should be used. Clamps must not impinge on the mesentery or its vasculature for fear of necrosis. Ideally, the bowel edges should be pink and bleeding prior to anastomosis. Excessive bleeding from the bowel wall may need oversewing if natural haemostasis is inadequate (Summary box 18.5).

Summary box 18.5

Essentials for safe bowel anastomosis

Local

- Good blood supply (no tension)
- Inverting anastomosis with appropriate suture
- Accurate apposition and suture technique (or stapling)
- Avoidance of tissue damage by clamps

Systemic

- Bowel preparation (and avoidance of spillage)
- Antibiotic prophylaxis
- Maintenance of good perfusion and tissue oxygenation during anaesthesia (correction of shock)
- Adequate nutritional attention
- Adequate resectional margins (cancer or inflammatory bowel disease) and avoidance of chemotherapy/radiotherapy

William Stewart Halsted, 1852–1922, Professor of Surgery, Johns Hopkins Hospital Medical School, Baltimore, MD, USA, described this suture in 1887.

Frank Gregory Connell, 1875–1968, Professor of Surgery, Rush Medical College, Chicago, IL, USA.

Emil Theodor Kocher, 1841–1917, Professor of Surgery, Berne, Switzerland.

Norman Alistair Matheson, Formerly Surgeon, Aberdeen Royal Infirmary, Aberdeen, Scotland.

Alexis Carrel, 1873–1944, was a Surgeon from Lyons in France who worked at the Rockefeller Institute for Medical Research in New York, NY, USA. He received the Nobel Prize for Physiology or Medicine in 1912 'in recognition for his works on vascular suture and the transplantation of blood vessels and organs.

End-to-end two-layer technique

This technique (Fig. 18.8) can be practised on basic skills jigs. The bowel ends must be brought together without tension. Stay sutures, which avoid the need for tissue forceps, may help with the placement of the posterior, continuous, seromuscular layer and allow rotation of the anastomosis. The all-layers continuous inner suture can be undertaken with a double-ended suture to help to keep the anastomosis even, going from the middle posteriorly to the lateral edge on each side. At the corners, one or two Connell 'loop-on-the-mucosa' sutures help to invert the mucosa (Fig. 18.8a). The double-ended suture can then be tied in the middle (on the anti-mesenteric side of the bowel). Finally, the anastomosis is inverted using a seromuscular, anterior, continuous Lembert suture. The apposition of bowel edges should, in each layer, be as accurate as possible. Bites should be approximately 5 mm deep and 5 mm apart. Suture materials should be of 2/0–3/0 size and made of an absorbable polymer, which can be braided (e.g. polyglactin), or a monofilament (e.g. polydioxanone), mounted on an atraumatic round-bodied needle. Braided, coated sutures are the easiest to handle and knot.

Alternatively, the inner continuous all-layers suture can be undertaken first. An inverting seromuscular Lembert layer is then applied second. This risks mesenteric vascular damage and is not recommended. It is crucial to make sure that only bowel of similar diameter is brought together to form an end-to-end anastomosis. 'Parachuting' or 'purse-stringing' a proximal dilated bowel lumen into narrower distal bowel risks a poor anastomosis and subsequent leakage. In such a case, a side-to-side or end-to-side anastomosis may be safer. The Cheatle split (making a cut into the anti-mesenteric border) may help to enlarge the lumen of distal, collapsed bowel. The mesentery should always be closed to avoid the later risk of an internal hernia through a persistent mesenteric defect. Care must be taken in preventing mesenteric vessel damage as the anastomosis may need to be revised.

End-to-end one-layer technique; end-to-side anastomosis

These anastomoses (Fig. 18.9) can be undertaken using open, avoiding the use of occlusion clamps, or closed techniques. They are useful in the following circumstances:

- when access is not easy, as in transabdominal oesophago-gastric anastomoses or after low anterior resection;
- when there is disparity in the bowel lumen;
- when the bowel serosa is lacking.

When interrupted sutures are required, a wide choice is available (Tables 18.1 and 18.2 above). There is no evidence that one technique is significantly superior to another (Fig. 18.10), but the interrupted single-layer extramucosal (seromuscular) suture is probably the most widely practised (Summary box 18.6).

Sir George Lenthal Cheatle, 1865–1951, Surgeon, King's College Hospital, London, England.

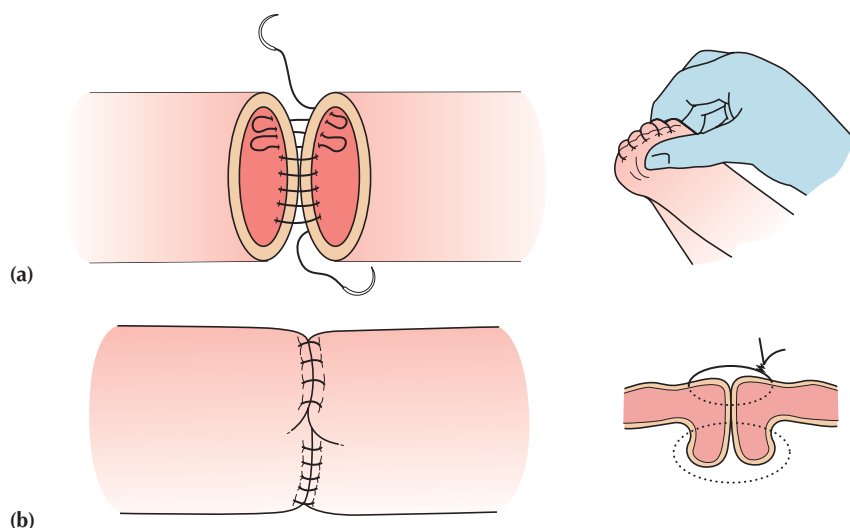

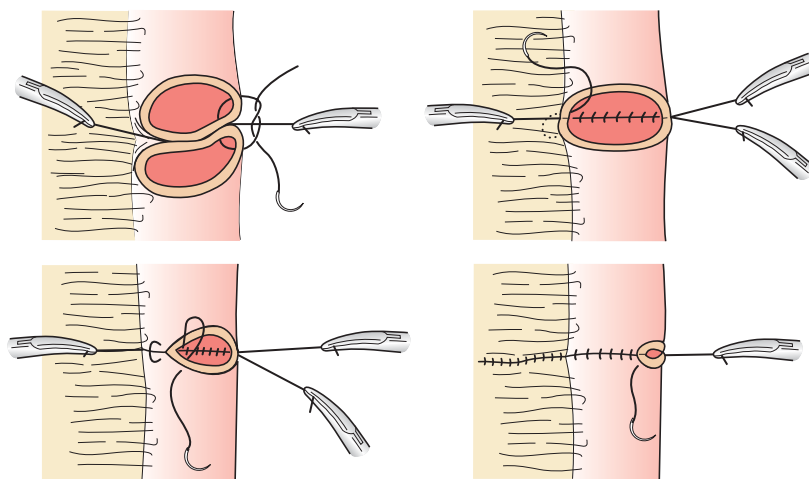

Figure 18.8 End-to-end, two-layer anastomosis in bowel (open). (a) The 'loop-on-the-mucosa' Connell stitch, which inverts the corners but is not haemostatic. (b) The second seromuscular outside layer that ensures mucosal inversion and can be performed as a single layer without the internal all-layers suture. The effect on a transverse section can be seen in the insert.

Summary box 18.6

Intestinal anastomosis

- Ensure viable bowel ends before and after anastomosis
- Use atraumatic clamps if soiling is a risk
- Avoid risk to mesenteric vessels by clamps or sutures
- Synthetic polymers are the most conventional sutures for hand-sewn inverting anastomoses
- Interrupted and continuous suture techniques are comparably safe
- Disposable staple units are an alternative with safe inverting or everting anastomoses

Anastomosis of vessels

Vascular anastomoses require more precision than bowel anastomoses as they must be immediately watertight at the end of the operation when the clamps are removed. The integrity of the suture also needs to be permanent. For this reason, polypropylene is one of the best sutures as it is not biodegradable. It should be used in its monofilament form, mounted on an atraumatic, curved, round-bodied needle. Knot security is important. The intimal suture line must be as smooth as possible to minimise the

risk of thrombosis and embolus, and regular to avoid leak. Suture size depends on vessel calibre: 2/0 is suitable for the aorta, 4/0 for the femoral artery and 6/0 for the popliteal to distal arteries. Microvascular anastomoses are made using a loupe and an interrupted suture down to 10/0 size (Summary box 18.7).

Summary box 18.7

Anastomosis of vessels

- Polypropylene-like sutures with indefinite integrity give the best results
- Intimal suture line must be smooth
- Knots must be secure
- Needle must pass from within outwards

Closure of an arteriotomy

The vessel walls must be treated with care, particularly the intima, and if manipulation is necessary, atraumatic forceps (such as DeBakey's) are needed. Vascular clamps should also be applied

Michael Ellis DeBakey, B. 1908, Professor of Surgery, Baylor University, Houston, TX, USA.

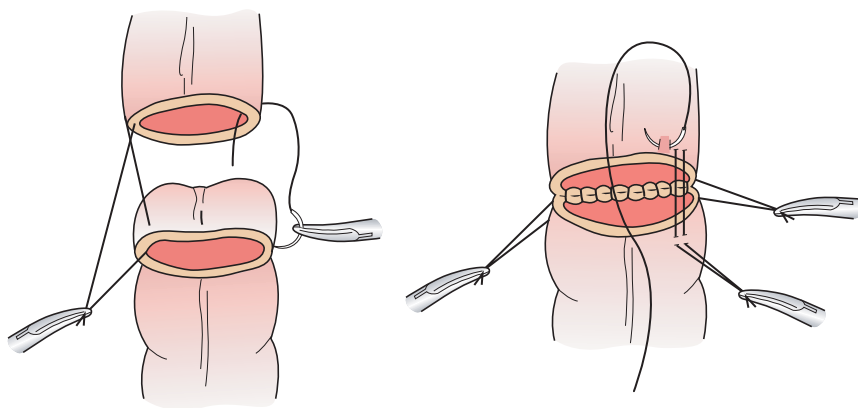

Figure 18.9 End-to-end, one-layer anastomosis in bowel (open).

with similar care. For the best exposure, the arterial wall can be retracted using a temporary looped suture, placed through all layers of the vessel at the midpoint of the proposed suture line and held on a haemostat. This exposure makes the first suture bite easier to place. Two single-ended sutures allow a knot to be placed externally at each end of the arteriotomy and a final knot to be easily placed in the middle at the end of each side of the arterial closure. Vessels should always be sewn with the needle moving from within to without the lumen to avoid creating an intimal flap and to fix any atherosclerotic plaque. The final closure is made easily at the middle of the arteriotomy where the

superior and inferior suture lines meet with the knot tied externally. This technique also simplifies the expulsion of air and any thrombus. The distal clamp is released before the final watertight knot is made. The proximal clamp can then be released without risk of distal embolus. Suture bites should be placed an equal distance apart, with the bite size dependent on the vessel diameter. Care needs to be taken to avoid damaging the suture, which can be torn by the instruments. The tip of the needle should be inserted at right angles to the surface of the intima and the curve of the needle followed to prevent vessel trauma. If the assistant follows by keeping the suture tight, the arteriotomy will be held up and open. This makes the next suture simple to place.

Closure of an arteriotomy with a vein patch

A transverse arteriotomy (Fig. 18.11) is less likely to stenose following closure than a longitudinal arteriotomy. However, a

Figure 18.10 Different types of single-row sutures. (a) Lembert. (b) All-layer. (c) Extramucosal.

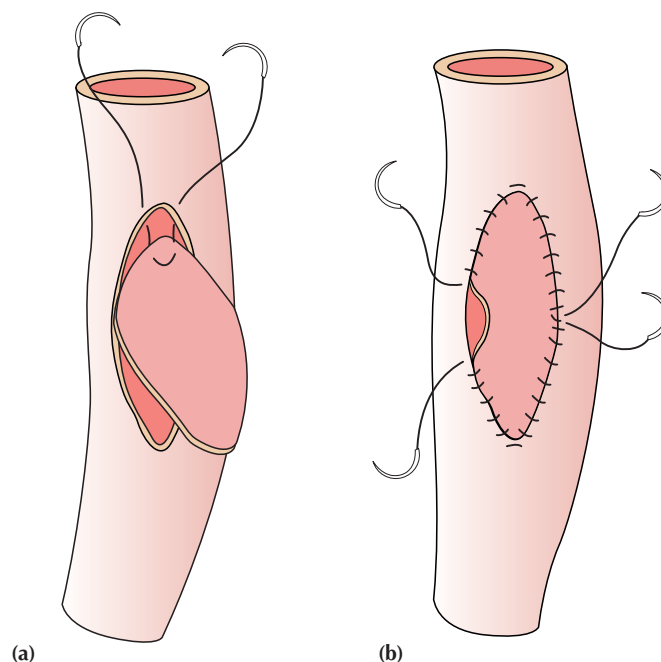

Figure 18.11 Closure of arteriotomy with a vein patch. This prevents stenosis. The use of double-ended sutures and an in-out technique from each end of the patch (a) allows final knots to be placed easily half-way down the patch and fixes the atherosclerotic plaque (b).

longitudinal arteriotomy is easier to make, and a vein patch graft can be used if there is any doubt about the size of the lumen. Once again, the suture line can be started at the top and bottom with a double-ended suture. The first knot is then placed half-way along the edge of the suture line. The closure is completed with a final knot on each side at the midpoint of the vein patch graft, using the in–out technique with fixation of plaque and avoidance of damage to the intima using atraumatic forceps.

End-to-end or side-to-side anastomoses

Most anastomoses involve the use of prosthetic material or vein grafts to bypass arterial disease. Continuous non-absorbable monomer sutures are used with the same in–out technique to ensure eversion. Double-ended sutures make the procedures easier. Gentle traction of the suture by the assistant keeps the lumen open as the suture line is completed. By leaving a tied suture long, the anastomosis can also be rotated to give better access to the suture line.

Complications after anastomoses

Difficult or poor exposure may lead to complications (Summary box 18.8).

Summary box 18.8

Complications after anastomosis

Leakage

- Bowel – peritonitis
- Vessel – haematoma, haemorrhagic shock (early), pseudoaneurysm (late)

Stenosis

- Bowel – obstruction after fibrous stricture or disease recurrence
- Vessel (early and late) – thrombosis, occlusion, gangrene

Inadequate mobilisation may leave an anastomosis under tension. A gentle respect for tissues is associated with fewer complications, although systemic factors need equal skill in recognition and correction (Summary box 18.9).

Summary box 18.9

Local and systemic adverse factors in anastomotic healing

Local

- Persisting disease process: cancer, chronic inflammation
- Distal obstruction
- Poor blood supply: rectum, oesophagus
- Poor technical aspects: haematoma, dead space, poor perfusion
- Presence of foreign body
- Gross contamination/infection

Systemic

- Shock of any cause
- Metabolic diseases: diabetes, uraemia, jaundice
- Immunosuppression: cancer, acquired immunodeficiency syndrome (AIDS), steroids
- Malnutrition: cancer

Complications include:

- 1 *Leakage*, which can occur early (vascular) or late (bowel), leading to haemorrhagic shock and peritonitis respectively.
- 2 *Bleeding* may need attention to a bowel edge prior to an anastomosis, by simple oversewing rather than diathermy, and revision if the anastomosis is complete. If overlooked, there may be the formation of a large haematoma (with risk of subsequent abscess if contaminated). The absence of bleeding at a bowel edge may indicate ischaemia; a bowel anastomosis that looks cyanosed needs serious consideration for refashioning. Urgent attention to persistent bleeding from an anastomotic edge is needed in vascular surgery, which may be arrested by: patience, gentle pressure and topical haemostatic agents such as Surgicel or Oxycel; an oversew at the bleeding anastomotic edge, which is undesirable as it may compromise the lumen; or the need for refashioning, which can be difficult, for example in an aortic neck. A pseudoaneurysm may result following revascularisation of a communicating haematoma.
- 3 Stenosis in bowel, which may be due to:
 - a fibrosis following a leak;
 - b inexperienced technique;
 - c recurrent tumour in a suture line.
- 4 Stenosis in arteries, which may be due to:
 - a technical errors;
 - b myo-intimal hyperplasia;
 - c recurrent atherosclerosis.

CONCLUSION

Two of the most basic skills in surgery are suturing and knot tying. These techniques ought to be mastered before the surgeon in training enters the operating theatre. The surgical skills laboratory is the place to practise and master the techniques. Without practice, that skill will not develop.

Principles of laparoscopic and robotic surgery

LEARNING OBJECTIVES

To understand:

- The principles of laparoscopic and robotic surgery
- The advantages and disadvantages of such surgery
- The safety issues and indications for laparoscopic and robotic surgery
- The principles of postoperative care

DEFINITION

Minimal access surgery is a marriage of modern technology and surgical innovation that aims to accomplish surgical therapeutic goals with minimal somatic and psychological trauma. This type of surgery has reduced wound access trauma as well as being less disfiguring than conventional techniques. With increasing experience it offers cost-effectiveness both to health services and to employers by shortening operating times, shortening hospital stays and allowing faster recuperation.

EXTENT OF MINIMAL ACCESS SURGERY

Minimal access surgery has crossed all traditional boundaries of specialties and disciplines. Shared, borrowed and overlapping technologies and information are encouraging a multidisciplinary approach that serves the whole patient rather than a specific organ system. Broadly speaking, minimal access techniques can be categorised as follows.

Laparoscopy

A rigid endoscope is introduced through a sleeve into the peritoneal cavity. This is inflated with carbon dioxide to produce a pneumoperitoneum. Further sleeves or ports are inserted to enable instrument access and their use for dissection (Fig. 19.1). There is little doubt that laparoscopic cholecystectomy has revolutionised the surgical management of cholelithiasis and has become the mainstay of management of uncomplicated gallstone disease. With improved instruments and more experience it is likely that other advanced procedures, such as laparoscopic colectomies for malignancy, previously regarded as controversial, will also become fully accepted.

Thoracoscopy

A rigid endoscope is introduced through an incision in the chest to gain access to the thoracic contents. Usually there is no requirement for gas insufflation as the operating space is held open by the rigidity of the thoracic cavity.

Endoluminal endoscopy

Flexible or rigid endoscopes are introduced into hollow organs or systems, such as the urinary tract, upper or lower gastrointestinal tract, and respiratory and vascular systems (see Chapter 11).

Perivisceral endoscopy

Body planes can be accessed even in the absence of a natural cavity. Examples are mediastinoscopy, retroperitoneoscopy and retroperitoneal approaches to the kidney, aorta and lumbar sympathetic chain. Extraperitoneal approaches to the retroperitoneal organs, as well as hernia repair, are now becoming increasingly commonplace, further decreasing morbidity associated with visceral peritoneal manipulation. Other, more recent, examples include subfascial ligation of incompetent perforating veins in varicose vein surgery.

Arthroscopy and intra-articular joint surgery

Orthopaedic surgeons have long used arthroscopic access to the knee and have now moved their attention to other joints, including the shoulder, wrist, elbow and hip.

Figure 19.1 Basic laparoscopic instruments (photo courtesy of Daniel Leff).

Combined approach

The diseased organ is visualised and treated by an assortment of endoluminal and extraluminal endoscopes and other imaging devices.

SURGICAL TRAUMA IN OPEN, LAPAROSCOPIC AND ROBOTIC SURGERY

Most of the trauma of an open procedure is inflicted because the surgeon must have a wound that is large enough to give adequate exposure for safe dissection at the target site. The wound is often the cause of morbidity, including infection, dehiscence, bleeding, herniation and nerve entrapment. Wound pain prolongs recovery time and, by reducing mobility, contributes to an increased incidence of pulmonary atelectasis, chest infection, paralytic ileus and deep venous thrombosis.

Mechanical and human retractors cause additional trauma. Body wall retractors tend to inflict localised damage that may be as painful as the wound itself. In contrast, during laparoscopy, the retraction is provided by the low-pressure pneumoperitoneum, giving a diffuse force applied gently and evenly over the whole body wall, causing minimal trauma.

Exposure of any body cavity to the atmosphere also causes morbidity through cooling and fluid loss by evaporation. There is also evidence to suggest that the incidence of post-surgical adhesions has been reduced by the use of the laparoscope because there is less damage to delicate serosal coverings. In handling intestinal loops, the surgeon and assistant disturb the peristaltic activity of the gut and provoke adynamic ileus.

Minimal access surgery has many advantages, such as a reduction in the trauma of access and exposure and an improvement in visualisation (Summary box 19.1).

Summary box 19.1

Advantages of minimal access surgery

- Decrease in wound size
- Reduction in wound infection, dehiscence, bleeding, herniation and nerve entrapment
- Decrease in wound pain
- Improved mobility
- Decreased wound trauma
- Decreased heat loss
- Improved vision

LIMITATIONS OF MINIMAL ACCESS SURGERY

Despite its many advantages, minimal access surgery has its limitations. To perform minimal access surgery with safety, the surgeon must operate remote from the surgical field, using an imaging system that provides a two-dimensional representation of the operative site. The endoscope offers a whole new anatomical landscape, which the surgeon must learn to navigate without the usual clues that make it easy to judge depth. The instruments are longer and sometimes more complex to use than those commonly used in open surgery. This results in the novice being faced with significant problems of hand–eye coordination.

Some of the procedures performed by these new approaches

are more technically demanding and are slower to perform. Indeed, on occasion, a minimally invasive operation is so technically demanding that both patient and surgeon are better served by conversion to an open procedure. Unfortunately, there seems to be a sense of shame associated with conversion, which is quite unjustified. It is vital for surgeons and patients to appreciate that the decision to close or convert to an open operation is not a complication but, instead, usually implies sound surgical judgement.

Another problem occurs when there is intraoperative arterial bleeding. Haemostasis may be very difficult to achieve endoscopically because blood obscures the field of vision and there is a significant reduction of the image quality owing to light absorption.

Another disadvantage of laparoscopic surgery is the loss of tactile feedback; this is an area of on-going research in haptics and biofeedback systems. Early work suggested that laparoscopic ultrasonography might be a substitute for the need to ‘feel’ in intraoperative decision-making. The rapid progress in advanced laparoscopic techniques, including biliary tract exploration and surgery for malignancies, has provided a strong impetus for the development of laparoscopic ultrasound. Although incompletely developed, this technique already has advantages that far outweigh its disadvantages.

In more advanced techniques, large pieces of resected tissue, such as the lung or colon, may have to be extracted from the body cavity. Occasionally, the extirpated tissue may be removed through a nearby natural orifice, such as the rectum or the mouth. At other times, a novel route may be employed. For instance, a benign colonic specimen may be extracted through an incision in the vault of the vagina. Several innovative tube systems have been shown to facilitate this extraction. Although tissue ‘morcellators, mincers and liquidisers’ can be used in some circumstances, they have the disadvantage of reducing the amount of information available to the pathologist. Recent reports of tumour implantation in the locations of port sites have raised important questions about the future of the laparoscopic treatment of malignancy. Although emerging evidence from large-scale UK and US prospective trials implicate surgical skill as an important aetiological factor, it is important to consider the biological implications of minimally invasive strategies on the tumours. The use of carbon dioxide and helium as insufflants causes locoregional hypoxia and may also change pH. The resultant modulation of spilled tumour cell behaviour is only now being elucidated.

Hand-assisted laparoscopic surgery is a well-developed technique. It involves the intra-abdominal placement of a hand or forearm through a minilaparotomy incision while pneumoperitoneum is maintained. In this way, the surgeon’s hand can be used as in an open procedure. It can be used to palpate organs or tumours, reflect organs atraumatically, retract structures, identify vessels, dissect bluntly along a tissue plane and provide finger pressure to bleeding points while proximal control is achieved. In addition, several reports have suggested that this approach is more economical than a totally laparoscopic approach, reducing both the number of laparoscopic ports and the number of instruments required. Some advocates of the technique claim that it is also easier to learn and perform than totally laparoscopic approaches, and that there may be increased patient safety.

There is a growing need for improvement in dissection techniques in laparoscopic surgery and, specifically, for improving the

safe use of electrosurgery and lasers. Ultrasonic dissection and tissue removal have been utilised by a growing number of specialties for several years. The adaptation of the technology to laparoscopic surgery grew out of the search for alternative, possibly safer, methods of dissection. The current units combine the functions of three or four separate instruments, reducing the need for instrument exchanges during a procedure. This flexibility, combined with the ability to provide a clean, smoke-free field, improves safety while shortening operating times.

Although dramatic cost savings are possible with laparoscopic cholecystectomy, the position is less clear-cut with other procedures. There is another factor that may complicate the computation of the cost–benefit ratio. A significant rise in the rate of cholecystectomy followed the introduction of the laparoscopic approach as the threshold for referring patients for surgery lowered. The increase in the number of procedures performed has led to an overall increase in the cost of treating symptomatic gallstones.

Three-dimensional systems are available but remain expensive and currently are not commonplace. Stereoscopic imaging for laparoscopy is still progressing. Future improvements in these systems will greatly enhance manipulative ability in critical procedures such as knot tying and dissection of closely underlying tissues. There are, however, some drawbacks, such as reduced display brightness and interference with normal vision because of the need to wear specially designed glasses for some systems. It is likely that brighter projection displays will be developed, at increased cost. However, the need to wear glasses will not be easily overcome.

Looking further to the future it is evident that the continuing reductions in the costs of elaborate image-processing techniques will result in a wide range of transformed presentations becoming available. It will ultimately be possible for a surgeon to call up any view of the operative region that is accessible to a camera and present it stereoscopically in any size or orientation, superimposed on past images taken in other modalities. Such augmented reality systems are being developed at present but are currently in relative infancy. It is for the medical community to decide which of these many potential imaginative techniques will contribute most to effective surgical procedures (Summary box 19.2).

Summary box 19.2

Limitations of minimal access surgery

- Reliance on remote vision and operating
- Loss of tactile feedback
- Dependence on hand–eye coordination
- Difficulty with haemostasis
- Reliance on new techniques
- Extraction of large specimens

ROBOTIC SURGERY

A robot is a mechanical device that performs automated physical tasks according to direct human supervision, a predefined program or a set of general guidelines using artificial intelligence techniques. In terms of surgery, robots have been used to assist surgeons during procedures. This has been primarily in the form of automated camera systems and telemanipulator systems, thus resulting in the creation of a human–machine interface.

Even though laparoscopic surgery has progressed greatly over the last two decades there are limitations. These include the restriction to two-dimensional views, reduced degrees of freedom, little or no tactile feedback and ergonomically difficult positions for the surgeon. Such problems undoubtedly affect surgical precision. This has led to interest in robotic master–slave systems (where the surgeon is the master, i.e. the operator, and the robot is the slave). Such devices have been under trial during the last 10 years. They offer many benefits, which have arisen as a result of new technology in lenses, cameras and computer software. The advantages are twofold: first for the patient (as per laparoscopic surgery, Summary box 19.1) and second for the surgeon. The advantages for the surgeon include better visualisation (higher magnification) with stereoscopic views; elimination of hand tremor allowing greater precision; improved manoeuvring as a result of the ‘robotic wrist’, which allows seven degrees of freedom; and the fact that large external movements of the surgical hands can be scaled down and transformed to limited internal movements of the ‘robotic hands’, extending the surgical ability to perform complex technical tasks in a limited space. Also, the surgeon is able to work in an ergonomic environment with less stress and achieve higher levels of concentration. The computer may also be able to compensate for the beating movement of the heart, making it unnecessary to stop the heart during cardiothoracic surgery. There may also be less need for assistance once surgery is under way.

Many surgical specialties have embraced the progression of robot-assisted techniques, including general surgery, cardiothoracic surgery, urology, orthopaedics, ear, nose and throat surgery and paediatric surgery. Specialities that use microsurgical techniques will particularly benefit in the future.

There are different robotic systems available (see Figs 19.2–19.5). Robotic camera systems include AESOP (Computer Motion, Goleta, California, USA) and EndoAssist (Armstrong

Figure 19.2 da Vinci manipulators used during robotic laparoscopic cholecystectomy. This demonstrates the robotic grasper holding and retracting the gall bladder neck while the robotic hook is used to free the overlying omentum on the gall bladder and cystic duct (courtesy of the Department of Biosurgery and Surgical Technology, Imperial College, London).

Figure 19.3 da Vinci console (photo courtesy of Daniel Leff).

Healthcare Ltd, High Wycombe, UK). Telerobotic manipulators include the da Vinci (Intuitive Surgical, Inc., Menlo Park, California, USA) and ZEUS (Computer Motion, Goleta, California, USA) manipulators. Finally, telerobotics and tele-mentoring has been combined in systems such as SOCRATES (Computer Motion, Goleta, California, USA). All of these systems offer different advantages to the operating surgeon, ranging from reducing the need for assistants and providing better ergonomic operating positions to providing experienced guidance from surgeons not physically present in the operating theatre.

PREOPERATIVE EVALUATION

Preparation of the patient undergoing laparoscopic or robotic surgery

Although the patient may be in hospital for a shorter period, careful preoperative management is essential to minimise morbidity.

History

Patients must be fit for general anaesthesia and open operation if necessary. Potential coagulation disorders (e.g. associated with cirrhosis) are particularly dangerous in laparoscopic surgery. As adhesions may cause problems, previous abdominal operations or peritonitis should be documented.

Examination

Routine preoperative physical examination is required as for any major operation. Although, in general, laparoscopic surgery allows quicker recovery, it may involve longer operating times and the establishment of the pneumoperitoneum may provoke cardiac arrhythmias. Severe chronic obstructive airways disease and ischaemic heart disease may be contraindications to the laparoscopic approach.

Particular attention should be paid to the presence or absence of jaundice, abdominal scars, palpable masses or tenderness.

Moderate obesity does not increase operative difficulty significantly, but massive obesity may make pneumoperitoneum difficult and standard instrumentation may be too short. Access may prove difficult in very thin patients, especially those with severe kyphosis.

Pre-medication

Pre-medication is the responsibility of the anaesthetist, with whom coexisting medical problems should be discussed.

Prophylaxis against thromboembolism

Venous stasis induced by the reverse Trendelenburg position during laparoscopic surgery may be a particular risk factor for deep vein thrombosis, as is a lengthy operation and the obesity of many patients. Subcutaneous fractionated heparin and anti-thromboembolic stockings should be used routinely in

addition to pneumatic leggings during the operation. Patients already taking warfarin for other reasons should have this stopped temporarily or converted to intravenous heparin, depending on the underlying condition, as it is not safe to perform laparoscopic surgery in the presence of a significant coagulation deficit.

Urinary catheters and nasogastric tubes

In the early days of laparoscopic surgery, routine bladder catheterisation and nasogastric intubation were advised. Most surgeons now omit these but it remains essential to check that the patient is fasted and has recently emptied the bladder, particularly before the blind insertion of a Verres needle. However, currently, most general surgeons prefer the direct cut-down technique into the abdomen for the introduction of the first port for the establishment of the pneumoperitoneum (Hasson technique).

Informed consent

The basis of many complaints and much litigation in surgery, especially laparoscopic surgery, relates to the issue of informed consent. It is essential that the patient understands the nature of the procedure, the risks involved and, when appropriate, the alternatives that are available. A locally prepared explanatory booklet concerning the laparoscopic procedure to be undertaken is extremely useful.

In an elective case, a full discussion of the proposed operation should take place in the out-patient department with a surgeon of appropriate seniority, preferably the operating surgeon, before the decision is made to operate. On admission it is the responsibility of the operating surgeon and anaesthetist to ensure that the patient has been fully counselled, although the actual witnessing of the consent form may have been delegated. The patient should understand what laparoscopic surgery involves and that there is a risk of conversion to open operation. If known, this risk should be quantified, for example the increased risk with acute cholecystitis or in the presence of extensive upper abdominal adhesions. The conversion rate will also vary with the experience and practice of the surgeon. Common complications should be mentioned, such as shoulder tip pain and minor surgical emphysema, as well as rare but serious complications including injury to the bile ducts and visceral injury from trocar insertion or diathermy.

A few patients may insist on having an open procedure (probably influenced by accounts of mishaps) and the surgeon should be prepared to offer this, although most will opt for laparoscopy if the surgeon has extensive experience and an impressive safety record.

When obtaining consent for robotic surgery patients should be offered appropriate literature so that they are able to provide fully informed consent. As these procedures are still not routine, this should be carried out by the operating surgeon and, if the procedure is in the context of a clinical trial, the appropriate ethical approval and subsequent paperwork should be available to the patient before signing the consent form (Summary box 19.3).

Janos Verres, 1903–1979, Chest Physician, and Chief of the Department of Internal Medicine, The Regional Hospital, Kapuvár, Hungary.
Harrith Hasson, Professor of Gynecology, Chicago, IL, USA.

Summary box 19.3

Preparation for laparoscopic or robotic surgery

- Overall fitness: cardiac arrhythmia, emphysema
- Previous surgery: scars, adhesions
- Body habitus: obesity, skeletal deformity
- Normal coagulation
- Thromboprophylaxis
- Informed consent

Preparation is very similar to that for open surgery and aims to ensure that:

- The patient is fit for the procedure
- The patient is fully informed and has consented
- Operative difficulty is predicted when possible
- Appropriate theatre time and facilities are available (especially important for robotic cases)

THEATRE SET-UP AND TOOLS

Operating theatre design, construction and layout is key to its smooth running on a daily basis. Originally, the video and diathermy equipment and other key tools used in laparoscopic surgery were moved around on stacks, taking up valuable floor space and cluttering up the theatre environment, which was not always ergonomic for the operating team. New theatres are designed with movable booms that come down from the ceiling; these are easy to place and do not have long leads or wires trailing behind them (Fig. 19.6). The equipment consists of at least two high-resolution LCD monitors, the laparoscopic kit for maintaining pneumoperitoneum and the audiovisual kit. The advent of DVD and other digital recording equipment has also led to these being incorporated into the rigs so that cases can be recorded with ease. This is further facilitated by cameras being inserted into the light handles of the main overhead lights so that open surgery can also be recorded without distracting the surgeons.

Image quality is vital to the success of laparoscopic surgery. New camera and lens technology allows the use of smaller cameras. Many centres now use 5 mm cameras routinely. Automatic focusing and charge-coupled devices (CCDs) are used to detect different levels of brightness and adjust for the best

Figure 19.6 Modern laparoscopic theatre set-up (photo courtesy of Daniel Leff).

image possible. Flat panel monitors with high definition images are used to give the surgeon the best views possible. The usability of the kit has also improved; touch screen panels and even voice-activated systems are now available on the market.

As minimally invasive and robotic procedures have become routine in some institutions, the dedicated theatre team for such procedures has also evolved. Surgeons and anaesthetists, as well as scrub and circulating nurses, have become familiar with working with the equipment and each other. The efficient working of the team is crucial to high-quality surgery and quick yet safe turnover times. Laparoscopic tools have also changed. Disposable equipment is more readily available, which does unfortunately increase the cost of the surgery. However, easy to use, ergonomically designed and reliable surgical tools are essential for laparoscopic and robotic surgery. Simple designs for new laparoscopic ports are now being studied, with the aim of reducing the incidence of port-site hernias; see-through ports that allow the surgeon to cut down through the abdomen while observing the layers through the cameras and new light sources within the abdomen may be simple ideas that affect surgical technique in the near future.

GENERAL INTRAOPERATIVE PRINCIPLES

Laparoscopic cholecystectomy is now the 'gold standard' for operative treatment of symptomatic gallstone disease. The main negative aspect of the technique is the increased incidence of bile duct injury compared with open cholecystectomy. Better understanding of the mechanisms of injury, coupled with proper training, will avoid most of these errors. The following sections highlight the important technical steps that should be taken during any form of laparoscopic surgery to avoid complications.

Creating a pneumoperitoneum

There are two methods for creation of a pneumoperitoneum: open and closed. The closed method involves blind puncture using a Verres needle. Although this method is fast and relatively safe, there is a small but significant potential for intestinal or vascular injury on introduction of the needle or first trocar. The routine use of the open technique for creating a pneumoperitoneum avoids the morbidity related to a blind puncture. To achieve this, a 1-cm vertical or transverse incision is made at the level of the umbilicus. Two small retractors are used to dissect bluntly the subcutaneous fat and expose the midline fascia. Two sutures are inserted each side of the midline incision, followed by the creation of a 1-cm opening in the fascia. Free penetration into the abdominal cavity is confirmed by the gentle introduction of a finger. Finally, a Hasson trocar (or other blunt-tip trocar) is inserted and anchored with the fascial sutures (Fig. 19.7). The open technique may initially appear time-consuming and even cumbersome; however, with practice, it is more efficient overall.

Preoperative problems

Previous abdominal surgery

Previous abdominal surgery is no longer a contraindication to laparoscopic surgery, but preoperative evaluation is necessary to assess the type and location of surgical scars. As mentioned earlier, the open technique for insertion of the first trocar is safer. Before trocar insertion, the introduction of a fingertip helps to ascertain penetration into the peritoneal cavity and also allows

Figure 19.7 Open technique with Hasson port. Apply safe principles of closed technique.

adhesions to be gently removed from the entry site. After the tip of the cannula has been introduced, a 0° laparoscope is used as a blunt dissector to tease adhesions gently away and form a tunnel towards the quadrant where the operation is to take place. This step is accomplished by a careful pushing and twisting motion under direct vision. With experience, the surgeon learns to differentiate visually between thick adhesions that may contain bowel and should be avoided and thin adhesions that would lead to a window into a free area of the peritoneal cavity (Fig. 19.8).

Obesity

Laparoscopic and robotic surgery have proved to be safe and effective procedures in the obese population. In fact, some procedures are less difficult than their open counterparts for the morbidly obese patient. Technical difficulties occur, however, in obtaining pneumoperitoneum, reaching the operative region adequately and achieving adequate exposure in the presence of an obese colon. Increased thickness of the subcutaneous fat makes insufflation of the abdominal cavity more difficult. With the closed technique, a larger Verres needle is often required for morbidly obese patients. Pulling the skin up for fixation of the soft tissues is better accomplished with towel clamps. Only moderate

Figure 19.8 Intra-abdominal adhesion.

force should be used to avoid separating the skin farther away from the fascia. The needle should be passed at nearly a right angle to the skin and preferably above the umbilicus where the peritoneum is more firmly fixed to the midline. The open technique of inserting a Hasson trocar is easier and safer for obese patients. The main difficulty is reaching the fascia. A larger skin incision (1–3 cm), starting at the umbilicus and extending superiorly, may facilitate this. To reach the operative area adequately, the location of some of the ports has to be modified and, in some instances, larger instruments are necessary. When the length of the laparoscope appears to be insufficient to reach the operative area adequately, the initial midline port should be placed nearer to the operative field.

Operative problems

Perforation of the gall bladder (see also Chapter 63)

Perforation of the gall bladder is more common with the laparoscopic technique than with the open technique. Some authors have reported an incidence of up to 30% but it does not appear to be a factor in increasing the early postoperative morbidity. However, it is well known that bile is not a sterile fluid and bacteria can be present in the absence of cholecystitis. Unless the perforation is small, closure with endoloops should be attempted to avoid contamination.

Bleeding

In some of the larger series, bleeding has been the most common cause for conversion to an open procedure. Bleeding plays a more important role in laparoscopic surgery because of factors inherent to the technique. These include a limited field that can easily be obscured by relatively small amounts of blood, magnification that makes small arterial bleeding appear to be a significant haemorrhage and light absorption that obscures the visual field.

How to avoid bleeding

As in any surgical procedure the best way to handle intraoperative bleeding is to prevent it from happening. This can usually be accomplished by identifying patients at high risk of bleeding, having a clear understanding of the laparoscopic anatomy and employing careful surgical technique.

Risk factors that predispose to increased bleeding include:

- cirrhosis;
- inflammatory conditions (acute cholecystitis, diverticulitis);
- coagulation defects: these are contraindications to a laparoscopic procedure.

Bleeding from a major vessel

Damage to a large vessel requires immediate assessment of the magnitude and type of bleeding. When the bleeding vessel is identified, a fine-tip grasper can be used to grasp it and apply either electrocautery or a clip, depending on its size. When the vessel is not identified early and a pool of blood forms, compression should be applied immediately with a blunt instrument, a cotton swab or with the adjacent organ. Good suction and irrigation are of utmost importance. Once the area has been cleaned, pressure should be released gradually to identify the site of bleeding. Insertion of an extra cannula may be required to achieve adequate exposure and at the same time to enable the concomitant use of a suction device and an insulated grasper. Although most of the bleeding vessels can be controlled laparoscopically,

judgement should be used in deciding when not to prolong bleeding but to convert to an open procedure at an early stage.

Bleeding from the gall bladder bed

Bleeding from the gall bladder bed can usually be prevented by performing the dissection in the correct plane. When a bleeding site appears during detachment of the gall bladder, the dissection should be carried a little farther to adequately expose the bleeding point. Once this step has been performed, direct application of electrocautery usually controls the bleeding. If bleeding persists, indirect application of electrocautery is useful because it avoids detachment of the formed crust. This procedure is accomplished by applying pressure to the bleeding point with a blunt, insulated grasper and then applying electrocoagulation by touching this grasper with a second insulated grasper that is connected to the electrocautery device. One must be careful to keep all conducting surfaces of the graspers within the visual field while applying the electrocautery current.

Bleeding from a trocar site

Bleeding from the trocar sites is usually controlled by applying upwards and lateral pressure with the trocar itself. Considerable bleeding may occur if the falciform ligament is impaled with the substernal trocar or if one of the epigastric vessels is injured. If significant continuous bleeding from the falciform ligament occurs, haemostasis is achieved by percutaneously inserting a large, straight needle at one side of the ligament. A monofilament suture attached to the needle is passed into the abdominal cavity and the needle is exited at the other side of the ligament using a grasper (Fig. 19.9). The loop is suspended and compression is achieved. Maintaining compression throughout the procedure usually suffices. After the procedure has been completed, the loop is removed under direct laparoscopic visualisation to ensure complete haemostasis. When significant continuous bleeding from the abdominal wall occurs, haemostasis can be accomplished either by pressure or by suturing the bleeding site. Pressure can be applied using a Foley balloon catheter. The catheter is introduced into the abdominal cavity through the bleeding trocar site wound, the balloon is inflated and traction is placed on the catheter, which is bolstered in place to keep it under tension. The catheter is left *in situ* for 24 hours and then removed. Although

Figure 19.9 Port-site bleeding controlled with sutures.

Frederic Eugene Basil Foley, 1891–1966, Urologist, Anker Hospital, St. Paul, MN, USA.

this method is successful in achieving haemostasis, the author favours direct suturing of the bleeding vessel. This manoeuvre is accomplished by extending the skin incision by 3 mm at both ends of the bleeding trocar site wound. Two figure-of-eight sutures are placed in the path of the vessel at both ends of the wound.

Evacuation of blood clots

The best way of dealing with blood clots is to avoid them. As mentioned, careful dissection and identification of the cystic artery and its branches, as well as identifying and carrying out dissection of the gall bladder in the correct plane, help to prevent bleeding from the cystic vessels and the hepatic bed. Nevertheless, clot formation takes place when unsuspected bleeding occurs or when inflammation is severe and a clear plane is not present between the gall bladder and the hepatic bed. The routine use of 5000–7000 units of heparin per litre of irrigation fluid helps to avoid the formation of clots. When extra bleeding is foreseen, a small pool of irrigation fluid can be kept in the operative field to prevent clot formation. After clots have formed, a large-bore suction device should be used for their retrieval. Care should be taken to avoid suctioning in proximity to placed clips.

Principles of electrosurgery during laparoscopic surgery

Electrosurgical injuries during laparoscopy are potentially serious. The vast majority occur following the use of monopolar diathermy. The overall incidence is between one and two cases per 1000 operations. Electrical injuries are usually unrecognised at the time that they occur, with patients commonly presenting 3–7 days after injury with complaints of fever and abdominal pain. As these injuries usually present late, the reasons for their occurrence are largely speculative. The main theories are: (1) inadvertent touching or grasping of tissue during current application; (2) direct coupling between a portion of bowel and a metal instrument that is touching the activated probe (Fig. 19.10); (3) insulation breaks in the electrodes; (4) direct sparking to bowel from the diathermy probe; and (5) current passage to the bowel from recently coagulated, electrically isolated tissue. Bipolar diathermy is safer and should be used in preference to monopolar diathermy, especially in anatomically crowded areas. If monopolar diathermy is to be used, important safety measures include attainment of a perfect visual image, avoiding excessive current

Figure 19.10 Direct coupling between bowel and laparoscope, which is touching the activated probe.

application and meticulous attention to insulation. Alternative methods of performing dissection, such as the use of ultrasonic devices, may improve safety.

Postoperative care

The postoperative care of patients after laparoscopic surgery is generally straightforward with a low incidence of pain or other problems. The most common routine postoperative symptoms are a dull upper abdominal pain, nausea and pain around the shoulders (referred from the diaphragm). There has been some suggestion that the instillation of local anaesthetic to the operating site and into the suprahepatic space, or even leaving 1 litre of normal saline in the peritoneum, serves to further decrease postoperative pain. It is a good general rule that if the patient develops a fever or tachycardia or complains of severe pain at the operation site, something is wrong and close observation is necessary. In this case routine investigation should include a full blood count, liver function tests, an amylase test and, probably, an ultrasound scan of the upper abdomen to detect fluid collections. If bile duct leakage is suspected, endoscopic retrograde cholangiopancreatography (ERCP) may be needed. If in doubt, re-laparoscopy or laparotomy should be performed earlier rather than later. Death following technical errors in laparoscopic cholecystectomy has often been associated with a long delay in deciding to re-explore the abdomen.

In the absence of problems, patients should be fit for discharge within 24 hours. They should be given instructions to telephone the unit or their general practitioner and to return to the hospital if they are not making satisfactory progress.

Nausea

About half of patients experience some degree of nausea after laparoscopic surgery and rarely this is severe. It usually responds to an antiemetic such as ondansetron and settles within 12–24 hours. It is made worse by opiate analgesics and these should be avoided.

Shoulder tip pain

The patient should be warned about this preoperatively and told that the pain is referred from the diaphragm and not due to a local problem in the shoulders. It can be at its worst 24 hours after the operation. It usually settles within 2–3 days and is relieved by simple analgesics such as paracetamol.

Abdominal pain

Pain in one or other of the port site wounds is not uncommon and is worse if there is haematoma formation. It usually settles very rapidly. Increasing pain after 2–3 days may be a sign of infection and, with concomitant signs, antibiotic therapy is occasionally required.

Analgesia

A 100-mg diclofenac suppository should be given at the time of the operation. It is important that the patient provides separate consent for this if the suppository is to be administered preoperatively. Suppositories may be administered a further two or three times postoperatively for relief of more severe pain. Otherwise 500–1000 mg of paracetamol 4-hourly usually suffices. Opiate analgesics cause nausea and should be avoided unless the pain is very severe. In this case, suspect a postoperative complication (as above). The majority of patients require between one and four doses of 1 g of paracetamol postoperatively.

Orogastric tube

An orogastric tube may be placed during the operation if the stomach is distended and obscuring the view. It is not necessary in all cases. It should be removed as soon as the operation is over and before the patient regains consciousness.

Oral fluids

There is no significant ileus after laparoscopic surgery except in resectional procedures such as colectomy or small bowel resection. Patients can start taking oral fluids as soon as they are conscious; they usually do so 4–6 hours after the end of the operation.

Oral feeding

Provided that the patient has an appetite, a light meal can be taken 4–6 hours after the operation. Some patients remain slightly nauseated at this stage but almost all eat a normal breakfast on the morning after the operation.

Patients will require advice about what they can eat at home. They should be told that they can eat a normal diet but should avoid excess. It seems sensible to avoid high-fat meals for the first week although there is no clear evidence that this is necessary.

Urinary catheter

If a urinary catheter has been placed in the bladder during the operation it should be removed before the patient regains consciousness. The patient should be warned of the possibility and symptoms of postoperative cystitis and told to seek advice in the unlikely event of this occurring.

Drains

Some surgeons drain the abdomen at the end of laparoscopic cholecystectomy although this is controversial. If a drain is placed to vent the remaining gas and peritoneal fluid it should be removed within 1 hour of the operation. If it has been placed because of excessive hepatic bleeding or bile leakage it should be removed when that problem has resolved, usually after 12–24 hours. Continued blood loss from a drain is an indication for re-exploration of the abdomen (Summary box 19.4).

Summary box 19.4

Surgical principles

- Meticulous care in the creation of a pneumoperitoneum
- Controlled dissection of adhesions
- Adequate exposure of operative field
- Avoidance and control of bleeding
- Avoidance of organ injury
- Avoidance of diathermy damage
- Vigilance in the postoperative period

DISCHARGE FROM HOSPITAL

Some surgeons discharge a proportion of their patients on the day of surgery but most are kept in overnight and discharged the following morning. Patients should not be discharged until they are seen to be comfortable and eating and drinking satisfactorily. They should be told that if they develop abdominal pain or other severe symptoms then they should return to the hospital or to their general practitioner.

Skin sutures

If non-absorbable sutures or skin staples have been used they can be removed from the port sites after 48 hours.

Mobility and convalescence

Patients can get out of bed to go to the toilet as soon as they have recovered from the anaesthetic and they should be encouraged to do so. Such movements are remarkably pain free when compared with the mobility achieved after an open operation. Similarly, patients can cough actively and clear bronchial secretions, and this helps to diminish the incidence of chest infections. Many patients are able to walk out of hospital on the evening of their operation and almost all are fully mobile by the following morning. Thereafter, the postoperative recovery is variable. Some patients prefer to take things quietly for the first 2–3 days, interspersing increasing exercise with rest. After the third day, patients will have undertaken increasing amounts of activity. The average return to work is about 10 days.

THE PRINCIPLES OF COMMON LAPAROSCOPIC PROCEDURES

The principles of common laparoscopic procedures are described in the appropriate chapters:

- laparoscopic cholecystectomy (Chapter 63);
- laparoscopic inguinal hernia repair (Chapter 57);
- laparoscopic anti-reflux surgery (Chapter 59);
- laparoscopic appendicectomy (Chapter 67).

Other elective laparoscopic or minimally invasive procedures that are becoming more widely utilised in certain specialist centres include:

- colectomy;
- splenectomy;
- nephrectomy;
- adrenalectomy;
- prostatectomy;
- thyroid and parathyroid surgery;
- aortic aneurysm surgery;
- single-vessel coronary artery bypass surgery;
- video-assisted thorascopic surgery (VATS).

Laparoscopy has also been used in certain emergency situations (in stable patients) in the hands of experienced laparoscopic surgeons. These may include diagnostic laparoscopy, repair of a perforated duodenal ulcer, laparoscopic appendicectomy, treatment of intestinal obstruction secondary to adhesions and, also, the laparoscopic evaluation of stable trauma patients.

Procedures that have been carried out using robotically assisted minimally invasive surgery include all of those listed above. Currently, robotic surgery still has certain disadvantages:

- increased cost;
- increased set-up of the system and operating time;
- socio-economic implications;
- significant risk of conversion to conventional techniques;
- prolonged learning curve;
- multiple repositioning of the arms can cause trauma;
- haemostasis;
- collision of the robotic arms in extreme positions.

Until these are overcome, by continued development of the technology and the drive of surgeons to progress in the field, robotically assisted surgery will not be commonplace. However, the potential for such systems is immense and continued research and clinical trials will pave the way for future generations of surgeons and patients alike.

THE FUTURE

Although there is no doubt that minimal access surgery has changed the practice of surgeons, it has not changed the nature of disease. The basic principles of good surgery still apply, including appropriate case selection, excellent exposure, adequate retraction and a high level of technical expertise. If a procedure makes no sense with conventional access, it will make no sense with a laparoscopic approach. Laparoscopic and robotic surgery training is key to allow the specialty to progress. The pioneers of yesterday have to teach the surgeons of tomorrow not only the technical and dextrous skills required but also the decision-making and innovative skills necessary for the field to continue to evolve. Training is often perceived as difficult as trainers have less control over the trainees at the time of surgery and caseloads may be smaller, especially in centres where laparoscopic and robotic procedures are not common. However, trainees now rightly expect exposure to these procedures and training systems should be adaptable for international exposure so that these techniques can be disseminated worldwide.

Improvements in instrumentation, the continued progress of robotic surgery and the development of structured training programmes are the key to the future of minimal access surgery. The use of robots in surgery has increased dramatically in the last decade. Indeed, robots are now available not only for assisting in surgery but also for aiding in the perioperative management of surgical patients. The remote presence systems (In Touch Health, Santa Barbara, California, USA; Figs 19.11 and 19.12) allow clinicians to assess patients in real time and interact with them while they are not on site or even if in a different continent. Continued advances in related technologies such as computer science will allow the incorporation of augmented reality systems alongside robotic systems to enhance surgical precision in image-guided surgery. Endoluminal robotic surgery is in its infancy but systems are being developed that will enable navigation within the colon to allow surgery on lesions in spaces that are accessible from the outside without an exterior incision being made. The advent of nanotechnology will also bring about much change in surgery. Miniaturisation will be possible, potentially allowing surgery at a cellular level to be carried out.

At present work has already started on single-port laparoscopy, in which a single port may act as a camera and have unfolding instruments open up once they are inside the peritoneum to perform the surgery, therefore reducing the number of port sites needed. Extensive research is also being carried out in the field of NOTES (natural orifice transluminal surgery). This is a technique whereby the peritoneal cavity is entered endoscopically, via a natural orifice (mouth, rectum, vagina) and the surgery is carried out using specialised endoscopic technology and techniques. Currently this has just started on a few human subjects, but most of the research is from animal models. NOTES cholecystectomy and appendectomy have been successfully

Figure 19.11 Remote presence robot (courtesy of the Department of Biosurgery and Surgical Technology, Imperial College, London).

Figure 19.12 Remote presence console (courtesy of the Department of Biosurgery and Surgical Technology, Imperial College, London).

carried out in humans. Minimising the potential contamination of the peritoneum and the ability to carry out a safe closure of the peritoneal entry site are the main technical challenges of this type of minimally invasive and essentially 'scarless' or 'incisionless' surgery.

It is certain that there is much that is new in minimal access surgery. Only time will tell how much of what is new is truly better.

The cleaner and gentler the act of operation, the less the patient suffers, the smoother and quicker his convalescence, the more exquisite his healed wound.

Berkeley George Andrew Moynihan (1920)

Postoperative care

CHAPTER

20

LEARNING OBJECTIVES

To understand:

- The system of postoperative care
- The common and serious postoperative complications, their recognition, avoidance and treatment
- The system of daily entries in patients' records
- The system for discharging patients

INTRODUCTION

The aim of postoperative care is to provide the patient with as quick, painless and safe a recovery from surgery as possible.

GENERAL MANAGEMENT

The immediate postoperative period

In the immediate postoperative period the patient is nursed in a recovery area using one-to-one nursing and continuous monitoring. The role of the recovery nurse is to ensure that the patient is protecting their airway, breathing freely and perfusing adequately (airway, breathing and circulation). The recovery nurse should also monitor the patient's pain as the anaesthetic wears off and ensure that there are no early complications developing, such as bleeding from the wound or loss of distal circulation and/or sensation. Blood pressure, pulse and oxygen saturation are therefore monitored regularly and the results charted. Trends seen on these charts reassure the recovery nurse that the patient is recovering well or warn that a complication is developing (Summary box 20.1).

Summary box 20.1

Postoperative period

- Ensure airway, breathing and circulation are satisfactory
- Monitor pain
- Watch for complications
- Monitor blood pressure, pulse and oxygen saturation

If there are any special aspects that need monitoring (e.g. return of sensation) then instructions on how they are to be monitored should be written clearly in the postoperative care section of the operative notes as well as given verbally to the recovery nursing staff at handover of the patient.

Patient recovery

Once patients are fully conscious and comfortable and their vital functions are stable they are transferred to the general ward; however, patients who are at high risk may be transferred to a high-dependency or intensive care unit.

While on the ward patients should be visited at least morning and evening by medical staff to ensure that there is steady progress. All staff on these rounds must wash their hands between every patient.

A simple system for ensuring that everything is checked and recorded is represented by the acronym SOAP (subjective, objective, assessment, plan).

Subjective

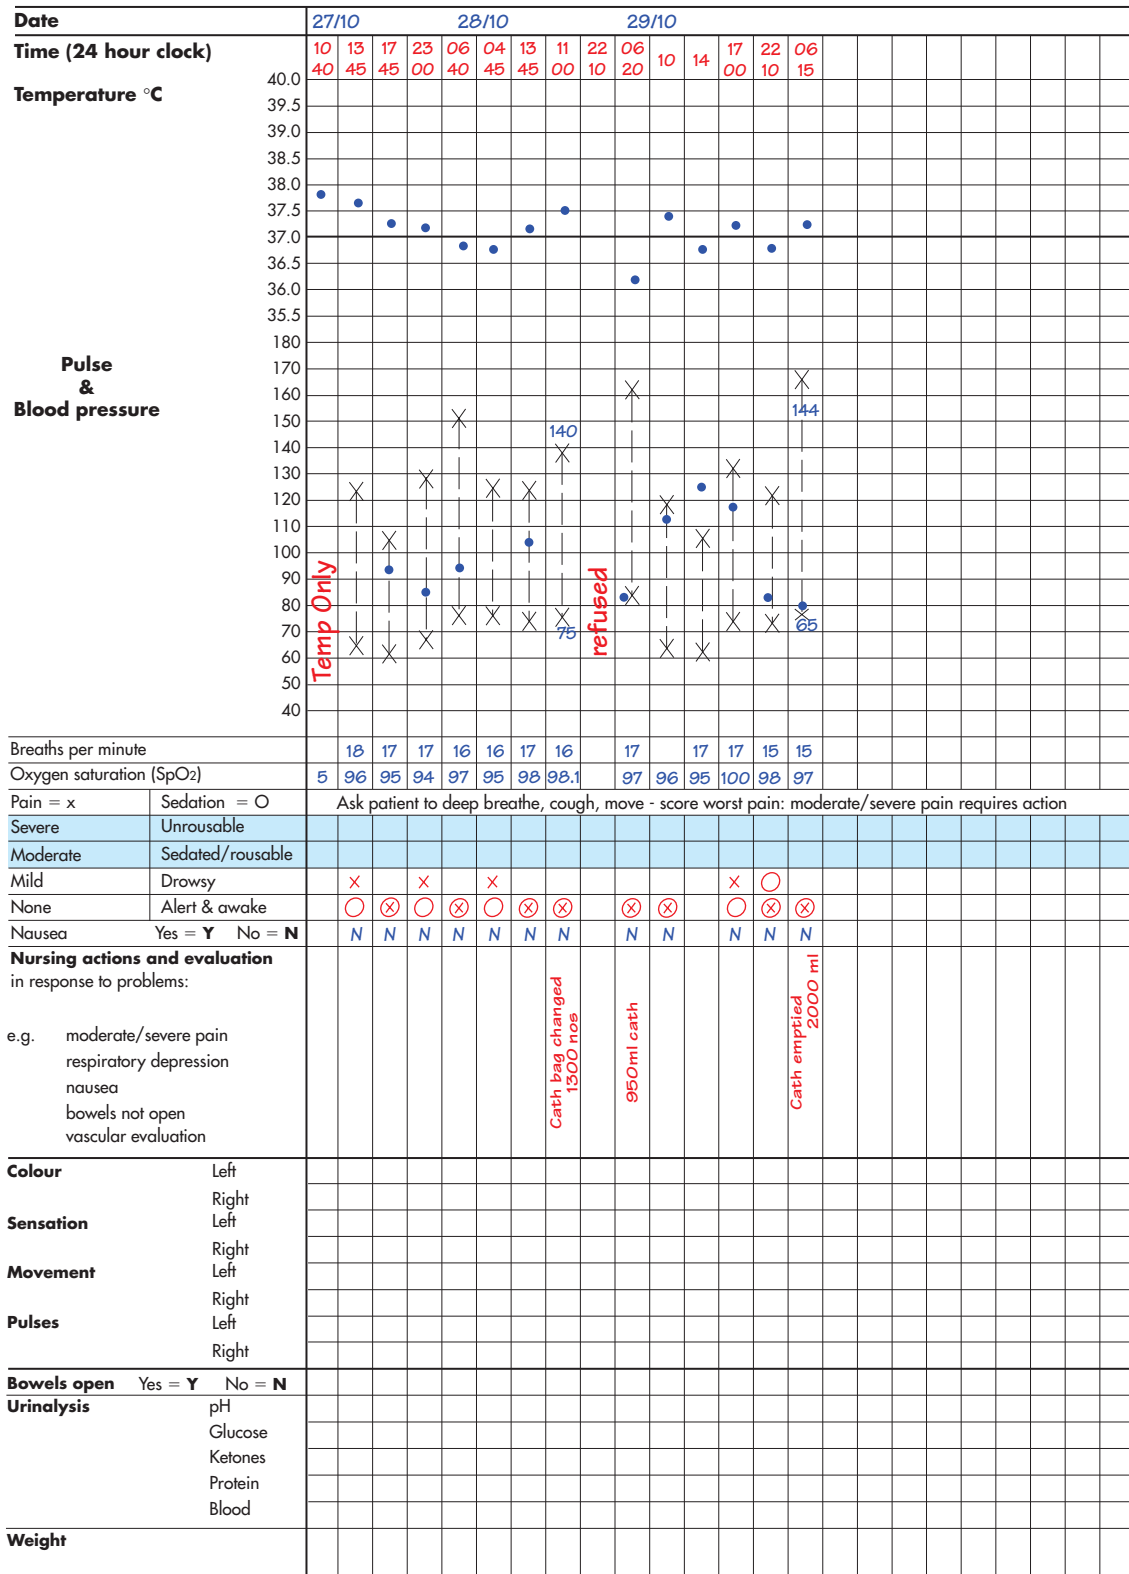

Ask the patient how they are. Specifically, ask about pain, nausea and mobility. Anxiety, disorientation or a change in behaviour are often the first signs that complications are setting in.

Objective

Check the patient's charts for temperature, pulse and respiration (TPR), fluid balance and any special observations recorded by the nurses (such as colour of graft) (Fig. 20.1). The patient's pressure areas should be checked but, if the wound is to be inspected, proper sterile precautions must be observed. If possible, wounds should be left undisturbed for 48 hours after surgery to prevent contamination but the skin around the edge of the dressing should be checked for redness or blistering. The nursing staff therefore need to be warned so that the appropriate trolley is ready. Specific examinations also need to be recorded, such as bowel sounds after abdominal surgery or distal neurovascular status after orthopaedic procedures.

Regularly review nutritional status in those patients who may be in negative nitrogen balance. Deterioration can be gradual but nevertheless serious. Review all laboratory results and investigations. Review the drug chart to ensure that drugs are not being continued unnecessarily. Record all relevant findings (both negative and positive) clearly in the notes.

OBSERVATION AND PAIN ASSESSMENT

1996/Queen's Medical Centre/Acute Pain Service

Figure 20.1 Postoperative nursing chart showing various monitoring parameters.

Assessment

Review all of the information obtained under S and O and list the problems that the patient is now facing which need addressing.

Plan

Formulate and agree a plan with the patient and the staff and record that plan in the notes. This includes anticipating when discharge from hospital might occur and ensuring that everything is in place (e.g. social services) to prevent any unnecessary delay.

This is the minimum set of notes required on each patient every day. These notes should be dated, signed and legible.

Pain management

This is discussed in Chapter 14.

Fluid management

This is covered in Chapter 16.

COMPLICATIONS ASSOCIATED WITH THE INTRODUCTION OF INFUSION/MONITORING SYSTEMS

Air embolism

This may occur when more than 15 ml of air is accidentally introduced during or after insertion of a venous catheter. The air enters the right atrium preventing adequate right heart filling and causing a drop in the blood pressure, a rise in the pulse rate and distension of the jugular venous pressure (JVP). It can be avoided by running fluids through the giving sets before connecting them to the patient. Patients should also be head-down when catheters are inserted into veins likely to be at a negative pressure (e.g. the jugular).

Phlebitis

A needle or catheter inserted into a vein will eventually result in inflammation around the area (phlebitis). The degree of phlebitis is related to not only the time of application but also the nature of the fluid being infused and the amount of bacterial contamination. Phlebitis may cause postoperative pyrexia and it is important that intravenous cannulae are regularly inspected for evidence of induration, oedema and tenderness and immediately removed if any of these signs are present. It is recommended that cannulae are marked with the date of insertion and changed at 72 hours. Cannulae that are carefully placed using full sterile precautions last longer than those which are not.

Finger necrosis

Arterial lines are usually inserted in patients who require continuous monitoring of pulse, blood pressure and arterial blood gases. They are usually inserted into the radial or femoral arteries. In some patients the blood supply to the hand arises predominantly from the radial artery, with little contribution from the ulnar artery. In these cases cannulation of the radial artery may disrupt the blood supply to the hand causing ischaemic necrosis of the fingers. In view of this it is important to check the patency of both arteries (using Allen's test) before inserting an arterial line (Summary box 20.2).

Edgar Van Nuys Allen, 1900–1961, Professor of Medicine, The Mayo Clinic, Rochester, MN, USA.

Summary box 20.2

Complications associated with monitoring systems

- Air embolism
- Phlebitis
- Finger necrosis

SPECIFIC POSTOPERATIVE COMPLICATIONS

Respiratory complications

Respiratory complications may be reduced by:

- using adequate analgesia, including epidurals, and using analgesia that depresses respiration carefully (e.g. opioids);
- administering oxygen using face masks or nasal prongs;
- arranging regular physiotherapy in patients with asthma and chronic obstructive airway disease;
- postponing surgery in patients with upper respiratory tract infections.

Shortness of breath

The commonest cause of postoperative dyspnoea (shortness of breath) and rapid shallow breathing is alveolar collapse or atelectasis. The diagnosis is confirmed by clinical examination and radiography (Fig. 20.2). Atelectasis usually responds to chest physiotherapy.

Abdominal surgical wounds may compromise respiratory function by splinting the diaphragm. Sudden onset of shortness of breath and tachypnoea (increased respiratory rate) may be caused by pulmonary embolism (Fig. 20.3), myocardial infarction/cardiac failure (Fig. 20.4), chest infection (Figs 20.5 and 20.6), pneumothorax (Fig. 20.7), acute bronchospasm or bronchopneumonia. These require immediate diagnosis and aggressive treatment.

A further cause of more gradual-onset postoperative shortness of breath is acute respiratory distress syndrome (ARDS). This may follow chest trauma, acute pancreatitis or sepsis, and results in poor oxygen transfer in the lungs even when the patient is given supplementary oxygen and is well perfused (Summary box 20.3).

Figure 20.2 Radiograph showing right upper lobe atelectasis (courtesy of Prof. Stephen Eustace, Dublin).

Figure 20.4 Radiograph showing a bilateral pleural effusion (courtesy of Prof. Stephen Eustace, Dublin).

Figure 20.6 Radiograph showing classical *Staphylococcus aureus* pneumonia (courtesy of Prof. Stephen Eustace, Dublin).

Summary box 20.3

Causes of acute postoperative shortness of breath

- Myocardial infarction and heart failure
- Pulmonary embolism
- Chest infection
- Exacerbation of asthma or chronic obstructive airway disease

When the doctor is called to see a patient who has become short of breath, oxygen should be started immediately while taking a history and performing an examination. Intravenous access is needed and bloods should be taken for a full blood count and determination of electrolytes and cardiac enzymes, if appropriate. Arterial blood gases (ABGs) may also be needed. If chest infection is suspected the sputum should be sent for microbiology and

Figure 20.7 Radiograph showing a right tension pneumothorax with tracheal deviation to the left (courtesy of Prof. Stephen Eustace, Dublin).

Gram staining; blood culture and a chest radiograph may also be required and antibiotics should be given. Physiotherapy and appropriate drugs will be required if there is chronic obstructive airway disease (COAD) or asthma. An electrocardiogram will also be needed to exclude cardiac causes.

Any foreign bodies in the mouth, including dentures and vomitus, should be removed. The neck should be extended and the jaw pulled forward to allow the tongue to come forward, freeing the airway. The oral airway should be maintained and protected by an airway, e.g. Geudel's airway. In patients who have had mouth, throat or neck surgery, a cricothyroidotomy may be required or the neck wound may need to be opened up to release the haematoma causing pressure on the airway.

Cyanosis

In patients whose airway is clear but who develop cyanosis the problem may be in the lungs or in the circulation.

Common problems in the lung may be acute bronchospasm as a result of an asthmatic attack or there may be a pneumothorax detected by loss of air entry into the upper chest. Circulatory problems include sudden blood loss causing a decreased venous return, myocardial infarction or a massive pulmonary embolism.

Cardiovascular complications

Hypotension

The commonest cause of low blood pressure postoperatively is hypovolaemia, as a result of either bleeding or insufficient fluid replacement; however, a myocardial infarction may also present with hypotension, as can an overdose of analgesics, especially opioids. Specifically, epidural anaesthesia may be complicated by hypotension because of the vasodilatation of veins. Septic shock may also present in this way.

Whatever the cause of hypotension, the emergency treatment requires an increase in the fluid input with administration of high-flow oxygen. The patient should also be tilted head-down to maintain cerebral perfusion. A thorough examination should then be performed to determine the cause of the collapse (Summary box 20.4).

Summary box 20.4

Low blood pressure postoperatively

- Is the patient dehydrated?
- Has the patient had an epidural anaesthetic?
- Is the patient losing blood?
- Is the patient on too much morphine?
- Has the patient had a myocardial infarct?

Hypertension

High blood pressure may be dangerous in patients with ischaemic heart disease or cerebrovascular disease as it may precipitate infarction or stroke. Most causes of hypertension relate to inadequate pain relief or anxiety and usually settle with appropriate analgesia.

Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology, (1891–1900), and of Medicine, (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.

Arthur Ernest Guedel, 1883–1956, Clinical Professor of Anesthesiology, The University of Southern California, Pasadena, CA, USA.

Deep vein thrombosis

There are several risk factors for deep vein thrombosis (DVT). Most patients with postoperative DVT show no physical signs; however, they may present with calf pain, swelling, warmth, redness and engorged veins. On palpation the muscle may be tender and there is a positive Homans' sign (calf pain on dorsiflexion of the foot); however, it must be emphasised that this sign is neither specific nor sensitive (Summary box 20.5).

Summary box 20.5

Risk factors for DVT

- Age > 60 years
- Recent surgery, particularly pelvic and lower limb surgery
- Immobilisation
- Trauma
- Oral contraceptive pill
- Obesity
- Heart failure
- Cancer
- Arteriopathy

Venography has been the standard diagnostic technique when DVT is suspected. It involves cannulation of a small vein in the foot and injection of contrast material to obtain a venogram. However, the deep veins of the lower limb may be scanned using duplex Doppler ultrasound to assess flow and thromboses. If a significant DVT is found (one that extends above the knee), treatment with intravenous heparin initially, followed by longer-term warfarin, should be started immediately. If untreated, DVT may result in chronic venous insufficiency, as a result of venous valvular damage, or pulmonary embolism, which may be fatal. In some patients with DVT, a caval filter may be required to decrease the possibility of pulmonary embolism.

Most hospitals have a DVT prophylaxis protocol. This may include the use of stockings, calf pumps and pharmacological agents such as low molecular weight heparin. No method of prophylaxis is foolproof and they all have their own complications, and so an optimal strategy needs to be developed, individualised to the patient and the operation that they are receiving (Summary boxes 6 and 7).

Summary box 20.6

Stratification of risk of DVT

Low

- Maxillofacial surgery
- Neurosurgery
- Cardiothoracic surgery

Medium

- Inguinal hernia repair
- Abdominal surgery
- Gynaecological surgery
- Urological surgery

High

- Pelvic elective and trauma surgery
- Total knee and hip replacement

John Homans, 1877–1954, Professor of Clinical Surgery, Harvard Medical School, Boston, MA, USA.

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler Principle' in 1842.

Summary box 20.7

Prevention of DVT

- Early mobilisation
- Hydration
- Compression stockings
- Low molecular weight heparin as prophylaxis
- Calf pumps
- Minimise use of tourniquets

Gastrointestinal complications

Postoperative nausea and vomiting

This is a common problem and results in patient weakness and demoralisation. It may have an adverse effect on the outcome of surgery including wound dehiscence and pulmonary aspiration if the patient's airway is unprotected. Prolonged nausea and vomiting results in increased pain levels and a prolonged hospital stay. The following are predisposing factors for nausea and vomiting in postoperative patients:

- poorly controlled pain;
- use of opioids;
- surgery on the gastrointestinal tract, orthopaedic surgery or ear, nose and throat (ENT) surgery;
- female sex;
- young adult;
- history of preoperative vomiting;
- history of motion sickness or migraine;
- acute gastric dilatation.

In those patients who do not respond to antiemetics, nasogastric tubes should be inserted and the stomach should be adequately decompressed to prevent aspiration (Table 20.1).

Urinary complications

Urine output (oliguria/anuria)

Oliguria may be defined as urine output less than the minimum obligatory volume ($0.5 \text{ ml kg}^{-1} \text{ h}^{-1}$).

The commonest cause of oliguria postoperatively is reduced renal perfusion resulting from perioperative hypotension or inadequate fluid replacement. If untreated, acute renal failure may develop. To ensure that fluid management is adequate, daily input/output charting should be maintained. The urine output should be measured on an hourly basis after major surgery to detect

Table 20.1 Treatment of postoperative nausea and vomiting

General measures	Adequate pain control Avoid opiates Keep stomach empty by aspirating (consider nasogastric tubes) Start oral feeding slowly Maintain hydration and blood pressure Epidural analgesia
Drugs	Dopamine receptor antagonists, e.g. prochlorperazine Metoclopramide H1 receptor antagonists, e.g. cyclizine 5HT receptor antagonists, e.g. ondansetron

early changes in renal function. The serum levels of urea and creatinine should be measured daily until the patient is fully recovered (see Chapter 17). The fluid chart must be checked daily by the medical staff and the fluid balance calculations checked, otherwise this important form of monitoring will be neglected and become unreliable. Patients who are left hypovolaemic or, hence, oliguric for any length of time will go into acute renal failure (Table 20.2).

If a postoperative patient develops a drop in the urine output it is sensible to first check whether the catheter is blocked. If hypovolaemia is suspected, a fluid challenge of 250 ml of intravenous fluid should be given over 1 hour. The urine output and JVP are then measured. If these parameters improve transiently then the patient is probably still underfilled and requires further fluid treatment. A central venous catheter may be considered to monitor intravascular volume. Once the patient has sufficient intravascular volume the urine output must be reassessed. If the urine output is still low then other causes must be sought. Sepsis needs to be aggressively treated and the opinion of critical care specialists may be sought. An abdominal ultrasound may be considered to exclude hydronephrosis resulting from blocked ureters. Nephrotoxic drugs should be stopped. If acute renal failure occurs or is imminent than the expertise of a nephrologist should be sought (Table 20.3).

Table 20.2 Common causes of acute renal failure

Prerenal	Hypotension Hypovolaemia
Renal	Nephrotoxic drugs Gentamicin Steroids Myoglobinuria Sepsis
Postrenal	Ureteric injury Blocked urethral catheter

Table 20.3 Prevention of postoperative renal failure

Monitor renal function	Serum urea, creatinine and electrolytes Urine output monitoring
Assess volume status	Pulse and blood pressure Serial body weight Central venous pressure Pulmonary capillary wedge pressure
Optimise cardiac function	Monitor cardiac output Consider inotropic support
Relieve urinary obstruction	Prompt diagnosis Catheter drainage Surgical correction
Avoid nephrotoxins	Limit toxins Avoid aminoglycosides Adjust drug doses
Prevent sepsis	Catheter care Drain abscesses Give antibiotics
Consider diuretics	Mannitol and frusemide (furosemide)

Urinary retention

This is frequently seen in postoperative patients, particularly men who are bed-bound postoperatively. The inability to void after surgery is particularly common with pelvic and perineal operations or after procedures performed under spinal anaesthesia.

The causes of retention are related to the interference of neural mechanisms that are usually responsible for normal bladder emptying and over-distension of the bladder. Pain, fluid deficiency and accessibility of urinals and bed pans, as well as noisy overcrowded wards, may contribute to the problem. Retention may be confirmed by ultrasound and may require catheterisation.

Catheterisation should be performed prophylactically when an operation is expected to last 3 hours or longer or when large volumes of fluid are administered.

Urinary infection

This is the one of the most commonly acquired infections in the postoperative period. Patients who are immunocompromised or diabetic, or who have pre-existing urinary tract contamination, urinary retention or a history or presence of catheterisation, are known to be at higher risk. In those patients who are catheterised for less than 48 hours, the risk of bacteriuria is about 5%. Symptoms of urinary tract infection and cystitis include dysuria and mild pyrexia; however, pyelonephritis may cause severe flank tenderness in addition to high temperatures. Urinary tract infections should always be considered in the differential diagnosis of a patient with a temperature postoperatively. The diagnosis is confirmed by dipsticking the urine and sending samples for culture and sensitivity. Treatment involves adequate hydration and proper bladder drainage together with the use of relevant antibiotics in the light of laboratory sensitivities.

COMPLICATIONS RELATED TO SPECIFIC SURGICAL SPECIALTIES

Abdominal surgery

The abdomen should be examined daily for evidence of excessive distension, tenderness or drainage from wounds or drain sites. Patients undergoing abdominal surgery should be warned that they will have some discomfort on movement and coughing despite analgesia. Oral fluids may be reintroduced in most patients early on and there is a trend towards earlier feeding.

In certain operations, such as those for intestinal obstruction, a nasogastric tube may be used. It is useful after oesophageal and gastric procedures but of less use in lower colonic operations. It is of particular use in those patients suffering from ileus or a marked level of altered consciousness who are therefore liable to aspirate. The nasogastric tube should be allowed to drain into a small plastic bag. Free drainage may be supplemented by continuous suction.

The main complications to look out for in a postoperative abdominal surgical patient are:

- anastomotic leakage;
- bleeding or abscess;
- slow recovery of intestinal motor function (ileus).

Localised infection

An abscess may present with persistent abdominal pain, focal tenderness and a spiking fever. The patient may have prolonged ileus. If the abscess is deep-seated these symptoms may be absent. The patient will have a neutrophilic leucocytosis and may have positive blood cultures. An ultrasound or computerised tomography (CT) scan of the abdomen should identify any suspicious collection.

Paralytic ileus

Paralytic ileus may present with nausea, vomiting, refusal to eat, bowel distension and absence of flatus or bowel movements. Abdominal radiography reveals a dilated bowel.

Following laparotomy, gastrointestinal motility temporarily decreases. Treatment is usually supportive with maintenance of adequate hydration and electrolyte levels. However, intestinal complications may prolong ileus and so should be actively sought and treated whenever ileus persists. The return of function of the intestine occurs in the following order: small bowel, large bowel, stomach. This pattern allows the passage of faeces despite continuing lack of stomach emptying and, therefore, vomiting may continue even when the lower bowel has already started functioning normally.

Orthopaedic surgery

In patients having any limb surgery, including hip or knee arthroplasty, the distal neurovascular status of the limb needs to be reviewed regularly. In postoperative trauma cases, evidence of compartment syndrome should be actively sought for and treated by fasciotomy if suspected, especially if there has been significant soft-tissue injury or prolonged use of the tourniquet.

Patients with compartment syndrome complain of unremitting pain out of proportion to that expected. The pain is unrelieved by simple analgesia and requires increasing amounts of pain relief. Clinical examination reveals excessive pain on passively stretching the muscles in the affected compartment. The compartment is usually swollen and tense. In later stages there may be altered sensation. Pallor, pulselessness and paralysis are late signs. Plasters should always be split for the first 24 hours and the nurses given instructions to watch and record distal circulation every 4 hours. Check radiographs are only taken if there is a suggestion that the fracture has moved and/or when there is still time to remanipulate if necessary. If the patient has an external fixator, the pin sites should be regularly inspected for signs of infection. In patients who have undergone open reduction and internal fixation of fractures, the neurovascular status of the limb must be checked every half an hour initially by the nurses in recovery and then on the ward as dictated by the postoperative instructions. Radiographs of the limb concerned are required on a regular basis postoperatively to ensure that the fracture is healing.

Most orthopaedic procedures are carried out under tourniquet control. These are associated with ischaemia of limbs if applied for an excessive period of time. In view of this, patients who have had tourniquets applied in theatre should have the vascular supply to the limb carefully monitored in the immediate postoperative period (Summary box 20.8).

Summary box 20.8**Compartment syndrome**

- Symptoms are pain, pain, pain
- Pain is greater than expected and unresponsive to analgesia
- The earliest sign is pain on passive stretching of muscles in the affected compartment
- Paralysis, paraesthesia and pulselessness are very late signs

Neck surgery

Patients having neck surgery, e.g. thyroid surgery, must be observed for accumulation of blood in the wound, which may cause rapid asphyxia. A check also needs to be made pre- and postoperatively for damage to the recurrent laryngeal nerve. The findings must be recorded in the medical notes.

Thoracic surgery

Patients who have undergone a lobectomy or pneumonectomy are susceptible to fluid overload in the first 24–48 hours postoperatively. Hence, fluid intake should be restricted in such patients during this time period. Moreover, chest drains require regular review, noting whether they continue to swing, bubble or produce excess fluid. If the fluid in a chest drain swings then the drain has been inserted correctly in the pleural cavity; changes in pressure during inspiration and expiration cause the fluid to swing. If the chest drain continues to bubble then a bronchopleural fistula probably exists. A haemothorax or pleural effusion will reveal itself as a prolonged loss of blood or fluid, respectively, into the drain. Cardiac patients require continuous electrocardiography monitoring.

Neurosurgery

The intracranial pressure should be monitored closely postoperatively. A rise may be signalled by a deterioration in the state of consciousness as well as by neurological signs including pupil reflexes. Some patients may have an intracranial monitoring device to allow for more sensitive monitoring.

Vascular surgery

The patency of grafts and anastomoses in patients with femoropopliteal bypasses and abdominal aneurysmal repairs needs to be checked by regular clinical assessment of the limbs and by Doppler ultrasound.

Plastic surgery

The viability of flaps is crucial and the perfusion needs to be monitored regularly. The blood supply may be compromised by position, dressings or collection of fluids or blood beneath the flap.

Urology

Catheter patency must be ensured following urological surgery. In patients who have undergone transurethral resection of the prostate (TURP), continuous bladder irrigation may be used, and pulmonary oedema may develop if excess glycine from the irrigation fluid is absorbed into the circulation.

Diabetic patients

Whenever possible, diabetic patients should be put first on the operating list to avoid keeping them starved for longer than

necessary as well as to provide adequate time for diabetic control to be stabilised during daylight hours. Diabetic patients undergoing surgery are usually commenced on a glucose–insulin infusion, and this should be continued until the patient is eating. If the patient is administered a long-acting insulin dose just before surgery or if too much insulin is given then there is the risk of hypoglycaemia. The maximum rate of infusion of insulin should rarely exceed 1.5 U h^{-1} when using 5% dextrose. The patient should be started on an insulin sliding scale and the blood glucose level should be measured regularly. If the patient develops symptoms and signs of hypoglycaemia, the insulin infusion should be decreased and the rate of glucose infusion increased. Erratic and high glucose levels postoperatively may be caused by occult infection. Measures taken to check for, assess and treat known complications of surgery must be recorded in the medical notes. If a patient comes to harm as a result of developing a postoperative complication, the monitoring will only be assumed to be as good as what has been recorded in the notes.

GENERAL COMPLICATIONS**Fever**

In total, 40% of patients develop pyrexia after major surgery; however, in 80% of cases no particular cause is found. Pyrexia does not necessarily imply sepsis. The inflammatory response to surgical trauma may manifest as temperature. In spite of this, a focus of infection must always be sought if a patient develops anything more than a slight pyrexia.

The causes of raised temperature postoperatively include:

- days 2–5: atelectasis of the lung;
- days 3–5: superficial and deep wound infection;
- day 5: chest infection including viral respiratory tract infection, urinary tract infection and thrombophlebitis;
- > 5 days: wound infection, anastomotic leakage, intracavitary collections and abscesses;
- infected intravenous cannula sites, DVTs, transfusion reactions, wound haematomas, atelectasis and drug reactions, which may also cause pyrexia of non-infective origin.

Patients with persistent pyrexia need a thorough review. Relevant investigations include full blood count, urine culture if urinary tract infection is suspected, sputum microscopy, chest radiography if indicated and blood cultures (Summary box 20.9).

Summary box 20.9**Fever**

- A very common problem postoperatively
- Consider problems in the lung, urine and wound

Prophylaxis against infection

In patients who have had foreign material inserted operatively, including a hip or knee prosthesis in orthopaedic surgery or aortic valves in cardiovascular surgery, up to three doses of a prophylactic antibiotic should be administered, usually one dose preoperatively and two postoperatively. Bacteria can be incorporated into the biofilm that forms on the surface of the implant, where they are protected from antibiotics and from the natural defences of the body; prophylactic antibiotics appear to

reduce the risk of any contamination developing into infection by destroying bacteria before they are incorporated into the biofilm.

Pressure sores

These occur as a result of friction or persisting pressure on soft tissues. They particularly affect the pressure points of a recumbent patient, including the sacrum, greater trochanter and heels. Risk factors are poor nutritional status, dehydration and lack of mobility. Those who are unconscious or who are unable to turn in bed should have their position in bed changed every 30 min to prevent pressure sores. High-risk patients may be nursed on an air filter mattress, which automatically alters the pressure areas. Early mobilisation prevents pressure sores and reduces respiratory complications (Summary box 20.10).

Summary box 20.10

Preventing pressure sores

- Address nutritional status
- Keep patients mobile or regularly turned if bed-bound

Confusional state

This develops in 10% of postoperative patients, especially elderly patients (Table 20.4). It is associated with increased morbidity and mortality as well as prolonged length of hospital stay.

Confusion may present with anxiety, incoherent speech,

Table 20.4 Causes of confusion

Renal	Renal failure/uraemia Hyponatraemia and electrolyte disorders Urinary tract infection Urinary retention
Respiratory	Hypoxia, e.g. chest infection Atelectasis
Cardiovascular	Pulmonary embolism Dehydration Septic shock Myocardial infarction Chronic heart failure Arrhythmia
Drugs	Opiates including heroin Hypnotics Cocaine Alcohol withdrawal Hypoglycaemia
Neurological	Epilepsy Encephalopathy Head injury Cerebrovascular accident
Idiopathic (rare)	Hypothyroid Hyperthyroidism Addison's disease

Thomas Addison, 1795–1860, Physician, Guy's Hospital, London, England, described the effects of disease of the suprarenal capsules in 1849.

clouding of consciousness and destructive behaviour, e.g. pulling out of cannulae. Disorientation and change of environment, particularly in patients with a history of dementia, may precipitate confusion. These patients may present with sleep deprivation, anxiety, impaired thinking and memory, and disturbed emotions.

Drains

Drains are used to drain purulent collections, to prevent accumulation of blood or to indicate the possibility of leaking surgical anastomoses. In clean surgery, such as joint replacement, blood collected in drains can be transfused back into the patient provided that an adequate volume (> 150 ml) is collected rapidly (< 12 hours) and that a specifically designed drain and filter system is used.

The use of surgical drains has decreased in recent years as the evidence for their benefits has been questioned. They can result in complications and so should be used carefully. The complications associated with abdominal drains include:

- trauma during insertion;
- failure to drain because of incorrect placement or blockage;
- complications caused by disconnection;
- sepsis at drain sites;
- drain site metastases;
- erosion by the drain of adjacent tissue and perforation of abdominal viscera.

The quantity and character of drain fluid can be used to identify any abdominal complication resulting in fluid leakage (e.g. bile or pancreatic fluid) or bleeding. The excess loss of body fluids through the drain should be replaced by additional intravenous fluids. Blood loss through the drain should be investigated for the source. Any underlying coagulopathy should be excluded by checking the coagulation profile and platelet count. Angiography may be useful to identify the source of blood loss.

The absence of blood in the drain does not exclude heavy postoperative bleeding. If the patient's blood pressure and urine output are lower than expected the wound needs checking for a collection. Inspection, palpation and ultrasound can all help identify a developing haematoma.

Drains should be removed once the drainage has stopped or become less than 25 ml day⁻¹, as they are a potential track for contamination and infection into a wound. Drainage of bile or faecal matter indicates disruption of a biliary or intestinal anastomosis.

Nutrition

This is discussed in Chapter 17.

Blood transfusion

Most hospitals have a protocol for determining the number of units of blood that should be cross-matched before any given operation. Patients who are anaemic should have elective surgery postponed while the anaemia is investigated and, if possible, treated. During the first 24 hours after surgery, plasma or extracellular fluid loss may result in an artificially high measurement of haemoglobin. In a stable patient a top-up transfusion is indicated if the haemoglobin level falls below 8 g dl⁻¹ or if the patient becomes short of breath. An unstable patient or one who may rebleed requires a higher threshold for transfusion. It is important that regular monitoring of pulse, blood pressure and temperature

is carried out during transfusion to enable any transfusion reaction to be detected.

Complications of blood transfusion

Major/minor ABO incompatibility causes tachycardia, pyrexia, rash and pruritus in minor cases, and flushing, urticaria, bronchospasm and hypotension in severe reactions. The transfusion should be stopped at once if the patient develops these symptoms. A sample of the blood from the donor and recipient should be sent for culture and the remainder of the blood in the bag sent back to the transfusion department for recross-matching. In severe reactions, steroids and anti-histamines may be required.

Transmission of infection, including hepatitis, human immunodeficiency virus and Creutzfeldt–Jakob disease (CJD), and immunodeficiency in the recipient are all risks of transfusion and are increasingly becoming issues that cause a patient great anxiety (Summary box 20.11).

Summary box 20.11

Complications of blood transfusion

- Allergy
- Transmission of infection

Mobilisation

Immobilisation increases the risk of DVT, urinary retention, atelectasis, pressure sores and faecal impaction, so patients are now mobilised as soon as possible after surgery.

After a laparotomy patients are encouraged to sit out in a chair, even on the first postoperative day. This helps improve ventilation and reduces subsequent pulmonary complications by reducing the pressure on the diaphragm.

Wound care

Within hours of the wound being closed the dead space fills up with an inflammatory exudate. Within 48 hours of closure a layer of epidermal cells from the wound edge covers the bridge and hence sterile dressings applied in theatre should not be removed before this time. Wounds should be inspected only if there is any concern about their condition or the dressing needs changing. Inspection of the wound should be performed under sterile conditions. The wound may be red or discoloured with evidence of discharge, which may be serosanguinous or purulent in nature. If the wound looks inflamed, a wound swab may need to be taken and sent for Gram staining and culture. Infected wounds may need treatment with antibiotics or wound washout. This is especially important if a large haematoma is suspected that has started to drain. An infected haematoma can only be treated by returning the patient to theatre and washing out the infected material. Samples should be sent for bacteriology (before any antibiotics are given), any dead tissue excised and bleeding vessels identified and closed off. If there is any suspicion that contaminated or non-viable tissue remains then the wound should not be closed. It should be packed and then reviewed daily until it is clean, otherwise infection, especially synergistic gangrene, may develop.

Wound dressings should also be removed if they are wet as soaked dressings increase the bacterial contamination of the wound. Skin sutures or clips are usually removed between 6 and

10 days after surgery. They should remain for a shorter period when applied to the face or neck and should be left in longer where incisions go across creases, e.g. in the groin or in incisions closed under tension. If the wound is healing satisfactorily then the patient may be allowed to shower 1 week after surgery.

Wound healing is delayed in patients who are malnourished. Vitamin C deficiency interferes with collagen synthesis and vitamin A deficiency affects the rate of epithelisation. Deficiency of copper and other trace elements affects scar formation. In patients who lack these trace elements, supplements should be administered to aid healing. Steroids also inhibit the adequate healing of wounds as they inhibit the inflammatory response as well as protein synthesis and fibroblast proliferation. Diabetes, particularly if uncontrolled, also has a deleterious effect on wound healing.

Wound dehiscence

This is the partial or complete disruption of any or all of the layers in a wound. If it occurs in the abdomen it may be very distressing to the patient, causing extrusion of the bowel and other organs. Dehiscence may occur in up to 3% of abdominal wounds.

Wound dehiscence most commonly occurs from the fifth to the eight postoperative day when the strength of the wound is at its weakest. It most commonly occurs in abdominal wounds where it may herald an underlying intra-abdominal abscess. However, it may also occur in thoracotomy wounds, in particular sternal wounds.

Wound dehiscence usually presents with a serosanguinous discharge. The patient may have felt a popping sensation during straining or coughing. Most patients will need to return to the operating theatre for resuturing. In some patients it may be appropriate to leave the wound open and treat with dressings or vacuum-assisted closure (VAC) pumps (Summary box 20.12).

Summary box 20.12

Risk factors in wound dehiscence

General

- Malnourishment
- Diabetes
- Obesity
- Renal failure
- Jaundice
- Sepsis
- Cancer
- Patients on steroids

Local

- Inadequate or poor closure of wound
- Poor local wound healing, e.g. because of infection, haematoma or seroma
- Increased intra-abdominal pressure, e.g. in postoperative patients suffering from chronic obstructive airway disease, during excessive coughing

DISCHARGE OF PATIENTS

Following treatment in hospital patients are discharged home where they will continue to recover. Postoperative orthopaedic patients may be transferred to a rehabilitation centre where adequate supervision can be given and there is access to

physiotherapy. Patients discharged home need a discharge letter detailing the postoperative plan for the patient. The 'immediate' discharge letter should leave the hospital with the patient. This is usually completed by the house surgeon and details the final diagnosis, the treatment and any complications that may have occurred. There should be advice for referring the patient back to hospital and indications for readmission if specific problems do occur. The GP should be informed of the subsequent care plan including follow-up arrangements. The formal discharge letter should be dictated as soon as possible after the discharge of the patient. It should detail preoperative findings, their management (operative or non-operative) and subsequent complications. Pathology results should be included if available and the basis of these in the subsequent care plan should be described along with the prognosis if appropriate.

Follow-up in clinic

Patients should only be reviewed in clinic when a key decision on management needs to be made. The findings and the care plan agreed with the patient at the clinic appointment should be included in a letter to the patient's GP as well as in a clear handwritten entry in the notes. This should include advice on how to recognise the onset of complications and what to do if there is concern. Patients should be discharged from clinic as soon as their GPs or they themselves can manage their care.

Day-case and fast-track surgery

There is a strong drive to do more surgery on a day-surgery basis; however, before patients are discharged home a check must be made that they are safe and that the discharge is appropriate to their best interests. Appropriate pain relief must be given and the

patient must be able to call or return to a predetermined place if complications or problems occur.

Fast-track surgery or enhanced recovery after surgery (ERAS) is a multimodal comprehensive programme aimed at enhancing postoperative recovery and outcome. It has been pioneered in abdominal surgery but plans are being made to introduce the protocol into other specialties. The planned discharge after 48 hours in patients undertaking even major surgery has demonstrated a reduction in potential complications and enhanced recovery. The main thrust is to reduce the psychological and physiological stresses associated with operations, hence reducing tissue catabolism and organ dysfunction. Published evidence confirms the benefits of fast-track surgery including reduced hospitalisation, lower morbidity, cost-effectiveness, patient satisfaction and safety, and a low readmission rate. The concept encompasses the essence of optimum postoperative care including preoperative patient education, improved anaesthesia and use of epidural analgesia, adoption of modern surgical principles, optimised dynamic pain relief, early ambulation and early oral nutritional supplementation.

Introduction to trauma

LEARNING OBJECTIVES

To gain an understanding of:

- The importance of time in trauma management
- How to assess a trauma problem

- How to respond to a trauma problem
- The value of planning

WHAT IS TRAUMA?

Trauma is the study of medical problems associated with physical injury. The injury is the adverse effect of a physical force upon a person. There are a variety of forces that can lead to injury, including thermal, ionising radiation and chemical; these are discussed in Chapter 28. However, the force involved in most injuries is mechanical. The subject of trauma therefore centres upon the deleterious effects of kinetic energy on the human frame. In the next group of chapters we will explore trauma from a variety of perspectives related to different specialities. In this introduction we will look at the aspects that bind the whole topic together.

THE SCALE OF THE PROBLEM

Trauma is recognised as a serious public health problem. In fact, it is the leading cause of death and disability in the first four decades of life and is the third most common cause of death overall.

Millions of people are killed or disabled by injury each year. Of the 5 million people killed as a result of injuries in 2000, approximately 1.2 million people died of road traffic injuries, 815 000 from suicide and 520 000 from homicides. In the UK the accidental and deliberate injury standardised death rate (SDR) is 27.28 deaths of all ages per 100 000 inhabitants per year. Hundreds of thousands who survive their injuries experience long-term or permanent disabilities, time lost from work or family responsibilities, costly medical expenses, profound change in lifestyle, pain and suffering, regardless of gender, race or economic status. An injury affects more than just the injured person; it affects everyone who is involved in the injured person's life. The consequences of the modern chimera of the motor vehicle accident (MVA) added to the global epidemic of violence can not be overstated.

Trauma is not just related to high-energy transfer in road accidents or violence. The elderly fall victim makes up the most common group to be admitted to hospital following injury in the UK. Fragility fractures represent an increasing load on health services. About 50 000 patients suffer a proximal femoral fracture

each year in the UK, which is about 10 times the number of poly-trauma victims. About 30% of those over the age of 65 who suffer a proximal femoral fracture will die within a year of the incident, and most of the others will have diminished independence and mobility. It can be appreciated that this represents a huge burden on the health services and society in general.

The great majority of injuries are not life- or limb-threatening. Here the challenge is not only to treat the minor injuries but also to differentiate between those injuries that have some important aspects and those that are genuinely straightforward. For instance, in children, one must always be alert to the potential for non-accidental injury (NAI). There is a chilling statistic that in 66% of cases when children die as the result of abuse there has been some previous relevant contact with a health professional or social services. Again in children we also have to be alert to those injuries that represent a threat to future growth, thus having an effect disproportionate to their initial appearance. In all age groups we need to be wary of pathological fractures; here the more important problem may not be the injury itself but the underlying disease process (Summary box 21.1).

Summary box 21.1

Trauma: the scale of the problem

- Trauma is the major cause of death in the young
- Fragility fractures are an increasing burden
- Look beyond the obvious in trauma management

THE IMPORTANCE OF TIME

An identifying feature in the study of trauma is time. At time zero the person/patient is at their normal baseline. There is then some interaction with an external force leading to injury. The subsequent development of pathology, the response of the body by way of compensation and healing, and the external responses by health professionals all have a timeline; that timeline originates at time zero, the moment of injury. The timeline may be used to compare and consider the progress from time zero to other significant events or deadlines that follow.

Figure 21.1 depicts an estimate of the periods of time that may elapse from time zero to death or irretrievable damage for various injuries. It reflects the fact that some problems tend to lead to earlier death than others. An obstructed airway, a tension pneumothorax, an extradural haematoma or an ischaemic limb will all tend to progress along a characteristic time-line after the moment of initial injury. This creates an 'imperative of time' that shapes and provides a basis for the hierarchy of our initial medical response to the injured patient. Thus, an obstructed airway will need emergency initial management at the scene of the accident. An ischaemic limb may be dealt with urgently once the patient has reached a definitive treatment centre. The order ABCD, that is *airway, breathing, circulation and disability* (neurology), of the ATLS (Advanced Trauma Life Support) system is founded upon this time dependence.

To the raw diagram of the time from injury to death or irretrievable damage may be added other components. These are the time to understand or assess the nature of the problem and the time to respond effectively to that which has been discovered. Each of these will take a finite length of time and this is shown schematically for a generic condition in Fig. 21.2. It can be seen that in this example there is adequate time for an orderly process of all the stages of assessment followed by a response before irretrievable damage or death.

The block of time for assessment may be broken down further. Understanding and assessing the nature of the problem usually hinges on diagnosing the injury. An injury may be discoverable by special investigation or careful physical examination, or be very

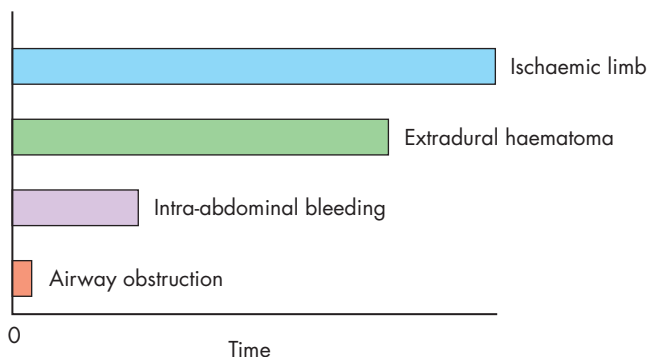

Figure 21.1 Estimated time from incident to death or irretrievable damage for various conditions.

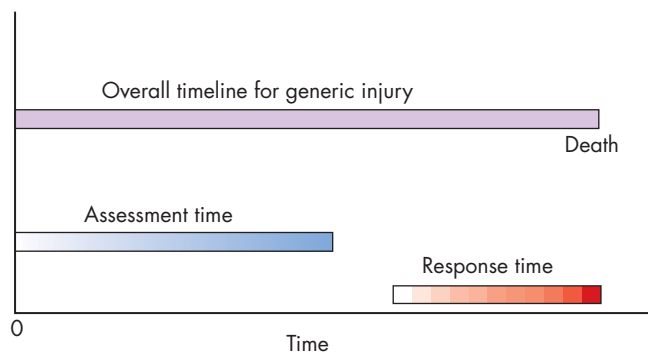

Figure 21.2 Diagrammatic representation of the relationship between assessment and response times. In this example there is time to assess and respond effectively before death.

obvious at different points on its timeline. An example is an evolving extradural haematoma: the initial skull fracture may be visible on radiography or computerised tomography (CT); as the haematoma develops it will first be visible on CT; later, it will be suspected on careful clinical examination; and, finally, it will become clinically very obvious. This is represented in Fig. 21.3a.

The next feature to add to the timeline is the response time. Once an obstructed airway is identified the response time to carry out a life-saving simple airway manoeuvre may be a matter of seconds. Thus, even at the stage when the diagnosis is clinically obvious there may still be time to resolve the problem before irretrievable damage occurs. However, when the diagnosis is an extradural haemorrhage, the average response time from identification of the problem to surgical resolution may be measured in hours. This may seem an unduly long time, but bringing the patient to an operating theatre with a neurosurgeon takes time to arrange as seen in Fig. 21.3b. If we now combine the various features of a timeline for the single condition of extradural haematoma, difficulties become apparent. In Fig. 21.3c it is seen that if the response is only initiated once the diagnosis is very obvious there may be insufficient time left to resolve the problem before death. This seems to suggest that we need to initiate a response to a problem before we are sure of its existence. This apparent paradox will be explored further. However, for the moment it can be likened to the need to identify a cancer at an early stage to give the best chance of successful treatment. A common approach to such a problem is to screen the at-risk population, and the same principle applies in trauma.

As we will see, much of the medical preparation and planning related to trauma is aimed at reducing the diagnosis time and the response time so that they will fit into the time available before death or irretrievable damage. To revise the meanings of these terms, the diagnosis time is the time between injury and recognition of the problem and the response time is the time that elapses between identifying the problem and the intervention required to deal with it being completed. We can reduce these times by using a practised approach to the initial stages of the

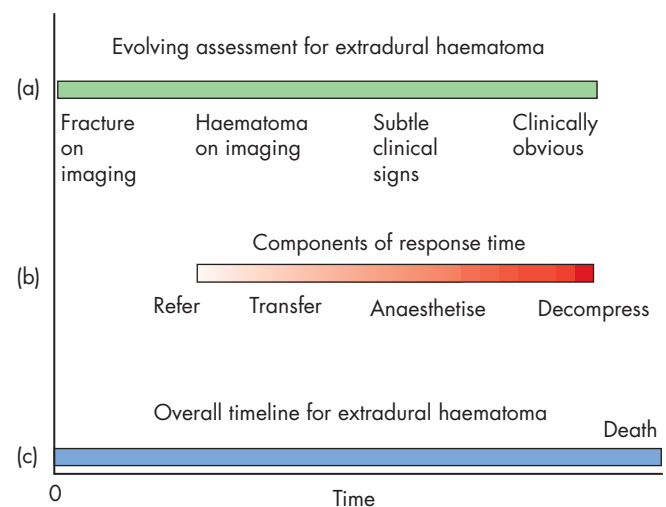

Figure 21.3 Diagrammatic representation of the relationship between assessment and response times for extradural haematoma. (a) The stages of assessment, (b) the components of the response, and (c) the overall time from incident to death. It can be seen that relying on obvious clinical signs gives insufficient time to respond effectively.

management of a polytrauma patient. This does not absolve us from thinking but it does mean that we can have a pre-existing structure upon which to build. This allows us to move forward more rapidly. This structured initial approach allows for more straightforward teamwork and standardisation of the equipment required. This practised familiarity brings confidence to a difficult situation.

The pressure of time determines the manner in which we deal with the multiply injured patient. The normal sequence of history, examination, provisional diagnosis, special investigations, diagnosis and management plan is not appropriate. When dealing with the multiply injured a quite different approach is needed. As will be seen, the primary survey used in ATLS combines the identification of life-threatening problems with their management. It has evolved to improve the chances of the necessary actions being taken within the available time to save life and limb. The system has to allow diagnosis and response within the timeline for the injuries sustained.

The model of a timeline need not be restricted to the multiply injured. The role of time when dealing with an elderly person who has been injured is still present but is frequently ignored. There may be hidden urgent issues. Thus, when dealing with the elderly we too readily label a patient with the most obvious problem (such as a hip fracture) without performing the vital initial physiological triage. They may have a primary cardiac, respiratory or neurological problem that has resulted in a fall and the response to this may be the most urgent issue. Therefore, the timeline is not only relevant to the acute and obviously urgent clinical issues. As noted at the beginning of this chapter a timeline may be used to compare and consider the progress from time zero to other significant events or deadlines that follow. The response time to arrange a discharge from hospital for the elderly patient may be protracted. Figure 21.4 demonstrates that, with such a long response time, to allow for discharge at the appropriate clinical time the social planning needs to commence almost at the time of admission. This is well before it would seem clinically reasonable but to achieve an efficient system it is quite necessary. This approach allows an emergency unit to get as close as is possible to the practice of effective elective units where discharge plans are made before the patient is admitted.

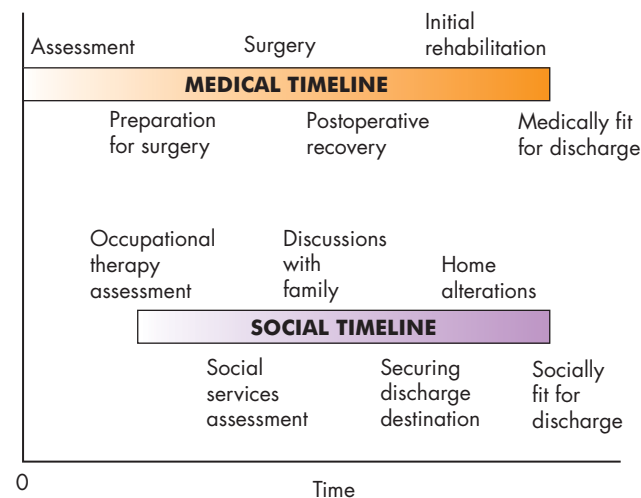

Figure 21.4 Social and medical timelines for an elderly patient with a proximal femoral fracture. Discharge can only occur when both are complete.

Time also plays a part in how we deal with more minor injuries. There is a need and expectation that these patients will be dealt with rapidly; however, there is then a danger, especially with inexperienced doctors, that corners will be cut and key problems missed. Focusing on the important issues without risking missing problems is a difficult skill. However, the risks can be reduced. Although not all patients will be seen by more than one doctor, another health professional, usually a nurse, will see them and their insights should not be ignored. A common safety net for the front-line medical staff is that all radiographs of patients discharged are independently reviewed by a radiologist. Should their findings differ from those in the clinical record the patient can be recalled and reassessed.

Timelines reveal that things change. As a consequence, reassessment can be of vital importance. An observation, a radiograph or a blood test are only snapshots in time. Repeated observation will reveal trends that may make a diagnosis more straightforward. Modern monitoring allows this continuing vigilance to be carried out more straightforwardly. Graphical recording of results in a single place makes trends easier to follow.

Although the pressure and relevance of time shapes our response to the injured it should not be allowed to degrade it (Summary box 21.2).

Summary box 21.2

The importance of time

- Time pressure shapes our management of trauma
- There is a finite time to assess
- There is a finite time to respond
- For success these must fit into the available time before irretrievable damage or death

ASSESSMENT AND RESPONSE

The breakdown of our approach to the injured into two components of assessment and response has been introduced. Although the two concepts overlap and intertwine it is helpful to explore them separately.

The assessment of trauma

At time zero, a person in their baseline condition comes together with an external force to produce injury. Understanding this relationship between the patient, the mechanism of injury and the injury produced is the key to understanding the problem that has to be solved. It is helpful both when making a diagnosis and a treatment plan for an individual and also for structuring the thinking of the management of trauma in general. The relationship can be expressed simply as: *mechanism + patient = injury*.

The initial nature of these variables may be quite obvious (overt) or hidden (covert). As clinicians we need to convert everything to the overt so that appropriate clinical responses can be made. We can only treat what we have found; we can only resolve the problems that we have identified.

A tidy relationship between the mechanism, the patient and the resulting injury is often obvious. Thus, a previously healthy 40-year-old man falling vertically 2 metres and landing on his feet may sustain an os calcis fracture. From this position of understanding we can move swiftly forward to investigate and treat.

In cases in which the mechanism is not known reliably the

other variables may be clearer and the equation can be rewritten as: *injury* – *patient* = *mechanism*. So, if we can see an obvious injury and we know that the patient was previously fit and well we may well be able to work out the likely mechanism of injury. This approach can be useful when assessing the unconscious patient. By using a presumptive mechanism of injury deduced from obvious clinical findings we can begin to search for covert injuries. For example, when an obtunded patient is brought in from a car crash and has facial and chest injuries, we can deduce that the impact was head-on and that we need to check particularly carefully for other injuries associated with such a mechanism, such as to the feet (around the pedals) and the knees (dashboard injuries). Thus, the real value of an equation is not in describing or demonstrating the overt or obvious but rather guiding the search for the covert or hidden.

On some occasions the equation appears not to apply at first sight and can be expressed as: *mechanism* + *patient* ≠ *injury*. This failure of the relationship is not real but apparent. If the three variables do not fit together something has probably been misjudged, and the factor that is causing the failure of the clinical picture to ‘add up’ must be sought. It may be that some aspect of the injury has not yet been discovered, the mechanism suggested may not be genuine or there may be some aspect of the patient before the injury of which one is unaware. To expand on this theme we will explore overt and covert examples of each of the variables in the equation (Summary box 21.3).

Summary box 21.3

The assessment of trauma

- Use all of the information: mechanism, patient and injury
- Allow the obvious features to be a guide to the less obvious

Overt mechanisms

Overt mechanisms of injury are the most common. The patient presents with a history that includes a mechanism. The broad groups of mechanisms described are blunt, penetrating, thermal and blast. We will concentrate on the first two groups as in civilian practice these are the most frequent. Usually the distinction between blunt and penetrating is quite clear, but even at this simple level some injuries with wounds are poorly served by this terminology. In orthopaedic trauma the distinction is best made by use of the terms open and closed. An open tibial fracture caused by a gunshot is accepted as a penetrating wound, whereas an open tibial fracture following a tackle at football would generally be considered as a blunt trauma with an open wound. Many penetrating injuries involve the use of weapons, whereas many blunt injuries are the result of acceleration/deceleration such as falls or road accidents. Although the precision in the use of words is helpful it is more important to understand the principles involved. In these circumstances it is important to understand the patterns of injury that may be associated with a particular mechanism and that when the skin is breached infection is more likely.

Penetrating mechanisms

The easiest of these to understand is the incision caused by a knife. We are used to knives both at home when we eat and as

surgeons when we operate. A knife has a sharp edge that may cut tissues with which it makes contact; these effects are easily appreciated because they happen in a timescale that we understand. A knife damages only what it can reach. A good history of the length of blade coupled with an entry point allows for a potential pattern of injury to be imagined and then individual components to be confirmed or excluded by examination, special investigation or wound exploration.

Thus, an incisional injury over an extremity is readily evaluated as long as the relevant anatomy is known. The distal perfusion, peripheral nerve function and tendon and muscle function can all be assessed by clinical examination. Should penetration of a joint be suspected then the problem is different. This is an example of a situation in which understanding the timeline is of value. The consequences of a septic arthritis are severe and if treatment is delayed until the condition is clinically obvious then it may be too late to remedy. Therefore the diagnosis of joint penetration needs to be excluded by screening the at-risk group. This exclusion can be achieved by exploration and washing out of the at-risk joint, which will normally require operating theatre time and an anaesthetic. If a large joint is involved, for example the knee, an algorithm such as that in Fig. 21.5 can help identify those joints that need formal exploration. One component of this algorithm is to fill the joint until tense with sterile saline and watch whether fluid leaks through the traumatic wound. This will indicate whether the joint has been penetrated. If the joint has been breached a formal procedure in an operating theatre is required, but this is now therapeutic and not exploratory. It is a sound general principle that operating theatre time should be for therapy and not diagnosis whenever possible.

In assessing the effects of an incisional mechanism over the torso the first step is again to decide which structures are at risk. This may seem simple but it is not always easy to determine the direction that a blade has entered. The anatomy can also be confusing; it is worth recalling that the abdominal contents extend

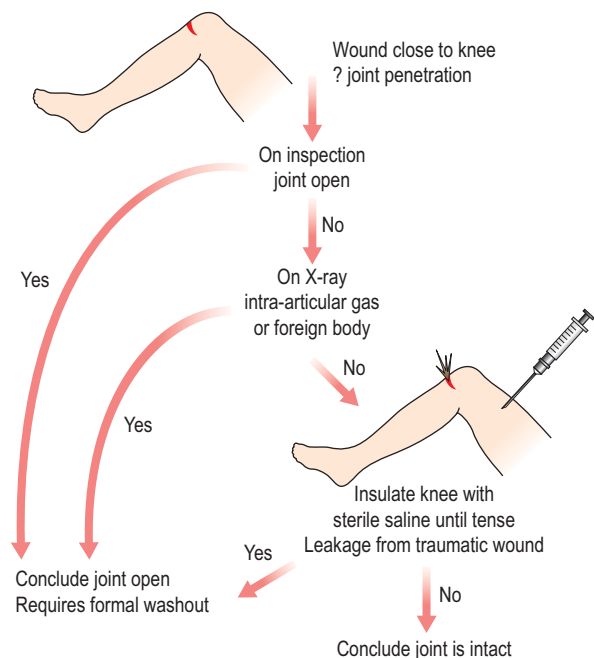

Figure 21.5 Algorithm for assessing a wound that has potentially entered a joint.

higher than normally expected, up to the level of the fifth rib in expiration. A notable feature of stab injuries is that they are often eminently treatable; even cardiac injuries can be treated with a realistic chance of success if identified early (Summary box 21.4).

Summary box 21.4

Incisional injuries

- Require knowledge of anatomy
- The abdominal contents extend high into the chest
- Even cardiac injuries are treatable if recognised early and treated quickly

Penetrating injuries caused by firearms are not so intuitively understood as incisional injuries. A low-velocity projectile behaves more or less like a stabbing injury. However, as the velocity increases, the energy increases in line with $E = \frac{1}{2}mv^2$; as the amount of energy increases, the ability of the system to dissipate that introduced energy in a simple way is overcome. In the case of high-velocity projectiles the result is not like anything we are familiar with in day-to-day life. Furthermore, these projectiles are deliberately designed to produce particular results: some are designed to kill whereas others are designed to maim but not kill. In a military conflict it is more disabling and demoralising to your opponent's forces if individuals do not die but consume resources in their treatment and protection.

The high-velocity bullet crushes particles of the human body in its pathway and produces lateral acceleration away from the point of impact. This motion of the tissue particles away from their original position produces a cavity. Two types of cavity are produced: (1) permanent cavity – one that remains after the initial impact; (2) temporary cavity – one that lasts for milliseconds, and may no longer be apparent during the physical examination of the wounded. This temporary cavitation can extend well beyond the boundaries of the apparent injury (Fig. 21.6). High-speed photography shows the dramatic nature of the temporary deformation, which happens on a timescale with which we are not generally familiar. Awareness of this phenomenon will lead the treating surgeon to perform an adequate exploration and, if appropriate, a more radical wound excision than would otherwise be used (Summary box 21.5).

Summary box 21.5

Firearm injuries

- Low-velocity bullets behave like knife injuries
- High-velocity bullets cause cavitation
- The temporary cavity is large and draws in foreign materials
- The permanent cavity is smaller and gives no clue to the extent of damage

Blunt mechanisms

The blunt mechanism can be considered as direct or indirect. A direct mechanism is when the damage occurs at or close to the site of impact. An indirect mechanism is when the damage occurs at a distant site after transmission of that force. The following examples, in which two different mechanisms leading to fracture of the ulna are considered, may help to understand this. Should an

Figure 21.6 (a) and (b) show a projectile passing through a gelatin block. In (a) there is low energy transfer and in (b) there is high energy transfer. (c) Shows the effect of high energy transfer on tissues. Photo courtesy of Prof J Ryan.

attacker strike with a strong stick the victim may protect their head by raising their arm. The blow will then fall on the ulna. This may cause an isolated fracture of that bone generally called a 'nightstick fracture' (a nightstick being a weapon of enforcement carried by the police). This is clearly a direct injury. All of the injury is concentrated at the site of application of the force; the soft tissues may be bruised, contused or lacerated at the site. A different situation occurs if a person falls on an outstretched hand. This may lead to a fracture of the ulna but here the mechanism is indirect. The force has been transmitted through the body's tissues to a site at some distance from its application. It is unlikely that an ulnar fracture would occur in isolation in such circumstances and the 'associated

injuries' should be sought. In this instance, the associated injury is often a dislocation of the radial head, the whole injury complex being called a Monteggia fracture dislocation. These injuries are demonstrated diagrammatically in Fig. 21.7. The injury is often missed and the consequences are severe in the growing child. Thus, we should always evaluate the elbow fully (radiologically and clinically) in an apparently 'isolated' ulnar fracture, especially if the mechanism was indirect, usually a fall onto the hand. The timeline in these circumstances is not pressing. The injury can be adequately treated for some weeks after it occurs, but once the diagnosis has been missed and the wrong label applied it becomes progressively more difficult to rectify.

An analogous situation occurs in the paired bones of the lower leg. A footballer may fracture the shaft of the fibula as the result of a direct blow; however, the fracture may be the consequence of an indirect twisting injury at the ankle. The direct injury is often a trivial injury requiring little or no treatment. The indirectly sustained high fibular fracture associated with an ankle injury is often quite unstable and requires operative treatment. A useful history of the mechanism is often very difficult to obtain in such circumstances. However, the history immediately after the injury may be helpful: a player who can continue to play or walk demonstrates some stability, whereas the person who cannot weight bear at all may have instability. Once again, as with the ulnar fracture, the associated injuries should be sought by clinical (tenderness away from the site of the obvious injury suggesting an indirect mechanism) and radiological assessment. Figure 21.8 shows how inferred instability of the ankle in an indirect injury is demonstrated by stress views taken under anaesthesia. This is another example of screening the at-risk population so that an appropriate treatment response can be made. If the initial opportunity of diagnosis is missed the condition may become clinically apparent only once united in a poor position and it is then difficult to resolve.

Figure 21.8 Ankle fracture. (a) The potential line of injury is shown by the hatching. (b) Neutral view under anaesthesia. (c) The instability is confirmed by the stress view, which shows the opening of the inferior tibiofibular syndesmosis.

The energy transmission in an indirect mechanism may be via a solid structure such as a bone, as in the examples above, or it may be via the soft tissues or fluid. Some of the resulting injuries can be quite unexpected. A compressive force to the abdomen will cause a rise in pressure that may be transmitted by the vascular system. A sudden back pressure at the heart can lead to damage to the valves. The results of direct mechanisms are easier to understand as the damaging effects are often more localised.

Even when the patient was alert before and after the event, it can be surprisingly difficult to be sure of the mechanism as it affected the injured part. The rapidity and unexpectedness of accidents means that precision in history is often hard to obtain.

Overt patients

The nature of some patients as a substrate for injury is obvious. Individuals with different physical characteristics will respond differently to mechanical insult. In the standard history taken, a quick categorisation of a patient is normally carried out.

As we take a history we intuitively group patients to assess the nature of their likely injuries. Children, adults and the elderly are three obvious separate groups. We anticipate different injuries in these different groups even if the mechanism is the same. For instance, if three people – a child, a young adult and an elderly person – fall together on an icy path, what might happen to them? The child will bounce, get up and do it again because it was fun. The adult will sprain or break their wrist. The elderly person breaks their hip.

Why the differences? With a low centre of gravity and less mass the child will have much less energy to dissipate in a simple fall. Their tissues are generally strong and more elastic and so do not break with trivial injury. Minor injuries in children are very common because they do a lot of silly things. However, there are times when their physical structure makes them vulnerable. As is discussed in Chapter 27, the growth plate of a bone can be a point

of relative weakness, particularly as the child approaches puberty.

The adult reacts quickly to the fall and so is able to dissipate energy using the hand and arm as a shock absorber. This may prevent injury but should this protective mechanism be overwhelmed a wrist injury may result.

The elderly person does not react as rapidly and so they fall further before their deceleration mechanisms come into play. They have more energy to dissipate and yet their tissues are less able to cope. They are therefore more vulnerable to a serious fracture.

Overt injuries

Some injuries are so obvious that they may present before any mechanism or patient details are known. It may therefore be the presence of one overt injury that leads to the search for another; the obvious injury is being used just as a history would in other circumstances. The most obvious injuries will be those that are visible externally. It is for this reason that there is an E at the end of ABCDE in the ATLS system: E is for exposure – look for the clues.

A wound suggests a penetrating injury and thought should be given to the underlying structures at risk. A contusion over the knee of a driver suggests a dashboard injury. Finger-shaped bruises on a child's arms suggest NAI.

A good example of a minor but obvious injury helping in a timeline is singed facial hair. Singed facial hair often associated with carbonaceous sputum suggests inhalational burns. Calling an anaesthetic colleague when singed nasal hair is first noted is far better than a crash call 15 min later when laryngeal oedema obstructs the airway of a patient with an inhalational burn.

Exposing the patient comes readily to those dealing with trauma. The perils of not exposing the patient were demonstrated in an infamous case in the UK. A patient already in hospital for another problem had 'collapsed' by the phone within the hospital and was dealt with by the cardiac arrest team. The patient responded poorly to treatment and it was only some time later that the bullet on their chest radiograph was noticed. Following this the bullet wound on their back was found. A helpful adage borrowed from radiology is that 'unless you are very lucky you only find what you look for'.

Covert mechanisms

Sometimes, when the normal relationship of *mechanism + patient = injury* does not seem to hold, the hidden information may be in the mechanism. The most obvious examples are in situations in which there has been a deliberate attempt to mislead.

Conscious sensible patients reporting their own injuries will generally tell the truth; however, sometimes to protect themselves or others they may fabricate a mechanism. The risk here is that if the mechanism is incorrect the wrong pattern of injuries may be anticipated. Potentially this could lead to an important injury being overlooked or diagnosed late. Thus, the man who fell from 6 metres when jumping from his lover's window does not help achieve an accurate diagnosis if he reports the mechanism as a twist to his ankle from a stumble. Similarly, if it is not admitted that an injury results from an assault then no action can reasonably be taken to help protect that person from further aggression. This situation is most commonly encountered when the patient is the victim of abuse within a relationship. The patient should be given the opportunity to tell their story, but it should not always be believed.

More commonly, the problem of a hidden mechanism arises when the patient is unable to give their own history. A very young child or an elderly person is both physically and mentally vulnerable. They may have been physically abused but be unable to report it. In these circumstances the mechanism of injury may have been criminal. A list of some of the factors that should make one suspicious of the history and suspect that NAI has occurred is given below:

- history clearly inconsistent with the injuries sustained;
- changing history;
- aggressive behaviour of carers at interview;
- injuries of different ages;
- posterior rib injuries;
- long bone fractures in a pre-ambulatory child.

The interests of the patient are paramount and so we need to not only identify injuries that need treatment but also protect patients from further harm. The timeline of importance here is that which has shown that 66% of children who die as the result of abuse have been in contact with a health or social work professional before the fatal episode. We have already accepted that to adequately treat an extradural haematoma we must respond to subtle indicators in the history and physical examination to allow our response to begin early enough to be effective. An analogous situation applies with child abuse – if we ignore the early signs we may be too late to prevent the later episode in which real harm is done. NAI is a very difficult problem to deal with. As clinicians we are more comfortable trying to help everyone; acting to police a situation does not come naturally. The simple early response is to admit the at-risk person on clinical grounds. This allows time for a considered response. Who provides this will depend on the situation where we work.

In some criminal situations the nature of any overt injuries may provide important evidence of the mechanism. Such evidence may be affected by our medical assessment and treatment. Although we should not compromise the medical management of an injured person, it is folly not to bear in mind at every stage that the victim of an assault may need good forensic evidence at some later date to convict their assailant. Indeed, the injured victim of an assault may later become a murder victim (Summary box 21.6).

Summary box 21.6

Covert mechanisms

- Patients usually tell the truth but may not if criminal activity is involved
- Fear of abuse may prevent vulnerable patients telling the truth
- If NAI is suspected you have a responsibility to take action
- Patients likely to have covert medical problems need careful checking even if their injury appears to have a simple mechanical cause

Covert patients

When the mechanism and the injury are obvious but inconsistent, it may be that there is something previously unknown about the patient to discover. Most commonly this is a pre-existing pathology. Thus, a healthy adult who breaks their femur following a trivial insult may well have had a pathological weakness of

the bone, such as a neoplasm. Thoughtless treatment of this as a simple fracture, without tissue diagnosis, staging, etc., may result in entirely inappropriate treatment with unnecessary loss of limb or life.

Injury in the older patient may be the manifestation of general health problems. Falls in the elderly can be divided into those caused by mechanical factors and those caused by medical problems. The division into these two categories is difficult in practice. However, it is true to say that, although the obvious injury may be the fractured proximal femur, the hidden patient factor may be the transient ischaemic attack or abnormal cardiac rhythm that caused the fall. Rather like the practice of the secondary survey looking for covert injury in the polytraumatised patient, a medical secondary survey is required as a screen in the elderly.

A hidden problem with the patient should also be sought in some potential child abuse cases. The defence in a court case may suggest that repeated injury was not the result of repeated abusive mechanisms but rather an undue propensity to injury. It may be claimed that the allegedly abused child has osteogenesis imperfecta and that the explanation of the multiple fractures is weak bones. The arguments here are a specialist area. Our role is more straightforward in providing a record of the initial evidence in an unbiased, professional and thorough manner.

Covert injuries

Looking for the hidden injury can follow three methods:

- 1 the deductive approach;
- 2 the look everywhere approach;
- 3 the focused exclusion approach.

The deductive approach – patterns of injury

One can apply common sense and experience to the search for hidden injuries. Injuries occur in patterns along the lines of energy transmission. Finding an obvious injury may therefore lead to one that is hidden. A good example is the child restrained by a lap seatbelt in the rear of a car involved in a frontal collision. There may be an obvious flexion spinal injury, e.g. a Chance fracture. What may be less obvious but should be sought is damage to the immobile retroperitoneal structures, the pancreas or duodenum.

Certain mechanisms are associated with particular patterns of injury. Thus, if the mechanism and perhaps some of the obvious injuries are known, one can seek the less obvious injury. An unrestrained passenger in a head-on car crash will hit their knee on the dashboard. If the tibia is the site of impact the patient has to

be evaluated for a potential rupture of the posterior cruciate ligament and a posterior hip dislocation. A dislocation of the knee should immediately raise concerns about damage to the popliteal artery and injury to it should be excluded. Table 21.1 gives some examples of patterns of associated injuries.

The look everywhere approach

One of the mainstays of trauma evaluation is the secondary survey. The essence is that once the initial life-saving manoeuvres have been completed you look everywhere for further injury. This detailed examination may take place shortly after admission, the following morning on the ward round or sometimes a week later when the patient first regains consciousness. A foot injury, a scaphoid fracture, a ruptured diaphragm and a peripheral nerve injury are all injuries that can be overlooked and cause long-term morbidity.

As its name suggests, the look everywhere secondary survey comes later in the sequence of the ATLS approach. However, the emphasis placed on the timeline at the beginning of this chapter and the need for early diagnosis is leading to a different look everywhere approach. The ATLS system has included a plain pelvic and a chest radiograph as part of the primary survey. This may confirm a clinical diagnosis but is also a screening tool to identify injuries that may progress to a clinical problem; the response to that injury can then be initiated earlier. The threshold for using more generalised investigations such as CT scanning, ultrasound, cardiac echo and magnetic resonance imaging (MRI) to check for these covert injuries is progressively being lowered. Some emergency departments now have CT scanners in their resuscitation rooms. A head-to-pelvis CT scan is being used to replace the early plain radiographs of the chest and the pelvis. A CT scan is more sensitive and specific and its use to identify injury before the clinical signs present is certain to increase.

The focused exclusion approach

Some injuries or conditions are for some reason missed on a surprisingly regular basis. This suggests that a normal deductive approach is not always adequate. When there is any suggestion of the presence of these injuries they should be actively sought and excluded. The evolution of head injury assessment in the UK illustrates this point very well. The National Institute for Health and Clinical Excellence (NICE) issues guidelines for clinical practice. The NICE guidelines for the investigation of head injury have lowered the threshold for a head CT, the objective being to

Table 21.1 Examples of patterns of injury

Mechanism	Obvious features	Covert injuries
Left-sided impact from road traffic accident	Lateral compression of the pelvis Left-sided pneumothorax	Splenic rupture Extradural haematoma
Flexion distraction (lap belt)	Chance fracture of the lumbar spine Dislocated knee Head injury	Duodenal rupture Popliteal artery disruption Cervical spine fracture
Electrocution	Burn on hand and collapse	Posterior dislocation of the shoulder
Dashboard impact	Knee wound	Posterior dislocation of the hip

George Quentin Chance, Formerly Director of Diagnostic Radiology, The Derby Group of Hospitals, Derbyshire, England.

avoid intracranial injuries being misdiagnosed and, more fundamentally, to demonstrate the problem at an early enough stage in the timeline for a medical response to be mounted. A consequence of very early imaging is that the findings, even on investigation, may not be well developed. As the guidelines suggest there needs to be a willingness to repeat investigations if indicated to detect evolving problems.

Other injuries that can cause disability but are easily missed are listed in Chapter 27. They are overlooked regularly so one must presume that the normal deductive processes for identifying them do not work. Therefore, if such injuries are suspected they should be positively excluded by focused history, examination and investigation (Summary box 21.7).

Summary box 21.7

Trauma assessment

- Know the timelines for important diagnoses
- Prioritise the assessment accordingly
- Positively exclude critical diagnoses
- If required, screen at-risk patients before clinical signs are apparent

The response to trauma

Once an assessment has been made based on the factors of mechanism, patient and injury discussed above, the response must be planned and executed. At the same time the patient will have an evolving response to injury. On the positive side, physiological compensatory and reserve mechanisms will be recruited and healing processes will be initiated. Countering this there may be progressive pathophysiological responses, the consumption of resources and decompensation.

The patient's response to injury

The patient's own homeostatic mechanisms will respond to the injury and there will be physiological and pathophysiological changes. In the light of this evolution of responses we may alter the nature or the timing of our interventions.

A simple example is body temperature. A drop in body temperature is common after injury; this may be due to exposure, inactivity, damp, blood loss or loss of vasomotor control. The body's own thermoregulatory mechanisms may not be able to resolve the problem and so we must be prepared to support that role – body temperature should be monitored and heat loss prevented as required. It may not be possible to do this adequately in an operating theatre during a surgical procedure.

Similarly, oxygenation can be monitored and support may be given by way of increased inspired oxygen or different modes of ventilation. However, it is often the case that the ventilators available in an operating theatre are not as sophisticated and flexible as those in an intensive care unit.

The response to blood loss is not only an evolving situation for an individual patient but our response to it also changes. The patient calls on compensatory mechanisms when blood is lost. As long as organ perfusion is adequate, low blood pressure is not a problem in its own right. The body has a finite resource of clotting factors and the injured lung does not tolerate excess fluid. These factors combined have led to a tendency to draw back from large-scale early fluid replacement. Instead, the emphasis is

placed on identifying and stopping the source of bleeding. The evolution of permissive hypotensive resuscitation will no doubt continue in parallel with the more liberal use of investigations such as CT, which allow early therapeutic treatment and not just supportive treatment.

The patient also mounts a generalised immunological response to trauma. This has an impact on their ability to tolerate surgical interventions. There is growing evidence that procedures should be timed and staged to better fit the conditions created by the patient's systemic immune response.

The medical response to injury

Initial management

The structure of ATLS is discussed in Chapter 22. For some patients reducing the elapsed time from injury to useful intervention is critical. Preparation can aid this process. When a department is made aware of the impending arrival of a seriously injured patient a decision is made as to whether to call the 'trauma team'; if appropriate, this will allow a trained team of nurses and doctors to be waiting to meet the patient. While waiting, equipment is made ready, a leader is identified and each team member is given a role. Protective clothing will be needed: gloves to protect from fluids and lead aprons to protect from X-rays.

For the medical and nursing staff the beginning of the patient's pathway can become familiar just like any routine journey and, thus, planning becomes less complex. However, if wasteful delays are to be avoided, alternatives need to be available if for some reason the routine cannot be followed. Anticipating and dealing with potential rate-limiting steps in the patient's journey will allow delays to be avoided and reduce the response time. The component of the response that will be the rate-limiting step will depend on local as well as general circumstances. Examples of causes of delay are obtaining a CT scan, getting the patient into an operating theatre or obtaining a necessary specialist opinion. Such steps that can potentially bring the progress of the patient to a halt need to be addressed early and sometimes in a way that may seem out of the normal sequence. This is one of the major roles of the team leader who should have an overview and be able to foresee and pre-empt problems. Whenever a system is protocol driven someone should be in a position to take the responsibility to break protocol if required to keep the overall process flowing.

Having a practised common pathway can be disadvantageous; a patient with the wrong 'label' may go along the wrong pathway. We all have to be wary of labelling. When a patient has sustained obvious polytrauma and arrives on a stretcher with a cervical collar in place it is initially straightforward and appropriate to label them as an emergency. Should two patients with identical histories and injuries arrive in an emergency department with one on a spine board and the other in a chair, the former will be treated as if more severely injured when in fact that may not be the case. We must make our own judgements on reasonable evidence and not rely on the labels (in this case the cervical collars) applied by others.

Labelling is most frequently a dangerous problem in the elderly. A patient with an obviously short externally rotated leg may be quickly given the label '#NOF' (fracture neck of femur). There are a number of problems with this practice. The notation itself is misleading as the fracture is often intertrochanteric; thus, PFF for proximal femoral fracture is a better term. However, even this is inappropriate as it concentrates on the orthopaedic label

rather than the whole patient. The incorrect label may mask the fact that the patient could be dying. The patient may have fallen as a consequence of a cardiac arrhythmia or other comorbidity; the early labelling as #NOF or PFF may therefore send the patient off on entirely the wrong pathway. All vulnerable patients should have a physiological triage to avoid such problems. This means assessing the airway, respiratory rate, blood pressure, pulse rate and consciousness. All of these assessments are more important, even in the elderly, than the presence of a fractured hip.

Beyond the first hour

The primary survey of ATLS encourages the identification and treatment of life-threatening problems. Once these have been addressed there may be other problems that require intervention. The timing and order of these interventions is a matter of judgement. There has been an evolution in the approach to the management of polytrauma. It has been variously said that a patient may be 'too sick to operate on' or that they may be 'too sick *not* to operate on'. The work of Bone in particular has promoted the concept of early definitive stabilisation of long bone fractures to allow better control of the pathophysiology of trauma. Others have highlighted the need in some circumstances for limited early intervention, sometimes called 'damage control surgery'. This is followed by definitive treatment when the patient is better able to tolerate it. In orthopaedic trauma the debate has focused on whether long bone fractures should be fixed temporarily or definitively. In general surgery the question is whether the abdomen should be definitively treated or packed. Any patient needing a sequence of interventions, e.g. laparotomy, femoral nailing, tibial nailing, should have the most important done first. Thus, if there needs to be a break in the procedures for any reason the most important interventions will have been completed. As each component of a sequence of procedures nears its

end, a decision needs to be made whether it is safe or appropriate to proceed to the next stage. Monitoring of core temperature, coagulation, base excess, etc., will help this decision to be made on rational grounds. If the patient's pathophysiology is deteriorating it may be decided to halt the surgery after life-saving or damage control surgery. An abdomen may be packed rather than subjected to a definitive procedure and the femoral fracture may be held with an external fixator rather than an intramedullary nail. The patient can then be transferred to the more controlled environment of an intensive care unit and return for definitive surgery when physiologically and immunologically better able to tolerate it; this may be hours or days later.

The evolving surgical plan can be crystallised into the patient's records as a written note. However, a very useful adjunct is to record it on a whiteboard in the operating theatre. This informs others of the intended pathway of treatment so that preparations can be made. An example of such a tactic is shown in Fig. 21.9. Note the alternative pathway that exists should the patient's general condition require a shorter procedure, when the femur can be temporarily stabilised with an external fixator rather than definitively fixed with a nail.

Local protocols and guidelines

A general guideline such as ATLS deals with some aspects of patient management and is used in many institutions. However, hospitals generally have individual policies to guide or direct decision making in smaller areas of practice. Examples are prophylaxis against infection and thromboembolism, the use of steroids in spinal injury and clearance of the cervical spine. These represent the efforts of individuals within an institution to plan for common and foreseeable circumstances. These protocols allow for easier and quicker decision making. Their application should protect the patient and, in an increasingly litigious world, the doctor as well.

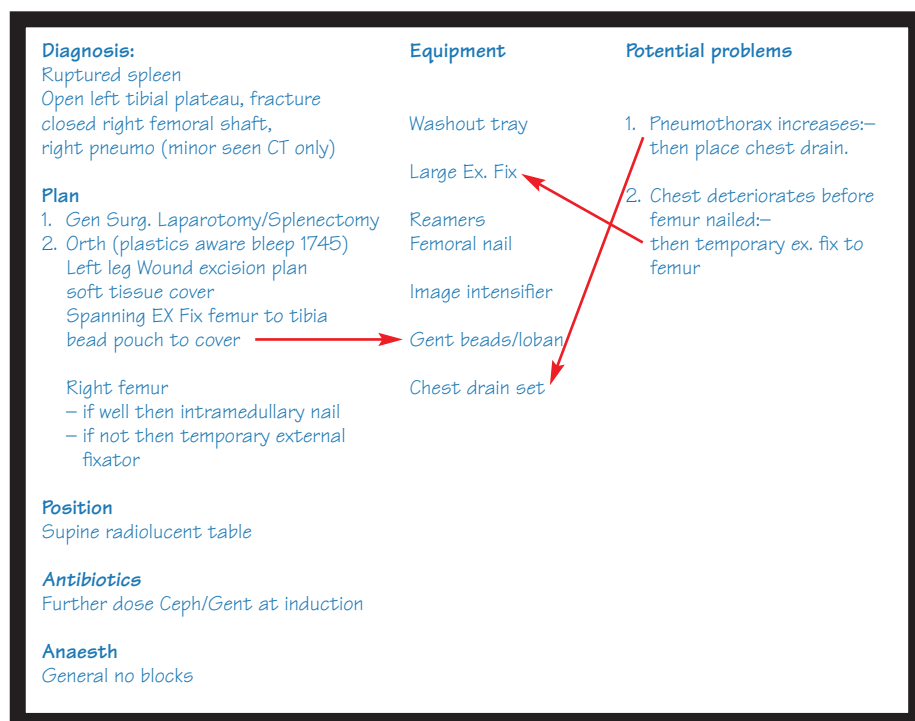

Figure 21.9 An example of a surgical tactic on a whiteboard in the operating theatre.

‘Clearing’ of the spine is a practice that has particular relevance to trauma. The early policy for managing the spine in poly-trauma patients is straightforward; it can be summarised as ‘suspect and protect’. This approach is widely employed and so in emergency departments very many patients have their spine protected. However, this is a precautionary protective approach and at some stage one has to have a strategy for discontinuing protection or ‘clearing’ the spine in those patients in whom it is not required. The ‘gold standard’ is clinical examination of the fully conscious, undistracted patient combined with any necessary investigations. The problem arises if a patient is not going to be fully conscious for some time. Maintaining spinal precautions for such a patient is costly, time-consuming and prone to complications. Pressure sores may develop under a collar, neck lines are less accessible and more nurses are needed for turning. However, the patients involved are likely to be those with higher-energy injury mechanisms in which spinal injury is more likely. Hospitals should have policies in place for such a situation. If no such policy exists and spinal precautions are withdrawn randomly it degrades the initial care that has been given. In the event that it is not possible to exclude spinal injury on clinical grounds the managing clinicians may request clearance on radiological grounds. The images should be assessed by an experienced radiologist and it must be recorded in the patient’s records and signed that the spine has been cleared. An example of such a policy for clearing the spine is given in Table 21.2.

Record-keeping for the injured patient is both important and difficult. It is often said that trends in a patient’s condition are more important than isolated observations. Because an injured patient may be cared for by a large number of individuals, trends can only become apparent by reference to the sequential recorded notes. If each individual clinician records their observations in an ‘individual’ manner it becomes very difficult to identify trends. Adoption of the Glasgow coma scale to monitor the level of consciousness demonstrates the advantage of using a consistent system of recording observations. Such sequential observations, especially when displayed on a single chart, demonstrate trends. The clinical evolution of a problem such as raised intracranial pressure secondary to an extradural haematoma is then easier to identify (Summary box 21.8).

Summary box 21.8

The response to trauma

- Guidelines and protocols speed and streamline management
- Pre-empt time-limiting steps to avoid delay
- Respond to the evolving condition of the patient

Responding to a local complex injury

Responding to a local complex injury, e.g. a fracture with a vascular injury, provides a good example of the difficulties that are

encountered when planning and executing a multispecialty procedure. A fracture with a vascular injury may be open or closed. The first imperative is to recognise that the vascular injury exists. The clock for the warm ischaemic time starts running at the time that the circulation is occluded; this may be the time of injury or later. Management plans and interventions can only make progress once the injury is noticed. It is clearly important to make the diagnosis as soon as possible. The presence of an occluded or divided artery should be detectable clinically. However, sometimes the initial vascular injury may lead to only a partial interruption of blood flow. With vigilance and a high level of suspicion, the correct diagnosis may be reached before complete occlusion. An example is with a penetrating injury to the thigh or a dislocated knee. Both injuries can be associated with vessel damage. An ankle–brachial index of less than 0.9 suggests arterial injury even in the presence of palpable pulses. This will prompt early arteriography, which may allow the surgical response to be prepared earlier and with more chance of success. This is another example of screening an at-risk group to reduce the assessment time and allow more time for a clinical response.

Once the vascular deficit is apparent the question that needs to be answered is at what level the injury is situated. If the level of injury is obvious, time expended in arteriography is not profitable.

Managing the injury usually requires the cooperation of at least two surgical disciplines. The first step is to agree on a working diagnosis. Both parties should be happy with the structure of the surgical plan. The surgical approach, that is the anatomical route for dissection, will need discussion. An example of how conflict may occur is given by the case of surgery in the vicinity of the knee: the ‘vascular approach’ may damage some of the medial hamstring structures that might be needed later in an orthopaedic reconstructive procedure. It is generally preferable to avoid multiple approaches, so a compromise should be considered.

The teams should then agree on the sequence of events. Management of the injury will require the completion of a number of steps; these may include restoration of perfusion, definitive vascular anastomoses, wound excision and exploration (if an open fracture), provisional fracture stabilisation, definitive fracture fixation and fasciotomies. If the vascular anastomosis is the first step to be completed, this may then discourage the thorough wound excision of an open fracture or hinder fracture fixation, and the anastomosis may itself be damaged. If the progress to theatre has been rapid it may be possible to carry out a rapid wound excision and fracture fixation and still leave time for an anastomosis before the safe warm ischaemia time of about 4 hours has been exceeded. The advantage of avoiding unnecessary angiography is apparent when working against the clock. If it is clear that there is not sufficient time for this sequence of definitive procedures to be followed it may be possible to place a temporary shunt in the vessels to allow perfusion so that fracture fixation may be completed before the definitive anastomosis is performed.

Table 21.2 An example of a policy for clearing the spine in the obtunded patient

Cervical spine	Fine-quality CT scans of C0–T4, reformatted and assessed in the axial, sagittal and coronal planes. Powers ratio to assess the atlanto-occipital junction
Thoracolumbar spine (T4 distally)	Either good-quality anteroposterior and lateral plain films or CT scans reformatted and assessed in the anteroposterior, lateral and axial planes

Planning an individual operation

The central part of a surgeon's work is operating. Dealing with injuries is not repetitive and so thought and planning are required. Even when an individual surgeon is involved in performing the surgery, care is delivered as part of a team. It is good practice to think through the plan for the operating theatre. Mental rehearsal of a procedure may allow potential hazards to be predicted and avoided. For example:

- As the procedure is planned it may become apparent that the proposed surgical approach will not allow the access required. In a whiteboard exercise this can readily be altered. This cannot be done if the first time this problem is appreciated is after the skin has been cut.
- It may be decided in planning that another surgeon is better suited to perform a particular procedure.

The use of the whiteboard in theatre, discussed earlier in the context of multiple injuries, is equally applicable for the isolated injury. An example of a surgical tactic for a segmental tibial fracture is given in Fig. 21.10. This not only helps the surgeon to

be clear about the procedure in his or her own mind but also informs others. The position of the patient, the surgical approach, position of the image intensifier, method of fracture reduction and instruments required, and method of fixation and implants required are all noted. Theatre staff, anaesthetic staff, radiographers, etc. can all see what is intended and it can also act as a teaching aid. A trainee may be asked to complete the whiteboard plan; they then have to commit to a plan of action and not just drift along. An important addition to the planned progress of the procedure is a list of potential problems or hazards. The strategies that will be used to deal with these problems should they arise can then be considered and prepared for (Summary box 21.9).

Summary box 21.9

Planning an individual operation

- Plan procedures before performing them
- Commit a plan to paper
- Share a surgical plan by use of a whiteboard

(a)

Diagnosis	Equipment	Problems/solutions
Open segmental fracture left tibia	<ul style="list-style-type: none"> - Radiolucent table - Tourniquet (during wound excision) - Soft tissue tray - Washout tray - 9 litres washout - Reamers - Cannulated tibial IM nail 	<ul style="list-style-type: none"> - Segment viable but too narrow to nail/proceed to bridge plate or ex. fix depending on soft tissue - Segment non-viable/remove segment place temp ex. fix with view to subsequent Ilizarov transport - On passing nail malalignment of proximal fragment/remove nail and place blocking screw
Procedure <ul style="list-style-type: none"> - Excise wound with plastics - Plan soft tissue cover - Secure nail entry point - Ream segment through traumatic wound - Statically lock nail - Dress wound with a bead pouch - Continue antibiotics until definitive soft-tissue cover 	In reserve external fixator/long plates	

Blocking screw

Figure 21.10 (a) Theatre whiteboard with surgical tactic and (b) radiograph for a complex grade IIIb open segmental tibial fracture. One of the foreseen problems has occurred as the proximal fragment is malreduced (c). The nail was removed and an anteroposterior blocking screw was placed (highlighted) (d and e). The fracture is then well reduced.

The response to the mechanism of injury (injury prevention)

When assessing the *mechanism + patient = injury* relationship it is easy for the doctor to focus on managing the injury; however, the mechanism of injury can also be addressed, that is we should aim to prevent rather than just treat injury.

When a mechanism of injury becomes particularly prevalent or has serious consequences it is prudent to take steps to either remove the mechanism or reduce the consequences.

Accidents occur in a variety of places: the home, the workplace and the roads are the most common. The strategy and motivation for prevention varies from place to place. Within the workplace there is legislation to protect employees and a tendency for an injured employee to sue the employer. Thus, although some work environments are naturally dangerous, many advances in safety have been made. Within the home, legislation has little effect on behaviour. The safety of the structure of a home may be influenced by building regulations but the thrust is on education of the individual. It is difficult to educate adults to behave more safely and so accidents in the home remain very common. Simple measures such as avoiding loose rugs or cables, polished floors and unnecessary steps are common sense. There is evidence to suggest that incorporating accident prevention education into the appropriate parts of the school curriculum is more likely to be successful.

Road safety is a contentious issue. The safe management of the kinetic energy of travel would seem to be a straightforward physical problem. Great advances have been made in the technology of motor vehicles to protect drivers. Restricting speed, separating vehicles travelling in different directions and segregating motor vehicles from vulnerable road users such as pedestrians are not popular measures. The political power of the motorist tends to obstruct progress in this area.

The response to the potential NAI is to involve the appropriate agencies in an attempt to prevent further problems. This is a difficult role for doctors as it involves having a quite different relationship with the patient and the family to that which is normally adopted. In general, our training is to be empathetic and trusting; however, we have to be alert, professional and act in the best interests of the child or other vulnerable person (Summary box 21.10).

Summary box 21.10

Response to the mechanism of injury

- The saying that 'prevention is better than cure' is true
- Legislation and education are required
- Prevent further abuse by responding to the initial clues

The response to patient factors

Another approach to injury prevention is to alter the patient. This particularly applies to the epidemic of injuries in the elderly. Falls are the commonest mechanism of injury, so one can try to address the cause or the effects of falls. Fall prevention clinics are now common. The at-risk patients are assessed and remediable causes of falls are addressed. Postural hypotension, transient ischaemic attacks, arrhythmias, etc. can be identified and treated. Unfortunately, the number of patients considered to be at risk is so large that the coverage of such clinics is as yet quite inadequate.

Elderly people will continue to fall, so we can try to minimise the effect of the fall. Schemes such as using hip protector pads to cushion a fall have been tried with limited success. The area most likely to expand and give results is that of strengthening the skeleton. Identifying those at risk of osteoporosis, screening them and then treating appropriately offers a hope of reducing the incidence of low energy fractures. There was initial scepticism about the expense of such treatments and the potentially huge number of people who would require them. It is now accepted that treatment targeted appropriately will be cost-effective by reducing later fractures with the consequent costs of hospitalisation, morbidity and mortality.

Another of the patient factors discussed earlier is when injury occurs in pathological tissues, the common example being a fracture of a bone with a neoplastic deposit. This should influence management in one of two ways. When there is a doubt as to whether the tumour is a primary or secondary it is important to think before treatment. Injudicious operative management of a fracture associated with a primary deposit may prejudice proper tumour management; when the situation allows a proper opinion should be obtained. When dealing with obvious secondary deposits the situation is quite different. Aggressive surgical management is often justified to allow an early return to function. A person with a limited life expectancy should not spend long periods of time rehabilitating (Summary box 21.11).

Summary box 21.11

Response to patient factors

- Pre-empt injury with the use of fall prevention clinics
- Carry out targeted osteoporosis treatment
- Do not treat thoughtlessly an injury that is possibly secondary to a primary neoplasm

CONCLUSION

Trauma is usually the adverse consequence of a mechanical force on a patient. The prime importance of time in trauma care needs to be appreciated. At time zero there is a relationship between the mechanism, the patient and the injury. The components of this relationship should fit together in a rational manner. When this rational fit is not apparent, great care should be taken to look for hidden injuries, pre-existing pathology or some deliberate deception in the given history.

There is a timeline that progresses from the moment of injury. Prompt understanding of the problems is key in allowing an early reaction. It may not be possible to wait for overt clinical signs and so diagnoses should be positively sought and in some circumstances patients screened. There is a minimum response time to initiate and complete the interventions to deal with the problems. Preparation can reduce this response time. Knowledge of realistic response times is important, because only then does the clinician know the real urgency of initiating action.

When presented with an injured patient the early management is largely protocol driven. As more details become known and the patient moves towards definitive care a more individual plan is made. This plan coordinates the different specialities and should be flexible to allow for evolving pathology. Someone should be responsible for the patient.

Trauma does not just consist of care of the young injured. Increasingly the injured patient will be elderly. The team involved needs to reflect the needs of these elderly patients.

Trauma need not only be addressed by tackling the injury itself. Preventative measures should be employed when particular mechanisms can be identified as being common or important causes of injury. For example, prophylactic measures may reduce the propensity for individuals to fall or reduce the consequences of those falls when they occur.

The following chapters in this section will look further at these principles as applied to specific regions or surgical disciplines (Summary box 21.12).

Summary box 21.12

Conclusion

- The management of trauma is dependent upon time
- Multiple specialties may be involved but do not lose sight of the overall problem
- Planning increases the chances of success

Early assessment and management of trauma

LEARNING OBJECTIVES

To identify:

- The sequence of priorities in the early assessment of the injured patient

To learn:

- The principle of triage in immediate management of the injured patient
- The concepts of injury recognition prediction based on the mechanism and energy of injury

To apply:

- The principles of primary and secondary surveys in the assessment and management of trauma

- Techniques for the initial resuscitative and definitive care aspects of trauma

To perform:

- The necessary protocols to allow early stabilisation of the patient leading on to definitive care

To recognise:

- Certain important groups of patients and their differing management

EPIDEMIOLOGY

Trauma is the commonest cause of death in the population between the ages of 1 and 40 years worldwide. It is a huge drain on health resources in both the developed and the developing world. By 2020, it is estimated that injuries will be the third leading cause of death and disability worldwide. In addition to killing people, injuries cause lifelong disabilities and many other health problems with serious consequences for individuals, families, communities and health-care systems.

The World Health Organization data published in 2002 revealed the following points worthy of consideration:

- An estimated 5 million people worldwide died from injuries in 2000 – a mortality rate of 83.7 per 100 000 population.
- Injuries accounted for 9% of the world's deaths in 2000 and 12% of the world's burden of disease.
- Road traffic injuries are the leading cause of injury-related deaths worldwide. More than 90% of the world's deaths from injuries occur in low- and middle-income countries.
- The low- and middle-income countries of Europe have the highest injury mortality rates.
- The South-east Asia and Western Pacific regions account for the highest number of injury deaths worldwide.
- Globally, injury mortality among men is twice that among women.
- Males in Africa and Europe have the highest injury-related mortality rates.
- Young people between the ages of 15 and 44 years account for almost 50% of the world's injury-related mortality.
- Mortality from road traffic injuries and interpersonal violence in males is almost three times higher than that in females.

- Injury profiles including morbidity and mortality statistics differ between Third and First World countries largely on account of the availability of health-care resources being significantly diminished in the Third World. Road traffic injuries in the developing world are now the third highest cause of death. Probable factors include the large numbers of pedestrians and cyclists (many living below the poverty line) involved in these injuries; overcrowding of public transport; poor road maintenance and few speed restrictions (Fig. 22.1).

Falls

Globally, an estimated 391 000 people died as a result of falls in 2002, making it the second leading cause of unintentional injury death worldwide after road traffic injuries. A quarter of all fatal falls occurred in the high-income countries. Europe and the Western Pacific region combined account for nearly 60% of the total number of fall-related deaths worldwide.

Males in the low- and middle-income countries of Europe have by far the highest fall-related mortality rates worldwide.

In all regions of the world, adults over the age of 70 years, particularly females, have significantly higher fall-related mortality rates than younger people. However, children account for the largest morbidity – almost 50% of the total number of disability-adjusted life-years (DALYs) lost globally to falls occur in children under 15 years of age.

With ever increasing population growth and increased life expectancy, the injury mortality and morbidity statistics are likely to be skewed towards the two ends of the age spectrum, making the paediatric and the elderly populations very important with respect to global health care and economics.

Figure 22.1 Worldwide annual incidence of injury.

Summary box 22.1

The steps in the ATLS philosophy

- Primary survey with simultaneous resuscitation – identify and treat what is killing the patient
- Secondary survey – proceed to identify all other injuries
- Definitive care – develop a definitive management plan

Although it has been acknowledged in recent literature that the ATLS philosophy has its limitations, it still remains probably the most significant advance in trauma care and management in the last three decades. In fact, once the attending clinician is versed in the structure and protocol of the philosophy, it becomes very easy to apply this to any trauma event whether large or small, hence the importance of its emphasis throughout this chapter. Later chapters will deal with the specifics of injury management by region but, before the clinician even gets to the definitive management, it is important that an initial assessment protocol is followed.

There are important considerations when managing paediatric trauma and trauma in the elderly population, which will be discussed later in this chapter.

Triage

Triage is an important concept in modern health-care systems, and three essential phases have developed:

- 1 pre-hospital triage – in order to despatch ambulance and pre-hospital care resources;
- 2 at the scene of trauma;
- 3 on arrival at the receiving hospital.

The brief behind establishing these systems focused on the identification of those immediately at risk of loss of life, then moving to the management of urgent cases and prioritising these into clinically stable but seriously ill and into the most appropriate order for evacuation, and identifying the most appropriate receiving unit. In many western countries, subspecialisation is becoming more and more common, and there are discrepancies in the local availability of services such as neurosurgery, vascular surgery, plastic surgery, orthopaedic surgery and even intensive care facilities in all district admitting units and, as in the US model, many places are giving consideration to the establishment of specialised trauma units that cater for those seriously injured. However, at present, the logistical systems and financial resources that have to be put in place make this an idealistic rather than a realistic goal. Nevertheless, the concept of triage is an important one and should be understood, and it remains the entry point to an organised system of care to maximise outcome in any medical framework.

In trauma, two types of triage situation usually exist:

- 1 *Multiple casualties*. Here, the number and severity of injuries do not exceed the ability of the facility to render care. Priority is given to the life-threatening injuries followed by those with polytrauma.
- 2 *Mass casualties*. The number and severity of the injuries exceed the capability and facilities available to the staff. In this situation, those with the greatest chance of survival and the least expenditure of time, equipment and supplies are prioritised (see Chapter 30).

INTRODUCTION

Modern trauma care is increasing in its complexity and management and, despite measures to reduce the incidence of trauma worldwide, it looks likely to remain the ‘unsolved epidemic’ of the future. The economic impact of trauma and injury is huge globally. Lost wages, medical expenses, administration costs, property damage and indirect costs contribute to the annual cost of over \$400 billion in the USA alone.

Many significant changes have improved trauma care, and many have concentrated on a systematic focused methodology for the management of trauma, particularly in the initial stages. In fact, one can argue that it is the initial assessment that is probably the most important factor in the subsequent outcome of the trauma patient, as it is at this stage that a subsequent care pathway and protocol is formed for definitive treatment.

In essence, trauma can be divided into two basic types:

- Serious and life-threatening injury;
- Significant trauma requiring treatment but not immediately life threatening.

While it is acknowledged that the two can and often do overlap, it is important for the initial assessment to efficiently and carefully distinguish between the two.

The approach to the traumatised patient is very different from that of a patient with an undiagnosed medical condition as, in the latter, an extensive history, past medical history, physical examination from head to toe, differential diagnosis and investigations ordered to confirm or refute this diagnosis are undertaken. In the trauma setting, it is often not possible to obtain such information immediately; hence, a standardised protocol of management is required. The Advanced Trauma Life Support (ATLS) system was therefore created initially in the USA and rapidly taken up globally. At present, over 40 countries worldwide are actively providing the ATLS course to their physicians. In the UK, it is a prerequisite qualification for higher surgical training, and the surgeon cannot be fully accredited unless he or she has successfully completed an ATLS provider course (Summary box 22.1).

MECHANISMS OF TRAUMA

Blunt trauma: patterns of injury

The most common cause of blunt trauma is the motor vehicle. Injuries related to motor vehicles are related to several key factors: the mass and speed of the vehicle at the moment of impact; whether the occupants of the vehicle were restrained; whether the occupant was ejected; and the interaction of the occupant or pedestrian with vehicle parts. Speed is a critical factor: a 10% increase in impact speed translates into a 40% rise in the case fatality risk for both restrained and unrestrained occupants. Ejection from a vehicle is associated with a significantly greater incidence of severe injury. Use of seatbelts is thought to reduce the risk of death or serious injury for front-seat occupants by approximately 45% (Fig. 22.2). Unbelted rear-seat occupants are also at increased risk of serious injury in motor vehicle accidents (MVAs); they may be ejected or thrown forward into the back of the front seat; the impact from unbelted rear-seat passengers on front-seat occupants can be a major determinant of injury. It is estimated that, when rear seatbelts are worn, the risk of death for belted front-seat occupants is reduced by 80%. Although seatbelts reduce mortality overall, they cause a specific pattern of internal injuries. Patients with seatbelt marks have been found to have a fourfold increase in thoracic trauma and an eightfold increase in intra-abdominal trauma compared with those without seatbelt marks (Fig. 22.3) (Summary box 22.2).

Summary box 22.2

Energy and injury prevention

- A 10% increase in speed of impact increases pedestrian fatality risk by 40%
- Seatbelts reduce the risk of injury in a vehicle by 45%

Figure 22.2 Unrestrained driver with severe craniofacial injury (courtesy of Johannesburg Hospital Trauma Unit).

Figure 22.3 Seatbelt mark after motor vehicle accident (courtesy of Johannesburg Hospital Trauma Unit).

In direct frontal MVAs, airbags provide a reduced risk of fatality of approximately 30%. In all crashes, the reduction in risk of death has been estimated at 11%. However, airbags may also cause specific patterns of injury. Three separate at-risk groups have been identified: adult drivers, school-aged children riding in the front passenger seat and infants installed in rear-facing infant car seats placed in the front passenger seat. Adults tend to have severe chest injuries; the infants usually sustain neck or head injury and are unrestrained. Children in the front seat have also died as a result of airbag deployment despite the use of lap and shoulder restraints. In order to reduce the risk of airbag-induced injury, children younger than 12 years should be properly restrained in the back seat. Infants (aged < 1 year) in rear-facing child safety seats should never ride in the front seat of a vehicle fitted with a passenger-side airbag. All vehicle occupants should wear seatbelts, and the seat should be moved as far back as possible from the steering wheel or dashboard.

Motorcyclists experience a death rate 35 times greater than the occupants of cars. Helmets reduce the risk of fatal head injury by about one-third and reduce the risk of facial injury by two-thirds. Fractures of the lower extremities are also common in motorcyclists, occurring in approximately 40% of motorcyclists hospitalised for non-fatal injuries. Injuries due to bicycles account for 800 deaths and approximately 500 000 injuries treated at hospitals every year in the US. Children aged 5–14 years have the highest rates of injury, and head injury accounts for 75% of the deaths. Helmets have been shown to reduce the risk of brain injury for bicyclists by nearly 90%.

Injuries to pedestrians occur disproportionately among school-aged children, the elderly and the intoxicated. Children are most at risk when they live in areas of high traffic density where kerbside parking is prevalent, traffic speed is high and few alternative play areas are available. Poverty, household crowding and poor parental supervision are compounding factors (Summary box 22.3).

Summary box 22.3

Types of injury

- Blunt, e.g. car bonnet
- Penetrating, e.g. knife
- Blast, e.g. bomb
- Crush, e.g. building collapse
- Thermal

Penetrating trauma

Although the incidence of penetrating injuries is increasing, such injuries are uncommon in the UK compared with other countries. Factors include the proximity of the underlying viscera to the path of the penetrating object and the velocity of the missile. The distance from the weapon to the wound may give important information regarding the energy of the injury and therefore predict internal damage.

Blast injury

Terrorism is now a global phenomenon. It is conceivable that civilian, as well as military, surgeons will be exposed to patients injured in explosions. (See Chapter 30).

Crush injury

The association between crush injury, rhabdomyolysis and acute renal failure was first reported during the Second World War in victims trapped during the 'London Blitz'. It has been reported in earthquake and mining accident survivors, after excessive exercise and when limbs have been forced into abnormal postures for prolonged periods, such as during general anaesthesia or coma induced by alcohol or drugs. Prolonged crushing of a muscle mass causes death of the muscle cells, with release of myoglobin and

Figure 22.4 Crush injury to the arm and chest due to prolonged entrapment in a motor vehicle accident (courtesy of Johannesburg Hospital Trauma Unit).

The London Blitz. This is the name given to the German air raids on London between the 7th of September 1940 and the 11th of May 1941, during which it is estimated that more than 15,000 people were killed. Blitz is short for Blitzkrieg, the German for 'lightning war'.

vasoactive mediators into the circulation. Injured muscle also sequesters many litres of fluid, reducing the effective intravascular volume, which results in renal vasoconstriction and ischaemia. Myoglobin is concentrated in the tubules, and precipitates, leading to tubular obstruction.

Early and aggressive volume loading of patients, preferably prior to extrication, is the best treatment. Intensive care is required with close attention to fluid balance and renal replacement therapy if required. Compartment syndrome of a limb may occur (Fig. 22.4) (Summary box 22.4).

Summary box 22.4

Crush injury

- Muscle cells die. If reperfused, they release myoglobin
- Injured tissue sequesters fluid
- Renal shutdown results
- Treatment is fluid loading with monitoring of renal output to maintain diuresis

Thermal injury

See Chapter 28 on Burns.

Alcohol and drugs

Alcohol and other forms of substance abuse are major associated factors in all forms of trauma. Drivers with illegal blood alcohol levels account for nearly one-third of non-fatal injuries, and half of driver deaths. Injury to drunken pedestrians shows even greater alcohol relatedness, as pedestrian accidents account for nearly three-quarters of adult traffic deaths. There is a strong association between problem drinking and high-risk behaviour, such as dangerous driving and violent, aggressive behaviour. Illicit drug use often leads to interpersonal violence as a consequence of the effects of the drugs and the crime required to fund the habit.

ASSESSMENT AND MANAGEMENT OF THE SERIOUSLY INJURED

It is important to remember the trimodal distribution of deaths from trauma with regard to time, first described by Trunkey in the 1980s. There are three 'peaks' as follows:

- Immediate – 50% of all deaths, not possible to save. Usually as a result of massive head injury/brainstem injury/major cardiovascular event.
- Early – within the first few hours, often death from torso trauma.
- Late – 20% of deaths. Usually from organ failure and sepsis, influenced by inadequate early resuscitation and care.

From this emerged the concept of the 'golden hour' to describe the urgent need for treatment of trauma victims within the first hour after injury.

Importance of the multidisciplinary team approach

The team approach to trauma is essential to achieve the best possible outcomes. It is, however, resource intensive. The available personnel and resources can become overwhelmed quickly

in non-hospital settings, smaller institutions in underdeveloped countries and mass casualty situations. Regardless of this, it is essential that the care team is organised prior to patient arrival. Leadership and unity of command are essential, as is communication, with rapid identification of the individual team members. A trauma team leader should be identified prior to patient arrival, who will direct the evaluation and initial resuscitation. By definition, therefore, the person responsible for this role should ideally not have an active hands-on role, but be more a 'traffic controller and information collator'. Additional physicians and midlevel providers are responsible for airway management, conducting primary and secondary surveys and other procedures as necessary. Radiographers should be immediately available and properly trained in the imaging required. Early consultation with senior neurosurgeons, general/vascular surgeons and orthopaedists will be needed. The changing modern media world requires that media involvement is usually immediate, and it is important that there is a spokesperson who acts as a mode of communication between the team caring for the individual(s) and the outside world. This is particularly important in the mass casualty situation where hospitals should have systems in place specifically for communication purposes. Of even more importance is the communication with the patient and members of their immediate family, who must not be neglected even in the seriously injured (Summary box 22.5).

Summary box 22.5

Managing a major trauma situation

- Plan for this eventuality
- Set up the team before the patients arrive
- Organise lines of communication and command

Preparation

- Pre-hospital phase – there must be good coordination and communication pathways set up prior to transfer of the injured from the scene of injury. This will allow time for mobilisation of the team and resources at the receiving hospital (Fig. 22.5).
- In-hospital phase – a resuscitation area should be available

Figure 22.5 The importance of teamwork in pre-hospital care (courtesy of the London Helicopter Emergency Service).

and secured. Equipment in this area should be checked daily and placed where it is immediately accessible. Warmed intravenous crystalloid solutions should be prepared and ready for immediate attachment on arrival. The laboratory team should be warned that blood may be urgently needed. The team should be prepared, ideally with specialty name badges, and standard disease prevention protocols should be put in place, e.g. masks, eye protection, water-impervious aprons, X-ray gowns, gloves, etc. Handover from pre-hospital personnel should be succinct and standardised: Mechanism of injury, Injuries identified including information on injuries to other casualties involved in the same event, vital Signs at the scene and any Treatment administered (MIST) is one such example.

PRIMARY SURVEY AND RESUSCITATION

This includes early triage, and many centres in the USA, UK and Europe have scoring systems to help to identify treatment priorities. The process is based on the energy of trauma, the vital signs and injuries sustained. Patient management must consist of a rapid primary evaluation, resuscitation of vital functions, a more detailed secondary assessment and, finally, the initiation of definitive care. This is the heartbeat core of the ATLS system and constitutes the ABCDE of trauma care (Summary box 22.6).

Summary box 22.6

ABCDE of trauma care

- A – Airway maintenance and cervical spine protection
- B – Breathing and ventilation
- C – Circulation with haemorrhage control
- D – Disability: neurological status
- E – Exposure: completely undress the patient and assess for other injuries

Airway with cervical spine protection

The airway must be evaluated first. If there is vocal response from the patient, then the patient's airway is not immediately at risk, but repeated assessment is prudent. If there is no or limited response, then a rapid investigation and assessment for signs of airway obstruction should be undertaken. This includes inspection for foreign bodies, maxillofacial or mandibular fractures, tracheal or laryngeal injury or oedema (see Fig. 22.2, p. 287).

The Glasgow Coma Score (GCS) is routinely used in head trauma, and further details can be found in Chapter 23. Patients with a significant head injury, where there is an altered level of consciousness or a GCS of 8 or less, usually require placement of a definitive airway. Special considerations must be given to the paediatric airway because of its unique anatomical laryngeal features (see the later section on paediatric trauma).

Measures to ensure a patent airway should be instituted while protecting the cervical spine. Initially, the chin lift or jaw thrust manoeuvres are recommended to achieve this task. A normal neurological examination should not exclude a cervical spine injury. Protection of the cervical spine should be maintained throughout either by stabilisation equipment or by a member of

The Glasgow Coma Score was introduced in 1977 by William Bryan Jennet and Graham Michael Teasdale of The Southern General Hospital, Glasgow, Scotland.

the trauma team when it is required that the patient be moved or turned (Summary box 22.7).

Summary box 22.7

Airway assessment

- Check verbal response
- Clear mouth and airway with large-bore sucker
- If GCS \leq 8, consider a definitive airway; otherwise use jaw thrust or chin lift

Breathing and ventilation

Oxygen must be administered to all trauma patients, usually at high flow and via a reservoir mask. Ventilation requires an adequately functioning chest wall, lungs and diaphragm, and each must be systematically evaluated. Signs of surgical emphysema, dilatation of the neck veins, symmetry of the chest wall, respiratory effort and rate should be evaluated and recorded. Percussion and auscultation should be performed both front and back after log rolling.

Acute tension pneumothorax, flail chest with contusion, massive haemothorax and open pneumothorax are examples of life-threatening injuries that must be identified in the primary survey, i.e. they are *not* radiological diagnoses. Critical findings include the absence of or asymmetry of breath sounds, tracheal deviation, hyperresonance (consistent with tension pneumothorax) or dullness to percussion (haemothorax). Treat pneumothorax, haemothorax and tension pneumothorax with a tube thoracostomy. As an emergency measure in tension pneumothorax, immediately decompress with the insertion of a needle into the pleural space in the mid-clavicular line two finger-breadths below the clavicle, followed by chest drain insertion. Furthermore, it should be noted that, when intubation and ventilation have been necessary in the unconscious patient, a re-evaluation should occur, as intubation and securing of the airway itself may unmask an underlying chest injury. Open chest wounds ('sucking') should be occluded with a three-sided dressing followed by intercostal drain placement through a separate incision. If there is evidence of massive haemothorax (> 1.5 litres of blood), it may lead to severe respiratory compromise, cardiac tamponade and compression of the affected lung; in this situation, operative control of the bleeding is likely to be required immediately (Summary box 22.8).

Summary box 22.8

Breathing

- Give 100% oxygen at high flow
- Check for tension pneumothorax
- Decompress at once if tension pneumothorax is suspected (needle in the second intercostal space)

Circulation and control of bleeding

Assessment here centres on three critical clinical observations:

- 1 *Conscious level.* If this is impaired or altered, one must assume that the patient has lost a significant amount of blood as cerebral perfusion has become compromised.

- 2 **Skin colour.** A patient with pink skin and warm peripheries is rarely critically hypovolaemic, and the converse is true for a pale, ashen, grey-looking patient with ominous signs of hypovolaemia.
- 3 **Pulse.** Full, slow, regular peripheral pulses are usual signs of relative normovolaemia, whereas a rapid, thready pulse or, worse still, one that is not peripherally palpable is a grave sign of hypovolaemic shock, and blood volume must be rapidly restored. Pulse rate changes occur as a rule prior to any shift in the blood pressure.

Recent emphasis has been given to the over-riding priority being primary haemorrhage control and timely surgical intervention rather than overaggressive fluid resuscitation ('permissive hypotension'), but one should guard against complacency, particularly in the at-risk groups, i.e. the elderly, children, patients with head injuries and those in whom the pre-hospital phase has been longer than normal. The elderly and the paediatric population will be discussed as special groups later in the chapter; they have very different physiological responses to volume loss (Summary box 22.9).

Summary box 22.9

Circulation (assessment and warning signs)

- Deteriorating conscious state
- Pallor
- Rapid thready pulse is a more reliable and earlier warning sign than a fall in blood pressure

Disability

The GCS allows for a very rapid assessment of the patient's level of consciousness, pupillary size and reaction, motor function and, therefore, injury level and is also a good prognostic indicator. Further details can be found in Chapter 23.

It should be noted, however, that hypoglycaemia, alcohol and drug abuse may also alter the level of consciousness and should also be excluded. As always throughout the assessment, one must evaluate and re-evaluate constantly to ensure that evolving problems are identified, especially after head injury.

Exposure

The patient must be fully exposed and examined front and back using a carefully controlled log roll. Spinal alignment must be maintained during this procedure with in-line traction. Hypothermia can be rapid following trauma, and warming air blankets are vitally important in the resuscitative phase.

Adjuncts to the primary survey

These include blood samples for full blood count (FBC), coagulation studies, plasma chemistry (urea and electrolytes and, sometimes, toxicology or other case-specific indices), transfusion screening (group and cross-match, etc.), 12-lead electrocardiography (ECG) monitoring and pulse oximetry, if available. The blood can be taken at the same time as securing intravenous access with two large-bore cannulae (14–16G). Other adjuncts are urinary and gastric catheters. Care should be taken when passing gastric catheters nasally in the presence of maxillofacial injury or suspected base of skull fracture. If urethral injury is suspected, as in the case of pelvic diastasis, one should obtain an

emergency room urethrogram prior to catheterisation. Rectal and external genital examination is necessary before catheterisation to rule out serious retroperitoneal injury. Signs include blood at the meatus, scrotal or labial ecchymosis and a high riding prostate in males. Perform a dipstick urinalysis to rule out occult haematuria (Summary box 22.10).

Summary box 22.10

Adjuncts to the primary survey

- Blood – FBC, urea and electrolytes, clotting screen, glucose, toxicology, cross-match
- ECG
- Two wide-bore cannulae for intravenous fluids
- Urinary and gastric catheters
- Radiographs of the cervical spine and chest

Radiographs that are routinely requested and should be available as portable images in the resuscitation room are:

- **Lateral cervical spine.** Note that a normal lateral cervical spine does *not* rule out injury to the cervical spine; once the patient has been successfully stabilised, it is essential that further X-rays are taken, i.e. anteroposterior view and peg/open mouth view. These views should then be correlated with the clinical cervical spine examination prior to announcing that the patient is cleared of cervical spine injury (Fig. 22.6).
- **Anteroposterior chest.** Look at mediastinal size and shift, evidence of pneumothorax/haemothorax (Figs 22.7 and 22.8), fractures of the ribs, surgical emphysema, diaphragmatic shape and position and evidence of pulmonary contusion. A widened mediastinal shadow may represent an aortic rupture.
- **Anteroposterior pelvis.** Looking essentially for fractures and pelvic discontinuity that have the potential for massive blood loss and fatality (Fig. 22.9).

Other more specialised forms of imaging, such as ultrasound, computerised tomography, angiography and diagnostic peritoneal

Figure 22.6 Lateral emergency room cervical spine X-ray showing complete subluxation of cervical vertebrae C5 and C6.

Figure 22.7 Gunshot to the chest (courtesy of Johannesburg Hospital Trauma Unit).

lavage, should be considered after the secondary survey and only when the patient is stable after initial resuscitation.

SECONDARY SURVEY

This starts *after* completion of the primary survey and once initial resuscitative measures have commenced. The purpose of the secondary survey is to identify all injuries and perform a more thorough 'head to toe' examination. If possible, it is here that the patient's history is reviewed. Again, the AMPLE mnemonic from the ATLS group is helpful here (Summary box 22.11).

Summary box 22.11

Review of patient's history (AMPLE)

- Allergy
- Medication including tetanus status
- Past medical history
- Last meal
- Events of the incident

Subsequent physical examination

Examine each region of the body for signs of injury, bony instability and tenderness to palpation.

- *Head and face.* Evaluate the head and face for maxillofacial fractures, ocular injury, open head injury and any evidence of bleeding or discharge from the ears suggestive of a basal skull fracture. Inspect the mouth, mandible, zygoma, nose and ears. This excludes midfacial injury and potential airway compromise.
- *Neck.* Inspect and palpate the cervical spine anteriorly and posteriorly for haematomas, crepitus, tenderness and evidence

Figure 22.8 Chest radiograph in the same patient as in Fig. 22.7, demonstrating a massive haemothorax (courtesy of Johannesburg Hospital Trauma Unit).

Figure 22.9 Open book pelvic fracture with haemodynamic instability requiring urgent stabilisation (courtesy of Johannesburg Hospital Trauma Unit).

of steps on palpation. In trauma where the cause and energy of injury is uncertain and where there has been a significant maxillofacial or head injury, assume a cervical spine injury until definitively excluded with radiology and clinical evaluation. The spine is held immobilised with a hard collar, sandbag and tape across the forehead. Wounds should be fully evaluated and formally explored in theatre if deeper than the platysma muscle layer.

- **Chest.** Review the primary survey and perform full palpation and auscultation of the chest wall front and (once log rolled) back. Palpate the entire chest wall including the clavicle, sternum and ribs. Sternal fractures have a high incidence of damage to the underlying cardiovascular structures, and monitoring must be present for 24–48 hours after injury. Distended neck veins, distant heart sounds and narrow pulse pressure may suggest cardiac tamponade.
- **Neurological.** Examine the GCS repeatedly (at least every 15 min). Perform a full neurological examination if the patient's condition allows. Any evidence of sensory and motor disturbance requires full spinal immobilisation and urgent review by the neurosurgeons or spinal orthopaedic surgeons with imaging as appropriate.
- **Abdomen and pelvis.** Inspect for distension, explore low-velocity local wounds to assess the depth of involvement; high-velocity injuries should be urgently evaluated in the operating room. Palpate the iliac crests for instability to detect significant fractures. Inspect the perineum for evidence of ecchymosis or bleeding. A rectal examination is needed to assess tone, prostate level and to look for bleeding. A high index of suspicion is often required with abdominal injuries, so frequent re-evaluation is important as injuries may not manifest themselves in the early stages.
- **Extremities.** It is often here that attention is diverted immediately when a dramatic injury to the limbs presents itself (Fig. 22.10). It is important to note that, unless there is severe

haemorrhage, the injury to the limb is not immediately life threatening and focus *must* be maintained on the primary survey and sequence as above. Obviously deformed limbs should be manipulated into as near anatomical alignment as possible, remembering to document neurovascular status before and after the intervention. Palpate the upper and lower limbs meticulously and systematically and document all findings. Remember to move the relevant joints to exclude dislocations. Neurovascular status must be recorded for each limb especially if a fracture is identified proximally.

- **Log roll.** Once the patient has been evaluated anteriorly, it is imperative that a log roll is performed to inspect the back. One member of the team is responsible for maintaining in-line spinal stabilisation (usually the anaesthetist when the patient is intubated), and it is on this person's orders that a gentle log roll is performed. Remember that at least four people are required for a safe log roll procedure: one for the spinal in-line traction, one for the torso and one for the pelvis and lower limbs (which ideally should be strapped together). The fourth person removes the spinal board and performs a detailed assessment of the back. Inspect the entire spine from occiput to sacrum for bony abnormalities. Identify any penetrating injuries or exit wounds from gunshot injuries and dress accordingly. Percuss, palpate and auscultate the posterior chest wall.

Re-evaluation

This cannot be stressed enough. It is an integral process in the initial assessment of major trauma and should not stop once the patient leaves the emergency room. It is often some hours or days before injuries to the hands, carpus, feet and ankles are picked up, and this is usually once the patient has stabilised and regained a level of consciousness. It is here that the initial triage of the patient can be assessed and modified accordingly, as minor trauma may evolve into major trauma as time passes.

Continuous monitoring is invaluable here, especially of the

Figure 22.10 (a–d) Severe degloving injuries to the upper and lower limbs following a high-speed road traffic accident. The initial appearance and severity of the injury should not detract from following the important ATLS sequence in evaluating and treating immediate life-threatening injuries.

vital signs and urinary output. In the adult, an output of $0.5 \text{ ml kg}^{-1} \text{ h}^{-1}$ should be adequate, whereas in the paediatric patient, one should expect twice this rate. Pulse oximetry is a useful real-time measure of oxygenation and is sensitive to sudden changes in the patient's ventilation and airway.

Analgesia

Often neglected, it is very important to provide relief of pain in the initial management. Pain and anxiety can produce changes to the vital signs, and it is important that adequate relief is provided. This is usually by a titrated intravenous dose of opiate. The dose must be administered judiciously to avoid respiratory depression and also masking important changes in the patient's status.

Documentation and legal considerations

It is very important to keep meticulous records. Time should be documented for all entries as, in the trauma setting, changes can be rapid. Accurate record-keeping can be facilitated by having a member of the nursing staff whose sole job is to collate and record the information – of course, this is resource dependent. Consent should be sought before treatment if possible; however, in cases where the patient has life-threatening

injury and consent is not possible, it makes sense to treat first and obtain formal consent retrospectively. Forensic evidence must be kept in cases admitted as a result of criminal activity; bullets, clothing, etc. must not be discarded but should be kept for the police. Blood alcohol concentrations and those of other drugs can be very important evidence and have substantial legal implications.

Definitive care and transfer

Definitive care will be discussed in subsequent chapters, but it is important to recognise that there should be as little delay as possible in reaching this stage. Much has been made of the 'golden hour' concept, and one often finds that the majority of patients spend this hour at the scene of injury. Increasingly, it is recognised that early transfer to an appropriate care facility is the most important contributor to successful outcome. When it becomes mandatory to transfer the patient from the initial receiving hospital, the patient must be haemodynamically and cardiovascularly stable. An experienced anaesthetist should be sent with the patient, the airway should be secured and the patient intubated if necessary. Life-saving surgery, e.g. splenectomy, may need to be performed prior to transfer for other injuries.

SPECIAL SUB-GROUP CONSIDERATIONS

Essentially, initial trauma assessment and management in those without serious life-threatening injury is very similar to the guidelines indicated previously. Obviously, a good triage system needs to be in place locally to give first priority to those seriously ill. The assessment philosophy above is a very simple and reproducible one, and there is no reason why similar guidelines and protocols should not be followed when managing those who are not seriously traumatised.

However, there remain two very important groups worthy of separate consideration in the initial management and assessment of trauma, and these are the paediatric and elderly populations. Trauma receiving centres are likely to admit a large proportion of these two population sub-groups in future purely as a result of the rising global population and the increased survival of paediatric numbers worldwide. Each will be considered separately highlighting the differences in initial trauma assessment and management from the adult population.

PAEDIATRIC TRAUMA

Injury is the leading cause of mortality among children and adolescents. Road traffic accidents are the leading cause followed by drowning, house fires, homicides and falls. In fact, falls represent the leading cause of injury in children below the age of 10 years. The sequence of assessment, i.e. ABCDE, resuscitation, secondary survey and definitive care, is the same for adults and children but, in children, the signs of severe injury may be delayed on account of their greater physiological capacity to respond to the injury initially. However, once the physiology decompensates, the rapid deterioration can be devastating. Most serious paediatric trauma is blunt head injury. As a result, it is respiratory distress that occurs more frequently than cardiovascular compromise. The treating physician must be aware of the anatomical and physiological characteristics that make children unique. Children have a smaller body mass and, therefore, there is a greater force applied per unit surface area. The energy is transmitted to a body with less fat, less connective tissue and an immature skeleton; therefore, injuries to multiple organs are more frequent. As the surface area to body volume ratio is high, thermal energy loss is higher and one must guard against hypothermia.

Airway and cervical spine control

Control of the airway is the first priority. Unlike adults, the cause of arrest is not usually cardiac, but respiratory. Anatomically, children differ from adults in that they have a smaller and anterior larynx, floppy epiglottis, short trachea and large tongue. As in the adult, the airway can be opened via the chin lift or jaw thrust manoeuvres. The mouth and oropharynx are cleared of secretions and debris and, prior to inserting mechanical methods of airway maintenance, the child must be pre-oxygenated. The oral

airway should only be inserted in the unconscious child or else gagging and vomiting are likely. The airway should be carefully inserted directly into the oropharynx rather than passing it backwards and rotating 180° as in the adult. This is to minimise iatrogenic injury to the soft palate in children. The size of the endotracheal tube is estimated by the diameter of the child's fifth digit or, more accurately, by the use of the Broselow tapes. Cuffed endotracheal tubes are rarely needed for children under 9 years of age because of the delicate structures within the airway and the fact that the cricoid ring provides an adequate seal. Children can have a more pronounced vagal response to intubation, and this can be minimised by atropine pretreatment, which also reduces the secretions, permitting easier visualisation. Nasotracheal intubation in children younger than 9 years should not be performed because of the possibility of damage to the cranial vault and to the fragile soft tissues causing bleeding. Once past the glottis, the tube should be advanced only 2–3 cm below the vocal cords as the trachea is shorter in infants, and there is a very real risk of intubating the right mainstem bronchus, compromising gaseous exchange. First auscultation and then chest X-ray should be performed to confirm the position of the tube, remembering to re-evaluate regularly to ensure that the tube has not dislodged. Surgical cricothyroidectomy is rarely indicated in the infant or small child, but can be performed in the older child (usually 12 years of age) when the cricothyroid membrane is easily palpable.

Cervical spine control is similar in the child and, again, injury must be assumed, particularly when there has been serious, significant, high-energy trauma.

Breathing and ventilatory control

The respiratory rate in the child decreases with age. Infants require 40–60 breaths per minute, whereas the older child breathes 20 times per minute (Table 22.1). Hypoxia is a common cause of cardiorespiratory arrest; however, before this, hypoventilation causes a respiratory acidosis, which is the commonest acid–base disturbance in the injured child. Correction must be through adequate and controlled ventilation. Flail chest and aortic rupture are uncommon in children due to the elastic nature and resilience of the underlying structures. Pulmonary contusions are not evident in the early chest X-ray but, as before, re-evaluation is necessary for the following 24–48 hours.

Circulation with haemorrhage control

Vital signs vary with age (Table 22.1). Hypotension is a late and ominous sign of hypovolaemic shock. A 30% reduction in circulatory volume is required to manifest a change in the vital signs. Tachycardia is the primary response to circulatory compromise in children but, as in adults, may well be anxiety induced. More subtle signs are loss of peripheral pulse, skin mottling, cooled extremities and reduced pulse pressure. If intravenous access has failed after two attempts, consideration should be given to intraosseous access, especially in children younger than 6 years of

Table 22.1 Paediatric vital signs

Normal vital signs by age	Pulse (beats per min)	Systolic blood pressure (mmHg)	Respiratory rate (breaths per min)
Infant (< 1 year)	160	80	40
Preschool (< 5 years)	140	90	30
Adolescent (> 10 years)	120	100	20

age. The uninjured proximal tibia is the ideal route or, alternatively, the distal femur. The infusion should be discontinued once suitable peripheral access has been acquired. Other options are percutaneous femoral vein access or saphenous vein cutdown at the ankle. Urinary output monitoring should take into account the differences in urinary output with age (Table 22.2).

Disability

Head injury is the commonest cause of disability and death among children in trauma. The principles of assessment and management are similar to those in the adult population with strict avoidance of hypoxia and hypovolaemia. Diffuse axonal injury is more common in children than in adults, who have a higher incidence of intracranial mass lesions.

Exposure

As mentioned above, surface area to volume ratios make children particularly vulnerable to environmental changes, hypothermia in particular. Precautions must be taken in the emergency setting to prevent this occurrence. Overhead lamps or heaters, warming blankets and warmed intravenous fluids and blood are often necessary (Fig. 22.11).

Paediatric secondary survey

This is essentially similar to the head to toe examination described earlier. Consideration must be given to the fact that the liver and spleen are the commonest organs to be injured, and

Table 22.2 Urine output by age in the paediatric population

Age	Optimal urine output
Infant (< 1 year)	2 ml kg ⁻¹ h ⁻¹
Preschool (1–5 years)	1.5 ml kg ⁻¹ h ⁻¹
Child–adolescent (6–16 years)	1 ml kg ⁻¹ h ⁻¹

many of these injuries can be managed non-operatively but, as usual, extreme vigilance in monitoring and re-evaluation is mandatory. A number of visceral injuries are more common in children:

- duodenal haematoma or pancreatic injury – secondary to a handlebar striking the right upper quadrant in under-developed anterior abdominal musculature;
- small bowel perforation and mesenteric injuries;
- bladder injury is more common due to pelvic shallowness;
- restraint from a lap belt (less common now) results in enteric disruption, especially if there is an associated ‘chance’ fracture of the lumbar spine.

Child abuse

Intentional harm to a child is a sad and distressing part of dealing with childhood injury. There are certain markers to look for, and early identification and alerting of child protection authorities may be the single most important intervention for the child involved and prevent a potential future fatality (Summary box 22.12).

Summary box 22.12

Markers for non-accidental injury

- Repeated hospital visits for minor injuries
- Late presentations and multiple visits to different hospitals
- Vague or inconsistent history from the child’s parent or guardian and the child
- Withdrawn behaviour of the child with resistance to examination
- History of abuse in a sibling
- Bite marks, finger marks, belt marks or cigarette burns
- Multiple fractures of different ages
- Perineal injury
- Intracranial haemorrhage without a history of MVA

Figure 22.11 External warming blanket (courtesy of Johannesburg Hospital Trauma Unit).

TRAUMA IN THE ELDERLY POPULATION

There has been recent exposure in the literature with regard to injury in this group of patients, and trauma in the elderly population presents many challenges for the treating physicians. Some of these are not easily overcome due to the fragility of the patient's physiological status and comorbid medical conditions. Despite these poor outcomes, several reviews have advocated an aggressive approach to management because as many as 85% of elderly people return to independent function after significant trauma. It has been documented that trauma care of the injured elderly in a recognised trauma centre resulted in a sevenfold increase in survival compared with a standard receiving unit. This implies that, if one applies careful and considerate management to this fragile group of individuals, good outcome is possible. Unfortunately, despite this, it is often this very group of individuals that is neglected and triaged to low-priority treatment when compared with the younger generation. A study by Velmahos *et al.* in the USA revealed that mortality was significantly reduced when trauma teams were activated purely on the criteria of age alone (70 years or above) rather than waiting for changes in vital parameters. In the USA, the three leading causes of mortality from injury are falls, road traffic accidents and burns. As many as 40% of elderly people who fall will die, but the majority survive resulting in increased hospital stay and repeated visits.

Once the problems have been identified, it is very important for the attending physician to take into consideration the physiological and biological fragility of the elderly trauma patient. It does not require high-velocity or high-energy trauma to put the elderly life at risk following injury. An elderly patient may only be surviving with just enough physiological reserve, and any injury no matter how insignificant may prove fatal (Fig. 22.12). Initial assessment and, more importantly, management has to be even more meticulous in this sub-group of patients. Iatrogenic fluid overload is common, as the newly qualified resident, well versed in the management of normal adult trauma, applies the same principles of resuscitation to the elderly patient. This is a fundamental error of judgement and can have devastating consequences.

The initial assessment, however, does follow the same basic rules of primary survey, resuscitation and secondary survey followed by definitive care or transfer.

Airway and cervical spine control

This is the same for the elderly as it is in the normal population. However, one should watch for dentition status, nasopharyngeal fragility as in children, macroglossia and cervical spine and temporomandibular joint arthritis. Stiffness in the cervical spine may make the usual airway clearing measures difficult.

Breathing and ventilation

In patients with a known history of chronic obstructive airways disease, it may be prudent to consider early intubation and ventilation because of their instability in maintaining respiratory drive. Mortality rates following chest injuries in the elderly are higher; rib fractures and pulmonary contusion are not well tolerated. Pulmonary complications such as atelectasis, pneumonia and pulmonary oedema occur with great frequency and are not helped, as mentioned, by overzealous fluid prescription.

Figure 22.12 Classical shortened externally rotated right lower limb of a subcapital fractured neck of femur – it should be emphasised that this represents a significant major trauma in this vulnerable group of elderly individuals.

Circulation

By the age of 65 years, nearly 50% of the population has coronary artery stenosis. The maximum heart rate decreases with age and, therefore, it may be difficult to detect ongoing hypovolaemic shock just from the pulse rate. Urinary response changes with age; the elderly kidney is more susceptible to damage from hypovolaemia, medications and other nephrotoxins. When assessing the cardiovascular status, it is important to try and establish what the normal systolic blood pressure (SBP) is for that particular patient. An SBP of 120 mmHg may be reassuring in the young but, in the elderly, the level may indicate severe and significant life-threatening shock. Because of this limited cardiac reserve, it is essential that diagnosis of haemorrhage is rapid with early adjuncts used to assist in the diagnosis. Retroperitoneal haemorrhage may occur from relatively minor pelvic or hip fractures, and a patient who fails to stabilise after fluid resuscitation may require prompt angiography and embolisation. Prompt treatment or transfer to an appropriate facility may be life saving.

Disability

Cerebral atrophy is common with increasing age. This leads to increased space within the cranium and therefore some protection from contusion. It is surprising how much blood can collect around the brain before there are overt symptoms. Pre-existing medical conditions may be a cause of confusion in the elderly, making assessment of head injury difficult. Osteoporosis can lead to increased risk of spinal fractures after even very minor injury. Spinal injury may be more common because of pre-existing stiffness and spinal stenosis, thus predisposing to central and anterior cord syndromes.

Exposure and environment

Reduced thermoregulatory ability is well documented in the elderly. Skin vascularity and dermal thickness reduce with age, making wound healing potentially hazardous. It is essential that, as in children, the elderly patient is protected from the effects of hypothermia during the initial assessment and management.

Secondary survey in the elderly

Again, a full head to toe examination must be undertaken after careful 'AMPLE' history-taking. Owing to the friable skin condition, spinal injury should be ruled out quickly, and prolonged use of the spinal board should be avoided, reducing the risk of pressure sores developing. It is commonly a musculoskeletal injury that the patient presents with after a fall, and this is largely as a consequence of pre-existing osteoporosis and osteopenia. Muscle mass decreases with age and, at the age of 50 years, the decline is as high as 10% per decade. The result of this is that the underlying bones and joints are less protected. The commonest fracture is in the proximal femur followed by the humerus and wrist. Isolated hip fractures do not generally cause shock, but the patient has sustained a serious injury to the body and general metabolism. Often, patients are dehydrated and have been lying on the floor for several hours before being discovered. Recent literature suggests that careful resuscitation in these patients followed by early surgical stabilisation improves survival significantly. Analgesia is important in the elderly. Morphine can be titrated and given in small intravenous doses (0.5–1 mg) until adequate pain relief is achieved. A comprehensive medication history allows careful planning of treatment and can serve as warning signs for potential problems. Above all, a multidisciplinary

nary approach must be adopted including the patient and their relatives if the definitive treatment plans are to be successful.

SUMMARY

Trauma is a massive and growing worldwide health burden. Despite injury prevention strategies, a significant number of the world's population will be exposed to or involved in trauma. In the initial assessment and management of these patients, it is demonstrated that the ATLS approach is still the most reproducible protocol for successful outcome. A team approach must be utilised, and good organisation of the system leads to very real reductions in mortality and morbidity globally. The paediatric and elderly are special groups of individuals who have unique inherent differences that must be recognised but, essentially, the framework for assessment remains the same. It is only through education and training that truly significant inroads can be made into this hugely debilitating and resource-intensive 'disease'.

Head injury

LEARNING OBJECTIVES

To understand:

- The anatomy and physiology of the skull and brain
- The classification of head injuries
- Secondary brain injury and its avoidance
- The safe treatment of head injuries

EPIDEMIOLOGY

Head injury is a frequent cause of emergency department attendance, accounting for approximately 3.4% of all presentations, with an incidence of around 450 cases per 100 000 population per year. In the UK, around 500 000 children with head injury attend hospital every year and head injury admissions account for nearly 10% of all paediatric hospital admissions.

Head injury associated with traumatic brain injury (TBI) occurs with an incidence of 20–40 cases per 100 000 population per year. It is the most common cause of death in young adults (age 15–24 years) and is more common in males than females. Road traffic accidents (RTAs) are the most common cause of TBI in the UK, followed by falls and assaults.

The cost of a poor outcome from TBI is measured not only in personal terms but also in the socio-economic costs of neuro-rehabilitation, long-term nursing and supportive care, and lost income generation.

PATHOPHYSIOLOGY

Brain metabolism

Brain oxygen consumption ($CMRO_2$, cerebral metabolic rate for oxygen) is about $3.5 \text{ ml } 100 \text{ g}^{-1} \text{ min}^{-1}$. The brain relies on blood-borne glucose for 90% of its energy requirements.

Cerebral blood flow and autoregulation

Normal cerebral blood flow is approximately $55 \text{ ml } 100 \text{ g}^{-1} \text{ min}^{-1}$ and is usually maintained at a constant level via mechanisms termed cerebral autoregulation. This is despite variations in mean arterial pressure (MAP) of between 50 and 150 mmHg.

In TBI, mechanisms of cerebral autoregulation become disordered. Cerebral blood flow then fluctuates with MAP and the brain is more vulnerable to hypotension.

Intracranial pressure and brain herniation

The brain is confined by a rigid container, the skull. The addition of a mass lesion can initially be compensated for by the displacement of cerebrospinal fluid (CSF) and venous blood out of the intracranial cavity. During this period the intracranial pressure

(ICP) will remain at normal levels (Fig. 23.1). As further expansion of the mass lesion occurs, quite small increases in volume result in relatively large increases in ICP, brain herniation and rapid clinical deterioration (Figs 23.2 and 23.3).

Primary vs. secondary brain injury

Primary brain injury occurs at the time of impact and includes injuries such as brainstem and hemispheric contusions, diffuse axonal injury and cortical lacerations.

Secondary brain injury occurs at some time after the moment of impact and is often preventable. The principle causes of secondary brain injury are hypoxia, hypotension, raised ICP, reduced cerebral perfusion pressure and pyrexia (Summary box 23.1). Prevention of secondary brain injury results in improved neurological outcome after head injury and may make the difference between independent survival and dependent survival/death.

Figure 23.1 As a mass lesion increases in size there is initially a compensation during which the intracranial pressure remains normal. After the point of decompensation, very small increases in size of the mass lesion cause marked increases in intracranial pressure.

Figure 23.2 Normal intracranial contents are brain tissue, cerebrospinal fluid (CSF) and arterial and venous blood. During the compensation phase, CSF and venous blood volumes are reduced. When this egress of CSF and venous blood is maximal, further increases in the size of the mass lesion will cause brain herniation.

Summary box 23.1

Causes of secondary brain injury

- Hypoxia: $PO_2 < 8$ kPa
- Hypotension: systolic blood pressure (SBP) < 90 mmHg
- Raised intracranial pressure (ICP): ICP > 20 mmHg
- Low cerebral perfusion pressure (CPP): CPP < 65 mmHg
- Pyrexia
- Seizures
- Metabolic disturbance

Figure 23.3 Brain herniation. Herniation of the cingulate gyrus under the falx cerebri is called subfalcine herniation (1). Herniation is associated with midline shift (2). Herniation of the uncus of the temporal lobe (3) is associated with compression of the ipsilateral third nerve. Central herniation (4) and tonsillar herniation (5) are associated with compression of brainstem structures.

CLASSIFICATION OF HEAD INJURY

Glasgow Coma Score

Severity of head injury is classified according to the Glasgow Coma Score (GCS) (Table 23.1), as the GCS – and in particular the motor score – is the best predictor of neurological outcome:

- minor head injury: GCS 15 with no loss of consciousness (LOC);
- mild head injury: GCS 14 or 15 with LOC;
- moderate head injury: GCS 9–13;
- severe head injury: GCS 3–8.

Blunt vs. penetrating

Head injury may be classified as blunt or penetrating. Penetrating head injuries are further divided into low-velocity injuries such as those caused by stabbing and high-velocity injuries such as gunshot injuries (Figs 23.4 and 23.5).

Morphological

A head injury may be classified according to the type of injury that has occurred.

Skull fractures may be divided into vault or base of skull fractures. Vault fractures may be open or closed, linear or comminuted, depressed or non-depressed. Base of skull fractures may or may not be associated with CSF rhinorrhoea and otorrhoea or cranial nerve palsy.

Intracranial haematomas may be extradural, subdural, subarachnoid or intracerebral. Areas of mixed-density intracerebral haematoma in head injury are termed contusions.

CLINICAL FEATURES

History

A history (Summary box 23.2) should begin with the mechanism of injury. A dangerous mechanism of injury such as a fall from a

Figure 23.4 High-velocity penetrating head injury. This axial computerised tomography (CT) scan of the head was performed for a patient with a gunshot injury. Note the frontal soft tissue swelling, skull fracture and intracranial air (black). The shotgun pellets cause large CT artefacts: one pellet is lodged in the frontal lobe, the other sits just in front of the brainstem in the prepontine cistern.

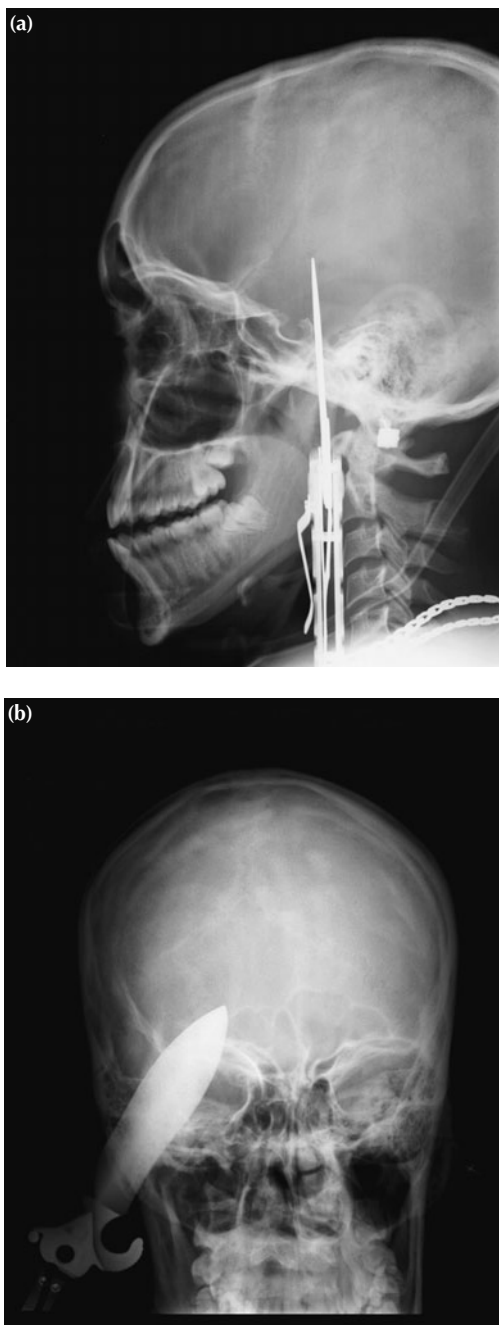

Figure 23.5 Low-velocity penetrating head injury. Lateral (a) and anteroposterior (b) skull radiographs of a patient who has sustained a stab wound to the head.

height or a high-speed motor vehicle accident should make you suspicious of multisystem injury, including spinal injury. A head injury with LOC when there is no clear accidental mechanism of injury should prompt you to think of non-accidental causes of collapse, such as syncope or aneurysmal subarachnoid haemorrhage, or medical conditions, such as hypoglycaemia.

Try to establish the neurological status of the patient at the time of the injury and soon afterwards. Is there a history of LOC or amnesia? Amnesia may be antegrade (for events after the injury) or retrograde (for events preceding the injury). Was the

patient responding, moving and talking appropriately after the incident? Was there evidence of seizure activity?

In the severely head-injured patient, what was the GCS at the scene, prior to intubation or on arrival at hospital? Have there been any abnormalities of pupillary responses? Is there a history of possible hypoxia or cardiovascular instability?

As with all trauma patients, any available history regarding pre-existing medical conditions, medication and drug allergies will be useful. In particular, the use of medications such as anti-coagulants or anti-platelet drugs will be relevant to a patient with an intracranial haematoma. Is there a history of alcohol or illicit drug use? Is the patient on insulin?

Summary box 23.2

Taking a history in head injury

- Mechanism of injury
- Loss of consciousness or amnesia
- Level of consciousness at scene and on transfer
- Evidence of seizures
- Probable hypoxia or hypotension
- Pre-existing medical conditions
- Medications (especially anticoagulants)
- Illicit drugs and alcohol

Examination

Examination (Summary box 23.3) should begin with resuscitation and a primary survey. The cervical spine should be immobilised with three-point fixation. 'D' in the ABCDE approach to a primary survey stands for disability and should include assessment of pupillary size and reactivity, GCS and the presence of focal neurological signs. A full head, neck and peripheral nerve examination is performed as part of the secondary survey. Neurological examination should be repeated frequently and recorded, as changes in neurological status imply alterations in ICP and changes in the GCS (especially deterioration) are much more important indicators of the need for treatment than any absolute level.

The GCS is composed of eye (E), verbal (V) and motor (M) responses (see Table 23.1). The best possible score is 15/15 and

Table 23.1 Glasgow Coma Score (GCS)

Eyes open	Spontaneously	4
	To verbal command	3
	To painful stimulus	2
	Do not open	1
Verbal	Normal oriented conversation	5
	Confused	4
	Inappropriate/words only	3
	Sounds only	2
	No sounds	1
	Intubated patient	T
Motor	Obeys commands	6
	Localises to pain	5
	Withdrawal/flexion	4
	Abnormal flexion (decorticate)	3
	Extension (decerebrate)	2
	No motor response	1

the worst possible score is 3/15. For each category, the score given is the best score obtained during the examination. For example, if a patient localises to pain on one side and extends to pain on the other then the motor score is 5/6. If the patient is not eye opening or obeying commands in response to verbal stimuli, then a painful stimulus must be applied. This stimulus should ideally be applied in the region of trigeminal nerve innervation, such as the supraorbital ridge, but it is commonly accepted practice to use a sternal rub or trapezius squeeze. A patient who is eye opening to painful stimuli, saying occasional words and flexing to pain has a GCS of 9/15 (E2, V3, M4). Always record the three components of the GCS and use this when communicating with other doctors. If a patient is intubated then the verbal score is 'T'. For example, a patient who opens eyes to speech (E2), is intubated (VT) and localises to pain (M5) has a GCS of 7T/15.

The pupillary light response should be recorded. The pupillary size is recorded in millimetres and the light response as present, sluggish or absent. Anisocoria or an asymmetrical sluggish response may suggest partial third nerve dysfunction on the side with the larger or sluggish pupil, implying uncal herniation as a result of a mass on the ipsilateral side. As the third nerve becomes increasingly compromised the ipsilateral pupil will become fixed and dilated. There are several pitfalls in the examination of pupillary responses in a head-injured patient. It may be difficult or impossible to expose the cornea because of periorbital bruising. Direct ocular trauma may cause a traumatic mydriasis that can be confused with a third nerve palsy. Traumatic mydriasis is suspected if there is evidence of ocular trauma and if the pupillary dilatation has been present since the time of injury. The patient may have cataracts or other pre-existing causes of anisocoria such as a Holmes–Adie pupil.

Secondary survey in a head-injured patient also includes a detailed examination of the head, face and neck. First, look and feel the scalp. There may be evidence of external head injury such as subgaleal haematoma or scalp laceration, which may be a cause of significant external blood loss. Palpation of a scalp laceration may reveal an underlying skull fracture with or without a CSF leak. Look for clinical evidence of skull base fracture: bilateral periorbital bruising (raccoon eyes), Battle's sign (bruising over the mastoid, see Fig. 23.6), CSF rhinorrhoea or otorrhoea, or haemotympanum. Bleeding from an ear may result from local trauma or from a skull base fracture with a perforated tympanum. A skull base fracture may be associated with a facial or vestibulo-cochlear cranial nerve injury. Examine the eyes. Look for evidence of injury to the conjunctiva or cornea. Re-examine the pupils. Using an ophthalmoscope, look for major hyphaema or retinal detachment. Examine eye movements: gaze paresis, dysconjugate gaze or roving eye movements suggest midbrain or brainstem dysfunction. Assess the facial skeleton for evidence of orbital ridge, zygomatic or maxillary fractures.

A peripheral nerve examination should record limb tone, evidence of motor weakness or sensory loss, and reflexes. In those patients with an associated spine injury it is important to document neurological deficits, particularly if the patient is likely to be

Figure 23.6 Battle's sign. A skull base fracture may be associated with bruising over the mastoid process.

moved to the operating theatre or to intensive care where such an assessment will not be possible for some time afterwards.

The neurological examination must be recorded and repeated in a patient admitted with head injury. A change in neurological status that is picked up early will result in timely investigation and treatment of emergent problems and will help prevent secondary brain injury.

Summary box 23.3

Examination in head injury

- Glasgow Coma Score
- Pupil size and response
- Lateralising signs
- Signs of base of skull fracture
 - Bilateral periorbital oedema (raccoon eyes)
 - Battle's sign (bruising over mastoid)
 - Cerebrospinal fluid rhinorrhoea or otorrhoea
 - Haemotympanum or bleeding from ear
- Full neurological examination: tone, power, sensation, reflexes

MANAGEMENT OF MILD HEAD INJURY (GCS 14–15)

The majority of patients presenting to hospital with a mild head injury are discharged from the emergency department after history, examination and a period of observation. The following criteria must be met before discharge: the patient must have a

A raccoon is a small mammal native to North and Central America which has a pale face with dark rings round its eyes.

Sir Gordon Morgan Holmes, 1876–1965, Physician, the National Hospital for Nervous Diseases, Queen Square, London, England.

William John Adie, 1886–1935, Physician, the National Hospital for Nervous Diseases, Queen Square, London, England.

William Henry Battle, 1855–1936, Surgeon, St. Thomas's Hospital, London, England.

GCS of 15/15 with no focal neurological deficit; the patient must be accompanied by a responsible adult and should not be under the influence of alcohol or other drugs; verbal and written head injury advice must be given to the patient and their accompanying adult.

Written head injury advice describes to patients the symptoms that should prompt them to obtain further medical advice, which usually involves a return to the emergency department. These include persistent or worsening headache despite analgesia, persistent vomiting, drowsiness, visual disturbance such as double or blurred vision, and development of weakness or numbness in the limbs.

Some patients with mild head injury are at significant risk of intracranial haematoma and require a computerised tomography (CT) scan. Selecting which patients should have a CT scan is not always easy. On the one hand, scanning all patients with minor head injury would be expensive, time-consuming and would unnecessarily expose thousands of patients to ionising radiation. On the other hand, a missed intracranial haematoma is a potentially life-threatening medical error. The National Institute for Health and Clinical Excellence (NICE) has published some guidelines for when to carry out a CT scan in a patient with mild head injury (Summary box 23.4). If a patient fulfils the criteria for a CT scan according to these guidelines, then the decision to discharge the patient without a scan should only be made by a senior clinician experienced in the management of head injury.

Summary box 23.4

NICE guidelines for computerised tomography (CT) in head injury

- Glasgow Coma Score (GCS) < 13 at any point
- GCS 13 or 14 at 2 hours
- Focal neurological deficit
- Suspected open, depressed or basal skull fracture
- Seizure
- Vomiting > one episode

Urgent CT head scan if none of the above but:

- Age > 65
- Coagulopathy (e.g. on warfarin)
- Dangerous mechanism of injury (CT within 8 hours)
- Antegrade amnesia > 30 min (CT within 8 hours)

MANAGEMENT OF MODERATE TO SEVERE HEAD INJURY

Management of a patient with a moderate to severe head injury begins with resuscitation and a primary survey. The principle aim of treatment is the prevention of secondary brain injury and this is best achieved by the avoidance of hypoxia and hypotension. It follows that investigations such as a CT scan of the head are of secondary importance to restoring normal oxygenation and blood pressure, even if that means going to the operating theatre to prevent on-going abdominal or pelvic blood loss. The cervical spine must be immobilised with three-point fixation until such time as an appropriate radiological investigation can be performed.

Having completed the primary survey and established the presence of a moderate to severe head injury, the next appropriate step is a CT scan of the head. This investigation is aimed

at identifying an intracranial haematoma, the evacuation of which will reduce intracerebral pressure and reduce the likelihood of secondary brain injury. The CT scan will also provide information about scalp soft tissue injury, skull fracture, including base of skull fracture, and lesions not requiring immediate surgery, such as small intracerebral contusions. In the case of an intubated patient, it is useful at this point to request, in addition to a CT scan of the head, a CT scan of the entire cervical spine with three-dimensional reformatting to expedite radiological cervical spine clearance.

Early consultation with the local neurosurgical service is advised. Simple measures to reduce ICP include positioning the patient with the head up 20–30° [reverse Trendelenburg (head up) when the spine has not been cleared] and making sure that the cervical immobilisation collar is not so tight as to restrict venous return from the head. In patients with pupillary dilatation suggesting acutely raised ICP, the administration of 0.5 mg kg⁻¹ of 20% mannitol will temporarily reduce ICP during interhospital transfer or on the way to theatre. Excessive use of this osmotic diuretic can lead to hypovolaemia and hypotension.

SURGICAL MANAGEMENT OF HEAD INJURY

Extradural haematoma

An extradural haematoma (EDH) is a neurosurgical emergency. An EDH is nearly always associated with a skull fracture and is more common in young male patients. The skull fracture is associated with tearing of a meningeal artery and a haematoma accumulates in the space between bone and dura. The most common site is temporal, as the pterion is not only the thinnest part of the skull but also overlies the largest meningeal artery – the middle meningeal. An EDH may also occur in other regions such as frontal as well as in the posterior fossa. They are not always arterial: disruption of a major dural venous sinus can result in an EDH. The force required to sustain a skull fracture can be surprisingly small – a fall from standing or a single blow to the head.

The classical presentation of an EDH, occurring in less than one-third of cases, is initial injury followed by a lucid interval when the patient complains of a headache but is fully alert and orientated with no focal deficit. After minutes or hours a rapid deterioration occurs, with contralateral hemiparesis, reduced conscious level and ipsilateral pupillary dilatation as a result of brain compression and herniation. This type of presentation reinforces the important point that there may be no primary brain injury with an EDH. Early recognition and treatment of the condition is likely to result in full recovery whereas delays in diagnosis and treatment can result in death from secondary brain injury. Of course, a patient with an EDH may also sustain a primary brain injury and have a reduced conscious level from the time of injury.

The features of an EDH on a CT scan are a lentiform (lens-shaped or biconvex) hyperdense lesion between the skull and brain (Fig. 23.7). There may be an associated mass effect on the underlying brain, with or without a midline shift. Areas of mixed density may be seen in a lesion that is actively bleeding.

The treatment of an EDH is immediate surgical evacuation

Friedrich Trendelenburg, 1844–1924, Professor of Surgery successively at Rostock (1875–1882), Bonn (1882–1895) and Leipzig (1895–1911), Germany. The Trendelenburg position was first described in 1885.

Figure 23.7 (a) An axial computerised tomography (CT) scan of a large left-sided extradural haematoma with mass effect and midline shift. (b) An axial CT scan of a left frontal extradural haematoma. Note the biconvex shape of the haematomas. (c) A surgical temporal bone exposure showing a linear skull fracture with underlying extradural haematoma visible through a burr hole.

via a craniotomy. Access to neurosurgical services often requires an interhospital transfer and delays in time to theatre have a direct impact on patient outcome. Expedited transfer and good communication between medical teams is the key to good results. The overall mortality for all cases of EDH is about 18% but for isolated EDH it is about 2%.

Acute subdural haematoma

Acute subdural haematoma (ASDH) differs from EDH in terms of pathophysiology, presentation and prognosis.

An ASDH accumulates in the space between the dura and the arachnoid. To produce a subdural haematoma there has usually been some disruption of a cortical vessel or brain laceration, and ASDH is nearly always associated with a significant primary brain injury. Patients with ASDH usually present with an impaired conscious level from the time of injury, but further deterioration can occur as the haematoma expands.

The CT appearance of an ASDH is also hyperdense (acute blood) but the haematoma spreads across the surface of the brain

giving it a rather diffuse and concave appearance (Fig. 23.8). This occurs because there is less resistance to blood moving through the subdural space than through the extradural space.

The treatment of an ASDH is usually evacuation via a craniotomy. Small haematomas with little mass effect may be managed conservatively in neurosurgical centres. It may be inappropriate to perform surgery on cases with a very poor prognosis: factors such as best GCS, pupillary reactivity, age and presence of anti-coagulants must be taken into account. Early consultation with neurosurgery is advised.

The mortality rate from ASDH is much higher than for EDH and is as high as 40% in some series.

Subarachnoid haemorrhage

Although aneurysms are the most common cause of spontaneous subarachnoid haemorrhage, trauma is by far the commonest cause of subarachnoid haemorrhage overall. In rare cases, a spontaneous aneurysmal haemorrhage immediately precedes a head injury. Traumatic subarachnoid haemorrhage is managed conservatively.

Figure 23.8 An axial computerised tomography (CT) scan of a right-sided acute subdural haematoma. Note the midline shift to the left. The right hemisphere is swollen relative to the left, reflecting an underlying primary brain injury on the right.

Chronic subdural haematoma

Chronic subdural haematomas (CSDH) usually occur in the elderly and are more common in those on anti-coagulant or anti-platelet agents. There is usually but not always a history of minor head injury in the weeks or months prior to presentation. It is thought that small bridging veins tear and cause a small ASDH which is clinically silent. As the haematoma breaks down it increases in volume, leading to a mass effect on the underlying brain.

Clinical features of CSDH include headache, cognitive decline, focal neurological deficits and seizures. It is important to exclude hypoxic, metabolic and endocrine disorders in this group of patients.

The CT appearance of a CSDH is variable. Acute blood (0–10 days) is hyperdense whereas subacute blood (10 days to 2 weeks) is isodense relative to brain; chronic blood (> 2 weeks) is hypodense. A CSDH will often have areas of more recent haemorrhage in more dependent (posterior) areas and is then termed an acute-on-chronic subdural haematoma. The extent of acute versus chronic blood is important as it affects the method of haematoma evacuation.

Treatment of a CSDH and most acute-on-chronic subdural haematomas is evacuation via burr hole(s) rather than craniotomy. This is an important distinction as burr holes can be easily performed under local anaesthetic in an elderly patient with extensive comorbidity.

Cerebral contusions

Cerebral contusions are common in head injury and result from the brain being damaged by impacting against the skull either at the point of impact (the ‘coup’) or on the other side of the head (‘contre-coup’) or as the brain slides forwards and backwards over the ridged cranial fossa floor (most often affecting the inferior frontal lobes and temporal poles).

Figure 23.9 (a) An axial computerised tomography (CT) scan showing cerebral contusions at the base of the frontal lobe bilaterally and in the right temporal pole. (b) An axial CT scan showing a right extradural haematoma as well as widespread cerebral contusions, which are worse in the left frontal lobe, and traumatic subarachnoid blood in the third and lateral ventricles.

Cerebral contusions on CT appear heterogeneous with mixed areas of high and low density (Fig. 23.9). There may be an associated mass effect. A contusion may be described as an intracerebral haematoma if the lesion contains a large amount of fresh haemorrhage and therefore appears uniformly hyperdense.

Cerebral contusions rarely require immediate surgical treatment. A head-injured patient with cerebral contusions must be admitted for observation as these lesions will tend to mature and expand for 48–72 hours following injury. A small proportion of cerebral contusions will require delayed surgical evacuation to reduce the mass effect.

Intracranial pressure monitoring

ICP monitoring is a useful adjunct in the management of unconscious patients with head injury. A sustained ICP of > 20 mmHg is associated with a worse outcome. The ICP can also be used to calculate the cerebral perfusion pressure (see Circulation and cerebral perfusion pressure, below). An ICP monitor may be parenchymal or ventricular (Fig. 23.10).

Decompressive craniectomy

Controversy still surrounds the use of decompressive craniectomy. The purpose of a decompressive craniectomy is to control the ICP in patients without a focal intracerebral haematoma in whom the ICP is refractory to maximal medical therapy. The operation involves removing a large section of skull and opening the dura, allowing the swollen brain to expand underneath the scalp (Fig. 23.11). The bone flap is stored and can be replaced 3–6 months later when the patient has made a good neurological recovery and the brain swelling has resolved.

Summary box 23.5

Surgical management of raised intracranial pressure

- Early evacuation of focal haematomas: EDH, ASDH
- Cerebrospinal fluid drainage via ventriculostomy
- Delayed evacuation of swelling contusions
- Decompressive craniectomy

MEDICAL MANAGEMENT OF SEVERE HEAD INJURY

Environment

Severe head injury is best managed in a neurointensive care setting and mortality is reduced compared with general units even if no neurosurgery is performed (Fig. 23.12). The patient should be positioned with the head up 30° if spinal clearance allows. It is important to ensure that the cervical immobilisation collar does not obstruct venous return from the head.

Figure 23.10 Intracranial pressure (ICP) monitoring. A tunnelled parenchymal ICP monitor can be inserted through a twist drill burr hole, in this case into the left frontal lobe.

Figure 23.11 Decompressive craniectomy. A right-sided decompressive craniectomy has been performed allowing the swollen right hemisphere to herniate through the skull defect. This procedure can help to control raised intracranial pressure. The bone flap can be stored and replaced at a later date.

Airway and ventilation

A definitive airway is required in cases of severe head injury for several reasons: the patient in traumatic coma is unable to protect their airway and is at risk of aspiration; gas exchange may be impaired; the safe interhospital transfer of a patient with an impaired conscious level and who is at risk of further neurological deterioration en route requires intubation.

Normal gas exchange in the head-injured patient must be confirmed and maintained. Hypoxia and hypercapnia will result in increased brain ischaemia and secondary brain injury. A single episode of hypoxia with a $PO_2 < 8$ kPa is associated with a worse outcome in traumatic coma.

Figure 23.12 Monitoring in neurointensive care. The traces from top to bottom display electrocardiogram (ECG), continuous arterial blood pressure, central venous pressure, intracranial pressure and oxygen saturation.

In the intubated patient, normocapnia is maintained: PCO_2 4.5–5.0 kPa. The cerebral vasculature is reactive to CO_2 levels. A rise in PCO_2 in a head-injured patient with an abnormally high ICP will result in generalised cerebral vasodilatation, an increase in cerebral blood volume, further raised ICP and reduced cerebral perfusion. Conversely, a fall in PCO_2 will result in generalised vasoconstriction, a fall in cerebral blood volume and a drop in ICP. Although this global effect on ICP may seem beneficial it occurs at the expense of perfusion of ischaemic areas of the brain and therefore will result in a higher likelihood of cerebral infarction than recovery from ischaemia. It is for this reason that hyperventilation to induce hypocapnia is used only by anaesthetists experienced in the care of head-injured patients as an emergency measure, to temporarily reduce ICP while definitive care or urgent investigation is being organised.

Circulation and cerebral perfusion pressure

Hypotension sits alongside hypoxia as a major cause of secondary brain injury. A single episode of hypotension with a systolic blood pressure of < 90 mmHg is associated with a worse outcome in traumatic coma. Cerebral perfusion pressure should be maintained at > 65 mmHg in severely head-injured patients. This is an independent prognostic factor in neurological outcome. Global cerebral perfusion can be estimated by the equation:

$$\begin{aligned} \text{Cerebral perfusion pressure} &= \text{mean arterial} & (23.1) \\ \text{pressure} - \text{intracranial pressure} \\ \text{CPP} &= \text{MAP} - \text{ICP} \end{aligned}$$

If the ICP is 20 mmHg, it follows that the MAP should be ≥ 85 mmHg.

Control of intracranial pressure

Normal ICP is 8–12 mmHg. A sustained ICP of > 20 mmHg is associated with poor outcome. As well as the environmental, respiratory and circulation measures outlined above, measures to reduce ICP include:

- *Sedation*, with or without muscle relaxants.
- *Use of diuretics*. Judicious use of diuretics such as furosemide and mannitol will temporarily reduce cerebral swelling and ICP.
- *Thermoregulation*. Pyrexia will increase the brain metabolic rate and should be avoided. Active cooling to reduce the metabolic rate is of questionable overall benefit but is used in some centres.
- *Use of barbiturates*. The use of agents such as thiopentone reduces the brain metabolic rate and helps reduce ICP. Barbiturates are associated with respiratory and metabolic complications and can take days to clear from the body. Dosage is guided by burst suppression on electroencephalogram (EEG) monitoring.
- *Maintaining fluid and electrolyte balance*. Severely brain-injured patients are susceptible to disturbances of sodium haemostasis such as diabetes insipidus and syndrome of inappropriate antidiuretic hormone (SIADH).
- *Seizure control*. Seizures increase the brain metabolic rate and should be controlled. Prophylactic anticonvulsants may reduce seizures in the first week.

Steroids in severe head injury are associated with increased mortality and should not be used.

Summary box 23.6

Medical management of raised intracranial pressure

- Position head up 30°
- Avoid obstruction of venous drainage from head
- Sedation +/- muscle relaxant
- Normocapnia 4.5–5.0 kPa
- Diuretics: furosemide, mannitol
- Seizure control
- Normothermia
- Sodium balance
- Barbiturates

Figure 23.13 Axial computerised tomography (CT) scans with bone windowing showing and minimally displaced right fronto-orbital, left frontal and left parietal fractures (a) and a displaced left parietal skull fracture (b).

SKULL FRACTURES

Skull vault fractures

Indications for surgery for skull fracture include elevation of significantly depressed fragments and wound debridement for compound fractures, particularly if there is evidence of underlying dural injury such as contusion or CSF leak. Fracture elevation is rarely needed for cosmesis alone (Fig. 23.13 on the previous page).

Base of skull fractures

Base of skull fractures may be associated with seventh or eighth nerve palsies. CSF otorrhoea or rhinorrhoea often resolves spontaneously. Antibiotics are not required prophylactically unless for concomitant facial fractures. A delayed craniotomy and anterior fossa dural repair is occasionally required for persistent CSF leak to prevent meningitis.

LONG-TERM SEQUELAE OF HEAD INJURY

Neurorehabilitation

Long-term management of the brain-injured patient requires the concerted efforts of medical, nursing, physiotherapy and speech and occupational therapy teams.

Neuropsychology

Neuropsychological sequelae are common after head injury and sometimes occur after relatively minor head injury. Post-concussional symptoms include headache, dizziness, impaired short-term memory and concentration, easy fatigability, emotional disinhibition and depression.

Seizures

Long-term epilepsy affects < 5% of patients admitted with head injury. The use of prophylactic anticonvulsants does not seem to change the long-term incidence of epilepsy.

Delayed CSF leak

Patients with delayed or on-going CSF leak should be investigated with CT cisternography or CSF isotope studies prior to surgical repair.

OUTCOMES AFTER HEAD INJURY

Outcome scores

The Glasgow Outcome Score (GOS) is shown in Table 23.2. A good recovery (GOS 5) does not mean that there is no deficit but implies independent functioning and the possibility of returning to work. Patients with GOS 4 remain independent though with a disabling deficit. Patients with severe disability (GOS 3) are dependent on others for at least some of their care. Patients in a vegetative state (GOS 2) show no awareness of themselves or their environment. This state is not considered permanent until at least 1 year after traumatic brain injury.

Table 23.2 Glasgow Outcome Score (GOS)

Good recovery	5
Moderate disability	4
Severe disability	3
Persistent vegetative state	2
Dead	1

Neck and spine

LEARNING OBJECTIVES

To be familiar with:

- The accurate assessment of spinal cord injuries
 - The mechanisms of spinal injuries and the pathophysiology of spinal cord trauma
 - The basic management of spinal trauma and the major pitfalls
- The prognosis of the various types of spinal cord injury, factors affecting functional outcome and common associated complications

EPIDEMIOLOGY OF SPINAL CORD INJURY

The incidence of spinal cord injury ranges from 27 to 47 cases per million population per year. Road traffic accidents remain the leading cause of spinal cord injuries worldwide. Pre-hospital survival and life expectancy of spinal cord injury victims have improved significantly.

EVOLUTION OF THE MANAGEMENT OF SPINAL CORD INJURY

There is clear evidence to show that fewer complications, a decreased length of stay and improved patient outcome occur when patients with spinal cord injury are treated in a specialised unit (Summary box 24.1).

Summary box 24.1

Spinal cord injury

- The incidence of spinal cord injury remains constant
- Pre-hospital and post-injury survival have increased significantly
- Outcome is improved in regional/national spinal cord injury centres

ANATOMY OF THE SPINE AND SPINAL CORD

Spinal column anatomy

The vertebral column is composed of a series of motion segments (Fig. 24.1). A motion segment consists of two adjacent vertebrae, intervertebral disc and ligamentous restraints (Fig. 24.2). The neural elements are contained within the spinal canal.

Figure 24.1 The spinal motion segment.

Figure 24.2 Ligamentous spinal restraints. (1) Anterior longitudinal ligament; (2) intervertebral disc and posterior longitudinal ligament; (3) facet joint capsule; (4) interspinous ligament; (5) supraspinous ligament.

Regional variations

Upper cervical spine anatomy is designed to facilitate motion (Fig. 24.3), and stability in this region is dependent on ligamentous restraints (Fig. 24.4). Upper cervical spinal cord injury is uncommon as the canal is capacious. The anatomy of each vertebra from C3–C7 is similar.

The cervicothoracic junction is a transitional zone, going from mobile to fixed, and is thus prone to injury. It may be difficult to visualise this area on radiography (Fig. 24.5).

The thoracic spine is relatively rigid because of the stabilising influence of the thorax. Significant disruption of the thoracic spine requires major energy transfer and associated visceral and vascular injuries are common.

The thoracolumbar junction is another transitional zone that is prone to injury; this is the most common area of injury outside the cervical spine (Fig. 24.6).

The three-column concept of spinal stability

The spinal column can be divided into three columns: anterior, middle and posterior (Fig. 24.7). When all three columns are injured the spine is unstable. Instability may also exist in some two-column injuries (Summary box 24.2).

Figure 24.3 Atlantoaxial bony anatomy.

Figure 24.4 Atlantoaxial ligaments.

Figure 24.5 Cervicothoracic facet subluxation (easily missed with inadequate radiography).

Figure 24.6 Coronal T2-weighted magnetic resonance imaging scan demonstrating a fracture dislocation at the thoracolumbar junction.

Summary box 24.2

Spinal column anatomy

- Upper cervical spine stability is dependent on ligamentous restraints
- Major energy transfer is required to significantly disrupt the thoracic spine
- The cervicothoracic and thoracolumbar junction are transitional zones and are therefore prone to injury
- The need for surgical fixation of a spine fracture depends upon the stability of the fracture type

Figure 24.7 The three-column model of spinal stability.

Spinal neuroanatomy

The spinal cord extends from the foramen magnum to the T12/L1 junction where it ends as the conus medullaris (Fig. 24.8). Below this level lies the cauda equina. Figure 24.9 illustrates a cross-section of the spinal cord. It consists of central grey matter (neuronal cell bodies) surrounded by white matter (axons). The lateral spinothalamic tracts transmit pain and temperature sensation, the lateral corticospinal tracts are responsible for motor function and the posterior columns transmit position, vibration and deep pressure sensation.

A spinal nerve root exits on both sides of the spinal cord at each level. There are eight cervical roots. The C1 root exits above the C1 body, the C2 root exits between C1 and C2 and the C8 root exits below C7. All thoracic and lumbar nerve roots exit below the pedicle of the same number.

PATHOPHYSIOLOGY OF SPINAL CORD INJURY

The primary injury

This injury occurs when the skeletal structures fail to dissipate the energy of the primary mechanical insult, resulting in direct energy transfer to the neural elements. The injury may occur directly by flexion, extension, axial loading, rotation or traction,

or by compression of the cord by a fragment of bone and/or disc material.

The secondary injury

Haemorrhage, oedema and ischaemia result in a biochemical cascade that causes the secondary injury. This may result in further loss of neurological function. Prolonged hypotension and poor oxygenation compound the situation so it is important that the patient is adequately resuscitated. The spinal column should be realigned as soon as possible in cases of cord injury in which dislocation or subluxation is present. Ongoing spinal cord compression from disc material and/or bony fragments may require surgical intervention (Summary box 24.3).

Summary box 24.3

Pathophysiology of spinal cord injury

- The spinal cord contains tracts that are topographically arranged
- Spinal cord injury involves both primary and secondary phases
- Therapeutic strategies are directed at reducing the secondary injury

Figure 24.8 The spinal cord ends at T12/L1 as the conus medullaris, which gives rise to the cauda equina.

PATIENT ASSESSMENT

Basic points

Approach every trauma patient in the same manner using Advanced Trauma Life Support (ATLS) principles. Assume that

Figure 24.9 A cross-section of the spinal cord. C, cervical; L, lumbar; S, sacral; T, thoracic.

every trauma patient has a spinal injury until proven otherwise; all assessment, resuscitation and life-saving procedures must be performed with full spinal immobilisation (Fig. 24.10). However, patients must be removed from spinal boards as soon as possible to avoid skin breakdown, particularly in cases of spinal cord injury and unconsciousness.

There should be a high index of suspicion of spinal injury if any of the following are evident:

- neurological deficit;
- multiple injuries;
- head injury;
- facial injury;
- high-energy injury (e.g. fall from a height);
- abdominal bruising from a seatbelt, suggestive of a possible lumbar spine injury.

The polytrauma patient

Spinal injuries often result from high-velocity trauma and associated injuries are common:

- spinal injury at another level: 10–15% of cases;
- head and facial injury: 26% of cases;
- major chest injury: 16% of cases;
- major abdominal injury: 10% of cases;
- long bone/pelvic fracture: 8% of cases.

The unconscious patient

Full assessment of the spine in this situation is difficult. Definitive clearance of the spine may not be possible in the initial stages. Spinal immobilisation should be maintained until magnetic resonance imaging (MRI) of the entire spine has been used to rule out injury or the cervical spine has been screened while being flexed and extended under image intensifier control.

The pain-free patient

In a conscious patient spinal injury can be excluded if:

- there is no pain;
- palpation of the spine is non-tender;
- neurological examination is normal;
- there is a pain-free range of movement;

Figure 24.10 Spinal immobilisation.

- there are no other serious injuries that may mask spinal symptoms (Summary box 24.4).

Summary box 24.4

Patient assessment

- Use ATLS principles in all cases of spinal injury
- In polytrauma cases suspect a spinal injury
- A second spinal injury at a remote level may be present in 10% of cases
- Spinal boards cause pressure sores

PERTINENT HISTORY

The mechanism and velocity of injury should be determined at an early stage.

PHYSICAL EXAMINATION

Initial assessment

It is important to be aware that spinal cord injury may mask signs of intra-abdominal injury.

Identification of shock

Three categories of shock may occur in spinal trauma:

- *Hypovolaemic shock*. This presents with hypotension, tachycardia and cold clammy peripheries. It is most often caused by haemorrhage and is treated with appropriate fluid replacement.
- *Neurogenic shock*. Hypotension occurs with a normal heart rate or bradycardia and warm peripheries. It is caused by unopposed vagal tone resulting from cervical spinal cord injury above the level of sympathetic outflow (C7/T1). Care must be taken to avoid fluid overload.
- *Spinal shock*. This is characterised by paralysis, hypotonia and areflexia. It usually lasts for only 24 hours. When it starts to resolve the bulbocavernosus reflex (Fig. 24.11) returns. The patient should be regularly reassessed neurologically to determine the true extent of neurological injury.

Spinal examination

The entire spine must be palpated and the overlying skin inspected. A formal spinal log roll must be performed to achieve this (Fig. 24.12). Significant swelling, tenderness or palpable steps or gaps suggest a spinal injury. Note the presence of any wounds that might suggest penetrating trauma and document the condition of the skin, particularly over the pressure areas.

Neurological examination

The American Spinal Injury Association (ASIA) neurological evaluation system (Fig. 24.13) is internationally accepted and has low inter- and intraobserver variability.

Motor function is assessed using the Medical Research Council (MRC) grading system (0–5) and is confined to key muscle groups. Sensory function is assessed using the dermatomal map (Fig. 24.13). Pinprick and light touch sensation are assessed at key dermatomal points and scored from 0 to 2. A rectal examination is performed to assess anal tone, voluntary anal contraction and perianal sensation. Preservation of perianal sensation

Figure 24.11 The bulbocavernosus reflex (this can be elicited in female patients by traction on the Foley catheter).

Figure 24.12 Spinal log roll.

indicates an incomplete cord injury and suggests that there should at least be some recovery.

On completion of the neurological assessment the following should be known:

- the presence or absence of a neurological injury;
- the probable level of injury;
- whether the injury is complete or incomplete;
- the type of spinal cord injury;
- the level of impairment.

Eugene Basil Foley, 1891–1966, Urologist, Anker Hospital, St. Louis, MN, USA.

Level of neurological injury

This is simply the most caudal (lowest) neurological level with normal neurological function.

Complete versus incomplete spinal cord injury

A spinal cord injury is incomplete when there is preservation of perianal sensation.

Types of incomplete spinal cord injury

Central cord syndrome This results from injury to the central portions of the spinal cord. This can occur when hyperextension results in the cord being pinched by pre-existing degenerative narrowing of the spinal canal. Distal motor function in the legs is typically spared whereas the upper limbs and hands may be profoundly affected. This reflects the topographical arrangement of the cord. Younger patients often recover substantially but may be left with a permanent loss of fine motor hand function.

Brown-Séquard syndrome This is typically seen in cord hemisection caused by penetrating trauma. This results in ipsilateral loss of power, proprioception and vibration sense with a contralateral loss of pain and temperature sensation below the level of injury because of the arrangement of the various spinal cord tracts (Fig. 24.9). This type of spinal cord injury carries a good prognosis.

Anterior spinal syndrome Flexion–compression injuries to the cervical spine may damage the anterior spinal artery, cutting off the blood supply to the anterior two-thirds of the spinal cord. Posterior column function is preserved but the prognosis is poor.

Posterior cord syndrome This rare injury results from isolated posterior column injury. Motor function is preserved but joint position sense is lost.

Cauda equina syndrome This is most frequently associated with large central disc herniations at L4/5 and L5/S1. Patients typically describe numbness around the perineum and down the inside of the thighs (saddle paraesthesia). They may also be unable to pass urine and have loss of anal tone. If possible, imaging and surgery should be undertaken within hours of the onset of symptoms as the prognosis deteriorates rapidly over time.

Level of neurological impairment

The ASIA neurological impairment scale is based on the Frankel classification of spinal cord injury:

- A: absent motor and sensory function;
- B: sensory function present, motor function absent;
- C: sensory function present, motor function present but not useful (MRC grade < 3/5);
- D: sensory function present, motor function useful (MRC grade ≥ 3/5);
- E: normal function (Summary box 24.5).

Charles Edward Brown-Séquard, 1817–1894, was a physiologist and neurologist who held a number of academic posts, amongst them Physician, The National Hospital for Nervous Diseases, Queen Square, London, England (1860–1864), Professor of Medicine, at Harvard University, Boston, MA, USA (1864–1878), and at The College de France, Paris, France (1878–1894). He described this syndrome in 1851.

Hans Ludwig Frankel, formerly Clinical Director, The National Spinal Injuries Centre, Stoke Mandeville, Buckinghamshire, England.

Figure 24.13 American Spinal Injury Association neurological evaluation.

Summary box 24.5

Physical examination

- Shock after spinal injury can be hypovolaemic, neurogenic or spinal
- The ASIA scoring system should be used to evaluate patients with spinal cord injury
- Prognoses of spinal injury depends on the type of injury

DIAGNOSTIC IMAGING

Plain radiographs

In total, 85% of significant spinal injuries will be seen on the standard lateral cervical spine radiograph recommended at the resuscitation of polytraumatised patients. If the thoracocervical junction cannot be visualised, even with a swimmer's view, a computerised tomography (CT) scan should be obtained.

Significant loss of vertebral body height, sagittal deformity and widening of the interpedicular distance (on the anteroposterior

view) may signify an unstable injury of a vertebra (Figs 24.14–24.16).

Computerised tomography

CT scanning remains the most sensitive imaging modality in spinal trauma. Complex fracture patterns can be understood and an accurate assessment of spinal canal compromise by bony fragments can be made (Fig. 24.17). Sagittal reconstruction is an important modality in assessing posterior column stability.

Magnetic resonance imaging

MRI is best at visualising the soft-tissue elements of the spine (Fig. 24.18). It is possible to see spinal cord haemorrhage and epidural and prevertebral haematomas. Spinal cord haemorrhage carries a poor prognosis. MRI is not good at assessing bony structures and has a relatively low sensitivity in identifying fractures (particularly those in the posterior element).

In cases of spinal trauma without neurological injury, plain radiographs and CT usually give sufficient information, unless it is particularly important to exclude disrupted ligaments (Summary box 24.6).

Figure 24.14 Large prevertebral haematoma.

Summary box 24.6

Diagnostic imaging of spinal injuries

- Clear visualisation of the cervicothoracic junction is essential
- Plain cervical spine radiographs fail to identify 15% of injuries
- The prevertebral soft tissue shadow should be evaluated carefully

CLASSIFICATION AND MANAGEMENT OF SPINAL AND SPINAL CORD INJURIES

General points

In cases of neurological injury, initial intervention is aimed at reducing the secondary injury, preventing further deterioration and allowing return of neurological function in some cases. Most spinal trauma centres no longer use steroids in cases of spinal cord injury as there is no evidence that they work.

Basic management principles

Spinal realignment

In cases of cervical spine subluxation or dislocation, skull tongs (Fig. 24.19) are used to apply traction. The alternative is open reduction and operative realignment using internal fixation (Fig. 24.20). A halo brace can be used to perform a closed realignment of cervical fractures (Fig. 24.21).

Stabilisation

If a spinal fracture or dislocation is unstable (moves abnormally when stressed) there is a risk of new or further neurological injury as well as painful post-traumatic deformity. Many spinal injuries can be managed non-operatively with external support but, when possible, internal fixation should be used. The only absolute

Figure 24.15 The anterior, posterior and spinolaminar lines are useful for identifying anterior translation on lateral radiographs of the neck. a, anterior; b, posterior; c, spinolaminar.

Figure 24.19 Skeletal traction using skull tongs.

Figure 24.18 Sagittal T2-weighted magnetic resonance imaging demonstrating a cervical spine subluxation and spinal cord contusion.

indication for surgery in spinal trauma is deteriorating neurological function. All other indications are relative.

Early stabilisation has the advantage that it allows early mobilisation of the patient.

Decompression of the neural elements

Spinal realignment is important in this regard. Compression of the cord by bone and/or disc material requires surgical removal

(Fig. 24.22). Most spinal surgeons agree that, in cases of incomplete cord injury and progressive neurology, expeditious surgery is appropriate.

In cases of complete cord injury timing of surgery is less important as the prognosis neurologically is unlikely to be affected; however, relatively early surgery with realignment and stabilisation may facilitate early mobilisation and reduce in-patient complications. Decompression of the spinal cord may also reduce the risk of post-traumatic syrinx formation (Summary box 24.7).

Summary box 24.7

Management of spinal trauma

- The management of spinal trauma depends on the presence or absence of neurological deficit
- Deteriorating neurological status is an absolute indication for surgical intervention
- Many spinal cord injury units no longer advocate the use of high-dose corticosteroids

SPECIFIC SPINAL INJURIES

Upper cervical spine (skull to C2)

Cranio-cervical dislocation

This injury is the consequence of high-energy trauma and is usually fatal. It may be anterior, posterior or vertical (Fig. 24.23). Power's ratio (Fig. 24.24) is used to assess skull translation. In survivors, careful occipitocervical fusion is required. A halo brace should be applied before surgery to prevent intraoperative dislocation.

Atlantoaxial instability

The most common form is a rotatory subluxation in children. This is usually of spontaneous onset but can be traumatic. The

Figure 24.20 (a) Thoracolumbar fracture–dislocation; (b) treated with open reduction and posterior fixation. (c) Bifacetal cervical spine dislocation; (d) posterior stabilisation following closed reduction.

child presents with a cock-robin appearance. Halter traction results in realignment in the majority of cases.

Isolated, traumatic transverse ligament rupture leading to C1/2 instability is uncommon and is treated with posterior C1/2 fusion (Fig. 24.25).

Occipital condyle fracture

This is an uncommon injury that is usually associated with head

A robin is a small red-breasted bird of the thrush family which carries its head on one side.

injuries and identified on CT. The majority of fractures are stable and can be treated in a hard collar for 8 weeks.

Jefferson fractures (C1 ring)

These injuries are associated with axial loading of the cervical spine, which can be stable or unstable (Fig. 24.26a and b). Associated transverse ligament rupture may occur (Fig. 24.26c). Unstable Jefferson fractures should be treated in a halo jacket for

Sir Geoffrey Jefferson, 1886–1961, Professor of Neurosurgery, University of Manchester, England.

Figure 24.21 External immobilisation using a halo jacket.

3 months followed by flexion–extension stress radiography to check stability. Persistent C1/2 instability will need C1/2 or occiput–C2 fusion.

Odontoid fractures

There are three types of odontoid fracture (Fig. 24.27). Type I fractures are uncommon and are usually stable, requiring no immobilisation. Type II fractures may fail to unite, particularly those with significant displacement on presentation and those in the elderly. Type III fractures extend into the C2 vertebral body and usually readily unite. Neurological injury is rare. The majority of acute injuries are treated non-operatively in a halo jacket for 3 months. Internal fixation with an anterior compression screw is indicated in displaced fractures in younger patients with good bone quality (Fig. 24.28).

Posterior C1/2 fusion is required in cases of non-union. Elderly patients often develop a fibrous pseudoarthrosis that is relatively stable and does not require surgery.

Figure 24.22 (a) Sagittal T2-weighted magnetic resonance imaging showing an L1 burst fracture and neural compression; (b) treated with combined anterior and posterior surgery.

Hangman's fracture

This injury can be considered as a traumatic spondylolisthesis of C2/3 resulting from bilateral C2 pedicle fractures secondary to hyperextension (Fig. 24.29). The majority can be treated non-operatively in a halo jacket or brace. Those with significant

Figure 24.23 Vertical occipitocervical dislocation.

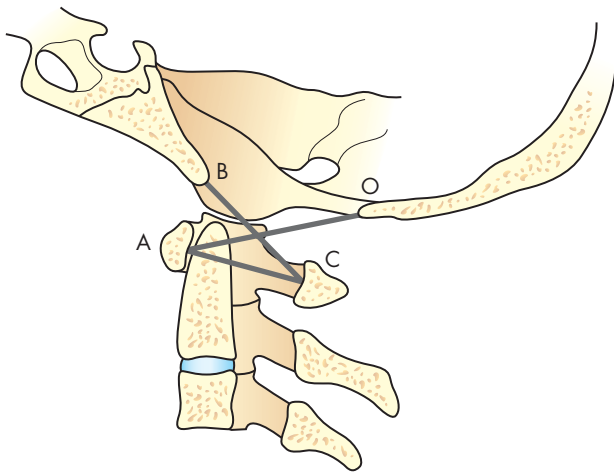

Figure 24.24 Power's ratio. BC/OA ≥ 1 indicates anterior translation, ≤ 0.75 indicates posterior translation. B, anterior margin of the foramen magnum; C, anterior margin of the C1 posterior arch; O, posterior margin of the foramen magnum; A, posterior margin of the C1 anterior arch.

displacement or associated facet dislocation are treated operatively, usually with posterior stabilisation.

Subaxial cervical spine (C3–C7)

The pattern of lower cervical spine injury depends on the mechanism of trauma. Many of the more severe injuries are associated with spinal cord injury.

Wedge fracture

This results from hyperflexion and is usually stable without neurological injury. It is treated in a brace or halo for 3 months.

Figure 24.25 (a) Atlantoaxial subluxation. (b) C1/2 posterior fusion using C1 lateral mass and C2 pedicle screws.

Burst fracture

This occurs secondary to axial loading of the cervical spine. Bony fragments may explode into the spinal canal and cause neurological injury (Fig. 24.30a). Surgical intervention may be required to remove the fractured vertebral body, decompress the spinal cord and then stabilise with internal fixation (Fig. 24.30b).

Burst fractures without neurological deficit can be treated non-operatively in a halo jacket.

Tear-drop fracture

The mechanism of injury is hyperextension. Unstable fractures require operative treatment.

Facet subluxation/dislocation

The pattern of injury ranges from facet subluxation, through unifacetal dislocation to bifacetal dislocation (Fig. 24.31). Bifacetal

Figure 24.26 Stable (a) versus unstable (b) Jefferson's fracture of C1. (c) Open mouth view of C1/2 demonstrating C1 lateral mass deviation. Rupture of the transverse ligament is present when the combined lateral mass deviation exceeds 6.9 mm.

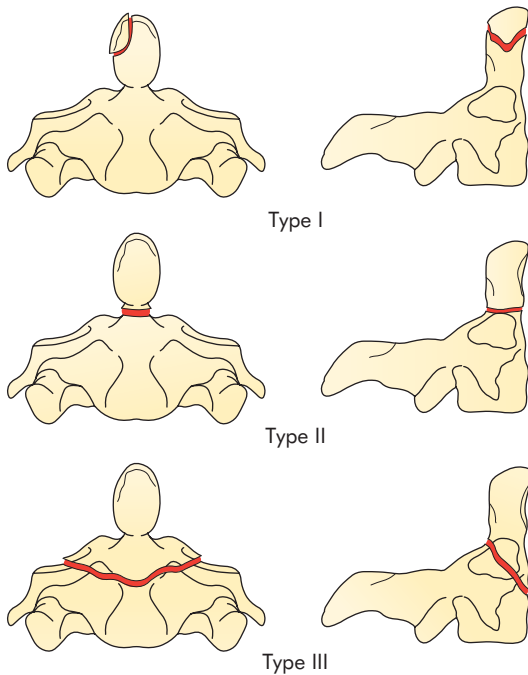

Figure 24.27 Types of odontoid fracture.

dislocation is associated with spinal cord injury in the majority of cases. The mechanism of injury is a combination of axial loading and flexion leading to compression at the anterior aspect of the spine and distraction of the posterior elements. The majority are pure ligamentous injuries with associated disruption of the inter-

Figure 24.28 (a) Type II odontoid fracture; (b) treated with an anterior compression screw.

vertebral disc. Surgical stabilisation is required in most cases; awake, closed reduction with skeletal traction is recommended when possible. In cases of incomplete paralysis or normal neurology, a pre-traction MRI should be considered to identify disc herniations that may then press on the cord and damage it during reduction (Summary box 24.8).

Summary box 24.8

Cervical spine injuries

- The majority of upper cervical spinal injuries are treated non-operatively
- Spinal cord injury is more commonly associated with subaxial cervical spinal injuries
- In cases of facet dislocation a pre-traction MRI should be considered

Figure 24.29 (a) Hangman's fracture of C2 with minimal forward translation. (b) C2/3 subluxation with spinal cord contusion.

Thoracic and thoracolumbar fractures

Fractures that are highly unstable with an associated risk of neurological deficit should be fixed surgically. The AO (Arbeitsgemeinschaft für Osteosynthesefragen) classifies fractures into three main types, A, B and C, with injuries becoming progressively more unstable from A to C. There is also an increasing risk of associated neurological injury.

Type A fractures primarily involve the vertebral body. Type B injuries have additional distraction/disruption of the posterior elements and type C injuries are rotational. The majority of type B and type C injuries require surgical stabilisation. Burst fractures are included in type A.

Thoracic spine (T1–T10)

Osteoporotic wedge compression fractures in the elderly are the most common injury in this group. These are stable so can be treated symptomatically. Fractures that remain sympto-

AO, Arbeitsgemeinschaft für Osteosynthesefragen which may be translated from the German as 'Working Party on Problems of Bone Repair'.

Figure 24.30 (a) Cervical burst fracture with spinal cord contusion; (b) treated by anterior decompression and reconstruction.

matic for more than 6 weeks can be treated with percutaneous bone cement augmentation, known as vertebroplasty. Specialised balloons can also be inserted and inflated in an attempt to restore vertebral height (kyphoplasty) and relieve pain (Fig. 24.32).

The combination of thoracic spine disruption and a sternal fracture (Fig. 24.33) carries a significant risk of aortic rupture. Multiple posterior rib fractures and rib dislocations above and below a thoracic spinal injury signify a major rotational injury to the chest and are associated with vascular injury and significant pulmonary contusion (Fig. 24.34).

Upper thoracic spinal column injuries can be difficult to diagnose with plain radiography. High-quality CT sagittal reformats are best.

Posterior instrumentation is indicated in almost all unstable thoracic spinal injuries as braces do not provide adequate stability and the risk of neurological deterioration can be considerable.

Figure 24.31 C5/6 bifacet dislocation.

Thoracolumbar spinal fractures (T11–S1)

The thoracolumbar junction is prone to injury as it represents a transition zone from fixed to mobile segments. There is a wide spectrum of possible injuries, ranging from minor wedge fractures to spinal dislocation (Fig. 24.35).

Burst fractures

These are comminuted fractures of the vertebral body. The distance between the pedicles is widened and bone is retropulsed into the spinal canal (Fig. 24.36). Many of these fractures can be treated non-operatively. Surgical intervention is indicated when there is neurological compromise or the fracture is unstable. Instability is determined by loss of anterior vertebral body height of $> 50\%$, sagittal plane angulation of $> 30^\circ$ and spinal canal compromise of $> 50\%$. An anterior approach with vertebral corpectomy, canal clearance and anterior reconstruction (Fig. 24.37) is the treatment of choice for a burst fracture with neurological compromise.

Chance fractures

These are flexion–distraction injuries and are classically associated with the use of lap belts (Fig. 24.38). They may be bony or soft tissue in nature and predominantly occur at the thoracolumbar junction. Duodenal, pancreatic and/or aortic rupture can occur in these injuries and there must be a high index of suspicion (Summary box 24.9).

Summary box 24.9

Thoracic and thoracolumbar fractures

- Unstable thoracic spine fractures are commonly associated with vascular and/or visceral injuries
- Thoracolumbar flexion–distraction injuries may result in duodenal, pancreatic and/or aortic rupture

SCIWORA (SPINAL CORD INJURY WITHOUT OBJECTIVE RADIOLOGICAL ABNORMALITY)

This phenomenon occurs in children and is related to hyperelasticity of the vertebral column. In most cases spinal cord traction is the mechanism of neurological injury.

MRI scanning may demonstrate the level of cord injury and is useful in demonstrating compressive lesions, e.g. epidural haematoma.

REHABILITATION AND PATIENT OUTCOME

The goal of spinal cord injury rehabilitation is to maximise remaining neurological function. The functional ability that may

Figure 24.36 Lumbar burst fracture with increase in interpedicular distance (a) and spinal canal compromise (b).

be achieved is dependent on the level of neurological impairment and this is outlined in Table 24.1.

Prognosis of spinal cord injury

Life expectancy following spinal cord injury

Despite continuing improvements in survival following spinal cord injury, life expectancy remains reduced (Table 24.2). Pneumonia, pulmonary emboli and septicaemia are the most frequent causes of premature death in this population group. Renal failure is no longer the leading cause of death because of advances in urological management. Age at injury and level of injury are the most important prognostic factors.

Prognosis for neurological recovery

The prognosis of incomplete cord injury is highly variable and is influenced by the type of cord injury (syndromes), age of the patient and associated injuries.

Figure 24.37 Anterior spinal reconstruction for a lumbar burst fracture.

Figure 24.38 A bony Chance fracture at the thoracolumbar junction secondary to a lap belt injury.

Complications associated with spinal cord injury

Pain and spasticity

Neurogenic pain is extremely common following spinal cord injury and in some cases may be difficult to control. Once reflex activity returns spasticity can be problematic. Intrathecal infusion of baclofen may be required in resistant cases.

Autonomic dysreflexia

This is a paroxysmal syndrome of hypertension, hypohydrosis (above level of injury), bradycardia, flushing and headache in response to noxious visceral and other stimuli. It is most commonly triggered by bladder distension or rectal loading from faecal impaction.

Neurological deterioration

Post-traumatic syringomyelia may cause late (> 3 months post-injury) neurological deterioration and occurs in 3–5% of spinal cord injury cases. Increase in pain and/or spasticity, ascending loss of pain and temperature sensation, and ascending loss of deep tendon reflexes are some of the features associated with this

Table 24.1 Expected functional outcome versus level of cervical spinal cord injury

Level of injury	Functional goal
C3–C4	Power wheelchair with mouth or chin control; verbalise care, communicate through adaptive equipment; may be ventilator dependent
C5	Power wheelchair; dress upper body; self-feed with aids; wash face with assistance
C6	Propel power wheelchair, possibly push manual wheelchair; transfer with assistance; dress upper body (lower body with assistance); self-groom with aids; bladder/bowel care with assistance; self-feed with splints; able to drive
C7	Manual wheelchair; independent transfer; dress (with aids), feed, bath and self-care; bladder and bowel care with assistance
C8–T4	Independent with most activities of daily living, transfers, manual wheelchair and bowel and bladder care
T5–T12	As above but with more ease; independent with all self-care activities. T12: possible to walk with walker and long leg braces (difficult and highly demanding)
L1–L5	Independent; walk with short or long leg braces
S1–S5	Independent; able to walk if capable of pushing off (S1) (may need brace); bladder, bowel and sexual function may remain compromised

Table 24.2 Life expectancy (years) post-injury according to severity of injury and age at injury

(a) For persons who survive the first 24 hours

Age at injury (years)	No SCI	Motor functional at any level	Paraplegic	Low tetraplegic (C5–C8)	High tetraplegic (C1–C4)	Ventilator dependent at any level
20	58.4	52.8	45.6	40.6	36.1	16.6
40	39.5	34.3	28.0	23.8	20.2	7.1
60	22.2	17.9	13.1	10.2	7.9	1.4

(b) For persons surviving at least 1 year post-injury

Age at injury (years)	No SCI	Motor functional at any level	Paraplegic	Low tetraplegic (C5–C8)	High tetraplegic (C1–C4)	Ventilator dependent at any level
20	58.4	53.3	46.3	41.7	37.9	23.3
40	39.5	34.8	28.6	24.7	21.6	11.1
60	22.2	18.3	13.5	10.8	8.8	3.1

SCI, spinal cord injury.

condition, which warrant early MRI assessment of the cord. Expanding cavities require neurosurgical intervention.

Thromboembolic events

Approximately 30% of spinal cord-injured patients develop a clinically significant deep vein thrombosis. Fatal pulmonary embolus is reported in 1–2% of all spinal cord injury deaths within the first 3 months of injury, with the highest risks within the first 3 weeks. Prophylactic intervention is therefore important in this patient group.

Heterotopic ossification and contractures

The most frequent areas affected by heterotopic ossification are hips, knees, shoulders and elbows. It occurs in 25% of spinal cord-injured patients. Patients should receive prophylactic sodium etidronate or indomethacin. Surgery for joint ankylosis should only be considered when the process becomes dormant (normal alkaline phosphatase level, negative isotope bone scan).

Soft tissue contractures around joints may occur where opposing muscle groups have unequal power. These are avoided by

appropriate physical therapy, positioning and splinting. Surgical release may be required in certain cases.

Trauma to the face and mouth

CHAPTER 25

LEARNING OBJECTIVES

To be able to:

- Recognise the life-threatening nature of facial injuries through compromise of the airway and associated head and spinal injuries

To have:

- A methodology for examining facial injuries

To know:

- The classification of facial fractures

To understand:

- The diagnosis and management of fractures of the middle third of the facial skeleton and the mandible
- The importance of early and accurate reimplantation of avulsed permanent teeth

To appreciate:

- The importance of careful cleaning and accurate suturing of facial lacerations

INTRODUCTION

Injuries to the orofacial region are common, but the majority are relatively minor in nature. A few are major and complex, requiring exacting technique and meticulous care in management. It must always be remembered that an intact and unscarred face is important to the well-being of the individual, and thus all injuries, however trivial, should be treated thoughtfully and sympathetically, with every effort made to produce an optimal outcome. In addition, even trivial blows to the face may:

- cause injuries that compromise the airway;
- directly or indirectly cause a head injury;
- cause injuries to the cervical spine.

EPIDEMIOLOGY

Injuries to the orofacial soft tissues, dentition and facial skeleton result from sporting activities, accidents and intentional violence. Formerly, road traffic accidents were the commonest cause of maxillofacial injuries in the UK. However, the compulsory wearing of seatbelts and the use of car air bags and laminated windscreens have reduced the incidence of such injuries as a result of road traffic accidents. However, the decrease in injuries from this source has been almost matched by the increase in deliberate injury from civil assault where 'putting the boot in' has become a fashion, with often appalling results.

Many studies have demonstrated significant variation in the aetiological causes of orofacial injuries in different parts of the world, and even within the same continent. This can perhaps be accounted for by both variation in data collection and also the classification of such injuries, which may vary significantly between researchers. In addition, many factors affect the causes of orofacial injuries, and these may also explain the varying

epidemiological and incidence figures seen in differing geographical regions:

- *Social factors.* Interpersonal violence has steadily increased and, in many countries, is now the commonest cause of orofacial injuries. This increase is noticed to a greater extent in conurbations and urban areas, often fuelled by alcohol excess and 'binge' drinking.
- *Climatic factors.* Countries lying within temperate latitudes often demonstrate variations in weather that may be associated with an increased incidence of injuries. The arrival of snow and freezing weather during the winter and increased traffic volumes and interpersonal violence during the warmer months of the year often produce seasonal variations in the incidence of injuries.
- *Road traffic accidents.* Legislation and improved vehicular design have lessened the number of injuries presenting as a result of road traffic accidents. Air bag provision, seatbelts, laminated windscreens and drink/drive laws have all helped in reducing orofacial injuries. The enforcement of lower speed limits has not, as yet, been shown to reduce injuries.

CLINICAL EFFECTS

The mouth and nasal passages form part of the upper aerodigestive tract, and lacerations and fractures of the facial skeleton may give rise to immediate or delayed respiratory obstruction. Immediate obstruction may arise from inhalation of tooth fragments, accumulation of blood and secretions, and loss of control of the tongue in the unconscious or semiconscious patient. To avoid this, the patient should always be nursed in the semiprone position (Fig. 25.1) with the head supported on the bent arm, and never lying on their back. Damaged teeth, blood and secretions can then fall out of the mouth, and gravity pulls the tongue

Figure 25.1 The patient should be nursed in the semiprone position to allow secretions, blood and foreign bodies to fall from the mouth.

forward. As the patient is manoeuvred into the correct nursing position, the neck should be supported and held in a neutral position – a protective collar is advisable until a fracture of the cervical spine has been excluded. An intracranial injury should always be considered as a possibility, however minor the injury to the face.

Initial haemorrhage after a facial injury can be dramatic. Sustained bleeding is unusual, but emergency measures to stabilise the facial fractures and control bleeding may be required. The most likely causes of circulatory failure in a facial injury are accompanying skeletal fractures or a ruptured viscus, and these should always be actively sought in the shocked patient.

Oedema is a particular feature of all fractures of the facial skeleton and tends to develop within 60–90 minutes. Thus, a patient with a shattered face may appear to have a good airway immediately after the blow, but the airway may change rapidly and become occluded by swelling of the tongue or facial and pharyngeal tissues. This problem must always be borne in mind when the middle third of the face is involved. In Le Fort III fractures (see below), the maxilla may be thrust downwards and backwards along the base of the skull. As it does so, the posterior teeth of the upper and lower jaws contact prematurely and the mouth is held open (Fig. 25.2), giving the impression of a good airway. As oedema develops, the soft palate and tongue may swell to meet, so closing the pharyngeal airway and leading to respiratory distress and even obstruction (Fig. 25.3). Whenever this is suspected, the ‘golden hour’ must be used to insert an oropharyngeal airway, even though the patient may appear conscious and the airway not obstructed. If this is not done, an emergency tracheostomy may have to be undertaken later with potential risk to the patient (Summary box 25.1).

Figure 25.2 A blow from the front of the face may separate the facial skeleton from the base of the skull and thrust it downwards and backwards.

Figure 25.3 Loss of nasopharyngeal space and oedema of the soft palate and tongue may close off the airway in severe maxillofacial injuries, 2–3 hours after the injury.

Summary box 25.1

Facial injuries

- Are potentially life-threatening (can compromise the airway)
- Can distract the clinician from other injuries
- May be associated with injuries to the brain and cervical spine
- Are cosmetically very important

EXAMINATION OF THE PATIENT

The examination of the patient should be under a good light with consideration of the airway and other collateral injuries in mind. It is easy to be distracted from examining the whole patient by the dramatic effects of the facial injury. The rapid onset of oedema may make examination of the face and routine head injury observations difficult – occasionally, it is impossible to prise the eyelids apart to examine the pupils, for instance. Lacerations should be explored first and, if necessary, cleaned using sterile saline or aqueous antiseptic solution.

Once the pattern and extent of soft-tissue injury has been established and recorded, attention should be directed towards the hard tissues. Regardless of the apparent site of the injury, the whole head should be examined visually and by palpation starting with the vault of the skull. A blow to the face may result in the head being thrown back against a hard object, and a bruise or laceration on the occiput can be missed. Bruising over the

mastoid process, or Battle's sign, may be indicative of a middle cranial fossa fracture. The face should be examined from the front. Any asymmetry and displacements should be noted, although oedema may make this difficult. Gentle palpation, using both hands and wearing surgical gloves, gives the most information in searching for step deformities. Tenderness over sites of known weakness and potential for fracture (see below) is a very good guide to the possibility of there being an underlying fracture. A suitable system is to examine from above downwards – the supraorbital and infraorbital ridges, the nasal bridge and the zygomas, including the arches. The mandible should then be examined starting at the condyles bilaterally and then following the posterior and lower border of the mandible as far as the midline. The majority of middle third injuries are accompanied by some degree of epistaxis (except isolated zygomatic arch fractures), and Le Fort II and III injuries frequently have a cerebrospinal fluid (CSF) leak with anterior or posterior CSF rhinorrhoea. A particularly useful sign in the fractured zygoma is the frequent subconjunctival haemorrhage, which will often be found to have no posterior limit when the patient is asked to look to the other side (Fig. 25.4). This may be suggestive of a fracture of the associated zygomatic complex.

The patient should then be examined intraorally with good illumination. The lips should be parted and the occlusion of the teeth examined. The maxillary and mandibular dentition normally 'fit' together even if the occlusion is naturally irregular – if they do not, a fracture of the jaws may be suspected. All fractures involving the alveolus (the tooth-bearing portion of the jaw in the dentate patient) tear the gingivae and are compound into the mouth (Fig. 25.5): the examiner should look for signs of bleeding. A haematoma in the floor of the mouth is a good indication of a fracture of the mandible, particularly in edentulous cases. Alignment of the teeth should be noted, and any missing or broken teeth and dental restorations/prostheses should be carefully recorded. The occlusal plane must be examined for the presence of step defects, often indicative of a fracture of the underlying bone. The patient should be asked to bring the teeth together, so

Figure 25.4 Fractures of the zygoma may often be associated with subconjunctival haemorrhage. This example shows no posterior border to the haemorrhage as the patient looks away from the side of the fracture.

William Henry Battle, 1855–1936, Surgeon, St Thomas' Hospital, London, England.

Figure 25.5 A fracture of the right parasymphysis of the mandible, demonstrating a tear of the gingivae in the lower right lateral incisor/canine region.

that any occlusal anomalies may be observed and, in some cases, independent movement of the fragments may then be detected. Movement of the jaw should be tested – deviation from the midline at rest or on opening suggests a fracture of the side to which the jaw is deviating.

If a fracture of the maxilla is suspected, the maxillary dental arch should be grasped between the index finger, middle finger and thumb of one hand in the incisor region, while the other is placed on the forehead. If the maxilla is fractured, gentle movement forward and backward, or side to side, will reveal movement between the examining hands. With the mandible, gentle manipulation across the suspected site of a fracture will confirm the presence of a fracture if 'springing' is felt and seen. Confirmation of a fractured zygoma may be made by palpating the fractured antral wall above the upper molar teeth in the buccal sulcus.

Soft-tissue injuries within the oral cavity should be identified and recorded. Lacerations of the oral mucosa may occur independently of hard-tissue injuries, and can often involve the buccal mucous membrane and tongue. Degloving lacerations most commonly involve the labial sulcus and the body of the mandible. Tongue injuries demand careful assessment as lacerations are often underestimated in terms of their depth and potential for dehiscence. Furthermore, tongue lacerations may be a source of potential haemorrhage, which may be delayed on occasion. Palatal lacerations tend to occur in young children who fall onto objects held in the oral cavity, especially pens and pencils. With such a history, the suspicion of retained foreign bodies must be considered.

The maxillofacial examination is then turned to the relevant cranial nerves. Anaesthesia or paraesthesia indicates a fracture proximally along the course of the nerve. Thus, anaesthesia/paraesthesia of the cheek and upper lip suggests a fracture involving the infraorbital foramen or floor of the orbit, while anaesthesia/paraesthesia of the lower lip suggests a fracture of the mandibular body. Facial palsy may indicate severance of branches of the facial nerve that are involved in facial lacerations, particularly penetrating wounds of the parotid gland. In the absence of lacerations, facial palsy may be suggestive of a fractured temporal bone.

It is important to confirm that the patient has sight in both eyes. This may be difficult in the very oedematous patient with

marked periorbital oedema, but a pen torch shone directly through the lids will confirm gross optic nerve function. Where possible, pupil size and reflexes to light should be observed and recorded, as should eye movements. Diplopia should be checked for by asking the patient to follow the light of a pen torch in both central and extremes of gaze. Diplopia may be indicative of damage to the III, IV or VI cranial nerves or, more commonly, damage to the thin orbital plates of bone, particularly the floor of the orbit.

All findings should be recorded accurately, preferably with diagrams to include measurements of lacerations, abrasions and areas of tissue loss. Photographs of the initial injury can be very helpful if litigation is likely to follow (Summary box 25.2).

Summary box 25.2

Examination of facial injuries

- Commence with lacerations and soft-tissue injuries
- Systematically examine bones including the occiput and cranial vault
- Check dental occlusion and palpate the mouth
- Check cranial nerves
- Photographs are useful

ADDITIONAL INVESTIGATIONS

Blood tests

Baseline full blood count and biochemistry should be obtained. Blood should be grouped when it is thought that significant bleeding has occurred and more bleeding is likely.

Radiological investigations

Table 25.1 demonstrates the radiographic views utilised in the diagnosis of maxillofacial injuries. Coronal computerised tomography (CT) scanning has superseded tomographic views in the diagnosis of orbital floor fractures, and coronal and axial CT scanning is often the choice of radiographic investigation in the more complex middle third fractures (Fig. 25.6). A chest radiograph is indicated if there is any suggestion of inhalation of dental fragments or dental prostheses. It should be remembered, however, that polymethylmethacrylate used in the construction of dentures may not appear radiopaque on plain radiographs.

Table 25.1 Radiological views for specific fractures

Site of fracture	Radiographs
Mandible: body and ramus	OPT, lateral obliques, lower occlusal, PA mandible
Mandible: condyles	OPT, PA mandible with mouth open, Toller transpharyngeal views
Maxilla	OM 15° and 30°, lateral facial bones
Zygomatic complex	OM 15° and 30°, submentovertex
Orbital blow-outs	OM 15° and 30° and tomograms
Nasal bones	Lateral nasal bones, occipitofrontal
Frontal bones	Lateral skull, occipitofrontal

OPT, orthopantomogram; PA, posteroanterior; OM, posteroanterior occipitomenital.

Figure 25.6 Computerised tomographic (CT) scan showing a comminuted fracture of the right maxilla and zygomatic complex (nasal pack in place).

Posteroanterior occipitomenital radiographs taken at 15° and 30° are the optimum initial radiographs to illustrate the site and displacement of a middle third fracture. A panoramic oral radiograph, or orthopantomogram (Fig. 25.7), is the radiograph of choice for the mandible as it shows the whole bone from condyle to condyle. If the patient cannot be positioned in the machines to achieve these views, radiographs should wait until the patient is fit enough. Poor radiographs can be misleading, and treatment can only be based on adequate radiographs or scans.

FRACTURES OF THE FACIAL SKELETON

Fractures of the facial skeleton may be divided into those of the upper third (above the eyebrows), the middle third (above the mouth) and the lower third (the mandible). Fractures tend to occur through points of weakness – the sutures and foramina – and in thin unsupported bone.

The upper third

The patterns of fracture of the skull tend to be random, but there are points of weakness, mainly involving the frontal sinuses and the supraorbital ridges.

The middle third

In 1911, René Le Fort classified fractures according to patterns which he created on cadavers using varying degrees of force. The Le Fort classification is used extensively today throughout the world. While Le Fort classified the fractures from superior to inferior, the custom today is that the classification runs inferiorly to superiorly (Fig. 25.8).

The Le Fort I fracture effectively separates the alveolus and palate from the facial skeleton above. The fracture line runs through points of weakness from the nasal piriform aperture

René Le Fort, 1869–1951, was a French Surgeon who classified facial fractures after macabre research in which he dropped rocks and other heavy objects on the faces of cadavers.

Figure 25.7 An orthopantomogram demonstrating a fracture of the left angle of the mandible.

Figure 25.8 Maxillary fractures as classified by Le Fort. (a) Le Fort I; (b) Le Fort II; (c) Le Fort III.

through the lateral and medial walls of the maxillary sinus, running posteriorly to include the lower part of the pterygoid plates.

The Le Fort II fracture is pyramidal in shape. The fracture involves the orbit, running through the bridge of the nose and the ethmoids, whose cribriform plate may be fractured, leading to a dural tear and CSF rhinorrhoea. It continues to the medial part of the infraorbital rim and often through the infraorbital foramen. By definition, the orbital floor is always involved. It continues posteriorly through the lateral wall of the maxillary antrum at a higher level than the Le Fort I fracture to the pterygoid plates at the back.

The Le Fort III fracture effectively separates the facial skeleton from the base of the skull – the fracture lines run high through the nasal bridge, septum and ethmoids, again with the potential for dural tear and CSF leak, and irregularly through the bones of the orbit to the frontozygomatic suture. The zygomatic arch fractures, and the facial skeleton is separated from the bones above at a high level through the lateral wall of the maxillary sinus and the pterygoid plates.

The Le Fort fractures are seldom confined exactly to the original classification, and combinations of any of the above fractures may occur.

The zygomatic complex

This is the most common fracture of the middle third of the face, apart from the nose. The fractures occur through points of weakness – the infraorbital margin, the frontozygomatic suture, the zygomatic arch and the anterior and lateral wall of the maxillary sinus. Tears of the antral mucosa may lead to epistaxis on the affected side, and damage to the infraorbital nerve may cause paraesthesia in its sensory distribution (Summary box 25.3).

Summary box 25.3

Fractures of the zygomatic complex

- Damage to the infraorbital nerve is common, causing numbness on the cheek

Blow-out fractures of the orbit

Direct trauma to the globe of the eye may push it back within the orbit. The globe is a fairly robust structure and, as it is thrust backwards, the pressure increases within the orbit, and the

weaker plates of bone may fracture, without necessarily fracturing the bones of the orbital rim. Such injuries can occur when a blunt object strikes the globe. The weakest plate of bone, most commonly the orbital floor, fractures, and the orbital contents herniate down into the maxillary antrum. This soft-tissue herniation may lead to muscular dysfunction, particularly the inferior oblique and inferior rectus, leading to failure of the eye to rotate upwards. Enophthalmos and diplopia can follow, although both may initially be concealed by oedema. Paraesthesia in the distribution of the infraorbital nerve may be an important clue to the blow-out fracture. Any fracture that involves the orbital floor (Le Fort II and zygomatic complex) must be considered to have the potential for orbital content entrapment too.

There should be a high index of suspicion of any possible orbital blow-out fracture. The signs and symptoms of such injuries are often masked in the early stages, with enophthalmos and ocular problems becoming apparent later. Significant delay in treatment may be associated with less success than early diagnosis and planned treatment (Fig. 25.9). It is wise to assume that, if any signs or symptoms are suggestive of a possible orbital floor injury, such an injury exists, until proven otherwise with coronal CT scans (Summary box 25.4).

Summary box 25.4

Blow-out fractures of the orbit

- Damage to the infraorbital nerve is common, causing numbness of the cheek
- Any fracture that involves the orbital floor (Le Fort II and zygomatic complex) has the potential for orbital content entrapment

Naso-ethmoidal complex fractures

Fractures of the naso-ethmoidal complex, as opposed to isolated nasal bone fractures, are usually comminuted fractures involving the nasal bones, frontal processes of the maxilla, medial and sometimes infraorbital rims and the maxillary processes/anterior sinus wall of the frontal bones. Such injuries can cause significant deformity (Fig. 25.10) and, because of disruption of the medial canthal ligaments, may cause traumatic telecanthus.

Figure 25.9 Previously undiagnosed left orbital blow-out fracture, presenting 3 months after the initial injury. Enophthalmos and lowered pupillary level are evident.

Figure 25.10 Naso-ethmoidal complex fracture, demonstrating gross nasal deformity and traumatic telecanthus.

Fractures of the mandible

The condylar neck is the weakest part of the mandible and is the most frequent site of fracture (Fig. 25.11), while other fractures tend to occur through unerupted teeth (the impacted wisdom tooth) or where the roots are long (the canine tooth). The mandible may fracture directly at the point of the blow, or indirectly where the force from the blow is transmitted and the mandible fractures at a point of weakness distant from the original blow. The latter is characteristically seen in the so called 'guardsman' fracture, where a blow to the chin point may cause a fracture of the symphysis or parasymphysis of the lower jaw, and indirect transmission of the kinetic energy causes a unilateral or bilateral fracture of the mandibular condyles. Individual sharp blows with a blunt instrument may fracture a segment away from the mandible. Blows from below may cause the mandible to be thrust upwards, fracturing the alveolus and teeth as they strike the maxillary dentition.

Much has been made in the past of the 'butterfly' fracture of the mandible. Here, a segment of mandible is detached from the rest of the mandible in the canine regions. The segment of bone may include the anterior insertion of the tongue (genioglossus and geniohyoid). Theoretically, the tongue may fall back and occlude the airway. First, the fracture is exceedingly rare and,

Figure 25.11 The patterns of fracture of the mandible. (1) The neck of the condyle is the most common site, followed by (2) the angle of the mandible through the last tooth. (3) The third point of weakness is in the region of the canine tooth.

A 'guardsman' fracture is so called because it refers to the Queen's Guards who, when they fainted on parade, still held themselves in a position of attention. As a consequence, if they fell forward, the first point of contact with the ground would be the point of the chin. This resulted in a direct fracture of the symphysis/parasymphysis of the mandible, and indirect fractures of both mandibular condyles.

second, the patient can still control the tongue, if nursed in the correct position (see earlier) (Summary box 25.5).

Summary box 25.5

Fractures of the mandible

- The condylar neck is the weakest and most common site
- Indirect transmission of energy may fracture the mandibular condyle(s)

TREATMENT

Soft-tissue injuries

Facial soft tissues have an excellent blood supply and heal well. They should be sutured as soon as possible following the injury after careful exploration, debridement and cleaning, particularly where foreign bodies may be embedded. Many lacerations may be closed using local anaesthesia, injecting into the edges of the wound. If the patient is due to have a general anaesthetic and there is a delay, the wounds should be temporarily closed in advance, using local anaesthesia. Tissue sufficiently traumatised to have lost its blood supply should be removed with a sharp scalpel, and the edge to which it is to be apposed trimmed to fit as appropriate.

Great care should be taken to replace tissues accurately, particularly in cosmetically important landmarks such as the vermilion border of the lips, the eyelids and nasal contours. Haemostasis is important. Muscle and underlying tissues should be brought together with absorbable sutures so that the edges of the wound lie passively within 2 mm of their final position. Then fine monofilament sutures (5/0 or 6/0) are used to bring the wound edges together (Fig. 25.12). Sutures should be placed so as to avoid compromising the blood supply of the apices of small flaps. Vacuum drains are used where there is concern over dead space beneath the wounds. The lacerations should be covered with antibiotic ointment two or three times per day, and broad-spectrum antibiotics should be prescribed. Ideally, alternate sutures should be removed from the third day with the remaining sutures removed on the fifth day.

Intraoral lacerations require careful debridement, and closure in layers with resorbable suture materials. Lacerations to mobile structures such as the tongue and soft palate can often be underestimated in terms of their depth. Failure to close the deeper layers of intraoral lacerations may predispose to later dehiscence,

Figure 25.12 Facial wound. The method of skin closure avoiding inversion of the wound edges. The skin suture has a greater bite of deep tissue than at the surface.

with resultant scars that are thickened and uncomfortable to the patient (Summary box 25.6).

Summary box 25.6

Facial lacerations

- Wounds must be cleaned to avoid tattooing
- Replace tissues accurately, especially the vermilion border

Skin loss

Loss of facial skin in any significant amount is a relatively rare occurrence in all but the more severe maxillofacial injuries. However, substantial skin and deeper tissue loss does occur as a result of human bite injuries (Fig. 25.13), most commonly the nose and ear. Small areas of tissue loss can be dealt with by careful undermining of the surrounding soft tissues, with the defect being closed primarily, providing there is no significant tension on the wound edges and no resulting distortion of the surrounding tissues or structures. Larger areas of skin loss require careful assessment and planned reconstruction with grafts and local tissue flaps.

Facial nerve injury

The branches of the facial nerve may be severed in the depths of a lateral facial wound. If this is suspected, primary repair should be attempted, particularly where clinical signs suggest that a major division is involved. Locating the divided branches in oedematous and damaged tissue can prove extremely difficult. Proximal and distal flaps in relatively normal adjacent tissue may have to be raised to identify the nerve on each side of the laceration. The severed nerve ends may then be approximated using

Figure 25.13 Skin and cartilage loss sustained as a result of human bite injuries. (a) Nose; (b) ear.

an operating microscope, and the nerve and laceration sutured. Attempts at primary repair should always be undertaken, as secondary repair is generally unsatisfactory (Summary box 25.7).

Summary box 25.7

Facial nerve injury

- Primary repair is the most appropriate treatment

Parotid duct

Lacerations in the same vicinity as those that transect the facial nerve may also transect the parotid duct. The suggested management is to insert a fine cannula in the parotid duct from within the mouth and pass it posteriorly until it appears in the wound. The position of the proximal duct should then be identified and this portion passed over the cannula, so approximating the severed portions of the duct. The two portions of the duct are then anastomosed, and the cannula left in position for several days in an attempt to prevent post-anastomotic stricture (Summary box 25.8).

Summary box 25.8

Parotid duct transection

- Cannulate from the mouth and anastomose over the stent

The lacrimal apparatus

The nasolacrimal apparatus may be involved in damage to the eyelids and skeletal facial injuries involving the naso-orbital region. The tissues are generally grossly oedematous, and the manipulation required to reduce the fractures adds to the difficulty of identifying the canaliculae. Most surgeons do not attempt repair primarily but refer to an ophthalmic surgeon if epiphora becomes a problem later. Surprisingly, few patients suffer epiphora after a year has elapsed from the injury.

Fractured nasal bones

The nasal bones are the most commonly fractured bones of the facial skeleton. Best results are obtained when soft-tissue oedema has been allowed to settle so that accurate reduction can be achieved. Surgery should ideally be carried out within a week of the injury as, if left any longer, reduction may become difficult or impossible. Reduction should be directed first to repositioning the nasal bones, disimpacting with Walsham's forceps with the external blade covered with rubber tubing, so as to avoid damage to the skin. The nasal bones are first moved laterally to disimpact them and then medially to reposition them. The septum is then grasped with Asch's forceps, manipulated until it is straight and then positioned in the groove of the nasal crest and vomer. It should be remembered, however, that the nasal septum often cannot be adequately manipulated into position and may require formal septoplasty at a later date. Asch's forceps may also be used to pull the disimpacted nasal bones forward to their previous position.

William Johnson Walsham, 1847–1903, Surgeon, St Bartholomew's Hospital, London, England.
Morris Joseph Asch, 1833–1902, Surgeon, New York Eye and Ear Hospital, New York, NY, USA.

Fractures involving the naso-ethmoidal complex require open reduction and fixation, and any disruption of the medial canthal attachments demands replacement of these structures in their correct anatomical position. The nasal bones may need supporting by a pack within the nasal bridge. Variations on nasal packing exist, but most packs should be removed at 2–3 days following the nasal bone reduction. A protective nasal plaster may be placed and should be removed at 5–7 days (Summary box 25.9).

Summary box 25.9

Nasal fractures

- Treatment is best undertaken within 1 week, once the swelling has settled

Frontal bone fractures

The presence of depressed frontal bone fractures and fractures of the posterior wall of the frontal sinus demands that neurosurgical collaboration should be sought. However, fractures of the anterior wall of the sinus are amenable to maxillofacial techniques for reduction and fixation. Access may be through pre-existing lacerations overlying the area, but excellent access with minimal morbidity is achieved using the bicoronal scalp flap (see later). Bone fragments may then be reduced and fixed using small titanium bone plates and screws (Fig. 25.14). Any missing bone should be replaced with bone grafts, thereby avoiding any cosmetic forehead depression postoperatively.

Figure 25.14 Radiograph demonstrating multiple plate fixation of an anterior wall in a frontal sinus fracture.

Fractures of the maxilla

The principle of reducing and stabilising fractures of the frontal and facial bones is that the surgeon starts at the top and works down. Where there are extensive lacerations, these may be used, perhaps with small extensions, to approach the fracture sites. Where no convenient lacerations exist, fractures of the frontal bone, supraorbital ridge and nasal root may be approached through a bicoronal incision at the vault of the skull, high in the hair line. The incision is taken from just in front of each ear across the vault of the skull and reflected forwards until the supraorbital ridges are exposed. The supraorbital nerves are identified and freed, and the flap extended as required. The nasal bones, lateral orbital rim, frontal bones and zygomatic arches may all be exposed through this approach. All the fractured bones may be reduced and fixed by stainless steel wire or titanium mini/microplates under direct vision. Bone deficiencies in this area may be made up with free, outer cortical cranial bone grafts, with the donor sites available through the bicoronal incision. Where there has been disruption of the medial canthal ligaments, these may be identified and sutured/wired to the opposite side to restore canthal width.

When the stabilisation of the upper part of the face is complete, attention may be turned to the midface. Incisions in the lower eyelid (blepharoplasty incision), lower conjunctival sac or infraorbital region are used to explore fractures of the infraorbital rim. These also give access to the orbital floor and are used to treat orbital blow-out fractures. The fractured rim may be fixed using mini/microplates or wires as above, and the floor of the orbit reconstructed with bone, titanium mesh or alloplastic material according to choice, often held by wires or screws.

The lower part of the maxilla is approached through a gingival sulcus incision above the maxillary teeth as far back as the second molar. Fractures may be identified with ease through this route and fixed with plates or wires. The dental arch is restored to its original shape as far as possible so that it matches the pre-morbid occlusion with the mandibular arch. To achieve accurate location, dental arch bars or eyelet wires (see below) may need to be applied. Where this is anticipated, the necessary wiring is undertaken before the main part of the operation is commenced.

The principle of treatment is to restore the fragments to their original position. To achieve this, it is usually necessary to reduce the maxilla first with Rowe's disimpaction forceps, which grasp the palate between the nasal and palatal mucosa. Considerable force is sometimes required in a series of downwards, forwards and sideways movements to mobilise it. After 2–3 weeks, full disimpaction is often impossible.

With the advent of maxillofacial plating systems, indirect or external fixation with pins, fames and haloes is seldom used. If the fragments are multiple and the whole restored maxilla remains unstable, external fixation may be the only answer. Then the principle is that the mandible is fixed to the cranium, with the maxilla as a 'sandwich' between the two. Cranial fixation is by means of a halo or supraorbital pins, and mandibular fixation is by pins inserted into the body of the mandible on each side. All the pins are connected together with connecting bars secured by universal joints. When the teeth of each jaw are fixed together

with intermaxillary fixation, the anteroposterior position of the facial bones is likely to be correct. The vertical dimension is adjusted through the connecting bars fixed by universal joints onto the pins. This means that the jaws are fixed together during recovery, and careful attention should be given to advising the recovery staff on how to release the apparatus in an emergency (Summary box 25.10).

Summary box 25.10

Fixation of maxillary fractures

- Orbital floor deficiencies can be made up with grafts, alloplasts or titanium mesh
- Dental wiring may be needed to stabilise the dental arch and achieve the correct occlusion
- External fixation is only rarely used

Fractures of the mandible

Fractures of the mandible were frequently reduced indirectly and then fixed with intermaxillary fixation (IMF). IMF is simply a means of splinting the upper and lower arches of teeth together (Fig. 25.15). However, the introduction of maxillofacial plating systems using initially stainless steel and latterly titanium has significantly altered the management of patients sustaining fracture of the mandible. Prior to the introduction of these plating systems, patients would often have their jaws 'wired together' for a period of up to 6 weeks. Now, although patients may be placed in temporary IMF during their operative procedure, it is more often than not released at the end of the procedure when the rigid plate fixation has been applied (Fig. 25.16).

The majority of fractures of the mandible require reduction and fixation under general anaesthetic. The fractures may be explored through intraoral or extraoral incisions according to the access required. Pre-existing lacerations overlying the mandible may be used to gain access to the fracture (Fig. 25.17). Any fractured teeth should be removed, as should those previously compromised by extensive caries or infection. It is unnecessary to remove healthy teeth in the fracture line. To be sure of achieving a correct dental occlusion, it is wise to use temporary intraoperative IMF. There are occasions where, in spite of rigid fixation with titanium miniplates, IMF or elastic traction is still required in the

Figure 25.15 Intermaxillary fixation using eyelet wires.

Norman Lester Rowe, 1915–1991, Maxillofacial Surgeon, Queen Mary's University Hospital, Roehampton, London, England.

Figure 25.16 A fractured mandible treated by open reduction and fixation using a titanium miniplate. No postoperative intermaxillary fixation (IMF) has been used. (a) Posteroanterior view; (b) orthopantomogram.

postoperative period. In this event, the IMF is removed during the recovery from anaesthesia, so as not to risk complications involving the airway. The IMF may then be reapplied when the patient has fully recovered from the general anaesthetic.

Fractures of the edentulous (non-tooth-bearing) mandible are generally reduced and then fixed using titanium plates. In the very atrophic mandible, the raising of the periosteum should be kept to a minimum as the blood supply to the jaw may be compromised.

Figure 25.17 Comminuted fracture of the mandible approached through a pre-existing laceration.

Where there is concern that the blood supply may be seriously disadvantaged by the insertion of plates, Gunning's splints may be constructed. These require dental impressions to be taken, and the splints are then constructed by the maxillofacial technician in the laboratory. In effect, they are like upper and lower dentures, but with the teeth replaced with plastic in which hooks are placed. Each splint is wired to the respective jaw – the mandible, with wires going around the mandible (circum-mandibular wires) and the maxilla by a choice of wiring techniques supporting the splint from a stable point in the middle third of the facial skeleton. When the fracture has been reduced and the splints wired in place, the hooks placed on the buccal surfaces of the splints are used to apply IMF and hence fixation for the reduced fracture (Summary box 25.11).

Summary box 25.11

Fixation of the mandible

- Plating has made long-term jaw wiring almost redundant

Fractures of the mandibular condyle may cause disturbance of the occlusion with deviation of the mandible to the side of the fracture. In unilateral fractures, which are minimally displaced, this disturbance may not be evident. However, displaced unilateral fractures and bilateral condylar fractures often present with such a disturbance and, as such, constitute an indication for open reduction and fixation of one of the condylar fractures to prevent the formation of an anterior open bite. This open bite develops due to the vertical pull of the muscles of mastication shortening the ramus height. The posterior teeth contact first and the anterior teeth remain apart. Functionally and cosmetically, this is very undesirable and is almost impossible to counteract by secondary procedures. Simply to fix the mandible in IMF, with or without a posterior bite block to overcome the tendency to open bite, is insufficient. Open reduction and fixation of the fractured mandibular condyle within 7–10 days of the original injury is indicated if such an anterior open bite is evident in a unilateral condylar fracture with significant displacement, or in a bilateral condylar fracture (Summary box 25.12).

Summary box 25.12

Fixation of mandibular condyles

- If displaced or bilateral, with significant occlusal disturbance, surgical intervention will be required
- Reduction and plating prevents anterior open bite

Fractures of the zygomatic complex

Second to the fractured nasal bone, this is the most common fracture of the middle third of the facial skeleton. Displacement is usually posteriorly, although it is important to assess the actual displacement by studying the occipitomental radiographs. Most fractures may be reduced by the Gillies temporal approach. This entails an incision in the hair line, superficial to the temporal

Thomas Brian Gunning, 1813–1889, American dentist.
Sir Harold Delf Gillies, 1882–1960, Plastic Surgeon, St Bartholomew's Hospital, London, England.

fossa, about 15 mm long, at 45° to the vertical. It is deepened down to and through the temporalis fascia. A channel is prepared behind the fascia and down to the body of the zygoma and arch. A Bristow's or Rowe's elevator is then inserted beneath the body of the zygoma or arch, according to the site of the fracture. Force is then applied in the opposite direction to the displacement of the fracture. After reduction, the position of the zygoma can be checked by palpating the bony prominences of the zygomatic arch, and the lateral and inferior orbital rims. As all fractures of the zygoma, other than those solely of the arch, involve the orbital floor, it is essential to apply a forced duction test to ensure no limitation of movement of the inferior oblique and inferior rectus muscles. For this to be done, the lower eyelid is retracted and the inferior rectus grabbed in the lower fornix. The globe can then be rotated upwards and should move freely. Any restriction in movement suggests entrapment of the infraorbital soft tissues, and the floor of the orbit should be explored as for a blow-out fracture (see below).

Should the fracture be unstable, open reduction and fixation of the fracture may be necessary. The frontozygomatic suture may be exposed by a small incision just behind the lateral part of the eyebrow and visualised. Displacements may be reduced and fixed with intraosseous wires or bone plates. Occasionally, it is necessary to explore and fix fractures at the infraorbital rim (see above) (Summary box 25.13).

Summary box 25.13

Fixation of fractures of the zygomatic complex

- The arch is elevated
- Ocular tethering should be checked if the fracture involves the orbital floor
- Regular postoperative observations must be made for retrobulbar haematoma

All patients who have had operations involving the orbit should have formal eye observations in the postoperative period. The condition of the eye, pupil size and light reaction should be recorded. Occasional complications occur, the most serious of which is a developing retrobulbar haematoma. Increasing proptosis and loss of vision constitute a postoperative emergency requiring immediate action to reduce the pressure of the haematoma.

Orbital blow-out fractures

The mechanism has been explained above. These fractures are ideally treated within 10–14 days of the original injury. The aim of treatment is to reduce any soft-tissue herniation of the periorbital (Fig. 25.18), restore the continuity of the orbital floor and restore any functional deficit of ocular function caused by extraocular muscle dysfunction. The floor of the orbit is approached either through a blepharoplasty incision in the lower eyelid or through the inferior fornix. Keeping superficial to the tarsal plate of the lower lid, the infraorbital margin is identified and the periosteum raised, attempting to avoid displacement of the delicate fragments of bone constituting the fracture. The periorbital soft tissues are gently separated from the bone of the

Figure 25.18 Coronal computerised tomographic (CT) scan showing a left orbital blow-out fracture, with evident soft-tissue herniation into the maxillary antrum.

fracture and freed so that no trapping or soft-tissue herniation into the antrum remains. Defects of the orbital floor may be made up with bone grafts from a variety of sources, titanium mesh or other suitably rigid materials. Many surgeons use reinforced silastic or resorbable materials. These materials may be fixed in place with wires, screws or plates. If the fragments are very unstable owing to comminution or the size of the blow-out is excessively large, packing the antrum via a Caldwell–Luc approach may be necessary. When the orbital floor has been adequately reduced and periorbital soft tissue freed from the fracture, the antrum may be packed from above downwards with ribbon gauze soaked in Whitehead's varnish, taking care not to overpack the antrum and so displace the orbital contents. The pack should be removed at 3 weeks (Summary box 25.14).

Summary box 25.14

Orbital blow-out fractures

- Defects of the orbital floor can be made up with bone graft or with synthetic materials

Intraoral injuries

Intraoral injuries will often occur in coexistence with facial and jaw injuries. However, oral injuries to the dentition, the dento-alveolar bone and the oral mucosa or combinations of these commonly occur in isolation and, in many cases, present to accident and emergency departments of general hospitals.

George Walter Caldwell, 1866–1946, Otolaryngologist, who practised successively in New York, NY, San Francisco, CA, and Los Angeles, CA, USA. He described his operation for treating suppuration in the maxillary antrum in 1893.

Henri Luc, 1855–1925, Otolaryngologist, Paris, France, described his operation in 1889.

Walter Whitehead, 1840–1913, Surgeon, the Royal Infirmary, Manchester, England. Whitehead's varnish consists of iodoform, benzoin, storax and Tolu balsam in ether.

Walter Rowley Bristow, 1882–1947, Orthopaedic Surgeon, St Thomas' Hospital, London, England.

Dental injuries

Isolated injury to the dentition is extremely common. Several studies have reported that up to one-third of 11-year-old children in the UK will have sustained some type of injury to their dentition.

Treatment of such dental injuries lies within the remit of the dental surgeon, but many of these patients may initially present to accident and emergency departments of general hospitals. Occasionally, urgent treatment may be necessitated, especially in respect of avulsed teeth.

Patterns of dental injury depend on several factors. The site of the blow, the resilience of the supporting structures of the teeth and the direction and energy of the impact all have an effect in determining the type of injury sustained. The possibility of underlying injury to the jaw and temporomandibular joint (TMJ) should always be considered and, as with maxillofacial injuries in general, the possibility of cervical spine and cerebral injuries should never be overlooked.

Dental injuries may be classified as crown fractures, root fractures or luxation injuries, with the last including avulsion injury. Combinations of the three main groups may also occur. Any missing fragment of tooth should be accounted for. Implantation of dental fragments into the perioral soft tissues and the possibility of inhalation must be excluded.

Loss of dental enamel may result in the exposure of dentine or the dental pulp (Fig. 25.19). Such injury will expose dentinal tubules, which allow bacterial, thermal and chemical irritants to attack the dental pulp. Whether such injury is symptomatic or not, referral to the patient's dental surgeon as soon as possible is necessitated as possible pulpal necrosis will complicate the chances of successful dental reconstruction of the damaged dentition.

Avulsed teeth

When teeth are completely avulsed, the periodontal ligament and cemental layers are ruptured. In addition, the periapical nerves and apical vessels are severed. Such teeth can be reimplanted, but the success of such reimplantation depends on several factors. The stage of root development, the length of time the tooth is in either dry or wet storage, the type of media used for wet storage, correct handling of the tooth and appropriate splinting are all factors affecting the overall prognosis in dental reimplantation.

Figure 25.19 Fractured upper central incisors, involving enamel and dentine.

Ideally, immediate reimplantation is the treatment of choice, but this is seldom feasible at the scene of the accident. Once out of the socket, periodontal ligament cells can survive a dry period of up to 30 minutes without significant harm. After 60 minutes of dry storage, few periodontal cells will retain their viability, and the chances of successful reimplantation decrease significantly. Wet storage can increase periodontal ligament cell vitality, and such storage may increase the chances of successful reimplantation. The patient's own saliva or fresh milk is the best transport medium available to the lay person. Water should not be used because of its osmotic effects on the periodontal ligament cells. The aim of delayed reimplantation should be to reimplant the tooth as soon as possible, once local anaesthetic has been administered. The socket should be gently irrigated with normal saline to remove any clot/debris. The tooth should be held by the crown, and the root gently irrigated with saline to remove debris before the tooth is firmly reimplanted in the socket. Referral to the patient's dental surgeon for semirigid fixation for a period of 7–10 days is necessary, and oral antibiotics are required for a period of 5–7 days following reimplantation (Summary box 25.15).

Summary box 25.15

Dental injuries

- Avulsed teeth should ideally be implanted within 60 minutes of the injury
- The best transport medium for avulsed teeth is the patient's own saliva or fresh milk

General

Fractures of the facial skeleton are almost always compound, and prophylactic antibiotics are important. Penicillin/amoxicillin and metronidazole singly or in combination are ideal for those patients who are not allergic. The cephalosporins are an alternative.

All patients with fractures of the facial skeleton benefit from intraoperative and postoperative dexamethasone to reduce facial oedema (Summary box 25.16).

Summary box 25.16

General principles in facial fractures

- Prophylactic antibiotics should be given
- Dexamethasone may reduce facial oedema

LEARNING OBJECTIVES

To understand:

- That the management of injury is based on physiology rather than anatomy
- The gross and surgical anatomy of the chest and abdomen
- The pathophysiology of torso injury
- The limitations of clinical assessment in the injured patient
- The special investigations and their limitations
- The operative approaches to the thoracic cavity
- The special features of an emergency room thoracotomy for haemorrhage control
- The indications for and techniques of the trauma laparotomy
- The philosophy of damage control surgery

INTRODUCTION

The torso is generally regarded as the area between the neck and the groin, made up of the thorax and abdomen. This is the largest area of the body and is commonly injured following both blunt and penetrating trauma. Because injury does not respect anatomical boundaries, division of the body into abdomen and thorax is artificial, and injury to the torso, with its associated physiological consequences, is more appropriate.

Traditionally, death from trauma has had a 'trimodal' distribution, with 50% of deaths occurring in the pre-hospital environment, 30% during the first few hours and the remaining 20% occurring later. With better pre-hospital care, patients are reaching hospital earlier, and now some 50% of deaths occur in the early in-hospital environment (Fig. 26.1).

About 42% of deaths are the result of brain injury, but some

39% of all trauma deaths are caused by major haemorrhage, usually from torso injury. Many of these are the result of a failure to appreciate the magnitude of the bleeding (Fig. 26.2).

Although initially, injury was treated on an anatomical basis, it has become clear that physiology should be the over-riding consideration, and the driver of successful resuscitation is therefore the restoration of normal physiology. Techniques such as 'damage control resuscitation' and 'damage control surgery' have dramatically improved survival through an understanding of the best techniques required to restore physiological stability.

The Advanced Trauma Life Support (ATLS) course of the American College of Surgeons was developed in 1977 and is the cornerstone of advanced resuscitation. The principles include:

- early assessment and primary survey;
- simultaneous aggressive resuscitation;

Figure 26.1 Changes in the trimodal distribution of trauma death. More efficacious emergency medical services has shifted pre-hospital to early hospital death. Today most deaths occur within 12 hours of arrival at hospital. Late deaths due to post-surgical complications are declining [from Turnkey, D.D. (1983) *Scientific American* **149**: 28–35; Sauaia, A. (1995) *Journal of Trauma* **38**: 185–93, Annual Report Klinik für unfallchirurgie, Universitätsklinikum Essen].

Figure 26.2 Causes of death in trauma. CNS, central nervous system; MOF, multiple organ failure.

- a careful secondary survey with full examination:
 - front to back;
 - top to toe;
- transfer to a definitive site of care.

The concept of the trauma team – with each person having designated responsibilities – was developed to enable a careful assessment to be made in patients with multiple injuries and a treatment plan to be developed that recognises the need to treat the greatest threats to life first and ensure the early control of major bleeding and contamination. The philosophy also includes the concept of triage:

- the sorting of patients, with the most severely injured patients being treated first;
- the sorting of injuries, so that the most compelling threats to life, e.g. bleeding sites, receive priority (Summary box 26.1).

Summary box 26.1

Trauma to the abdomen

- The proportion of patients surviving severe torso injury until arrival at hospital is increasing
- 40% of all trauma deaths are a result of torso injury
- Rapid assessment and resuscitation will improve survival rates

INJURY MECHANISMS ASSOCIATED WITH TORSO TRAUMA

With a careful history and an understanding of the injury mechanism it is often possible to predict the type of injury that might occur. For example, in motor vehicle accidents:

- motor vehicle occupants, if unrestrained, suffer a classic ‘triad’ of injury to the face, chest and knees;
- pedestrians suffer injury to the lower legs and pelvis from the vehicle, with an associated head injury from the impact with the ground;
- lap belts can result in acute flexion over the belt with corresponding vertebral injury;
- injuries to the duodenum and/or pancreas can occur as a result of compression between, for example, the steering wheel or a seatbelt and the vertebral column.

For specific anatomy, refer also to the chapters on individual organ injury (Chapters 21–30).

- general surgery requires a knowledge of anatomy and pathology;
- trauma surgery requires a knowledge of physiology and anatomy.

Injury often traverses different anatomical zones of the body, affecting anatomical structures on both sides of traditional anatomical zones. These zones are known as junctional zones.

Junctional zones

The key junctional zones are:

- between the neck and the thorax;
- between the thorax and the abdomen;
- between the abdomen, the pelvic structures and the groin.

These zones represent surgical challenges in terms of both the diagnosis of the area of injury and the surgical approach, which have to be balanced against the physiological stability of the patient.

Root of the neck

Most injuries affecting the base of the neck (junctional zone 1) also affect the upper mediastinum and thoracic inlet. Choice of access is determined by the need for surgical control of the vascular structures contained within.

The mediastinum

The zone overlying the mediastinum with its major vessels and the heart is also an extremely high-risk area for penetrating wounds. Any wound in this region should immediately raise the suspicion of an associated cardiac or major vascular injury even in the absence of initial gross physical signs.

Diaphragm

The thorax and abdomen are separated by the diaphragm. The diaphragm is mainly responsible for breathing, and moves with breathing from the fourth to the eighth interspace. Any penetrating injury of the lower half of the chest may therefore have penetrated the diaphragm and entered the abdomen. Injuries in this junctional zone, therefore, should be evaluated as if both cavities had been penetrated (Fig. 26.3).

Pelvic structures and groin

The pelvis contains a large plexus of vessels, both venous and arterial. Should injury occur, control of haemorrhage can prove to be exceptionally difficult and may require control of both inflow and outflow. This may involve surgical control at the groin of the external iliac and femoral vessels, as well as at the aortic and cava level.

Retroperitoneum

Injury to the retroperitoneum is often difficult to diagnose, especially in the presence of other injury, and the signs may be masked. Intraoperative diagnostic tests (ultrasound and diagnostic peritoneal lavage) may be negative. The best diagnostic modality is the computerised tomography (CT) scan, but this requires a physiologically stable patient. The retroperitoneum is divided into three zones (Fig. 26.4):

Figure 26.3 The extent of the abdomen.

Figure 26.4 The zones of the retroperitoneum. Zone 1: central; zone 2: lateral; zone 3: pelvic.

- zone 1 (central): central haematomas should always be explored, with proximal and distal vascular control;
- zone 2 (lateral): lateral haematomas are usually renal in origin and can be managed non-operatively, sometimes with angioembolisation;
- zone 3 (pelvic): pelvic haematomas are exceptionally difficult to control and should, whenever possible, not be opened; they should be controlled with packing (intra- or extrapelvic) and angioembolisation (Summary box 26.2).

Summary box 26.2

Junctional zones

- Neck
- Mediastinum
- Diaphragm
- Groin
- Retroperitoneum

Injuries in these large zones pose diagnostic and treatment problems

CRITICAL PHYSIOLOGY

Resuscitation of all injuries to the chest and abdomen should follow traditional ATLS principles (Table 26.1).

Bleeding is the major problem with torso trauma. This may be obvious at the time of evaluation; however, in the young fit individual, bleeding into the chest and abdomen may be subtle and difficult to assess (Table 26.2). Bleeding occurs from five major sites – ‘one on the floor and four more’:

- external (i.e. skin);
- chest;
- abdomen;
- pelvis;
- extremities (e.g. fractures).

Although obvious injury may be present, traditional indicators are unreliable in young patients. As always, the physiology should be assessed, especially in the light of the history of the injury. Another reason why traditional indicators (such as pulse rate) may be unreliable is because the patient is ‘unseen’ before arrival in the resuscitation room and the previous physiological state is unknown – a fit individual may have a very low pulse rate

Table 26.1 ATLS principles of resuscitation

A	Airway
B	Breathing
C	Circulation
D	Disability (neurology)
E	Environment and Exposure

Table 26.2 Clinical indicators of potential on-going bleeding in torso trauma

Physiological	Increasing respiratory rate Increasing pulse rate Falling blood pressure Rising serum lactate
Anatomical	Visible bleeding Injury in close proximity to major vessels Penetrating injury with a retained weapon

normally and so a raised rate for that individual may still appear as low.

THORACIC INJURY

Thoracic injury accounts for 25% of all injuries. In a further 25%, it may be a significant contributor to the subsequent death of the patient. In most of these patients, the cause of death is haemorrhage.

Chest injuries are often life-threatening, either in their own right or in conjunction with other system injuries. About 80% of patients with chest injury can be managed non-operatively, and the key is early physiological resuscitation followed by diagnosis. A reproducible and safe approach to the diagnosis and management of chest injury is taught by the ATLS course of the American College of Surgeons.

Investigation

Routine investigation in the emergency department of injury to the chest is based on clinical examination, supplemented by chest radiography. In the unstable patient, chest radiography is the investigation of first choice, provided that it does not interfere with resuscitation. Ultrasound can be used to differentiate between contusion and the actual presence of blood. A chest tube can be a diagnostic procedure as well as a therapeutic one, and the benefits of insertion often outweigh the risks.

The pitfalls of investigation are:

- failure to auscultate both front and back (an inflated lung will 'float' on a haemothorax, so auscultation from the front may sound normal);
- failure to check whether the trachea is central;
- failure to pass a nasogastric tube if rupture of the diaphragm is suspected;
- pursuing radiological investigation (radiography or CT scan) before, or instead of, resuscitation if the patient is haemodynamically unstable.

Computerised tomography scan

The CT scan, especially using the newer multislice scanning technology, has become the principal and most reliable examination for major injury in thoracic trauma. Scanning with contrast allows for three-dimensional reconstruction of the chest and abdomen, as well as of the bony skeleton. In blunt chest trauma the CT scan will allow the definition of rib and vertebral fractures, as well as showing haematomas, pneumothoraces and pulmonary contusion. In penetrating trauma the scan may show the track of the missile and allow the planning of definitive surgery.

CT scanning has replaced angiography as the diagnostic modality of choice for the assessment of the thoracic aorta (Summary box 26.3).

Summary box 26.3

Investigation of chest injuries

- Directly or indirectly involved in 50% of trauma deaths in the USA
- 80% can be managed non-operatively
- A chest radiograph is the investigation of first choice
- A spiral CT scan provides rapid diagnoses in the chest and abdomen
- A chest drain can be diagnostic as well as therapeutic

Management

Most patients who have suffered penetrating injury to the chest can be managed with appropriate resuscitation and drainage of haematoma.

If a sucking chest wound is present, this should not be fully closed but should be covered with a piece of plastic, closed on three sides, to form a one-way valve, and then an underwater drain should be placed. No attempt should be made to close a sucking chest wound until controlled chest drainage has been achieved.

In blunt injury most bleeding occurs from the intercostal or internal mammary vessels and it is relatively rare for these to require surgery. If bleeding does not stop spontaneously the vessels can be tied off or encircled. In blunt chest compressive injury there is injury to the ribs and frequently to the underlying structures as well, with an associated lung contusion (Summary box 26.4).

Summary box 26.4

Closed management of chest injuries

- About 80% of chest injuries can be managed closed
- If there is an open wound insert a chest drain
- Do not close a sucking chest wound until a drain is in place
- If bleeding persists, the chest will need to be opened

The patient *in extremis* with exsanguinating chest haemorrhage will be discussed in the section on Emergency room thoracotomy (ERT; p. 345).

Life-threatening injuries can be remembered as the *deadly dozen*. Six are immediately life-threatening and should be sought during the primary survey and six are potentially life-threatening and should be detected during the secondary survey (Table 26.3).

Efficient initial assessment should focus on identifying and correcting the immediate threats to life. A high index of suspicion must be maintained thereafter to diagnose the potential threats to life as their symptoms and signs can be very subtle. Early consultation and referral to a trauma centre is advised in cases of doubt.

Immediate life-threatening injuries

Airway obstruction

Early preventable trauma deaths are often due to lack of or delay in airway control. Dentures, teeth, secretions and blood can

Table 26.3 The 'deadly dozen' threats to life from chest injury

Immediately life threatening	Airway obstruction Tension pneumothorax Pericardial tamponade Open pneumothorax Massive haemothorax Flail chest
Potentially life threatening	Aortic injuries Tracheobronchial injuries Myocardial contusion Rupture of diaphragm Oesophageal injuries Pulmonary contusion

contribute to airway obstruction in trauma. Bilateral mandibular fracture, expanding neck haematomas producing deviation of the pharynx and mechanical compression of the trachea, laryngeal trauma such as thyroid or cricoid fractures and tracheal injury are other causes of airway obstruction.

These patients need intubation (with simultaneous protection of the cervical spine). Early intubation is very important, particularly in cases of neck haematoma or possible airway oedema. Airway distortion can be insidious and progressive and can make delayed intubation more difficult if not impossible.

Tension pneumothorax

A tension pneumothorax develops when a 'one-way valve' air leak occurs either from the lung or through the chest wall. Air is forced into the thoracic cavity without any means of escape, completely collapsing the affected lung. The mediastinum is displaced to the opposite side, decreasing venous return and compressing the opposite lung.

The most common causes are penetrating chest trauma, blunt chest trauma with parenchymal lung injury and air leak that did not spontaneously close, iatrogenic lung punctures (e.g. due to subclavian central venepuncture) and mechanical positive-pressure ventilation.

The clinical presentation is dramatic. The patient is panicky with tachypnoea, dyspnoea and distended neck veins (similar to pericardial tamponade). Clinical examination can reveal tracheal deviation (a late finding – not necessary to clinically confirm diagnosis), hyperresonance and absent breath sounds over the affected hemithorax. Tension pneumothorax is a clinical diagnosis and treatment should not be delayed by waiting for radiological confirmation (Fig. 26.5).

Treatment consists of immediate decompression and is managed initially by rapid insertion of a large-bore needle into the second intercostal space in the mid-clavicular line of the affected hemithorax. This is immediately followed by insertion of a chest tube through the fifth intercostal space in the anterior axillary line.

Figure 26.5 Radiological appearance of a tension pneumothorax.

Pericardial tamponade

Pericardial tamponade must be differentiated from tension pneumothorax in the shocked patient with distended neck veins. It is most commonly the result of penetrating trauma. Accumulation of a relatively small amount of blood into the non-distensible pericardial sac can produce physiological obstruction of the heart. All patients with penetrating injury anywhere near the heart plus shock must be considered to have cardiac injury until proven otherwise. Classically the presentation consists of venous pressure elevation, decline in arterial pressure with tachycardia, and muffled heart sounds (note that this can mimic tension pneumothorax). A high index of suspicion and further diagnostic investigations (e.g. chest radiography showing an enlarged heart shadow or a cardiac echo showing fluid in the pericardial sac, and insertion of a central line with a rising central venous pressure) are required for the subclinical case. In cases in which major bleeding from other sites has taken place, the neck veins may be flat.

Needle pericardiocentesis may allow the aspiration of a few millilitres of blood, and this, along with rapid volume resuscitation to increase preload, can buy enough time to move to the operating room. However, in penetrating injury to the heart there is usually a substantial clot in the pericardium, which may prevent aspiration. Pericardiocentesis has a high potential for iatrogenic injury to the heart and it should at the most be regarded as a desperate temporising measure in a transport situation [under electrocardiogram (ECG) control]. The correct immediate treatment of tamponade is operative (sternotomy or left thoracotomy), with repair of the heart in the operating theatre if time allows or otherwise in the emergency room.

To summarise, the pitfalls of pericardial tamponade are:

- neck veins may be flat if the patient has bled substantially from elsewhere and is therefore in volume collapse;
- the central venous pressure may not be elevated if the circulating volume is depleted, e.g. because of other injuries;
- pericardiocentesis is a temporising measure only with a high complication rate and is not a substitute for immediate operative intervention – it proves only that there is a 'clot' on both ends of the needle!

Open pneumothorax ('sucking chest wound')

This is due to a large open defect in the chest (> 3 cm), leading to equilibration between intrathoracic and atmospheric pressure. Air accumulates in the hemithorax (rather than in the lung) with each inspiration, leading to profound hypoventilation on the affected side and hypoxia. Signs and symptoms are usually proportionate to the size of the defect. If there is a valvular effect, increasing amounts of air will result in a tension pneumothorax (see above).

Initial management consists of promptly closing the defect with a sterile occlusive plastic dressing (e.g. Opsite), taped on three sides to act as a flutter-type valve. A chest tube is inserted as soon as possible in a site remote from the injury site. Definitive treatment may warrant formal debridement and closure, preferably in the operating room, and all such patients should be referred early.

The following points are important in the management of an open pneumothorax:

- a common problem is using too small a tube – a 28FG or larger tube should be used in an adult;

- if the lung does not reinflate, the drain should be placed on low-pressure (5 cm water) suction;
- a second drain is sometimes necessary (but see Tracheo-bronchial injuries);
- physiotherapy and active mobilisation should begin as soon as possible.

Massive haemothorax

The most common cause of massive haemothorax in blunt injury is continuing bleeding from torn intercostal vessels or occasionally the internal mammary artery.

Accumulation of blood in a hemothorax can significantly compromise respiratory efforts by compressing the lung and preventing adequate ventilation. Such massive accumulation of blood presents as haemorrhagic shock with flat neck veins, unilateral absence of breath sounds and dullness to percussion. The treatment consists of correcting the hypovolaemic shock, insertion of an intercostal drain and, in some cases, intubation.

Blood in the pleural space should be removed as completely and rapidly as possible to prevent on-going bleeding, empyema or a late fibrothorax. Clamping a chest drain to tamponade a massive haemothorax is usually not helpful.

Initial drainage of more than 1500 ml of blood or on-going haemorrhage of more than 200 ml h⁻¹ over 3–4 hours is generally considered an indication for urgent thoracotomy.

The following points are important in the management of massive haemothorax:

- clinical examination may be misleading if only done from the supine position, as the lung may 'float' on the haemothorax and breath sounds anteriorly may be normal;
- caution is required in a case that drains more than 500 ml into the drainage bottle but has persistent dullness or radiographic opacification.

Flail chest

A flail chest occurs when a segment of the chest wall does not have bony continuity with the rest of the thoracic cage. This condition usually results from blunt trauma associated with multiple rib fractures, i.e. three or more ribs fractured in two or more places. The blunt force required to disrupt the integrity of the thoracic cage typically produces an underlying pulmonary contusion as well. The diagnosis is made clinically, not by radiography. On inspiration the loose segment of the chest wall is displaced inwards and less air therefore moves into the lungs. To confirm the diagnosis the chest wall can be observed for paradoxical motion of a chest wall segment for several respiratory cycles and during coughing. Voluntary splinting as a result of pain, mechanically impaired chest wall movement and the associated lung contusion are all causes of the hypoxia. The patient is also at high risk of developing a pneumothorax or haemothorax.

Traditionally, treatment consisted of mechanical ventilation to 'internally splint' the chest until fibrous union of the broken ribs occurred. The price for this was considerable in terms of intensive care unit resources and ventilation-dependent morbidity. Currently, treatment consists of oxygen administration, adequate analgesia (including opiates) and physiotherapy. If a chest tube is *in situ*, intrapleural local analgesia can be used as well. Ventilation

in situ is Latin for 'in place'.

is reserved for cases developing respiratory failure despite adequate analgesia and oxygen. Surgery to stabilise the flail chest is currently in use again; it may be useful in a selected group with isolated or severe chest injury and pulmonary contusion who have been shown to benefit from internal operative fixation of the flail segment.

Potentially life-threatening injuries

Thoracic aortic disruption

Traumatic aortic rupture is a common cause of sudden death after an automobile collision or fall from a great height. The vessel is relatively fixed distal to the ligamentum arteriosum, just distal to the origin of the left subclavian artery. The shear forces from a sudden impact disrupt the intima and media. If the adventitia is intact, the patient may remain stable. For the subgroup of immediate survivors, salvage is frequently possible if aortic rupture is identified and treated early. It should be clinically suspected in patients with asymmetry of upper or upper and lower extremity blood pressure, widened pulse pressure and chest wall contusion. Erect chest radiography can also suggest thoracic aortic disruption, the most common radiological finding being a widened mediastinum (Fig. 26.6). The diagnosis is confirmed by aortography or a contrast spiral CT scan of the mediastinum (Fig. 26.7) and to a lesser extent by transoesophageal echocardiography.

Initially, management consists of control of the systolic arterial blood pressure (to less than 100 mmHg). Thereafter, an endovascular intra-aortic stent can be placed or the tear can be operatively repaired by direct repair or excision and grafting using a Dacron graft.

The following points are important in the management of thoracic aortic disruption:

- in the presence of competing chest and abdominal injury, treat the abdominal injury first;
- look for a difference in the measured pressures between the arms and legs and for a radiofemoral delay;
- if the mediastinum is widened on the supine film, repeat the X-ray in the erect position if possible;
- the 'gold standard' for diagnosis in aortic rupture is the aortogram, but a multislice CT scan with contrast yields similar results.

Figure 26.6 Chest radiograph showing a widened mediastinum.

Figure 26.7 Computerised tomography scan showing aortic disruption.

Tracheobronchial injuries

Severe subcutaneous emphysema with respiratory compromise can suggest tracheobronchial disruption. A chest drain placed on the affected side will reveal a large air leak and the collapsed lung may fail to re-expand. If after insertion of two drains the lung fails to re-expand, referral to a trauma centre is advised.

Bronchoscopy is diagnostic. Treatment involves intubation of the unaffected bronchus followed by operative repair.

Blunt myocardial injury

Significant blunt cardiac injury that causes haemodynamic instability is rare. Blunt myocardial injury should be suspected in any patient sustaining blunt trauma who develops ECG abnormalities in the resuscitation room.

Although a good deal has been written regarding diagnosis, the most reliable sign of significant injury to the myocardium is an abnormal 12-lead ECG. Two-dimensional echocardiography may show wall motion abnormalities. A transoesophageal echocardiogram may also be helpful. There is very little evidence that enzyme estimations have any place in diagnosis; a rise in troponin I may be a useful adjunct but is not of primary value in making the diagnosis.

All patients with myocardial contusion diagnosed by conduction abnormalities are at risk of developing sudden dysrhythmias and should be monitored for the first 24 hours. After this interval the risk for sudden onset of dysrhythmias decreases substantially, unless the patient comes under significant extra stress such as that produced by a general anaesthetic.

Diaphragmatic injuries

Any penetrating injury to or below the fifth intercostal space should raise the suspicion of diaphragmatic penetration and, therefore, injury to abdominal contents. Diagnostic laparoscopy may have a role in this situation.

Blunt injury to the diaphragm is usually caused by a compressive force applied to the pelvis and abdomen. The diaphragmatic rupture is usually large, with herniation of the abdominal contents into the chest. Diagnosis of blunt diaphragmatic rupture is missed even more often than penetrating injuries in the acute phase.

Most diaphragmatic injuries are silent and the presenting features are those of injury to the surrounding organs. There is no single standard investigation. Chest radiography after placement of a nasogastric tube may be helpful (as this may show the stomach herniated into the chest). Contrast studies of the upper or lower gastrointestinal tract, CT scan and diagnostic peritoneal lavage all lack positive or negative predictive value. The most accurate evaluation is by video-assisted thoracoscopy (VATS) or laparoscopy, the latter offering the advantage of allowing the surgeon to proceed to a repair and additional evaluation of the abdominal organs.

Operative repair is recommended in all cases. All penetrating diaphragmatic injury must be repaired via the abdomen and not the chest, to rule out penetrating hollow viscus injury.

The thorax is at negative pressure and the abdomen is at positive pressure. The late complication of rupture of the diaphragm is herniation of abdominal contents into the chest. These include

stomach, small bowel, large bowel and spleen. Strangulation of any of the contents can occur, which has a high mortality rate.

Oesophageal injury

Most injuries to the oesophagus result from penetrating trauma; blunt injury is rare. A high index of suspicion is required if the diagnosis is to be made in a timely manner. The patient can present with odynophagia (pain on swallowing foods or fluids), subcutaneous or mediastinal emphysema, pleural effusion, air in the retro-oesophageal space and unexplained fever within 24 hours of injury. Mediastinal and deep cervical emphysema must be seen as evidence of an aerodigestive injury until proven otherwise.

The mortality rate rises exponentially if treatment is delayed for more than 12–24 hours. A combination of oesophagogram in the decubitus position and oesophagoscopy confirm the diagnosis in the great majority of cases. The treatment is operative repair and drainage.

Pulmonary contusion

Pulmonary contusion is caused by haemorrhage into the lung parenchyma, usually underneath a flail segment or fractured ribs. This is a very common, potentially lethal chest injury and the major cause of hypoxaemia after blunt trauma. It is an independent risk factor for pneumonia and adult respiratory distress syndrome (ARDS).

The natural progression of pulmonary contusion is worsening hypoxemia for the first 24–48 hours. The chest radiography findings are typically delayed and non-segmental. Contrast CT scanning can be confirmatory. If abnormalities are seen on the admission chest radiograph, the pulmonary contusion is severe. Haemoptysis or blood in the endotracheal tube is a sign of pulmonary contusion.

In mild contusion the treatment is oxygen administration, aggressive pulmonary toilet and adequate analgesia. In more severe cases mechanical ventilation is necessary. Although one should be careful not to overload these patients with fluid to avoid pulmonary oedema, establishment of normovolaemia is critical for adequate tissue perfusion and fluid restriction is not advised.

EMERGENCY THORACOTOMY

Emergency thoracic surgery is an essential part of the armamentarium of any surgeon dealing with major trauma. A timely thoracotomy for the correct indications can be the key step in saving an injured patient's life.

Indications for thoracotomy include:

- internal cardiac massage;
- control of haemorrhage from injury to the heart;
- control of haemorrhage from injury to the lung;
- control of intrathoracic haemorrhage from other causes;
- control of massive air leak.

Thoracotomy can be broadly divided into the following:

- emergency (resuscitative) thoracotomy for control of life-threatening bleeding;
- planned thoracotomy for repair of specific injury.

The clinical decision as to whether a casualty requires an ERT can be transferred to the operating room or whether further investigations are required can be more complex than it initially

sounds. It is far better to perform a thoracotomy in the operating room, either through an anterolateral approach or a median sternotomy, with good light and assistance and the potential for auto-transfusion and potential bypass, than it is to attempt heroic emergency surgery in the resuscitation suite. However, if the patient is *in extremis* with a falling systolic blood pressure, despite volume resuscitation, there is no choice but to proceed immediately with a left anterolateral thoracotomy in an attempt to relieve the situation. In certain circumstances, when care is futile, it may not need to be performed at all. A resuscitation room thoracotomy following blunt trauma has limited indications and is rarely successful.

Emergency room thoracotomy

ERT should be reserved for those patients suffering penetrating injury *in whom signs of life are still present*. Patients who have received cardiopulmonary resuscitation (CPR) in the pre-hospital phase of their care are unlikely to survive, and electrical activity must be present. The survival rates for ERT in patients with penetrating trauma in whom the blood pressure is falling despite adequate resuscitation are shown in Table 26.4.

It is important to make a distinction between:

- ERT for the control of haemorrhage or tamponade or, in some situations, for internal cardiac massage;
- urgent planned thoracotomy for definitive correction of the problem – this usually takes place preferably in the more controlled environment of the operating theatre.

In certain situations, ERT is considered futile:

- CPR in the absence of endotracheal intubation for more than 5 min;
- CPR for more than 10 min (with or without endotracheal intubation);
- blunt trauma when there have been no signs of life at scene (see above).

Planned emergency thoracotomy

Planned emergency thoracotomy implies an emergency thoracotomy performed as a planned procedure in the operating room, directed at the management of a specific injury. As such, the approach chosen is dependent on the indication for surgery and the organ injured (Table 26.5). The thoracotomy may be right- or left-sided, and these may be joined, resulting in the so called 'clamshell incision'. Alternatively, certain organs are best approached through a median sternotomy.

Posterolateral thoracotomy is not generally used in the emergency situation because of the difficulties in positioning of the patient.

Continuing blood loss

The first principle of all care is to assess and treat the patient according to the physiology. Initial blood loss of more than

Table 26.4 Survival rates for thoracotomy in patients with penetrating trauma

Blood pressure despite resuscitation	Survival (%)
> 60 mmHg	60%
> 40 mmHg	30%
< 40 mmHg	3%

Table 26.5 Different approaches to the contents of the chest cavity

Approach	Best for
Left anterolateral thoracotomy	Left lung and lung hilum Thoracic aorta Origin of left subclavian artery Left side of heart Lower oesophagus
Right anterolateral thoracotomy	Right lung and lung hilum Azygos veins Superior vena cava Infracardiac inferior vena cava Upper oesophagus Thoracic trachea
Median sternotomy	Anterior aspect of heart Anterior mediastinum Ascending aorta and arch of aorta Pulmonary arteries Carina of the trachea

1500 ml indicates the potential for class III shock, and any on-going bleeding must be dealt with surgically, as soon as possible. Similarly, an on-going blood loss of more than 200 ml h⁻¹ for 3 consecutive hours requires resuscitative surgery to stop the bleeding.

ABDOMINAL INJURY

Patients who have suffered abdominal trauma can generally be classified into the following categories based on their physiological condition after initial resuscitation:

- haemodynamically 'normal' – investigation can be full and treatment planned;
- haemodynamically 'stable' – investigation is more limited and is aimed at establishing whether the patient can be managed non-operatively, whether angioembolisation can be used or whether surgery is required (and, if so, which cavity);
- haemodynamically 'unstable' – immediate surgical correction of the bleeding is required.

A trauma laparotomy is the final step in the pathway to delineate intra-abdominal injury. Occasionally it is difficult to determine where the compelling source of bleeding is in the shocked multiply injured patient and, if doubt still exists, especially in the presence of other injuries, a laparotomy may still be the safest option.

Investigation

Investigations are driven by the cardiovascular status of the patient. A patient's physiology is the key to the value of radiological imaging, as stable patients will generally be able to have a CT scan. Radiography for the evaluation of torso trauma is only of limited value in stable trauma patients, as CT will provide greater and more anatomically accurate information. This applies to the chest, abdominal cavity and pelvis.

In patients with penetrating injury, metal markers (e.g. bent paper clips) should be placed on all external wounds before plain films are taken, irrespective of the area being radiographed, as this allows an assessment of the trajectory and helps to correlate

Figure 26.8 Abdominal radiograph of a gunshot wound showing bullet markers.

the number of holes and the number of missiles (i.e. whether two holes are indicative of one missile passing through or two missiles, both retained internally) (Fig. 26.8).

The patient's physiology must be assessed and, if there is an indication that the patient is bleeding, then the source must be found. Blood loss into the abdomen can be subtle and there may be no clinical signs (blood is not an irritant and may not initially cause any abdominal pain). Distension may be subjective. If stable, the best and most sensitive modality is a CT scan with intravenous contrast; however, in the unstable patient, this is generally not possible. Examination in unstable patients should take place in the emergency department or operating theatre.

Diagnostic peritoneal lavage

Diagnostic peritoneal lavage (DPL) is a test used to assess the presence of blood in the abdomen. A gastric tube is placed to empty the stomach and a urinary catheter is inserted to drain the bladder.

A cannula is inserted below the umbilicus, directed caudally and posteriorly. The cannula is aspirated for blood (> 10 ml is deemed as positive) and, following this, 1000 ml of warmed Ringer's lactate solution is allowed to run into the abdomen and is then drained out. The presence of > 100 000 red cells μl^{-1} or > 500 white cells μl^{-1} is deemed positive (this is equivalent to 20 ml of free blood in the abdominal cavity). Drainage of lavage fluid via a chest drain indicates penetration of the diaphragm.

Although DPL has largely been replaced by focused abdominal sonar for trauma (FAST; see below), it remains the standard in many institutions where FAST is not available or is unreliable. DPL is especially useful in the hypotensive, unstable patient with multiple injuries as a means of excluding intra-abdominal bleeding.

DPL has a 97–98% sensitivity rate for blood and a 1% complication rate. In total, 10–15% of laparotomies performed on the

Sydney Ringer, 1835–1910, Professor of Clinical Medicine, University College Hospital, London, England.

basis of a 'positive' DPL do not require active intervention. In principle, therefore, a negative DPL is often more helpful than a positive one, because the presence of blood in the abdomen does not necessarily require surgery.

Focused abdominal sonar for trauma

FAST is a technique whereby ultrasound imaging is used to assess the torso for the presence of blood, either in the abdominal cavity or in the pericardium. The purpose of the ultrasound evaluation of the injured casualty is to determine the presence of free intra-abdominal or pericardial fluid. The technique therefore focuses only on four areas:

- pericardial;
- splenic;
- hepatic;
- pelvic.

There is no attempt to determine specific injury. Repeated studies have shown that FAST is a rapid, reproducible, portable and non-invasive bedside test that is equally of use in the hospital resuscitation room or on military deployment. FAST can be performed simultaneously with resuscitation and it has been unequivocally demonstrated that trained operators can perform FAST accurately. It is commonly used as the bedside investigation of choice for detection of intra-abdominal blood in abdominal trauma. Extensions of the FAST technique to include assessment of the chest for haemothorax and pneumothorax, as well as assessment of the extremities, depend on the experience of the operator and are not yet widely accepted.

FAST is accurate for the detection of > 100 ml of free blood; however, it is very operator and experience dependent and, especially if the patient is very obese or the bowel is full of gas, it may be unreliable. Hollow viscus injury is difficult to diagnose, even in experienced hands, with a low sensitivity (29–35%) for organ injury without haemoperitoneum. FAST is unreliable for excluding injury in penetrating trauma. If there is doubt, the FAST examination should be repeated (Summary box 26.5).

Summary box 26.5

FAST

- It detects free fluid in the abdomen or pericardium
- It will not reliably detect less than 100 ml of free blood
- It does not identify injury to hollow viscus
- It cannot reliably exclude injury in penetrating trauma
- It may need repeating or supplementing with other investigations

Computerised tomography

CT has become the 'gold standard' for the intra-abdominal diagnosis of injury in the stable patient. The scan is performed using intravenous contrast and often oral contrast as well. CT is sensitive for blood and has the added advantage of sensitivity for the diagnosis of retroperitoneal injury. An entirely normal abdominal CT is usually sufficient to exclude injury.

The following points are important when performing CT:

- despite its tremendous value, it remains an inappropriate investigation for unstable patients who have a risk of rapid decompensation while in the scanner;

- if duodenal injury is suspected from the mechanism of injury, oral contrast may be helpful;
- if rectal and distal colonic injury is suspected in the absence of blood on rectal examination, rectal contrast may be helpful;
- in multislice CT examinations, fat may erroneously appear to be 'free air'.

Diagnostic laparoscopy

Diagnostic laparoscopy (DL) is a valuable screening investigation in penetrating trauma to detect or exclude peritoneal penetration and/or diaphragmatic injury in stable patients following an abdominal or thoracoabdominal stab wound. DL is not appropriate for use in the unstable patient.

In most institutions, evidence of penetration requires a laparotomy to evaluate organ injury, as it is difficult to exclude all intra-abdominal injuries laparoscopically. When used in this role DL reduces the non-therapeutic laparotomy rate. DL is not a substitute for open laparotomy, especially in the presence of haemoperitoneum or contamination.

INDIVIDUAL ORGAN INJURY

Liver

The majority of injuries to the liver occur as a result of blunt injury. Most are relatively minor in severity and can be managed non-operatively. Many are not even suspected at the time. With the widespread use of CT for the evaluation of trauma patients, minor solid organ injury (liver, spleen, kidneys) is being diagnosed more frequently. Many of these injuries were not even recognised before the use of CT scanning.

Blunt liver trauma occurs as a result of direct injury. The liver is a solid organ and compressive forces can easily burst the liver substance. The liver is compressed between the force and the rib cage or vertebral column.

Penetrating trauma to the liver is relatively common, primarily related to the size of the liver in the abdominal cavity and, therefore, its vulnerability to injury. Bullets have a shock wave and when they pass through a solid structure such as the liver they cause significant damage some distance from the actual track of the bullet. Not all penetrating wounds require operative management and a number may stop bleeding spontaneously.

In the stable patient, CT is the investigation of choice. It provides information on the liver injury itself, as well as on injuries to the adjoining major vascular and biliary structures. Close proximity injury and injury in which there is a suggestion of a vascular component should be reimaged, as there is a significant risk of the development of subsequent ischaemia.

Liver injury can be graded using the American Association for the Surgery of Trauma (AAST) Organ Injury Scale (OIS) (www.aast.org/injury). These are useful as research and audit tools and can be used to help drive management decisions.

Management

With liver injury it is the cardiovascular status of the patient that ultimately drives the patient towards either the operative or the non-operative approach. The CT images and volume of blood in the abdomen can be assessed to give an idea of the severity of the liver injury; however, even high-grade injuries may be managed non-operatively in the stable patient. Surgery is required only in

the presence of other organ injury, increasing instability or failure of non-operative management.

The management of liver injuries can be summarised as ‘the four Ps’:

- push;
- Pringle;
- plug;
- pack.

At laparotomy the liver is reconstituted as best as possible in its normal position and bleeding is controlled by direct compression (push). The inflow from the portal triad is controlled by a Pringle’s manoeuvre, with direct compression of the portal triad, either digitally or using a soft clamp (Fig. 26.9). This has the effect of reducing arterial and portal venous inflow into the liver although it does not control the backflow from the inferior vena cava and hepatic veins. Any holes due to penetrating injury can be plugged directly and, after controlling any arterial bleeding, the liver can then be packed (see Damage control surgery, p. 350).

Bleeding points should be controlled locally when possible and, after packing, such patients should undergo angiography; any vessels that are still bleeding can be embolised. It is not usually necessary to suture penetrating injuries of the liver. If there has been direct damage to the hepatic artery it can be tied off. Damage to the portal vein must be repaired, as tying off the portal vein carries a greater than 50% mortality rate. If it is not technically feasible to repair the vein at the time of surgery, it should be shunted and the patient referred to a specialist centre (see Damage control, p. 350). A closed suction drainage system must be left *in situ* following hepatic surgery.

Penetrating injuries and deep tracts can be plugged using silicone tubing or a Sengstaken–Blakemore tube.

Finally, the liver can be definitively packed, restoring the anatomy as closely as possible (see Damage control surgery). Placing omentum into cracks in the liver is not recommended (Summary box 26.6).

Summary box 26.6

Liver trauma

- Blunt trauma occurs as the result of direct compression
- Penetrating trauma of the upper abdomen or lower thorax can damage the liver
- CT scanning is the investigation of choice
- Surgical management consists of push, Pringle, plug and pack
- The hepatic artery can be tied off but not the portal vein (stent)
- Closed suction should always be used

Biliary injuries

Isolated traumatic biliary injuries are rare and occur mainly from penetrating trauma. They often occur in association with injuries to other structures that lie in close proximity, e.g. common bile duct injuries are often associated with portal vein injuries. The common bile duct can be repaired over a T-tube or drained and referred to appropriate care as part of damage control.

Spleen

Splenic injury occurs from direct blunt trauma; the spleen is often injured by direct energy applied to the overlying ribs (ninth to 11th ribs). Most isolated splenic injuries, especially in children, can be managed non-operatively. However, in adults, especially in the presence of other injury, physiological instability, coagulopathies, etc., laparotomy and direct splenorrhaphy should be considered. The spleen can be packed, repaired or placed in a mesh bag. Splenectomy may be a safer option, especially in the unstable patient with multiple potential sites of bleeding. In certain situations, selective angioembolisation of the spleen can play a role.

Following splenectomy there are significant though transient changes to blood physiology. The platelet count rises and may reach $10^7 \mu\text{l}^{-1}$. The white cell count rises and may mimic sepsis.

Pancreas

Most pancreatic injury occurs as a result of blunt trauma. The major problem is that of diagnosis, because the pancreas is a retroperitoneal organ and, therefore, examinations such as DPL, FAST, etc. are non-specific. CT remains the mainstay of accurate diagnosis. Amylase estimation is only relatively helpful because a low amylase (present in up to 50% of injury) does not exclude pancreatic injury.

Classically the pancreas should be treated with conservative surgery and closed suction drainage. Injuries are treated according to the OIS system of the AAST. Injuries to the tail are treated by closed suction drainage, with distal pancreatectomy if the duct is involved. Proximal injuries (to the right of the superior mesenteric artery) are treated as conservatively as possible, although partial pancreatectomy may be necessary. The pylorus can be temporarily closed (pyloric exclusion) in association with a gastric drainage procedure. A Whipple’s procedure (pancreaticoduodenectomy) is rarely needed and should not be performed in the emergency situation because of the very high associated

Allen Oldfather Whipple, 1881–1963, Valentine Mott Professor of Surgery, The College of Physicians and Surgeons, Columbia University, New York, NY, USA.

mortality rate. A damage control procedure with packing and drainage should be performed and the patient referred for definitive surgery once stabilised.

Stomach

Most stomach injuries are caused by penetrating trauma. Blood may be present and is diagnostic if found in the nasogastric tube.

Surgical repair is performed but great care must be taken to examine the stomach fully, as an injury to the front of the stomach can be expected to have an 'exit' wound elsewhere on the organ.

Duodenum

Duodenal injury is frequently associated with injuries to the adjoining pancreas. Like the pancreas the duodenum lies retroperitoneally and so injuries are hidden and only discovered late or at laparotomy performed for other reasons. The only sign may be gas in the periduodenal tissue seen at CT.

Smaller injuries can be repaired primarily. Major injuries and those also involving the head of the pancreas should undergo initial damage control surgery and be referred for definitive care.

Small bowel

The small bowel is frequently injured as a result of blunt trauma. The individual loops may be trapped, causing high-pressure rupture of a loop or tearing of the mesentery. In penetrating injury, wounds may be multiple.

Small bowel injuries need urgent repair at laparotomy. Haemorrhage control as always takes priority and these wounds can be temporarily controlled with simple sutures. The small bowel can be temporarily occluded until haemorrhage control has been achieved. In blunt trauma the mesenteric vessels can be torn and bleeding actively – this may dictate the extent of a resection (see Damage control surgery). Resections should be carefully planned to limit the loss of viable small bowel but should be weighed against an excessive number of repairs or anastomoses. A combination of resection and repair should be used to avoid loss of significant lengths of bowel. Haematomas in the small bowel mesenteric border need to be explored to rule out perforation. With low-energy wounds, primary repair can be performed after debridement of any dead tissue, whereas more destructive wounds associated with military type weapons require resection and anastomosis.

Colon

Injuries to the colon from blunt injury are relatively infrequent. However, in penetrating injury, colonic injuries are not uncommon. If relatively little contamination is present and the viability of the colon is satisfactory, such wounds can be repaired primarily. If, however, there is extensive contamination, the patient is physiologically unstable or the bowel is of doubtful viability, then the colon can be closed off or a subsequent defunctioning colostomy formed.

Rectum

Only 5% of colon injuries involve the rectum. The majority are caused by penetrating injury, although occasionally the rectum may be damaged following fracture of the pelvis. Digital rectal examination to assess for the presence of blood is part of the examination of the trauma patient and, especially with an abdominal penetrating injury, the presence of blood is evidence of

colorectal injury. These injuries are often associated with bladder and proximal urethral injury.

The location of the injury determines the management strategy. With intraperitoneal injuries, the rectum is managed as for colonic injuries. Full-thickness extraperitoneal rectal injuries should be managed with either a diverting end-colostomy and closure of the distal end (Hartmann's procedure) or a loop colostomy. Presacral drainage is generally no longer used.

In penetrating trauma it is important that the number of small bowel holes and missiles, e.g. bullets, add up to an even number, because although occasionally wounds may be tangential, this is the exception rather than the rule. For every 'entrance' wound there should either be an 'exit' wound or a residual missile.

Renal and urological tract injury

In the stable patient CT scanning with contrast is the investigation of choice. CT will enable the assessment of renal injury and, with delayed films, will enable the assessment of more distal injury.

For assessment of bladder injury a cystogram should be performed. A minimum of 400 ml of contrast is instilled into the bladder via a urethral catheter. The volume is essential because a small volume may not leak from a small bladder injury once the cystic muscle has contracted. It is important to assess the films as follows:

- with two views – anteroposterior and lateral;
- on two occasions – full and post-micturition.

Generally, renal injury is managed non-operatively unless the patient is unstable. The kidney can be angioembolised if required.

Ureteric injury is rare and is generally due to penetrating injury. Most ureters can be repaired or diverted if necessary.

Intraperitoneal ruptures of the bladder, usually from direct blunt injury, will require surgical repair. Extraperitoneal ruptures are usually associated with a fracture of the pelvis and will heal with adequate urine drainage (Summary box 26.7).

Summary box 26.7

Injuries to structures in the abdomen

- In children splenic injury can be managed non-operatively
- Duodenal injuries are associated with pancreatic damage
- Small bowel injuries need urgent repair
- Large bowel injuries can be resected and stapled off in damage limitation surgery
- Rectal injuries may be best managed initially with a defunctioning colostomy
- Kidney and urinary tract damage is best diagnosed with enhanced CT scanning
- Intra-abdominal bladder tears need formal repair and drainage

ABDOMINAL COMPARTMENT SYNDROME AND THE OPEN ABDOMEN

Raised intra-abdominal pressure has far-reaching consequences for the patient; the syndrome that results is known as abdominal

Henri Albert Charles Antoine Hartmann, 1860–1952, Professor of Clinical Surgery, The Faculty of Medicine, The University of Paris, Paris, France.

compartment syndrome (ACS). ACS is a major cause of morbidity and mortality in the critically ill patient and its early recognition is essential (Table 26.6).

In all cases of abdominal trauma in which the development of ACS in the immediate postoperative phase is considered a risk, the abdomen should be left open and managed as for damage control surgery.

DAMAGE CONTROL

Following major injury, protracted surgery in the physiologically unstable patient with the 'deadly triad' – the combination of hypothermia, acidosis and coagulopathy – carries a very high mortality rate. 'Damage control' or 'damage limitation surgery' is a concept that originated from naval architecture, whereby a ship was designed to have areas sealed off in the case of damage, to limit flooding.

The application of damage control to the trauma patient has come from the realisation that minimising surgery until the physiological derangement can be corrected is the best way of improving outcome. The surgery is restricted to only two goals:

- stopping any active surgical bleeding;
- controlling any contamination.

The operation is then suspended and the abdomen temporarily closed. The patient's resuscitation continues in the intensive care unit. Once the physiology has been corrected, the patient warmed and the coagulopathy corrected, the patient is returned to the operating theatre for any definitive surgery.

The key philosophy of damage control can be summarised as follows:

- to keep the patient alive at any cost, utilising an unconventional approach and abbreviated surgical technique to limit the depletion of physiological reserve;
- to be part of the resuscitation process, in which there is initial surgical control of haemorrhage and contamination followed by rapid closure, assisting in the restoration of normal physiology.

Table 26.6 Effect of raised intra-abdominal pressure on individual organ function

Organ	Effect
Renal	Increase in renal vascular resistance leading to a reduction in glomerular filtration rate and impaired renal function
Cardiovascular	Decrease in venous return resulting in decreased cardiac output because of both a reduction in preload and an increase in afterload
Respiratory	Increased ventilation pressures because of splinting of the diaphragm, decreased lung compliance and increased airway pressures
Visceral perfusion	Reduction in visceral perfusion
Intracranial effects	Severe rises in intracranial pressures

Damage control resuscitation

This is a new concept that has evolved following recent military experience, in which the concept of damage control has been broadened to include the techniques used in resuscitation as well as in surgery. In the group of unstable trauma patients who are candidates for damage control surgery the time in the emergency department is minimised and the resuscitation of the patient is carried out in the operating room and not in the resuscitation bay. The resuscitation is individualised through repeated point of care testing in the operating room of haemoglobin level, acidosis (pH and lactate) and clotting, and is therefore directed towards the early delivery of biologically active colloids, clotting products, recombinant factor VIIa and whole blood in order to buy time. The physiological disturbances that are associated with the downward spiral of acidosis, coagulopathy and hypothermia in these serious injuries are predicted and attempts are made to avoid them rather than react to them.

Damage control surgery

The decision that damage control surgery is required should be made at the earliest opportunity, preferably in the emergency department or at the beginning of the operation. An early decision improves communication of the strategy with the whole surgical and anaesthetic team, expedites time to the operating room, limits time in surgery and allows earlier admission thereafter to the intensive care unit where the resuscitation can be best completed. Damage control is a staged process (Table 26.7).

Patient selection is the key to appropriate damage control. This is summarised in Table 26.8.

The initial surgical focus is haemorrhage control, which is followed by control and limitation of contamination. This is achieved using a range of abbreviated techniques including simple ligation of bleeding vessels, shunting of major arteries and veins, drainage, temporary stapling off of bowel, and therapeutic packing.

Following the above the abdomen is closed in a temporary fashion using a sheet of plastic (e.g. Opsite) over the bowel, an intermediate pack to allow suction, and a further sheet of adherent plastic drape to the skin to form a watertight and airtight seal. Suction is applied to the intermediate pack area to collect abdominal fluid. This technique is known as the 'Vacpac' or 'Opsite sandwich' (Fig. 26.10).

The closure is not without its own significant morbidity including atmospheric enteric fistula formation, heat loss and excessive fluid loss and, therefore, attempts to close the abdomen should be proactive. Successful closure may require aggressive off-loading of fluid and even haemofiltration to achieve this if the patient will tolerate it. The best situation is closure of the abdominal fascia, or, if this cannot be achieved, then skin closure only. Occasionally, mesh closure can be used, with skin grafting over the mesh and subsequent abdominal wall reconstruction.

Table 26.7 The stages of damage control surgery

Stage	
I	Patient selection
II	Control of haemorrhage and control of contamination
III	Resuscitation continued in the intensive care unit
IV	Definitive surgery
V	Abdominal closure

Table 26.8 Indications for damage control surgery

Anatomical	Inability to achieve haemostasis Complex abdominal injury, e.g. liver and pancreas Combined vascular, solid and hollow organ injury, e.g. aortic or caval injury Inaccessible major venous injury, e.g. retrohepatic vena cava Demand for non-operative control of other injuries, e.g. fractured pelvis Anticipated need for a time-consuming procedure
Physiological (decline of physiological reserve)	Temperature < 34°C pH < 7.2 Serum lactate > 5 mmol l ⁻¹ [N (Normal) < 2.5 mmol l ⁻¹] Prothrombin time (PT) > 16 s Partial thromboplastin time (PTT) > 60 s > 10 units blood transfused Systolic blood pressure < 90 mmHg for > 60 min
Environmental	Operating time > 60 min Inability to approximate the abdominal incision Desire to reassess the intra-abdominal contents (directed relook)

As soon as control has been achieved the patient is transferred from the operating theatre to the intensive care unit where resuscitation is continued; the aim of this is the correction of hypothermia, acidosis and coagulopathy. Following this, further physiological investigation or radiological intervention can be carried out.

The next stage of damage control is definitive surgery. The team should aim to perform definitive anastomoses, vascular reconstruction and closure of the body cavity within 24–72 hours of injury; however, this must be individualised to the patient, the response to critical care resuscitation and the injury complexes, and must be judged on its own merits. Undue haste and a premature return to theatre will convert a definitive second operation into a second damage control procedure and result in further physiological insult for the patient; however, undue delay may increase the risk of intra-abdominal sepsis and the progression of previously unrecognised injuries.

The abdomen is closed as soon as possible, bearing in mind the risks of ACS.

**Figure 26.10** Abdominal closure following damage control surgery.

Thoracic damage control is conceptually based on the same philosophy, i.e. that haemorrhage control and focused surgical procedures minimise further surgical insult and lead to improved survival in the unstable trauma patient. The focus of thoracic damage control is to rapidly control bleeding and limit air leaks using the fastest procedures available to minimise the operative time.

In abdominal damage control, abbreviated surgical techniques are performed that will require secondary procedures. The physiological impact of injuries to the thorax dictate that the thoracic techniques utilised are more single-stage definitive techniques. These are often performed in an abbreviated and occasionally more radical fashion, e.g. using staplers to resect injured lung, the lung twist to temporarily control lung parenchymal bleeding, *en masse* pneumonectomy and, more rarely, thoracic packing for diffuse bleeding and rapid techniques for the temporary closure of the chest.

The indications and techniques for emergency thoracotomy have already been described.

Damage control applies equally to the extremities, with shunting of blood vessels, fasciotomy and removal of contaminated tissue. Subsequent definitive management can be carried out at a later stage (Summary box 26.8).

Summary box 26.8**Damage control**

- Resuscitation is carried out in the operating room using biologically active fluids
- Surgery is the minimum needed to stabilise the patient
- The aim of surgery is control of haemorrhage and limitation of contamination
- Secondary surgery is aimed at definitive repair

en masse is French for 'in a body'.

INTERVENTIONAL RADIOLOGY

Interventional radiology can be useful in the management of torso trauma as both an investigative and a therapeutic tool for patients with vascular injury. Angioembolisation following demonstration of on-going bleeding in splenic and renal injury is a valuable technique. Interventional radiology is also widely used to evaluate for and control pelvic bleeding when clinically appropriate. Significant liver injuries that require therapeutic packing at laparotomy are at risk of on-going bleeding. Arteriography can be used to define and embolise bleeding vessels before a planned return to the operating room. In penetrating trauma, interventional radiology can be used to identify pseudoaneurysms and arteriovenous fistulae, which can be stented if required.

NON-OPERATIVE MANAGEMENT

Universally preferred for the management of solid organ injury in haemodynamically stable children, non-operative management of solid abdominal organ injury has rapidly gained acceptance in the management of adults as well. A stable patient and accurate imaging by CT are prerequisites for this approach. More widespread CT now accurately diagnoses many low-grade organ injuries to the liver, spleen and kidneys, which are frequently self-limiting with minimal intra-abdominal blood loss. Close observation for any signs of deterioration or bleeding is important as 2–15% will have concomitant hollow viscus injuries. Failure of non-operative management is uncommon and typically occurs within the first 12 hours after injury. Therefore, if correctly selected, the vast majority of these patients will avoid surgery,

requiring less blood transfusion and sustaining fewer complications than operated patients.

Antibiotics in torso trauma

There is no level 1 evidence to recommend the use of antibiotics for the insertion of chest drains. However, they should be used in all cases of penetrating abdominal trauma.

Extremity trauma

LEARNING OBJECTIVES

To gain an understanding of:

- How to identify whether an injury exists
- The important injuries not to miss
- The principles of the description and classification of fractures
- The range of available treatments
- How to select an appropriate treatment

INTRODUCTION

The objective when managing any injured person is to restore maximum function with minimum risk. The first duty is to identify and treat any immediate threats to life. The management of skeletal injuries has to take its rightful place in the overall care of the patient. For the multiply injured, following the Advanced Trauma Life Support (ATLS) system, this rightful place is usually when the primary survey and initial resuscitation have been completed. Very occasionally the haemorrhage associated with a fracture may be life-threatening; thus a pelvic injury may require urgent stabilisation or a major open fracture direct pressure to control blood loss. Most often, extremity injuries are encountered in the secondary survey. The relevant history, including the mechanism of the incident, a top-to-toe clinical examination and appropriate special investigations can be taken into account. Extremity injuries are identified and diagnosed, and their treatment is then planned and executed according to priority.

DIAGNOSIS, DESCRIPTION AND CLASSIFICATION OF INJURY

The first step is to establish the existence of an injury; it can then be described, classified and treated. Missing an injury can be serious, both medically and legally. It is usually easy to diagnose a musculoskeletal injury and so we become complacent. However, Table 27.1 contains a list of injuries for which it is known from the mistakes of others that the diagnosis is easily missed and that this error may have adverse consequences. We may each have only one chance in our career to make some of these diagnoses, so we must be prepared for the first case. We cannot just learn constructively from our own experience.

Assessment – history and examination

A relevant history should be taken. This will provide symptoms, a mechanism and general information about the patient. From the symptoms and mechanism likely injuries can be considered, sought and excluded. The general history should include factors that may affect diagnosis, treatment and objective. Known

metastatic disease or generalised bone pathology will contribute to the diagnosis and affect the management plan. Diabetes and the use of anticoagulants are two common factors affecting management. Because the aim of treatment is restoration of function it is necessary to be clear as to the level of pre-injury function. This is gauged from occupation, hobbies, handedness and responsibilities. A mother with young children may need rapid restoration of function; a sportsperson or musician may not accept what would normally be considered a good result.

In isolated injuries, examination should focus on the history and symptoms. Local features of tenderness, deformity, abnormal movement and loss of function will then guide the use of investigations. In many respects the most important part of the clinical examination is of those areas adjacent to the area to be investigated, for it is here that many injuries are missed. For instance, in the case of injuries to the lower extremity, many hindfoot, mid-foot and Achilles tendon injuries are missed as the investigation chosen is often an ankle radiograph, and when this is normal the patient is falsely reassured.

In the multiply injured or obtunded patient, the absence of

Table 27.1 Extremity injuries not to miss

Posterior dislocation of the shoulder
Lateral condylar mass fracture of the distal humerus
Peri-lunate dislocation
Scaphoid fracture
Tarsometatarsal fracture dislocation
Compartment syndrome
Vascular injury with knee dislocation
Talar neck fracture
Slipped upper femoral epiphysis
Achilles tendon rupture

Achilles, the Greek Hero, was the son of Peleus and Thetis. When he was a child his mother dipped him in the Styx, one of the rivers of the Underworld, so that he should be invulnerable in battle. The heel by which she held him did not get wet, and was, therefore, not protected. Achilles died from a wound in the heel which he received at the siege of Troy.

history and symptoms is compensated for by performing a top-to-toe clinical examination as part of the secondary survey.

The discovery of one injury is not the conclusion of the search but a prompt to look for associated injuries. This search is guided by the knowledge that injuries occur in patterns, e.g. a dislocated knee is often associated with a vascular injury, a head injury may mask a fractured cervical spine. In 15% of cases in which a spinal fracture has been identified there is another spinal injury at a separate site. An important discipline, particularly when managing the multiply injured patient, is the repeat examination; the 'morning after' ward round is a time for a further secondary survey to search for occult injuries. Once the information has been gathered there should be a rational relationship such that *patient + mechanism = injury*.

Principles of investigation

Imaging is performed to confirm or exclude possible injury guided by the history and examination. It adds precision to the diagnosis, which aids in planning treatment. A summary of the available methods is given in Table 27.2.

For almost 100 years the mainstay of the orthopaedic surgeon's investigation has been the plain radiograph. Radiographs should include orthogonal views (two views at 90° separation) and, for long bones, should show the joints above and below the injury. Other imaging modalities are now being used more frequently. Computerised tomography (CT) scans are invaluable for defining more complex patterns of a fracture, particularly adjacent to a joint. They are now also being used for the global assessment of the multiply injured person. As scan acquisition times decrease and physiological monitoring improves, the dangers for the multiply injured patient of being isolated in a scanner are reduced and the benefits of accurate diagnosis increased. Ultrasound is used to assess soft-tissue structures, e.g. Achilles tendon or rotator cuff injuries. Magnetic resonance (MR) scanning is used primarily to show soft-tissue injury, particularly around the knee. Imaging needs to be used intelligently; there is an adage in radiology that 'unless you are very lucky you only find what you look for'. Injuries with a reputation for being missed, such as a posterior dislocation of the shoulder, should be actively sought whenever there is any chance that they may be present (Fig. 27.1) (Summary box 27.1).

Summary box 27.1

Finding an injury

- Relate all of the information gathered in the equation *patient + mechanism = injury*
- Look specifically for 'easily missed injuries'
- Re-examine the multiply injured patient

DESCRIPTION AND CLASSIFICATION OF MUSCULOSKELETAL INJURY

Description of injury

An injury needs to be described in plain language. This initial act of description is for the benefit of the diagnosing doctor, *not* for someone else. It begins to translate the information that has been gathered into a rational entity, which can then guide management. This act of description naturally leads to classification. Classification encourages precision in assessment and again aids management decisions; however, the limitations of classification should be recognised. Even the common systems are interpreted by individuals in a surprisingly wide variety of ways. Effective communication depends on a sensible blend of description and classification.

The soft-tissue injury

There are two components of soft-tissue injury that need to be identified: the degree of damage to the soft-tissue envelope around the fracture and the integrity of the important structures passing through the area, primarily the arteries and nerves. The state of the soft-tissue envelope over a fracture is an indicator of the degree of compromise of the local blood supply and resistance to infection. Open and closed fractures are the most easily recognised group. An open fracture is present when the fracture haematoma is exposed by a breach in an epithelial surface; this is usually skin but is sometimes mucous membrane of the bowel or vagina. When present a wound should initially be described in plain terms, e.g. 'a ragged 6-cm laceration over the anterior aspect of the midshaft of the left tibia with contused skin edges but no gross contamination'. A photograph, including a scale, should be obtained. The wound

Table 27.2 Investigation modalities

Modality	Good for	Problems
Plain radiographs	Fractures and dislocations. Easily available	Radiation. Not good for soft tissues
Computerised tomography	Bony spinal injury Global view in polytrauma Planning treatment of complex fractures	Radiation dose. Availability. Safety in severe injuries
Ultrasound scan	Soft-tissue injuries	Operator dependency
Magnetic resonance imaging	Soft-tissue problems and fractures	Availability and expensive Difficult to use in the ventilated patient
Bone scan	Stress fractures and tumours	Radiation dose
Fluoroscopy	Checking progress of surgery	Small field of view Quality Image distortion

Figure 27.1 Posterior dislocation of the shoulder. (a) Anteroposterior view; (b) origin of the light bulb sign; (c) axial projection demonstrating how much easier it is to visualise the injury on this view; (d) axial projection highlighting this point and further demonstrating the impacted fracture in the humeral head, or Hill-Sachs lesion.

should then be covered and not be disturbed again until definitive treatment is given in an operating theatre.

Just because a fracture is closed does not mean that the injury to the soft-tissue envelope cannot be described. There may still be bruising, swelling, contusion, tissue shearing or crushing. The closed soft-tissue injury may have characteristics that will affect the timing of interventions and the likely outcome.

Injuries to arteries and nerves

Major arterial injuries may be limb- or life-threatening and require early recognition. Suspicion will be raised by a history of penetrating trauma or of displaced injuries at particular sites, e.g. the knee. It should be routine to record the circulation distal to a fracture or dislocation. This record should be specific, e.g. 'dorsalis pedis present' or 'capillary refill < 2 s', not just 'neurovascularly intact'. The role and timing of diagnostic imaging techniques is debatable because although they aid diagnosis, they also delay treatment. The warm ischaemia time should be kept to below 4 hours. If the level of the injury is clinically obvious it is best to proceed to treatment; on-table arteriography can then be obtained if required.

Nerve injuries should be identified by clinical examination and recorded. It is important that if operative treatment of a fracture is planned the preoperative neurological status is recorded. As with the vascular examination, the findings should be recorded in such a way that they can be interpreted without ambiguity. This should not be taken as an invitation to be precise

beyond knowledge. For instance, if the examiner does not know the function of the axillary nerve it is misleading to record that it has been tested. A diagram recording findings is often the simplest method of record.

Compartment syndrome

When the hydrostatic pressure within a fascial compartment increases sufficiently it will compromise the effective circulation within the compartment leading to tissue ischaemia and necrosis. The most reliable clinical symptom is disproportionately severe pain, and the most useful sign is pain on passive stretching of the involved compartment. It is not an easy diagnosis to make as patients are expected to have pain after a fracture; the symptoms may be masked by analgesics. Additionally, examination may be difficult because of the placement of splints and dressings. Of note is that peripheral pulses are generally not affected and alteration in sensation is a late sign. The nature of the fracture is not a good guide to development of the syndrome. It can occur with low-energy and high-energy injuries, closed or open. Compartment syndromes are most frequently recognised in the lower leg, but they can occur wherever there is a closed compartment. Some injuries require particular vigilance, including crush injuries to the foot and hand, and displaced humeral supracondylar fractures in children.

The reliance on pain to achieve a diagnosis is clearly a problem in the obtunded patient. Here there is a good argument for measurement of compartment pressures. There is some evidence

that it may be wise to monitor the compartment pressure in all tibial fractures.

The bony injury

To the soft-tissue injury is added a description of the bony injury. The terminology used in this description is illustrated in Fig. 27.2. Now look at Fig. 27.3 and describe what you see. Plain language should be used to describe the injury: thus, a '45° oblique fracture at the junction of the proximal and middle thirds of the right tibia with an associated fibular fracture' gives a clear unambiguous picture (this example is used again later). A satisfactory description generally needs the following components:

- which bone is injured;
- the region of the bone injured;
- whether the fracture is simple or multifragmentary;

Figure 27.2 Descriptive terms for fractures.

Figure 27.3 Fracture of the shaft of the tibia.

- the direction of the fracture line – transverse, oblique or spiral;
- whether the fragment is displaced or undisplaced;
- if displaced, the alignment, length and rotation;
- any evidence of pre-existing pathology;
- any associated joint dislocation.

Although in adults the fracture line is generally complete, i.e. it extends through both cortices, in children the different mechanical qualities of the bone may lead to other patterns in which the fracture line is incomplete. These are termed torus and greenstick fractures (Fig. 27.4). Compression fractures occur when cancellous bone is crumpled; an example is a wedge compression fracture of a vertebral body. A similar injury is an impacted fracture; here the fracture occurs at the metaphyseal/diaphyseal junction. The hard cortical bone is driven into the cancellous bone, analogous to a cone being driven into an ice-cream; this pattern commonly occurs at the humeral neck. Some injuries are hard to describe in plain language, for example physal injuries in children. Almost all communication utilises the Salter–Harris classification, which is described later (Summary box 27.2).

Summary box 27.2

Describing an injury

Use plain language to describe:

- Location
- Soft-tissue component
- Bony injury

Figure 27.4 Types of bony injury. (a) Uninjured bone; (b) adult transverse fracture failure across the whole bone; (c) greenstick fracture; the bone has failed on the tension side; (d) torus or buckle fracture; the bone has failed on the compression side.

Robert Bruce Salter, formerly Professor of Orthopaedic Surgery, The University of Toronto, Ontario, Canada.
W. R. Harris, formerly Professor of Orthopaedic Surgery, The University of Toronto, Ontario, Canada.

Classification of injury

To formalise the description of the injury, use a classification. This encourages precision in the assessment and may enhance communication and management decisions.

Soft-tissue injury

Despite the emphasis placed upon management of the soft tissues, it remains common practice that unless it is an open injury the soft-tissue component of an injury is described and not classified. There are classification systems available for closed soft-tissue injuries when required.

Open injuries are generally classified; the system most commonly used is that of Gustillo and Anderson. This classification is based on a study of a large group of open tibial fractures. Of note is that the grade of the injury is not determined by the size of the wound alone: thus, a high-energy fracture with a < 1 cm wound is a grade III fracture. The injury cannot be finally classified until its full extent is appreciated on completion of the initial wound excision. The classification is summarised in Table 27.3.

Bony injury in adults

There are many eponymous and anatomically localised fracture classification systems; some are referred to later. Some fractures are common enough and sufficiently well studied that evidence-based treatment related to such a local system can be carried out. However, many fractures are treated on the basis of 'principles' and, therefore, a principle-based system of classification is required. The AO (Arbeitsgemeinschaft für Osteosynthesefragen)

Table 27.3 Gustillo and Anderson open fracture classification

Type I	A low energy open fracture with a wound less than 1 cm long and clean
Type II	An open fracture with a laceration more than 1 cm long without extensive soft tissue damage, flaps or avulsion
Type III	Characterised by high energy injury irrespective of the size of the wound. Extensive damage to soft tissues, including muscles, skin, and neurovascular structures, and a high degree of contamination. Multifragmentary and unstable fractures
Sub-groups of type III	
A	Adequate soft tissue cover of a fractured bone after stabilisation
B	Inadequate soft tissue cover of a fractured bone after stabilisation ie flap coverage required
C	Open fracture associated with an arterial injury requiring repair

Ramon Balgoa Gustilo, Surgeon, Hennepin County Medical Center, Minneapolis, MN, USA.

John T. Anderson, Surgeon, Hennepin County Medical Center, Minneapolis, MN, USA.

AO is short for *Arbeitsgemeinschaft für Osteosynthesefragen* which may be translated from the German as 'Working Party on Problems of Bone Repair'.

system provides such a principle-based comprehensive classification of fractures. It allows and encourages a comparison of fractures of similar types from different body regions. Principle-based treatment can flow from this principle-based classification. Thus, it can easily be seen that a partial articular fracture of the distal radius is very similar to that of a tibial plateau. The system is organised to identify the site and nature of a fracture. Initially, the site is identified by two numbers: the first records which bone is involved and the second which segment of that bone (Fig. 27.5). The classified fracture is recorded as an alphanumeric; for instance, the tibial fracture described at the beginning of this section is a 42A2. The '4' and the '2' are simply shorthand for the tibial shaft. The letter begins to define the nature of the fracture as shown in Fig. 27.6; in this case it is a simple or 'A-type' diaphyseal fracture. The final number given refines the record of the fracture pattern; for a simple diaphyseal fracture '1' represents a spiral, '2' an oblique and '3' a transverse fracture. The system goes into further detail but this requires reference to the AO classification book (see Further reading).

Thus, although the alphanumeric is not what one would use for verbal communication with a colleague, it does have advantages. It requires clear consideration of the fracture pattern to reach a conclusion, i.e. it directs the assessment. It allows succinct recording in a database, which is then easily searched. Thus, the principle-based classification system guides principle-based treatment.

Growth plate injuries

In children some fractures are similar to those seen in adults, but there are also specific injuries to the growth plate region. The physis contains cells that are responsible for longitudinal bone growth. Trauma is the most common cause of physeal arrest, which may be partial or complete. A bridge of bone (bony bar) forms between the epiphysis and metaphysis. From then on growth will be altered leading to relative shortening or angulation.

The classification of Salter and Harris is used to describe the nature of the epiphyseal injury. These patterns of injury are shown in Fig. 27.7 and a description of the types and their characteristics is given below:

- Type I – a transverse fracture along the line of the physis; the growing zone is not usually injured so there is no growth disturbance. This fracture is common.
- Type II – similar to a type I injury but the fracture line deviates off into the metaphysis at one end, producing a metaphyseal fragment; seldom affects growth. This fracture is common.
- Type III – passes along the physis and then deviates into the epiphysis (intra-articular); rarely results in significant deformity but can lead to joint incongruity. This fracture is not common.
- Type IV – crosses the physis passing from the epiphysis into the metaphysis; interferes with the growing layer of cartilage cells so can cause premature focal fusion of the physis followed by deformity. This fracture is not common.
- Type V – a crush injury of the physis; associated with growth disturbances at the physis. Diagnosis may be difficult as the radiograph may look normal; however, premature closure of the physis reveals the diagnosis. This fracture is rare.
- Type VI – rare injury consisting of an injury to the perichondral structures by direct trauma, e.g. heat or chemical (Summary box 27.3).

Figure 27.5 The AO classification system: the first two numbers specify the site of the fracture.

Summary box 27.3

The value of classification

- Encourages and directs evaluation of the injury
- Assists planning of treatment
- Guides prognosis
- Results in easier data retrieval
- Allows comparison with the results of other surgeons

THE RESPONSE TO INJURY

The natural response to a fracture, that is the natural history of a fracture, is that the broken bone will heal. It may well heal in a satisfactory position and have a satisfactory functional outcome. However, it may fail to unite, be slow to unite, unite in a poor position, become infected or have a combination of these problems. Consideration of these possible outcomes and how we might influence them is at the heart of making management decisions.

Bone healing

Fractures naturally tend to heal and may do so by indirect or direct mechanisms:

- *Indirect (secondary) bone healing.* Indirect (secondary) bone healing occurs with a callus precursor and is referred to as enchondral ossification. This tends to occur when the bone ends are not perfectly aligned and when there is some movement at the fracture site during the healing process. Such secondary bone healing is broadly characterised by three main phases: inflammation, repair with callus formation and remodelling of immature woven bone to mature lamellar bone. It may be thought of as the natural way for a bone to heal.

- *Direct (primary) bone healing.* This occurs without callus formation. It is like the normal process of remodelling with cutting cones crossing the fracture and new lamellar bone being laid down. It tends to occur when the fracture ends are closely opposed and there is no relative movement between them.

Figure 27.6 The AO classification system: the letter defines the nature of the fracture.

Figure 27.7 The Salter–Harris classification of growth plate injuries.

Thus, one of the components of a successful outcome in fracture healing is for the healing tissues to differentiate into bone. For this to occur the appropriate mechanical and biological conditions have to be met. Perren and Cordey in 1980 proposed the ‘interfragmentary strain theory’. They suggested that loading that leads to an increase in the length of the bone (strain) of less than 2% is advantageous to fracture union. Applying this theory has led to two approaches to fracture fixation. One may try to achieve absolute stability between fragments when bone is fixed so that the broken surfaces do not move relative to each other. This leads to direct healing. It is achievable in simple fracture patterns when they are reduced precisely and compressed together. Relative stability is when the fracture fragments can move relative to each other. The amount of movement between the fracture fragments does not only depend upon the surgical construct but also on the applied loads. Therefore, before commencing definitive treatment it is important to consider what one is trying to achieve. Does the patient need to weight-bear, does the joint need to be mobilised early and are there multiple injuries to consider? Unsurprisingly, this means considering the whole patient and not just the broken bone.

Bone union is not just dependent upon mechanical factors. The healing tissues require an adequate blood supply. Therefore, when the injury has led to significant soft-tissue damage, union is likely to be slow. At the time of surgery, care must be taken to minimise disruption to the blood supply of the healing tissues. Smoking has been shown to delay fracture healing. Non-steroidal anti-inflammatory medications also seem to delay fracture healing; they are therefore best avoided in situations in which union is likely to be slow.

Adverse outcomes

Malunion

Malunion is when the bone unites in an incorrect position. What constitutes an incorrect position is debatable and varies from

bone to bone. As a guide, an articular step should not be greater than the thickness of the articular cartilage. In the lower limb angulation or rotation should not exceed 5°. Visible deformity is seldom acceptable.

Non-union

Non-union of a fracture may be defined as failure to show progressive clinical or radiographic signs of healing. The principle types of non-union are atrophic, hypertrophic and infected. These can be secondary to failure of biology and/or mechanical environment and patient factors (smoking). In atrophic non-union, the fracture gap is filled by fibrous tissue and the bone fragments remain mobile. Hypertrophic union occurs when there is excessive movement at the fracture site, leading to abundant periosteal bone formation. Union fails because stability is insufficient to allow bridging of the fracture gap. If stability is provided, union is likely.

Infected non-union

Infected non-union merits a separate mention as it is a potentially catastrophic complication. Its treatment is often prolonged, multistaged and can result in loss of the limb. Open fractures are therefore treated with minimisation of infection as the main priority. The risk–benefit balance should always be considered before embarking on treatment.

Delayed union

Delayed union is the term used to describe a fracture that has not healed in the expected time. Fractures in children tend to heal more rapidly than fractures in adults, and upper limb fractures can heal more quickly than lower limb fractures. Fractures in children may unite (the bone ends stick together) within 2–3 weeks and consolidate in 4–6. Femoral fractures in adults may take 12 weeks to unite and 24 weeks until they are as strong as they were before (consolidation) (Summary box 27.4).

Summary box 27.4

Fracture healing

- **Mechanics** – the strain theory – determine whether healing is indirect or direct
- **Biology** – the blood supply needs to be intact; avoid smoking and non-steroidal anti-inflammatory drugs
- **Infection** – must be guarded against

Understanding outcome

Estimating the potential benefits and disadvantages of treatment interventions can be difficult. Table 27.4 lists the potential advantages and disadvantages of treatment. A key factor is to have some knowledge of the natural history of the injury, i.e. what will happen if nothing is done. When this is known some estimate can be made of the potential for improvement or the risk of doing harm.

It can help to look at outcome in a graphical manner; such a picture can help to conceptualise when and how vigorously to intervene. In Fig. 27.8a the blue line shows what the progress of the patient would have been if the injury had not occurred: the general quality of life is plotted against the passage of time. Even had the injury not occurred at some stage the quality of life would deteriorate and the patient would eventually die. The red line

Figure 27.8 Graphical representation of the potential benefits and disadvantages of treatment interventions. (a) The hatched area between the two curves represents the potential for beneficial therapeutic intervention. The beige area beneath the natural history curve represents the potential for detrimental effects of intervention. (b) The area of potential benefit can be divided into three phases: recovery, functional and degenerative.

Table 27.4 Risks and benefits of fracture treatment

Benefits	Risks
Pain relief	Anaesthesia
Prevention of infection	Introduction of infection
Restoration of anatomy	Damage to soft tissues and neurovascular structures
Early movement of the limb	Devitalising bone
Early movement of the patient	Need for implant removal
Improved function	Financial cost (cost of treatment)
Reduced risk of secondary arthritis	
Financial cost (time off work)	

shows the natural history of an imagined injury, that is the effect of the injury on the patient's quality of life without any treatment being given. Thus the area between these curves represents the opportunity for treatment to provide some improvement on the natural history, presuming that the best we can hope for is to get the patient's condition back to what it would have been had the injury not occurred.

Figure 27.8b shows how the possible clinical benefit can be divided into an early, plateau and late phase. The early phase equates to improved function during recovery or while healing is

taking place, e.g. an intramedullary nail for a femoral shaft fracture. The plateau (functional) phase equates to better function after healing, e.g. ensuring leg length equality, stable joints and decreased pain. The late phase relates to the avoidance of secondary complications such as degenerative arthritis. If the patient's outcome dips below the natural history curve at any stage then it can be seen that treatment has actually caused a poorer outcome than if none had been offered. Thus the area below the natural history curve represents the potential for treatment to be disadvantageous and cause harm.

Such a graphical approach can be used to illustrate whether or not treatment interventions are rational. This can be seen with the examples given later for the treatment of pathological and paediatric injuries. What is clear is that unless the natural history of an injury is known then rational treatment decisions are not possible.

PRINCIPLES OF FRACTURE MANAGEMENT

As noted above the aims of treatment are to restore function safely with minimal complications. The first principle is to consider whether any intervention is necessary; many fractures require no or just symptomatic treatment. The interventional management of the bony injury has two components: reduction and stabilisation. They can each be achieved by a variety of methods and these methods will have mechanical and biological consequences.

Reduction

A fracture can be reduced by closed or open means. Each method has the same components, being some way of moving the fragments and some way of judging whether the desired position has been achieved. The accuracy of reduction required varies from site to site, with the nature of the planned stabilisation and with the anticipated mode of healing.

The assessment of the adequacy of fracture reduction may be made within the zone of injury or outside of it. Direct viewing of the fracture ends may be with the naked eye at open operation or by using imaging or arthroscopy. Outside of the zone of injury the adequacy may be assessed with reference to the other limb, again by just looking or by imaging. Generally, a combination of methods is used. Reference to Fig. 27.2 (see p. 356) demonstrates that the fracture with rotational deformity is difficult to depict graphically and for the same reason is often not noticed on radiography or at open surgery. However, merely looking at the whole limb and comparing it with the normal side generally reveals whether the rotational reduction is adequate.

The other component of reduction is moving or manipulating the fragments. Manipulating a fracture by a closed technique, i.e. without surgically exposing the bone, is an art. The key is to utilise the remaining soft tissues; they will tend to guide the bony fragments. The most elegant way is to reverse the mechanism of the injury. Charnley in 1950 demonstrated this with a simple model; it is easy to make a similar model using a broken pencil and some sellotape. The sequence of injury and reversal is illustrated in Fig. 27.9.

At open operation the bony fragments can be manipulated just as in a closed reduction; it is easier because the bony

Sir John Charnley, 1911–1982, Professor of Orthopaedic Surgery, The University of Manchester, Manchester, England.

Figure 27.9 How absolute and relative stability can be achieved. The same implants may be used to achieve different mechanical effects.

fragments can be watched. The fragments can also be moved by applying clamps directly to the bone. The adequacy of the reduction with a simple fracture pattern can be judged by direct reference to the fracture fragments themselves, just as when making a simple jigsaw. With more complex fracture patterns exposure of all of the individual fragments may devitalise them and so reduction is assessed indirectly by restoring the overall position of the limb (Summary box 27.5).

Summary box 27.5

Reduction

- Reduction has two components – moving the fragments and assessing adequacy
- Each component can be carried out within the zone of injury or beyond the zone of injury

Stabilisation

Most often when a fracture has been reduced it needs to be held or stabilised while healing progresses.

When choosing a technique of stabilisation the aim is to:

- 1 optimise the biological and mechanical environment to create conditions favourable for fracture healing;
- 2 reduce the period of disability by speeding healing or allowing function during the healing process.

The mechanical environment can be altered to achieve the desired stability, either absolute or relative. *Absolute stability* is when the bone behaves as if it is not fractured. This is generally achieved by precise reduction and compression of the fracture ends. No displacement should occur during the loading permitted

in the postoperative period. This provides the environment for direct bone healing. In contrast, *relative stability* will produce a situation that allows some movement in proportion to the load applied. This stimulates callus formation and secondary bone healing. Fig. 27.9 shows some of the configurations that can be used to achieve relative and absolute stability. Simple fracture patterns allow absolute stability to be obtained; in the more complex fracture patterns the biological cost of achieving precise reduction (soft-tissue stripping, etc.) may outweigh the advantages.

Methods used for stabilising a fracture

Casting and splinting

A cast is a moulded orthopaedic appliance that may be composed of plaster of Paris or fibreglass; it is useful in the stabilisation of a fracture, either as a temporary or a definitive treatment.

When a cast is applied it should be remembered that, following a fracture, there may be significant soft-tissue swelling which may increase before it subsides. By applying a full (circumferential) cast, the increasing swelling will lead to tightness of the limb within the cast. There is then a risk of neurovascular damage, skin damage and compartment syndrome. A plaster slab may be used instead, in which the plaster material is not circumferential but the securing bandages are, and, as a consequence, tightness can still occur. The best way to avoid tightness is to apply a full cast and then split it through all of the layers down to the skin once it has set. Whichever method is used for treatment the surgeon should assess the risk of cast tightness and take appropriate

Plaster of Paris is a white crystalline powder, Calcium Sulphate Hemihydrate, $\text{CaSO}_4 \frac{1}{2}\text{H}_2\text{O}$, which sets hard when water is added to it.

precautions. This may involve admitting a patient for a period of observation or providing instructions for the patient and family to follow in the event of problems.

When a cast has been applied as a first aid measure to provide stability and comfort, no particular moulding is required. However, when the fracture has been manipulated and reduced as described in Fig. 27.10 the cast needs to be applied in such a way as to prevent redisplacement. This requires the use of the available intact structures. The soft-tissue hinge is placed in tension and the reduced bone is placed in compression. The cast is then applied and moulded to stabilise the fracture using a so called 'three-point fixation'. Once moulded, plaster providing such three-point fixation appears bent; this leads to the adage that 'if you want a straight bone then you need a bent plaster' (Fig. 27.11).

The advantages and disadvantages of casting and splinting are described in Table 27.5.

Traction

Traction is pulling to change or hold the position of fracture fragments. The advantages and disadvantages of traction are given in Table 27.6. The technique works because of the integrity of the

Figure 27.10 (a–d) Representation of how the mechanism of injury causes the bony and soft-tissue injury. (e–h) Representation of how the residual mechanical properties of the tissues may be used to effect and hold a reduction.

Figure 27.11 (a) The position achieved at the end of the manipulation described in Figure 27.11. (b) Demonstration of how by moulding the cast the intact periosteum is kept under tension and the bone under compression; thus, the remaining mechanical properties are used to achieve stability.

surrounding soft tissues (otherwise, on pulling, the fragments would just get further apart). Traction can be used both as a temporary and as a definitive treatment. Traction splints are often used for temporary stabilization of a fracture. So long as the patient is not moving, for Newton's law to be satisfied, there must be equal opposing forces. Static traction, that is between two fixed points, is well illustrated by a Thomas-type splint (Fig. 27.12a). This gives pain relief and stability, allowing the patient to be transported. In dynamic traction the pull is exerted by a system of weights, balanced with the patient's own body weight, which provides the opposing force (Fig. 27.12b).

Table 27.5 Advantages and disadvantages of casting and splinting

Advantages	Disadvantages
No wound	Limited access to the soft tissues
No interference with fracture site	Cumbersome (particularly in the elderly)
Cheap	Interferes with function
Adjustable	Poor mechanical stability
No implants to remove	'Plaster disease'

Sir Isaac Newton, 1642–1727, Lucasian Professor of Mathematics, Cambridge University, Cambridge, England.

Hugh Owen Thomas, 1834–1891, A General Practitioner of Liverpool, England. He is regarded as 'The Founder of Orthopaedic Surgery' although never holding a hospital appointment preferring to treat patients in their own homes. He introduced the Thomas splint in 1875.

Figure 27.12 (a) Static traction with a Thomas splint. The force and counterforce are contained within a static system. The load is applied to the patient through the tibial traction pin via a cord tightened with a Spanish windlass. The counterforce is applied through pressure by the splint on the ischial tuberosity. (b) A dynamic system in which the load is applied by weights suspended from the tibial pin and the counterforce is the patient's own weight.

Table 27.6 Advantages and disadvantages of traction

Advantages	No wound in zone of injury No interference with fracture site Materials cheap Adjustable
Disadvantages	Restricts mobility of patient Expensive in hospital time Skin pressure complications Pin site infection Thromboembolic complications

Traction can be applied either using the skin (skin traction) or by direct coupling to the bone with pins or wires (skeletal traction). It can be simple or complicated. The simplest practical example of traction is the use of a collar and cuff to treat a proximal humeral fracture. As long as the patient is upright, gravity provides the traction. The role of the doctor is simply to advise the patient to sleep in a chair instead of a bed to maintain the dependency of the arm. More complex systems of weights, counterweights and pulleys can be used to provide the appropriate force required to maintain alignment of a lower limb fracture. The concept of a controlled and uncontrolled fragment is helpful; failure to understand this can lead to failure of traction. As the terms suggest, a controlled fragment is one that the surgeon can manoeuvre into the position that he or she wishes; an uncontrolled fragment is one over which the surgeon has no control. Thus, in the proximal femoral fracture the proximal fragment tends to remain flexed and abducted however great the traction, i.e. it is uncontrolled. The key is to move the controlled distal fragment into line with the uncontrollable proximal fragment.

In the UK traction is rarely used for definitive treatment in adults. Although the equipment for traction is inexpensive, the

technique is costly in terms of the length of hospital stay. Public opinion has also changed and there is an unwillingness to remain in hospital for prolonged periods. Nursing a patient on traction can be difficult once the familiarity with the system is lost. Prolonged bed rest may lead to pressure sores, thromboembolism, pneumonia and atelectasis.

Plates and screws

A screw is normally used to join two things together. Instinctively we expect a screw to squeeze these things together when tightened. This is achieved because the hole under the screw head is greater in diameter than the threads of the screw, which allows the screw to glide in this hole. Thus, further tightening after the head impacts will cause compression. This method can be used to compress two bony fragments (the technique is then called a lag screw) or a plate to the bone. When a fracture can be reduced precisely a lag screw may be used to compress the fragments together to provide absolute stability. This single vulnerable lag screw will provide absolute stability but will not provide a strong durable fixation. It may be protected by a plate, termed a neutralisation plate. This is a classic method of stable internal fixation and is ideal for fractures such as those of the radial and ulnar shafts. The same plate and screws may be used in different ways, to provide different sorts of fixation. Table 27.7 shows the advantages and disadvantages of plate fixation.

Open reduction and internal fixation (ORIF) is the term generally associated with the use of such implants in the fashion described above. However, as with other branches of surgery, fracture fixation has become less invasive. With better intraoperative imaging, minimally invasive osteosynthesis (MIO) has evolved in which fractures are reduced and fixed through smaller incisions. It is presumed that this will reduce morbidity and speed recovery.

A recent development is the locking plate. Here the screw has a threaded head that tightens into the plate. The screws are not floppy within the plate but 'lock' when tightened. This gives angular stability similar to that of an external fixator and seems particularly advantageous in elderly bone and at metaphyseal/diaphyseal junctions.

Intramedullary nailing

The diaphysis of a long bone with its medullary canal is essentially a tube. It has long been realised that there are advantages to placing the stabilisation device inside the canal. The technique has evolved alongside improvements in intraoperative radiographic imaging. In this situation the surgeon's eyes are the image

Table 27.7 Advantages and disadvantages of plate and screw fixation

Advantages	Can be used when anatomical reduction is required Allows early mobilisation Can provide absolute or relative stability
Disadvantages	May interfere with fracture site Periosteal/soft-tissue damage Does not normally allow for immediate load-bearing Potential for infection Metalwork complications ?Need for plate removal

intensifier. An intramedullary nail is usually made of steel or titanium. It may be solid, hollow or slotted in cross-section. An intramedullary nail will by its nature protect against angulatory displacement and translation. To extend the range of fractures suitable for stabilisation with a nail the implant normally has transverse holes at either end; this allows locking of the nail to the bone with further screws to control rotation and length.

Modern nailing is a minimally invasive technique. The nail is introduced in a series of planned steps, aided by specific instrumentation. After fracture reduction a guidewire is placed down the medulla, which then guides reamers. These enlarge or make uniform the canal until finally the nail itself can be introduced. Nails can be placed with or without reaming and much (probably too much) has been made of the comparison. Table 27.8 summarises this debate.

Because standard nails are introduced at the ends of a bone they are not suitable for the growing bone where they would transgress a growth plate. Elastic nails have been developed that can be placed without disrupting the physis. By using opposing pre-bent elastic nails, sufficient stability can be gained to control a paediatric fracture. They have revolutionised the treatment of children's femoral fractures in the same way that standard nails have for adult fractures. They allow for early mobilisation and a much earlier discharge from hospital.

The advantages and disadvantages of intramedullary nailing are described in Table 27.9.

External fixation

External fixation is a mechanical construction to hold a fracture. Each side of the fracture is coupled to the fixator and the major part of the device is external to the skin. The couple to the bone is via either half-pins (that is stiff metal rods typically 5–6 mm in diameter) or tensioned wires (typically 1.8 mm in diameter), which are then secured to the frame by clamps.

Table 27.8 A comparison of reamed vs. unreamed nailing (an assumption is that nails used unreamed are usually thinner than those used reamed)

	Reamed IMN	Unreamed IMN
Insertion time	Longer	Quicker
Time to union	Shorter	Longer
Size of implant	Larger	Smaller
Reduction of distal fractures	Easier	More difficult
Strength of construct	More	Less

IMN, intramedullary nail.

Table 27.9 Advantages and disadvantages of intramedullary nailing

Advantages	Minimally invasive Early weight-bearing Less periosteal damage than open reduction and internal fixation Seldom need removal
Disadvantages	Increased risk of fat emboli/chest complications Infection difficult to treat Difficult to remove if broken

A great advantage of external fixation is that the immediate environment of the fracture may be left intact with the frame bridging the zone of injury (Table 27.10). This facility to bridge an injured area is commonly used as a temporary measure. For a complex fracture this can provide safe stability while the condition of the soft tissue improves or further imaging is obtained, or the patient's general condition improves before other definitive fixation. When used for definitive treatment external fixation also has the advantage over internal fixation in that the mechanical properties of the frame can be adjusted to suit the changing mechanical needs of the healing bone. This concept is most simply applied when a frame is destabilised as a fracture heals so that progressively more load is taken through the bone. It may be that the fracture is thought to require more stability in which case the frame may be adjusted to apply continuous compression. The mechanical environment may be manipulated in more complex ways. Callus may be distracted to allow for correction of a deformity, lengthening of a limb or transport of a bone segment to fill a defect. These advanced uses of external fixation were to a large extent developed by Ilizarov using tensioned wire circular frames.

The prime disadvantage is that an external fixator always has 'pin sites', i.e. the point where the pins or wires penetrate the skin. The pin sites require care as they may become infected or tether soft tissues, thereby interfering with function, and may generally irritate the patient. An infected pin site may compromise a later planned change to another technique for definitive fixation; however, it is usually safe to leave a frame in place for up to 10 days. A poorly placed temporary fixator may compromise the later definitive treatment and so a plan is always helpful.

Specific indications for external fixators include:

- emergency stabilisation of a long bone fracture in the poly-trauma patient thought too unwell to have other interventions – 'damage control orthopaedics';
- stabilisation of a dislocated joint after reduction, e.g. a spanning fixator across the knee joint while the vascular surgeons repair an arterial injury with a knee dislocation;
- complex periarticular fractures – temporary stabilisation to allow the soft tissues to settle before definitive fixation, e.g. a distal tibial (pilon) fracture;
- fractures associated with infection;
- treating fractures with a bone loss.

Table 27.10 Advantages and disadvantages of external fixation

Advantages	No interference with fracture site Adjustable after application: alignment; biomechanics Soft tissues accessible for plastic surgery Rapid stabilisation of fracture Hardware easy to remove
Disadvantages	Pin site infection Interferes with plastic surgical procedures Soft-tissue tethering Cumbersome for the patient

Gavriil Abramovich Ilizarov, 1921–1993, Orthopaedic Surgeon, Kurgan, Western Siberia, Russia.

Wires

A Kirschner wire (also called a K-wire) is a thin, flexible wire made of stainless steel, available in various diameters. The wires can be smooth or threaded (the latter are used in situations in which backing out of the pin is undesirable). They have multiple uses as shown in Table 27.11. Transfixing wires can be passed percutaneously to keep fracture fragments reduced. They are cheap and often quick and simple to use. They have been used extensively around the hand and wrist as definitive fixation. Another common use of wires is for temporary fixation intraoperatively. Thus, a provisional reduction can be held with wires while the more definitive and robust fixation is applied.

Flexible wires are also used in fracture fixation. In situations in which the mechanical loads on the fracture are predictable a technique called tension band wiring is popular. Thus, at the patella and the olecranon a 'figure-of-eight' tension band wire can provide reliable stability. This is a dynamic fixation such that, when a predictable load is applied to the bone, compression across the fracture site is actually increased.

Complications of K-wires are pin track infection, wire breakage, loss of fixation and migration of the wire. Migration of a wire is a potentially serious problem and, as a consequence, their use in some areas is ill-advised. K-wires placed around the clavicle have been known to migrate, penetrating the thoracic cavity and even the heart.

Arthroplasty

Arthroplasty surgery for degenerative change has the objective of relieving pain and restoring function. Similar objectives apply in the treatment of the injured. It is thus strange that replacing the damaged surfaces of a joint is seen by some as a failure of fracture surgery. This is quite illogical as there are clearly situations when this is the best treatment. Prosthetic replacements, manufactured from metal alloys, may be used for treating articular fractures affecting a variety of joints. The implants used can be seen in Chapters 31–38 on elective orthopaedics, in which joint replacement is a mainstay of treatment. The indications in trauma may be fracture or patient related. In general, the problems of late loosening or wear mean that their use is confined to the older patient. The principles are discussed in the section on hip fractures (intracapsular fractures), but replacement surgery can be indicated in proximal humeral, elbow and occasionally knee injuries. In the proximal humerus, a multi-fragmentary fracture that is considered unsalvageable by internal fixation methods can be treated with a shoulder hemiarthroplasty.

The advantages of prosthetic replacement over internal fixation are earlier full weight-bearing and the elimination of non-union, avascular necrosis and failure of fixation. The disadvantages include a more extensive procedure, increased blood loss and the risk of prosthetic dislocation.

Table 27.11 Indications for K-wire insertion

Temporary fixation
Definitive fixation – with small fracture fragments (e.g. wrist fractures and hand injuries)
Tension band wiring (fractures of the patella and olecranon)
Temporary immobilisation of a small joint

Martin Kirschner, 1879–1942, Professor of Surgery, Heidelberg, Germany, introduced the use of skeletal traction wires in 1909.

MANAGEMENT BY TYPE AND REGION

Having discussed the principles of assessment and the principles of the available treatments for extremity injury the two can now be amalgamated. The motive for treatment is to restore function, to reduce the area on the graph between the curve of the natural history of the injury and that of the uninjured person. The AO classification distinguishes between diaphyseal and metaphyseal fractures and they are approached differently. Many fractures can be managed without operation. Table 27.12 gives some of the general indications for operative stabilisation. Two simple questions to ask of a fracture are: 'Does it need to be reduced?' and 'Does it need to be held?'

Diaphyseal fractures

The diaphysis is composed predominantly of a tube of dense cortical bone. Fracture treatment is aimed at restoring function by achieving bony union with correction of the length, alignment and rotation. In many diaphyseal fractures, if the bone heals with the adjacent joints in their normal relationship, the anatomical reduction of the fracture fragments at the fracture site is of secondary importance. This is demonstrated in Fig. 27.13 which shows C-type fractures treated in this way.

Femoral shaft fractures

The anatomy of the proximal femur allows easy access to the medullary canal for inserting an intramedullary device nail. A statically locked intramedullary nail is suitable for the vast majority of adult femoral shaft fractures irrespective of their pattern. With an isolated femoral shaft fracture the patient can be expected to mobilise rapidly postoperatively and may only be hospitalised for a few days.

Traction was traditionally used as definitive treatment for these fractures but it is now most commonly used as a first aid measure to provide pain relief and maintain length while transferring a patient or before operative fixation. Both methods of treatment can have satisfactory outcomes but the earlier return to function favours surgery.

Tibial shaft fractures

When the fracture is sufficiently stable, generally an A-type pattern, casting is the safest and cheapest choice. A full-leg cast is

Table 27.12 Indications for surgery in limb trauma (the main indication is that operation will produce a better outcome; the principles are given below)

A fracture requiring treatment that is unsuitable for non-operative measures
Open fractures
Failed non-operative management
Multiple injuries
Pathological or impending pathological fractures
Displaced intra-articular fractures
Fractures through the growth plate, where arrest is possible (Salter–Harris type III–V)
Avulsion fractures that compromise the functional integrity of a ligament/tendon around a joint (e.g. olecranon fracture)
Established non-unions or malunions

Figure 27.13 (a) and (d) are C-type or segmental tibial fractures. Each was a high-energy injury. (b) and (e) show a temporary spanning external fixator applied in each case. (c) and (f) show definitive relative stability was achieved with different methods of bridging fixation. Healing was by indirect means in both cases. Despite irregularities at the fracture sites the overall position was satisfactory and function was good.

applied and split to the skin. Once the risk of compartment syndrome has passed the cast is completed. By 4 weeks it can generally be changed to a moulded, patella tendon-bearing, below-knee cast. This allows the knee to move. Cast treatment requires frequent and careful monitoring and there should be no hesitation in changing the cast should the reduction be deteriorating. To correct minor deformity in a controlled and comfortable manner the cast may be wedged.

Surgery to a tibial shaft fracture is often indicated either as a result of instability (B- or C-type fractures) or other injuries. Currently, when surgery is required, intramedullary nailing is the most frequent choice. There is a high incidence of anterior knee pain following this and so it should be used with caution in those patients who have to kneel. Malunion is common in nailed fractures of the proximal tibial shaft; thus, plating fractures closer to the metaphysis is a good option, provided that the soft tissues are

satisfactory. External fixation remains a good option for a wide range of shaft fractures. The subcutaneous position of the tibia makes pin placement and pin site care relatively straightforward. The tibia is the most common of the major bones to be involved in an open fracture. When soft-tissue procedures will be necessary, intramedullary nailing gives the plastic surgeons the best access for soft-tissue reconstruction and is generally the stabilisation method of choice.

Humeral shaft fractures

In humeral shaft fractures the maintenance of limb length and alignment is nowhere near as important as in the leg. The majority of humeral shaft fractures can be treated non-operatively with a simple protective functional brace and a collar and cuff. This is the safest and cheapest option. The indications for operative management include an open fracture, the presence of other injuries such as head injury, multiple injuries, ipsilateral arm fractures and failed non-operative management. In these circumstances, fixation and stability can be achieved by either plating or intramedullary nailing. The rate of non-union is significantly higher when nailing the humerus than when nailing the femur or tibia; thus, plating is generally the treatment of choice. Figure 27.14 shows a plated B-type diaphyseal fracture. Should the need for fixation be combined with signs of radial

nerve damage, plating has the advantage of allowing exploration of the nerve.

Radius and ulna

Although the radius and ulna appear outwardly similar to other long bones, they can best be visualised as the two components of a large joint. Their relationship requires precise anatomical restoration if they are to function normally in supination and pronation. This precision is best and most easily achieved by open reduction and plate fixation (Summary box 27.6).

Summary box 27.6

Diaphyseal fractures

- Restore length, alignment and rotation
- Consider whether primary or secondary bone healing is the objective
- Radius and ulna need precise reduction to function

Metaphyseal fractures

Fractures in the metaphyseal region are classified as A type if they are extra-articular, B type if they are partial articular and C type if they are complete articular.

In an A-type fracture the joint surfaces remains intact so congruity is not an issue. Therefore, the problem may be thought of as being similar to that of treating a diaphyseal fracture; however, there are two differences that need attention. First, the injury and the subsequent treatment, being close to a joint, are more liable to cause joint stiffness. Second, the bone on either side of the fracture is not of a similar type or quality. It is generally easier to obtain a mechanical hold on the diaphyseal bone of the shaft than on the spongy bone of the metaphysis; thus the quality of fixation may be imbalanced. This imbalance in fixation is even more apparent when dealing with osteoporotic bone.

With B- and C-type fractures the joint surfaces themselves are involved. Thus, in addition to providing stability and overall alignment, the congruity of the joint surface is also important.

The management of metaphyseal injuries to the distal humerus, distal radius, distal femur, proximal tibia and distal tibia is very similar and is principle based with some regional influences. The main difference between the various sites is the scale of the metalware employed.

In an A-type metaphyseal fracture the emphasis is on maintaining length, alignment and rotation while allowing continued function. This requires sound fixation as demonstrated in Fig. 27.15. In this instance the fixation has been achieved with a plate and screws but it could equally have been carried out with an external fixator.

In a B-type partial articular fracture joint congruity is the prime objective. This can often be maintained with relatively lightweight fixation as the load borne by the metalware itself is less (Fig. 27.16). B-type fractures when they require surgery are nearly always treated with screws, or screws and plates.

The C-type or complete articular fracture combines both of these features, having the need for joint congruity and alignment, and is demonstrated in the tibial plateau in Fig. 27.17. The articular component of the fracture is generally held with screws, allowing for interfragmental compression. The metaphyseal component of the fracture may be held as in the A-type fracture, with plates and screws or an external fixator.

Figure 27.14 A B-type humeral shaft fracture. This fracture could not be controlled by non-operative means and was treated with lag screws protected by a plate.

Figure 27.15 An A-type or extra-articular metaphyseal fracture. A plain lateral radiograph of this Smith-type fracture (a and b). Fracture fixed to a plate. There is *no* interfragmental compression. The plate is pushing against or buttressing the distal fragment (c and d).

Achieving the final definitive fixation for an articular fracture may be the final step in the procedure. A good example is a pilon fracture. The soft tissue surrounding the ankle is particularly vulnerable following injury. It is therefore common practice to place a spanning external fixator across the joint until such time as appropriate investigations are available and the soft tissues are ready for definitive surgery.

Distal radial fractures

Because of the frequency of their occurrence distal radial fractures deserve separate mention. The common fractures in this area are A type, i.e. extra-articular. The Colles' fracture with dorsal and radial angulation can generally be treated by manipulation and casting. When this does not provide sufficient stability

a useful technique to have available is intrafocal wiring, popularised by Kapandji. In this technique, the wires are placed through the fracture site, then angled to stabilise the distal fragment and secured through the opposite cortex of the proximal fragment (Fig. 27.18).

When the displacement is in the opposite direction, i.e. volar, the so called Smith's fracture stability is difficult to achieve by casting. Access for wiring is awkward and so plating is generally employed.

The management of intra-articular distal radial fractures, particularly in the young adult, is evolving rapidly. The advent of CT has allowed for a better understanding of the patterns of injury. When there is significant articular displacement, formal open reduction and fixation with plates and screws is being performed in a very similar fashion to dealing with a tibial plateau fracture but with smaller implants. Customised locking plates are being used more frequently. Despite the popularity of these approaches the strength of the supporting evidence is not great.

Ankle fractures

The eventual functional outcome of ankle fractures depends upon the position of union. Thus, if the fracture is stable it requires only symptomatic treatment. An unstable ankle fracture requires reduction and maintenance of reduction until bony union. This can be achieved operatively or non-operatively. The important step is therefore to assess the stability. This may be inferred by the clinical history (a dislocated ankle) or the pattern of bony injury (e.g. both medial and lateral bony injury) or it may be assessed directly by an examination under anaesthesia. The maintenance of reduction is more reliable with operation and so in the younger patient this is generally the preferred option. In the elderly there is no clear evidence for choosing between operative and non-operative management.

Managing fractures in the skeletally immature

Many injuries are dealt with in an analogous way in the child and the adult; however, there are naturally differences. As discussed in Chapter 21 there needs to be constant vigilance for evidence of non-accidental injury.

Children's fractures heal more rapidly than adults'. The acceptable reduction may differ because of the extent of remodelling that is possible. This remodelling potential is dependent upon the growth remaining and the location of the fracture. The nearer the fracture is to the growth plate, the greater the remodelling capacity. Deformity is more acceptable in the plane of motion of the adjacent joint. Remodelling is greatest at the ends of the bone that contribute most to longitudinal growth. For example, fractures at the distal femur have more potential to remodel than proximal femoral fractures. Significant remodelling is also expected at the proximal humerus (70% of longitudinal growth). Children younger than 10 years of age have a greater potential capacity to remodel than children older than 10 years of age.

Repeated attempts to reduce a physal fracture may injure the physis leading to growth arrest. Internal fixation should not cross the physis. When this is absolutely necessary, the smallest and smoothest pin should be used.

Trauma is the commonest cause of physal arrest, and occurs

Abraham Colles, 1773–1843, Professor of Surgery, The Royal College of Surgeons in Ireland, and Surgeon, Dr. Steven's Hospital, Dublin, Ireland.

Robert William Smith, 1807–1873, Professor of Surgery, Trinity College, Dublin, Ireland, described the reverse Colles' fracture in 1847.

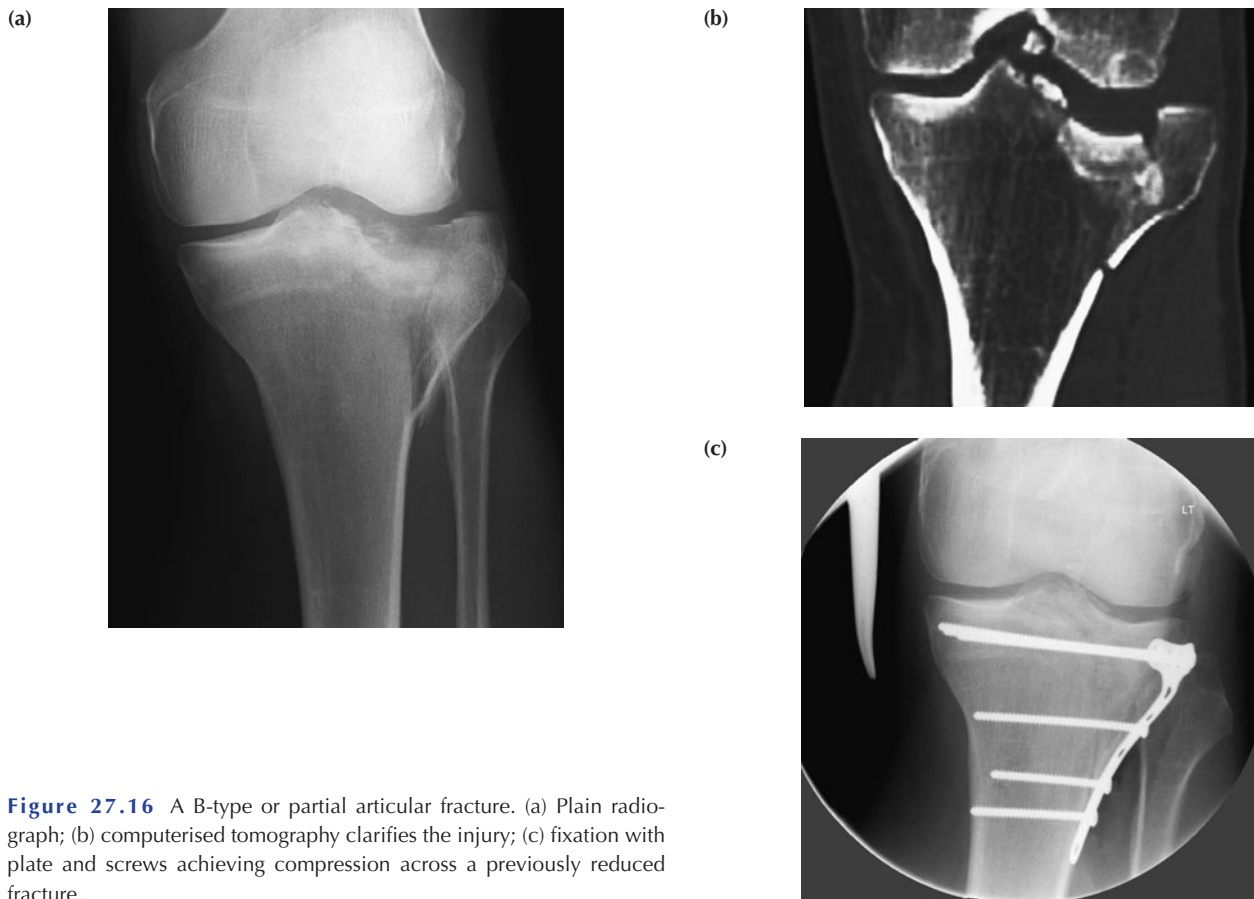

Figure 27.16 A B-type or partial articular fracture. (a) Plain radiograph; (b) computerised tomography clarifies the injury; (c) fixation with plate and screws achieving compression across a previously reduced fracture.

when a bony bridge forms between the metaphysis and epiphysis. Complete arrest is most commonly seen after a crush injury to the growth plate (Salter–Harris type V). The commonest area for growth arrest is the distal femur, proximal and distal tibia and the distal radius. Injured physal plates tend to close prematurely before the normal contralateral side, despite the successful restoration of growth.

The thicker and stronger periosteum contributes both to fracture stability and to fracture reduction if some of it (known as the ‘periosteal hinge’) remains intact on the compression side of the fracture. The physis is weaker than bone in torsion, shear and bending, and so fractures easily.

Children rarely experience non-union and frequently heal their fractures more rapidly than adults. In general, the rate of healing is inversely proportional to age.

Complications unique to childhood include growth arrest, progressive angular or rotational deformity and overgrowth of a long bone (post-femoral fracture).

The indications for operative intervention are fewer in children than adults (see Pathological failure, p. 376; Fig. 27.27c). The generally benign natural history of children’s fractures means that the risk of complications often does not balance favourably against a small potential advantage.

Specific injuries

Distal radial fracture

The commonest area of fracture in children is the distal radius. Fractures proximal to the growth plate may be treated

symptomatically or by manipulation under anaesthesia (MUA). There is no clear rule as to the amount of deformity that can be accepted. Clinically obvious deformity should probably be corrected at any age; otherwise, a maximum radiological deformity of 20° is acceptable in the plane of movement of the adjacent joint. As puberty approaches, fractures should be treated as for the adult.

A special case is when the distal radial fracture is sufficiently displaced to require manipulation that the ulna itself is intact. Secondary redisplacement is common under these circumstances and it is advisable to hold the radius with primary K-wiring. When the growth plate is involved in a distal radial fracture it is generally a Salter–Harris type I or II injury. MUA and casting is usually adequate and growth disturbance is uncommon after primary treatment; however, should the fracture reduction be lost, one should seldom proceed to a second manipulation. The second manipulation is much more likely to cause damage to the physis and subsequent growth problems.

Distal humeral (supracondylar) fracture

The markedly displaced supracondylar fracture is associated with two main complications. Neurovascular compromise may arise early and residual deformity is a late complication. The treatment of the former is early reduction, as the bone spike protruding from the proximal fragment may actually be pressing on the structures. Should the problem be with the circulation it will generally be resolved once reduction is carried out. Even when the brachial artery itself is involved there is usually adequate distal flow from

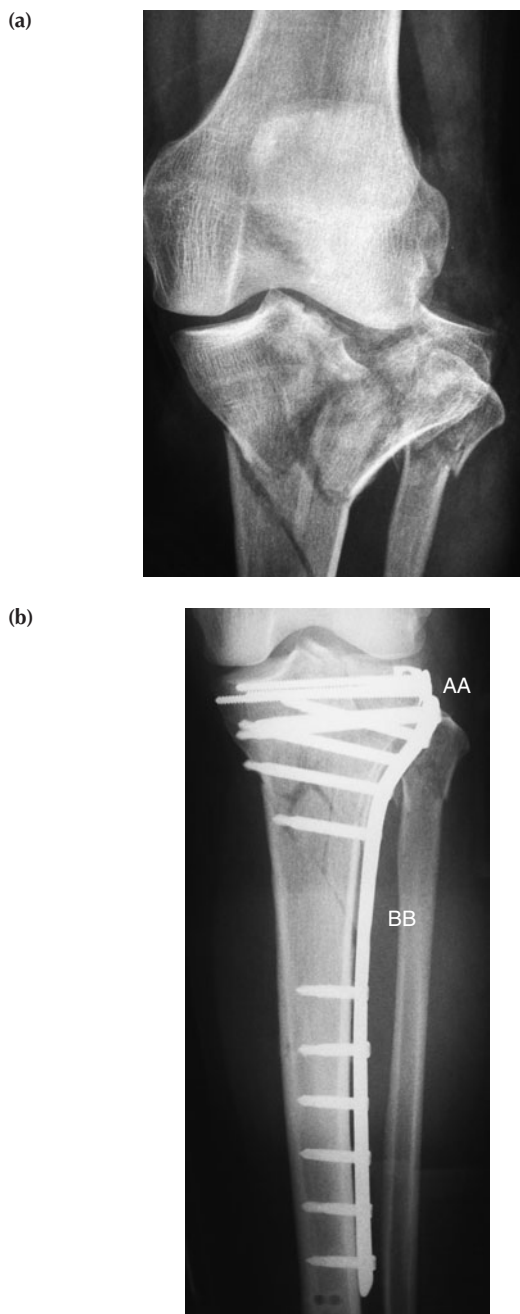

Figure 27.17 (a) A C-type proximal tibial articular fracture, i.e. none of the joint remains attached to the diaphysis. (b) The small plate and screws (AA) are used to compress the joint fragments, aiming for absolute stability. The heavy duty fixed angled device (BB) spans the fracture and provides relative stability.

the collateral vessels provided as a sonata me is carried out. Arterial repair is seldom necessary.

The late complication of a supracondylar fracture is deformity. This is due not to an interference with growth (the fracture is proximal to the growth plate) but to poor initial reduction or loss of reduction. As noted above, deformity in the plane of the adjacent joint tends to correct satisfactorily. It is the varus/valgus angulatory deformity that is critical at the elbow. This is very difficult to assess initially as the deformity only

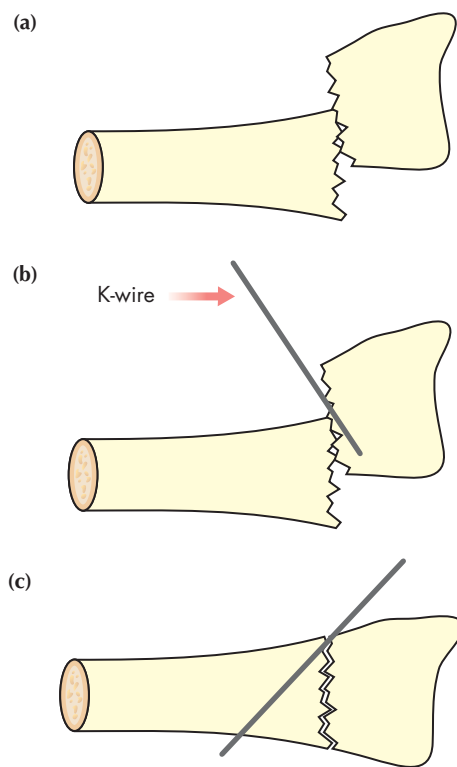

Figure 27.18 (a) A displaced distal radial fracture. (b) A wire is introduced percutaneously by hand through the fracture site. (c) The fracture is manipulated into a reduced position (*not* levered using the wire). Once reduced the wire is advanced under power into the opposite cortex, securing the reduction.

becomes obvious once full extension is regained, which may be many months later.

A minimally displaced supracondylar fracture is a benign injury and can be treated symptomatically. When a displaced fracture can be manipulated into a satisfactory position it sometimes appears stable as soon as the elbow is put in flexion. It is tempting to leave this injury in a flexed cast for stability. The authors' opinion is that if a supracondylar fracture needs to be reduced it should then be held with K-wires.

Lateral condylar mass fracture

This injury is easily missed and is an example of the apparently benign injury that may have significant morbidity if it goes unrecognised. Clinically the clue is localised lateral tenderness. The radiograph may show just a flake off the distal humeral metaphysis above the capitellum (Fig. 27.19). This is an intra-articular fracture that crosses the growth plate. If it is displaced or unstable it should be primarily fixed. A injury of this nature that is missed can progress to non-union or malunion with growth arrest, or, if an attempt is made to reduce the fracture late under direct vision, it may develop avascular necrosis.

Slipped upper femoral epiphysis

This injury is readily missed. A painful hip in a child approaching puberty should arouse suspicion. The injury can be diagnosed on plain radiography as seen in Fig. 27.20. When treated in its early stages the outcome is excellent; if it progresses to a more severe slip then the outcome is poor.

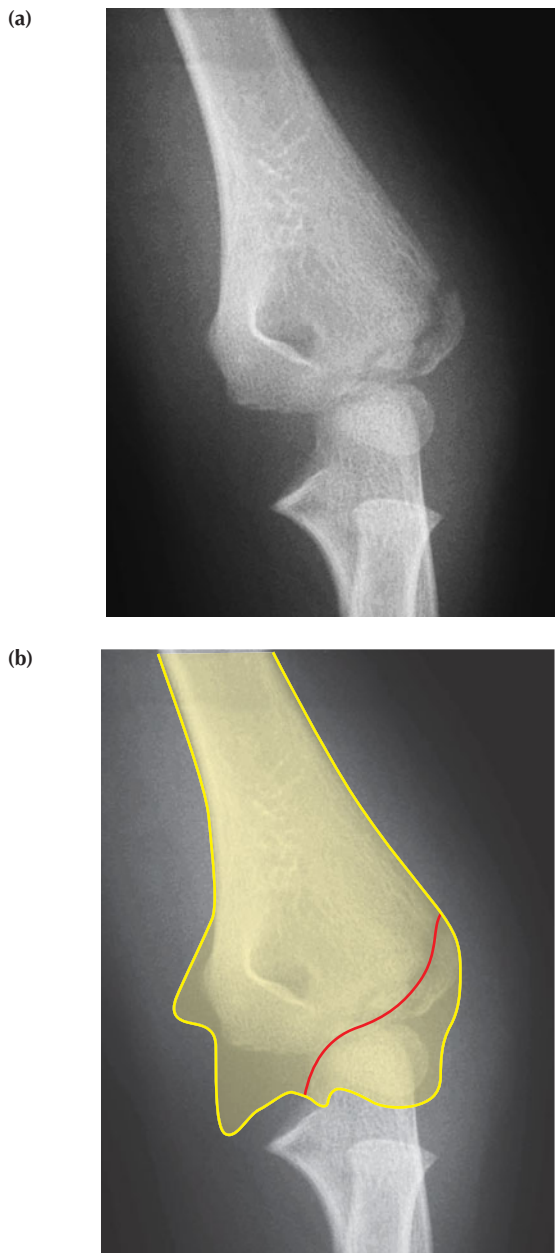

Figure 27.19 Lateral condylar mass fracture. (a) Plain radiograph showing the metaphyseal fracture. (b) The yellow shows the shape of the distal humerus including the cartilaginous analogue, and the red shows the true extent of the injury, i.e. a significant intra-articular fracture.

Femoral shaft fracture

The management of femoral shaft fractures in children is evolving in a similar way to how the management of the adult fracture evolved, albeit 20 years later. These fractures can be managed with traction and the shorter time to union makes this more acceptable. Until recently, unless there was another indication for surgical fixation such as a head injury or other long bone fracture, most were managed non-operatively; now, only in the very young is this the case. With children under 12–15 kg, simple gallow's traction is appropriate. Here the legs are suspended vertically with the buttocks just off the bed. This maintains an adequate position and nappy changes are straightforward. With older

Figure 27.20 Slipped left upper femoral epiphysis. (a) Plain radiograph; (b) the injury highlighted.

children, as the necessary period of traction increases, so does the tendency for operative fixation. Standard intramedullary nailing poses a risk to the proximal growth plate and should be avoided in girls below 12 years and boys below 14 years. As previously mentioned, flexible intramedullary nails may be placed to avoid the growth plate (Fig. 27.21).

Tibial shaft fracture

In a child with an unstable tibial fracture that is not amenable to cast management, external fixation, elastic nailing and plating are all reasonable options (Summary box 27.7).

Summary box 27.7

Fractures in the skeletally immature

- Do not forget non-accidental injury
- Be reluctant to re-manipulate a physal injury
- Elastic nails are a significant step forward in fracture treatment in children
- Not many fractures require operative intervention in children

Figure 27.21 Femoral shaft fracture in a child, which has been stabilised with elastic nails.

Osteoporotic fractures

In osteoporosis there is a decrease in bone mass and strength. Eventually, a relatively minor strain can cause a fracture (fragility fracture). These fractures, occurring mainly in the elderly, constitute the bulk of the orthopaedic trauma workload of a UK hospital. They can sometimes be treated in just the same way as injuries in younger stronger bone. However, there are other considerations. The elderly have less capacity to tolerate an injured limb and, thus, it is often not possible for them to partially weight-bear. Therefore, if treatment is to allow them to function, fixation must be able to tolerate full weight-bearing. If this cannot be achieved then it is frequently necessary for the patient to have a prolonged period of hospitalisation. For general management it is important to follow local guidelines for osteoporosis management and falls prevention.

Internal fixation in osteoporotic bone remains a challenge. The hold of screws inserted into the bone is often suboptimal. This leads to 'backing out' of the screws and subsequent loss of fracture reduction. Locking plates may help to overcome this problem. In a locking plate and construction the integrity of the structure depends upon the tightness of the screw in the plate rather than the tightness of the screw in the bone (Fig. 27.22b).

The need for early restoration of function would seem to guide the surgeon towards more intervention. However, this has to be balanced against the poorer quality of the soft tissues and, therefore, the greater likelihood of wound problems. However, on balance, the treatment of fractures in the elderly is generally more aggressive to try to achieve earlier function as depicted in the outcome curves discussed earlier.

Figure 27.22 Variations in fixation technique suited to osteoporotic bone. (a) Norian bone substitute has been injected to support the lateral tibial plateau in the partial articular fracture. (b) A locking plate in a proximal humerus. The screws are threaded into the plate to make a fixed-angle device.

Intra-articular fractures

It is not always necessary to obtain a perfect anatomical reduction of an intra-articular fracture in an elderly osteoporotic patient, and it is even more difficult to hold it. The long-term complication of degenerative change is of relatively less importance in the elderly. Thus, in dealing with a tibial plateau fracture in an older person the object of operative fixation is different from that in the younger person – it is primarily stability and not congruity that is required. The first stage of an operation to treat a tibial plateau fracture in the elderly is an examination under anaesthesia. If the joint is stable then there is no indication for operative treatment. When operation is required it can be helpful to augment the bone. Figure 27.23a shows a case in which the bone substitute Norian has been used to help support the reduced joint surface.

Proximal femoral fractures

Proximal femoral fractures fall into two groups: extracapsular and intracapsular. The blood supply to the femoral head and neck travels down through the hip capsule and then back up the femoral neck. Fractures of the femoral neck inside the capsule

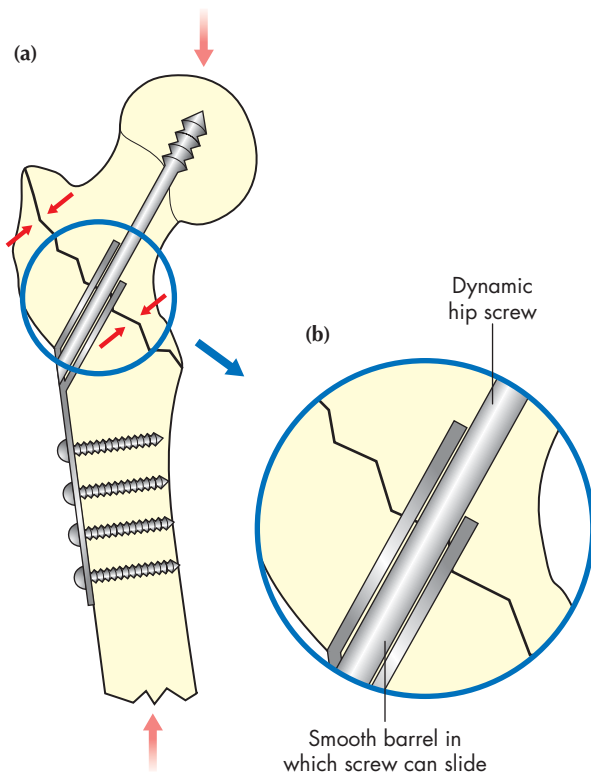

Figure 27.23 (a) A dynamic hip screw for fixing a trochanteric proximal femoral fracture. This allows for compression at the fracture site on load-bearing and protects the femoral head from penetration by the screw when the osteoporotic bone settles. (b) Insert to show the sliding screw in the barrel.

(intracapsular or subcapital) are liable to sever the blood supply to the head of the femur and so need to be treated differently to those outside the capsule.

Extracapsular fracture

Biological fixation principles are used to fix this type of fracture. Indirect reduction using a traction table is followed by fixation with a dynamic hip screw (DHS) placed using an image intensifier. The dynamic nature of the implant allows the fragments to impact together when the patient walks, as shown in Fig. 27.23. This stimulates healing while improving stability and protects the femoral head from penetration by the implant.

Intracapsular fracture

Most patients presenting with an intracapsular (subcapital) fractured neck of femur are elderly and osteoporotic. Early mobilisation offers their best chance of sustaining such independence as they have. If the fracture has displaced, then the probability is that fixation of the articular fragment will be tenuous and prone to failure, coupled with the knowledge that the femoral head may have lost its blood supply. An elderly patient will have difficulty protecting a delicate fixation. Therefore, often the treatment of choice is to simply replace the compromised femoral head with an artificial head (a hemi-arthroplasty). This treatment is not ideal in younger patients, but what then what constitutes a 'younger' patient is open to debate. The alternatives for the younger patient are:

(a) to make an attempt to reduce and fix the fracture generally holding it reduced with screws placed under image intensifier

control, in the knowledge that a proportion of these fixations will fail but that if successful the patient has their own hip.

Or:

(b) to perform a total hip replacement, which is mechanically sounder but a more extensive procedure and more expensive.

This question of fixing or replacing in relation to articular fractures has analogies in other joints (Summary box 27.8).

Summary box 27.8

Osteoporotic fractures

- Fragility fractures are the commonest cause of trauma admission
- The elderly do not tolerate immobility
- Fixation techniques are extended with fixed-angle devices and bone augmentation
- Manage osteoporosis
- Manage falls

Injuries to the foot and hand

Foot injuries

Severe injuries to the foot are surprisingly disabling. They have a greater tendency to impact on the ability to work than long bone fractures.

Foot injuries are frequently missed, especially in the polytrauma setting. Even when injury is suspected the clinical localisation of an injury and the interpretation of radiographs can be difficult.

Calcaneal fractures

The os calcis is the largest and most frequently fractured hindfoot bone. The commonest cause of injury is a fall from a height. Associated injuries include lumbar spine and lower extremity fractures, occurring in 10–20% of cases. Plain radiographs often do not demonstrate the scale of destruction and CT is necessary for evaluation. Figure 27.24 shows an intra-articular fracture of the os calcis. When accurate reduction and fixation is achievable it would seem to be beneficial. When a good reduction is not achievable the benefit of operation is less clear.

Talus fractures and dislocations

The talus consists of three parts (head, neck and body) and articulates superiorly with the distal tibia and inferiorly with the calcaneus and navicular. The talus has no muscular or tendinous attachments and therefore its blood supply is tenuous. The blood supply comes from two sources: extraosseous and intraosseous. Talar neck fractures are the commonest injury and are usually high energy (historically termed 'aviator's astragalus'). A significant complication is avascular necrosis of the talus. The goal of treatment is anatomical reduction and stable fixation, which helps reduce the risk of osteonecrosis. Hawkins' sign can be seen approximately 6–8 weeks after injury on plain radiographs. This appears as subchondral lucency of the talar dome, which signifies bony reabsorption, i.e. a viable bone.

Tarsometatarsal (Lisfranc) joint injuries

The tarsometatarsal joint is a very strong weight-bearing structure. It requires significant force to injure it. Poorly treated

Jacques Lisfranc de St. Martin, 1790–1847, Professor of Surgery and Operative Medicine, Paris, France.

Figure 27.24 Axial (a) and sagittal (b) views of a displaced intra-articular fracture of the os calcis. (c and d) Intraoperative views of the reconstruction. Both the overall shape and the articular surface have been restored.

injuries of this joint can give rise to long-term debilitating symptoms. It is therefore surprising that these injuries are frequently missed. The key to diagnosis is careful localisation of symptoms and signs, which when looked for are usually significant. Once suspected the injury is then confirmed on plain radiography and delineated further with CT. The treatment of the displaced injury is open reduction and internal fixation.

Achilles tendon rupture

Up to 20% of these injuries are missed at initial presentation. The typical history of a sensation of being kicked behind the ankle whilst playing sport is frequently given. Sometimes there is a palpable gap. Simmonds' test – squeezing the calf to produce passive plantarflexion of the ankle – is usually positive. Many regimes for treatment exist. A logical progression is to confirm the diagnosis on ultrasound, proceeding to percutaneous repair of those tendons with a gap of > 5 mm in plantarflexion, and treating those with a smaller gap non-operatively.

Franklin Adin Simmonds, 1911–1983, Orthopaedic Surgeon, The Rowley Bristow Hospital, Pyrford, Surrey, England.

Hand injuries

Some injuries to the hand are easily missed and are therefore worth discussing further.

Scaphoid fracture

The scaphoid is the most commonly injured carpal bone. The scaphoid is made up of the proximal and distal poles, a tubercle and the waist. The proximal pole is completely intra-articular and receives all of its blood supply from the distal branches of the radial artery. This enters the scaphoid in a retrograde fashion (distal to proximal). Therefore, fractures in the proximal pole are most at risk of non-union or avascular necrosis. In contrast, distal pole fractures tend to heal without problems. Figure 27.25 shows a scaphoid fracture and demonstrates how awkward it can be to make the diagnosis on standard anteroposterior and lateral views of the wrist.

The mechanism of injury is typically a fall onto the outstretched hand with the wrist in radial deviation and dorsiflexed. Fractures of the scaphoid waist occur most frequently. Examination usually reveals tenderness in the anatomical snuff-box. The suspected diagnosis is initially based on clinical findings. Plain radiographs may not show a fracture line for up to 10 days.

Figure 27.25 Scaphoid fracture. (a) Anteroposterior and lateral views in which the injury is difficult to see. (b and c) Oblique views with the fracture line highlighted. (d) In this case of a young patient the fracture was treated with early fixation.

Therefore, a patient with an equivocal examination is treated in a cast. Immobilisation is implemented empirically to reduce the risk of non-union and subsequent avascular necrosis. A repeat clinical and radiographic assessment should be performed between 10 and 14 days post-injury. In the presence of a fracture line the cast is reapplied. If the radiographs are normal but clinical suspicion remains, further imaging using a bone scan or MRI scan can be helpful. Open reduction (using a compression screw) is required for unstable fractures (> 1 mm displacement or angulation). Complications of scaphoid fractures include non-union, avascular necrosis, malunion and carpal instability.

Lunate dislocation

The lunate forms a part of the proximal row of the carpus with the scaphoid and triquetrum. Articulating with the radius, this row forms the radiocarpal joint.

The lunate resides in the concavity of the lunate fossa of the distal radius. Interosseus ligaments hold it to the adjacent scaphoid and triquetrum.

Perilunate dislocations are often unrecognised. Clinical examination reveals significant swelling of the entire carpus. The diagnosis is made with plain radiographs (Fig. 27.26); the lateral view demonstrates the 'spilled tea cup sign' with volar tilt of the lunate. Acute injuries may be initially treated with closed reduction and casting. Irreducible or unstable injuries require open reduction and stabilisation with K-wires. Note that associated injuries such

Figure 27.26 Perilunate dislocation. (a) A plain lateral radiograph of the wrist. (b) The outline of the perilunate dislocation is highlighted. Cap, capitate; Lun, lunate; Rad, radius.

as scaphoid and radial styloid fractures, as well as median nerve injury, should be excluded.

Thumb metacarpophalangeal ulnar collateral ligament

The integrity of this ligament is important for effective lateral key pinch. Injury to the ulnar collateral ligament is commonly referred to as 'gamekeeper's thumb' or 'skier's thumb', and is caused by the thumb being forced laterally away from the rest of the hand. Tenderness is located on the ulnar aspect of the metacarpophalangeal joint. To assess the integrity of the ligament, perform a stress test.

Cast immobilisation can be used in the treatment of partial tears with a good endpoint. A complete tear with instability (excessive opening of the joint when compared with the other side) or a displaced fracture requires open repair.

Pathological failure

When abnormal bone gives way, this is referred to as a pathological fracture. Examples include primary bone tumours and bony metastases, osteomyelitis, metabolic bone disease (osteomalacia, Paget's disease, osteoporosis) and haematopoietic disease (myeloma, lymphoma, leukaemia). Up to 80% of metastatic disease arises from the breast, thyroid, lungs, kidneys and prostate. The most common locations include the ribs, spine, pelvis, humerus and femur.

The typical history is of a minor trauma. This aspect of the history should alert the surgeon to the possibility of an underlying bony pathology. Physical examination should be directed to identifying the primary cause of the lesion. When suspected, investigations should be performed to ascertain the underlying pathology before definitive treatment. Blood tests, a chest radiograph and full-length views of the fractured bone are essential. A bone scan is the most sensitive indicator of skeletal disease.

If it is possible that the bony deposit is a primary tumour then operative treatment should not be commenced without careful thought. Many primary tumours can be treated constructively; however, this treatment may be compromised if tissue planes are disrupted by ill-considered operative management.

The common situation is a fracture through a metastasis and the presumption is that the patient has a limited life expectancy. Treatment is therefore aimed at regaining immediate mobility and relief of pain. As can be seen in Fig. 27.27 there is a clear rationale for aggressive treatment to restore function despite the risks. A patient with a limited life expectancy does not have the time to invest in prolonged treatment and rehabilitation. Adjuvant radiotherapy or chemotherapy should be considered in consultation with an oncologist.

The goals of surgical treatment are to reduce pain and to splint the bone so that the patient can use it. Femoral, tibial and humeral fractures are nailed where possible. Some juxta-articular fractures that would require protection if treated with ORIF and bone grafting may be mobilised earlier if bone cement is substituted for the graft. Prophylactic stabilisation should be considered in patients with metastases where there has been cortical bone destruction of $\geq 50\%$ or a femoral lesion longer than 2.5 cm, pathological fracture of the lesser trochanter and persistent pain after irradiation (Summary box 27.9).

Sir James Paget, 1814–1899, Surgeon, St. Bartholomew's Hospital, London, England.

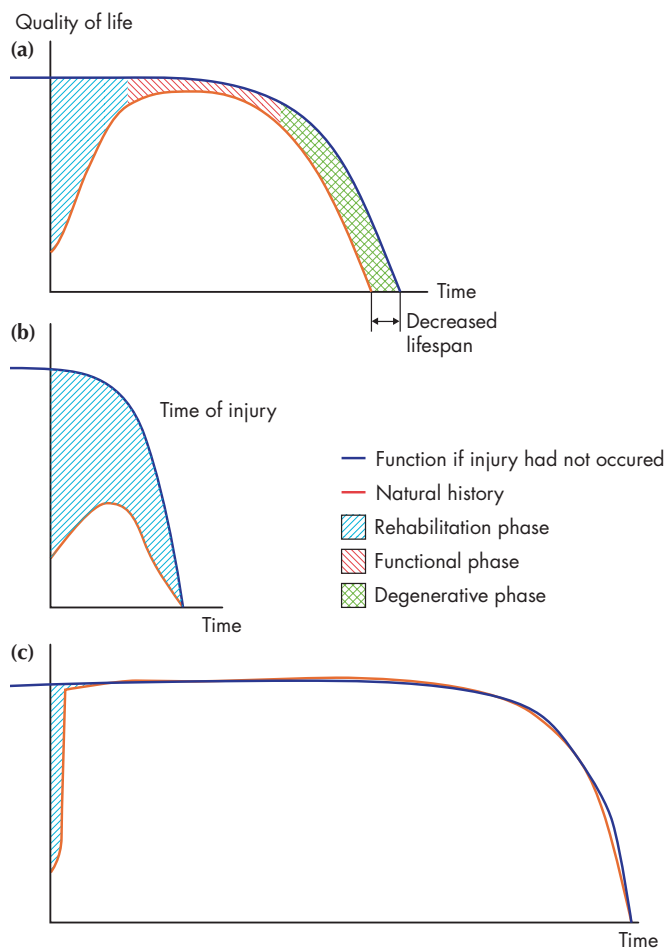

Figure 27.27 Comparative outcome curves for a normal adult (a), pathological fracture (b) and paediatric fracture (c). (a) The generic outcome curve as shown in Figure 27.8 for a patient with a life expectancy of >20 years. There is a rehabilitation, functional and degenerative phase to consider. (b) It is seen that the short life expectancy of a patient with a pathological fracture secondary to metastases means that only the rehabilitation phase is relevant. The patient must be able to function before bone healing. This justifies aggressive treatment. (c) The paediatric fracture with benign natural history. Any marginal early gain has to be considered in the light of great potential for long-term detriment should there be complications.

Summary box 27.9

Pathological failure

- Do not operate on what might be a primary tumour without careful thought
- Fractures through secondary tumours are treated aggressively to optimise early function

CONCLUSION

The management of extremity trauma is in theory quite straightforward. The first step is to realise that an injury exists as a missed injury cannot be treated. The injury then needs to be understood – this generally involves description and classification. When there is clear evidence as to the best method of treatment for a

particular injury this should be followed. When such evidence is lacking, as is generally the case, the treatment of fractures is generally principle based (Summary box 27.10).

Summary box 27.10

Summary of extremity trauma

- Realise that an injury exists
- Find the characteristics of the injury, describe and classify it
- Consider the natural history of the injury
- Treatment is guided by outcome if known or by principle if not
- Beware of injuries that are 'easily missed'

Burns

CHAPTER 28

LEARNING OBJECTIVES

To assess:

- The area and depth of burns

To understand:

- Methods for calculating the rate and quantity of fluids to be given

- Techniques for treating burns and the patient
- The pathophysiology of electrical and chemical burns

INTRODUCTION

The incidence of burn injury varies greatly between cultures. In the UK (population 65 million), each year around 175 000 people visit accident and emergency (A&E) departments suffering burns, of whom about 13 000 need to be admitted. About 1000 have severe burns requiring fluid resuscitation, and half of the victims are under 16 years of age.

The majority of burns in children are scalds caused by accidents with kettles, pans, hot drinks and bath water. Among adolescent patients, the burns are usually caused by young males experimenting with matches and flammable liquids. In adults, scalds are not uncommon but are less frequent than flame burns. Most electrical and chemical injuries occur in adults. Cold and radiation are very rare causes of burns. Associated conditions in adults, such as mental disease (attempted suicide or assault), epilepsy and alcohol or drug abuse, are underlying factors in as many as 80% of patients with burns admitted to hospital in some populations.

Legislation, health promotion and appliance design have reduced the incidence of burns, with regulations regarding flame-retardant clothes and furniture, the promotion of smoke alarms, the design of cookers and gas fires, the almost universal use of cordless kettles and the education of parents to keep their hot water thermostat to 60°C all playing their part (Summary box 28.1).

Summary box 28.1

Prevention of burns

A significant proportion of burns can be prevented by:

- Implementing good health and safety regulations
- Educating the public
- Introducing of effective legislation

The last 50 years have seen great strides made to reduce both morbidity and mortality from burn injuries. The coming years will

see a better understanding of the control of physiology along with improvements in reconstruction and rehabilitation.

A vast spectrum of injuries can arise from a burning accident, from the trivial to some of the most dramatic injuries that humans survive. The management of the major burn injury represents a significant challenge to every member of the burns team – burns doctors, surgeons, anaesthetists, ward and theatre nurses, physiotherapists, occupational therapists, dietitians, bacteriologists, physicians, psychiatrists, psychologists and the many ancillary staff whose cleaning and supply services are vital to the successful running of a burns unit. A large burn injury will have a significant effect on the patient's family and friends and the patient's future.

The importance of multidisciplinary care needs to be stressed for the adequate and effective care of the burn patient.

THE PATHOPHYSIOLOGY OF BURN INJURY

Burns cause damage in a number of different ways, but by far the most common organ affected is the skin. However, burns can also damage the airway and lungs, with life-threatening consequences. Airway injuries occur when the face and neck are burned. Respiratory system injuries usually occur if a person is trapped in a burning vehicle, house, car or aeroplane and is forced to inhale the hot and poisonous gases (Summary box 28.2).

Summary box 28.2

Warning signs of burns to the respiratory system

- Burns around the face and neck
- A history of being trapped in a burning room
- Change in voice
- Stridor

INJURY TO THE AIRWAY AND LUNGS

Physical burn injury to the airway above the larynx

The hot gases can physically burn the nose, mouth, tongue, palate and larynx. Once burned, the linings of these structures will start to swell. After a few hours, they may start to interfere with the larynx and may completely block the airway if action is not taken to secure an airway (Summary box 28.3).

Summary box 28.3

Dangers of smoke, hot gas or steam inhalation

- Inhaled hot gases can cause supraglottic airway burns and laryngeal oedema
- Inhaled steam can cause subglottic burns and loss of respiratory epithelium
- Inhaled smoke particles can cause chemical alveolitis and respiratory failure
- Inhaled poisons, such as carbon monoxide, can cause metabolic poisoning
- Full-thickness burns to the chest can cause mechanical blockage to rib movement

Physical burn injury to the airway below the larynx

This is a rare injury as the heat exchange mechanisms in the supraglottic airway are usually able safely to absorb the heat from hot air. However, steam has a large latent heat of evaporation and can cause thermal damage to the lower airway. In such injuries, the respiratory epithelium rapidly swells and detaches from the bronchial tree. This creates casts, which can block the main upper airway.

Metabolic poisoning

There are many poisonous gases that can be given off in a fire, the most common being carbon monoxide, a product of incomplete combustion that is often produced by fires in enclosed spaces. This is the usual cause of a person being found with altered consciousness at the scene of a fire. Carbon monoxide binds to haemoglobin with an affinity 240 times greater than that of oxygen and therefore blocks the transport of oxygen. Levels of carboxyhaemoglobin in the bloodstream can be measured. Concentrations above 10% are dangerous and need treatment with pure oxygen for more than 24 hours. Death occurs with concentrations around 60%.

Another metabolic toxin produced in house fires is hydrogen cyanide, which causes a metabolic acidosis by interfering with mitochondrial respiration.

Inhalational injury

Inhalational injury is caused by the minute particles within thick smoke, which, because of their small size, are not filtered by the upper airway, but are carried down to the lung parenchyma. They stick to the moist lining, causing an intense reaction in the alveoli. This chemical pneumonitis causes oedema within the alveolar sacs and decreasing gaseous exchange over the ensuing 24 hours, and often gives rise to a bacterial pneumonia. Its presence or absence has a very significant effect on the mortality of any burn patient.

Mechanical block on rib movement

Burned skin is very thick and stiff, and this can physically stop the ribs moving if there is a large full-thickness burn across the chest.

INFLAMMATION AND CIRCULATORY CHANGES

The dangers to the airway and respiration described above are readily apparent, but the cause of circulatory changes following a burn are more complex. The changes occur because burned skin activates a web of inflammatory cascades. The release of neuropeptides and the activation of complement are initiated by the stimulation of pain fibres and the alteration of proteins by heat. The activation of Hageman factor initiates a number of protease-driven cascades, altering the arachidonic acid, thrombin and kallikrein pathways.

At a cellular level, complement causes the degranulation of mast cells and coats the proteins altered by the burn. This attracts neutrophils, which also degranulate, with the release of large quantities of free radicals and proteases. These can, in turn, cause further damage to the tissue. Mast cells also release primary cytokines such as tumour necrosis factor alpha (TNF- α). These act as chemotactic agents to inflammatory cells and cause the subsequent release of many secondary cytokines. These inflammatory factors alter the permeability of blood vessels such that intravascular fluid escapes. The increase in permeability is such that large protein molecules can also now escape with ease. The damaged collagen and these extravasated proteins increase the oncotic pressure within the burned tissue, further increasing the flow of water from the intravascular to the extravascular space.

The overall effect of these changes is to produce a net flow of water, solutes and proteins from the intravascular to the extravascular space. This flow occurs over the first 36 hours after the injury but does not include red blood cells. In a small burn, this reaction is small and localised but, as the burn size approaches 10–15% of total body surface area (TBSA), the loss of intravascular fluid can cause a level of circulatory shock. Furthermore, once the area increases to 25% of TBSA, the inflammatory reaction causes fluid loss in vessels remote from the burn injury. This is why such importance is attached to measuring the TBSA involved in any burn. It dictates the size of inflammatory reaction and therefore the amount of fluid needed to control shock (Summary box 28.4).

Summary box 28.4

The shock reaction after burns

- Burns produce an inflammatory reaction
- This leads to vastly increased vascular permeability
- Water, solutes and proteins move from the intra- to the extravascular space
- The volume of fluid lost is directly proportional to the area of the burn
- Above 15% of surface area, the loss of fluid produces shock

Hageman is the surname of the individual in whom the deficiency of the factor was first discovered.

OTHER LIFE-THREATENING EVENTS WITH MAJOR BURNS

The immune system and infection

The inflammatory changes caused by the burn have an effect on the patient's immune system. Cell-mediated immunity is significantly reduced in large burns, leaving them more susceptible to bacterial and fungal infections. There are many potential sources of infection, especially from the burn wound and from the lung if this is injured, but also from any central venous lines, tracheostomies or urinary catheters present.

Changes to the intestine

The inflammatory stimulus and shock can cause microvascular damage and ischaemia to the gut mucosa. This reduces gut motility and can prevent the absorption of food. Failure of enteral feeding in a patient with a large burn is a life-threatening complication. This process also increases the translocation of gut bacteria, which can become an important source of infection in large burns. Gut mucosal swelling, gastric stasis and peritoneal oedema can also cause abdominal compartment syndrome, which splints the diaphragm and increases the airway pressures needed for respiration.

Danger to peripheral circulation

In full-thickness burns, the collagen fibres are coagulated. The normal elasticity of the skin is lost. A circumferential full-thickness burn to a limb acts as a tourniquet as the limb swells. If untreated, this will progress to limb-threatening ischaemia (Summary box 28.5).

Summary box 28.5

Other complications of burns

- Infection from the burn site, lungs, gut, lines and catheters
- Malabsorption from the gut
- Circumferential burns may compromise circulation to a limb

IMMEDIATE CARE OF THE BURN PATIENT

Pre-hospital care

The principles of pre-hospital care are:

- *Ensure rescuer safety.* This is particularly important in house fires and in the case of electrical and chemical injuries.
- *Stop the burning process.* Stop, drop and roll is a good method of extinguishing fire burning on a person.
- *Check for other injuries.* A standard ABC (airway, breathing, circulation) check followed by a rapid secondary survey will ensure that no other significant injuries are missed. Patients burned in explosions or even escaping from fires may have head or spine injuries and other life-threatening problems.
- *Cool the burn wound.* This provides analgesia and slows the delayed microvascular damage that can occur after a burn injury. Cooling should occur for a minimum of 10 min and is effective up to 1 hour after the burn injury. It is a particularly important first aid step in partial-thickness burns, especially scalds. In temperate climates, cooling should be at about 15°C, and hypothermia must be avoided.

- *Give oxygen.* Anyone involved in a fire in an enclosed space should receive oxygen, especially if there is an altered consciousness level.
- *Elevate.* Sitting a patient up with a burned airway may prove life-saving in the event of a delay in transfer to hospital care. Elevation of burned limbs will reduce swelling and discomfort.

Hospital care

The principles of managing an acute burn injury are the same as in any acute trauma case:

- A Airway control.
- B Breathing and ventilation.
- C Circulation.
- D Disability – neurological status.
- E Exposure with environmental control.
- F Fluid resuscitation.

The possibility of injury additional to the burn must be sought both clinically and from the history, and treated appropriately. The major determinants of severity of any burn injury are the percentage of TBSA that is burned, the presence of an inhalation injury and the depth of the burn (Summary box 28.6).

Summary box 28.6

Major determinants of the outcome of a burn

- Percentage surface area involved
- Depth of burns
- Presence of an inhalational injury

These aspects are therefore some of the primary diagnostic aims of the acute admission and, although there is this vast spectrum of burns severity, most of the principles covered below will apply to all patients. Not all burned patients will need to be admitted to a burns unit (Summary box 28.7).

Summary box 28.7

The criteria for acute admission to a burns unit

- Suspected airway or inhalational injury
- Any burn likely to require fluid resuscitation
- Any burn likely to require surgery
- Patients with burns of any significance to the hands, face, feet or perineum
- Patients whose psychiatric or social background makes it inadvisable to send them home
- Any suspicion of non-accidental injury
- Any burn in a patient at the extremes of age
- Any burn with associated potentially serious sequelae including high-tension electrical burns and concentrated hydrofluoric acid burns

Airway

The burned airway creates symptoms by swelling and, if not managed proactively, can completely occlude the upper airway. The treatment is to secure the airway with an endotracheal tube until the swelling has subsided, which is usually after about 48 hours. The symptoms of laryngeal oedema, such as change in voice, stridor, anxiety and respiratory difficulty, are very late

symptoms. Intubation at this point is often difficult or impossible owing to swelling, so acute cricothyroidotomy equipment must be at hand when intubating patients with a delayed diagnosis of airway burn. Because of this, early intubation of suspected airway burn is the treatment of choice in such patients. The time-frame from burn to airway occlusion is usually between 4 and 24 hours, so there is time to make a sensible decision with senior staff and allow an experienced anaesthetist to intubate the patient (Summary box 28.8).

Summary box 28.8

Initial management of the burned airway

- Early elective intubation is safest
- Delay can make intubation very difficult because of swelling
- Be ready to perform an emergency cricothyroidotomy if intubation is delayed

Thus, the key in the management of airway burn is the history and early signs, rather than the symptoms. The history is that of obligatory inhalation of hot gases such as in a house or car fire. Clues include blisters on the hard palate, burned nasal mucosa and loss of all the hair in the nose (the anterior hairs are often burned), but perhaps the most valuable signs are the presence of deep burns around the mouth and in the neck (Summary box 28.9).

Summary box 28.9

Recognition of the potentially burned airway

- A history of being trapped in the presence of smoke or hot gases
- Burns on the palate or nasal mucosa, or loss of all the hairs in the nose
- Deep burns around the mouth and neck

Breathing

Inhalational injury

Time is a factor; anyone trapped in a fire for more than a couple of minutes must be observed for signs of smoke inhalation. Other signs that raise suspicion are the presence of soot in the nose and the oropharynx and a chest radiograph showing patchy consolidation.

The clinical features are a progressive increase in respiratory effort and rate, rising pulse, anxiety and confusion and decreasing oxygen saturation. These symptoms may not be apparent immediately and can take 24 hours to 5 days to develop.

Treatment starts as soon as this injury is suspected and the airway is secure. Physiotherapy, nebulisers and warm humidified oxygen are all useful. The patient's progress should be monitored using respiratory rate, together with blood gas measurements. If the situation deteriorates, continuous or intermittent positive pressure may be used with a mask or T-piece. In the severest cases, intubation and management in an intensive care unit will be needed.

The key, therefore, in the management of inhalational injury is to suspect it from the history, institute early management and observe carefully for deterioration.

Thermal burn injury to the lower airway

These rare injuries can occur with steam injuries. Their management is supportive and the same as that for an inhalational injury.

Metabolic poisoning

Any history of a fire within an enclosed space and any history of altered consciousness are important clues to metabolic poisoning. Blood gases must be measured immediately if poisoning is a possibility. Carboxyhaemoglobin levels raised above 10% must be treated with high inspired oxygen for 24 hours to speed its displacement from haemoglobin. Metabolic acidosis is a feature of this and other forms of poisoning.

Once again, the key to diagnosing these injuries is suspicion from the history. Blood gas measurement will confirm the diagnosis. The treatment is oxygen.

Mechanical block to breathing

Any mechanical block to breathing from the eschar of a significant full-thickness burn on the chest wall is obvious from the examination. There will also be carbon dioxide retention and high inspiratory pressures if the patient is ventilated. The treatment is to make some scoring cuts through the burned skin to allow the chest to expand (escharotomy). The nerves have been destroyed in the skin, and this procedure is not painful for the patient.

ASSESSMENT OF THE BURN WOUND

Assessing size

Burn size needs to be formally assessed in a controlled environment. This allows the area to be exposed and any soot or debris washed off. Care should be taken not to cause hypothermia during this stage. In the case of smaller burns or patches of burn, the best measurement is to cut a piece of clean paper the size of the patient's whole hand (digits and palm), which represents 1% TBSA, and match this to the area. Another accurate way of measuring the size of burns is to draw the burn on a Lund and Browder chart (Fig. 28.1), which maps out the percentage TBSA of sections of our anatomy. It also takes into account different proportional body surface area in children according to age. The rule of nines, which states that each upper limb is 9% TBSA, each lower limb 18%, the torso 18% each side and the head and neck 9%, can be used as a rough guide to TBSA outside the hospital environment (Summary box 28.10).

Summary box 28.10

Assessing the area of a burn

- The patient's whole hand is 1% TBSA, and is a useful guide in small burns
- The Lund and Browder chart is useful in larger burns
- The rule of nines is adequate for a first approximation only

Assessing depth from the history

The first indication of burn depth comes from the history (Table 28.1). The burning of human skin is temperature and time dependent. It takes 6 hours for skin maintained at 44°C to suffer irreversible changes, but a surface temperature of 70°C for 1 s is all that is needed to produce epidermal destruction. Taking an

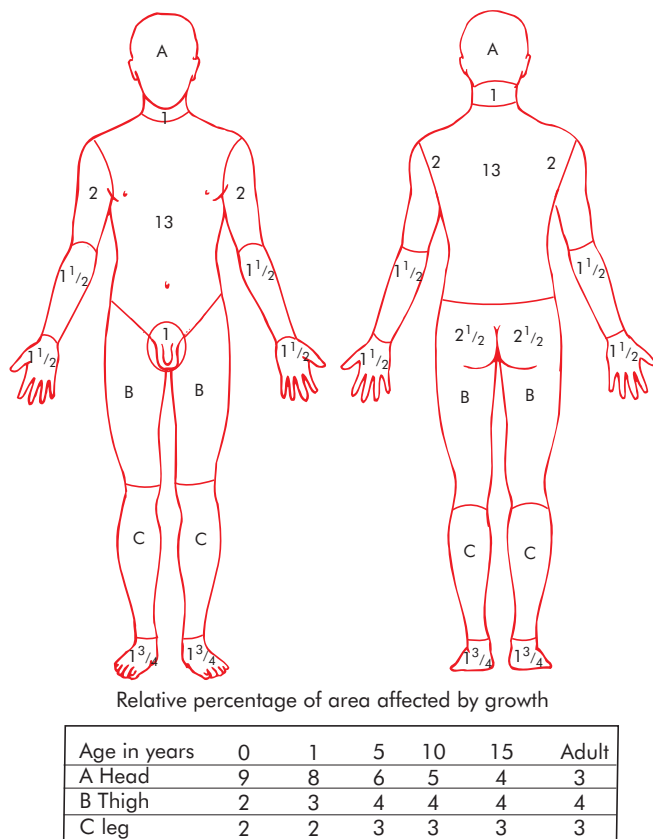

Figure 28.1 The Lund and Browder chart.

Table 28.1 Causes of burns and their likely depth

Cause of burn	Probable depth of burn
Scald	Superficial, but with deep dermal patches in the absence of good first aid. Will be deep in a young infant
Fat burns	Deep dermal
Flame burns	Mixed deep dermal and full thickness
Alkali burns including cement	Often deep dermal or full thickness
Acid burns	Weak concentrations superficial, strong concentrations deep dermal
Electrical contact burn	Full thickness

example of hot water at 65°C: exposure for 45 s will produce a full-thickness burn, for 15 s a deep partial-thickness burn and for 7 s a superficial partial-thickness burn (Summary box 28.11).

Summary box 28.11

Assessing the depth of a burn

- The history is important – temperature, time and burning material
- Superficial burns have capillary filling
- Deep partial-thickness burns do not blanch but have some sensation
- Full-thickness burns feel leathery and have no sensation

Superficial partial-thickness burns

The damage in these burns goes no deeper than the papillary dermis. The clinical features are blistering and/or loss of the epidermis. The underlying dermis is pink and moist. The capillary return is clearly visible when blanched. There is little or no fixed capillary staining. Pinprick sensation is normal. Superficial partial-thickness burns heal without residual scarring in 2 weeks. The treatment is non-surgical (Fig. 28.2).

Deep partial-thickness burn

These burns involve damage to the deeper parts of the reticular dermis (Fig. 28.3). Clinically, the epidermis is usually lost. The exposed dermis is not as moist as that in a superficial burn. There is often abundant fixed capillary staining, especially if examined after 48 hours. The colour does not blanch with pressure under the examiner's finger. Sensation is reduced, and the patient is unable to distinguish sharp from blunt pressure when examined with a needle. Deep dermal burns take 3 or more weeks to heal without surgery and usually lead to hypertrophic scarring (Fig. 28.4, see page 384).

Full-thickness burns

The whole of the dermis is destroyed in these burns (Fig. 28.5, see page 384). Clinically, they have a hard, leathery feel. The appearance can vary from that similar to the patient's normal skin to charred black, depending upon the intensity of the heat. There is no capillary return. Often, thrombosed vessels can be seen under the skin. These burns are completely anaesthetised: a needle can be stuck deep into the dermis without any pain or bleeding.

FLUID RESUSCITATION

The principle of fluid resuscitation is that the intravascular volume must be maintained following a burn in order to provide sufficient circulation to perfuse not only the essential visceral organs such as the brain, kidneys and gut, but also the peripheral tissues, especially the damaged skin (Summary box 28.12).

Summary box 28.12

Fluids for resuscitation

- In children with burns over 10% TBSA and adults with burns over 15% TBSA, consider the need for intravenous fluid resuscitation
- If oral fluids are to be used, salt must be added
- Fluids needed can be calculated from a standard formula
- The key is to monitor urine output

Intravenous resuscitation is appropriate for any child with a burn greater than 10% TBSA. The figure is 15% TBSA for adults. In some parts of the world, intravenous resuscitation is commenced only with burns that approach 30% TBSA. If oral resuscitation is to be commenced, it is important that the water given is not salt free. It is rarely possible to undergo significant diuresis in the first 24 hours in view of the stress hormones that are present. Hyponatraemia and water intoxication can be fatal. It is therefore appropriate to give oral rehydration with a solution such as Dioralyte.

The resuscitation volume is relatively constant in proportion

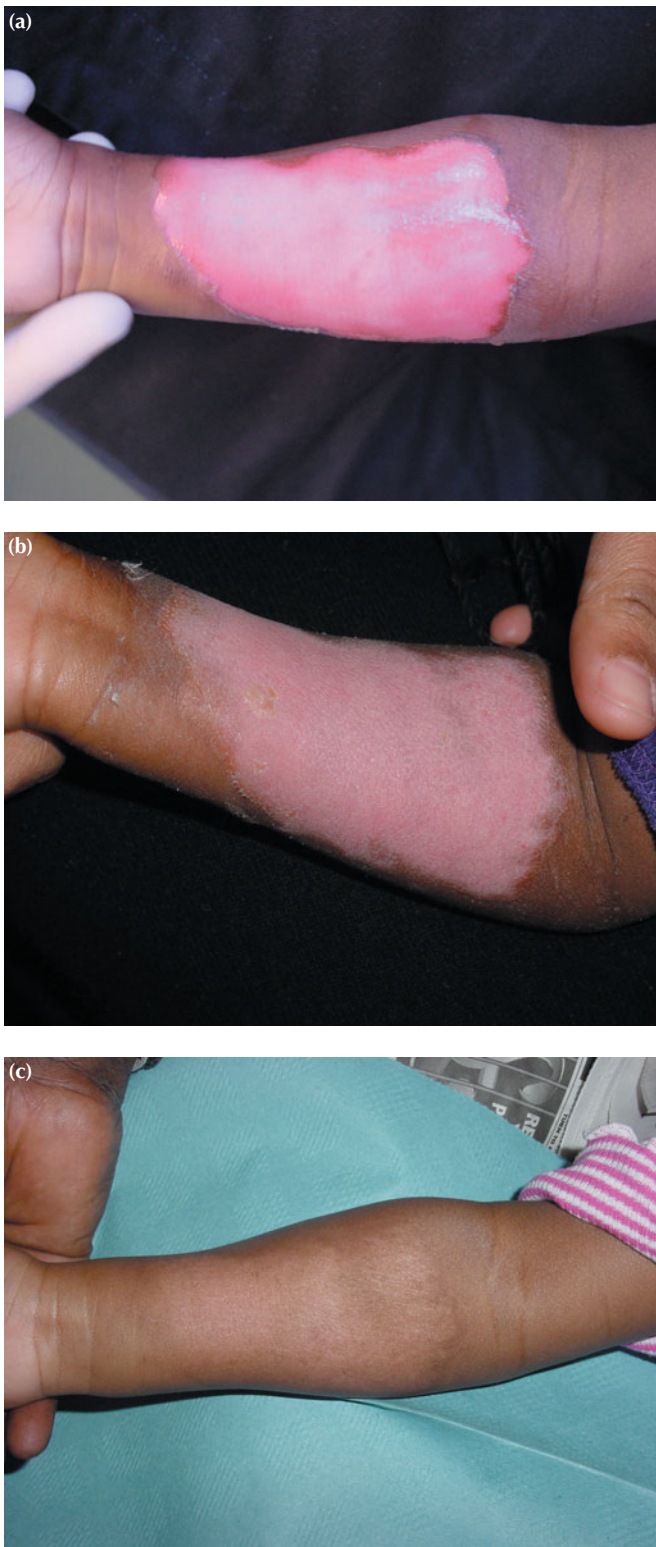

Figure 28.2 (a) A superficial partial-thickness scald 24 hours after injury. The dermis is pink and blanches to pressure. (b) At 2 weeks, the wound is healed but lacks pigment. (c) At 3 months, the pigment is returning.

Figure 28.3 (a) A deep dermal burn undergoing tangential shaving. The dead dermis is removed layer by layer until healthy bleeding is seen. The burn is pale because it was dressed with silver sulphadiazine cream, but no blanching was visible under this layer. The patient was unable to differentiate between pressure from the sharp and blunt ends of a needle. (b) A thin, split-thickness graft harvested from the thigh. (c) The thin graft is placed in the dermal remnants. The rete pegs can be seen between the remnants of the dermis through the graft.

Figure 28.4 Hypertrophic scarring following a deep dermal burn.

to the area of the body burned and, therefore, there are formulae that calculate the approximate volume of fluid needed for the resuscitation of a patient of a given body weight with a given percentage of the body burned. These regimens follow the fluid loss, which is at its maximum in the first 8 hours and slows, such that, by 24–36 hours, the patient can be maintained on his or her normal daily requirements.

There are three types of fluid used. The most common is Ringer's lactate or Hartmann's solution; some centres use human albumin solution or fresh-frozen plasma, and some centres use hypertonic saline.

Perhaps the simplest and most widely used formula is the Parkland formula. This calculates the fluid to be replaced in the first 24 hours by the following formula:

$$\begin{aligned} \text{Total percentage body surface area} \times \text{weight (kg)} & \quad (28.1) \\ \times 4 = \text{volume (ml)} \end{aligned}$$

Half this volume is given in the first 8 hours, and the second half is given in the subsequent 16 hours.

Crystalloid resuscitation

Ringer's lactate is the most commonly used crystalloid. Crystalloids are said to be as effective as colloids for maintaining intravascular volume. They are also significantly less expensive. Another reason for the use of crystalloids is that even large protein molecules leak out of capillaries following burn injury; however, non-burnt capillaries continue to sieve proteins virtually normally.

In children, maintenance fluid must also be given. This is normally dextrose–saline given as follows:

- 100 ml kg⁻¹ for 24 hours for the first 10 kg;
- 50 ml kg⁻¹ for the next 10 kg;
- 20 ml kg⁻¹ for 24 hours for each kilogram over 20 kg body weight.

Hypertonic saline

Human albumin solution (HAS) is a commonly used colloid.

Hypertonic saline has been effective in treating burns shock for many years. It produces hyperosmolarity and hypernatraemia. This reduces the shift of intracellular water to the extracellular space. Advantages include less tissue oedema and a resultant decrease in escharotomies and intubations.

Colloid resuscitation

Plasma proteins are responsible for the inward oncotic pressure that counteracts the outward capillary hydrostatic pressure. Without proteins, plasma volumes would not be maintained as there would be oedema. Proteins should be given after the first 12 hours of burn because, before this time, the massive fluid shifts cause proteins to leak out of the cells.

Figure 28.5 (a) A full-thickness burn on admission just prior to escharotomy. The wound is wrapped in cling film while in transit. The patient's facial burn is shown in Figure 28.8. (b) Excision of the same full-thickness burn, down to healthy fat.

Sydney Ringer, 1835–1910, Professor of Clinical Medicine, University College Hospital, London, England.
Alexis Frank Hartmann, 1898–1964, Paediatrician, St. Louis, MO, USA.

The commonest colloid-based formula is the Muir and Barclay formula:

- $0.5 \times \text{percentage body surface area burnt} \times \text{weight} = \text{one portion}$;
- periods of 4/4/4, 6/6 and 12 hours respectively;
- one portion to be given in each period.

Monitoring of resuscitation

The key to monitoring of resuscitation is urine output. Urine output should be between 0.5 and 1.0 ml kg⁻¹ body weight per hour. If the urine output is below this, the infusion rate should be increased by 50%. If the urine output is inadequate and the patient is showing signs of hypoperfusion (restlessness with tachycardia, cool peripheries and a high haematocrit), then a bolus of 10 ml kg⁻¹ body weight should be given. It is important that patients are not over-resuscitated, and urine output in excess of 2 ml kg⁻¹ body weight per hour should signal a decrease in the rate of infusion.

Other measures of tissue perfusion such as acid–base balance are appropriate in larger, more complex burns, and a haematocrit measurement is a useful tool in confirming suspected under- or overhydration. Those with cardiac dysfunction, acute or chronic, may well need more exact measurement of filling pressure, preferably by transoesophageal ultrasound or with the more invasive central line.

TREATING THE BURN WOUND

Escharotomy

Circumferential full-thickness burns to the limbs require emergency surgery (Fig. 28.6). The tourniquet effect of this injury is easily treated by incising the whole length of full-thickness burns. This should be done in the mid-axial line, avoiding major nerves (Table 28.2). One should remember that an escharotomy can cause a large amount of blood loss; therefore, adequate blood should be available for transfusion if required.

Figure 28.6 A full-thickness burn to the upper limb with a mid-axial escharotomy. The soot and debris have been washed off.

Ian Fraser Kerr Muir, formerly Plastic Surgeon, The Aberdeen Royal Infirmary, Aberdeen, Scotland.
Thomas Laird Barclay, D. 2007, formerly Plastic Surgeon, The Royal Infirmary, Bradford, England.

Table 28.2 Key features of escharotomy placement

Upper limb	Mid-axial, anterior to the elbow medially to avoid the ulnar nerve
Hand	Midline in the digits. Release muscle compartments if tight. Best done in theatre and with an experienced surgeon
Lower limb	Mid-axial. Posterior to the ankle medially to avoid the saphenous vein
Chest	Down the chest lateral to the nipples, across the chest below the clavicle and across the chest at the level of the xiphisternum
General rules	Extend the wound beyond the deep burn. Diathermy any significant bleeding vessels. Apply haemostatic dressing and elevate the limb postoperatively

Thereafter, the management of the burn wound remains the same irrespective of the size of the injury. The burn needs to be cleaned, and the size and depth need to be assessed. Full-thickness burns and deep partial-thickness burns that will require operative treatment will need to be dressed with an antibacterial dressing to delay the onset of colonisation of the wound.

Full-thickness burns and obvious deep dermal wounds

The four most common dressings for full-thickness and contaminated wounds are listed in Summary box 28.13.

Summary box 28.13

Options for topical treatment of deep burns

- 1% silver sulphadiazine cream
- 0.5% silver nitrate solution
- Mafenide acetate cream
- Serum nitrate, silver sulphadiazine and cerium nitrate

Dressings with nanocrystalline silver

- *Silver sulphadiazine cream (1%)*. This gives broad-spectrum prophylaxis against bacterial colonisation and is particularly effective against *Pseudomonas aeruginosa* and also methicillin-resistant *Staphylococcus aureus*.
- *Silver nitrate solution (0.5%)*. Again, this is highly effective as a prophylaxis against *Pseudomonas* colonisation, but it is not as active as silver sulphadiazine cream against some of the Gram-negative aerobes. The other disadvantage of this solution is that it needs to be changed or the wounds resoaked every 2–4 hours. It also produces black staining of all the furniture surrounding the patient.
- *Mafenide acetate cream*. This is popular, especially in the USA, but is painful to apply. It is usually used as a 5% topical solution but has been associated with metabolic acidosis.

Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology (1891–1900) and of Medicine (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.

- *Silver sulphadiazine* and *cerium nitrate*. This is also a very useful burn dressing, especially for full-thickness burns. It induces a hard effect on the burned skin and has been shown in certain instances, especially in elderly patients, to reduce some of the cell-mediated immunosuppression that occurs in burns. Cerium nitrate forms a sterile eschar and is specially useful in treating burns when a conservative treatment option has been chosen. Cerium nitrate has also been shown to boost cell-mediated immunity in these patients.

Superficial partial-thickness wounds and mixed-depth wounds

Around the world, a wide variety of substances are used to treat these wounds, from honey or boiled potato peel to synthetic biological dressings with live cultured fibroblasts within the matrix. This is testament to the fact that superficial partial-thickness burns will heal almost irrespective of the dressing. Thus, the key lies with dressings that are easy to apply, non-painful, reduce pain, simple to manage and locally available. The choice of dressings does, however, become crucial in the case of burns that border on being deep dermal (Fig. 28.7). Here, the choice of dressing can make the difference between scar and no scar and/or operation and no operation. Some of the options for dressing choice are described below.

If the wound is heavily contaminated as a result of the accident, then it is prudent to clean the wound formally under a general anaesthetic. With more chronic contamination, silver sulphadiazine cream dressing for 2 or 3 days is very effective and can be changed to a dressing that is more efficient at promoting healing after this period.

The simplest method of treating a superficial wound is by exposure. The initial exudate needs to be managed by frequent changes of clean linen around the patient but, after a few days, a dry eschar forms, which then separates as the wound epithelialises. This is often used in hot climates and for small burns on the face. However, this method is painful and requires an intensive amount of nursing support. A variation on this theme is to cover the wound with a permeable wound dressing such as Mefix or Fixamol. This allows the wounds to dry but, because it is a covering, it avoids the problems of the wound adhering to the sheets and clothes. A similar method of managing these types of burn is to place a Vaseline-impregnated gauze (with or without an antiseptic such as chlorhexidine) over the wound. An alternative is a fenestrated silicone sheet (e.g. Mepitel). These can then be backed with swabs to absorb the exudate. The Vaseline gauze or silicone layer is used to prevent the swabs adhering to the wound and reduces the stiffness of the dry eschar, preventing it from cracking so easily. The swabs need to be changed after the first 48 hours as they are often soaked. After that, they can be left for longer.

More interactive dressings include hydrocolloids and biological dressings. Hydrocolloid dressings need to be changed every 3–5 days. They are particularly useful in mixed-depth burns as the high protease levels under the occlusive dressings aid with the debridement of the deeper areas of burn. They also provide a moist environment, which is good for epithelialisation. Duoderm is a hydrocolloid dressing. There is good evidence for its value in burns.

Biological, synthetic (e.g. Biobrane) and natural (e.g. amniotic membranes) dressings also provide good healing environments

Figure 28.7 (a) A scald to the chest from boiling water, mainly superficial but in some areas close to being deep dermal. This was treated with a hydrocolloid dressing. (b) There are two tiny areas of hypertrophy indicating how close the burn was to being deep dermal. The good first aid this patient received probably made a difference to the outcome.

and do not need to be changed. They are ideal for one-stop management of superficial burns, being easy to apply and comfortable. However, they will become detached if applied to deep dermal wounds as the eschar needs to separate. They are therefore not as useful in mixed-depth wounds (Summary box 28.14).

Summary box 28.14

Principles of dressings for burns

- Full-thickness and deep dermal burns need antibacterial dressings to delay colonisation prior to surgery
- Superficial burns will heal and need simple dressings
- An optimal healing environment can make a difference to outcome in borderline depth burns

Early debridement and grafting is the key to effectively treating deep partial- and full-thickness burns in a majority of cases.

ADDITIONAL ASPECTS OF TREATING THE BURNED PATIENT

Analgesia

Acute

Analgesia is a vital part of burns management. Small burns, especially superficial burns, respond well to simple oral analgesia, paracetamol and non-steroidal anti-inflammatory drugs. Topical cooling is especially soothing. Large burns require intravenous opiates. Intramuscular injections should not be given in acute burns over 10% of TBSA, as absorption is unpredictable and dangerous.

Subacute

In patients with large burns, continuous analgesia is required, beginning with infusions and continuing with oral tablets such as slow-release morphine. Powerful, short-acting analgesia should be administered before dressing changes. Administration may require an anaesthetist, as in the case of general anaesthesia or midazolam and ketamine, or less intensive supervision, as in the case of morphine and nitrous oxide.

Energy balance and nutrition

One of the most important aspects in treating burns patients is nutrition. Any adult with a burn greater than 15% (10% in children) of TBSA has an increased nutritional requirement. All patients with burns of 20% of TBSA or greater should receive a nasogastric tube. (Feeding should start within 6 hours of the injury to reduce gut mucosal damage.) A number of different formulae are available to calculate the energy requirements of patients (Summary box 28.15).

Summary box 28.15

Nutrition in burns patients

- Burns patients need extra feeding
- A nasogastric tube should be used in all patients with burns over 15% of TBSA
- Removing the burn and achieving healing stops the catabolic drive

Burn injuries are catabolic in the acute episode. Successful management of the patient's energy balance involves a number of strategies. The catabolic drive continues while the wound remains unhealed and, therefore, rapid excision of the burn and stable coverage of the wound are the most significant factors in reversing this. Obligatory energy utilisation must be reduced to a minimum by keeping the patient warm with good environmental control. The excess energy requirements must be provided for and the nutritional balance monitored by measuring weight and nitrogen balance.

Commonly used feeding formulae

Curreri formula

Age 16–59 years: (25)W + (40)TBSA
Age 60+ years: (20)W + (65)TBSA

Sutherland formula

Children: 60 kcal kg⁻¹ + 35 kcal%TBSA
Adults: 20 kcal kg⁻¹ + 70 kcal%TBSA

Protein needs

Greatest nitrogen losses between days 5 and 10
20% of kilocalories should be provided by proteins

Davies formula

Children: 3% kg⁻¹ + 1 g%TBSA
Adults: 1 g kg⁻¹ + 3 g%TBSA

Monitoring and control of infection

Patients with major burns are immunocompromised, having large portals of entry to pathogenic and opportunistic bacteria and fungi via the burn wound (Summary box 28.16). They have compromised local defences in the lungs and gut due to oedema, and usually have monitoring lines and catheters, which themselves represent portals for infection.

Summary box 28.16

Infection control in burns patients

- Burns patients are immunocompromised
- They are susceptible to infection from many routes
- Sterile precautions must be rigorous
- Swabs should be taken regularly
- A rise in white blood cell count, thrombocytosis and increased catabolism are warnings of infection

Control of infection begins with policies on hand-washing and other cross-contamination prevention measures. Bacteriological surveillance of the wound, catheter tips and sputum helps to build a picture of the patient's flora. If there are signs of infection, then further cultures need to be taken and antibiotics started. This is often initially on a best guess basis, hence the usefulness of prior surveillance; close liaison with a bacteriologist is essential. In patients with large burns that remain catabolic, the core temperature is usually reset by the hypothalamus above 37°C. Significant temperatures are those above 38.5°C, but often other signs of infection are more useful to the clinician. These include significant rise or fall in the white cell count, thrombocytosis, increasing signs of catabolism and decreasing clinical status of the patient.

Nursing care

Burns patients require particularly intensive nursing care. Nurses are the primary effectors of many decisions that directly affect healing. Bandaged hands and joints, stiff and painful, need careful coaxing. Personal hygiene, baths and showers all become time-consuming and painful but are vital parts of the patient's physiotherapy. Their success or failure has a powerful psychological impact on the patient and his or her family.

Physiotherapy

All burns cause swelling, especially burns to the hands. Elevation, splintage and exercise reduce swelling and improve the final outcome. The physiotherapy needs to be started on day 1, so that the message can be reinforced on a daily basis.

Psychological

A major burn is an overwhelming event, outside the normal experience, which overwhelms the patient's coping ability, suspends the patient's sense of safety and causes post-traumatic

reactions. These are normal and usually self-limiting, receding as the patient heals. The features of this intensity of experience are of intrusive reactions, arousal reactions and avoidance reactions.

The intrusive reactions include flashbacks and other intrusive experiences. Arousal reactions include sleep disturbance, anger and panic attacks. Avoidance reactions include avoidance behaviour and emotional numbness. Patients also often have a sense of grief, guilt and self-blame. Psychological help and support for the patient and family is an important part of treating a severely burned patient. Vigilance for post-traumatic stress disorder is also important.

SURGERY FOR THE ACUTE BURN WOUND

Any deep partial-thickness and full-thickness burns, except those that are less than about 4 cm², need surgery. Any burn of indeterminate depth should be reassessed after 48 hours. This is because burns that initially appear superficial may well deepen over that time. Delayed microvascular injury is especially common in scalds (Summary box 28.17).

Summary box 28.17

Surgical treatment of deep burns

- Deep dermal burns need tangential shaving and split-skin grafting
- All but the smallest full-thickness burns need surgery
- The anaesthetist needs to be ready for significant blood loss
- Topical adrenaline reduces bleeding
- All burnt tissue needs to be excised
- Stable cover, permanent or temporary, should be applied at once to reduce burn load

The essence of burns surgery is control. First and foremost, the anaesthetist needs good control of the patient. A wide-bore cannula should be used, and the patient's blood pressure must be monitored adequately. If a large excision is considered, then an arterial line (to monitor blood pressure) and a central venous pressure monitor are needed. The anaesthetist also needs measurements and control of the acid–base balance, clotting time and haemoglobin levels. The core temperature of the patient must not drop below 36°C otherwise clotting irregularities will be compounded, so the temperature in the operating environment must be kept warm.

For most burn excisions, subcutaneous injection of a dilute solution of adrenaline 1:1 000 000 or 1:500 000 and tourniquet control are essential for controlling blood loss.

In deep dermal burns, the top layer of dead dermis is shaved off until punctate bleeding is observed and the dermis can be seen to be free of any small thrombosed vessels (Fig. 28.3a, see page 383). A topical solution of 1:500 000 adrenaline also helps to reduce bleeding, as does the application of the skin graft. The use of a tourniquet during burn excisions in the limbs helps to decrease blood loss and maintain control.

Full-thickness burns require full-thickness excision of the skin (Fig. 28.5b, see page 384). In certain circumstances, it is appropriate to go down to the fascia but, in most cases, the burn excision is down to viable fat. Wherever possible, a skin graft should be applied immediately. With very large burns, the use of

synthetic dermis or homografts provides temporary stable coverage and will allow complete excision of the wound and thus reduce the burn load on the patient.

Postoperative management of these patients obviously requires careful evaluation of fluid balance and levels of haemoglobin. The outer dressings will quickly be soaked through with serum and will need to be changed on a regular basis to reduce the bacterial load within the dressing.

Physiotherapy and splints are important in maintaining range of movement and reducing joint contracture. Elevation of the appropriate limbs is important. The hand must be splinted in a position of function after grafting, although the graft needs to be applied in the position of maximal stretch. Knees are best splinted in extension, axillae in abduction. Supervised movement by the physiotherapists, usually under direct vision of any affected joints, should begin after about 5 days.

Delayed reconstruction and scar management

Delayed reconstruction of burn injuries is common for large full-thickness burns. In the early healing period, acute contractures around the eye need particular attention. Eyelids must be grafted at the first sign of difficulty in closing the eyelids, and this must be done before the patient has any symptoms of exposure keratitis (Fig. 28.8). Other areas that require early intervention are any contracture causing significant loss of range of movement of a joint. This is particularly important in the hand and axilla (Summary box 28.18).

Summary box 28.18

Delayed reconstruction of burns

- Eyelids must be treated before exposure keratitis arises
- Transposition flaps and Z-plasties with or without tissue expansion are useful
- Full-thickness grafts and free flaps may be needed for large or difficult areas
- Hypertrophy is treated with pressure garments
- Pharmacological treatment of itch is important

Established contracture can be treated in a number of ways. Burn alopecia is best treated with tissue expansion of the unburned hair-bearing skin. Tissue expansion is also a useful technique for isolated burns and other areas with adjacent normal skin. Z-plasty is useful in the situation in which there is a single band and a transposition flap is useful in wider bands of scarring (Fig. 28.9). In areas of circumferential or very broad areas of scarring, the only real treatment is incision and replacement with tissue. By far the best tissue for replacement is from either a full-thickness graft or vascularised tissue as in a free flap. Occasionally, the situation requires the less ideal covering of split skin, possibly with an artificial dermis such as Integra (Fig. 28.10). These last two options require prolonged scar management after their use.

Hypertrophy of many scars will respond to pressure garments. These need to be worn for a period of 6–18 months. Where it is difficult to apply pressure with pressure garments, or with smaller areas of hypertrophy, silicone patches will speed scar maturation, as will intralesional injection of steroid. Itching and dermatitis in burn scar areas are common. Pharmacological treatment of itch is an essential adjunct to therapy.

Figure 28.8 (a) A mixed superficial and deep burn to the face after a petrol explosion. The patient's airway was protected prior to transfer. He has an orogastric tube and feeding has commenced. (b) The face dressed with a hydrocolloid dressing. The endotracheal tube is wired to the teeth. (c) Day 6: the swelling is still present. (d) Six weeks after injury. With the mouth wide open, the lower eyelids are pulled down, demonstrating the intrinsic and extrinsic shortening of the eyelids. (e) Three months after injury. The eyelids have been grafted but note the contracture of the lips. (f) Six months after injury. The patient has had grafts to the upper and lower lips.

Figure 28.9 A transposition flap bringing normal skin across a scarred elbow.

MINOR BURNS/OUT-PATIENT BURNS

Local burn wound care

Blisters

Whether to remove blisters or leave them intact has been the subject of much debate. Proponents of blister removal quote laboratory studies which show that blister fluid depresses immune function, slowing down chemotaxis and intracellular killing and also acting as a medium for bacterial growth.

Conversely, other authors advocate leaving blisters intact as they form a sterile stratum spongiosum. Leaving a ruptured blister is not advised.

Initial cleaning of the burn wound

Washing the burn wound with chlorhexidine solution is ideal for this purpose.

Topical agents

For initial management of minor burns that are superficial or partial thickness, dressings with a non-adherent material such as Vaseline-impregnated gauze or Mepitel are often sufficient. These dressings are left in place for 5 days. These burns, by definition, should be healed after 7–10 days. Various topical creams and

Figure 28.10 (a) A healed full-thickness leg burn prior to resurfacing with Integra. (b) The burn scar has been excised, and the raw surface of the artificial dermis is shown prior to split-skin grafting. (c) The rest after resurfacing with the artificial dermis Integra. The skin is smoother but remains scarred and still has no skin appendages such as hair or sweat glands.

ointments have been used for the treatment of minor burns. All published comparative data show no advantage of these agents over petroleum gauze.

Silver sulphadiazine (1%) or Flamazine is the most commonly used topical agent. However, it should be avoided in pregnant women, nursing mothers and infants less than 2 months of age because of the increased possibility of kernicterus in these patients.

Dressing the minor burn wound

This very important facet of burn care has unfortunately had virtually no objective studies. The aims of dressing are to decrease wound pain and to protect and isolate the burn wound. The small superficial burn requires Vaseline gauze or another non-adherent dressing such as Mepitel as the first layer. Following this, gauze or Kerlix is wrapped around with sufficient tightness to keep the dressing intact but not to impede the circulation. This is further wrapped with bandage. It is important to realise that bulkiness of dressings in the minor burn wound depends upon the amount of wound discharge. A special case is burns of the hands where dressings should be minimised so as not to impede mobilisation and physiotherapy.

Synthetic burn wound dressings are popular as they:

- decrease pain associated with dressings;
- improve healing times;
- decrease out-patient appointments;
- lower overall costs.

Biobrane is a bilaminar dressing made up of an inner layer of knitted nylon threads coated with porcine collagen and an outer layer of rubberised silicone impervious to gases but not to fluids and bacteria. Wounds to be dressed with Biobrane should be carefully selected. Burn wounds should be fresh (less than 24 hours), sensate, show capillary blanching and refill. Biobrane should be applied to the wound after removal of all blisters. It should be checked at 48 hours for adherence and any signs of infection. It should be removed if any sign of infection is found.

Duoderm or hydrocolloid dressings are not bulky, help in healing and can be kept in place for 48–72 hours. They provide a moist environment, which helps in re-epithelialisation of the burn wound.

Healing of burn wounds

Burns that are being managed conservatively should be healed within 3 weeks. If there are no signs of re-epithelialisation in this time, the wound requires debridement and grafting.

Infection

Infection in the minor burn should be tackled very aggressively as it is known to convert a superficial burn to a partial-thickness burn and a partial- to a deep partial-thickness burn respectively. It should be managed using a combination of topical and systemic agents. Debridement and skin grafting should also be considered.

Itching

Most burn patients have itchy wounds. Histamine and various endopeptides are said to be the causative factors of itching. This is another area that lacks controlled trials; therefore, management varies greatly. Anti-histamines, analgesics, moisturising creams, aloe vera and antibiotics have all been tried with varying degrees of success.

Traumatic blisters

The healed burn wound is prone to getting traumatic blisters because the new epithelium is very fragile. Non-adherent dressings usually suffice; regular moisturisation is also useful in this condition.

NON-THERMAL BURN INJURY

Electrical injuries

Electrical injuries are usually divided into low- and high-voltage injuries, the threshold being 1000 V (Summary box 28.19).

Summary box 28.19

Electrical burns

- Low-voltage injuries cause small, localised, deep burns
- They can cause cardiac arrest through pacing interruption without significant direct myocardial damage
- High-voltage injuries damage by flash (external burn) and conduction (internal burn)
- Myocardium may be directly damaged without pacing interruption
- Limbs may need fasciotomies or amputation
- Look for and treat acidosis and myoglobinuria

Low-tension injuries

Low-tension, or domestic appliance, injuries do not have enough energy to cause destruction to significant amounts of subcutaneous tissues when the current passes through the body. The resistance is too great. The entry and exit points, normally in the fingers, suffer small deep burns; these may cause underlying tendon and nerve damage, but there will be little damage between. The alternating current creates a tetany within the muscles, and thus patients often describe how they were unable to release the device until the power was turned off. The main danger with these injuries is from the alternating current interfering with normal cardiac pacing. This can cause cardiac arrest. The electricity itself does not usually cause significant underlying myocardial damage, so resuscitation, if successful, should be lasting.

High-tension injuries

High-tension electrical injuries can be caused by one of three sources of damage: the flash, the flame and the current itself.

When a high-tension line is earthed, enormous energy is released as the current travels from the line to the earth. It can arc over the patient, causing a flash burn. The extremely rapid heating of the air causes an explosion that often propels the victim backwards. The key here is that the current travelled from the line to the earth directly and not through the patient. The flash, however, can go on to ignite the patient's clothes and so cause a normal flame burn.

In accidents with overhead lines, the patient often acts as the conduction rod to earth. In these injuries, there is enough current to cause damage to the subcutaneous tissues and muscles. The entry and exit points are damaged but, importantly, the current can cause huge amounts of subcutaneous damage between these two points. These can be extremely serious injuries.

The damage to the underlying muscles in the affected limb can cause the rapid onset of compartment syndrome. The release of the myoglobins will cause myoglobinuria and subsequent renal dysfunction. Therefore, during the resuscitation of these patients,

Figure 28.11 (a) An exit wound of a high-tension injury, with a dead big toe and significant damage to the medial portion of the second toe. (b) Amputation and cover with the lateral portion of the second toe.

efforts must be made to maintain a high urine output of up to 2 ml kg^{-1} body weight per hour. Severe acidosis is common in large electrical burns and may require boluses of bicarbonate. These patients are also at risk of myocardial damage as a result of direct muscle damage rather than by interference with cardiac pacing. This gives rise to significant electrocardiogram changes, with raised cardiac enzymes. If there is significant damage, there is rapid onset of heart failure. In the case of a severe injury through a limb, primary amputation is sometimes the most effective management (Fig. 28.11).

Chemical injuries

There are over 70 000 different chemicals in regular use within industry. Occasionally, these cause burns. Ultimately, there are two aspects to a chemical injury. The first is the physical destruction of the skin, and the second is any poisoning caused by systemic absorption (Summary box 28.20).

Summary box 28.20

Chemical burns

- Damage is from corrosion and poisoning
- Copious lavage with water helps in most cases
- Then identify the chemical and assess the risks of absorption

The initial management of any chemical injury is copious lavage with water. There are only a handful of chemicals for which water is not helpful, for example phosphorus, which is a component of some military devices, and elemental sodium, which is occasionally present in laboratory explosions. These substances need to be physically removed with forceps; however, it is extremely rare that any medical practitioner will encounter these in his or her lifetime. The more common injuries are caused by either acids or alkalis. Alkalis are usually the more destructive and are especially dangerous if they have come into contact with the eyes. After copious lavage, the next step in the management of any chemical injury is to identify the chemical and its concentration and to

elucidate whether there is any underlying threat to the patient's life if absorbed systemically.

One acid that is a common cause of acid burns is hydrofluoric acid. Burns affecting the fingers and caused by dilute acid are relatively common. The initial management is with calcium gluconate gel topically; however, severe burns or burns to large areas of the hand can be subsequently treated with Bier's blocks containing calcium gluconate 10% gel. If the patient has been burnt with a concentration greater than 50%, the threat of hypocalcaemia and subsequent arrhythmias then becomes high, and this is an indication for acute early excision. It is best not to split-skin graft these hydrofluoric acid wounds initially, but to do this at a delayed stage.

Ionising radiation injury

These injuries can be divided into groups depending on whether radiation exposure was to the whole body or localised. The management of localised radiation damage is usually conservative until the true extent of the tissue injury is apparent. Should this damage have caused an ulcer, then excision and coverage with vascularised tissue is required.

Whole-body radiation causes a large number of symptoms. The dose of radiation either is or is not lethal. A patient who has suffered whole-body irradiation and is suffering from acute desquamation of the skin has received a lethal dose of radiation, which can cause a particularly slow and unpleasant death. Non-lethal radiation has a number of systemic effects related to the gut mucosa and immune system dysfunction. Other than giving iodine tablets, the management of these injuries is supportive (Summary box 28.21).

Summary box 28.21

Radiation burns

- Local burns causing ulceration need excision and vascularised flap cover – usually with free flaps
- Systemic overdose needs supportive treatment

August Karl Gustav Bier, 1861–1949, Professor of Surgery, Berlin, Germany.

Cold injuries

Cold injuries are principally divided into two types: acute cold injuries from industrial accidents and frostbite (Summary box 28.22).

Summary box 28.22

Cold injuries

- The damage is more difficult to define and slower to develop than burns
- Acute frostbite needs rapid rewarming, then observation
- Delay surgery until demarcation is clear

Exposure to liquid nitrogen and other such liquids will cause epidermal and dermal destruction. The tissue is more resistant to cold injury than to heat injury, and the inflammatory reaction is

not as marked. The assessment of depth of injury is more difficult, so it is rare to make the decision for surgery early.

Frostbite injuries affect the peripheries in cold climates. The initial treatment is with rapid rewarming in a bath at 42°C. The cold injury produces delayed microvascular damage similar to that of cardiac reperfusion injury. The level of damage is difficult to assess, and surgery usually does not play a role in its management, which is conservative, until there is absolute demarcation of the level of injury.

Plastic and reconstructive surgery

CHAPTER 29

LEARNING OBJECTIVES

To understand:

- The spectrum of plastic surgical techniques used to restore bodily form and function
- The relevant anatomy and physiology of tissues used in reconstruction
- The various skin grafts and how to use them appropriately
- The principles and use of flaps
- How to use plastic surgery to manage difficult and complex tissue loss

HISTORICAL CONTEXT

Reconstructive plastic (from the ancient Greek *plassein*, to mould or shape – also the stem for our modern use of the materials termed plastics) surgery involves using various techniques to restore form and function to the body when tissues have been damaged by injury, cancer or congenital loss. Its origins can be traced back to ancient Egypt, with wound care depicted in hieroglyphs on papyrus, to India in the sixth century BC, where Sushruta described using the forehead flap to reconstruct a nose, and to Al-Zahrawi, the tenth-century Islamic surgical scholar from Cordoba. Modern techniques were developed after the First World War, especially with Sir Harold Gillies' work on reconstructing facial injuries (Fig. 29.1), which was enabled by new safe anaesthetic intubation (Sir Ivan Magill). Later in the twentieth century, renewed understanding of detailed soft tissue anatomy led to an explosion in the use of new flaps, which with microsurgical methods, craniofacial surgery and tissue expansion resulted in an entirely new set of techniques becoming available to surgeons for reconstructing parts.

Today, the need for reconstructive plastic surgery, especially in developing nations, has never been greater. Road, war and domestic injury inflict life-diminishing effects, which plastic surgery can reduce. The reconstructive surgeon's 'toolbox' is now very diverse and will continue to grow in order to address problem wounds and tissue defects, which arise as modern medical care is more successful in treating cancer, preserving life into old age and salvaging victims of trauma.

ANATOMY RELATED TO RECONSTRUCTIVE SURGERY

Skin

The surface of the skin is important as a biological layer for homeostasis. Restoring the skin surface is therefore critical even if the underlying structures can await later reconstruction. Epidermis regenerates from deeper follicular elements, with the most superficial layer losing vascularity and acting as a barrier to fluid loss and providing important protection against invasion by micro-

Figure 29.1 Sir Harold Gillies operating during the First World War – 'the birth of plastic surgery'. Picture by Henry Tonks (by kind permission of the Royal College of Surgeons of England).

Sir Harold Delf Gillies, 1882–1960, Plastic Surgeon, St. Bartholomew's Hospital, London, England.

Sir Ivan Whiteside Magill, 1888–1986, Anaesthetist, Westminster Hospital, London, England.

Henry Tonks, 1862–1937, commenced a career in surgery, but abandoned it for art, and became, from 1917 to 1930, Slade Professor at the Westminster School of Art, London, England.

organisms. (Epidermal keratinocytes can be artificially cultured *in vitro* and are used in some wound management systems.)

The depth of the dermis and the amounts of elastin and skin adnexal elements such as sweat glands and hair follicles vary depending on the functional requirements of the area concerned. This means that some areas are much more vulnerable to injury than others, e.g. the fine flexible elastic skin of the eyelid rapidly suffers a full-thickness burn after a flash burn, whereas thick back skin suffers only a partial loss after the same flash burn.

Skin vascularity is derived from fine perforating vessels that run through underlying muscles or through fascial septal layers, and then horizontally in a subcutaneous plane from which capillaries branch (Fig. 29.2). Nerves run axially out from major trunks and are less well defined than most perforating blood vessels.

When local, random-pattern skin flaps are raised, they are lifted at the subcutaneous level and are nourished by the subdermal plexus of blood vessels. However, this plexus can only survive a limited distance from the more substantial arterial branches running in the fascial, septal or muscle-perforating planes. Understanding the anatomy of different parts of the skin and tissues to be moved is a key element of successful plastic surgery.

Without skin, wounds heal by *secondary intention* with fibrosis and contracture (Fig. 29.3), and underlying structures are vulnerable to necrosis, chronic infection and dysfunction.

Graft anatomy

Split-thickness skin grafts

Split-thickness skin grafts are harvested by taking all of the epidermis together with some dermis, leaving the remaining dermis behind to heal the donor site. The thicker the dermis that is taken (seen by more brisk punctate bleeding at the donor site; Fig. 29.4), the more durable will be the graft once healed (although it might take longer and require more care), but also the more difficult will be donor site healing (Summary box 29.1).

Summary box 29.1

Split-thickness skin grafts

- Thicker knife-gap settings recognised give rise to fewer but brisker bleeding points on the donor site
- Thicker grafts heal with less contracture and are more durable
- Thinner donor sites heal better
- Grafts are hairless and do not sweat (these structures are not transferred)

Full-thickness skin grafts

Full-thickness grafts are harvested to incorporate the whole dermis, with the underlying fat trimmed away – unless elements of fat (or even cartilage as well) are deliberately left attached to form a *composite graft*. Full-thickness and composite grafts require the best handling and postoperative nursing to help ensure that they ‘take’ in their transplanted site.

How does a skin graft survive?

Split-thickness skin grafts survive initially by *imbibition* of plasma from the wound bed; after 48 hours fine anastomotic connections

In vitro is Latin for ‘in the glass’.

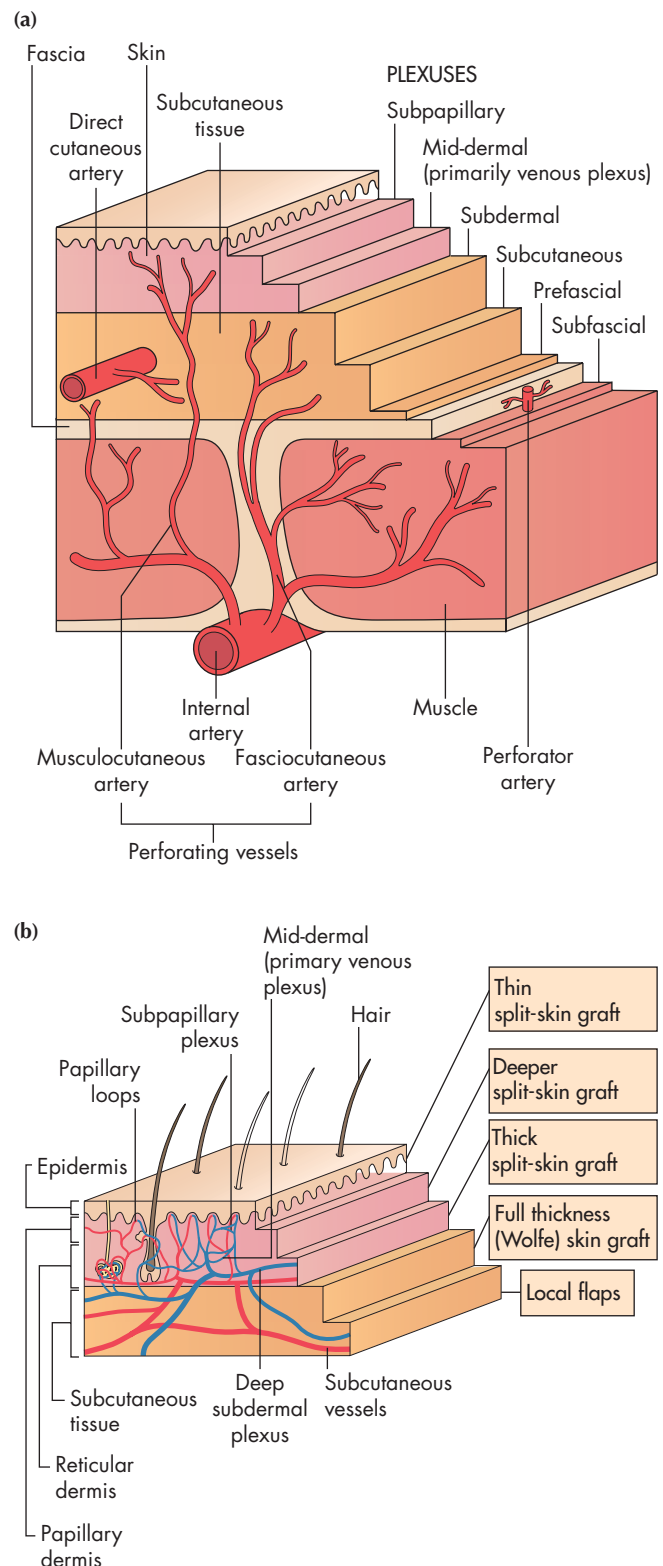

Figure 29.2 Diagram of skin anatomy with vascular plexus.

are made, which lead to *inosculation* of blood. Capillary ingrowth then completes the healing process with fibroblast maturation. Because only tissues that produce granulation will support a graft, it is usually *contraindicated* to use grafts to cover exposed tendons, cartilage or cortical bone.

Figure 29.3 A severely contracted hand following burn to the dorsal aspect.

Figure 29.4 Fine punctate bleeding from a split-thickness skin graft donor site.

Skin grafts inevitably contract, with the extent of contracture determined by the amount of dermis taken with the graft and the level of postoperative splintage and physiotherapy applied to the grafted site.

CLASSIFICATION

The reconstructive 'toolbox'

Plastic surgery has a number of means available for managing a given problem. Sometimes, a problem is managed using a 'ladder' approach, with the simplest methods being used first and only moving to more complex methods when absolutely necessary. However, this is not always the best way to proceed. If resources permit, it is often more cost-effective and better functionally for the patient to begin with a more complex treatment, with other easier managements held in reserve as 'lifeboats'. Plastic surgeons now prefer to think of the range of options available as a 'toolbox' from which they can take the most appropriate method to solve

a problem, taking into account available skill, resources and the consequences of failure.

The scope of plastic surgery

The tools of reconstruction are used for a wide range of conditions:

- trauma:
 - soft-tissue loss (skin, tendons, nerves, muscle);
 - hand and lower limb injury;
 - faciomaxillary;
 - burns;
- cancer:
 - skin, head and neck, breast, soft tissue sarcoma;
- congenital:
 - clefts and craniofacial malformations;
 - skin, giant naevi, vascular malformations;
 - urogenital;
 - hand and limb malformations;
- miscellaneous:
 - Bell's (facial) palsy;
 - pressure sores;
 - aesthetic surgery;
 - chest wall reconstruction.

A few key principles that can also be applied to other surgical specialties should be observed. In many reconstructions, success depends upon good rapid wound healing, which itself depends upon attention to detail from the surgeon. Adequate debridement, careful technique, gentle handling of tissues and consideration of blood supply are all key factors that influence outcome (Table 29.1).

The placement of incisions can be critical, especially in reducing the appearance of scars on the face and in areas of tension. When possible, incisions should lie in the lines of minimal tension (described by Langer but frequently different from those originally noted) (Fig. 29.5).

Grafts

Grafts are tissues that are transferred without their blood supply, which therefore have to revascularise once they are in a new site. They include the following:

- *Split-thickness skin grafts* (of varying thickness). These are sometimes called Thiersch grafts. They are used to cover all sizes of

Table 29.1 Plastic surgery principles

Optimise wound by adequate debridement or resection

Figure 29.5 Lines of relaxed skin tension.

wound, are of limited durability and will contract. They may be used to provide valuable temporary wound closure before better cosmetic secondary correction after rehabilitation.

- *Full-thickness skin grafts* (Wolfe grafts). Used for smaller areas of skin replacement where good elastic skin that will not contract is required (such as fingers, eyelids, facial parts).
- *Composite skin grafts* (usually skin and fat, or skin and carti-

lage). Often taken from the ear margin and useful for rebuilding missing elements of nose, eyelids and fingertips.

- *Nerve grafts*. Usually taken from the sural nerve but smaller cutaneous nerves may be used.
- *Tendon grafts*. Usually taken from the palmaris longus or plantaris tendon (runs just anteromedial to the Achilles tendon) and used for injury loss or nerve damage correction.

Flaps

Flaps are tissues that are transferred with a blood supply. They therefore have the advantage of bringing vascularity to the new area. Flaps can be raised to consist of any specific tissue; for skin flaps the following will illustrate the types that exist (Fig. 29.6):

- *Random flaps*. Three sides of a rectangle, bearing no specific relationship to where the blood supply enters; the length to breadth ratio is no more than 1.5:1. This pattern can be lengthened by 'delaying' the flap, a process in which the cuts are partially made and the flap is part lifted at a first operation; it is then replaced, thus 'training' the blood supply from a single border of the rectangle. At a second procedure it is raised further and finally transferred.
- *Axial flaps*. Much longer flaps, based on known blood vessels supplying the skin. This technique was rediscovered in the 1960s/70s and enables many long thin flaps to be safely moved across large distances.
- *Pedicled/islanded flaps*. The axial blood supply of these flaps means that they can be swung round on a stalk or even fully 'islanded' so that the business end of the skin being transferred can have the pedicle buried (Fig 29.7).

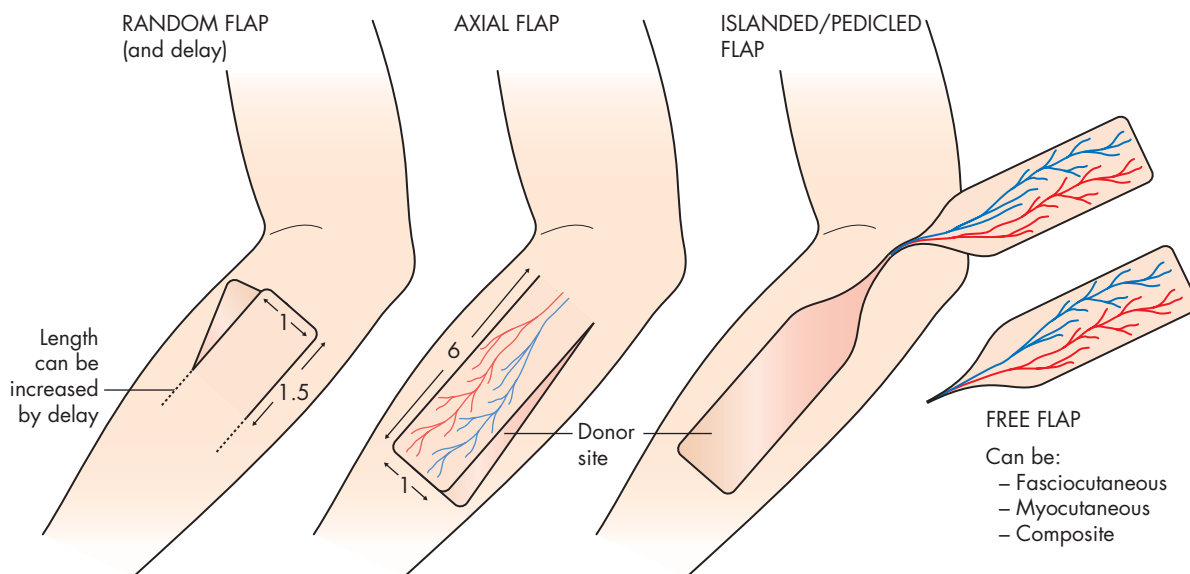

Figure 29.6 Skin flaps, from simple to complex.

Karl Thiersch, 1822–1895, Professor of Surgery, Leipzig, Germany. He was a pioneer of free skin grafts, and described his method of skin grafting in 1874.

John Reissburg Wolfe, 1824–1904, Ophthalmic Surgeon, Glasgow, Scotland, described full thickness skin grafts in 1875, and in the same year used forearm skin to construct an eyelid.

Achilles, the Greek Hero, was the son of Peleus and Thetis. When he was a child his mother dipped him in the Styx, one of the rivers of the Underworld, so that he should be invulnerable in battle. The heel by which she held him did not get wet, and was, therefore, not protected. Achilles died from a wound in the heel which he received at the siege of Troy.

Figure 29.7 (a–c) Islanded pedicled flap used from instep to resurface heel defect.

- *Free flaps.* The blood supply has been isolated, disconnected and then reconnected using microsurgery at the new site (Fig. 29.8).
- *Composite flaps.* Various tissues are transferred together, often skin with bone or muscle (osseocutaneous or myocutaneous flaps respectively).
- *Perforator flaps.* This description refers to a whole new subgroup of axial flaps in which tissues are isolated on small perforating vessels that run from more major blood vessels to supply the surface.

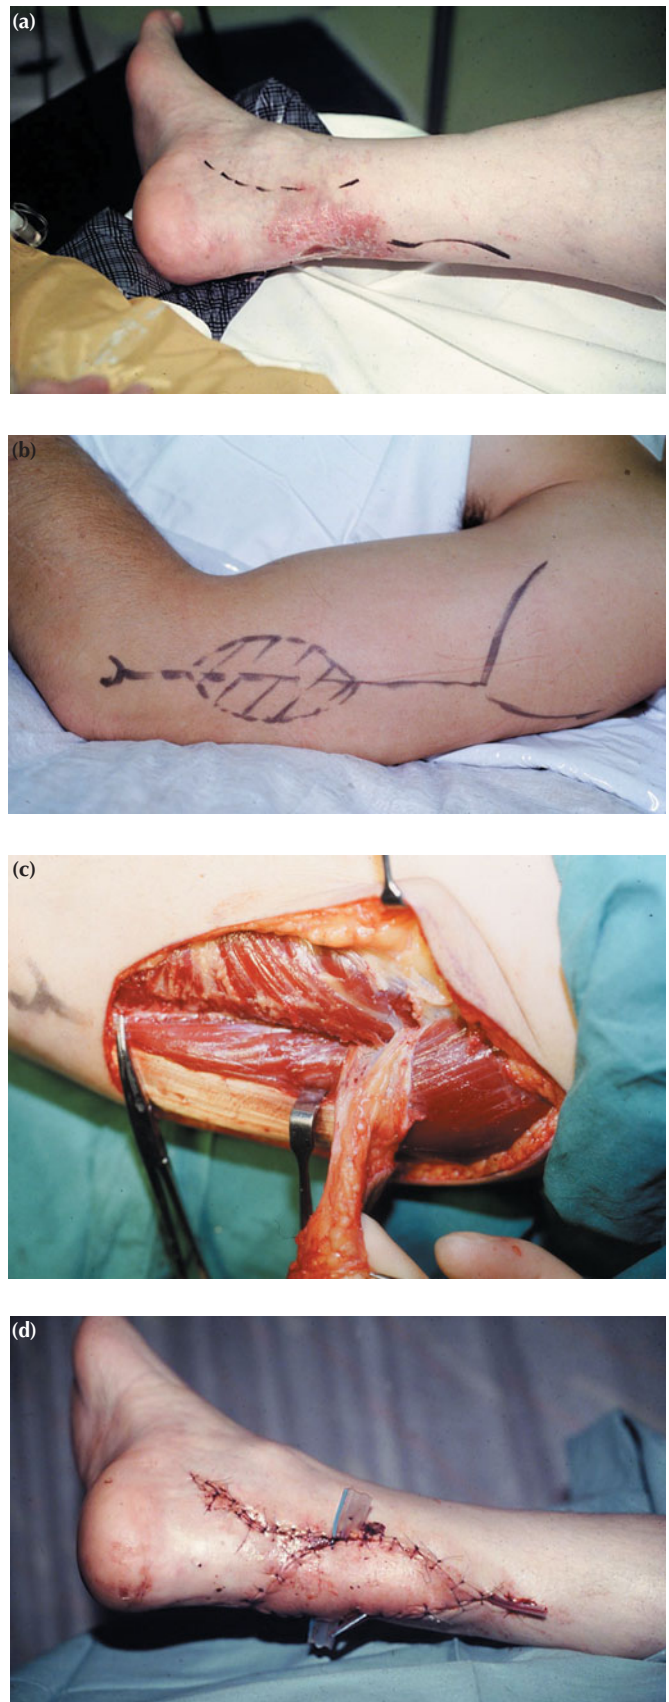

Figure 29.8 (a–d) Free lateral arm fasciocutaneous flap used to resurface a tendo Achilles defect.

Skin substitutes

One solution to the problem presented by major skin loss with inadequate skin donor sites has been to use artificially engineered skin substitutes. These vary from thin sheets of autologous keratinocytes, to artificial collagen matrices with embedded fibroblasts and a keratinocyte sheet covering. They are costly but are becoming widely used, and it is likely that tissue-engineered products will continue to be developed in an attempt to solve difficult reconstructive problems.

Tissue expansion

This technique is valuable in using 'local' tissue for reconstruction. The natural ability of tissue to expand has been harnessed clinically since the experiments of Austad and the clinical work of Radovan in the 1970s. It is a technique borrowed from nature, and it is observed during pregnancy when skin expands over the underlying mass. It involves placing a device – usually an expandable balloon constructed from silicone – beneath the tissue to be expanded and progressively enlarging the volume with fluid while the overlying tissue accommodates to the changed vascular pressure (Fig. 29.9). The fluid (usually sterile saline) is introduced via a self-sealing port attached to a filling tube that enters the balloon. It may be introduced as frequently as can be tolerated by the patient until the tissues are stretched enough to be used for reconstruction. The tissues expanded do not hypertrophy but there are major changes in the collagen structure.

The process is time-consuming although it can be very valuable in problematic cases. It is invaluable for sharing remaining areas of scalp hair after severe burns, removing major congenital skin naevi and restoring full-thickness skin over previously grafted limb wounds.

It must *never* be used under irradiated tissues (such as mastectomy sites), which will not expand but necrose (Summary box 29.2).

Summary box 29.2

Tissue expansion

Advantages

- Well-vascularised tissue
- Tissue next to defect so likely to be of similar consistency
- Good colour match

Disadvantages

- Multiple expansion episodes (sometimes painful)
- Cost of device
- High incidence of infection and extrusion (especially limbs)

Vacuum-assisted closure

The use of negative pressure applied to a tissue defect has positive effects on wound closure, as well as making difficult and complex wounds more manageable during the early stages of granulation. Exudate is removed and the suction pressure affects angiogenesis and tissue regeneration. The technique can be applied as part of early wound management before definitive surgical closure has been planned, or in some cases to avoid the need for surgery altogether. The foam sponge dressing is connected by a tube to a negative pressure pump that can be controlled to give intermittent suction.

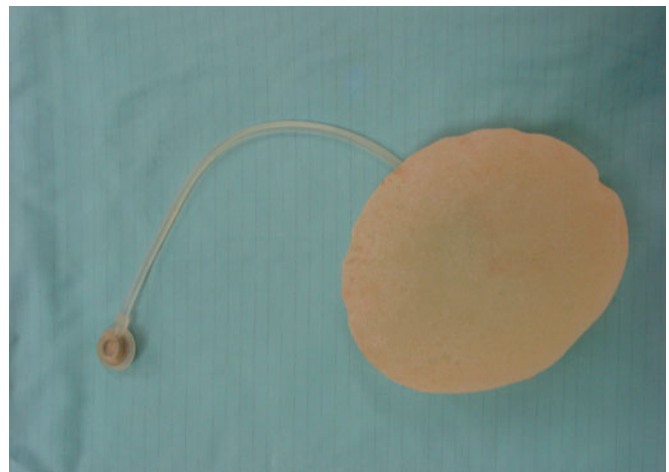

Figure 29.9 Tissue expander.

Implants and prosthetics

Many tissue deficiencies cannot be adequately reconstructed with autologous tissue, however sophisticated the technique used. In such circumstances, implants are part of the reconstructive surgical 'toolbox'; they include solid and soft silicone materials, many forms of filler including collagen and polymers, and osseointegratable anchor points for prosthesis fixation.

Figure 29.10 Hand-held skin knife (a) and harvesting skin with hand-held knife (b).

ASSESSMENT AND DIAGNOSTIC PLANNING

Formation of a definitive treatment plan, carefully considering all available options for care with the whole of the patient's needs in mind, is a vital component of wise plastic surgical practice. This is never more so than when managing major trauma cases in the acute setting or when planning major cancer man-

agement, which might be staged over a period of treatments and procedures. If the reconstructive surgeon can be involved in early wound debridement and incisions, vital flap pedicles can be protected and the functional and cosmetic outcome made optimal. This pattern of shared team care has become the norm in many units demonstrating good outcomes from major trauma salvage.

Figure 29.11 Power dermatome harvest of a split-thickness skin graft, with the correct method of providing skin tension (a–d), and dressing of donor site with adhesive material (e).

The initial assessment of wounds involves adequate removal of devitalised tissue, assessment of which vital structures will need reconstruction immediately and which might be better reconstructed later, and assessment of the degree of contamination involved, which will require further cleaning. Further planning will include the definitive soft-tissue cover of the wound and functional rehabilitation with full psychosocial rehabilitation.

TREATMENT AND COMPLICATIONS

Split-thickness skin grafts

Split-thickness skin grafts are taken with either hand-held (Fig. 29.10) or powered skin knives (Fig. 29.11). The most used donor site is the thigh, with the buttock preferable in children and cosmetically sensitive individuals. For larger grafts almost any flat surface can be harvested, including the scalp if shaved (a very good and useful donor site). The thickness of the graft harvested, ease of graft 'take' and donor site healing must be weighed against the lack of durability of thin split-thickness skin grafts.

Split grafts can be perforated to allow exudates to escape and improve 'take'; they can be further meshed to allow expansion (Fig. 29.12). This is carried out on a device that cuts a series of

slits along the skin, allowing it to expand from a ratio of anything from 1:1.5 to about 1:6.

Grafts will only take on a bed on which they can become vascularised. Preparation of the wound bed is therefore an essential part of a successful graft (Figs 29.13 and 29.14). Graft failure is commonly caused by pus, exudate or residual dead tissue beneath the skin, haematoma or shearing forces. A clean healthy wound bed with a meshed graft tied in place to stop movement will encourage success. The group A β -haemolytic *Streptococcus* can destroy split grafts completely (and also convert a donor site to a full-thickness defect) and so the presence of this micro-organism is a *contraindication* to grafting.

Full-thickness skin grafts

Small dermal grafts (Wolfe grafts) can be taken from behind the ear, the groin creases and the neck, with easy direct closure of the donor site. Older people can sustain larger harvests because of skin laxity. Large full-thickness skin graft use is uncommon and requires great care to obtain a good take. Large donor sites

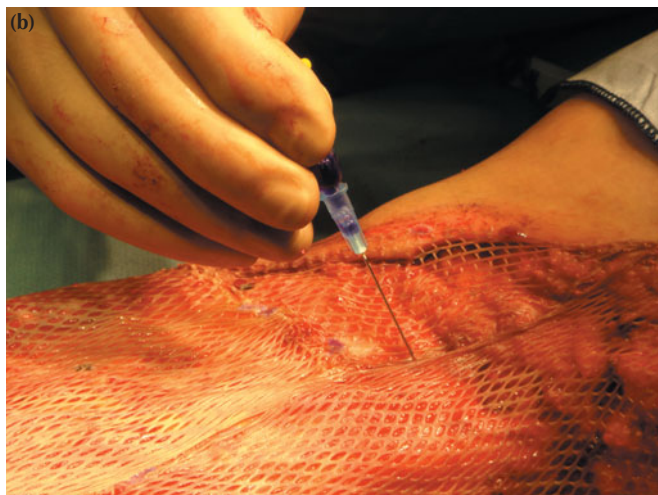

Figure 29.12 Split-thickness skin graft mesher (a) and meshed skin applied to wound (b).

Figure 29.13 Cleaning a wound of excessive granulation tissue before grafting.

Figure 29.14 Application of a firm pressure dressing to ensure stability of the graft.

require secondary split-thickness skin grafting. Major secondary burn contractures of the face and flexion creases can achieve remarkable functional and cosmetic improvement using such large grafts, particularly as the remaining facial muscle function can still produce a more natural appearance than when covered by a bulky full-thickness skin flap. Smaller full-thickness grafts are useful for contracture release around sensitive facial and extremity structures.

Technique

The shape of the graft needed is drawn and copied onto a small template (paper or cloth), which is used to transfer the same shape to the donor site. Full-thickness skin is cut; grafts take best if additional underlying fat is removed, after which the graft is applied with normal skin tension and tied down with a pressure dressing. The graft will remain vulnerable to shearing forces for several weeks after application.

Flaps

Local flaps

A local flap is raised next to a tissue defect in order to reconstruct it. Basic patterns include (Fig. 29.15):

- *transposition flap*: the most basic design, leaving a graftable donor site (Fig. 29.16);
- *Z-plasty*: for lengthening scars or tissues;

TRANSPOSITION FLAP

Z-PLASTY

Two triangular transposition flaps interposed

(a)

BILOBED FLAP

Uses a flap to close a convex defect, and a second smaller flap to close the donor site

BIPEDICLE FLAP

A 'bucket-handle' flap supplied from both ends. Useful to rebuild the lower eyelid

(b)

RHOMBOID FLAP

A parallelogram shaped transposition flap

ROTATION FLAP

(c)

Figure 29.15 Local flap diagrams. (a) Transposition and Z-plasty flaps; (b) bilobed and bipedicle flaps; (c) rhomboid and rotation flaps. (continued opposite)

ADVANCEMENT FLAP

Simple rectangular (with or without Burrow's triangle excision at base)

V to Y

Y to V

Usually multiple to release band scars over joints
This is one of the most effective means of releasing moderate isolated band burn scars over flexion creases

1 Burn scar with long ellipse around it

2 Mark a long zig-zag along the scar

3 Add in the horizontal lines to the zig-zag; each becomes a 'Y'

4 The cut lines will look something like this

Advance the tips of the zig-zags into the spaces

5 The finished wound will look something like this
Pad it well, and be sure to splint open when not exercising

(d)

(e)

Figure 29.15 (continued) Local flap diagrams. (d) Advancement flaps; (e) multiple Y-to-V plasty for burn scar.

Figure 29.16 (a–c) Example of transposition flap (in this case from glabellar area to inner canthal defect). (continued overleaf)

Figure 29.16 (continued) (d and e) Appearance at 1 month post-transfer.

- *rhomboid flap*: for cheek, temple, back and flat surface defects;
- *rotation flap*: for convex surfaces;
- *advancement flap*: for flexor surfaces; may need triangles excised at the base to make it work (commonly called Burrow's triangles);
- *V-to-Y advancement*: commonly used for fingertips and extremities;
- *bilobed flap*: for convex surfaces, especially the nose (Fig. 29.17);
- *bipedicle flap*: for eyelids, rarely elsewhere.

All flaps must be raised in the subcutaneous plane. Gentle undercutting of margins helps to close the donor site. The art of making local flaps work is to pull available local spare lax skin into the defect, so that the scar when closed sits in a good 'line of

Figure 29.17 (a–c) Example of a bilobed flap (in this case from nose to defect on tip following excision of a basal cell carcinoma). (d) Appearance at 6 weeks post-transfer.

election'. Local flaps are usually not based on specific blood vessels but are very useful in head and neck and smaller defect reconstructions. Good planning is essential to gain the best result from these flaps (Summary box 29.3).

Summary box 29.3

Local flaps

Benefits

- Best local cosmetic tissue match
- Often a simple procedure
- Local or regional anaesthesia option

Disadvantages

- Possible local tissue shortage
- Scarring may exacerbate the condition
- Surgeon may compromise local resection

Combined local flaps

In some circumstances, such as burn contracture release, local flaps can usefully be combined to import surplus tissue from a wide area adjacent to a scar or defect that needs removal. Examples are the W-plasty and the multiple Y-to-V plasty, which is a very versatile means of releasing an isolated band scar contracture over a flexion crease (Fig. 29.18).

Distant flaps

To repair defects in which local tissue is inadequate, distant flaps can be moved on long pedicles that contain the blood supply. The pedicle may be buried beneath the skin to create an island flap or left above the skin and formed into a tube.

The most common means of moving flaps long distances while still attached are with a long muscular pedicle that contains a dominant blood supply (a *myocutaneous flap*) (Fig. 29.19) or with a long fascial layer that likewise contains a major septal blood supply (a *fasciocutaneous flap*) (Fig. 29.20). These flaps can carry large composite skin parts for reconstruction very great distances, e.g. from the abdomen to the chest (for breast reconstruction),

from the chest to the face (for oral cancer reconstruction) and from the calf to the knee.

There are a vast number of carefully described myocutaneous and fasciocutaneous flaps throughout the body, all of which are based on known blood vessels. They are reliable when the anatomy of the blood supply is known by the surgeon and the skin is raised carefully in continuity with the underlying fascia or muscle, through which the small perforating vessels run to supply the piece of skin that is being transferred. They are the 'workhorse' of plastic surgery worldwide because they do not require complex equipment to raise and they can solve the majority of reconstructive problems.

Microsurgery and perforator flaps

With fine instruments and materials it has become commonplace to be able to disconnect the blood supply of the flap from its donor site and reconnect it in a distant place using the operating microscope.

The free tissue transfer is now the best means of reconstructing major composite loss of tissue in the face, jaws, lower limb and many other body sites, as long as resources allow it (Fig. 29.21). The operative procedure is similar whether the defect is newly produced from a recent injury or cancer resection or whether it is to be used for the secondary correction of a deformity such as rebuilding a mastectomy deformity. At the site of the defect the surgeon must be sure that all contaminated and dead tissue has been thoroughly cleared and cleaned, a process commonly described as debridement, although that term strictly refers to the release of constricting tissue. If this removal of poorly viable tissue is in doubt, then consideration should be given to delaying the reconstruction.

The surgeon must then find a suitable blood supply for the tissue transfer at the site to be reconstructed. A good arterial flow in and venous return out, without external tissue pressure (such as from surrounding wound induration), is of paramount importance in achieving a successful transfer. The flap is then raised (Table 29.2) and transferred using magnification (Fig. 29.22). Free muscle transfers should be reanastomosed within 1–2 hours if possible; fasciocutaneous flaps are more robust and can survive slightly greater ischaemic times (Summary box 29.4).

Figure 29.18 (a and b) Y-to-V flap to release axillary contracture.

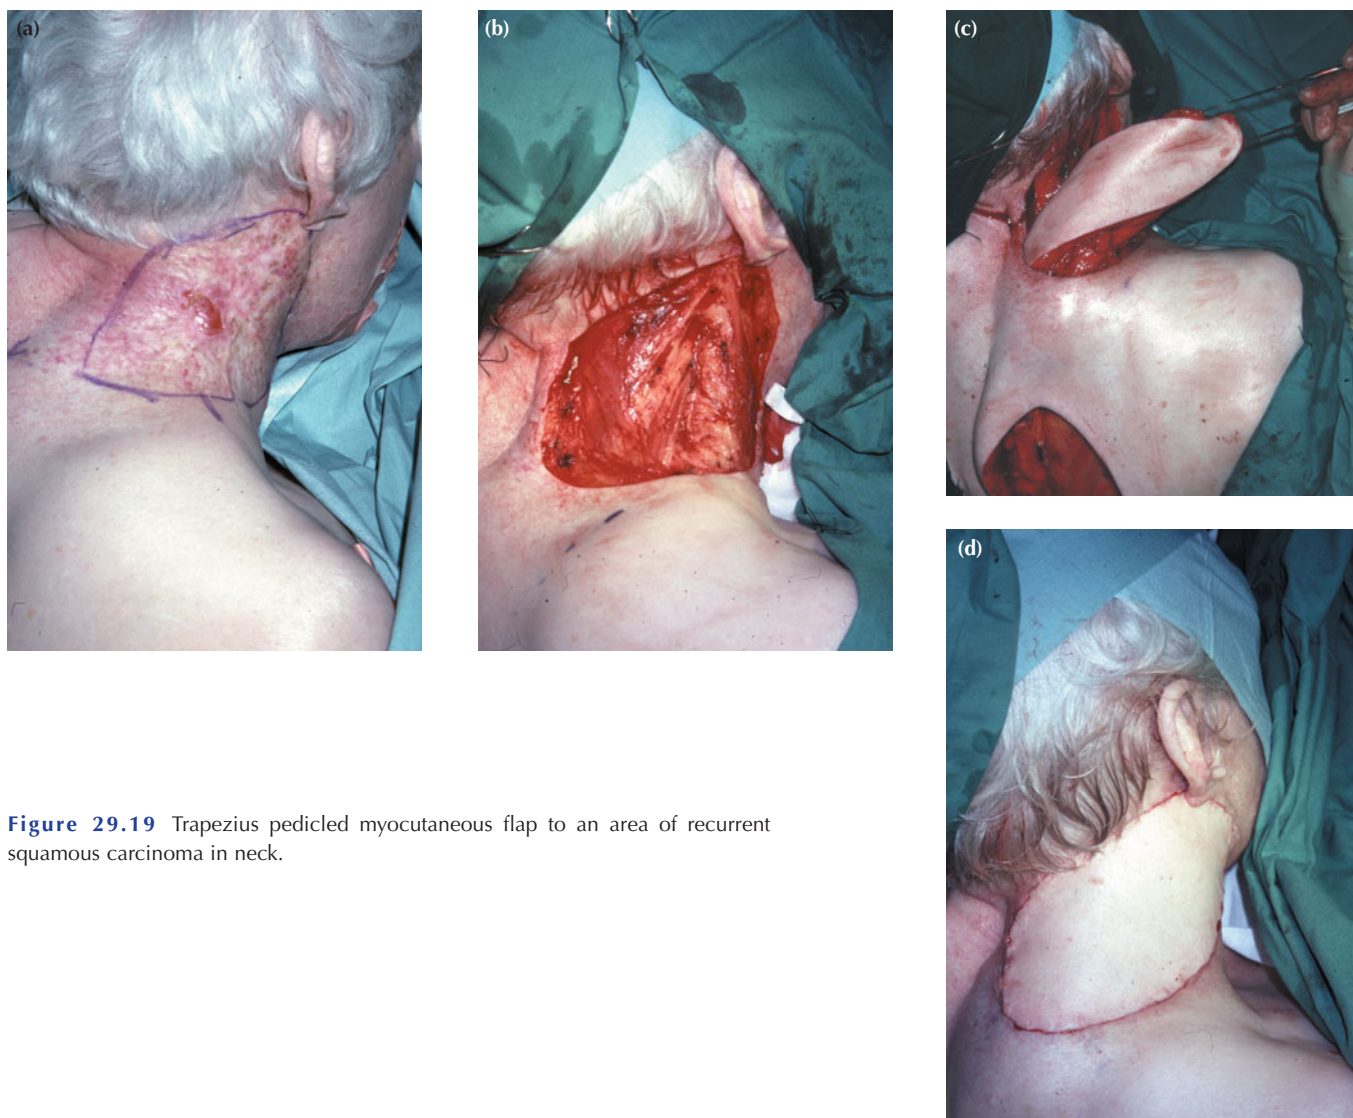

Figure 29.19 Trapezius pedicled myocutaneous flap to an area of recurrent squamous carcinoma in neck.

Table 29.2 Common free tissue transfer donor sites

Muscle only	Latissimus dorsi Rectus abdominis Gracilis
Myocutaneous	Latissimus dorsi Transverse rectus abdominis
Fasciocutaneous	Radial forearm flap Scapular Lateral arm
Osseous	Groin Fibula (may be cutaneous as well) Forearm Iliac crest
Fascial	Temporoparietal
Miscellaneous	Jejunum – for oesophageal reconstruction Pectoralis minor – for facial reanimation Omentum – for chest wall and limb defects

Summary box 29.4

Free tissue transfer (or free flap)

Advantages

- Being able to select exactly the best tissue to move
- Only takes what is necessary
- Minimises donor site morbidity

Disadvantages

- More complex surgical technique
- Failure involves total loss of all transferred tissue
- Usually takes more time unless the surgeon is experienced

Recent developments have led to surgeons dissecting distant flaps free from the carrier muscle or fascia, to reduce further the donor morbidity. These distant 'perforator' flaps increase the flexibility of the use of the flap tissue while reducing donor site problems. Future flap design is moving towards individualised flaps

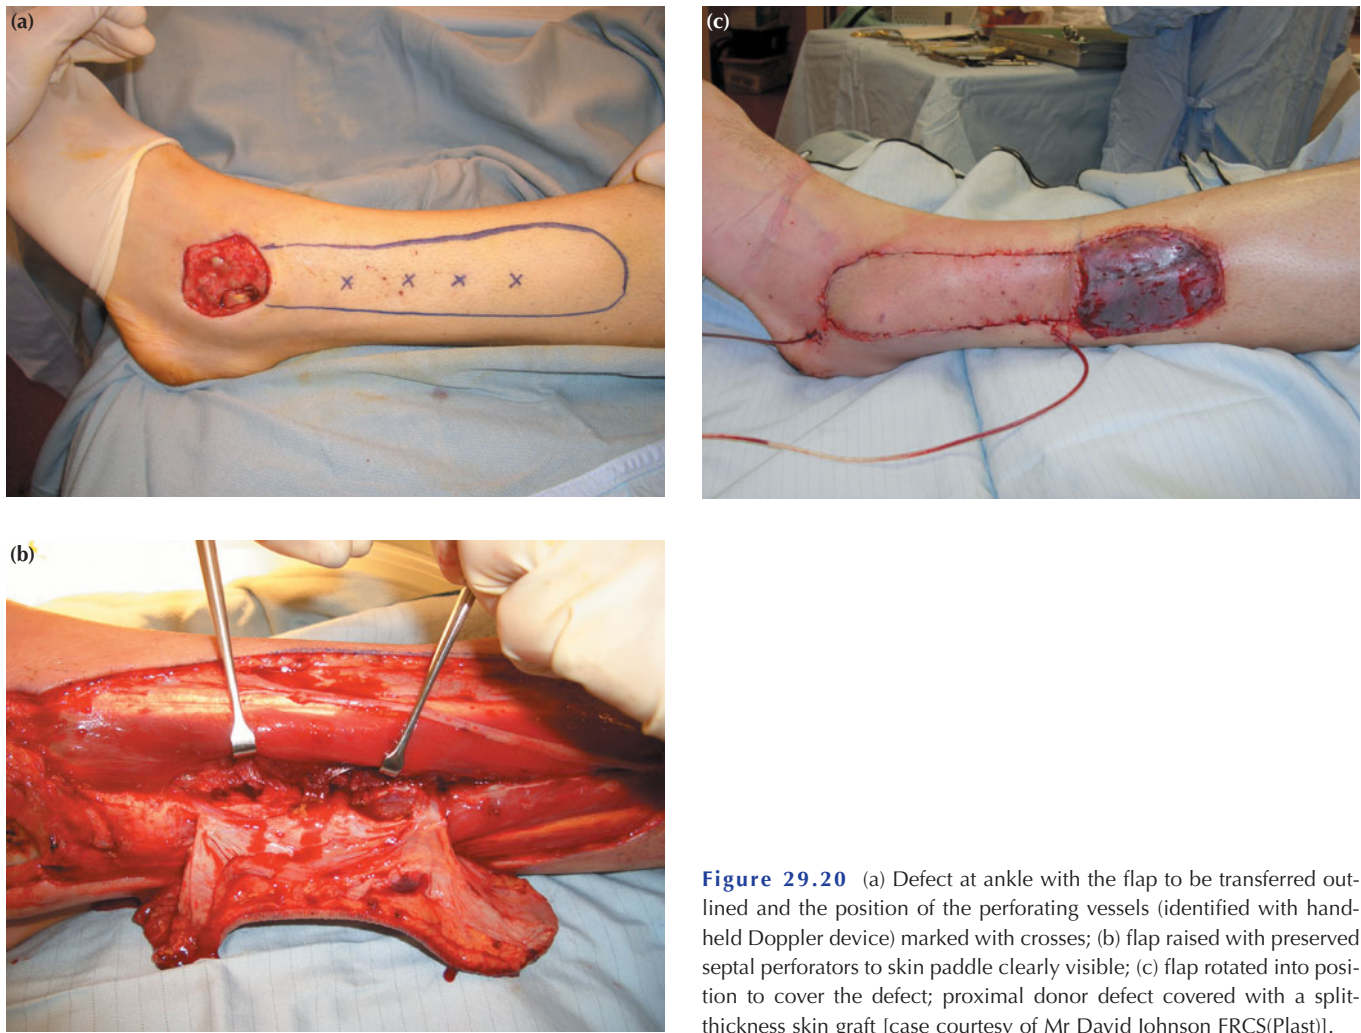

Figure 29.20 (a) Defect at ankle with the flap to be transferred outlined and the position of the perforating vessels (identified with handheld Doppler device) marked with crosses; (b) flap raised with preserved septal perforators to skin paddle clearly visible; (c) flap rotated into position to cover the defect; proximal donor defect covered with a split-thickness skin graft [case courtesy of Mr David Johnson FRCS(Plast)].

Figure 29.21 (a–c) Large myocutaneous free flap (latissimus dorsi) to cover an exposed cranial defect following the excision of advanced basal cell carcinoma [case courtesy of Mr David Johnson FRCS(Plast)].

Figure 29.22 Large 'chimeric flap' of latissimus dorsi and serratus anterior muscles (a) to cover a complex open wound of the foot and ankle (b), illustrating the donor site (c and d) and fully covered defect (e and f) [case courtesy of Mr David Johnson FRCS(Plast)].

customised in freestyle fashion for the specific reconstructive requirement demanded.

Care of flaps and monitoring

After a flap has been moved it should be observed for tissue colour, warmth and turgor, and be pressed to assess blanching and capillary refill time. Loss of arterial inflow results in pale, cold, flaccid tissue; loss of venous outflow results in blue congestion, increased turgor, rapid capillary refill and initially a warm flap. In a pedicled flap, such venous congestion may be relieved by releasing suture tension; applying leeches to suck out excess venous blood is a last resort when no other means of restoring venous drainage can be obtained.

The most common causes of flap failure are:

- poor anatomical knowledge when raising the flap (such that the blood supply is deficient from the start);
- flap inset with too much tension;
- local sepsis or a septicaemic patient;
- the dressing applied too tightly around the pedicle;
- microsurgical failure in free flap surgery (usually caused by problems with surgical technique).

'Wet, warm and comfortable'

The best advice for postoperative flap care for major tissue transfers is to keep the patient 'wet, warm and comfortable'. This means that the patient should be well hydrated with a hyperdynamic circulation, a very warm body temperature and well-controlled analgesia to reduce catecholamine output.

Reconstructing complex areas

Certain areas such as the eyelids, nose, lips, ears, genitalia, fingers, breast and intraoral structures often require a combination

of methods to produce the most functional and acceptable outcome for the patient. Planning such reconstruction involves considering each cosmetic subunit involved in the defect and bringing the best tissue to rebuild it. An example is the Indian forehead rhinoplasty of Sushruta, which involves transposition of a pedicled fasciocutaneous flap from forehead to nose, with the donor site usually thin skin grafted but occasionally closed primarily in small flaps. It remains the finest means of transporting cosmetically correct tissue to the nose.

Disaster surgery

CHAPTER 30

'At all defining moments in history, either the man defines the moment or the moment defines the man.'

Ron Shelton, from the film 'Tin Cup'

LEARNING OBJECTIVES

To recognise and understand:

- The common features of various disasters
- The principles behind the organisation of the relief effort and of triage in treatment and evacuation

- The role and limitations of field hospitals
- The features of conditions peculiar to disaster situations and their treatment

INTRODUCTION

Natural disasters such as floods and earthquakes provide a constant reminder of the awesome power and capricious nature of our planet. The depletion of the ozone layer and global warming mean that the future may hold in store natural events that will be even greater in magnitude than the ones experienced before. Alongside the ravages of nature is our own propensity to damage our fellow man. National conflicts and ideological differences have not lessened over the millennia and the resultant 'unnatural disasters' have the potential to rival the natural ones in enormity and the impact on human life. The spectre of terrorist attacks on major world cities constantly haunts security organisations and health-care providers.

COMMON FEATURES OF MAJOR DISASTERS

Any event that results in the loss of human life is disastrous, but most accidents, such as aeroplane and train crashes, are limited in the number of people involved. Conversely, tsunamis and nuclear explosions leave in their wake massive destruction over large areas, which may transcend national boundaries. All the apparatus of a society that respond to such disasters (the civil administration, emergency services, fire brigades and hospitals) may themselves be rendered non-functional (Fig. 30.1). Large numbers of people may require immediate shelter and food in addition to their requirements for medical care.

A breakdown of communication is inevitable and is accompanied by widespread panic and a disruption of civil order. Access to the disaster area may be limited because of the destruction of bridges, road and rail links. In the face of such extensive damage to the infrastructure of society, the armed forces are usually called upon to help restore civil order and initiate the reconstructive effort (Summary box 30.1).

Figure 30.1 Damage to emergency medical services.

Summary box 30.1

Common features of major disasters

- Massive casualties
- Damage to infrastructure
- A large number of people requiring shelter
- Panic and uncertainty among the population
- Limited access to the area
- Breakdown of communication

FACTORS INFLUENCING RELIEF EFFORTS AND PROVISION OF MEDICAL AID

Communication is the critical factor that determines the response from the authorities. Its restoration is a priority so that first-hand information about the magnitude of the disaster can be obtained as quickly as possible. Wireless technology and satellite imagery have

revolutionised the way in which real-time information can be obtained (Fig. 30.2). Even so, there is a lag period between the occurrence of the disaster and the response from the establishment.

The location of the disaster area, whether rural or urban, has a significant bearing on relief efforts. Terrorist attacks and nuclear events are more likely to be targeted towards large population centres where emergency services are better developed and high-standard hospital facilities are available. On the other hand they are also densely populated, cramped with high-rise buildings and may have limited access by road and air. Natural disasters can strike anywhere but can be particularly difficult to manage if they

occur in remote areas as relief efforts are hampered by geographical isolation and the lack of a suitable infrastructure for dealing with a major calamity.

The time-frame in which a disaster occurs also has an impact on the relief efforts. Earthquakes and blasts unleash havoc in fractions of a second but floods and hurricanes may continue for several days and nuclear fallout can damage the ecosystem for years to come. Another noteworthy aspect is the state of development of the country; disasters in the developing world can seldom be managed without significant outside assistance (Summary box 30.2).

Figure 30.2 Satellite image showing destruction of a bridge as a result of flood.

Summary box. 30.2

Factors influencing rescue and relief efforts

- Status of communications
- Location, whether rural or urban
- Accessibility of the location
- Time-frame in which disaster occurs
- Economic state of development of the area

SEQUENCE OF RELIEF EFFORTS AFTER A DISASTER

Establishing a chain of command

In many countries there are organisations that deal with disasters, such as the Federal Emergency Management Authority (FEMA) in the USA. In others, an ad-hoc administrative hierarchy is established to coordinate the efforts of the teams participating in relief efforts. The actual organisation that deals with a particular disaster will depend upon the circumstances but the principles of each organisation remain the same (Fig. 30.3).

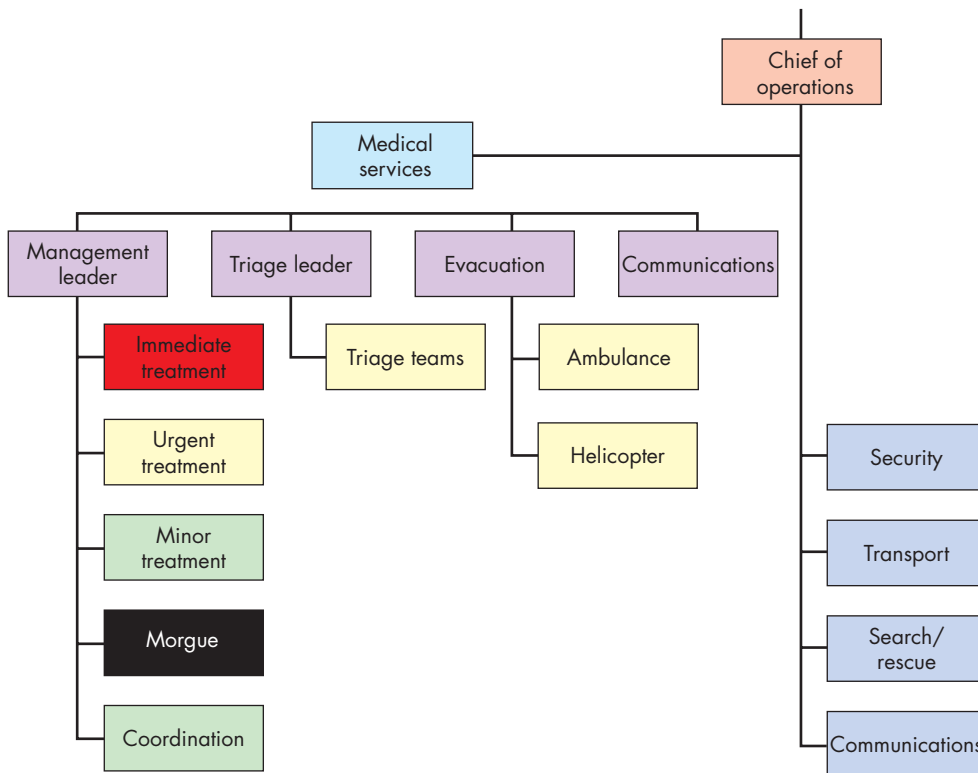

Figure 30.3 Organisation chart for disaster management.

Damage assessment

The first and often the most difficult objective in disaster management is an accurate assessment of the damage and the number of casualties. All sources of information must be employed, not just the official channels. Given the public's morbid fascination with such events, the 24-hour news services are frequently the first on the scene and can be an important source of information.

Mobilising resources

The next step is mobilisation of human and material resources appropriate to the size and nature of the disaster. Although all modes of transport available need to be considered, helicopters are the quickest way in for the first responders (Fig. 30.4).

The initial groups of personnel to respond must include experienced senior staff who can quickly assess the situation, make immediate decisions and organise further assistance.

Rescue operation

Early coordination of the rescue effort will allow optimal use of limited resources. Self-help will already be under way in the form of the less injured helping the more gravely hurt. Rescue teams

Figure 30.4 Heli-evacuation.

from the outside must work with local volunteers who are familiar with the area.

The first priority is to prevent further damage from occurring, both to people and to the infrastructure. Fires should be put out, people moved away from falling debris and well-meaning non-professionals stopped from embarking on hazardous rescue efforts.

The types of injuries that will be encountered by rescue workers will depend upon the delay between the start of the disaster and the arrival of rescue workers. Patients with head injuries and abdominal and thoracic trauma will either have been treated or have succumbed to their injuries within 48–72 hours of a disaster. After the first 2 weeks, the only casualties requiring treatment are those with complex limb trauma (Fig. 30.5).

Coordination with relief agencies

A laudable aspect of globalisation is the immediate outpouring of help from governments and various non-government organisations that occurs in response to a disaster on the other side of the world. Some organisations, for example Rescue and Preparedness in Disasters (RAPID), deal with search and rescue whereas others, such as the International Committee of the Red Cross (ICRC) and Oxfam, provide general disaster-related relief (Fig. 30.6). United Nations (UN) agencies such as the World Health Organization (WHO), the World Food Programme (WFP) and the UN High Commissioner for Refugees (UNHCR) deal with medical care, food provision and refugees respectively. The authorities need to coordinate the efforts of these organisations for optimal results, as medical aid in isolation is inadequate without the simultaneous provision of safe drinking water, food, clothing and shelter. The scale of the disaster and the immediate and long-term requirements should be clearly communicated so that appropriate and timely help is received. Rescue teams should be prepared to be self-sufficient and not rely on the local infrastructure, which may have been destroyed.

Safety of the helpers

Rescue and relief workers are a diverse group of individuals and, whereas policemen and members of rescue organisations are trained to deal with the breakdown in civil order that occurs in

Figure 30.5 Time line showing the type of injuries encountered at different times in a disaster.

Figure 30.6 Oxfam and the International Committee of the Red Cross provide generalised relief.

the wake of disasters, volunteer workers may have little experience of such situations. It is not uncommon for mobs to loot stores of food and other essentials in a disaster, especially if help has arrived late. This results in injuries, occasionally serious, to personnel trying to provide an equitable distribution of goods. During armed conflicts and civil wars, rival groups have prevented humanitarian assistance reaching the neediest, and even structures bearing the Red Cross and Red Crescent have been targeted. It is therefore imperative that the local authorities make it a point to safeguard the lives and property of aid workers to allow them to work without duress and fear.

Dealing with the media

Disasters act like a magnet to the media and, in today's world of 24-hour news coverage, the media exert a powerful influence in shaping public opinion. They are frequently accused of dramatising the situation and only emphasising the inadequacies of the relief effort. Aid workers may find dealing with the media difficult as their priorities are rightly different. Nevertheless it is essential to establish a working relationship between the two groups. To prevent conflicting statements a spokesperson should be appointed, who must be kept informed of the latest situation. With careful handling the media can become a powerful ally and play a constructive role in identifying problems, galvanising aid and keeping the public informed.

Triage

Derived from the French verb 'trier', triage means 'to sort' and is the cornerstone of the management of mass casualties. It aims to identify the patients who will benefit the most by being treated the earliest, ensuring *the greatest good for the greatest number*. Its value has been proved in battlefields since the Napoleonic wars and it is still practised in hospital emergency departments. In a broader sense it determines who will be treated first, what mode of evacuation is best and which medical facility is optimal for the management of the patient. Numerous studies show that only 10–15% of disaster casualties are serious enough to require hospitalisation. By sorting out the minor injuries, triage lessens the immediate burden on medical facilities. Deciding who should receive priority when faced with hundreds of seriously injured

victims is a daunting prospect. There is a tendency for senior doctors to believe that their services are better utilised in the actual management of patients rather than in triage. This is a mistake and it is crucial that this task be undertaken by someone senior, who has the training and experience to make these crucial decisions. It is important to remember the changing clinical picture of an injured person. To keep pace, triage needs to be undertaken at various levels, i.e. in the field, before evacuation and at the hospital.

Triage areas

For efficient triage the injured need to be brought together at one location. Any undamaged structures that can accommodate and shelter a large number of wounded, such as school buildings and stadia, are suitable. A good water supply and ease of access are useful. Areas should then be reserved for patient holding, emergency treatment and decontamination (in the event of discharge of hazardous materials). An area should also be designated to serve as a morgue, preferably a little removed from the holding and treatment areas.

Practical triage

Emergency life-saving measures should proceed alongside triage and actually help the decision-making process. The assessment and restoration of airway, breathing and circulation are critical and are discussed in Chapter 22. A simple visual check of the injuries is notoriously unreliable. Vital signs and a general physical examination should be combined with a brief history taken by a paramedic or volunteer worker if it is available.

Documentation for triage

Accurate documentation is an inseparable part of triage and should include basic patient data, vital signs with timing, brief details of injuries (preferably on a diagram) and treatment given. In addition, a system of colour-coded tags attached to the patient's wrist or around the neck is employed by emergency medical services. The colour denotes the degree of urgency with which a patient requires treatment (Fig. 30.7).

Triage categories

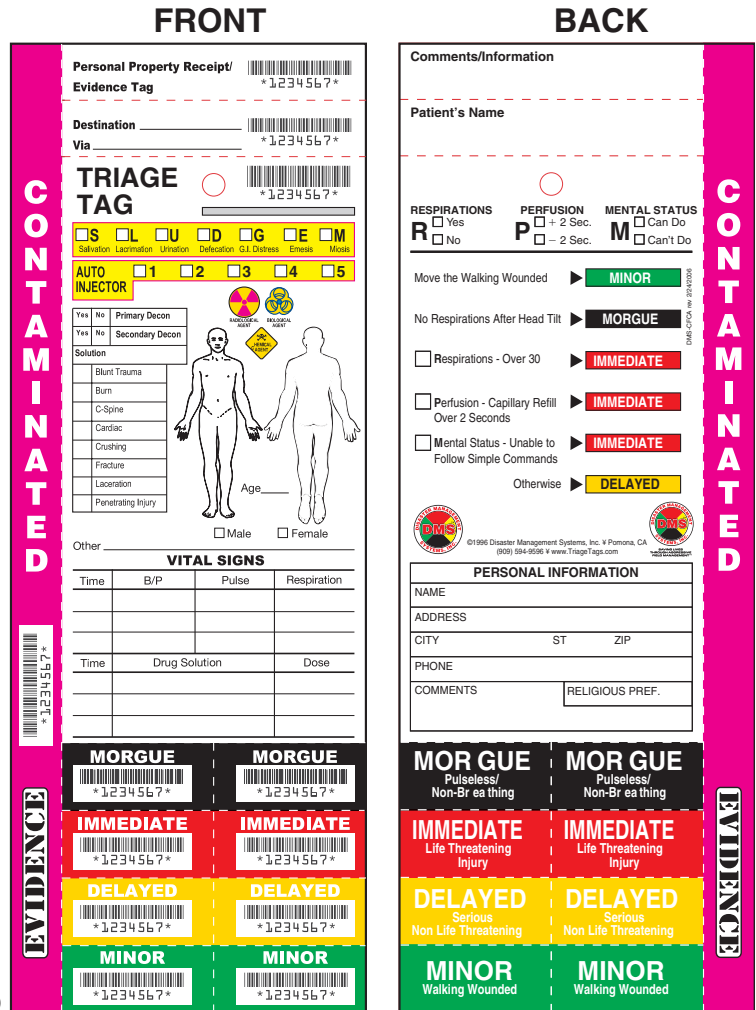

There is no universally accepted method of triage. Nevertheless, all methods use simple criteria based on vital signs and a rapid clinical assessment, taking into account the patient's ability to walk, the mental status and the presence or absence of ventilation or capillary perfusion. A commonly used four-tier system is presented in Table 30.1. Triage carries serious consequences, especially for patients who are consigned to the unsalvageable category. It should be carried out with compassion but also be clear and decisive.

Evacuation of casualties

This is a major logistics exercise especially in a 'diffuse' catastrophe such as an earthquake or a tornado. It is good practice to carry out a quick re-triage before deciding on the sequence of transport and destination of the injured. Decisions regarding the best destination for each patient need to be based on how far it is safe for them to travel and whether the facilities that they need for definitive treatment will be available. If decisions are not made carefully some hospitals may be swamped with patients whereas others with

(a)

(b)

Figure 30.7 Triage tags. (a) Courtesy of TACDA & METTAG products, American Civil Defense Association. (b) Courtesy of Disaster Management Systems.

Table 30.1 Triage categories

Priority	Colour	Medical need	Clinical status	Examples
First (I)	Red	Immediate	Critical but likely to survive if treatment given early	Severe facial trauma, tension pneumothorax, profuse external bleeding, haemothorax, flail chest, major intra-abdominal bleed, extradural haematomas
Second (II)	Yellow	Urgent	Critical, likely to survive if treatment given within hours	Compound fractures, degloving injuries, ruptured abdominal viscus, pelvic fractures, spinal injuries
Third (III)	Green	Non-urgent	Stable, likely to survive even if treatment is delayed for hours to days	Simple fractures, sprains, minor lacerations
Last (0)	Black	Unsalvageable	Not breathing, pulseless, so severely injured that no medical care is likely to help	Severe brain damage, very extensive burns, major disruption/loss of chest or abdominal wall structures

better facilities receive only a small number. The paramedics accompanying the casualties should be familiar with safe transport techniques. A patient with a spinal injury should be strapped to the spine board, the hard collar adjusted and the head fixed to the board with tape. Chest tubes, urinary catheters, endotracheal tubes, tracheotomy tubes and intravenous lines must be properly secured. These measures will help prevent the 'second accident' that plagues casualty transportation. For patients obliged to travel for a long time, an adequate supply of essentials such as intravenous fluids, dressings, pain medication and oxygen must be arranged. Care must be exercised in the case of unaccompanied minor children; cases must be clearly documented and social services informed (Summary box 30.3).

Summary box 30.3**Essentials of casualty evacuation**

- Re-triage to prioritise the injured
- Select appropriate medical facilities
- Select appropriate means of transport
- Prevent the 'second accident'
- Ensure an adequate supply of materials

Field hospitals

The decision to set up field hospitals will depend upon the location of the disaster, the number of casualties and the speed with which evacuation can be affected. The two basic types of field hospitals are the traditional tented structure and the modular type housed in containers (Fig. 30.8).

The modular type is self-contained and can be operational as soon as it reaches the disaster area but the containers are heavy and require an intact road or rail link to be transported. The tented structures require an initial period of setting up before they can be functional but they are very portable and components can be carried in small vehicles or air dropped. Whichever type is chosen, it must be equipped with an X-ray plant, operating rooms, vital signs monitors, sterilising equipment, a blood bank, ventilators and basic laboratory facilities.

Management in the field

Field hospitals principally function in three main areas (Table 30.2).

First aid

Care for patients with minor injuries involves suturing of lacerations, splinting simple fractures and sprains and applying bandages

Table 30.2 Type of treatment given in field hospitals

	Examples	Further
First aid	Suturing cuts and lacerations, splinting simple fractures	Review at local hospital
Emergency care for life-threatening injuries	Endotracheal intubation, tracheotomy, relieving tension pneumothorax, stopping external haemorrhage, relieving an extradural haematoma, emergency thoracotomy/laparotomy for internal haemorrhage	After damage control surgery, transfer patients to base hospitals once stable
Initial care for non-life-threatening injuries	Debridement of contaminated wounds, reduction of fractures and dislocations, application of external fixators, vascular repairs	Transfer patients to base hospitals for definitive management

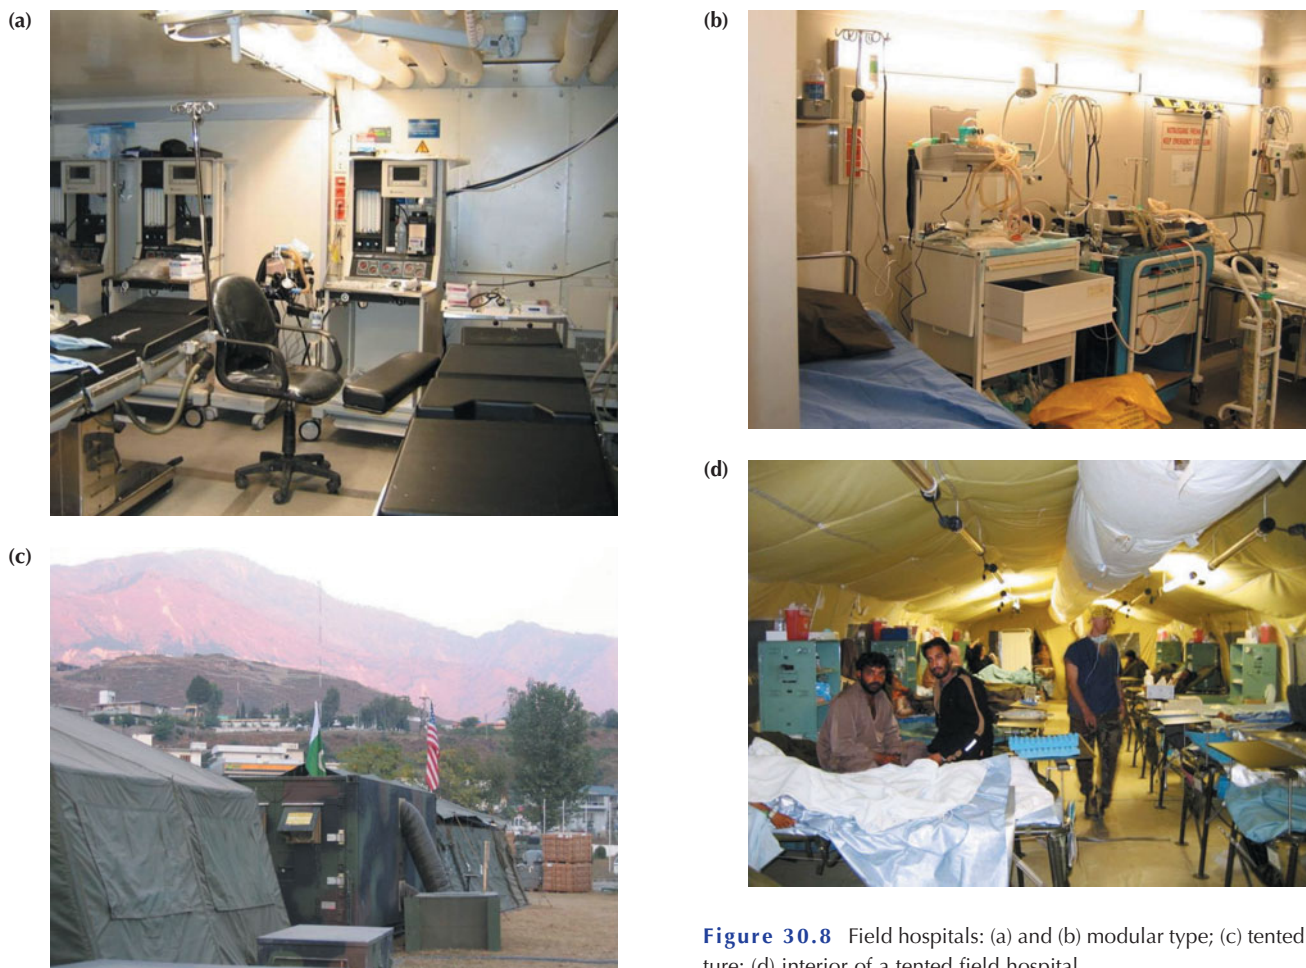

Figure 30.8 Field hospitals: (a) and (b) modular type; (c) tented structure; (d) interior of a tented field hospital.

to cuts and bruises. Most of these ‘walking wounded’ can be sent away with antibiotics and pain relievers and asked to follow-up at their usual hospital or the field hospital.

Emergency care for immediate life-threatening injuries

There are many patients who may be saved by relatively simple measures provided that they are taken urgently. Endotracheal intubation, tracheotomy, relieving a tension pneumothorax, closing an open pneumothorax and stopping profuse external haemorrhage fall into this category. Major procedures may include an emergency thoracotomy or laparotomy to stop massive or persistent internal bleeding and evacuation of an extradural haematoma. These procedures are indicated in the field only if the patient is unlikely to survive an attempt at transfer to a base hospital. Amputation for clearly devitalised limbs and gas gangrene should be undertaken at field hospitals.

Initial care for non-life-threatening injuries

Many patients will present with serious injuries that require complex, prolonged care. Compound limb fractures, degloving injuries, dislocations of major joints, major facial injuries and complex hand injuries all fall into this category. These patients will need specialised orthopaedic and plastic surgical care requiring transfer to the appropriate facility. Replantations of totally amputated limbs and other extensive reconstructive procedures should not be attempted in field hospitals as they are very time

consuming and divert resources and personnel to the treatment of a few patients.

Debridement

Taken from the French meaning to ‘unleash or cut open’, debridement has come to mean more than simply the laying open of tissues. It plays a crucial part in the management of trauma. Wounds sustained in disasters are often heavily contaminated, containing foreign bodies and non-viable tissues (Fig. 30.9). Debridement reduces the chances of anaerobic and necrotising infections and can prevent systemic sepsis. The following principles of debridement apply to all contaminated wounds, including gunshot and shrapnel injuries:

- It should be undertaken by surgeons who are well versed in trauma surgery, in a sterile environment with good lighting.
- After the administration of anaesthesia, the first step is a thorough cleansing of the injured area by copious irrigation with normal saline, preferably carried out under tourniquet to reduce blood loss. Pulse lavage, if available, is ideal for this but a large syringe can also be used (Fig. 30.10). Next, the wound is palpated and all foreign matter is removed using forceps. In-driven dirt is best removed using a nail brush as even small particles of retained dirt result in permanent tattooing. Dirt intimately enmeshed in the soft tissues can only be removed by excision. Open joints should be thoroughly irrigated and all foreign material removed.

Figure 30.9 Gross contamination typically seen in wounds sustained in disasters. The radiograph shows numerous radio-opaque foreign bodies in the soft tissues.

- Wounds with a small external opening but more extensive cavitation (firearm injuries, high-impact injuries) should be generously enlarged in a longitudinal direction along with the deep fascia to gain better access and decompress the underlying muscles. This helps to visualise the damaged structures, gain proximal and distal control for vascular injuries and identify severed ends of major nerves and tendons.
- The next step is excision of all dead and devitalised tissue. It is advisable at this stage to let down the tourniquet to check the vascularity of the tissues. Skin excision should be kept to a minimum as it is quite resistant to trauma and only the margins of the wound need to be trimmed back to healthy

Figure 30.10 Lavage with normal saline to decontaminate a wound.

bleeding edges. Removal of devitalised muscle is essential and should be undertaken generously. Muscle that is pale or dark in colour, has a soft consistency, does not contract on pinching and does not bleed on cutting is definitely non-viable. Small pieces of crushed bone lying free should be removed. Large segments of bone that retain some soft-tissue attachment should be left undisturbed. In patients with traumatic amputations, the bone ends are tidied, the skin and muscle edges trimmed to the lowest level possible and the wound left open.

- In patients with associated fractures, skeletal stabilisation should be obtained before embarking on any repairs. External fixators are invaluable for this and make wound management easier (Fig. 30.11).
- In major trauma in the acute setting, only vascular repairs are justified. For lacerated vessels the ends are trimmed and anastomosis performed. In case of loss of substance of the vessel wall a vein patch or reversed vein graft may be used. Silicone tubing may be used as a temporary bypass (stent) while vascular repair is being carried out in patients with critically compromised distal circulation.
- Nerves and tendons should not be dissected out nor any attempt made at definitive repair in wounds with tissue devitalisation and gross oedema, as it leads to poor results. The key structures should simply be identified and the edges trimmed and tagged with non-absorbable sutures to facilitate repair during subsequent exploration.
- Wounds sustained in disasters are heavily contaminated and not suitable for primary closure. However, blood vessels (whether repaired or simply exposed) and exposed joint surfaces need to be covered. This can be achieved by using adjoining muscle or skin loosely tacked with a few sutures. The wound is then covered with fluffed gauze and sterile cotton and the extremity splinted with a plaster of Paris slab, even if there is no fracture. For the upper extremity, elevation with a drip stand and, for the lower limb, elevation on a couple of pillows are important to reduce oedema.
- Broad-spectrum antibiotics, such as third-generation cephalosporins, are started prophylactically and continued for 5–7 days.
- The wound should be reinspected at 24–48 hours to assess the viability of the tissues and the distal circulation. The wounds are closed between the fourth and sixth day if there is no infection. Tension should be avoided and liberal use of partial-thickness skin grafts to achieve wound closure is

Figure 30.11 External fixators provide skeletal stabilisation and allow easy management of the soft tissues.

recommended. Skin staplers are particularly useful and time saving when dealing with large numbers of casualties.

- In wounds with gross infection no attempt at closure is made until infection is eradicated. These wounds are re-explored to make sure that there are no residual foreign bodies or devitalised tissue. Surface swabs are not useful but tissue should be taken for microbiological culture. Vacuum-assisted closure (Vac-Pac) has emerged as a very useful tool for irregular and deeply cavitating wounds. It utilises low-pressure suction to evacuate exudate, promote sprouting of granulation tissue and reduce the size of the wound (Fig. 30.12). Once the wounds are free from infection secondary closure can be undertaken (Summary box 30.4).

Summary box 30.4

Principles of debridement and initial wound care

- Obtain generous exposure through skin and fascia
- Identify neurovascular bundles
- Excise devitalised tissue
- Remove foreign bodies
- Repair major vessels
- Obtain skeletal stabilisation with external fixators
- Only tag cut tendons and nerves
- Leave wound open and delay primary closure
- Avoid tight dressings
- Elevate injured limb

DEFINITIVE MANAGEMENT

This is undertaken at major hospitals. Hospitals should be alerted to the expected number of casualties so that the staff are prepared. Hospitals are selected on the basis of the facilities available and the number of injured that they can handle. The number of beds available is seldom a good guide to capacity as the ancillary resources required for trauma patients are more than for the typical case mix of a hospital. It is estimated that only half the bed strength of a hospital should be utilised to provide optimum care.

Figure 30.12 Use of low-pressure vacuum therapy in preparing a wound for secondary closure.

Hospital reorganisation

Hospitals are organised according to the type of patients treated and the facilities that they offer, but reorganisation of services is unavoidable during disasters. This includes transferring patients with non-urgent conditions to other facilities, augmenting surgical services, reorganising the specialist rota and redesignating medical wards as surgical care areas to accommodate the patient load. A quick check of hospital inventories should be undertaken to ensure availability of essential equipment and medicines and an appeal for blood donations should be broadcast (Summary box 30.5).

Summary box 30.5

Sequence of the relief effort in major disasters

- Establish chain of command
- Establish communication
- Damage assessment
- Mobilise resources
- Rescue operation
- Triage
- Emergency treatment
- Evacuation
- Definitive management

SPECIFIC ISSUES

There is no injury that is peculiar to disasters. Destruction of buildings and explosions can produce the whole spectrum of external injuries from minor cuts to extensive degloving, compound fractures and amputations. Internal organ damage is frequent and, unless immediate help is available, accounts for the major share of early mortality figures. People trapped under fallen buildings may suffer crush injuries and crush syndrome if the duration is prolonged. Those near an explosion can suffer injury to the lungs and abdominal viscera, as well as burns because of the heat of the blast.

Crush injuries and missile injuries cause extensive tissue damage and gross contamination, both favourable conditions for anaerobic and micro-aerophilic infections.

Limb salvage

The Mangled Extremity Severity Score (MESS) and its modifications are useful in making a judgement about limb salvage. In the past, extensive tissue loss, neurovascular damage and loss of long fragments of bone were all considered indications for amputation. Currently, with the use of microvascular flaps, wounds of any dimension can be covered with healthy tissue in a single stage. If performed in time, vascular repairs can salvage most acutely ischaemic limbs. Distraction osteogenesis and vascularised bone transfers can restore bony continuity in all but the most massive bone losses. In view of these developments the indications for amputation in trauma have undergone a paradigm shift and the majority of patients who reach a tertiary-care facility within 24 hours are candidates for limb salvage (Fig. 30.13). This assumes that debridement and, if required, vascular repairs have been performed in a field medical facility. Restoration of vascular continuity is the critical issue and a limb is unlikely to survive if vascular repairs of major limb vessels are delayed for more than 4–6 hours.

Figure 30.13 Badly traumatised lower limb. Reconstruction has been performed using a microvascular rectus abdominis flap covered with a skin graft.

Facial injuries

The management of facial injuries follows the same general principles of debridement and delayed closure as already outlined. Because of the functional and cosmetic importance of facial structures, skin and soft-tissue excisions are kept to a minimum. There is a robust blood supply to the face and the ability to counter infection is therefore very high. Even in patients who present late with gross contamination, a careful debridement followed by delayed primary closure can lead to good results (Fig. 30.14).

Tetanus

This potentially fatal condition, also called 'lockjaw', is caused by *Clostridium tetani*, a Gram-positive spore-forming bacillus occurring naturally in the intestines of humans and animals and in the soil. It enters the body through a wound and replicates, thriving on the anaerobic conditions present in devitalised tissues. It produces tetanospasmin, a potent exotoxin that binds to the neuromuscular junctions of the central nervous system neurones, rendering them incapable of neurotransmitter release. This leads to failure of inhibition of motor reflex responses to sensory stimulation. The result is generalised contractions of agonist and antagonist muscles causing tetanic spasms. The median incubation period is 7 days, ranging from 4–14 days.

Early symptoms are painful spasms of the masseter and facial muscles resulting in the classical risus sardonicus (Fig. 30.15). The spasms spread to involve the muscles of respiration and the laryngeal musculature. Spasms of the paravertebral and extensor limb musculature produce opisthotonus, an arching of the whole

body. Laryngeal muscle spasm leads to apnoea and, if prolonged, to asphyxia and respiratory arrest. The spasms can be brought on by the slightest of sensory stimuli. They may be sustained and severe enough to produce long-bone fractures and joint dislocations.

The diagnosis is obvious once it is fully manifest. There are three aspects of management:

- *Prevention.* Wounds contaminated with soil are likely to harbour the organism and active immunisation is indicated by administering 0.5 ml of tetanus toxoid intramuscularly. Patients with gross contamination of deeply cavitating wounds should also receive 250–500 U of human anti-tetanus globulin (ATG) intramuscularly to provide passive immunisation and neutralise the circulating toxin (in clinical tetanus, 3000–10 000 U of ATG should be administered). Wound manipulation should be avoided for 2–3 hours after ATG administration to minimise tetanospasmin release.
- *Local wound care.* This includes a thorough wound debridement to eliminate the anaerobic environment. Intravenous administration of $10\text{--}24 \times 10^6$ U day⁻¹ of penicillin G is effective and should be continued for 10–14 days. The wound should be closed using the delayed primary or secondary closure techniques (see above).
- *Supportive care for established disease.* These patients are nursed in an intensive care unit (ICU) environment, free from strong sensory stimuli. Unnecessary manipulations are avoided. Diazepam is useful in preventing the onset of spasms but if spasms become frequent and sustained the patient should be paralysed, intubated and placed on a ventilator. The patient is

Figure 30.14 Late-presenting facial injury with gross contamination. A thorough debridement followed by delayed primary closure has yielded good results.

then gradually weaned off the ventilator under cover of anti-convulsants. The overall mortality rate is around 45%, prognosis being determined by the incubation period and the time from the first symptom to the first tetanic spasm. In general, shorter intervals indicate a poorer prognosis. Clinical tetanus does not result in immunity and so survivors should receive active immunisation with toxoid to prevent recurrence.

Necrotising fasciitis

This is a dangerous and rapidly spreading infection of the fascial planes leading to necrosis of the subcutaneous tissues and overlying skin. It is caused by β -haemolytic streptococci and, occasionally, *Staphylococcus aureus* but may take the form of a polymicrobial infection associated with other aerobic and anaerobic

pathogens, including *Bacteroides*, *Clostridium*, *Proteus*, *Pseudomonas* and *Klebsiella*. It is termed Fournier's gangrene when it affects the perineal area and Meleney's synergistic gangrene when it involves the abdominal wall. The underlying pathology is identical and includes acute inflammatory infiltrate, extensive necrosis, oedema and thrombosis of the microvasculature. The area becomes

Theodor Albrecht Edwin Klebs, 1834–1913, Professor of Bacteriology successively at Prague, Czechoslovakia, Zurich, Switzerland and the Rush Medical College, Chicago, IL, USA.

Jean Alfred Fournier, 1832–1915, the founder of the Venereal and Dermatological Clinic, Hôpital St Louis, Paris, France.

Frank Lamont Meleney, 1889–1963, Professor of Clinical Surgery, Columbia University, New York, NY, USA.

Figure 30.15 Risus sardonicus of 'lockjaw' (courtesy of Dr Samira Ajmal FRCS).

oedematous, painful and very tender. The skin turns dusky blue and black secondary to the progressive underlying thrombosis and necrosis (Fig. 30.16). The area may develop bullae and progress to overt cutaneous gangrene with subcutaneous emphysema. It spreads to contiguous areas but occasionally also produces skip lesions that later coalesce. It is accompanied by fever and severe generalised toxicity. Renal failure as a result of hypovolaemia and cardiovascular collapse caused by septic shock may occur. The rate

of progression can catch the unwary by surprise and unless aggressively treated it leads to serious consequences with a mortality rate approaching 70%.

The diagnosis is usually made on clinical grounds. Creatinine kinase levels may show enormous elevation and biopsy of the fascial layers can confirm the diagnosis. Patients are admitted to ICU and treated aggressively with careful monitoring of volume derangements and cardiac status. Oxygen supplementation is advantageous and endotracheal intubation is required in patients unable to maintain their airway.

High-dose penicillin G along with broad-spectrum antibiotics such as third-generation cephalosporins and metronidazole should be given intravenously until the patient's toxicity abates. The cornerstone of management is surgical excision of the necrotic tissue. The fascial planes are opened with ease as the infection produces inflammatory degloving and the yellowish-green necrotic fascia is visible. Devitalised tissue should be removed generously, preferably going beyond the area of induration. This can lead to profuse bleeding and it is wise to have blood already cross-matched. The wound is lightly packed with fluffed gauze and dressed. This process should be continued on a daily basis as the necrosis is prone to spread beyond the edges of the excised wound. In patients who survive, this results in a large wound, which will require skin grafting or flap coverage.

Recently, the role of hyperbaric oxygen (HBO) has become more established. It is claimed that it is bactericidal, improves neutrophil function and promotes wound healing. The patient is placed in a high-pressure chamber and 100% oxygen administered at a pressure of 2–3 atmospheres. Studies have shown a

Figure 30.16 (a) Necrotising fasciitis at presentation and (b) rapid progression seen after 24 hours. (c) Typical bullae and induration.

reduction in mortality rate in patients treated with HBO (9–20%) compared with patients who did not receive HBO (30–50%). The main limitation to its use is availability of the pressure chamber.

Gas gangrene

This is a dreaded consequence of inadequately treated missile wounds, crushing injuries and high-voltage electrical injuries. It is a rapidly progressive, potentially fatal condition characterised by widespread necrosis of the muscles and subsequent soft-tissue destruction. The common causative organism is *Clostridium perfringens*, a spore-forming, Gram-positive saprophyte that flourishes in anaerobic conditions. Other organisms implicated in gas gangrene include *C. bifermentans*, *C. septicum* and *C. sporogenes*. They are present in the soil and have also been isolated from the human gastrointestinal tract and female genital tract. Non-clostridial gas-producing organisms such as coliforms have also been isolated in 60–85% of cases of gas gangrene.

Clostridium perfringens produces many exotoxins but their exact role is unclear. Alpha-toxin, the most important, is a lecithinase, which destroys red and white blood cells, platelets, fibroblasts and muscle cells. The phi-toxin produces myocardial suppression whereas the kappa-toxin is responsible for the destruction of connective tissue and blood vessels.

Wounds become contaminated with clostridial spores and the devitalised tissue, foreign bodies and premature wound closure provide the anaerobic conditions necessary for spore germination. The usual incubation period is < 24 hours but it can range from 1 hour to 6 weeks. A vicious cycle of tissue destruction is initiated by rapidly multiplying bacteria and locally and systemically acting exotoxins. Locally, this results in spreading necrosis of muscle and thrombosis of blood vessels while progressive oedema further compromises the blood supply. The typical feature of this condition is the production of gas (composed of nitrogen, hydrogen sulphide and carbon dioxide) that spreads along the muscle planes. Systemically, the exotoxins cause severe haemolysis and, combined with the local effects, this leads to rapid progression of the disease, hypotension, shock, renal failure and acute respiratory distress syndrome (ARDS).

The earliest symptom is acute onset of pain that increases in severity as the myo-necrosis progresses. The limb swells up and the wound exudes a serosanguinous discharge. The skin is involved secondary to underlying muscle necrosis, turning brown and progressing to a blue-black colour with the appearance of haemorrhagic bullae (Fig. 30.17). The characteristic sickly sweet odour and soft tissue crepitus caused by gas production appear with established infection but the absence of either does not exclude the diagnosis. These local signs are accompanied by pyrexia, tachycardia disproportionate to body temperature, tachypnoea and alteration in mental status.

The diagnosis is made on the basis of history and clinical features: a peripheral blood smear may suggest haemolysis; a Gram stain of the exudate reveals large Gram-positive bacilli without neutrophils; and the biochemical profile may show metabolic acidosis and renal failure. Radiography can visualise gas in the soft tissues and computerised tomography (CT) scans are useful in patients with chest and abdominal involvement.

Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology (1891–1900) and Medicine (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.

Figure 30.17 Typical picture of spreading gas gangrene caused by crush injury.

Patients should be admitted to ICU and treated aggressively with careful monitoring. High-dose penicillin G and clindamycin, along with third-generation cephalosporins, should be given intravenously until the patient's toxicity abates. The mainstay of management is early surgical excision of the necrotic tissue. The muscle planes are opened through generous longitudinal incisions and all devitalised tissue is removed, going beyond the area of induration. Abdominal involvement may necessitate excision of the wall musculature. Excision should be continued daily until the process of necrosis has stopped spreading. In established gas gangrene with systemic toxicity, amputation of the involved extremity is life saving and should not be delayed. No attempt is made at closure, amputation stumps are left open and the wound is lightly packed with saline-soaked gauze and dressed.

The role of HBO is not as clear as in necrotising fasciitis but it is recommended in severe cases if the facilities are available.

Blast injuries

Mechanism of explosive blast injury

The explosive pressure accompanying the bursting of bombs or shells ruptures their casing and imparts a high velocity to the fragments. These can cause even more devastating injury to the tissues than bullets. In addition, all explosions are accompanied by a complex blast wave composed of a blast pressure wave (dynamic overpressure) and the mass movement of air (blast wind). Like sound waves, blast pressure waves flow over and around an obstruction and affect anyone sheltering behind a wall or in a trench. A mass movement of air from the rapid expansion of gases at the centre of the explosion displaces air at supersonic speed. This results in injury patterns ranging from traumatic amputation to total body disruption. When a blast pressure wave hits the body, the force of the impact sets up a series of stress waves that are capable of internal injury, particularly at air–fluid interfaces. Thus, injury to the ear, lungs, heart and, to a lesser extent, the gastrointestinal tract is notable.

General management of blast injuries

The structures injured by the primary blast wave, in order of prevalence, are the middle ear, the lungs and the bowel. However, the commonest urgent clinical problem in survivors is penetrating injury caused by blast-energised debris and fragments of the exploding device. Many of those exposed will have blunt, blast

and thermal injuries in addition to more obvious penetrating wounds. The deafness of blast victims caused by tympanic membrane rupture makes communication difficult and may complicate early assessment. Here, the primary survey and resuscitation phases of a system such as Advanced Trauma and Life Support (ATLS) are particularly apt. The management of penetrating wounds differs little from that of missile wounds referred to earlier. The soft-tissue wounds are usually heavily contaminated with dirt, clothing and secondary missiles such as wood, masonry and other materials from the environment. Such contaminants may be driven deeply into adjacent tissue planes opened up by the force of the explosion. In blast injuries, one cannot be sure of complete wound excision and it is imperative that wounds should be left open at the end of the initial operation and delayed primary closure performed.

Crush injury and syndrome

A crush injury occurs when a body part is subjected to a high degree of force or pressure, usually after being squeezed between two heavy or immobile objects. Damage related to crush injury includes lacerations, fractures, bleeding, bruising, compartment syndrome and crush syndrome. It can have disastrous consequences on local tissues with extensive destruction and devitalisation (Fig. 30.18).

Crush syndrome

The association between crush injury, rhabdomyolysis and acute renal failure was first reported in victims trapped during the 'London Blitz'. It is seen in earthquake and mining accident survivors and in battlefield casualties. Prolonged crushing of muscle releases myoglobin and vasoactive mediators into the circulation. It also sequesters many litres of fluid, reducing the effective intravascular volume and resulting in renal vasoconstriction and ischaemia. The myoglobinuria leads to tubular obstruction.

The treatment of crushed casualties should begin as soon as they are discovered. Rescuers must be alert to the presence of associated injuries (Fig. 30.19). Aggressive volume-loading of patients, preferably before extrication, is the best treatment. After provision of first aid and starting intravenous fluids the patient should be catheterised to measure output. In adults, a saline infusion of 1000–1500 ml h⁻¹ should be initiated. Alkalinisation increases the solubility of acid haematin in urine and aids its excretion and should be continued until myoglobin is no longer detectable in the urine. Mannitol administration can reduce the reperfusion component of this injury. Once a flow of urine is observed, a mannitol–alkaline diuresis of up to 8 l day⁻¹ should be maintained, keeping the urinary pH greater than 6.5.

Intensive care is required with close attention to fluid balance and renal replacement therapy if required.

Figure 30.18 Extensive crush injury in a man trapped in a fallen house. The depth to which the soft tissues have been devitalised is seen clearly.

The London Blitz. This is the name given to the German air raids on London between 7 September 1940 and 11 May 1941, during which it is estimated that over 15 000 people were killed. Blitz is short for Blitzkrieg, the German for 'lightning war'.

Figure 30.19 Rescuers must be prepared for injuries to the spine. Treatment of crush syndrome should start before extrication.

Compartment syndrome

For further details see Chapter 27.

Hypothermia

Hypothermia is a major cause of morbidity and mortality during disasters in cold regions and at high altitudes. It develops rapidly if the individual is immersed in water, covered with wet clothing or exposed to windy conditions. The body responds to cold temperatures by peripheral vasoconstriction as a result of catecholamine release and shivering caused by increased tone of the musculature. If the hypothermia continues unabated, the body's metabolism declines, with bradycardia and hypoventilation. The risk of ventricular fibrillation increases at temperatures below 28°C (82.4°F) and cerebral metabolism is decreased by 6–7% per 1°C drop in temperature.

In mild hypothermia symptoms are vague, including dizziness, lethargy, joint stiffness and nausea. The skin becomes pale and cold and the patient may exhibit confusion and impaired judgement, which progresses to uncoordinated movements and slurred speech. In severe hypothermia the mental status is further impaired, leading to hallucinations, stupor, and coma. Cardiac arrest usually occurs at 20°C (68°F).

The diagnosis is based on a history of exposure and is confirmed by rectal temperatures of 35°C (95°F) or less. The principles of treatment in the field include preventing further heat loss, restoring the core temperature and avoiding ventricular fibrillation.

The patient should be moved into dry shelter and wet clothing removed. A fire should be built or a stove lit to increase the temperature of the surroundings. No fluids should be given by mouth and the patient should be warmed passively. This is a safe and simple method of treating mild hypothermia and often the only choice in the field. The patient is covered with blankets or a sleeping bag and rewarmed for 24 hours at a room temperature of 25–33°C (77–91.4°F). Blood volume should be expanded using crystalloid solutions (warmed to 45°C/111°F). In adults, 300–500 ml should be administered rapidly, with the subsequent rate of infusion adjusted according to the blood pressure.

Severe hypothermia (< 28°C/82.4°F) should be treated as a life-threatening emergency. If the patient is breathing, humidified oxygen (10 l min⁻¹) should be administered using a non-rebreathing mask. If the patient is not breathing, ventilation should be initiated with an Ambu(RT) bag connected to a humidified, heated oxygen delivery system. Supplemental oxygen is necessary to pre-

vent hypoxia, reduce the risk of ventricular fibrillation and treat pulmonary oedema.

Even after prolonged cardiac arrest, resuscitation is possible, and patients should not be declared dead until they are first rewarmed. If the patient is still not breathing, endotracheal intubation should be undertaken to maintain the airway. External cardiac compression must be continued in pulseless patients for some time. A central line or a venous cut-down should be established to administer warm fluids and for pressure measurements. A Foley catheter is passed to monitor urine output. Cardiac arrhythmias represent an immediate threat to life, but most revert spontaneously with rewarming. At core body temperatures below 30°C (86°F), the heart is usually unresponsive to defibrillation and inotropic agents, so medications are best withheld until rewarming has been achieved.

In severe hypothermia, active rewarming is required, which involves the internal or external addition of heat to the body: externally by heating blankets and warm water immersion; internally by heated humidified inhalation, peritoneal dialysis, haemodialysis or extracorporeal bypass.

Frost bite and immersion injuries

For further details see Chapter 28.

HANDING OVER

Follow-up and secondary problems

The medical aspect of disaster management does not involve a single short-term effort. It requires a long-term commitment and involvement of various disciplines. Because of the large numbers of casualties, the initial treatment received by patients is directed towards the anatomical restoration of damaged structures. This does not always translate into good functional results. There are therefore numerous patients who will need secondary procedures such as nerve, tendon and bone grafts, release of contractures and treatment of chronic infection (osteomyelitis). This second wave of patients is encountered 3–6 months following a major catastrophe and appropriate arrangements should be made to deal with this.

Designated centres

Initially, the casualties seen in major disasters are scattered amongst many hospitals. After the first few weeks most of the acute problems have been dealt with and only those patients who require longer-term treatment remain. At this point it is advisable to designate a particular hospital as a centre for patients with spinal cord injuries and complex limb trauma, who require combined orthopaedic and plastic surgical care along with rehabilitation. It concentrates resources and expertise and makes it easier to follow up these patients. This may not always be possible because of logistic reasons, as many patients prefer to be treated near their places of residence.

DISASTER PLANS

Disasters are by their very nature unforeseen events and planning for them may seem paradoxical. It has, however, been shown that

Frederic Eugene Basil Foley, 1891–1966, Urologist, Anker Hospital, St Paul, MN, USA.

disaster planning not only works but also saves lives. Unfortunately, the message only seems to register in the aftermath of a real disaster. Disaster planning is a wide field but a résumé of the important aspects follows.

Establishment of a national level disaster management organisation

This is the first step in the planning for disasters. Most developed countries already have such an agency, which can formulate policy at the national level and has the infrastructure to react quickly when the need arises.

Anticipating disasters

Areas close to active volcanoes and geological fault lines are at risk from seismic disturbances whereas regions along major rivers are liable to flood. The urban centres of all countries are now potential targets for terrorist attacks. It is important to not only carry out threat assessments but also, if possible, set up an early warning system. This allows information to be relayed to the population at risk, hopefully before a calamity occurs. For this to work there has to be close liaison with the meteorological services, seismology experts and intelligence agencies.

Evacuation planning

Evacuation of large population centres as a prelude to or in the wake of an impending disaster is a complex exercise. Yet it may be the most prudent course of action to remove as many people as possible from harm's way. Clear identification of exit routes for different areas must be determined and communicated to the populations at risk. Evacuation drills are very useful in areas that are at high risk of natural calamities and for high-rise buildings in urban areas.

Organisation of emergency services

Emergency services such as the fire brigade, police and ambulance service must have definite roles and areas of responsibility

assigned to them to ensure a smooth and coordinated response during a crisis. Members of these teams must be included in the planning phase to ensure that the final plan is practicable and reflects the situation on the ground.

Medical planning

The role of medical services has been discussed in detail in the preceding sections. Identification of hospitals able to take large numbers of casualties and the location of areas that can be used for patient holding and triage in case of mass casualties is very important. Planners should estimate realistically the number of acute patients that each hospital in a region can treat optimally. Hospitals that offer specialised services, e.g. trauma and burns centres, intensive care facilities and neurosurgical services, should be identified and their role during a major crisis made clear. Ambulance services and search and rescue organisations must be kept fully informed of the situation at all times because they will be responsible for patients reaching the appropriate destinations. Suitable hospitals in the surrounding areas must be designated as overflow hospitals in the eventuality of a very large volume of patients.

Clinical examination

LEARNING OBJECTIVES

To understand how to:

- Take a general orthopaedic history
- Perform a systematic examination of each region of the musculoskeletal system

INTRODUCTION

The components of the musculoskeletal system include the bones, joints, ligaments, muscles and tendons as well as the neurological and vascular structures. A simple system allows a concise yet comprehensive history to be taken and a reliable examination to be performed, which will reveal all of the common as well as the more rare but dangerous musculoskeletal problems that are likely to be encountered in clinical practice.

HISTORY

Introduction

- Introduce yourself and check the patient's name.
- Explain what you are going to do, obtain verbal consent and ensure that the patient is comfortable.

Take a history

- *Presenting complaint.* Start with an open-ended question. Ask the patient to 'explain what the problem is' in their own words. Ask the patient what their hopes and expectations are from the interview.
- *History of the presenting complaint* ('the three Ws'). When did you first notice the problem? What were you doing when it started? Was it sudden or did it develop gradually?
- *Associated symptoms.* Ask about the following: pain; swelling; instability – 'giving way'; mechanical symptoms (e.g. locking, clicking, clunking); loss of power; altered sensation.
- *Functional impairment.* Ask whether the patient is having difficulties performing activities of daily living: upper limb, e.g. personal hygiene, feeding; lower limb, e.g. putting on shoes and socks, standing.
- *Past medical history (PMH).* Comorbidities may affect the patient's fitness for an anaesthetic, e.g. diabetes, asthma, previous heart attack or stroke. Check for any previous problems with anaesthetics.
- *Past relevant surgical procedures.*
- *Drug history.* Ask about the following in particular: anticoagulants, steroids, aspirin, immunosuppressants, oral contraceptive pill and hormone replacement therapy.
- *Social history.* Tailor questions to the patient's condition:

patient's age; hand dominance; employment status; dependents; alcohol; smoking and hobbies; home help; accommodation – own house, residential or nursing home; use of walking aids; mental test score assessment (Summary box 31.1).

Summary box 31.1

Taking a history

- Introduce yourself and put the patient at ease
- Explain what you are doing and ensure that the patient agrees
- Presenting complaint – ask an open question
- History of presenting complaint and associated symptoms
- Functional impairment
- Past medical history and relevant surgical history
- Drug and social history

MUSCULOSKELETAL EXAMINATION

General principles

Apley described a useful and systematic approach to clinical examination. This approach is divided into three parts:

- look;
- feel;
- move.

Look

The inspection begins as soon as you enter the examination room. Look around the room for any walking aids. Remember to look at the whole patient and not just at the joint of interest. For example:

- look at the hands for rheumatoid arthritis;
- look at the eyes for Horner's syndrome;
- look for any obvious upper or lower limb or spinal deformity.

Alan Graham Apley, 1914–1996, Director of Orthopaedic Surgery, St. Thomas' Hospital, London, England.
Johann Friedrich Horner, 1831–1886, Professor of Ophthalmology, Zurich, Switzerland, described this syndrome in 1869.

Gait

The gait cycle is all of the activity between the initial contact of the foot with the ground and the succeeding initial contact of the same limb. There are two main stages: the stance phase (60%) and the swing phase (40%). Ask the patient to stand, and inspect from the front, side and back. Then, ask the patient to walk using any walking aids. Some of the types of limp that might be present are described in Table 31.1.

Focused inspection

Adequately expose the joint above and below. Expose the opposite limb for comparison. Make sure that the patient is comfortable. It may be easier for you and the patient if they remain standing for the first part of the examination. When a couch is used, make sure that it is in the centre of the room (not against the wall) so that you can work on both sides of the patient.

Remember that all joints are covered by an envelope of soft tissues and skin. Look at the *skin* for:

- surgical scars;
- bruising (may indicate recent injury or a bleeding disorder);
- erythema (e.g. cellulitis);
- ulcers (e.g. arterial, vascular or neuropathic);
- rashes;
- sinuses (e.g. secondary to osteomyelitis);
- hair loss and the presence or absence of sweating;
- pigmentations or raised lesion (e.g. café au lait spots or neurofibromas).

Look at the *soft tissues* for:

- swelling (e.g. may indicate a joint effusion);
- lumps (consider which tissue layer they are arising from);
- muscle wasting (e.g. may be secondary to disuse atrophy, neuropathy);
- muscle fasciculation (lower motor neurone pathology).

Look at the *bones* for:

- abnormal limb alignment – comparison with the other side may be helpful;
- deformity.

Feel

Ask the patient if they have any areas of tenderness. Ensure that you do not cause the patient pain – watch their face as you feel. It may be easier (especially with children) to feel the normal side first.

Table 31.1 Types of limp

Type of limp	Pathology
Antalgic	Hip joint arthritis
Trendelenburg	Weakness of hip abductors
High-stepping gait	Foot drop secondary to common peroneal nerve palsy
Spastic	Cerebral palsy
Ataxic	Cerebellar pathology

Friedrich Trendelenburg, 1844–1924, Professor of Surgery, Rostock (1875–82), Bonn (1882–95), and Leipzig, Germany (1895–1911). The Trendelenburg position was first described in 1885.

Skin

The aim of sensory testing is to establish a pattern of sensory loss. Look for a dermatomal (may indicate spinal root or peripheral nerve pathology) or glove and stocking distribution (may indicate a neuropathy, e.g. diabetes).

Perform a screening test by lightly stroking both limbs. Record whether the patient feels a difference. If none is noticed there is no need to spend more time on the neurological examination. If there is a difference then a full neurological examination should now be performed.

Soft tissues

- *Tenderness.* Try to determine the actual anatomical structure from which the pain arises (e.g. subcutaneous fat, bursae, nerves, arteries).
- *Lumps and effusions.* Determine the characteristics of any lump or effusion using Table 31.2 as a guide.
- *Pulses.* Palpate the distal pulses (or capillary return) of the limb. Recording distal neurovascular status before and after surgery is essential. Acute loss of circulation to a limb is a surgical emergency. Absence of distal pulses is an absolute contraindication to elective surgery in that limb.

Bone

Palpate the contours of the joint and assess for tenderness. For superficial joints, such as the knee, the joint line can be felt and checked for lumps and tenderness.

Move

There are three stages to assessing movement. The words used to describe a particular movement are shown in Table 31.3.

- *Active.* Ask the patient to move the joint within the limits of their pain.
- *Passive.* Move the joint yourself. Record the range of movement in ‘degrees’ (a goniometer may be helpful).
- *Stability.* Stability has a *static* and a *dynamic* component: static tests assess the integrity of the ligaments and joint (bone) surfaces; dynamic tests assess the integrity and functions of the muscles and tendons. Ask the patient to actively move the joint through its range of motion while you try to stop the movement. Record power using the Medical Research Council (MRC) grading system as illustrated in Table 31.4. Consider the muscles that drive each movement, the

Table 31.2 Swelling – an acronym for history and examination of a lump

Start	Did it appear after trauma or gradually on its own?
Where	Anatomical site and layer (skin, fat, muscle); does it move in relation to these?
External features	Size, surface and definition of margins
Lymph nodes	Are the local ones enlarged?
Liquid	Is it fluctuant? Can it be transilluminated?
Internal features	Is it hard? Is it tender?
Noise	Is there a thrill? Is there a bruit?
General	Examination of the whole patient for general lumps

Table 31.3 Terminology used to describe the direction of movement

Flexion	Forward or anterior movement of the trunk or limb
Lateral flexion	Bending of the forward-facing head and trunk to either side
Extension	Backward or posterior movement
Abduction	A movement away from the midline of the body
Adduction	A movement towards the midline of the body
Internal rotation	Rotation towards the midline of the body
External rotation	Rotation away from the midline
Supination	Movement of the forearm so that the palm faces anteriorly
Pronation	Movement of the forearm so that the palm faces posteriorly
Circumduction	A combination of flexion, abduction, extension and adduction without rotation
Inversion	Movement of the foot that directs the sole of the foot medially
Eversion	Movement of the foot that directs the sole of the foot laterally
Retraction	Backwards movement of the head, jaw or shoulders

peripheral nerves that supply them and the nerve root values (Table 31.5).

In the following sections, in addition to the approach of 'Look, Feel, Move', we have included details of special tests for each joint as well as neurological examination of the limb. The peripheral nerve examination comprises sensory and motor testing, reflexes, tone and coordination and proprioception (Summary box 31.2).

Summary box 31.2

Musculoskeletal examination

- Introduce yourself and put the patient at ease
- Assess the gait
- Look
- Feel
- Move
- Special tests
- Neurological examination
- Pulses

Table 31.4 The Medical Research Council grading system of muscle power

Grade	Description
0	No movement
1	Flicker of movement
2	Active movement with gravity elimination
3	Active movement against gravity
4	Active movement against resistance but power less than full
5	Normal power

CLINICAL EXAMINATION OF THE SPINE

The spinal column consists of 33 vertebrae with 23 intervertebral discs. This is supported by numerous ligaments and para-spinal muscles.

When observed from the front (coronal plane) with the patient standing and the hips and knees fully extended, the head should be centred over the sacrum. A 'plumb line' dropped from the spinous process of C7 should fall through the gluteal crease (Fig. 31.1). If it falls to either side of the cleft, lateral tilt of the spine is present. The ear, shoulder and greater trochanter of the hip should lie in the same vertical plane. When the patient is observed from the side, assess the four physiological sagittal plane curves (cervical and lumbar lordosis, and the thoracic and sacral kyphosis) (Fig. 31.2).

Cervical spine

Look

Ensure that the shoulders, back muscles and scapulae can be seen. Look for muscle wasting and asymmetry of the neck creases and check that the shoulders are level and that there is a normal cervical lordosis (range 20–40°).

Feel

Stand behind the patient and support the patient's chin:

- *Soft tissues.* Feel for spasm of the para-spinal muscles.
- *Bone.* Palpate the spinous processes (tenderness and alignment); the spinous processes of C7 (vertebra prominens) and T1 are usually large and are easily palpable at the base of the neck.

Move

Motion occurs in three planes: flexion/extension, bending and rotation (Fig. 31.3):

- *Flexion (45°)/extension (55°).* Ask the patient to bend their neck forwards – place the chin on the chest. Measure the

**Figure 31.1** Plumb line.

Table 31.5 Peripheral nerves

Root level	Sensation	Motor	Reflex
C5	Lateral upper arm	Deltoid	Biceps
C6	Lateral forearm	Wrist extension	Brachioradialis
C7	Middle finger	Triceps	Triceps
C8	Little finger	Finger flexors	–
T1	Medial forearm	Interossei	–
L1	Anterior thigh	Psoas	–
L2	Anterior thigh/groin	Quadriceps	–
L3	Anterior and lateral thigh	Quadriceps	–
L4	Medial leg and foot	Tibialis anterior	Knee jerk
L5	Lateral leg and first dorsal web space	Extensor hallucis longus	–
S1	Lateral and plantar foot	Gastrocnemius/perineals	Achilles
S2–S4	Perianal	Bladder and foot intrinsic	–

**Figure 31.2** Standing sagittal profile of cervical and lumbar lordosis (a), and thoracic (b) and sacral (c) kyphosis.

Figure 31.3 Cervical spine flexion/extension (a and b), rotation (c) and bending (d).

distance from the chin to the sternum. Ask the patient to extend their neck by looking up at the ceiling.

- *Right/left bending* (40°). Ask the patient to lay their ear on their ipsilateral shoulder.
- *Right/left rotation* (70°). Ask the patient to look over each shoulder while not moving the chest wall.

Neurological

Focus your examination on the C5 to T1 nerve roots. These supply the upper extremities (Fig. 31.4).

Figure 31.4 Spurling's test for cervical spine nerve root entrapment. Extend the cervical spine and rotate the head to each shoulder in turn. The presence of a shooting pain down the arm may indicate cervical nerve root compression.

Thoracic spine

Pathology commonly presents with pain and deformity. The thoracic spine is normally convex with a gentle kyphosis (normal range 20–45°).

Look

Ensure that the front and the back from the neck to the gluteal cleft can be visualised. Note skin markings (e.g. café au lait spots, hairy patches). These may suggest occult neurology or bony pathology.

- *Front*. Asymmetry of the shoulder and rib cage suggests scoliosis.
- *Back*. Look for a difference in the height of the iliac crests (pelvic tilt). Assess for coronal plane deformity such as scoliosis (lateral curvature of the thoracic spine with rotation). A rib hump suggesting a structural scoliosis may be visible.
- *Side*. Assess for sagittal plane deformity such as an increased kyphosis.

Feel

Palpate with one hand supporting the patient's pelvis.

Move

Range of motion is limited in the thoracic spine:

- '*Forward bending test*' (Fig. 31.5). Ask the patient to bend forwards to touch their toes:
 - *structural scoliosis*: a rib hump will increase in size (bulge posteriorly on the thoracic convex side) as the patient bends forwards; this is diagnostic of idiopathic thoracic scoliosis (rotatory deformity);
 - *functional scoliosis*: the spine straightens as the patient bends forwards and no rib hump is visible; this flexible deformity is

Figure 31.5 Forward bending test.

secondary to other abnormalities such as abnormal leg lengths and muscle spasm in the lumbar region.

- *Lateral bending* can be used to assess the flexibility of a scoliosis. Radiographs are taken in this position to supplement the assessment.

Lumbar spine

Examination should include the pelvis, hips, lower limbs, gait and peripheral vascular system as well as the lumbar region. Irritation of nerves in the lumbar spine can mimic problems in the lower limb. Always consider referred pain.

Look

- *Back.* Check the skin at the base of the spine for hairy tufts and dimples (underlying spina bifida). Prominence of the spinal muscles on one side may be the result of muscle spasm secondary to pain.
- *Side.* The lumbar spine has a smooth concavity known as the lumbar lordosis (normal range is 40–60°). Muscle spasm is a cause of loss of the normal lordosis.

Feel

Feel for any ‘step-off’ in the spinous processes. This may indicate forward slippage of one of the vertebrae on another.

Move

Movement occurs in flexion, extension, lateral bending and rotation (Fig. 31.6). Record the motion in each plane in degrees. Remember that a significant portion of lumbar flexion is achieved through the hip joint.

- *Forward flexion* is a measure of lumbar flexibility. The skin of the lumbar spine stretches as the patient bends forwards. To measure flexion, place the tip of your thumb over the T12–L1 junction and the tip of your index finger of the same hand over the lumbosacral junction. Ask the patient to bend forwards and touch the toes (normal range 40–60°). Measure the distance by which your thumb and the tip of your index finger separate.
- *Lateral bending.* Ask the patient to slide their right hand down the outer side of their right leg and then their left hand down the outside of their left leg. Note the distance that each hand moves down that side of the thigh.
- *Rotation.* Stand behind the patient and hold their pelvis still with both hands. Ask the patient to twist around and look over their shoulder. Note the angle that the shoulder girdle forms with the pelvis (range 3–18°).

Special tests

- *Lasègue’s straight leg raise test* (Fig. 31.7). This test increases tension along the sciatic nerve (L5 and S1 nerve roots). With the patient supine, elevate the leg with the knee bent to check pain-free movement of the hip. Then, the knee is straightened, allowing the hip to extend until tension is removed from the hamstring muscles. Finally, the ankle is dorsiflexed firmly, tugging on the sciatic nerve. If the patient experiences pain running down the leg the test is positive.
- *Contralateral stretch test.* Elevate the asymptomatic leg; if pain is reproduced in the other leg the test is considered positive (Summary box 31.3).

Figure 31.6 Lumbar flexion/extension, lateral bending (a) and rotation (b).

Charles Ernest Lasègue, 1816–1863, Professor of Medicine, The University of Paris, and Physician, La Salpêtrière, Paris, France.

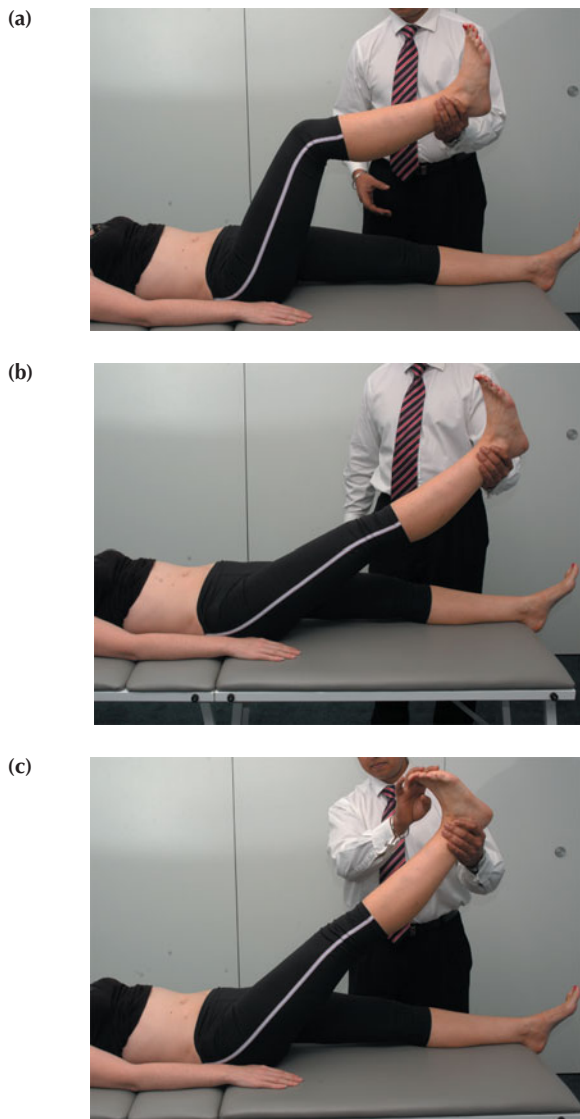

Figure 31.7 Lasègue's straight leg test.

Summary box 31.3

Spine examination

Inspection of the standing patient

- From the front and back (coronal plane)
- From the side (sagittal plane)

Palpation

- Palpation of the posterior bony elements and the para-spinal muscles

Move

- Assess flexion, extension, lateral rotation and bending

Neurological

- Assess sensation, tone, power, reflexes, proprioception and coordination

Special tests

- Spurling's test
- Forward bending test
- Lasègue's straight leg test
- Contralateral stretch test

CLINICAL EXAMINATION OF THE HAND AND WRIST

The hand and wrist should be thought of as one functional unit. The muscles may be divided into extrinsic (the muscle bellies in the forearm) and intrinsic (origins and insertions within the hand alone). The 'flexors' (volar side) flex the wrist and fingers and the 'extensors' (dorsal surface) extend the digits and fingers.

Look

Inspect the posture of both hands. A nerve lesion will produce a specific resting position (e.g. an ulnar nerve lesion will produce clawing of the little and ring fingers).

- *Skin*. Assess for scars, discolouration (café au lait spots, erythema) and loss of hair. The nails may reveal systemic disease (e.g. psoriatic pitting). Look for tight bands in the palm (Dupuytren's contracture). Loss of sweating is seen in complex regional pain syndrome.
- *Soft tissue*. Centrally located swellings at the wrist may indicate a ganglion arising from the wrist joint itself; de Quervain's tenosynovitis may present with a swelling around the radial styloid.
- Check for thenar, hypothenar (Fig. 31.8) and intrinsic muscle wasting. To assess thenar eminence wasting, place the hands side by side with the thumbs upwards and look down and

Figure 31.8 Thenar (a) and hypothenar (b) wasting.

Baron Guillaume Dupuytren, 1777–1835, Surgeon, Hôtel Dieu, Paris, France, described this condition in 1831.
Friedrich Joseph de Quervain, 1868–1940, Professor of Surgery, Berne, Switzerland, described this form of tenosynovitis in 1895.

compare the thenar regions. Patterns of muscle wasting are shown in Table 31.6.

- **Bones.** Look for bony deformity (dinner fork deformity, Colles' fracture). Typical bony deformities are described in Table 31.7.

Feel

- **Skin.** If there is any question of abnormal sensation on a simple stroke test comparing both sides, proceed to the two-point discrimination test using the sharp ends of a paper clip. Record the minimum distance between the tips of the paper clip at which the patient is able to recognise two points. Table 31.8 describes the anatomical region supplied by the median, ulnar and radial nerves.
- **Pen sliding test.** To assess the absence or presence of sweating, slide a pen along the radial border of the index finger. If the pen slides smoothly, this may indicate loss of sweating.
- **Soft tissue:**
 - **blood vessels:** check the radial and ulnar artery pulses; assess the capillary refill time, which is normally less than 2 s; Allen's test should be performed before surgery (Table 31.9 and Fig. 31.9);
 - **nerves:** compressive neuropathies are most commonly seen affecting the median nerve [see Tinel's (Fig. 31.10a) and Phalen's (Fig. 31.10b) test in Table 31.9];
 - **palmar fascia:** feel for palmar thickening and skin pits; long finger-like structures (cords), most commonly affecting the ring and little fingers, are suggestive of Dupuytren's disease.
- **Bones.** Palpate from the radial to the ulnar side of the wrist joint. In the trauma setting, palpate the anatomical snuff box (Fig. 31.11). A fracture of the scaphoid may cause tenderness.

Table 31.6 Patterns of muscle wasting in the hand

Thenar wasting	Median nerve palsy (C8)
Hypothenar wasting	Ulnar nerve palsy (T1)
Intrinsic wasting	Ulnar nerve palsy (T1)

Table 31.7 Bony deformities of the hand

Anatomical site	Name	Association
Distal interphalangeal joint (DIPJ)	Heberden's nodes	Osteoarthritis
Proximal interphalangeal joint (PIPJ)	Buchard's node	Osteoarthritis
Hyperextension of the metacarpo-phalangeal joint (MCPJ), flexion of the PIPJ and hyperextension of the DIPJ	Boutonnière deformity	Rheumatoid arthritis
Hyperextension of the MCPJ and PIPJ and flexion of the DIPJ	Swan neck deformity	Rheumatoid arthritis
Flexion of the MCPJ with hyperextension of the interphalangeal joint	Z deformity of the thumb	Rheumatoid arthritis
Subluxation of the MCPJ	Ulnar drift	Rheumatoid arthritis

The scaphoid tubercle, pisiform and the hook of hamate are all palpable on the volar aspect of the wrist.

Move

The wrist can be moved into flexion and extension, and ulnar and radial deviation.

- **Wrist.** Extension is tested by asking the patient to push the hands together into a 'prayer' position (Fig. 31.12a). If there is loss of extension, the palms will not meet and/or one forearm will be dropped. It is essential that the elbows remain at the same level. Palmar flexion is tested in a similar fashion but with the hands pointing down and the back of the hands in contact (Fig. 31.12b). Ulnar and radial deviation are tested by taking the patient's hand in your own and moving the hand into these directions.
- **Hand.** A general screening assessment is to ask the patient to roll up their fingers from full extension to full flexion. This will reveal a trigger finger.

Extensors and flexors

Asking the patient to grip two of your fingers in their fist tests the power of the extensors of the wrist (radial nerve) because they are needed to brace the wrist. It also tests the power of the flexors in the forearm (median nerve). Asking the patient then to extend and spread their fingers apart against resistance tests the intrinsic muscles of the hand (mainly the ulnar nerve).

Finger flexors

- **Superficialis tendon test.** The flexor digitorum profundus (FDP) usually has one muscle belly from which tendons to all of the fingers arise. The FDP can be immobilised by holding all of the fingers in extension; this allows the superficialis tendon to be tested in isolation. Hold all of the fingers in full extension except the finger to be tested. Ask the patient to actively flex that finger. If the test finger is able to flex, the superficialis tendon to that finger is working. Repeat for the other fingers individually (Fig. 31.13).

Abraham Colles, 1773–1843, Professor of Surgery, The Royal College of Surgeons in Ireland, and Surgeon, Dr. Steven's Hospital, Dublin, Ireland.

Edgar van Nuys Allen, 1900–1961, Professor of Medicine, The Mayo Clinic, Rochester, MN, USA.

Jules Tinel, 1879–1952, Physician, Hôpital Beaujon, Paris, France.

George S. Phalen, Contemporary, Orthopaedic Surgeon, The Cleveland Clinic, Cleveland, OH, USA.

William Heberden (Snr), 1710–1801, a Physician who practised first in Cambridge, and later in London, England.

Charles Jacques Bouchard, 1837–1915, Physician, Dean of the Faculty of Medicine, Paris, France.

Boutonnière is French for 'button-hole'.

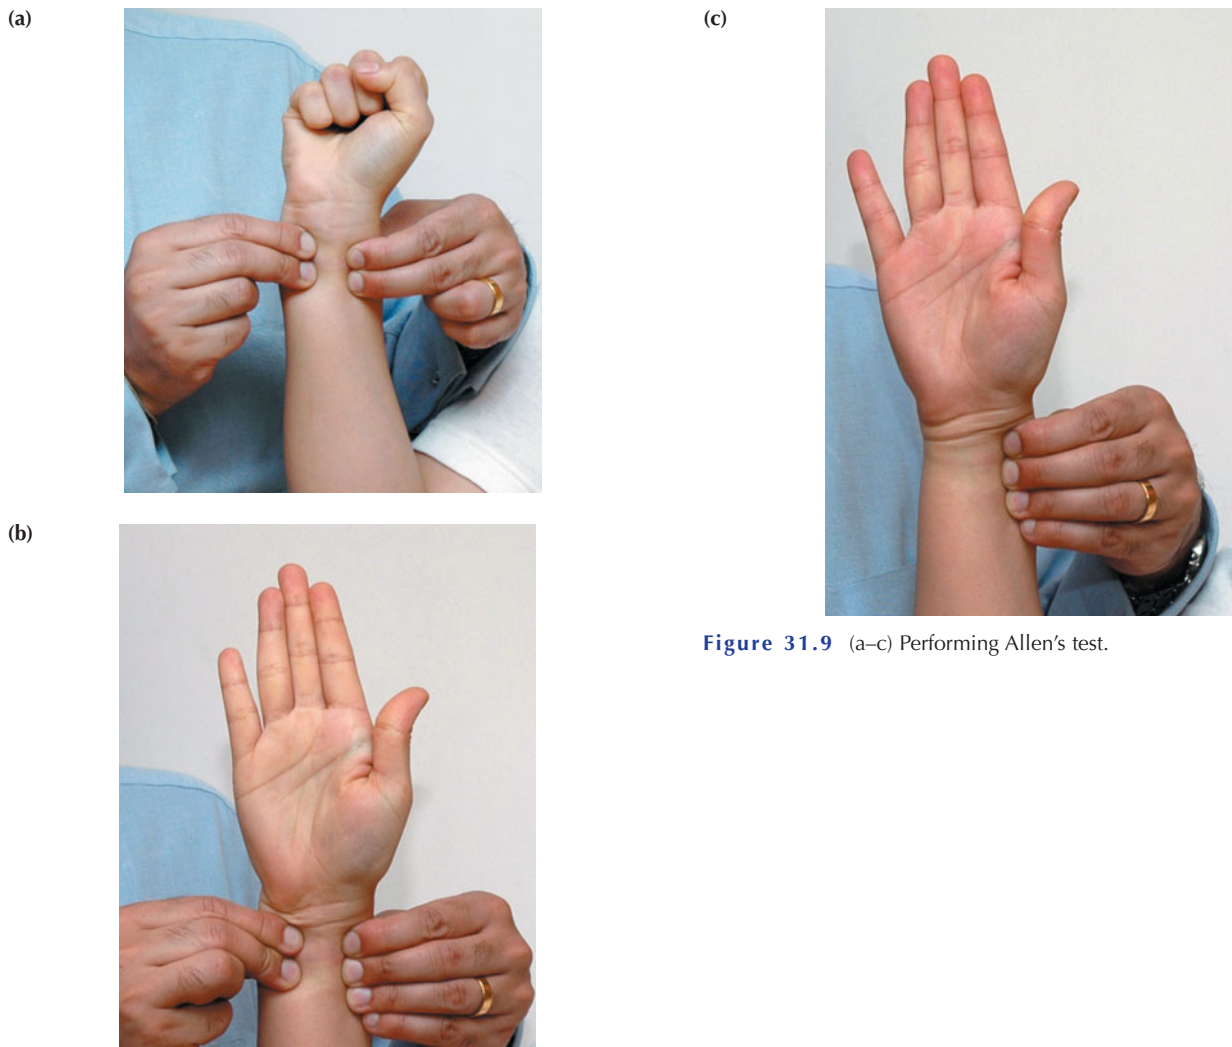

Figure 31.9 (a–c) Performing Allen's test.

Table 31.8 Sensory distribution of the nerve supply to the hand

Nerve	Sensory distribution
Ulnar	Little finger and ulnar half of the ring finger
Median	Thumb, index, middle and radial half of the ring finger
Radial	Base of the thumb on the dorsum of the hand

Table 31.9 Special hand tests

Test	Technique	Significance
Allen's test	Elevate the hand and apply digital pressure on the radial and ulnar arteries to occlude them. Ask the patient to make a fist several times. The tips of the finger should go pale. Release each artery in turn and observe the return of colour	Tests the adequacy of the blood supply to the hand from the radial and ulnar arteries and the arcade between them
Tinel's test	Tap over the nerve of interest. Tingling may indicate nerve compression	Identifies compression of a peripheral nerve
Phalen's test	Place the wrist in maximum flexion with the elbows extended	Compression of the medial nerve causes paraesthesia
Froment's sign	Ask the patient to grip a sheet of paper between the index finger and thumb of both hands. Grip the paper yourself similarly. Ask the patient to resist as you attempt to pull the paper away.	A positive test indicated by flexion of the thumb interphalangeal joint suggests weakness of the adductor pollicis muscle supplied by the ulnar nerve. Recruitment of the median nerve-innervated flexor pollicis brevis explains the thumb posture

Figure 31.10 (a) Tinel's test; (b) Phalen's test.

Figure 31.12 Testing the range of (a) wrist extension; (b) wrist flexion.

Figure 31.13 Testing the (a) flexor digitorum superficialis; (b) flexor digitorum profundus.

Figure 31.11 Palpating the anatomical snuff box between the tendons of extensor pollicis longus and abductor pollicis brevis.

Other muscles

- **Thenar eminence:**
 - The abductor pollicis brevis, opponens pollicis and flexor pollicis brevis can be tested together by opposing the thumb to the little finger.
 - The flexor pollicis longus supplied by the anterior interosseus nerve (branch of the median nerve) can be tested by asking the patient to bring the tips of the thumb and index finger together (the 'OK' sign – Fig. 31.14).
 - The integrity of the extensor pollicis longus tendon is tested by asking the patient to lift the thumb off a table with the palm flat on the table (Fig. 31.15).
- **Adductor pollicis.** Test using Froment's sign (see Table 31.9 and Fig. 31.16).

Thumb abductor pollicis brevis

This muscle is supplied by the median nerve. With the hand lying flat on a table with the palm facing upwards, ask the patient to raise the thumb towards the ceiling. Ask the patient to resist as you push the thumb back towards the palm (Fig. 31.17) (Summary box 31.4).

Summary box 31.4

Hand and wrist examination

Inspection of the standing patient

- Dorsum and palm – asymmetry, deformity, muscle wasting

Inspection of the supine patient

- Skin, scars, soft tissues
- Palpation of bony structures and joints of the hand

Movements

- Wrist – flexion and extension, ulnar and radial deviation
- Hand – thumb movements, metatarsophalangeal joints and small joints of the hand

Special tests

- Allen's test
- Tinel's and Phalen's test for the median nerve
- Froment's sign
- Finkelstein's test

Figure 31.14 Test for flexor pollicis longus supplied by the anterior interosseus nerve.

Jules Froment, 1878–1946, Professor of Clinical Medicine, Lyons, France.

Figure 31.15 Testing the integrity of extensor pollicis longus.

Figure 31.16 Froment's sign; the arrow illustrates the flexed posture of the thumb interphalangeal joint, indicating weakness of the ulnar nerve-innervated adductor pollicis muscle.

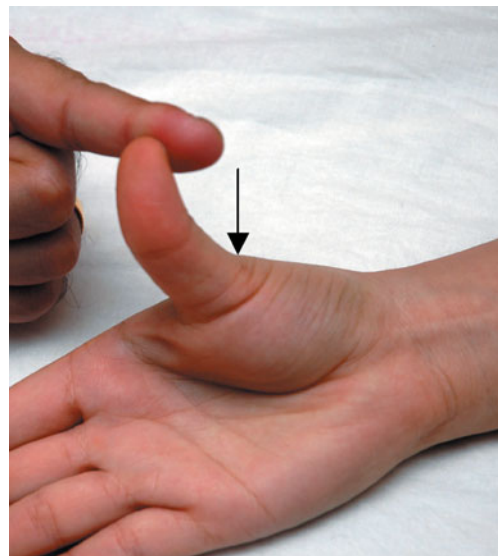

Figure 31.17 Testing the power of the abductor pollicis brevis supplied by the median nerve.

CLINICAL EXAMINATION OF THE ELBOW

The elbow is a hinge joint formed by the articulation of the ulna and radius with the humerus.

Look

Look for obvious asymmetry, abnormal posture and deformity (cubitus varus or valgus).

- *Skin.*
- *Soft tissues.* Look for any swellings, e.g. olecranon bursa, rheumatoid nodules, gouty tophi.
- *Muscle wasting.* Examine the biceps and triceps muscle bulk. Note that compression of the ulnar nerve at the elbow leads to wasting distally in the hypothenar eminence and intrinsic muscles of the hand – assess the hand for the presence of clawing and wasting.
- *Bone.* With the elbow in extension, look at the axis between the upper arm and forearm. There is a physiological valgus ('carrying angle') of 9–14° (2–3° greater in women) (Fig. 31.18). This angle allows the elbow to be tucked into the waist depression above the iliac crest:
 - cubitus varus (gun-stock deformity): the carrying angle is reversed, secondary to a supracondylar fracture;
 - cubitus valgus: the carrying angle is increased, caused by malunion of a distal humeral fracture;
 - there is normally a physiological hyperextension of the elbow (5°).

Feel

- *Soft tissues.* An effusion may be elicited by performing a cross-fluctuation test. The ulnar nerve can be rolled under your fingers placed between the medial epicondyle and the olecranon. Test the distal sensation in the hand and assess the vascular status.
- *Bones.* The three palpation landmarks are the medial and lateral epicondyles and the apex of the olecranon. These form an equilateral triangle when the elbow is flexed to 90°. The radial head is palpated with the examiner's thumb while the other hand pronates and supinates the forearm. On the medial side, palpate the medial epicondyle. Posteriorly, palpate the olecranon fossa.

Move

- *Flexion–extension.* The normal range is from –5° (slight hyperextension) to 150°. Ask the patient to bend the elbow from the fully straight position (Fig. 31.19).
- *Pronation and supination.* With the elbows at 90° and the palms facing upwards (full supination), ask the patient to turn the forearm so that the dorsum of the hand faces upwards (full

Figure 31.18 Carrying angle of the elbow illustrating the normal cubitus valgus.

Figure 31.19 (a) Elbow flexion; (b) elbow extension.

Figure 31.20 Testing forearm rotation: (a) mid-prone position; (b) full supination; (c) full pronation.

pronation) (Fig. 31.20). The normal values are 70° pronation and 90° supination.

Special tests and diagnoses

Tennis elbow and golfer's elbow

These are inflammatory processes of the tendons that attach the large muscle mass of the forearm to the lateral or medial epicondyle.

- *Medial epicondylitis* (synonym = golfer's elbow). The medial epicondyle is the common origin of the forearm flexors and the

pronator muscle. Palpate the medial epicondyle for tenderness. The diagnostic test is resisted wrist flexion, which reproduces the pain over the medial epicondyle.

- *Lateral epicondylitis* (synonym = *tennis elbow*). The lateral epicondyle is the common origin of the forearm extensors. Palpate for tenderness – usually just distal (5–10 mm) to the epicondyle near the origin of the extensor carpi radialis brevis muscle. Wrist extension against resistance with the elbow extended should provoke the patient's symptoms (Summary box 31.5).

Summary box 31.5

Elbow examination

Inspection of the standing patient

- Front – asymmetry, carrying angle, deformity
- Back – olecranon fossa

Inspection of the supine patient

- Skin, scars, soft tissues, deformity
- Palpation of bony structures

Movements

- Flexion and extension, pronation and supination

Special tests

- Tennis and golfer's elbow
- Stability testing
- Ulnar nerve compression
- Biceps tendon

CLINICAL EXAMINATION OF THE SHOULDER

Pain arising from the shoulder joint may be felt anterolaterally. Referred pain may present from the cervical spine, heart, mediastinum and the diaphragm.

Look

Assess the attitude of the limb.

- *Skin*. Check for surgical scars. An anterior scar is used for the deltopectoral approach. At the side, the deltoid splitting approach and lateral arthroscopic portals may be seen. Posteriorly, arthroscopic portal sites can be seen.
- *Soft tissues*. Wasting of the deltoid muscle is commonly seen after shoulder dislocation when there is a temporary loss of function of the axillary nerve that supplies it.
- *The rotator cuff* comprises four muscles: supraspinatus, infraspinatus, subscapularis and teres minor. Wasting of these muscles may occur following a rotator cuff injury.
- *Bone*. Look for any obvious deformity or prominence. A fracture of the middle third clavicle is the commonest cause. A dislocation may be suspected by a loss of normal shoulder contour. The more common anterior dislocation often presents with an anterior bulge and a squared-off shoulder.

Feel

Generalised pain in the shoulder may arise from the neck or the shoulder joint itself. More localised pain is often indicative of acromioclavicular joint pathology.

- *Skin*. Test sensation in the upper part of the lateral aspect of the arm ('regimental badge area') (Fig. 31.21). Loss may

Figure 31.21 The area of skin supplied by the axillary nerve – the 'regimental badge area'.

indicate damage to the axillary nerve (following shoulder dislocation).

- *Bones*. Palpate the acromioclavicular and sternoclavicular joints and the clavicle.

Move

Differentiate between movements of the shoulder joint and scapulothoracic movement of the scapula on the chest wall. Patients with a painful shoulder will commonly move from the scapulothoracic joint. Stabilise the scapula by placing the thumb over the coracoid process and the fingers of the same hand over the spine of the scapula. Start in the 'neutral position' with the arms by the side, elbows extended and the palm facing forwards. Note any pain throughout the range of movement (Fig. 31.22).

- *Forward flexion*. Ask the patient to raise their hands in front to touch the ceiling while keeping the elbows extended (0–180°).
- *Extension*. Ask the patient to extend both arms behind (0–30°).
- *Abduction*. Shoulder abduction involves the glenohumeral joint and scapulothoracic movement. The first 60° of movement is mainly at the glenohumeral joint. Beyond this the scapula begins to rotate on the thorax and final movements are almost entirely scapulothoracic. Raise the arms sideways until the fingers point to the ceiling (180°).
- *Adduction*. Ask the patient to touch their other shoulder tip.
- *Internal rotation*. Ask the patient to touch their back with the dorsum of the hand and to raise their hand up the back as high as possible (normal range is thoracic spine level T7–9).
- *External rotation*. With the arms by the sides, bend the elbow to 90° and rotate the forearms to the mid-prone position. Ask the patient to separate their hands as much as possible (0–40°).

Special tests and diagnoses

Impingement syndrome

This is impairment of rotator cuff function within the subacromial bursa. It may lead to inflammation (tendinitis) or a partial or

(a)

(b)

(c)

(d)

(e)

Figure 31.22 Movements of the shoulder: (a) forward flexion; (b) extension; (c) adduction; (d) internal rotation; (e) external rotation.

full-thickness tear. Impingement is characterised by pain and weakness on abduction and internal rotation.

- *Painful arc test* (Fig. 31.23). Ask the patient to abduct their arms from their sides. The presence of pain from 60° to 120° is positive.
- *Jobe's test (empty can)* (Fig. 31.24). Ask the patient to abduct the arm to 90° elevation in the scapula plane with full internal rotation (empty can position). Ask the patient to resist downward pressure. The presence of pain is a positive test.

Shoulder instability

Instability may be defined as a shoulder that slips in and out of joint (dislocation) more than once or twice, or frequently slips partially out of joint and then returns on its own. Instability can be anterior, posterior, inferior or multidirectional.

- *Apprehension test* (Fig. 31.25). With the patient supine or standing, flex the elbow to 90° and abduct the shoulder to 90°. Now externally rotate the shoulder. Apprehension indicates anterior instability (Summary box 31.6).

Summary box 31.6

Shoulder examination

Inspection of the standing patient

- Front – asymmetry, deformity
- Side – muscle wasting
- Back – muscle wasting, scapula

Inspection of the supine patient

- Skin, scars, soft tissues, deformity
- Palpation of shoulder girdle (sternum to scapula)

Movements

- Flexion and extension, abduction and adduction, internal and external rotation

Special tests

- Impingement syndrome – painful arc, Jobe's test, Hawkins' test
- Shoulder instability – apprehension, relocation test, sulcus sign
- Rotator cuff assessment
- Acromioclavicular joint pathology
- Frozen shoulder vs. glenohumeral osteoarthritis

Figure 31.23 Painful arc test for rotator cuff impingement.

Figure 31.24 Jobe's test for rotator cuff impingement.

Figure 31.25 Anterior apprehension test for anterior shoulder instability.

CLINICAL EXAMINATION OF THE HIP JOINT

The hip is a synovium-lined ball and socket joint. Typical clinical diseases of the hip that may be encountered in children and adults are shown in Table 31.10.

A patient complaining of hip pain should undergo a careful examination of the spine, abdomen, pelvis, groin and thigh. In addition, consider a gynaecological examination in women.

Look

With the patient standing, look at the front, side and back of the hip. Look around the room for walking aids and heel raises in the shoes.

- *Skin.* Look for scars and sinuses.
- *Soft tissues.* Muscle wasting may be present as a consequence of hip arthritis or primary muscle or neurological disease.
- *Bone.* Look at the posture of the limb and assess for adduction deformity; fixed adduction may be present in severe osteoarthritis and cerebral palsy, and makes the leg appear short because the pelvis is tilted (apparent shortening).

Feel

- *Soft tissues.* Tenderness overlying the greater trochanter may suggest trochanteric bursitis or an abductor enthesopathy.

Table 31.10 Common clinical diseases of the hip in children and adults

Children	Adults
Developmental dysplasia of the hip	Primary osteoarthritis
Transient synovitis of the hip	Secondary osteoarthritis
Perthe's disease	Inflammatory arthritis
Septic arthritis and osteomyelitis	Avascular necrosis
Slipped capital femoral epiphysis	Labral tears
Juvenile idiopathic arthritis	Referred pain

Move

The hip joint can be moved into flexion, extension, abduction and adduction and internal and external rotation (Fig. 31.26). True hip movement ends when the pelvis begins to move. To detect true hip movement simultaneously place a finger/hand on the anterior superior iliac spine (ASIS) contralateral to the hip being examined. Remember to compare both sides.

Passive movement

Hip flexion and extension (120–0°)

The patient is asked to lie on their back and then roll themselves into a ball, flexing the hips and the spine fully. A comparison of the flexion of the two hips can be made in this position. The patient is then asked to hold onto one knee with both hands (thereby fixing the pelvis in flexion) and the other leg is allowed to extend down onto the couch. A note is made of any fixed flexion deformity (inability of the thigh to come down onto the couch). This hip is then returned to full flexion and the patient grasps that knee while dropping the other hip into extension. This modified Thomas's test is the most comfortable and accurate way of measuring flexion and extension of the hip (Fig. 31.27).

Rotation

- *Internal rotation (45°).* With the hip flexed to 45° and the knee in 90° of flexion, hold the front of the knee with one hand and the foot with the other. Internally rotate the hip (the foot goes outwards), then externally rotate the hip (the foot goes in). The angle that the tibia makes with the vertical indicates the range of movement. Pain at the extremes of movement suggest inflammation in the hip.
- *Abduction (40°).* The hip should be abducted by moving the leg away from the midline with the other hand on the patient's pelvis to detect any tilt in the pelvis.

Special tests

- *Trendelenburg test* (Fig. 31.28). Face the patient and ask them to place their hands on the palm of your hands for support. Then ask them to stand first on one leg, then the other. Increased pressure from the opposite hand as they take weight through the weak hip indicates a positive Trendelenburg test.
- *Leg length discrepancy (LLD).* The inequality may be in the hip joint, femur, tibia, ankle or foot or a combination of these. The pathology may be from the bone being too short or too long (Summary box 31.7). When assessing LLD, place both legs in the same position. For example, if there is an adduction deformity

Hugh Owen Thomas, 1834–1891, General Practitioner, Liverpool, England. He is regarded as the founder of Orthopaedic Surgery. He never held a hospital appointment preferring to treat patients in their own homes.

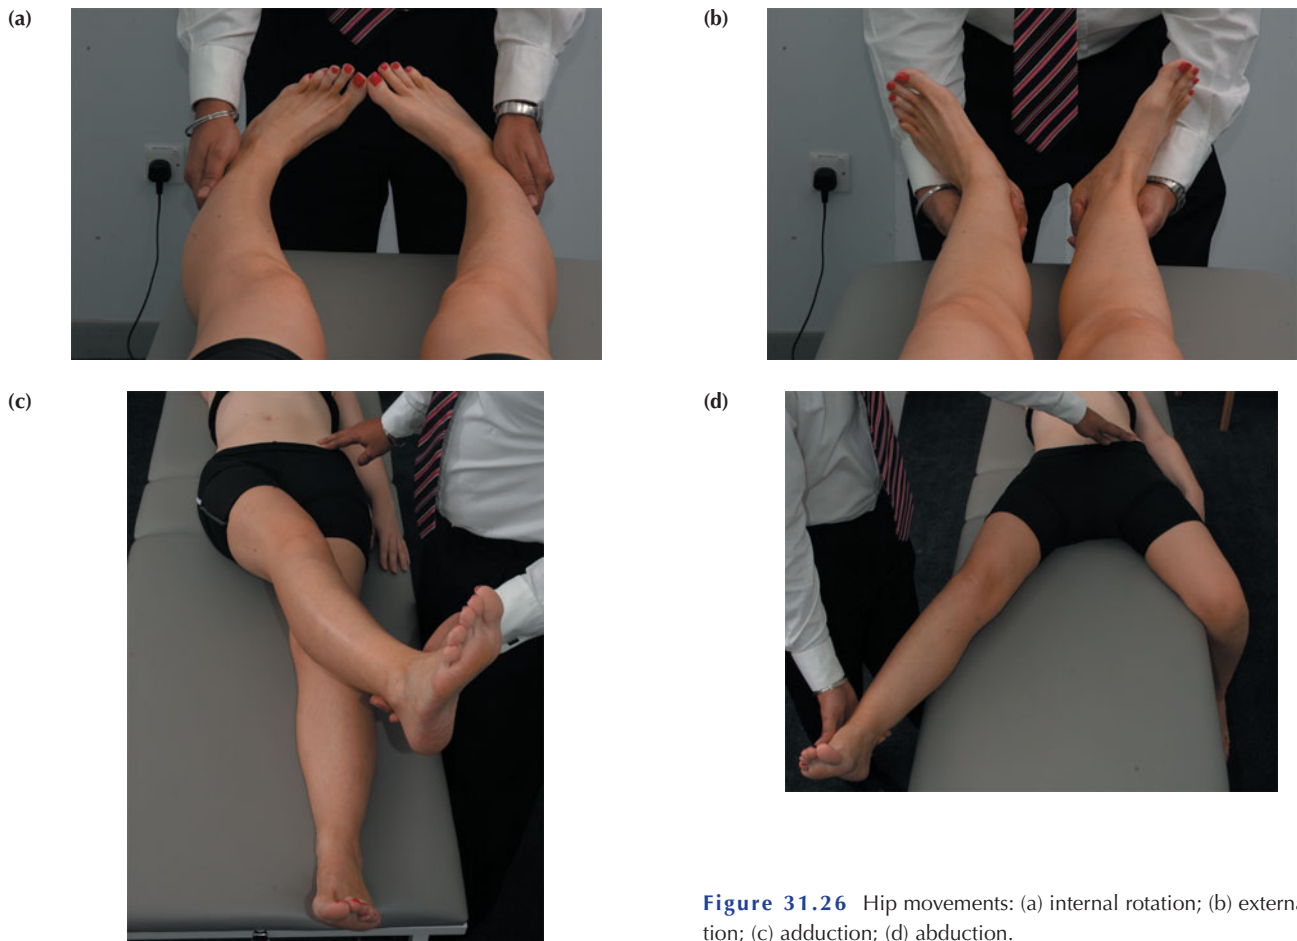

Figure 31.26 Hip movements: (a) internal rotation; (b) external rotation; (c) adduction; (d) abduction.

present in the affected leg, place the good leg in the same degree of adduction. LLD can be caused by a real difference in the leg lengths (the bones are different lengths) or by a deformity that makes the leg appear short because the pelvis must be tilted to get the leg onto the ground. The first is called ‘real’ LLD. The second is called ‘apparent’ LLD. Both are real to the patient but the cause and therefore the treatment are different.

- *Gait.* Hip disease can present with an altered gait pattern. The common types of abnormal gait are described in Table 31.11 (Summary box 31.8).

Summary box 31.7

Common causes of limb length inequality in the hip

- Osteoarthritis
- Hip fracture
- Hip dislocation
- Hip dysplasia
- Avascular necrosis
- Fixed flexion deformity

Table 31.11 Common limps observed in hip disease

Gait Pattern	Description
Weak: Trendelenburg	May lead to pelvic sway or tilt. The patient swings the body over the weak hip to stay in balance when it is weight bearing
Painful: antalgic	The rhythm is dot-dash, with a short period spent on the painful limb
Unbalanced: broad-based	May be caused by ataxia, e.g. cerebellar pathology. The rhythm also tends to be disordered
Loss of muscle control: high-stepping	May be due to loss of proprioception or a drop foot. This leads to difficulty in clearing the toes during the swing phase and the patient compensates by externally rotating the leg and flexing the hip and knee
Deformity: in-toeing	Can be caused by persistent femoral anteversion. The foot may catch on the back of the calf of the weight-bearing leg, tripping the patient

Figure 31.27 Modified Thomas's test for assessing a fixed flexion deformity. A fixed flexion deformity of the right hip is indicated by an inability to fully straighten the right leg (arrow).

(a)

(b)

Figure 31.28 Trendelenburg test.

Summary box 31.8

Hip examination

Inspection of the standing patient

- Front – pelvic tilt, rotational deformity
- Side – lumbar lordosis
- Back – pelvic tilt, scoliosis, gluteal wasting
- Gait – Trendelenburg, antalgic

Inspection of the supine patient

- Skin, scars, soft tissues, deformity
- Palpation of the anterior joint line, adductor origin, greater trochanter, ischial tuberosity

Movements

- Flexion and extension
- Abduction and adduction
- Internal and external rotation

Special tests

- Thomas's test
- Leg length assessment – real/apparent
- Trendelenburg test
- Snapping hip
- Impingement tests

CLINICAL EXAMINATION OF THE KNEE

The knee is a synovial hinged joint. There are three compartments: medial, lateral and patellofemoral. The quadriceps, quadriceps tendon, patella, patella tendon and tibial tuberosity comprise the extensor mechanism of the knee.

The anterior cruciate ligament (ACL) provides primary restraint to anterior displacement of the tibia. The posterior cruciate ligament (PCL) provides posterior restraint of the tibia. The medial collateral ligament (MCL) resists valgus and external rotation forces whereas the lateral collateral ligament (LCL) resists varus forces.

Look

Look at the front, sides and back of both knees and for any walking or mobility aids or external appliances.

- *Skin.* Check for scars.
- *Soft tissues.* Look for wasting of the quadriceps and swelling in front of and behind the knee.
- *Bone.* Look for overall alignment (varus or valgus deformity). Measure the intermalleolar distance if a valgus deformity is present. With varus deformity, measure the distance between the medial aspect of both knees. From the side of the knee look for fixed flexion or recurvatum (hyperextension).

Gait

Look for antalgic gait (osteoarthritis) and varus thrust (collapse of the knee into more varus as weight is taken on that leg).

Feel

- *Soft tissue.* Feel the tendons for quadriceps and patellar tendon rupture.
- *Fluid displacement test.* Place your hand on the superior aspect of the suprapatellar pouch and move it inferiorly, attempting to displace any fluid into the knee joint. Maintain your hand at the

level of the superior pole of the patella. Now look to see if the normal gutters on either side of the knee are less noticeable because of fluid distension. Stroke the back of your hand over either gutter in turn. Look at the opposite gutter to see if there is filling.

- **Patellar tap test.** This test is used when a large effusion is present. Place one hand on either side of the patella and, with the other hand, push down on the patella. With an effusion, fluctuance is present as the patella moves towards the joint.
- **Bone.** Feel the tibial tuberosity, inferior pole of the patella, patella facets, origin and insertion of the knee ligaments and joint line (medial and lateral). Remember to palpate for any popliteal swellings. Note the height of the patella.

Move

The knee moves principally in flexion (0–135°) and extension (from 0 to –10°) (Fig. 31.29). Assess hyperextension by placing one of your hands on the anterior aspect of the distal femur. Now lift the distal tibia with the other hand. Measure the angle or the height that the heel can be lifted off the couch before the knee starts to move.

Perform a lag test to assess the integrity of the extensor mechanism. The patient is asked to lift the leg up off the bed (10°) with the knee straight. They are then asked to bend the knee and then straighten it again with the leg still held in the air. If they are unable to re-straighten the knee they have a positive lag. This indicates significant weakness of the quadriceps mechanism.

In the presence of an apparent fixed flexion deformity of the knee (seen in osteoarthritis), decide if this is arising from the knee or hip joint. To differentiate, sit the patient up with the knees hanging over the edge of the couch; this obliterates the effect of any hip flexion deformity. Passively try to extend the

knee fully. With a flexion deformity of the knee, this is not possible.

Special tests

Collateral ligaments

To assess the ligaments, place the leg under your arm. Flex the knee to 10° to relax the posterior capsule (the MCL and LCL are taut in full extension and lax in flexion). Stress each ligament in turn by applying a valgus or varus force. With your index fingers simultaneously palpate over the collateral ligaments. Assess for signs of instability (excessive opening of the joint). The quality of the endpoint should be noted. Compare both sides (Fig. 31.30).

- **Medial collateral ligament.** A lax MCL or deficient lateral compartment may cause knee instability when applying a valgus stress. It is important to note that the valgus stress test should be applied with the knee in 30° of flexion. Valgus instability in full extension (0°) should alert you to a possible posterior structure injury (e.g. posterior capsule, posterior cruciate ligament).
- **Lateral collateral ligament.** A lax LCL or deficient medial compartment may cause knee instability when applying a varus stress in 10° of flexion. Instability in full extension (0°) suggests injury to the medial structures. In a suspected lateral injury, evaluation of the peroneal nerve must be performed.

Anterior cruciate ligament

The most sensitive test for evaluation of the ACL is the Lachmann test.

- **The Lachmann test** (Fig. 31.31). Flex the knee to 15–30° and pull the proximal tibia forwards. Excessive laxity may indicate rupture of the ACL. Anterior translation of the tibia associated with a soft or no endpoint is a positive test. The test may be negative in chronic ruptures as the ACL stump can scar to the PCL.
- **Anterior draw test** (Fig. 31.32a). Flex both knees to 90° and look for a posterior sag (compare the height of the tibial tuberosities). This may indicate an injury to the PCL. Stabilise the feet by sitting on them. Now place your hands around the proximal and posterior aspect of the tibia. With your index fingers, push up the hamstrings to remove their effect. Now pull the tibia forwards and measure any laxity; any laxity must be compared with the other knee. The degree of laxity can be graded: grade I (0–5 mm), grade II (5–10 mm) and grade III (> 10 mm).

Posterior cruciate ligament

The PCL is the primary restraint to posterior tibial translation between 30° and 90° of knee flexion. At 90°, the PCL accepts 95% of the posterior translational forces. Isolated PCL injuries are graded by the degree of posterior translation of the tibia with the knee in 90° of flexion. Look for a posterior sag with the knees flexed to 90°. The posterior draw test is the most reliable clinical test for a PCL injury.

- **Posterior draw test** (Fig. 31.32b). Perform the test with the knee flexed to 90°. Push the anterior aspect of the proximal tibia posteriorly and compare any laxity with the other side. If more than 10 mm of posterior tibial translation is noted at 30° and/or 90° of knee flexion, a combined PCL and posterolateral corner injury may be present. An evaluation of the competency of the posterolateral corner is necessary.

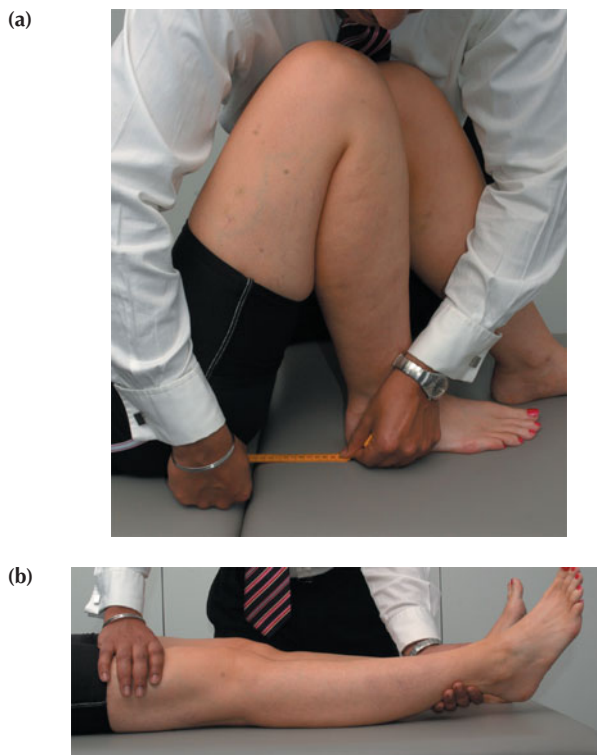

Figure 31.29 Knee flexion and extension.

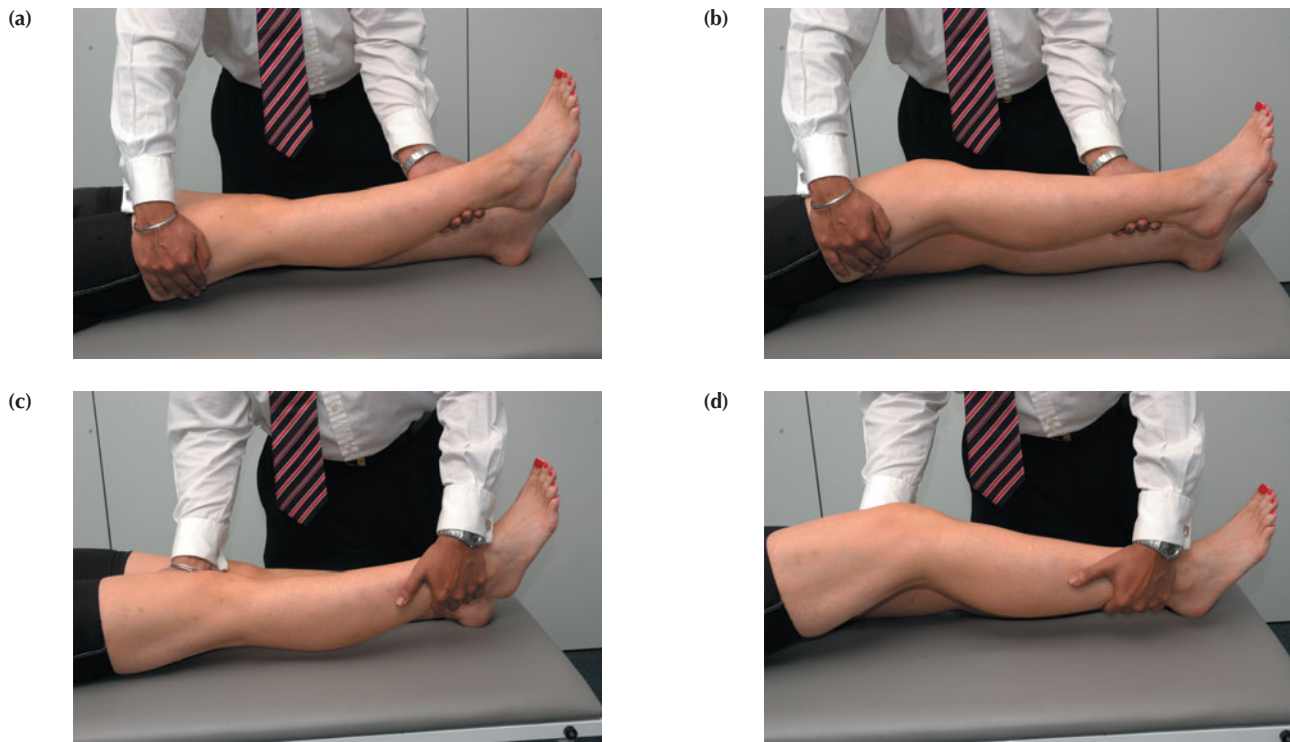

Figure 31.30 Assessing the medial and lateral collateral ligaments.

Menisci

The presence of palpable joint line tenderness is the most sensitive clinical examination test for a meniscal tear. Flex the knee to 90° and palpate the joint line using your thumb and index finger. Note any areas of tenderness. The well-known tests for meniscal tears (McMurray's test and Apley's grind test) are unreliable and so are not described here.

Figure 31.31 Lachmann's test: flex the knee to 15–30° and pull the proximal tibia forwards.

Figure 31.32 (a) Anterior draw test for anterior cruciate ligament stability; (b) posterior draw test for posterior cruciate ligament stability.

Thomas Porter McMurray, 1887–1949, Professor of Orthopaedic Surgery, Liverpool University, Liverpool, England.

Patellofemoral joint

The patella normally enters the trochlea from a lateral position and becomes centralised with increasing knee flexion, travelling in a 'J' pattern. Measure the 'Q' angle.

- *Patellar tracking* (Fig. 31.33). Sit the patient and ask them to let their legs hang off the end of the couch with the knees flexed to 90°. Ask the patient to slowly extend the knee to full extension. Toward the end of extension, look for lateral subluxation of the patella ('J' sign). This indicates maltracking.
- *Patellar apprehension (Fairbank's test (for instability))*. Attempt

Figure 31.33 Patellar tracking.

Sir Harold Arthur Thomas Fairbank, 1876–1961, Orthopaedic Surgeon, King's College Hospital, London, England.

to laterally displace the patella with the knee in extension. Patients with instability contract their quadriceps muscle or complain of pain. With the patient supine and the quadriceps relaxed, flex the knee to 30° whilst trying to push the patella laterally. With instability the patient may react with apprehension. In addition, the quadriceps muscle may contract in an attempt to realign the patella.

Patellar tendon

The patellar tendon serves as the distal extent of the extensor mechanism. Rupture usually occurs at the osseotendinous junction. This results in an inability to actively perform and maintain full knee extension. A rupture presents with diffuse swelling in the anterior knee. A high-riding patella (patella alta) is present secondary to the unopposed pull of the quadriceps muscle. A defect in the tendon is usually palpable. When the rupture extends through the medial and lateral retinaculæ, active extension is lost.

Quadriceps tendon rupture

Rupture of the quadriceps tendon occurs relatively infrequently and usually in patients older than 40 years of age. The patient presents with swelling, tenderness and a palpable defect in the tendon (Summary box 31.9).

Summary box 31.9

Knee examination

Inspection of the standing patient

- Front – alignment (varus/valgus/rotational deformity), muscle bulk
- Side – fixed flexion deformity
- Back – popliteal swellings, hamstrings
- Gait – antalgic, high stepping gait (foot drop), varus thrust

Inspection of the supine patient

- Skin, scars, soft tissues, deformity
- Palpation of the extensor mechanism, medial and lateral joint lines and collateral ligaments, hamstrings, tibial tuberosity, fibular head

Movements

- Flexion and extension

Special tests

- Patellar apprehension test and extensor mechanism
- Cruciate ligaments
- Collateral ligaments
- Menisci

CLINICAL EXAMINATION OF THE FOOT AND ANKLE

The foot can be divided into three parts – the hindfoot (calcaneus, talus), the midfoot (navicular, cuboids, cuneiforms) and the forefoot (metatarsals and phalanges).

Look

Ask the patient to stand and assess the overall limb alignment. Assess pelvic obliquity, limb length discrepancy (and its level), valgus/varus deformities of the knee and rotational alignment. Check for contractures of the hips and knees, Now focus your attention on the foot itself:

- *Foot shape.* Assess the overall shape of the forefoot from the front. From the side, look for the normal medial arch (Fig. 31.34a). The hindfoot is best appreciated from behind. Now look at the vertical relationship between the Achilles tendon and the calcaneus (normal heel valgus of 5–7°). Look from behind and count the number of toes that can be seen. The

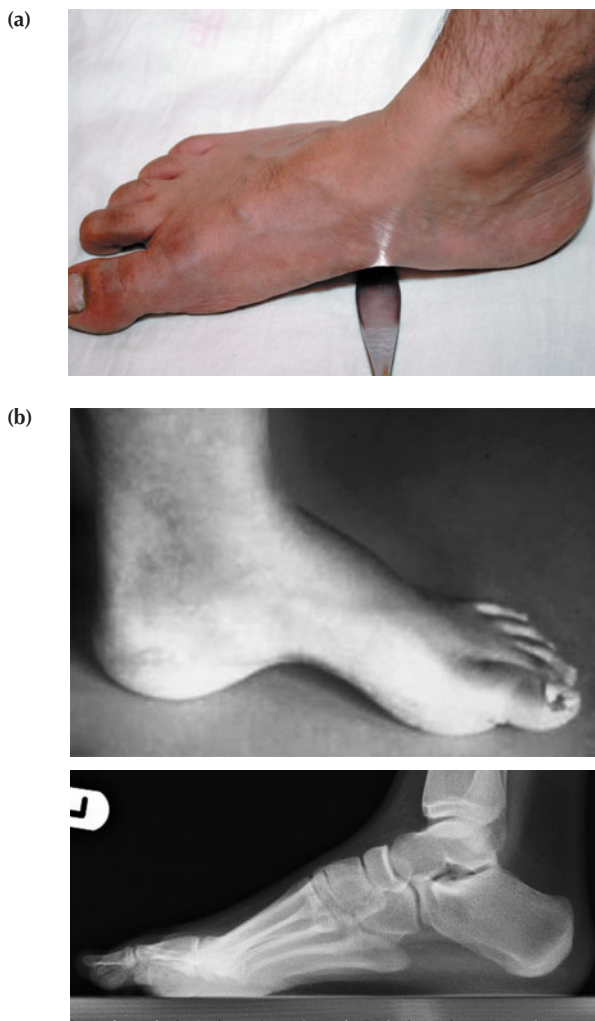

Figure 31.34 (a) Normal medial longitudinal arch of the foot. (b) Clinical and radiological appearance of pes cavus.

‘too many toes’ sign demonstrates increased forefoot abduction [pes planus (flat foot)] and a splayed forefoot. Foot shapes that may be encountered include neutral foot (no overall deformity), skew foot (hindfoot valgus and forefoot adduction), metatarsus adductus (neutral hindfoot and adduction of the metatarsus), pes planus (collapse of the medial arch) and pes cavus or high arch (increased medial arch). The possible causes of pes planus and pes cavus are shown in Summary boxes 31.10 and 31.11 respectively.

Summary box 31.10

Causes of pes planus

- Normal variant
- Hyperlaxity syndrome, e.g. Marfan’s syndrome
- Tarsal coalition – rigid and painful flat foot (Fig. 31.39a, p. 453)
- Tibial posterior dysfunction

Summary box 31.11

Causes of pes cavus (Fig. 31.34b)

- Spinal anomalies, e.g. spina bifida
- Hereditary sensorimotor neuropathies such as Charcot–Marie–Tooth disease
- Charcot foot (e.g. neuropathic foot)
- Post-compartment syndrome (e.g. Volkmann’s ischaemic contracture)

- *Skin.* A bunion or red swelling on the medial aspect of the metatarsophalangeal joint (MTPJ) is common. This is an area of inflamed skin with an underlying subcutaneous bursa and a joint osteophyte. Systemic manifestations include gouty tophi and thin fat pads under the metatarsal heads as seen in rheumatoid arthritis. Remember to assess the appearance of the nails.
- *Soft tissues.* Swelling may indicate soft tissue or joint pathology. Muscle wasting is most commonly seen on the dorsum of the foot and in the clefts between the metatarsals. If present, a full neurological examination of the upper and lower limbs should be performed including the spine.
- *Bones.* Look for any bony prominences or exostoses. Common forefoot deformities are shown in Table 31.12.

Table 31.12 Common forefoot deformities

Deformity	Metatarsophalangeal joint	Proximal interphalangeal joint	Distal interphalangeal joint
Claw toe	Hyperextension	Flexion	Flexion
Hammer toe	Normal	Flexion	Flexion
Mallet toe	Normal	Normal	Flexion
Hallux valgus or varus	Valgus or varus position	Normal	–

Antoine Bernard-Jean Marfan, 1858–1942, Physician, Hôpital des Enfants-Malades, Paris, France, described this syndrome in 1896.

Jean Martin Charcot, 1825–1893, Physician, La Salpêtrière, Paris, France.

Pierre Marie, 1853–1940, Neurologist, Hospice de Bicêtre, Paris, France, later becoming Professor of Pathological Anatomy in the Faculty of Medicine, and finally, in 1918, Professor of Neurology.

Howard Henry Tooth, 1856–1925, Physician, St. Bartholomew’s Hospital, and the National Hospital for Nervous Diseases, Queen Square, London, England, described peroneal muscular atrophy in 1886, independently of Charcot and Marie.

Richard von Volkmann, 1830–1899, Professor of Surgery, Halle, Germany, described this condition in 1881.

Gait

Ask the patient to walk up and down the room. Look for a high stepping gait (foot drop), painful (antalgic) gait (ankle and foot joint pain) and a short propulsive phase (forefoot pain).

Footwear

Inspect the footwear. This may reveal areas of abnormal weight bearing. With normal wear of the sole a corner is typically worn off the posterolateral aspect of the heel (heel strike). In addition, there may be a circular wear pattern under the ball of the big toe (toe-off phase).

- *External appearance.* Look at the materials used, the metal supports and heel raise, depth and width.
- *Internal appearance.* Look at the insoles, arch supports and heel cups.

Feel

- *Skin.* Reduced sensation in a glove and stocking distribution is seen with diabetes.
- *Soft tissues.* The posterior tibial and the dorsal pedis pulses should be identified (Fig. 31.35). Palpate the tibialis anterior tendon and the long extensor tendons on the dorsum of the foot. From the back, palpate the Achilles tendon. Palpate the peroneal tendons from the lateral side and the tibialis posterior tendon from the medial side. The sinus tarsi can be assessed. This is an anatomical space bounded by the talus and calcaneus and is recognisable as a soft-tissue depression

Figure 31.35 (a) Palpation of the posterior tibial pulse; (b) palpation of the dorsalis pedis pulse.

anterior to the lateral malleolus. It is filled with fat and the extensor digitorum brevis muscle. Sinus tarsi syndrome may occur. This may be caused by injury to the interosseous talocalcaneal ligament or the subtalar joint. There is pain and tenderness over the sinus tarsi with subjective hindfoot instability. The pain is characteristically relieved by local anaesthetic injection.

- *Bones.* Feel for deformity, bony prominences and loose bodies:
 - *ankle joint:* the medial and lateral malleoli, anterior and posterior joint line, lateral gutter and ligament complex, the syndesmosis (front of the ankle), medial gutter and medial ligament complex;
 - *subtalar joint:* palpate each facet;
 - *midtarsal joints:* the talonavicular and calcaneocuboid joints;
 - *tarsometatarsal joints (TMTJ):* note that the second TMTJ is several millimetres proximal to the others; movement is minimal in the second ray, limited in the third ray, moderate in the fourth and fifth rays and very variable in the first ray.
- *Specific structures to palpate:*
 - *calcaneus (heel bone):* the commonest cause of pain is plantar fasciitis; this may present with numbness, burning and electric shock sensations, which are worse in the morning and improve as the day goes on; identify the exact point of tenderness;
 - *tendons:* examine for contracture of the Achilles tendon insertion and the peroneal or tibialis posterior tendons;
 - *head of talus:* invert and evert the patient's foot;
 - *sustentaculum tali:* palpate one fingerbreadth below the medial malleolus; this important structure serves as an attachment for the spring ligament;
 - *cuneiforms (medial, middle and lateral), MTPJs, web spaces and all the forefoot bones.*

Move

The movements of the foot and ankle are linked via the ankle, subtalar and midfoot joints. Remember the acronyms PAED – pronation, abduction, eversion and dorsiflexion – and SAPI – supination, adduction, plantarflexion and inversion.

Ankle (Fig. 31.36)

- *Dorsiflexion.* Test dorsiflexion with the knee both flexed and extended. If restriction is greater with the knee extended than flexed, the contracture is principally in the gastrocnemius. Restriction that is equal in all knee positions is caused by a contracture principally of the soleus.
- *Plantarflexion.* Ask the patient to touch the floor with their foot (15°). Weakness suggests injury to the Achilles tendon or pathology affecting the S1 nerve root.

Subtalar joint (Figs 31.37 and 31.38)

Hold the talar neck and ask the patient to move their heel from side to side. Repeat using a hand on the heel to move the joint and apply a varus and valgus stress while feeling for movements of the talus. Holding the talus as opposed to the tibia isolates subtalar from ankle motion. (Normal range is 5° in each direction.)

- *Inversion.* Ask the patient to move their foot in towards them.
- *Eversion.* Ask the patient to move their foot out to the side.

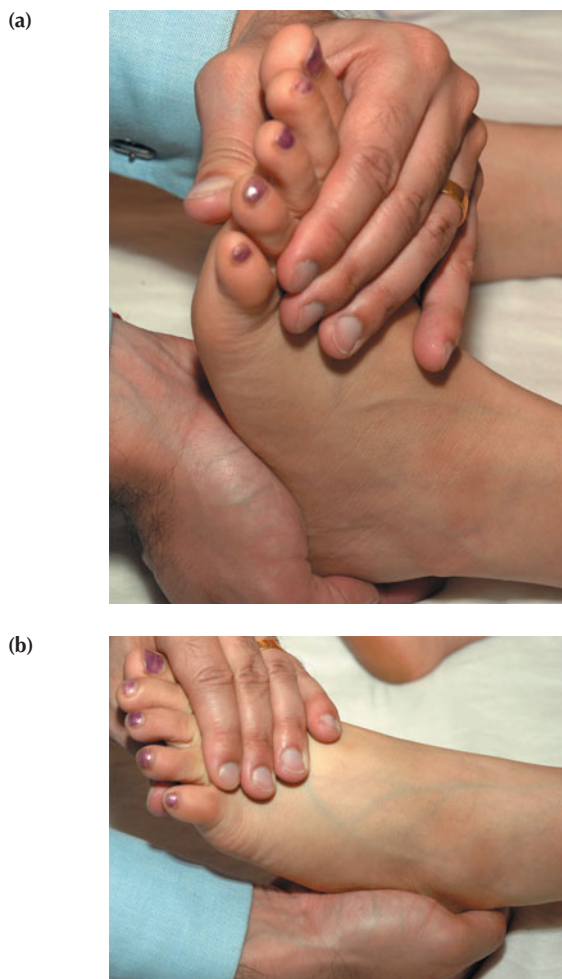

Figure 31.36 (a) Ankle dorsiflexion and (b) ankle plantarflexion.

Figure 31.37 Testing subtalar joint motion.

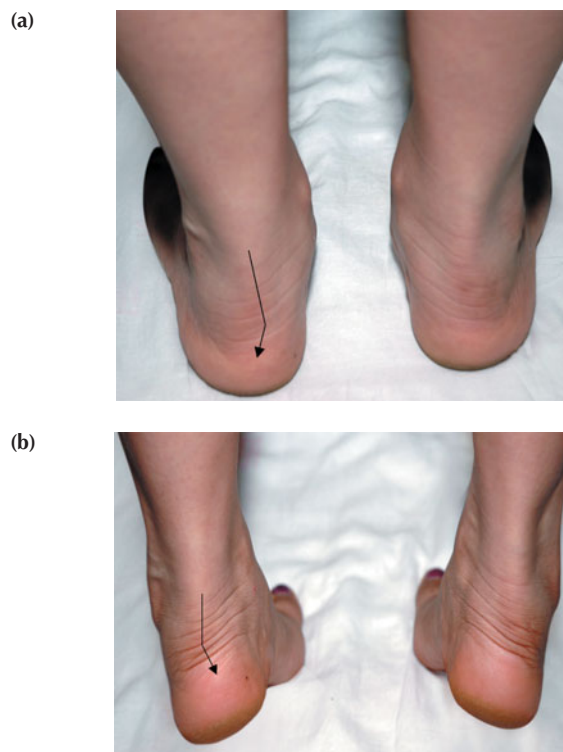

Figure 31.38 Testing subtalar joint flexibility.

Midtarsal joint

Hold the heel with one hand and move the forefoot medially (adduction = 20°) and laterally (abduction = 10°) with the other hand.

Tarsometatarsal joint

Hold the midfoot and manipulate each metatarsal up and down to estimate the passive range of movement.

Metatarso-phalangeal joint

Test extension ($70\text{--}90^\circ$) by asking the patient to lift the toes to the ceiling and test flexion (45°) by pointing the toes to the floor. Normal toe-off requires $35\text{--}40^\circ$ of dorsiflexion.

Special tests

Achilles tendon

Feel the gastrocnemius and soleus bellies and the whole length of the tendon for gaps (rupture), tenderness or swelling. Also identify the posterolateral (Haglund's) prominence of the calcaneus and palpate the retro-Achilles bursa.

The best test for integrity of the tendon is the *Thompson's* or *Simmonds' test*. Do not be misled by the patient's ability to stand on tiptoes – some people can do this using their long toe flexors alone. Lie the patient prone and allow the calves to rest on your

Achilles, the Greek Hero, was the son of Peleus and Thetis. When he was a child his mother dipped him in the Styx, one of the rivers of the underworld, so that he should be invulnerable in battle. The heel by which she held him did not get wet, and was, therefore, not protected. Achilles died from a wound in the heel which he received at the siege of Troy.

Patrik Haglund, 1870–1937, Swedish Orthopaedic Surgeon.

Franklin Adin Simmonds, 1911–1983, Orthopaedic Surgeon, The Rowley Bristow Hospital, Pyrford, Surrey, England.

forearms. Squeeze each calf in turn and watch for movement at the ankle joint. Lack of movement may indicate a rupture.

Subtalar joint flexibility

Ask the patient to stand on their toes and observe the heel from behind; the heel moves normally from valgus to varus indicating flexibility. The *Coleman's block test* is used to assess the flexibility of the subtalar joint. Ask the patient to stand on a 2-cm block with the great toe over the medial edge, resting on the floor. Now look from behind. If the hindfoot varus remains, the subtalar joint is fixed. If it corrects to valgus, the joint is mobile (Fig. 31.38).

Flat foot flexibility

Use the *Windlass* and *Jack's test* to distinguish a flexible from a fixed flat foot (Fig. 31.39):

- *Windlass test*. Ask the patient to stand on their toes and observe the arch of the foot on the medial aspect. As soon as the patient stands on their toes, the arch forms. Failure of this indicates a fixed flat foot.
- *Jack's test*. With the patient standing, lift up the great toe. The arch should form in the flexible flat foot.

Figure 31.39 (a) Flat foot appearance with a reduced medial longitudinal arch; (b) Windlass test; (c) Jack's test.

Ankle stability

Trauma to the ankle is a common cause of instability. Accurate assessment may be difficult in the acute setting because of pain.

- *Anterior draw test*. With the foot resting over the bed, hold the heel with one hand and the front of the tibia with the other. Move the heel forwards on the fixed tibia. Compare with the other side. Instability of the syndesmosis may be palpable (Fig. 31.40).
- *Squeeze test for distal tibiofibular stability*. Compress the proximal calf. Pain at the ankle may indicate separation of the distal fibula from the tibia.
- *Tilt test*. Hold the talus at the neck rather than the heel so that you can be sure that any tilt is in the ankle and not the subtalar joint.

Tarsometatarsal joint stability

Stability can be assessed by pushing each joint up and down. Standing lateral radiographs may be used in addition.

Tibialis anterior

Ask the patient to walk on their heels with their feet inverted; the tibialis anterior tendon can be seen. With the patient's feet resting over the edge of the couch, ask the patient to actively dorsiflex and invert their foot to reach your hand. Palpate the tibialis anterior muscle.

Tibialis posterior

Pathology of the tibialis posterior typically presents with postero-medial ankle pain, swelling and gradual onset of a flat foot. When assessing the tendon, look for swelling along its course, a flat foot with heel valgus, the 'too many toes' sign and prominence of the talar head. Palpate for tenderness, swelling or gaps in the tendon. To test integrity:

- Ask the patient to perform a single foot tiptoe test on both sides. The inability to lift the affected heel off the ground is suggestive of a tibialis posterior tendon injury or insufficiency.
- To test strength, position the foot in the plantarflexed and inverted position. Ask the patient to hold this position while you push against their foot.

Dorsiflexors

Tendinitis of the long toe dorsiflexors usually presents in athletes. Pain affects gait in the early contact phase. Palpate for swelling,

Figure 31.40 Anterior draw test.

gaps or any tenderness. Ask the patient to move the foot into dorsiflexion and to hold this position while you push the foot down.

Inability to dorsiflex the foot is referred to as foot drop. Causes include stroke, spinal injury, spinal stenosis or disc prolapse, peripheral nerve injury (e.g. sciatic, common and deep peroneal) or a peripheral neuropathy.

Peroneals

Peroneal tendon pathology presents with swelling and/or pain of the lateral hindfoot or midfoot. There may be a history of the ankle 'giving way'. Presentations of peroneal tendon pathology include:

- 'peroneal spasm': may be seen in tarsal coalition; here, the muscles are usually contracted secondary to the hindfoot valgus;
- *peroneal tendon dislocation*: attempt to dislocate the tendons by dorsiflexing and everting the foot.

The peroneus longus may be palpated just before it crosses under the foot to insert onto the base of the first metatarsal. Ask the patient to plantarflex the first metatarsal. Test strength and integrity by active and resisted eversion while you palpate the tendons for swelling, tenderness or gaps.

Morton's neuroma

This condition represents thickening of the tissue that surrounds the digital nerve leading to the toes as the nerve passes under the ligament connecting the metatarsals in the forefoot. It is most frequent between the third and fourth toes. A neuroma presents with burning pain in the ball of the foot that radiates to the involved toes. The condition is difficult to diagnose and requires a high index of suspicion. Palpate in the web space between the symptomatic toes for a mass. Compression of the metatarsals may

Thomas George Morton, 1835–1903, Surgeon, The Pennsylvania Hospital, Philadelphia, PA, USA, described this condition in 1876.

elicit a 'click' between the bones (Molders' click) (Summary box 31.12).

Summary box 31.12

Ankle and foot examination

Inspection of the standing patient

- Front – alignment, foot shape and deformity
- Side – medial arch
- Back – heel position
- Gait – antalgic, high stepping gait (foot drop)

Inspection of the supine patient

- Skin, scars, soft tissues, bony deformity
- Palpation of the ankle, subtalar, midfoot and forefoot joints

Movements

- Dorsiflexion, plantarflexion, inversion, eversion

Special tests

- Flexibility of the subtalar joint and a flat foot
- Joint stability, Morton's neuroma
- Tendons – tibialis posterior and anterior, Achilles tendon, peroneals and dorsiflexors

Sports medicine and sports injuries

LEARNING OBJECTIVES

To understand:

- The common sports injuries
- The treatment and rehabilitation plans in sports medicine
- The common conditions associated with different joints
- The importance of rehabilitation

INTRODUCTION

When the normal physical limits of human tissues are exceeded, injury occurs. This is particularly associated with participation in any form of physical activity. Understanding how the injury occurred, the biomechanics of the forces involved, the relevant anatomy, the healing process and how to rehabilitate the injured joint are encompassed in the field of sports medicine.

The incidence of injuries differs between different sports. Although obviously aggressive physical contact sports, e.g. rugby, American football and wrestling, have a high incidence of major injuries, it is of note that sports such as cricket also have a high incidence of injuries (2.6–24.4 per 10 000 hours played). Many of these injuries are relatively minor injuries to the hand, but all need to be treated appropriately to prevent a chronic state occurring.

DIAGNOSIS OF SPORTS INJURIES

History

The incident leading to the injury can provide valuable information on the nature of the injury and also reveal occult injuries. For example, the direction of impact in a sliding football tackle should alert you to the nature of any knee or ankle injuries – damage to the medial collateral ligament (MCL) of the knee from a lateral impact, inversion injury of the ankle.

Injuries can be broadly classified as:

- acute extrinsic injuries, e.g. haematoma, cuts, grazes;
- acute intrinsic injuries – this is when a structure has been stressed beyond its limit, e.g. ligament sprains, dislocations and fractures;
- chronic injuries, which may be exacerbated by a new event.

Examination

Accurate diagnosis of the injury immediately after the incident is often difficult, with pain and muscle spasm masking signs. The principles of Advanced Trauma Life Support (ATLS) should also be considered before focusing on the more obvious injury.

Subsequent examination during the process of recovery may require you to watch the individual actually perform their sport, to enable an accurate assessment of the injury and how it might be prevented in the future.

PROTECTIVE EQUIPMENT AND ORTHOTICS

When correctly used, protective equipment can help prevent injuries occurring (Fig. 32.1); however, it can provide an athlete with a false sense of security that injuries may not happen; for example, protective head gear will not necessarily prevent concussion. Badly fitting protection may in itself cause injury, e.g. ulceration and infections.

The principles of protection may be achieved by:

- absorbing the energy of the impact;
- diffusing the impact over a larger area;
- limiting the movement of a joint;
- preventing infection.

REHABILITATION

Rehabilitation of the injured athlete is an essential part of the treatment plan. By dividing it into four stages an effective rehabilitation plan can be devised.

Stage one involves the immediate treatment of the injury. Use of the basic acronym PRICE will help reduce the length of the inflammatory process and promote quicker rehabilitation:

- protect;
- rest;
- ice;
- compression;
- elevation.

Stage two involves restoring the movement of the injured joint. Pain and swelling have usually started to settle.

Drugs have a role to play in the treatment of most injuries and can help reduce the time needed before a return to sport is possible.

Figure 32.1 (a–c) Protective equipment.

Simple analgesics such as non-steroidal anti-inflammatory drugs (NSAIDs) are beneficial in reducing pain and oedema. Corticosteroids, e.g. cortisone and prednisolone, are also useful in reducing oedema and inflammation in chronic conditions; however, they are associated with re-rupture of tendons and long-term use is also associated with osteoporosis. Before prescribing any drugs it is important to be aware of the International Olympic Committee's guidelines on doping for athletes (Table 32.1), for example whether a given drug is banned. A positive drug test can have a devastating effect on an athlete's career and on your reputation.

Restoration of movement is an essential part of the rehabilitation process: the longer a structure is out of use the more atrophy there will be. In severe cases, contractures and osteoporosis may develop.

Initially, passive movements may be applicable, using continuous passive movement machines. As healing occurs, more active

exercises can be undertaken. These include isometric exercises, in which the muscle is contracted but the joint controlled by it is not moved. Isotonic exercises are those in which the muscle contracts under a constant load and the joint is moved through a range of movement. A physiotherapist is an essential part of the rehabilitation team, to control and monitor progress.

GENERAL TISSUE INJURIES

Different types of tissue sustain different types of damage and heal at differing rates.

Muscles

Bleeding within any muscle may be extensive and it is essential to recognise whether this is intramuscular bleeding, and therefore more prone to compartment syndrome, or intermuscular bleeding.

Table 32.1 Classes of banned drugs

Class of drug	Mode of action	Examples
Stimulants	These cause the autonomic nervous system to speed up different parts of the brain, resulting in faster reflexes. This may help sprinters. Increased confidence and aggression may help boxers. The secondary weight loss may be desirable in dancers and gymnasts	Amphetamines, cocaine, ephedrine, caffeine, β_2 -agonists, phenylpropanolamine
Anabolic steroids	These drugs can increase muscle bulk, strength, weight and acceleration. They improve injury repair, reduce recovery time and improve overall performance	Stanozolol, nandrolone, testosterone, oxandrolone, methandione
β_2 -Agonists	As well as acting as stimulants, when taken systemically they can have powerful anabolic effects. Clenbuterol has a marked stimulatory effect on fast-twitch muscle fibres and causes lipolysis	Clenbuterol, salbutamol, terbutaline, salmeterol
Narcotics	These can result in an increased pain threshold and a feeling of invincibility, which may be beneficial in sports in which aggression and physical contact are required, e.g. rugby	Morphine, pethidine, buprenorphine
Peptides and hormones	Actions are specific to the hormone. Erythropoietin can increase the number of circulating red blood cells, improving the oxygen-carrying capacity of the athlete. This is useful in distance and endurance sports	Human chorionic gonadotrophin, human growth hormone, erythropoietin
Diuretics	These can help induce rapid and temporary weight loss as well as masking the use of other banned substances. This can help in weight-category sports such as rowing and horse racing	Furosemide, bendroflumethiazide, mannitol, bumetanide

Intermuscular bleeding is more likely to be responsible for superficial bruising and is less prone to compartment syndrome.

The principles of treating any soft tissue injury are the same and the PRICE formula is again useful.

The patient requires rehabilitation and education to prevent the injury from recurring. Occasionally, the haematoma does not resolve and a cyst may develop. This may require surgical excision but there is an associated risk of infection. Deep bruising may produce osteoid – myositis ossificans traumatica – which is difficult and slow to treat.

Tendons

Tendons consist of dense type 1 collagen bundles that are attached to the bone by Sharpey's fibres. The bundles or fascicles are surrounded by a sheath of connective tissue called the epitendon, which is in turn enclosed within a paratendon (tendon sheath). The tendons transmit load from the muscles to the bone.

When tendons are damaged they repair themselves by fibroblasts laying new collagen and macrophages clearing the damaged tissue. This means that there is a period of weakness, approximately 7–10 days post injury, when care should be taken in the mobilisation protocol to avoid re-rupture. It may take 6 months for full strength to return.

Tendon pathology (apart from rupture) can be divided into three types:

- *paratendinitis* – this is inflammation of the paratendon and is very painful; it responds well to conservative therapies;

- *paratendinitis with tendinosis*;
- *pure tendinosis* – this is degeneration within the tendon and may only manifest itself when a rupture has occurred; pre-rupture prophylactic treatment is difficult and controversial.

Ligaments

Ligaments transmit tensile forces across joints and help stabilise them. They are similar in structure to tendons but have a higher elastin content and mechanoreceptors for proprioception.

Ligament injuries can be graded as follows:

- grade 0: normal ligament, normal joint stability;
- grade 1: tenderness of the injured ligament, no increase in joint laxity;
- grade 2: partial disruption – tenderness and increased joint laxity with an endpoint;
- grade 3: complete disruption – tenderness and marked increase in joint laxity with no endpoint.

When assessing the stability of joints it is essential to compare both sides. There is a great deal of variation in laxity between and among different groups, e.g. young vs. old, women vs. men, those with hypermobility disorders.

The principles of treatment are the same as for tendons, while remembering that prolonged immobilisation can cause stiffness and reduce the strength of the repair. There is, therefore, a fine balancing act between early mobilisation with reduced swelling and stiffness and mobilisation too early, resulting in re-injury and delayed healing.

Bursae

Between most joints and the overlying tissues there are small

William Sharpey, 1802–1880, Professor of Anatomy and Physiology, University College, London, England, described these fibres in 1848.

fluid-filled endothelium-lined sacs, which decrease the frictional forces. These sacs can become inflamed, swollen and acutely painful. Common sites are the:

- olecranon;
- psoas tendon;
- greater trochanter;
- pre-patellar;
- infrapatellar;
- retrocalcaneal.

The symptoms are usually self-limiting and settle without intervention. Occasionally, aspiration, steroid injections or excision may be required.

Bone

Bone is a unique dynamic structure that is continuously adapting throughout life and which heals itself depending on the stresses placed on it (Wolff's law). Fractures heal best when the broken ends of the bone are opposed. Healing occurs in three recognised phases:

- *inflammation*: immediate haematoma formation followed by granulation tissue formation over the next few days;
- *repair*: immature callus forms over weeks and more mature bone over the following months;
- *remodel*: remodelling of the bone occurs according to Wolff's law.

Stress fractures

Any repetitive activity may cause a stress fracture in virtually any bone (Fig. 32.2). They are common and characterised by poorly localised pain that is worse on exercise. Confirming the diagnosis in the early stages can be difficult as plain radiographs will appear normal. Technetium bone scans or magnetic resonance imaging (MRI) will often clarify the diagnosis.

Stress fractures are more common in endurance athletes and women. Other pathologies or contributing factors need to be considered, including osteosarcoma and chronic compartment syndrome.

Treatment involves resting from the exacerbating activity; this often requires long periods without undergoing training. Psychological support and alternative forms of exercise will need to be organised to help the athlete through this depressing time (Summary box 32.1).

Summary box 32.1

General tissue injuries

- Define tendon pathology
- Classify ligament injuries
- Name the common bursa sites
- Three phases of bone repair

PELVIS, HIP AND THIGH INJURIES

Massive trauma to this area produces fractures and dislocations that can be life-threatening (see Chapter 27). Soft-tissue injuries

Julius Wolff, 1836–1902, Professor of Orthopaedic Surgery, Berlin, Germany, enunciated 'Wolff's Law' in 1892.

Figure 32.2 Radiograph of a metatarsal stress fracture.

in this area may be subtle and easily missed as attention is focused on the larger fractures and dislocations.

Quadriceps contusion (cork thigh, charley horse)

This is usually the result of a direct blow. A haematoma develops in the rectus femoris with pain, swelling and stiffness. Compartment syndrome needs to be excluded. Initially, the knee should be immobilised in extension; then the muscle is gradually returned to pain-free movement.

Quadriceps rupture

This may occur when kicking balls, especially in football and rugby. Classically, the patient cannot perform a straight leg raise. The torn tendon ends need to be brought together and held as securely as possible so that gentle mobilisation (low load) can be started as soon as possible and stiffness avoided.

Hamstring strain

This is common and usually occurs after a quick muscle contraction. It is usually the short head of the biceps that tears. It should respond to the standard PRICE formula.

Groin strain

This is a difficult area to diagnose and treat. The differential diagnosis includes:

- herniae;
- fractures;
- tumours;
- gynaecological and urinary problems;
- sexually transmitted diseases, e.g. *Chlamydia*;
- stress fractures;
- osteitis pubis.

All athletes are prone to groin strains and they can quickly become an acute-on-chronic injury. Treatment is conservative whenever possible and surgery should not be considered before 6–12 months of treatment.

Bony injuries

Besides the usual fractures and dislocations that may be seen, the pelvis is susceptible to a number of other injuries:

- *Avulsion of the iliac spine.* This is seen in adolescent footballers following a sudden contraction of the rectus femoris or after the leg is brought rapidly to a standstill (such as kicking a wet football) (Figs 32.3 and 32.4).
- *Ischial apophysitis.* This inflammation of the ischial tuberosity is seen in adolescent runners. Occasionally, the hamstring may actually avulse.
- *Osteitis pubis.* This is a self-limiting condition with tenderness of the symphysis pubis and is common in cricketers (Fig. 32.5).

Figure 32.3 Radiograph of a ruptured rectus femoris.

Figure 32.4 Computerised tomography scan demonstrating a ruptured rectus femoris.

Figure 32.5 Computerised tomography scan of osteitis pubis with cyst formation.

KNEE AND KNEE INJURIES

The knee is a complex hinge joint that also allows some rotational movement. It is highly susceptible to injury from most sports, in particular contact sports. Pain felt in the knee area may be referred from the hip, spine or ankle.

Ligamentous injuries

The knee has four main ligaments.

Medial collateral ligament

When a lateral (valgus) force is applied to the knee, the MCL is susceptible to damage, particularly at the femoral insertion, resulting in pain and valgus instability. Grade 1 and 2 tears are usually partial, whereas grade 3 injuries are characterised by > 1 cm of joint opening and other associated ligament injuries. Treatment involves bracing, early weight-bearing and quadriceps exercises.

Lateral collateral ligament

When a medial (varus) force is applied to the knee, the lateral collateral ligament (LCL) is susceptible to damage. Isolated injuries to this ligament are rare because of the presence of other reinforcing structures, e.g., the biceps femoris, iliotibial band and popliteus. However, damage to the LCL is often associated with more extensive disruption of the posterolateral corner, which is a far more significant injury often requiring surgical intervention.

Cruciate ligaments

There are two cruciate ligaments in the knee, which are intracapsular and extrasynovial. They prevent anterior and posterior translation of the tibia on the femur.

Anterior cruciate ligament

Anterior cruciate ligament (ACL) injuries are the most common knee ligament injuries seen in all forms of sport. They are more common in women, jumpers and footballers. An ACL injury is a classic twisting injury with internal rotation and anterior translation of the tibia. In the acute injury there is pain and often a large haemarthrosis, making assessment of the ligament difficult.

Diagnosis of an ACL injury can be made using a number of diagnostic tests, including the anterior draw test and Lachman's test (see Figs 32.6–32.8). Once the haemarthrosis has resolved, examination is easier and a positive pivot shift, anterior draw test or Lachman's test are usually conclusive. It is associated with other injuries, such as an MCL sprain and meniscal tear, so these need to be excluded.

Rehabilitation of the quadriceps and hamstrings may stop many athletes requiring surgical intervention; however, if instability of the knee continues, surgical reconstruction may be appropriate (Fig. 32.9).

Posterior cruciate ligament

Posterior cruciate ligament (PCL) injuries are less common and are frequently misdiagnosed. The severity of the damage can easily be underestimated. They usually result from a direct blow to the tibia. The 'dashboard injury' is a PCL rupture caused by a motor vehicle accident (MVA). An unrestrained person in the front seat is thrown forwards onto the dashboard. The knee takes the brunt of the force and the tibia is driven backwards. When

Figure 32.6 Anterior draw test.

Figure 32.7 Lachman's test.

Figure 32.8 Magnetic resonance imaging of a ruptured anterior cruciate ligament.

the mobility of the injured knee is compared with that of the other side, a posterior sag can be clearly seen (Fig. 32.10).

Often the posterolateral corner complex is also damaged and acute reconstruction is now advocated. The surgery is complex and the results are variable.

Meniscal injuries

Menisci are avascular semilunar structures made from fibrocartilage. They help transmit load and act as shock absorbers in the knee. When a rotatory force is applied between the femur and the tibia, i.e. twisting to change direction, then a tear can occur in the meniscus.

There is usually pain and a small effusion may develop over a few days. There is not usually any blood in this as menisci have no blood supply. If a bucket-handle tear results then the patient

Figure 32.9 Radiograph of a postoperative anterior cruciate ligament repair.

Figure 32.10 Posterior sag of the knee.

may find that the knee locks. The McMurray and Apley grind tests are sometimes positive. An MRI scan may help if the diagnosis is unclear but, ultimately, arthroscopic resection of the tear may be required (Fig. 32.11). In adolescents, meniscal repair is encouraged, especially if the tear is in the periphery where there is a blood supply.

Patellofemoral injuries

This joint is subject to numerous problems such as tracking disorders, instability, chondromalacia patellae and bursitis. The most common symptom is anterior knee pain.

Chondromalacia patellae

This is said to be softening of the patellar articular cartilage although the true aetiology is not known. It is particularly common in female adolescents although the cartilage may appear normal on arthroscopy. Treatment should be centred around quadriceps strengthening and taping exercises, to improve the strength and coordination of the muscle that controls tracking of the patella.

Patellar instability

Dislocation and subluxation may be the result of significant trauma but are frequently chronic conditions, made worse by poor musculature and a shallow femoral trochlea (Fig. 32.12).

Immediate management should be to reduce the patella and sometimes aspirate the haemarthrosis (if large) for pain relief. Immobilisation in extension for 2 weeks combined with isometric quadriceps exercises should be started. When the quadriceps bulk has returned and stability of the knee improved then a graduated return to activity can be undertaken.

Recurrent dislocation and subluxation may require a surgical procedure to overcome the problem, but there is no ideal solution.

Patellar tendinitis (jumper's knee)

This is an apophysitis (inflammation) of the patellar tendon as it inserts into the patella. It is associated with pain, swelling and

Figure 32.11 *In situ* meniscal tear as seen on a magnetic resonance imaging scan.

crepitus. Conservative management with physiotherapy is the mainstay of treatment. Surgery is rarely required.

Hoffa's disease

Bleeding into the anterior fat pad can cause anterior knee pain. It is most common in adolescents and those with hypermobility and may start with a hyperextension injury. Gymnasts and those practising sports requiring flexibility are more at risk. Treatment should start with modifying activities and occasionally arthroscopic resection.

Plica syndrome

Plica are folds of synovial membrane within the knee. If they become scarred or thickened from trauma or overuse, pain and clicking may result. This can occur in any sport but is more common in football, skiing and rugby. It is often an incidental finding in a normal arthroscopic examination. Surgical resection may relieve the problem.

Thomas Porter McMurray, 1887–1949, Professor of Orthopaedic Surgery, the University of Liverpool, Liverpool, England.
Alan Graham Apley, 1914–1996, Director of Orthopaedic Surgery, St. Thomas' Hospital, London, England.

Albert Hoffa, 1859–1907, Orthopaedic Surgeon, Berlin, Germany, described chronic synovitis of the knee in 1904.

Figure 32.12 Dislocated patella.

Iliotibial band syndrome

The insertion of the iliotibial band into the lateral epicondyle may become inflamed. This is particularly common in runners. Stretching, rest and, if necessary, steroid injections should resolve it (Summary box 32.2).

Summary box 32.2

Knee injuries

- The knee is a hinge joint allowing flexion, extension and some rotation
- There are four main knee ligaments, all susceptible to injury
- The menisci act as shock absorbers and assist in reducing friction
- Pain in the knee may be referred – look for other causes

ANKLE INJURIES

Ankle sprains

Soft-tissue injuries around the ankle joint are common and usually involve the anterior talofibular ligament and the calcaneofibular ligament. Eversion/abduction forces cause trauma to the medial ligament complex, whereas inversion/adduction forces lead to injury of the lateral complex.

Type I sprains involve minor ligamentous injury, type II sprains occur with incomplete ligamentous injury and type III sprains involve complete disruption of a ligament or multiple ligaments.

Ankle sprain diagnosis can be difficult in the acutely painful, post-traumatic ankle joint. Immediate treatment should involve the PRICE routine, which will assist in the recovery; the ankle joint should then be reassessed after 4–7 days. Routine anteroposterior and lateral radiographs should be taken when indicated to exclude a bony injury. Stress views may be indicated but often require a general anaesthetic. MRI imaging of the ankle joint has been shown to be 90% accurate in diagnosing lateral ligament injuries.

Complete rupture of the medial ligament rarely occurs in isolation and is often associated with disruption of the syndesmosis. Damage to either of these structures leads to lateral shift of the talus on eversion of the ankle (Fig. 32.13). This can predispose to prolonged instability because of failure of the ligament to heal and osteoarthritis as the talus repeatedly impinges on the tibia.

Treatment of an ankle sprain aims to provide a stable ankle with good anatomical alignment and function. Type I and II sprains (incomplete ligament rupture) require protection with an ankle brace or strapping, with early mobilisation and functional

Figure 32.13 Ankle showing a talar shift (bar).

range of motion exercises. It is essential for patients to undergo neuromuscular retraining exercises directed by a physiotherapist to help provide a stable ankle with a good range of movement. The treatment of type III sprains is controversial. Some advocate early surgical repair; however, secondary repair of ruptured ligaments, even years later, has produced comparable results.

Peroneal tendon injuries

Injuries to the peroneal tendons are relatively rare and often misdiagnosed but they can be serious as the peroneal tendons are the dynamic stabilisers of the hindfoot in inversion. They are more prevalent in patients with cavus feet or feet with high medial longitudinal arches. If the sheath is damaged they may sublux anteriorly, giving a snapping sensation. This will require surgical repair. Plain radiography, computerised tomography (CT) or MRI may be helpful in confirming the diagnosis.

Low-grade sprains should respond to bracing and physiotherapy. Complete rupture of the peroneal tendons requires surgical exploration and repair.

Tibialis posterior injuries

Disorders of the tibialis posterior lead to unilateral flat foot deformity. It is more common in women and in the middle-aged athlete and is often a chronic injury. It is characterised by hindfoot valgus along with pronation and abduction of the fore- and midfoot respectively. The deformity is easily identified in the weight-bearing patient; however, it is not always apparent on the lateral X-ray.

Pain around the medial ankle and hindfoot is common, exacerbated by exercise. If it is untreated the foot remains in a chronically pronated position and the pain shifts laterally.

Treatment consists of orthotic shoe implants or splinting to improve the foot position, thereby relieving the pain caused by the foot deformity. This can be combined with NSAIDs and localised steroid injections if indicated. Surgical repair in severe cases may be warranted.

Tibialis anterior injuries

Acute inflammation within the tendon sheath of the tibialis anterior tendon is common in long-distance runners. There is pain, swelling and crepitus over the tendon. It usually resolves with a period of rest and rehabilitation.

Achilles tendon injuries

Tendinitis

This is pain and/or swelling of the Achilles tendon. If the inflammation of the tendon becomes chronic then the tendon develops multiple microtears and loses its organised structure; this is called Achilles' tendonosis. Achilles' tendinitis is caused by a sudden increase in activity that involves the Achilles tendon, i.e. plantarflexion. It is common in athletes and those who participate in sports on an infrequent basis. Patients with pes

Achilles, the Greek hero, was the son of Peleus and Thetis. When he was a child his mother dipped him in the Styx, one of the rivers of the Underworld, so that he should be invulnerable in battle. The heel by which she held him did not get wet, and was, therefore, not protected. Achilles died from a wound in the heel that he received at the siege of Troy.

planus (flat feet) are more susceptible to develop Achilles' tendinitis as their flat, over-pronated foot places greater demands on the tendon.

Ultrasound or MRI is helpful to confirm the diagnosis.

Initially, the condition should be treated by immobilisation in a cast or boot to rest the tendon combined with NSAIDs and PRICE. Physiotherapy with stretching and strengthening exercises is often beneficial. Cases that fail to respond to conservative measures may require surgical repair.

Rupture

The feeling of a sharp blow to the back of the ankle and an inability to dorsiflex the foot are characteristic of an Achilles tendon rupture. It is classically seen in middle-aged squash and badminton players. Clinically, it can be confirmed using Simmonds' test; this involves squeezing the calf muscles and seeing the foot plantarflex if the tendon is intact.

Tears at the musculotendinous junction can be treated conservatively using a plantarflexed cast or boot for 6–9 weeks. Mid-substance tendon tears can be treated conservatively or by surgical repair. Re-rupture in the first year following injury can occur with either treatment method: there is a 6–10% risk after treatment with conservative methods vs. 3–4% after operative repair. In the long term the re-rupture rate is the same but the risk of nerve damage and skin necrosis is solely associated with operative repair (Summary box 32.3).

Summary box 32.3

Ankle injuries

- Ankle sprains are graded from I to III, depending on the structures that are injured
- Common tendon injuries are to the Achilles tendon, tibialis posterior and peroneal tendons

FOOT INJURIES

Plantar fasciitis

Typically, this may occur in a middle-aged active patient with a unilateral painful heel. Pain is worse in the morning and on getting out of bed or up from a chair. The pain becomes a dull ache increasing in severity.

Clinically, there may be an area of tenderness around the calcaneal tuberosity on the inferomedial aspect of the calcaneum. A calcaneal spur is present in 50% of cases, which is of unknown significance.

Treatment is varied and includes shoe inserts/heel cups, NSAIDs and local steroid injections. Success with each modality is variable but, as the condition is usually self-limiting over a period of 18 months, one will probably be associated with curing the condition. In cases that are resistant to conservative management, surgical release of the origin of the plantar fascia may be indicated.

Retrocalcaneal bursitis

The calcaneal insertion of the Achilles tendon has a superficial bursa that can become irritated; an associated Haglund's (bony

lump) deformity may also be present. It responds well to footwear modification. Occasionally, surgical resection of the calcaneal tuberosity may be attempted but the lump often recurs.

Nerves

Sural nerve entrapment

This commonly occurs in runners and presents with pain along the lateral aspect of the foot. It is often associated with chronic ankle sprains due to the presence of scar tissue. Nerve conduction studies show slow conduction. Initial treatment with manipulation/massage of soft tissues to break down adhesions should help. In resistant cases surgical release is required.

Morton's neuroma

There are many theories regarding the aetiology of Morton's neuroma but it is widely accepted that it occurs in the post-traumatic foot, especially with associated metatarsal fractures.

Patients complain of pain or aching around the metatarsal heads that is exacerbated by walking and relieved by rest or massaging the affected area. Ultrasound or MRI confirms the diagnosis. Lifestyle and footwear modification with or without injection of steroids into the affected web space have limited success. Surgical resection of the neuroma forms the mainstay of treatment.

Bones

Turf toe (plantar capsular ligament sprain)

Pain at the metatarsophalangeal joint (MTPJ) of the big toe may be caused by repetitive jamming of the big toe or pushing off while running and jumping. It is a classic cricketing injury. Hyperextension of the first MTPJ tears the MTPJ capsule and causes pain, swelling and stiffness. Joint instability and even dislocation at the MTPJ can occur in severe cases.

Diagnosis is by clinical means with radiography being performed to exclude any fractures. Treatment consists of avoiding the activity for 3–4 weeks with elevation and ice, to allow the capsule to heal. Orthotic shoe inserts that limit movement at the MTPJ can help to prevent recurrence.

Metatarsalgia

Pain felt in the ball of the foot around the metatarsal heads is called metatarsalgia. It commonly occurs at the heads of the second, third and fourth metatarsals. It is caused by excessive pressure being exerted on the metatarsal heads because of poor footwear, participating in high-impact activities without proper footwear, pes cavus, a tight Achilles tendon, first ray instability, hammer toe or claw toe.

The pain is under one or more of the metatarsal heads and the patient may describe it as a feeling of walking on pebbles.

Treatment is by adaptation of footwear and use of an orthotic metatarsal insole, which offloads the metatarsal heads.

Freiberg's disease

Avascular necrosis of the second metatarsal head is called Freiberg's disease (Fig. 32.14). It is most commonly seen in ado-

lescents before epiphyseal closure. Pain is diffusely spread in the forefoot. Treatment consists of activity modification with or without orthotic insoles or metatarsal bars. Surgical resection will leave a short toe.

Sever's disease (calcaneal apophysitis)

Sever's disease is heel pain developing in the teenager and is associated with a growth spurt. The hindfoot has poor flexibility and altered biomechanics. The vertical orientation of the apophyseal plate where the Achilles tendon inserts into the calcaneum makes it prone to shearing forces. It is common in soccer players and gymnasts who perform frequent running or jumping movements. Treatment consists of activity modification and stretching exercises and may be coupled with heel cushion inserts. Once the growth plate fuses the symptoms should resolve.

Stress fractures

Stress fractures are classically associated with constant impact sports, such as running or jumping on hard surfaces. Common sites for fractures are the neck of the second metatarsal (March fractures), the sesamoids of the great toe and the navicular in dancers and horse riders. It is caused by repetitive loading of the bone leading to microfractures across the bone. If the rate of formation of microfractures exceeds the reparative ability of the bone, a stress fracture forms and causes pain.

They are more common in women and this may be associated with the 'female athlete triad' of bulimia/anorexia, amenorrhoea and osteoporosis.

The treatment of stress fractures is rest from the causative activity, usually for 6–8 weeks. This does not mean a cessation of all sport but rather adapting and using other training modalities to maintain fitness, muscle strength and flexibility. A premature return to sport may result in a chronic injury developing (Summary box 32.4).

Figure 32.14 Radiograph of Freiberg's disease.

Thomas George Morton, 1835–1903, Surgeon, the Pennsylvania Hospital, Philadelphia, PA, USA, described this condition in 1876.
Albert Henry Freiburg, 1869–1940, Professor of Orthopaedic Surgery, the University of Cincinnati, OH, USA, described this condition in 1926.

James Warren Sever, 1878–1964, Orthopaedic Surgeon, the Children's Hospital, Boston, MA, USA, described apophysitis of the os calcis in 1912.
March fractures are so called because they commonly occur in troops who have marched long distances.

Summary box 32.4

Foot injuries

- Plantar fasciitis is common and difficult to treat
- Nerve impingement is common, especially in the interdigital nerves
- Fractures of the bones may cause avascular necrosis
- Stress fractures are common and require activity adaptation

SHOULDER AND UPPER LIMB INJURIES

The shoulder consists of three joints, all of which can be injured. The glenohumeral joint is inherently unstable and is therefore prone to injury, particularly in sports that rely on throwing.

Instability

Shoulder instability is extremely common and can range from dislocations through to subluxations. Eventually, it may require a minimal external force for such events to occur. Males under the age of 25 years with a first-time dislocation have a 60% chance of recurrence, a 10% chance of contralateral instability and a 20% chance of developing arthritis.

Dislocations should be reduced as quickly as possible and, after a short period of immobilisation, intensive rehabilitation should be started to build strength and coordination around the shoulder.

Tendinitis and tears of the rotator cuff

Damage to the rotator cuff is particularly common in bowlers and the older athlete. Overload and impingement as a result of abnormal acromial anatomy may be at fault. It is characterised by pain over the anterior shoulder that radiates down the arm, is worse at night and which presents difficulties in raising the arm above the head. Speed's and Yergason's tests are usually positive. Treatment includes modifying activities and cortisone injections. Arthroscopic debridement can also be considered.

Rotator cuff tears are more common in the elderly athlete and are rarely amenable to surgery. In the younger athlete a significant force must have been applied for a tear to occur; repair offers a good chance of success.

Acromioclavicular joint dislocation

This is common in cyclists, wrestlers and after a fall onto the shoulder. Unless the clavicle buttonholes through the muscle, treatment is usually conservative.

Occasionally, a direct blow to the lateral end of the clavicle may result in osteolysis of the end of the clavicle. This is usually self-limiting but does leave a noticeable gap.

Sternoclavicular joint dislocation

Again, this is associated with falls onto the shoulder, resulting in dislocation of the joint anteriorly. It can be treated conservatively. Urgent reduction is needed if the displaced bone is compromising the thoracic outlet.

Muscles

Rupture of the pectoralis major, long head of the biceps and subscapularis are the most common muscle injuries around the

shoulder. They are particularly common in weightlifters and wrestlers, in which case an association with performance-enhancing drugs should be considered. Biceps ruptures can be treated conservatively but the other two injuries may require surgical repair (Summary box 32.5).

Summary box 32.5

Shoulder and upper limb injuries

- The shoulder is a complex series of joints that work in synchrony
- It is particularly susceptible to injury in throwing sports
- Instability should be treated aggressively to prevent chronic conditions developing

THE ELBOW

Injuries to the elbow are less common than injuries to other joints and are generally caused by overuse. This occurs in golf, tennis, baseball and events involving throwing.

Lateral and medial epicondylitis

Lateral epicondylitis (tennis elbow)

This is tendinitis of the origin of the extensor carpi radialis brevis and is a problem in older athletes. Pain is localised to the insertion of the extensor muscles on the lateral side of the elbow and is typically made worse by shaking hands or opening doors. It is self-limiting over a year; treatment with NSAIDs, acupuncture and injections have all proved to be effective.

Medial epicondylitis (golfer's elbow)

This is inflammation of the flexor tendon origin on the medial side of the elbow and is caused by exercise involving repetitive throwing. Pain radiates from the medial epicondyle down the forearm and is exacerbated by pronation. There may be associated ulnar nerve symptoms. Treatment is the same as for lateral epicondylitis.

Osteochondritis dissecans of the elbow

Although this condition can affect any joint, gymnasts and cricketers are particularly at risk. It involves spontaneous necrosis of the capitellum, resulting in bony fragments that cause crepitus, pain and locking of the joint. Arthroscopic removal is advised.

THE HAND AND WRIST

Injuries to the hand and wrist are very common in all forms of sport. They can terminate a sporting career and can have a devastating effect on everyday life.

The anatomy of the hand is highly complex, with tendons, muscles, nerves and synovial sheaths all working closely together to allow fine, complex movements. Even relatively minor damage to any of these structures can affect the whole function of the hand.

Careful assessment of the injured hand is essential. Each individual nerve and tendon should be examined. A small puncture wound can suggest that there is only minimal damage

internally; however, a missed severed tendon or index finger lateral digital nerve can have long-term major consequences.

Compression of the nerves

The median nerve

Repetitive weight training can cause compression of the median nerve in a number of areas: the ligament of Struthers, pronator teres, carpal tunnel and the origin of the flexor digitorum superficialis.

Symptoms of parasthesiae and a positive Tinel's sign are diagnostic. Treatment by activity modification should relieve the symptoms although, occasionally, surgical release is required.

The ulnar nerve

As the ulnar nerve traverses Guyon's canal it may be compressed. This can occur in cyclists who hyperextend their wrists and press down on the handlebars. Again, activity modification and splinting should relieve the symptoms.

The radial nerve

Compression of the radial nerve can be hard to differentiate from lateral epicondylitis. If the radial nerve is compressed, stressing the extensor carpi radialis brevis should reproduce the symptoms. Again, activity modification and forearm splinting should resolve this.

The carpus

Fractures and dislocations of the carpus are discussed in Chapter 27. The scaphoid bone is particularly vulnerable in gymnasts and weightlifters who dorsiflex their wrists under extreme loads. This causes the scaphoid to impact against the radius and gives wrist pain. An osteophyte develops causing impingement; this usually needs excision.

Sir John Struthers, 1823–1899, Professor of Anatomy, the University of Aberdeen, Scotland.

Jules Tinel, 1879–1952, Physician, Hôpital Beaujon, Paris, France.

Jean Casimir Felix Guyon, 1831–1920, Professor of Surgical Pathology, Paris, France.

Fingers

Dislocations of the joints and injuries to the collateral ligaments and tendons are very common injuries. For example, game-keeper's/skier's thumb is caused by marked radial deviation of the proximal phalanx on the metacarpal, causing the ulnar collateral ligament to stretch and ultimately rupture. Partial tears can be treated in a splint but complete ruptures will need surgical intervention. Mallet/baseball finger is a rupture of the distal insertion of the extensor tendon and can be treated conservatively. The more subtle ruptured middle slip of the extensor mechanism at the proximal interphalangeal joint is often missed, resulting in a boutonnière deformity, which will often need surgical intervention.

Flexor tendons may also rupture at the distal interphalangeal joint. This is commonly seen in rugby and wrestling as the athlete attempts to grab the opponent's jersey, hence the name jersey finger; it requires early surgical intervention.

The spine

LEARNING OBJECTIVES

To learn:

- The salient features relating to the history and examination of the spine
- The investigations commonly used in the field of spinal disorders
- The treatment principles for common conditions affecting the spine

EPIDEMIOLOGY

The lifetime prevalence of low back pain has been reported at between 60 and 80%. By comparison, the lifetime prevalence of true sciatica has been reported at 5.3% in men and 3.7% in women. It is generally accepted that 90% of acute episodes of low back pain settle, allowing return to work within 6 weeks. However, some 3–4% of the population aged between 16 and 44 years and 5–7% of the population aged between 45 and 64 years will report back problems as a 'chronic sickness'.

The lifetime prevalence of neck pain reported in the literature varies from 66% to 71%. A higher prevalence is noted in females, those of advanced years, those with previous injury and those with perceived high job demands. The true incidence of brachialgia has not been reported in the literature.

CLINICAL ANATOMY

The normal thoracic kyphosis is between 20° and 50° (mean 35°) and increases with age. The normal lumbar lordosis is between 40° and 80° (mean 60°). Most lumbar lordosis occurs between L4 and S1, and decreases with age. When standing, the normal sagittal vertical axis (sagittal plumb-line) falls from the odontoid process through the C7–T1 disc space and crosses the spinal column at the T12–L1 disc space, before reaching the posterior superior corner of the S1 vertebral body.

The spinal nerve roots include 8 cervical, 12 thoracic, 5 lumbar, 5 sacral and 1 coccygeal. Dorsal and ventral roots join to form spinal nerves. The ventral root and the dorsal root ganglion lie within the intervertebral foramen. The neural foramen is bounded superiorly and inferiorly by pedicles, anteriorly by the disc and posteriorly by the facet joint. Degenerative changes in these structures may lead to neural compromise. Disruption of the medial or inferior pedicle cortex with pedicle instrumentation should be avoided to minimise the risk of injury to the nerve root or dura. When considering the spinal canal, it is helpful to describe parasagittal subdivisions including the central canal, lateral recess, foraminal and extraforaminal zones to assist when

correlating radiological findings with operative findings. Laminal overlap within the lumbar spine decreases from L1 to S1 so that, at the L5–S1 level, discectomy requires *less* bone removal than a more proximal discectomy (Summary box 33.1).

Summary box 33.1

The spinal canal

The spinal canal may be divided into:

- Central canal
- Lateral recess
- Foraminal zone
- Extraforaminal zone

The blood supply of the spinal cord is derived from the vertebral, deep cervical, intercostal and lumbar arteries. The arteries of the spinal cord include the anterior spinal artery and two posterior spinal arteries. In the cervical spine, the anterior spinal artery arises from the vertebral artery. The vertebral artery enters the transverse foramen of C7 and travels cephalad to pass through the foramen magnum. Radicular arteries enter the vertebral canal through the intervertebral foramen and divide into anterior and posterior radicular arteries, which in turn supply the anterior and posterior spinal arteries. The most significant radicular artery to the cervical cord arises from the deep cervical artery and travels with the left C6 spinal nerve. The radicular artery of Adamkiewicz makes a major contribution to the anterior spinal artery, supplying the lower spinal cord. It originates on the left in 80% of people, usually accompanying the ventral root of T9, T10 or T11, but can originate anywhere from T5 to L5. Ligation of segmental vessels over the midpoint of the vertebral body will minimise the risk of injury to this important artery.

Albert Adamkiewicz, 1850–1921, Professor of Pathology, The University of Krakow, (Cracow), Poland, described the arterial supply of the spinal cord in 1882.

Injury to the superior gluteal artery and cluneal nerves can occur during bone graft harvest from the posterior iliac crest. The incision should, therefore, stay within 70 mm of the posterior iliac crest. An incision made parallel to the cluneal nerves and perpendicular to the posterior iliac crest decreases the morbidity. The lateral femoral cutaneous nerve may be injured when harvesting bone from the anterior iliac crest. By operating at least 2 cm posterior to the anterior superior iliac crest and harvesting from the outer cortex of the ilium, the risk is reduced.

HISTORY AND PHYSICAL EXAMINATION

History taken from a patient with back pain should include questions on age, history of malignant disease, unexplained weight loss, intake of immunosuppressive drugs, duration of symptoms, responsiveness to previous treatment, pain that is worse at rest and urinary or other infections. In cauda equina syndromes, there will usually be a history of difficulty with micturition, loss of anal sphincter tone and faecal incontinence, saddle anaesthesia around the anus, perineum and genitals, and widespread progressive motor weakness in the legs and gait disturbance (Summary box 33.2).

Summary box 33.2

Cauda equina syndrome

A spectrum of:

- Low back pain
- Uni- or bilateral sciatica
- Saddle anaesthesia
- Motor weakness in the lower extremities
- With variable rectal and urinary symptoms

For patients with neck pain, sensory disturbance, widespread motor weakness and long tract signs, the possibility of cervical myelopathy should be considered. For the diagnosis of spinal stenosis, the most commonly found symptom from the history is reduced walking distance. Other specific causes of back pain such as infections, benign tumours and inflammatory disease are found in fewer than 1% of patients seen in general practice. Summary box 33.3 lists the commonly accepted 'red flags' that allow diagnostic triage into those with serious pathology of the spine (such as fractures, tumours or cauda equina syndrome) and those without serious pathology.

Summary box 33.3

'Red flags' according to the evidence-based guidelines (the most common indications from history and examination for pathological findings requiring special attention)

- Back pain in children <18 years with considerable pain or onset >55 years
- History of violent trauma
- Constant progressive pain at night
- History of cancer
- Systemic steroids
- Drug abuse, human immunodeficiency virus infection
- Weight loss
- Systemic illness
- Persisting severe restriction of motion
- Intense pain or minimal motion
- Structural deformity
- Difficulty with micturition
- Loss of anal sphincter tone or faecal incontinence; saddle anaesthesia
- Widespread progressive motor weakness or gait disturbance
- Inflammatory disorders (ankylosing spondylitis) suspected
- Gradual onset <40 years
- Marked morning stiffness
- Persisting limitation of motion
- Peripheral joint involvement
- Iritis, skin rashes, colitis, urethral discharge
- Family history

The psychosocial history helps to estimate prognosis and to plan therapy. The New Zealand guidelines introduced the concept of 'yellow flags'. The most useful items are a history of failed previous treatment, substance abuse and disability compensation. Brief screening questionnaires for depression and psychosocial problems offer important therapeutic opportunities.

The examination should exclude pathology of the shoulder, hip, knee, sacroiliac joint and vascular system. The normal range of motion in the cervical spine is 45° of flexion, 55° of extension, 70° of rotation and 40° lateral bend. Spurling's test for radiculopathy is a reproduction of arm pain by hyperextension and lateral rotation towards the symptomatic side. This manoeuvre decreases the size of the intervertebral foramen. Tone, power, coordination, reflexes and sensation should be checked on both upper and lower limbs (Tables 33.1 and 33.2). Myelopathy or upper motor neurone (UMN) lesions are suggested by hyperreflexia, a positive Hoffmann's sign (if the middle finger is flicked

Table 33.1 Neurological evaluation of the upper limb

Neurological level	Motor	Sensation	Reflex
C5	Deltoid	Lateral arm	Biceps
C6	Wrist extensors and extensor carpi radialis longus	Lateral forearm	Brachioradialis
C7	Triceps	Middle finger	Triceps
C8	Long finger flexors	Medial forearm	No reflex
T1	Interosseus muscles	Medial arm	No reflex

Johann Hoffmann, 1857–1919, Professor of Neurology, Heidelberg, Germany.

Table 33.2 Neurological evaluation of the lower limb

Neurological level	Motor	Sensation	Reflex
L2	Hip flexion	Anterior thigh, groin	No reflex
L3	Knee extension	Anterior and lateral thigh	Patellar (L3, 4)
L4	Ankle dorsiflexion	Medial leg and foot	Patellar (L3, 4)
L5	Extensor hallucis longus	Lateral leg and foot	No reflex
S1	Ankle plantarflexion	Lateral foot and little toe	Achilles

into extension, the thumb and other fingers flex briskly), upgoing plantar responses and, in the case of a high cervical myelopathy, a positive scapulohumeral reflex (tapping on the spine of the scapula or tip of the acromion in the caudal direction leads to elevation of the scapula or abduction of the humerus). Other manifestations of hyperreflexia include ankle and patellar clonus. Typical signs of radiculopathy [lower motor neurone (LMN) lesion] include flaccid paralysis, muscle atrophy, loss of reflexes and muscle fasciculation.

Schober's test determines the degree of actual excursion in flexion and extension, which is decreased in ankylosing spondylitis. Functional testing by observation of heel walking (ankle dorsiflexion L4 myotome), toe walking (ankle plantarflexion S1 myotome) and deep knee bend (quadriceps L3 and L4 myotomes) can give a quick assessment of lower limb power. However, formal testing of all five myotomes should be performed (Table 33.2). The knee, ankle and Babinski reflexes should also be assessed. A positive passive straight leg raise test produces radicular pain distal to the knee at less than 70° of elevation. If the contralateral straight leg raise is positive for radicular pain in the symptomatic leg, this is strongly suggestive of nerve root compression. Lasègue's sign denotes straight leg raise radiculopathy aggravated by ankle dorsiflexion, while the bowstring sign denotes straight leg raise radiculopathy aggravated by applying pressure over the popliteal fossa. The femoral stretch test is less specific than the sciatic straight leg raise. When positive, it produces anterior thigh symptoms and indicates an L3 or L4 radiculopathy. The patient is examined in the prone position with the knee flexed, and the hip is then passively extended.

The sacroiliac joints can be assessed by applying manual compression across the iliac wings or by performing the FABER (flexion, abduction, external rotation, figure-of-four test) test of the hip to rule out sacroiliac instability and pain.

Examination for scoliosis involves inspection of the patient standing and in forward flexion (Adams' test) to assess rib or loin prominence. Relative shoulder heights and waist asymmetry should be noted. The skin should be examined for cutaneous neurofibromata, café au lait patches or axillary freckles commonly present in neurofibromatosis. Neurological examination should include abdominal reflexes. Leg lengths should be measured. In the case of kyphosis, the sagittal alignment and forward gaze should be assessed.

Waddell *et al.* (1979) developed and validated a series of signs and tests that have proved helpful in identifying individuals

who are magnifying or exaggerating symptoms. The signs include three observations of pain behaviour (pain in a non-anatomical distribution, pain out of proportion to the stimulus, exaggerated pain behaviour such as grimacing) and four tests (skin roll produces 'radicular' symptoms, pain on simulated spinal rotation, back pain on axial compression of the head, and variable straight leg raise in the supine and sitting positions). Waddell's signs of incongruity do not explain why a patient is exaggerating. A patient may be seeking some secondary gain. Patients with three or more of these signs typically respond poorly to either surgery or physiotherapy unless the underlying cause of the abnormal behaviour is corrected (Summary box 33.4).

Summary box 33.4

Non-organic physical signs in low back pain

- *Tenderness*: superficial or non-anatomical
- *Simulation tests*: axial loading or rotation
- *Distraction tests*: variable straight leg raises
- *Regional disturbances*: non-anatomical sensory or motor loss
- *Over-reaction*: grimacing, muscle tremor, etc.

INVESTIGATIONS

The most common diagnostic imaging tests used to evaluate spinal disorders include plain radiographs, magnetic resonance imaging (MRI), computerised tomography (CT), CT myelography and isotope bone scanning. These investigations are extremely sensitive but relatively non-specific. For example, at least one-third of asymptomatic patients have been noted to have 'abnormalities' on MRI scans. All investigations must therefore be carefully correlated with the clinical findings.

Plain radiographs

It is not necessary to order spine radiographs for every patient presenting with neck or low back pain. Plain radiographs of a patient with cervical, thoracic or lumbar pain may be indicated for those patients less than 20 years of age or over 50 years of age, for patients who have failed to respond to conservative treatment, for patients who have sustained trauma or suffered night pain or with a history of carcinoma, fever or weight loss. Standing radiographs of the whole spine are important for the full assessment of scoliosis. Radiographs cannot diagnose early-stage tumour or infection, because significant bone destruction (between 40% and 60% of bone mass) must occur before a radiographic abnormality is detected (Summary box 33.5).

Joseph Francois Felix Babinski, 1857–1932, Neurologist, Hôpital de la Pitié, Paris, France.
Charles Ernest Lasègue, 1816–1863, Professor of Medicine, The University of Paris, and Physician, La Salpêtrière, Paris, France.

Summary box 33.5

Need for plain radiography

Plain radiographs of the lumbar, thoracic or cervical spine may be indicated for:

- Patients under 20 years of age
- Patients over 50 years of age
- History of trauma
- History of carcinoma
- History of night pain, fever or weight loss

Magnetic resonance imaging

This allows detailed visualisation of the disc, thecal sac, epidural space, neural elements, paraspinal soft tissues and bone marrow, while avoiding the use of ionising radiation. It is contraindicated for patients with pacemakers, drug pumps or spinal cord stimulators.

Computerised tomography

This investigation is the best test for bone anatomy. Three-dimensional reconstructions are often useful for the assessment of congenital spinal deformity. CT myelography is now rarely used, but does have utility in revision cases or for those patients unable to have MRI.

Bone scintigraphy

Isotope bone scanning is a highly sensitive, but non-specific test useful for screening of the skeletal system for metastatic disease, discitis or vertebral body osteomyelitis, or to assess the relative activity of bone lesions such as pars interarticulares defects or a pseudarthrosis. When investigating spondylolysis, a single-photon

emission CT (SPECT) scan will provide both planar and cross-sectional images. ^{99m}Tc hydroxymethylene diphosphate is administered intravenously. The technetium is adsorbed into the hydroxyapatite matrix of bone, and the activity is recorded with a gamma camera. In the case of multiple myeloma or purely lytic metastases, the bone scan may not show increased activity as these tumours may not stimulate a significant *osteoblastic* response. The use of a mobile gamma probe can assist in the perioperative localisation and excision of both osteoid osteoma and osteblastomas.

Bone densitometry

Bone density can be measured using dual-energy X-ray absorptiometry (DEXA). It is widely used to assess bone mass and is necessary to confirm the diagnosis of osteoporosis. The bone density is usually checked at three sites: the spine, the hip and the distal radius.

Discography

This involves the injection of a radio-opaque contrast agent into a presumed degenerated and painful disc as a preoperative test for performing spinal fusion or as a method of choosing the level of fusion (Fig. 33.1). It is commonly used in the lumbar spine, and less commonly in the cervical spine. It is possible to assess disc morphology and to confirm whether or not the intervertebral disc is the pain generator. Although controversial, there are reports in the literature demonstrating improved outcome following lumbar fusion in patients who were selected by positive lumbar discography.

Facet joint injections

For patients who predominantly have facet joint arthropathy, X-ray-guided facet joint injections may be both diagnostic and

Figure 33.1 Lumbar discography. Anteroposterior (a) and lateral (b) radiographs following injection of contrast media into the lower three lumbar discs. Typical low back pain was reproduced when injecting the L4/5 and L5/S1 disc. The patient experienced no pain when the L3/4 disc was injected.

therapeutic. Local anaesthetic combined with steroid is injected in the region of the facet.

Foraminal epidural steroid injections

For patients with radiculopathy due to a prolapsed intervertebral disc or lateral recess stenosis, a targeted foraminal epidural steroid injection of local anaesthetic and steroid may provide important diagnostic information and have a lasting therapeutic effect. The introduction of these techniques has been shown to significantly reduce the number of patients required to undergo traditional lumbar microdiscectomy.

Spinal biopsy

CT-guided or open biopsy is often performed to obtain tissue for diagnostic study in cases of suspected tumour and/or infection.

CLASSIFICATION

It is useful to classify low back pain into three main groups: mechanical, non-mechanical and miscellaneous (Table 33.3).

TUMOURS OF THE SPINE

Metastatic tumours

These are the most common tumours of the spine, accounting for 98% of all spine lesions. The commonest malignancies that metastasise to the spine include breast (21%), lung (14%), prostate (7.5%), renal (5%), gastrointestinal (5%) and thyroid (2.5%). The most frequent pathway for spread of metastatic deposits is through the venous system. Batson's plexus of veins extends along the entire spinal column, providing a connection with the major organ systems most commonly involved in metastatic spinal disease. Other methods by which metastatic disease spreads to the spine are listed in Table 33.4 (Summary box 33.6).

Summary box 33.6

Commonest malignancies that metastasise to the spine (in order of frequency)

- Breast
- Lung
- Prostate
- Renal
- Gastrointestinal
- Thyroid

Over 80% of patients with spinal metastases present with progressive unremitting *pain*, and only 20% present with spinal cord compression. Plain radiographs may show an absent pedicle (see Fig.

Table 33.3 Classification of low back pain (Carragee and Hannibal 2004)

I	Mechanical	e.g. spondylolysis, spondylolisthesis, facet joint arthropathy, discogenic low back pain, spinal stenosis
II	Non-mechanical	e.g. tumour, infection, inflammatory spondyloarthropathy
III	Miscellaneous	e.g. osteoporosis, viscerogenic referred pain, psychogenic pain

33.3a) ('winking owl' sign), vertebral cortical erosion and/or vertebral collapse. Investigations should include a full blood count (FBC), erythrocyte sedimentation rate (ESR), calcium, phosphate, alkaline phosphatase, prostate-specific antigen, serum protein electrophoresis, thyroid function tests, nutritional indices and either a CT-guided or open biopsy. Most metastases are *osteoblastic* and will show up on bone scintigraphy; however, osteolytic lesions such as multiple myeloma and hypernephroma may not show up on an isotope bone scan.

Treatment options include orthotic treatment, steroids (dexamethasone), radiotherapy, chemotherapy, hormonal therapy, surgery or a combination of any of the above. Radiotherapy promotes re-ossification of the vertebral body and reduces tumour load. It can be very effective for reducing 'bone pain'. Breast, lung and prostate metastases and lymphoma are highly radiosensitive. Gastrointestinal adenocarcinoma, metastatic melanoma, thyroid and renal carcinoma are radioresistant. Small cell carcinoma of the lung, Ewing's sarcoma, thyroid carcinoma, breast carcinoma and neuroblastoma are usually sensitive to chemotherapy and should have chemotherapy as the first line of management. Adenocarcinoma of the lung is resistant to chemotherapy.

Surgery should be reserved for those patients whose life expectancy exceeds 3 months. Indications for surgery include a lack of definitive diagnosis, progressive neurological deficit despite the administration of steroids and/or radiotherapy, spinal instability, incapacitating pain or radioresistant tumours. Relative contraindications to surgery include multiple spinal metastases, widespread visceral or brain metastases or an expected survival of less than 3 months. Preoperative embolisation of spinal tumours can dramatically reduce perioperative blood loss, which is particularly useful for vascular tumours such as renal cell carcinoma, thyroid carcinoma and Ewing's sarcoma.

Surgical approaches usually involve spinal decompression and stabilisation with instrumentation over multiple segments. The anterior column may be reconstructed with allograft, methylmethacrylate, titanium mesh or carbon fibre cages.

Primary spine tumours

These may be benign, intermediate or malignant. They include the *bone-forming tumours* such as osteoid osteoma, osteoblastoma (Fig. 33.2) and osteosarcoma, the *cartilage-forming tumours* such as chondroma, osteochondroma and chondrosarcoma, the *giant cell tumours* such as osteoclastoma, the *round cell tumours* such as Ewing's sarcoma, malignant lymphoma and myeloma, the *vascular tumours* such as haemangioma and haemangioendothelioma (Fig. 33.3) and a number of *tumour-like lesions* such as the aneurysmal bone cyst or eosinophilic granuloma. These are discussed further in Chapter 37.

Benign tumours tend to occur in the posterior elements; malignant tumours tend to involve the vertebral body. Osteoblastoma, aneurysmal bone cyst and giant cell tumour all

Oscar V. Batson, 1894–1979, an American Otolaryngologist.

James Ewing, 1866–1943, Professor of Pathology, Cornell University Medical College, New York, NY, USA, described this type of sarcoma in 1921.

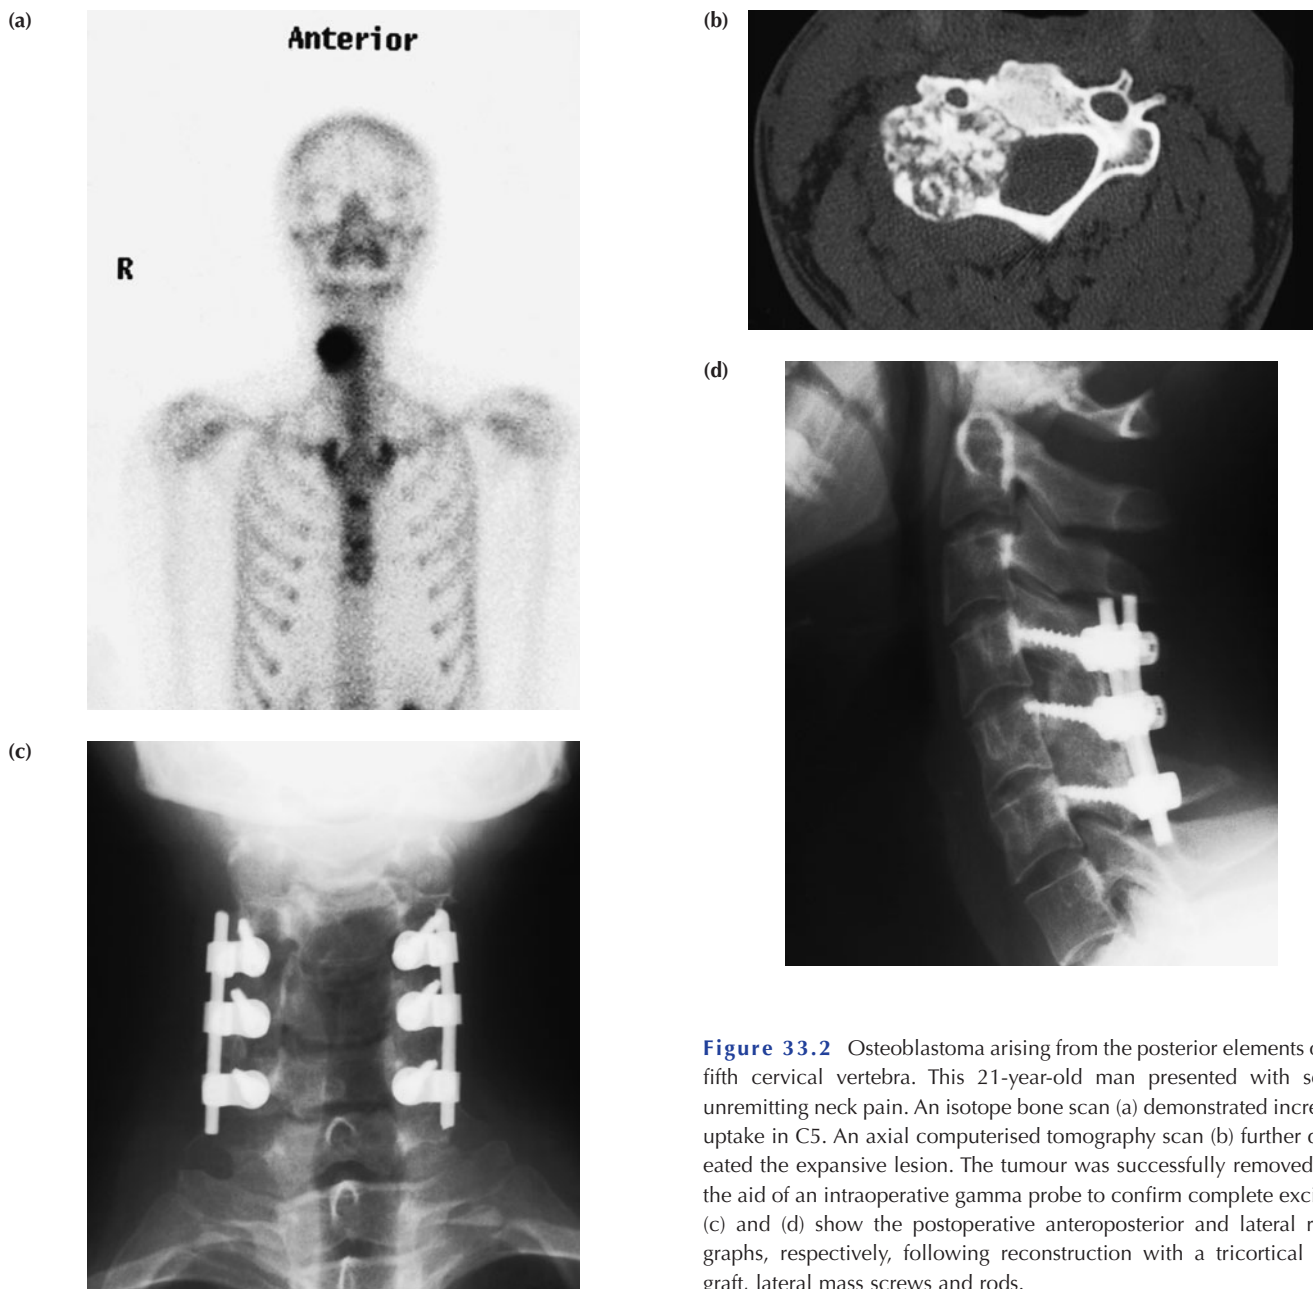

Figure 33.2 Osteoblastoma arising from the posterior elements of the fifth cervical vertebra. This 21-year-old man presented with severe unremitting neck pain. An isotope bone scan (a) demonstrated increased uptake in C5. An axial computerised tomography scan (b) further delineated the expansive lesion. The tumour was successfully removed with the aid of an intraoperative gamma probe to confirm complete excision. (c) and (d) show the postoperative anteroposterior and lateral radiographs, respectively, following reconstruction with a tricortical bone graft, lateral mass screws and rods.

have a relatively high rate of local recurrence. These tumours may present with pain or neurological deficit. The WBB (Weinstein, Boriani, Biagini) surgical staging system divides the vertebra into 12 radiating zones in clockwise order and allows an assessment of the extent of the tumour and assists in planning whether *en bloc* tumour excision is feasible.

Table 33.4 Methods by which metastatic disease spreads to the spine

1	Embolisation through the venous system (Batson's plexus)
2	Embolisation through the arterial system
3	Direct extension
4	Lymphatic spread

Osteoid osteoma was first described by Jaffe in 1935. The tumour consists of a small nidus of highly vascularised osteoblasts producing osteoid surrounded by dense sclerotic bone. Patients usually present between the ages of 10 and 25 years and complain of night pain that is not relieved by non-steroidal anti-inflammatory drugs or salicylates. The typical pain is related to prostaglandin production by the nidus.

Osteoblastomas are histologically very similar to osteoid osteomas, but are larger, with a nidus greater than 15 mm in diameter, and they behave in a more aggressive way (Fig. 33.2). Curative treatment of these lesions involves complete surgical excision of

Henry Lewis Jaffe, 1896–1979, American Pathologist.

Figure 33.3 Haemangioendothelioma arising from the body of the 11th thoracic vertebra. This 34-year-old man presented with signs of spinal cord compression and severe pain in the lower thoracic region. The anteroposterior radiograph (a) demonstrated loss of both pedicles at T11. Axial computerised tomography (b) confirmed a lytic lesion. Magnetic resonance imaging (c) demonstrated spinal cord compression on the axial T1-weighted scan. The patient underwent a staged posterior stabilisation, total *en bloc* spondylectomy and anterior column reconstruction. (d) and (e) show the postoperative anteroposterior and lateral radiographs respectively.

the nidus. The preoperative administration of radiopharmaceuticals and a sterile gamma probe intraoperatively can help to localise these bony tumours and confirm complete excision at the conclusion of surgery.

Intradural tumours

These are rare. They may be intramedullary (within the substance of the cord) or extramedullary (outside the cord). Most are extramedullary and benign; the commonest are meningiomas and neurofibromas. Intramedullary tumours include ependymomas and astrocytomas.

Intradural tumours can be multiple, occurring as part of a systemic syndrome (e.g. von Recklinghausen syndrome, neurofibromatosis type I and von Hippel–Lindau syndrome, multiple haemangioblastomas). Any malignant tumour can metastasise via the normal cerebrospinal fluid pathways. Patients usually show progressive neurological deficits with little pain.

Ependymomas are treated by surgical resection, with radiotherapy reserved for malignant or incompletely resected lesions. Astrocytomas are often infiltrative, with variable histology. They may be treated surgically using the carbon dioxide laser or ultrasonic aspirator, whereas others believe radiation therapy to be the treatment of choice.

INFECTIONS OF THE SPINE

Pyogenic infections

Pyogenic vertebral osteomyelitis is primarily a lesion of the disc and its osseous margins (Fig. 33.4). The most common method by which an organism spreads to the spine is via the haematogenous route (either by lodging in the end-arteriolar network in the vertebral end-plate or via retrograde flow from the pelvic venous plexus to the perivertebral venous plexus of Batson). Alternative routes include contiguous spread from adjacent soft tissue infection or direct implantation, e.g. traumatic penetration. The disc is nearly always involved in pyogenic vertebral infection. In contrast, granulomatous infection typically does *not* involve the disc space.

Risk factors for pyogenic vertebral osteomyelitis include advancing age, intravenous drug abuse, diabetes, renal failure, recent infections and trauma. *Staphylococcus aureus* accounts for 30–55% of infections. Gram-negative organisms such as *Escherichia coli*, *Pseudomonas* species and *Proteus* species are associated with recent genitourinary infections or procedures and intravenous drug abuse. Anaerobic infections are uncommon, but may be seen in diabetic patients and after penetrating trauma.

The principles of treatment of bone infection are discussed in Chapter 37.

Operative intervention should be considered for:

- an open biopsy (when a closed biopsy has failed);
- failure of medical management (persistent pain, elevated ESR);

Friedrich Daniel von Recklinghausen, 1833–1910, Professor of Pathology, Strasbourg, France, described generalised neurofibromatosis in 1882.
Eugen von Hippel, 1867–1939, Ophthalmologist, Göttingen, Germany.
Arvid Lindau, 1892–1958, Pathologist, Lund, Sweden.
Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology, (1891–1900), and of Medicine, (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.
Theodor Escherich, 1857–1911, Professor of Paediatrics, Vienna, Austria, discovered the *Bacterium Coli Commune* in 1886.

- drainage of abscesses;
- decompression of spinal cord compression;
- correction of progressive spinal deformity;
- correction of progressive spinal instability.

The surgical approach should include radical anterior debridement with reconstruction followed by staged or simultaneous posterior spinal stabilisation.

Epidural abscess

This condition is often a surgical emergency. The majority of cases occur within the thoracic spine. The patient presents with increasing pain, fevers, raised ESR and raised white cell count. Without treatment, significant neurological deficit occurs and, eventually, paralysis may develop.

Tuberculosis

This is discussed in Chapter 5.

DEGENERATIVE CONDITIONS OF THE SPINE

Cervical radiculopathy

Patients present with neck and arm pain (brachialgia), paraesthesia and motor weakness in the distribution of the compromised nerve root (radiculopathy). A disc herniation at the C5–C6 level causes compromise of the C6 nerve root, resulting in weakness of the biceps and wrist extensors, loss of the brachioradialis reflex and diminished sensation of the radial forearm into the thumb and index finger. Foraminal stenosis caused by degenerative changes may also lead to radiculopathy.

Symptoms often settle with conservative treatment including physiotherapy to restore lordosis and range of motion, medication for neuropathic pain (amitriptyline, gabapentin or pregabalin) or fluoroscopically guided foraminal epidural steroid injections of local anaesthetic and steroid. Intractable pain or functional neurological deficit is an indication for surgical intervention. Surgical options include anterior cervical discectomy (with or without the application of a cervical spine locking plate), posterior lamino-foraminotomy or cervical total disc replacement.

Cervical myelopathy

Degenerative change in the cervical spine leading to spinal cord compression is the commonest cause of cervical myelopathy in patients over 55 years of age (Fig. 33.5). LMN changes occur at the level of the lesion, with atrophy of the upper extremity muscles, particularly the intrinsic muscles of the hands. UMN findings are noted *below* the level of the lesion and may involve both upper and lower extremities. Typically, spasticity and hyperreflexia are noted in the legs. There may be neck pain, stiffness, spastic gait, loss of manual dexterity or problems with sphincter control.

The method of surgical decompression depends on where the pathology is located. For multilevel disease, a cervical laminectomy from C3 to C6 is commonly performed. If the cervical spine is kyphotic, additional instrumentation (lateral mass screws and posterior rods) should be added to restore cervical lordosis and assist in achieving a fusion. An alternative to laminectomy is canal-expansive laminoplasty. This procedure gained popularity in Japan, where the incidence of ossification of the posterior

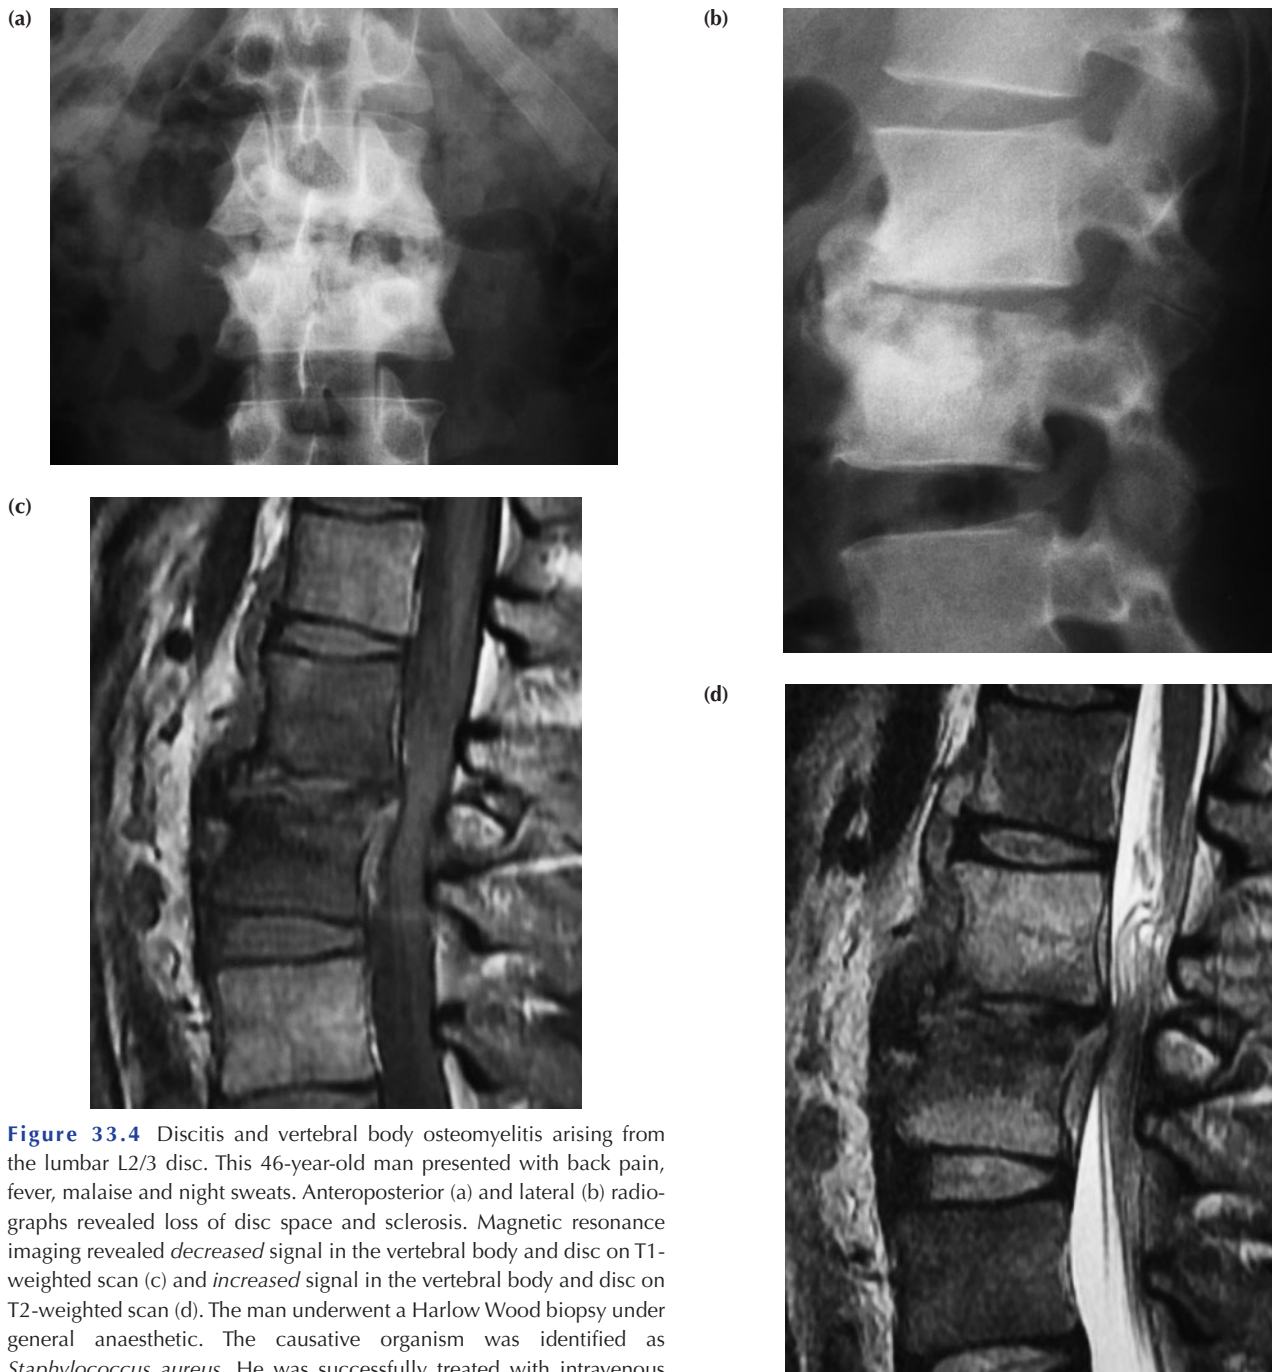

Figure 33.4 Discitis and vertebral body osteomyelitis arising from the lumbar L2/3 disc. This 46-year-old man presented with back pain, fever, malaise and night sweats. Anteroposterior (a) and lateral (b) radiographs revealed loss of disc space and sclerosis. Magnetic resonance imaging revealed *decreased* signal in the vertebral body and disc on T1-weighted scan (c) and *increased* signal in the vertebral body and disc on T2-weighted scan (d). The man underwent a Harlow Wood biopsy under general anaesthetic. The causative organism was identified as *Staphylococcus aureus*. He was successfully treated with intravenous antibiotics and an orthosis.

longitudinal ligament remains high. Anterior surgical options include anterior corpectomy and strut grafting.

Axial neck pain

Surgery for pure axial neck pain is controversial. Many authors have used cervical discography in an attempt to isolate the pain source before proceeding with anterior cervical discectomy and fusion. However, reviewing the literature, there is *no* evidence of benefit for this type of surgery for this indication.

Thoracic disc herniation

Thoracic disc herniations are rare, accounting for less than 2% of all discectomy procedures. Disc protrusions occur predominantly in the distal thoracic segments between T8 and T12. Herniations may be soft or calcified. Typically, the patient presents with axial pain, radiculopathy or myelopathy. MRI is invariably required to demonstrate protrusions and the degree of neural compromise. Thoracic disc protrusions identified on MRI may be *asymptomatic*. Conservative treatment including

Figure 33.5 Cervical myelopathy. Magnetic resonance image showing a block fusion at C6/7 with adjacent level degenerative changes and compromise of the spinal cord at C3/4, C4/5 and C5/6. Signal change was noted within the cord, particularly at the C4/5 level.

non-steroidal anti-inflammatory drugs, physiotherapy and general fitness should be tried initially. Discectomy and interbody fusion is an appropriate surgical treatment for progressive spinal cord compression or unremitting radicular pain. Surgery may be performed via a thoracotomy or, for a soft disc prolapse, via a thoracoscopic approach. Surgery for pure axial pain is not recommended.

Lumbar disc herniation

A symptomatic lumbar disc herniation occurs during the lifetime of approximately 2% of the population. Risk factors include male gender, age (30–50 years), heavy lifting or twisting, stressful occupation, lower income and cigarette smoking.

Herniations may be described as a *protrusion* (displaced disc material remains in continuity with the disc of origin and contained by the annulus fibrosus), an *extrusion* (disc material migrating through the annulus fibrosus but contained by the posterior longitudinal ligament) or *sequestered* (disc material lying free in the spinal canal). This material may be *central*, *posterolateral*, *foraminal* or *extraforaminal*. Over 90% of lumbar disc herniations occur at the L4–5 or L5–S1 levels. A posterolateral disc protrusion will affect the *traversing* root, e.g. an L5–S1 disc protrusion affects the S1 nerve root. A far-lateral disc protrusion (extraforaminal) will affect the *exiting* nerve root, e.g. far-lateral L5–S1 disc protrusion affecting the L5 nerve root (Fig. 33.6). Symptoms typically commence with a period of back pain followed by sciatica. There may be paraesthesia, motor weakness, loss of reflexes and a reduction in straight leg raise.

A large midline disc herniation may compress the cauda equina, leading to a syndrome defined by bowel and/or bladder difficulties, saddle anaesthesia and lower limb sensory and motor deficits. Surgery for cauda equina syndrome should be performed

Figure 33.6 Far-lateral disc prolapse at L5/S1. A right-sided far-lateral disc protrusion is noted at L5/S1 on the T1-weighted (a) and the T2-weighted (b) magnetic resonance imaging scan. The patient presented with an L5 radiculopathy.

within 24 hours of the onset of symptoms to allow the optimum recovery of neural elements.

For simple sciatica, a period of 6–12 weeks of conservative treatment is advised. Up to 70% of patients will settle within this period. Epidural steroid injections may be helpful. Microdiscectomy is the standard surgical intervention for those in whom conservative treatment has failed. Surgical excision removes both the source of the pressure and the initiator of the inflammatory response.

Spinal stenosis

Spinal stenosis is characterised by back, buttock or leg pain. Symptoms are often provoked by exercise. Symptoms of spinal claudication can be distinguished from vascular claudication because they are frequently associated with neurological symptoms, are often worse in extension, and pedal pulses are present on clinical examination.

Plain radiographs may show degenerative changes with or without degenerative spondylolisthesis. MRI scans will reveal neural compromise. Stenosis is caused by a combination of facet joint hypertrophy, disc bulge and ligamentum flavum thickening.

Symptoms progress in approximately 20% of patients who receive no treatment. The condition may be treated successfully by surgical intervention. Laminectomy with preservation of the facet joints is a reasonable option, particularly when normal lumbar lordosis is preserved. Others prefer multilevel laminotomies with undercutting of the facet joints, trimming of the ligamentum flavum and removal of disc bulges. Such a segmental procedure is considered to be less destabilising than laminectomy. Preservation of the midline structures via a spinous process osteotomy is an alternative approach. Recently, an interspinous process decompression system (X-stop) has been found to be effective for patients suffering from lumbar spinal stenosis when compared with non-operative therapy.

Discogenic low back pain

Discogenic low back pain has been defined as a continuum of diagnostic categories (internal disc disruption, degenerative disc disease, segmental instability) reflecting various stages of degenerative pathology affecting the intervertebral disc. Patients typically present with chronic relapsing episodes of low back pain. MRI studies may show decreased signal intensity within the disc, high-intensity zones in the posterior annulus (suggestive of an annular tear) and surrounding Modic changes in the adjacent end-plates. A recent study has compared rehabilitation with spinal fusion for such candidates. The authors concluded that both groups reported reductions in disability during the 2 years of follow-up and recommended that patients should be offered rehabilitation prior to surgical intervention.

For those patients who fail to improve with conservative measures, provocative lumbar discography may help to confirm the pain generator. Intradiscal electrothermal therapy (IDET) was heralded as a new treatment for patients with discographically proven discogenic low back pain. There are two randomised controlled trials assessing the efficacy of IDET. The first showed modest overall benefit, and the second showed IDET to be no more effective than placebo for the treatment of chronic discogenic low back pain.

Lumbar fusion may be considered for treatment of low back pain of discogenic origin in patients who fail to improve after a minimum of 6 months of appropriate non-surgical care. In one randomised study, lumbar fusion diminished pain and decreased disability more efficiently than commonly used non-surgical treatment. Many techniques including non-instrumented posterolateral fusion, instrumented posterolateral fusion, anterior lumbar interbody fusion (Fig. 33.7), posterior lumbar interbody fusion and combined anterior and posterior (circumferential) fusion have been used. The literature remains unclear as to the best method; however, it seems apparent that lumbar interbody fusion, i.e. the anterior or posterior techniques, provides a higher fusion rate when compared with posterolateral fusion, although this does not necessarily translate to a superior clinical outcome.

A recent study has compared a total disc replacement (Fig. 33.8) with an anterior lumbar interbody fusion for the treatment of mechanical low back pain caused by one-level degenerative disc disease. The authors found the clinical outcomes in both groups to be *equivalent* at 2 years, suggesting that total disc replacement remained a viable option for this condition.

Figure 33.7 Anterior lumbar interbody fusion. The PEEK (polyethylene terephthalate) cage has been packed with bone graft prior to insertion (a); (b) and (c) show the anteroposterior and lateral postoperative radiographs respectively.

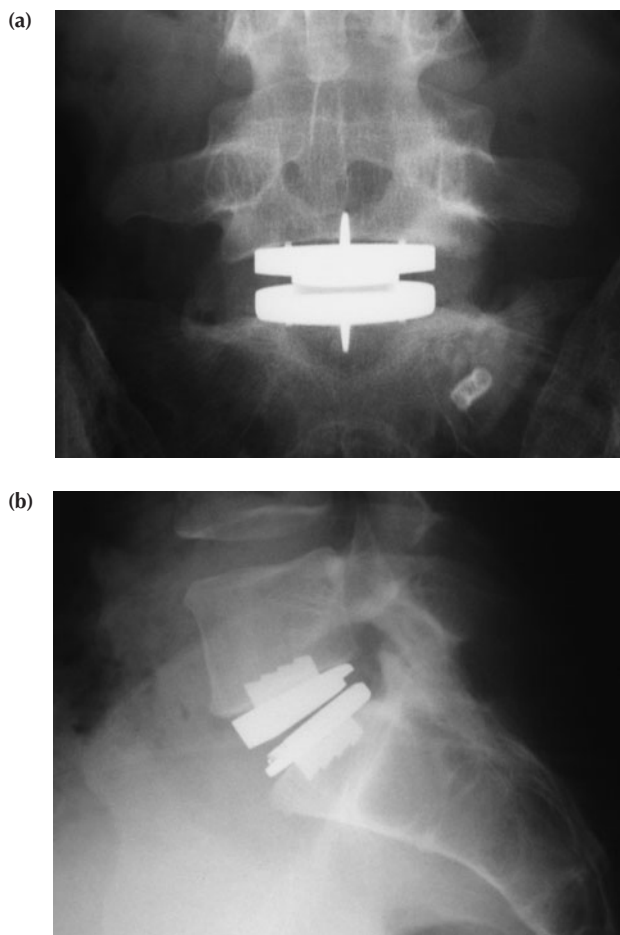

Figure 33.8 Lumbar total disc replacement. (a) Anteroposterior radiograph with 30° of cranial inclination. (b) Lateral radiograph with the implant appropriately positioned.

SPONDYLOLYSIS AND SPONDYLOLISTHESIS

Spondylolysis

This is a unilateral or bilateral defect in the region of the pars interarticularis without vertebral slippage. Persistent motion through the fracture may result in a pseudarthrosis. The incidence is reported at approximately 4% by the age of 6 years and 6% by the age of 14 years. Many cases remain asymptomatic. The incidence in the young athletic population varies between 15% and 47%.

The diagnosis may be made with standing anteroposterior and lateral X-rays of the lumbosacral spine. Oblique radiographs are no longer acceptable because of the high radiation dose. SPECT scanning and a reverse-gantry CT scan are usually used to make the diagnosis, although MRI is increasingly being used as a first-line investigation.

Treatment involves rest, non-steroidal anti-inflammatory medication, activity modification and a lumbosacral orthosis that reduces lumbar lordosis. For patients who remain symptomatic despite an adequate trial of non-operative care, surgery in the form of a direct repair (modified Buck's fusion) may be indicated. Patients under 25 years of age without evidence of disc or facet

pathology and with a pars defect of less than 3–4 mm have favourable outcomes following such a direct repair. If disc degeneration is established, then an alar transverse or intertransverse lumbar fusion is recommended.

Spondylolisthesis

Spondylolisthesis is a forward slippage of the vertebral body engendered by a break in the continuity or elongation of the pars interarticularis (Fig. 33.9). Wiltse *et al.* (1976) classified spondylolisthesis into six types (Table 33.5).

The Meyerding classification describes the degree of slip and refers to the amount of translation of the superior vertebra relative to the inferior vertebra (Table 33.6). One vertebra may sublux completely on the underlying vertebra, a condition called spondyloptosis.

Patients may present with back pain, an associated L5 nerve root pain and/or hamstring spasm. For patients past the third decade of life, it is unusual for spondylolisthesis to produce pain and, more commonly, the pain results from secondary degenerative changes in the disc and facet joints.

Figure 33.9 Lytic spondylolisthesis L4/L5. (a) Lateral radiograph showing a Meyerding grade I spondylolisthesis. The patient underwent a decompression and instrumented fusion *in situ* (b).

Table 33.5 The Wiltse classification of spondylolisthesis

Type 1	Dysplastic	Associated with congenital deficiency of the L5–S1 articulation
Type 2	Isthmic	Associated with a lesion of the pars interarticulares. Three subtypes: 2A: lytic defect of the pars 2B: elongated or attenuated pars 2C: acute pars fracture
Type 3	Degenerative spondylolisthesis	Segmental instability due to disc degeneration and facet arthrosis
Type 4	Traumatic	Acute fracture in the region of the posterior elements, other than the pars interarticulares
Type 5	Pathological	Generalised bone disease resulting in attenuation of the pars (e.g. metabolic, neoplastic)
Type 6	Post-surgical	After decompression of the lumbar spine

Table 33.6 The Meyerding classification for the degree of slip of spondylolisthesis

Grade I	1–25%
Grade II	26–50%
Grade III	51–75%
Grade IV	76–100%

For patients who have intractable low back or radicular pain, progressive slips in skeletally immature patients or neurological symptoms, surgery may be indicated. For low-grade slips (Meyerding grade I/II), an *in situ* posterolateral fusion is the procedure of choice. If there is *objective* evidence of neural compression (e.g. weakness of extensor hallucis longis), a spinal decompression should be performed at the same time.

For high-grade (Meyerding grade III/IV) slips, treatment is more controversial. Opinion is divided on whether to reduce the slip first and then fuse, or simply to fuse *in situ*. Problems with reduction include injury to the L5 nerve root, cauda equina nerve roots and sacral fixation failure. Neurological complications may be avoided by slow reduction with an external fixator followed by definitive fusion.

INFLAMMATORY SPONDYLOARTHROPATHY

Rheumatoid arthritis

Between 33% and 50% of patients develop atlanto-axial subluxation (AAS) within 5 years of diagnosis of rheumatoid arthritis. Some 2–10% of patients with AAS develop myelopathy over the next 10 years. Once diagnosed with myelopathy, 50% of patients die within 1 year. Approximately 20% of patients develop symptomatic subaxial disease. Neurological symptoms may occur as a result of direct compression by bone or soft tissue or from neural ischaemia.

The Ranawat classification of neurological function is useful for patients with rheumatoid arthritis (Table 33.7) (Summary box 33.7).

Chitranjan S. Ranawat, Orthopaedic Surgeon, The Hospital for Special Surgery, New York, NY, USA.

Summary box 33.7

Recommendations for spinal surgery in rheumatoid arthritis

- AAS with a posterior atlanto-dental interval (PADI) of 14 mm or less
- AAS with at least 5 mm of basilar invagination
- Subaxial subluxation with a sagittal canal diameter of 14 mm or less

Table 33.7 Ranawat classification of neurological function

Grade	Description
I	No neurological deficit
II	Subjective weakness with hyperreflexia and dysaesthesia
III	Objective weakness with long tract signs Two subtypes: IIIa Ability to walk IIIb Quadriparetic/non-ambulatory

Rheumatoid patients with myelopathy often have a very poor prognosis. In one series, 100% became bedridden within 3 years of onset of myelopathy and one-third died suddenly. The morbidity is very high, with only 25% of patients (Ranawat IIIb) who underwent surgical decompression having a favourable outcome. Early surgical stabilisation is therefore recommended. Techniques of occipitocervical fixation now utilise bicortical screw fixation to the occiput, transarticular fixation across the C1–2 joint and lateral mass screws in the subaxial cervical spine.

Ankylosing spondylitis

This condition is discussed in Chapter 37.

Should a patient with ankylosing spondylitis (AS) present following trauma, a high index of suspicion for occult fractures should be present. It is common for AS patients to develop epidural haematomas with subtle neurological deficit.

Patients with a significant fixed flexion deformity at the cervicothoracic junction ('chin-on-chest' deformity), limited forward gaze, eating and swallowing difficulties may be treated with an extension osteotomy of the cervical spine (Fig. 33.10). Surgery

Figure 33.10 Cervical osteotomy for correction of cervico-thoracic kyphosis. Planned resection lateral view for closing wedge osteotomy (left) and lateral view after closure of the osteotomy (right).

is performed under general anaesthesia after an awake fiberoptic intubation. The spinal cord is monitored with somatosensory and motor-evoked potentials. A halo is applied and the osteotomy carried out at the C7–T1 level. The osteotomy is closed under precise control and stabilised with instrumentation and a posterior fusion.

Primary thoracic kyphosis can be corrected by multiple thoracic osteotomies, or the overall spinal deformity can be corrected by a compensatory osteotomy in the lumbar spine. Lumbar osteotomy is best performed by a transpedicular closing wedge osteotomy at the second or third lumbar vertebra, i.e. below the conus and held in place by rigid posterior instrumentation and fusion.

SPINAL DEFORMITY

Spinal deformity may be categorised into a coronal plane deformity (scoliosis) or a sagittal plane deformity (kyphosis). Further classification may be made on the basis of aetiology into congenital, neuromuscular, syndrome-related and idiopathic. The appropriate radiograph for scoliosis is a standing posteroanterior projection of the whole spine. When surgery is contemplated, supine lateral bending radiographs are performed to assess the flexibility of the curve. Curve magnitude is assessed using the Cobb method. This involves identifying the superior end-plate of the most cranial vertebra pointing in towards the concavity, and the inferior end-plate of the most caudal end-plate pointing in towards the concavity, and measuring the angle subtended by these two lines. The criterion for diagnosis of scoliosis is a Cobb angle of 10° or more. Curves of less than 10° are referred to as spinal asymmetry (Summary box 33.8).

Summary box 33.8

Aetiology of scoliosis

- Congenital
- Neuromuscular
- Syndrome-related
- Idiopathic

Skeletal maturity may be assessed radiographically using the Risser sign, which describes the ossification of the iliac apophysis. The status of the triradiate cartilage of the acetabulum may also be useful to assess remaining growth potential. The triradiate cartilage closes before the iliac apophysis appears (Risser 0) at about the time of peak growth velocity. Patients with abnormal neurological examination, e.g. asymmetrical abdominal reflexes, or patients for whom surgical correction is planned should have an MRI examination of the *whole* spine to look for intraspinal pathology (e.g. syringomyelia, low-lying conus, diastematomyelia or a tethered cord). These findings may well result in a change in the operative strategy.

Congenital scoliosis

This is caused by vertebral anomalies that produce a frontal plane growth asymmetry. The anomalies are present at birth, but the curvature may take years to be clinically evident. These deficiencies occur in the embryonic period of intrauterine development (before 48 days' gestation) and are commonly associated with cardiac and urological abnormalities. It is thought that the *Homeobox* genes of the Hox class are responsible for congenital spinal malformations. Hemivertebrae can readily be detected on antenatal ultrasound at 20 weeks.

Congenital spinal anomalies can be classified into defects of *segmentation*, defects of *formation* or a combination of the two (mixed). Radiographs may show asymmetry in the number of pedicles, absent ribs or rib fusions. An unsegmented bar is suggested when the corresponding ribs and/or pedicles are conjoined. Block or wedge vertebrae have a low chance of progression. Hemivertebrae have a risk of progression of between 1° and 2.5° per year. Unilateral unsegmented bars progress at the rate $6\text{--}9^\circ$ per year, and unilateral unsegmented bars with contralateral hemivertebrae are at the greatest risk of progression, sometimes exceeding 10° per year.

Specific associations have been described in the VACTERLS syndrome including the following congenital anomalies: vertebral, anorectal, cardiac, tracheo-oesophageal fistula, radial limb dysplasia, lung abnormalities and single umbilical artery.

Close observation of spinal growth is required until skeletal maturity is reached. Brace treatment is ineffective for the primary structural curve, which is often short and rigid, but it may have a role in the control of compensatory curves. Investigations should include renal ultrasound, cardiac echo and MRI of the whole spine (intraspinal pathology is present in up to 30%).

For progressive curves, surgical options include posterior fusion *in situ*, hemivertebra excision with correction, convex hemiepiphyodesis combined with a Luque trolley construct, or combined anterior and posterior fusion. Anomalous blood supply of the spinal cord is not uncommon, and great care must be taken when tying off segmental vessels on the front of the spine.

Neuromuscular scoliosis

This may be due to *neuropathic* disorders, such as cerebral palsy, spinocerebellar degeneration, syringomyelia, quadriplegia, spinal muscular atrophy and poliomyelitis, or *myopathic* disorders, such as Duchenne muscular dystrophy and myotonic dystrophy. A

Joseph Charles Risser, Professor of Orthopaedic Surgery, Loma Linda University, Los Angeles, CA, USA.

Guillaume Benjamin Amand Duchenne, 1806–1875, a neurologist who worked successively in Boulogne and Paris, France, but who never held a hospital appointment.

progressive spinal deformity producing disturbance in quality of life or threatening compromise of cardiorespiratory function can be treated by correction and fusion using a posterior approach. There is good evidence that stabilisation of the spine in children with Duchenne muscular dystrophy who are able to walk, before the respiratory compromise is too severe to allow a general anaesthetic, may increase their lifespan by several years. Problems not uncommonly encountered during operations on children with neuromuscular scoliosis include excessive blood loss, malignant

hyperthermia, latex allergy and difficulty with monitoring neurological function.

Idiopathic scoliosis

Idiopathic scoliosis can be divided into *early onset* (before 8 years of age) (Fig. 33.11) and *late onset* (after 8 years of age; typical adolescent idiopathic scoliosis) (Fig. 33.12). The distinction is important, as the number of alveoli in the lung does not increase after the age of 8 years. Patients with severe curves in

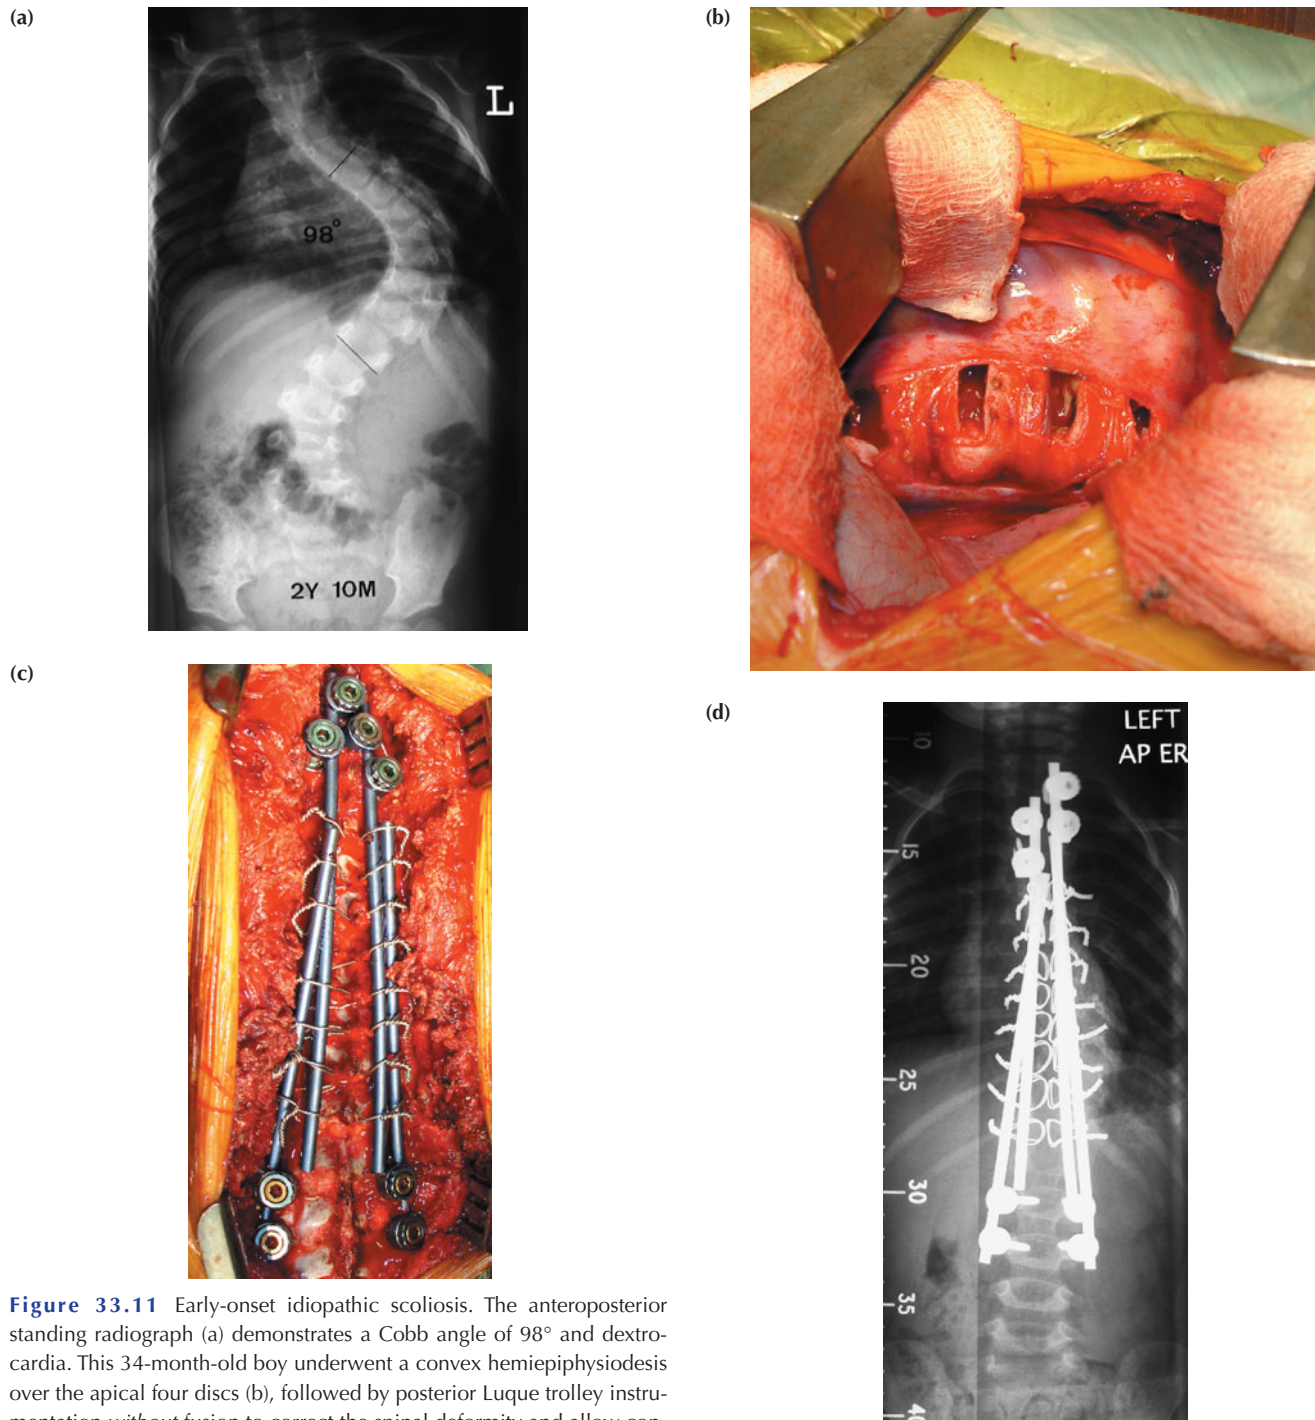

Figure 33.11 Early-onset idiopathic scoliosis. The anteroposterior standing radiograph (a) demonstrates a Cobb angle of 98° and dextrocardia. This 34-month-old boy underwent a convex hemiepiphysiodesis over the apical four discs (b), followed by posterior Luque trolley instrumentation *without* fusion to correct the spinal deformity and allow continued growth (c and d).

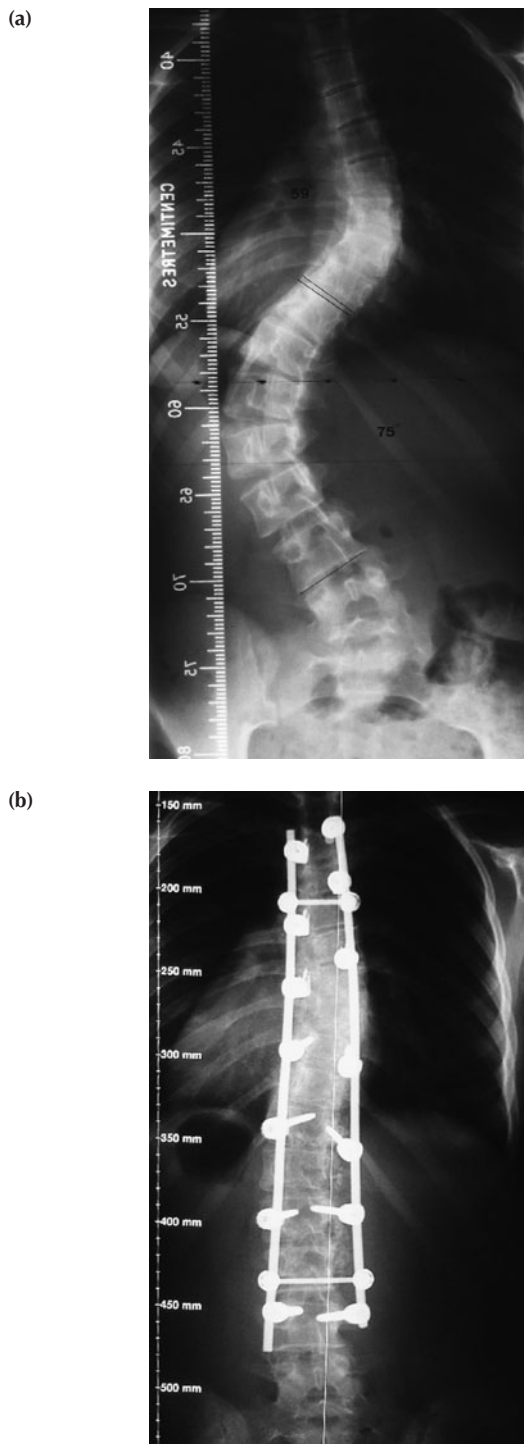

Figure 33.12 Late-onset idiopathic scoliosis. This 15-year-old girl had a progressive scoliosis with unacceptable cosmesis. The standing radiograph (a) demonstrated a right thoracic curve with a Cobb angle of 59° and a left thoracolumbar curve of 75°. Both curves were flexible on supine bending films. She underwent a posterior correction and instrumented fusion from T4 to L4 (b).

the early-onset group may develop cor pulmonale and right ventricular failure resulting in premature death. Adolescent idiopathic scoliosis is associated with a normal or near-normal life expectancy.

The prevalence of curves with a Cobb angle greater than 10° is between 0.5% and 3%. The prevalence of curves greater than 30° is between 1.5 and 3 per 1000. Risk factors for progression include female gender, remaining skeletal growth, curve location and curve magnitude. Not all curves stabilise when skeletal maturity is reached. In long-term studies, 68% experienced curve progression; the most marked progression of 1° per year was observed in thoracic curves between 50° and 75°.

Idiopathic curves of less than 25° are monitored with clinical and radiographic examination. In growing children (Risser 0–1, pre-menarche) with curves between 20° and 29°, a brace may be indicated. Bracing is used to prevent curve progression and generally does not lead to permanent curve improvement. Curves beyond 45° are not amenable to brace treatment.

Surgery in the form of corrective instrumentation and spinal fusion is indicated for curve progression beyond 40°, truncal imbalance and unacceptable cosmesis. Surgery may involve posterior surgery, anterior surgery or a combination of both. During surgery, continuous electrical spinal cord monitoring is used in the form of somatosensory evoked potentials and, more recently, motor-evoked potentials. The risk of permanent neurological injury for such patients is 0.02% (1:5000); the risk of incomplete neurological injury is 0.4% (1:250).

Scheuermann's kyphosis

This condition was initially described as a rigid kyphosis associated with wedged vertebral bodies usually involving the 7th to 10th thoracic vertebrae, presenting with backache. At least three adjacent vertebrae must be wedged by at least 5° each. Typically, a thoracic kyphosis of 50–90° may exist. The incidence has been estimated at 1–8% of the population. The condition is more common in males.

Physiotherapy directed at postural improvement and hamstring release may be useful. Bracing for skeletally immature patients with kyphosis up to 65° may be effective in arresting progression. Indications for surgery include pain, progressive deformity greater than 70°, unacceptable cosmesis, and neurological and cardiac pulmonary compromise. Neurological deficits have been reported relating to thoracic disc herniation, epidural cysts or hyperkyphosis.

If surgery is contemplated, a hyperextension lateral radiograph (over a bolster) is performed to assess flexibility. If the kyphosis fails to correct to less 50°, an anterior release and disc excision may be required. This may be carried out via a thoracotomy or an endoscopic approach, to be followed by a posterior correction and fusion, typically from T2 to L2. Alternatively, posterior chevron osteotomies may prevent the need for an anterior release. Care should be taken if the curve has a low apex (e.g. T10–11), when posterior instrumentation should be extended to the first lordotic disc.

DEVELOPMENTAL ABNORMALITIES

Developmental abnormalities of the spine and spinal cord can be divided into primary bony disorders (e.g. congenital scoliosis as

Holger Werfel Scheuermann, 1877–1960, Radiologist, The Municipal Hospital, Sundby, Copenhagen, Denmark, described Juvenile Kyphosis in 1920.

discussed above) and primary neurological disorders (e.g. spina bifida, Arnold–Chiari malformation and spinal dysraphism).

Spina bifida

Spinal bifida is caused by a failure of fusion of the vertebral arches and possibly the underlying neural tube. Spina bifida cystica has an incidence of 1:300 live births. This is now decreasing as a consequence of folic acid supplementation, antenatal ultrasound and the measurement of alpha-fetoprotein levels. The condition is usually obvious at birth. A neurological examination of the structures *below* the defect should be carefully performed. The head should be examined for evidence of hydrocephalus (bulging fontanelle or excessive head circumference). There are two basic types:

- *Meningocele*: the meninges herniate through the bony defect and are covered by skin.
- *Myelomeningocele*: the roof of the defect is formed by exposed neural tissue with 75% of cases developing hydrocephalus.

A meningocele with good-quality skin over the defect may be treated conservatively. A meningocele with a more prominent sac can be excised at 3–6 months. The management of myelomeningocele is more controversial. Enthusiasm for closing all defects has been replaced by a more selective approach with the recognition that it was inappropriate to operate on children with severe hydrocephalus, a large open defect and no distal neurological function. The majority of these children die in their first year from hydrocephalus or from an infection if closure is not attempted. With antibiotics, early surgical closure and shunts to prevent hydrocephalus, half the children who survive the first 24 hours will reach school age.

The aims of surgery are to return the nervous tissue to the spinal canal, to preserve the cerebrospinal fluid absorption capacity and to cover the defect with fascia and skin. Following surgery, regular examinations are required to detect hydrocephalus. Long-term problems include skin, bone and joint deformity and the complications associated with a neuropathic bladder.

Arnold–Chiari malformation

Arnold–Chiari malformation occurs when the medulla oblongata and the cerebellar tonsils extend through the foramen magnum into the cervical spinal canal, causing pressure on the lower medulla. Hydrocephalus and impaired neurological function are common, and there is a strong association with spina bifida and syringomyelia. The presentation is variable because of its complex aetiology. Symptoms may include headache, vomiting, visual disturbance, diplopia, mental dullness, lack of coordination, paralysis of the extremities, cerebellar ataxia and sensory disorders. Plain radiographs may show a *small* posterior cranial fossa, but the condition is best demonstrated by MRI or CT myelography. Management consists of decompressing the foramen magnum and, usually, the posterior arch of the atlas to restore normal cerebrospinal fluid flow.

Julius Arnold, 1835–1915, Professor of Pathological Anatomy, The University of Heidelberg, Heidelberg, Germany, described this condition in 1894.

Hans Chiari, 1851–1916, Professor of Pathological Anatomy, Strasbourg, Germany, (Strasbourg was returned to France in 1918 after the end of the First World War) gave his account of this condition in 1891.

Spinal dysraphism

This is a group of disorders arising from abnormal embryological formation of tissues: all are associated with a progressive neurological deficit as the result of cord tethering and traction or cord compression. There is a strong association with spina bifida.

In diastematomyelia, there is an abnormal bony or cartilaginous spur projecting across the middle of the vertebral canal, dividing the dural tube and spinal cord in two. Between 50% and 70% of patients have a skin naevus, dimple or hairy patch when the spine is examined. Diastematomyelia is more common in females and most commonly occurs in the thoracolumbar region. It often presents during the growth spurt with upper limb weakness, abnormal gait, urinary incontinence or spinal deformity.

Syringomyelia

In 1824, Olivier d'Angers described a spinal cord cavity in continuity with the fourth ventricle, which he called syringomyelia. Patients may present with sensory disturbance, weakness of the hands, loss of pain and temperature sensation or progressive kyphoscoliosis. Hindbrain herniation can lead to headache, neck ache, ataxia, spasticity and lower cranial nerve palsies.

If associated with a type I Arnold–Chiari malformation (where cerebrospinal fluid outflow obstruction is implicated), then a posterior cranial fossa decompression is indicated to restore cerebral spinal fluid outflow through the foramen of Magendie. If the cause is an intramedullary spinal cord tumour, excision of the tumour should restore cerebrospinal fluid communication with the central canal. If the origin of the syrinx is post traumatic, the obstruction should be relieved by decompression. Fluid diversion should not be the primary or only treatment of syringomyelia. Notwithstanding this, diversion to the peritoneum (syringo-peritoneal) or pleural spaces (syringo-pleural) has been used with moderate success.

METABOLIC BONE DISEASES AFFECTING THE SPINE

Osteoporosis

This is characterised by a decreased amount of normally mineralised bone per unit volume, resulting in skeletal fragility and an increased risk of fracture. Osteoporosis may be classified into primary or secondary types.

Primary osteoporosis is further subdivided into type I or postmenopausal osteoporosis and type II or senile osteoporosis. Type I osteoporosis is due to oestrogen deficiency occurring in females, 5–10 years after the menopause. It is associated with vertebral body fractures, intertrochanteric hip fractures and distal radial fractures. Type II osteoporosis occurs as a result of ageing and calcium deficiency. It is associated with vertebral body fractures, femoral neck fractures and pelvic fractures. Secondary osteoporosis occurs as a result of endocrinopathies such as Cushing's disease.

Bone mineral density is measured with dual-energy X-ray absorptiometry (DEXA). Ideally, the bone density is measured in

Francois Magendie, 1783–1855, Professor Pathology and Physiology, The College of France, Paris, and Physician, Hôtel Dieu, Paris, France.

Harvey Williams Cushing, 1869–1939, Professor of Surgery, The Johns Hopkins University, Baltimore, MD (1903–1912), and at The Harvard University Medical School, Boston, MA, USA (1912–1932), described this syndrome in 1932.

the spine, distal radius and hip with bone mineral density reported in terms of two absolute values: T-score (units of standard deviation compared with the density of a healthy 30-year-old) and Z-score (units of standard deviation compared with age- and sex-matched control subjects). The World Health Organization has defined osteoporosis in terms of the T-score: osteoporosis is said to occur when the T-score is more than 2.5 standard deviations below the peak. A 1-point decrease in standard deviation in the T-score is associated with a 2.5-fold increased risk of a spine fracture.

Patients with osteoporosis may present with pain after minimal trauma or loss of height and an exaggerated thoracic kyphosis. Medications used to prevent and treat osteoporosis include the bisphosphonates (alendronate, risedronate), oestrogen or hormone replacement therapy and calcitonin.

Patients with painful thoracic fractures may be treated with short-term bed rest, analgesics and a spinal orthosis. If still painful 6 weeks after the injury, patients may be considered for vertebroplasty or kyphoplasty. Vertebroplasty involves the injection of polymethylmethacrylate bone cement (PMMA) under pressure into the vertebral body under fluoroscopic guidance. The goal of the procedure is to *stabilise* the spine and *decrease pain* associated with compression fractures.

Kyphoplasty, on the other hand, involves inserting bilateral bone tamps with balloons into the vertebral body. These are inflated under fluoroscopic control with the bone tamp re-expanding the body, elevating the end-plates to reduce the fracture deformity. The balloons are then deflated and removed, and PMMA is placed into the cavity created by the balloons. The goals of kyphoplasty are *spinal stabilisation*, *pain relief* and *restoration of vertebral body height*. Significant complications have been reported, including nerve root injury and spinal cord injury resulting from cement extravasation along with cement embolism, infection and hypotension.

Osteomalacia

This is characterised by delayed or impaired mineralisation of bone matrix resulting in bone fragility. Causes include nutritional deficiency, gastrointestinal malabsorption and renal tubular defects. Patients present with generalised bone pain and tenderness in the appendicular skeleton. Findings may include

pseudofractures, Looser's zones and biconcave vertebra (cod-fish vertebra). Laboratory investigations may show a low or normal serum calcium, elevated parathyroid hormone, low serum phosphate, raised serum alkaline phosphatase and increased urine phosphate. A bone biopsy will show increased width and extent of osteoid seams. The disease is usually treated with vitamin D therapy with or without calcium supplementation.

Upper limb – pathology, assessment and management

LEARNING OBJECTIVES

To understand:

- Anatomy and physiology relevant to upper limb pathology

To be able to explain:

- The diagnosis and treatment of common upper limb problems

SHOULDER GIRDLE

Anatomy and function

The humerus, scapula, clavicle, manubrium sterni and chest wall are the osseous elements of the shoulder girdle. The main muscle groups are those that control the scapulothoracic and glenohumeral joints, in order that the hand may be placed in space, as defined by a sphere centred on the latter. The clavicle, through the medial sternoclavicular joint and the lateral acromioclavicular joints, acts as a load-transmitting bony strut between the upper limb and the axial skeleton. The whole shoulder girdle moves around the sternoclavicular joint, controlled and limited by those muscles between the thorax and scapula (e.g. trapezius, levator scapulae, rhomboids, serratus anterior and pectoralis minor) and thorax and humerus (e.g. pectoralis major and latissimus dorsi). The glenohumeral joint is controlled by the deltoid and the rotator cuff muscles, the latter composed of the anterior subscapularis, superior supraspinatus and superoposterior infraspinatus and teres minor. The scapula is integral to shoulder motion by moving around the posterior aspect of the thorax and, in combination, these joints comprising the shoulder girdle afford the greatest range of motion of all the joints of the body, with stability primarily the function of soft-tissue static and dynamic stabilisers (Fig. 34.1) (Summary box 34.1).

Summary box 34.1

Function of the shoulder

- To enable the hand to manipulate the environment as described by an arc centred on the shoulder joint
- The design is a compromise between mobility, stability and strength

Clinical history and physical examination

The clinical history and examination are detailed in Chapter 31, but the essential elements to clarify are those that commonly pertain to either loss of joint stability, e.g. anterior/posterior/multidirectional/habitual instability, or loss of joint motion, e.g. primary or secondary frozen shoulder, and pain sources around

the shoulder girdle, e.g. calcific tendinitis, rotator cuff disease, superior labrum anterior posterior (SLAP) tears, etc.

Congenital abnormalities

Sprengel's shoulder

This is the commonest congenital pathology around the shoulder, and is due to the abnormal descent of the scapula from its embryonic midcervical position. The clinical presentation is a high, small and rotated scapula with a connection to the cervical spine in 50% of cases, by a bony bar, fibrous band or an omovertebral body. Other congenital deformities may be associated, notably rib abnormalities, scoliosis of the thoracic spine or cervical spine

Figure 34.1 Relative motion of the elements of the shoulder girdle.

Otto Gerhard Karl Sprengel, 1852–1915, Surgeon, Grossherzogliches Krankenhaus (the Grand Ducal Hospital), Brunswick, Germany, described congenital high scapula in 1891.

anomalies including the Klippel–Feil syndrome (congenital fusion of the cervical vertebrae) (Fig. 34.2). The management is usually for cosmetic rather than functional reasons, especially in unilateral cases. Excision of the omovertebral body or superior angle has a satisfactory cosmetic effect. When functional improvement is the primary goal, complex reconstructive procedures are required.

Acquired abnormalities

The vast majority of acquired conditions present with some degree of pain in the shoulder region. The commonest of these acquired pathologies involve the rotator cuff musculature, especially the supraspinatus muscle–tendon unit. The spectrum of pathology that affects the rotator cuff presents, in order of severity, with painful arc syndrome, subacromial impingement, partial-thickness tears, full-thickness tears and cuff tear arthropathy. Calcific tendinitis, frozen shoulder and degenerative arthritis form the remainder of the common painful conditions of the shoulder (Summary box 34.2).

Summary box 34.2

Shoulder pain

- The second commonest musculoskeletal pain after back pain
- The supraspinatus muscle–tendon unit is most commonly diseased and painful

Rotator cuff disease

The rotator cuff musculature, in particular the supraspinatus tendon, has a relatively poor blood supply, and this predisposes it to degeneration and tearing. The anterolateral portion of the tendon is initially affected; the resultant swelling can lead to impingement on the undersurface of the anterior acromion with

Figure 34.2 Sprengel's shoulder (right) of a 4-year-old girl.

Maurice Klippel, 1858–1942, Neurologist, Hôpital Tenon, Paris, France.
André Feil, 1889–?, Neurologist, Paris, France.
Klippel and Feil described this condition in a joint paper in 1912.

its attached coracoacromial (CA) ligament. This leads to pain, particularly on active abduction or flexion, and initially leads to a painful arc between 60° and 120° (Fig. 34.3).

It is believed that abnormalities of the bone occur, with hooking of the anterior acromion. These may be secondary changes, rather than the primary cause of the pain, but surgical treatment is often to remove part of the undersurface of the acromion and CA ligament (Fig. 34.4).

History and examination

The commonest patient characteristics are middle-age, a history of overuse or specific injury or a gradual onset of symptoms. The pain tends to be exacerbated with overhead activities and reaching across the body, e.g. putting washing on a line or grooming the opposite side of the head. Weakness is a feature in some patients that indicates a rotator cuff tear, as opposed to tendonitis.

Physical examination can rarely reveal local tenderness. Active movements may be limited and usually reproduce the symptoms, which occur between 60° and 120° of abduction and flexion (Fig. 34.3). There is usually much less pain on passive movement, and this confirms the mechanical and dynamic nature of the pain. Weakness of the supraspinatus and infraspinatus, when found, suggests the possibility of a tear in the muscles. Specific impingement tests have been described and help to confirm the diagnosis (Figs 34.5 and 34.6). Radiographs may be normal, but there are usually signs of subacromial sclerosis (Summary box 34.3).

Figure 34.3 Arcs of shoulder girdle motion with subacromial impingement pain between 60° and 120° of abduction, and acromioclavicular joint pain between 170° and 180°.

Figure 34.4 The three commonest acromial morphologies.

Summary box 34.3

Supraspinatus problems

- Commonly in middle-age
- Activity related, especially the arm above the head
- No local tenderness
- Passive movement is less painful than active
- Local anaesthetic into the subacromial region is diagnostic
- Subacromial steroid is therapeutic in the early tendonosis stage
- Steroids should not be injected without knowledge of the presence of a tear

Subacromial injection of local anaesthetic can temporarily improve symptoms, if the diagnosis is correct, and is a valuable diagnostic tool. Steroid injections should only be used if the patient is not a surgical candidate, or if there is clinical and other diagnostic information to exclude the presence of a repairable tear. In such cases, the steroid, in the form of a depot, can lead to

symptom resolution, although this tends to be temporary. In cases of tendonosis, the anti-inflammatory steroid effect allows the rotator cuff the opportunity to be rehabilitated adequately.

Investigations

An out-patient clinic subacromial local anaesthetic injection is a useful confirmatory test. Imaging modalities include plain radiography, ultrasound and magnetic resonance imaging (MRI). The last two can determine the presence, size and location of a tear, and are useful preoperative planning tools (Fig. 34.7).

Figure 34.5 Hawkin's impingement test. Impingement pain is reproduced when the shoulder is internally rotated with 90° of forward flexion, thereby locating the greater tuberosity underneath the acromion.

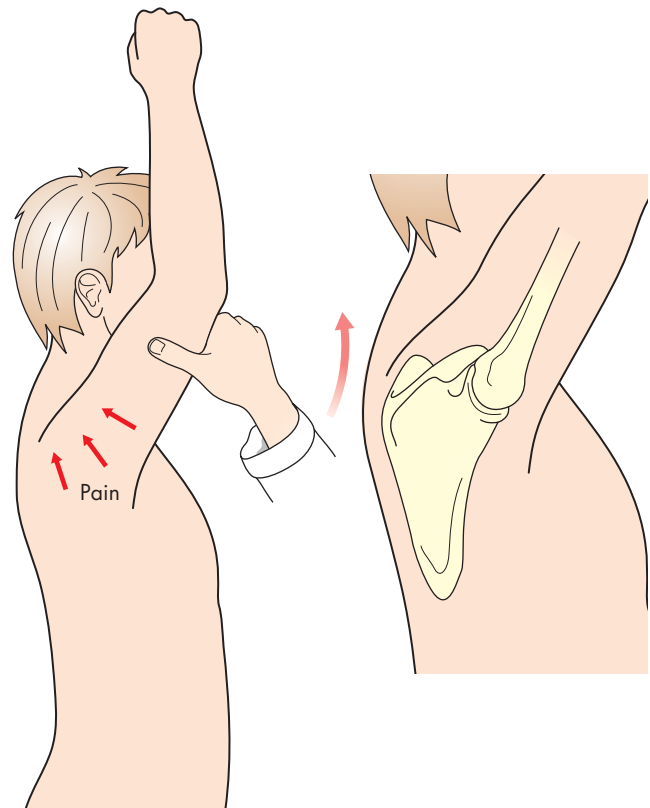

Figure 34.6 Neer's impingement test. Pain is reproduced with full forward flexion.

(Middle) T2-weighted coronal magnetic resonance imaging scan demonstrating a retracted supraspinatus tear (red arrow). (Bottom) Postoperative AP radiograph demonstrating anchor fixation of the rotator cuff tear.

Treatment

It is likely that most early cuff disease, impingement and tendinosis, will settle with non-operative treatment. The initial treatment is by a maximum of three depot steroid injections over a 12-month period if each injection is demonstrated to give good symptomatic relief. Specific rehabilitation should aim to balance the whole rotator cuff, thereby resisting the proximal vector of the deltoid. Surgery is required in those who do not respond to this non-operative rehabilitation or if the symptoms persist beyond a reasonable period of time, as defined by the patient and surgeon, a minimum period of 6 months. Rotator cuff decompression (arthroscopic or open) is performed by removing the acromial overhang and dividing the CA ligament.

In addition, repair of a rotator cuff tear may be required. In the absence of a rotator cuff tear, the prognosis is good (Summary box 34.4).

Summary box 34.4

Treatment of subacromial irritation

- Non-operative treatment includes injections and cuff rehabilitation
- Surgery is indicated if symptoms fail to settle after a minimum of 6 months
- Surgery decompresses the rotator cuff

Rotator cuff tears

Patients with rotator cuff tears are generally older than patients with impingement, and it should be remembered that such tears form a spectrum of pathology from an early stage with small tears to the late stage of complete tear of all muscles. The supraspinatus muscle tears initially at the anterolateral edge of the tendon, progressing posteriorly to include the remainder of the supraspinatus, infraspinatus and teres minor, thereby creating, in the end-stage pathology, a bald greater tuberosity. The muscle–tendon unit retracts medially once detached. The patient is usually unaware of the rotator cuff tearing, and large tears of several years' duration may be present before the patient seeks medical attention (Fig. 34.8) (Summary box 34.5).

Summary box 34.5

Rotator cuff tears

- Occur in older age groups compared with impingement
- 4–20% of 40- to 50-year-olds have an asymptomatic tear
- > 50% of > 70-year-olds have an asymptomatic tear
- Treatment is required in symptomatic patients unresponsive to conservative management
- Outcomes are better following surgical repair of smaller than larger tears
- Subacromial decompression is important for pain relief following cuff repair
- Staged rehabilitation is crucial for good outcomes after surgical intervention

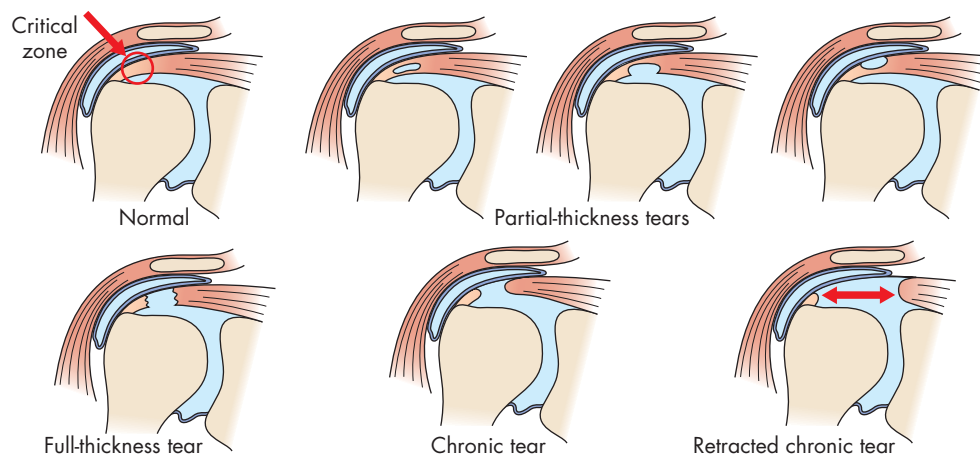

Figure 34.8 Various stages of rotator cuff tear. Initial partial-thickness tears have the potential to progress to full-thickness and retracted tears.

Small tears of the supraspinatus

These are very common and may be found in up to 50% of the normal population, according to MRI data, in the absence of any specific shoulder symptoms. The tear is usually less than 1 cm in length and, in the absence of pain, is insufficient to cause any observable weakness.

Treatment of small tears is dependent on the presence and severity of cuff symptoms. In the absence of symptoms, conservative cuff rehabilitation and regular review generally suffice. Symptom and/or tear progression are indicators for rotator cuff repair, with adjunctive decompression if impingement is defined to be a significant part of the pathology.

Intermediate tears

Tears of 2–4 cm are usually associated with symptoms of impingement and/or weakness of the shoulder, and frequently require decompression and repair of the supraspinatus. Arthroscopic or open approaches can be adequately utilised to perform the repair and decompression. The tendon is mobilised and then sutured into a bony trough created on the edge of the greater tuberosity, using suture anchors or osseous sutures. Results of repair are good for intermediate tears, but full recovery will take several months, with an emphasis placed on a graduated rehabilitation protocol.

Large rotator cuff tears

Tears greater than 5 cm (massive) may extend into the infraspinatus and teres minor and are usually associated with weakness of the shoulder. Abduction is typically limited to below 60°, often with a characteristic hunching of the shoulder (Fig. 34.9). With such massive tears, superior humeral head migration can occur, thereby further impairing function. A consequence of the resultant joint incongruity is secondary osteoarthritis of the glenohumeral joint, known as ‘cuff tear arthropathy’ (Fig. 34.10).

Large cuff tears that are significantly symptomatic and debilitating to the patient should be considered for repair and subacromial decompression. However, such chronic, degenerate tears are not always repairable, even after surgical mobilisation, because of

Figure 34.9 A 75-year-old patient with a > 5 cm retracted rotator cuff tear attempting to abduct the left shoulder, which is limited, by lack of balanced motor power, to below 60°.

Figure 34.10 A massive rotator cuff tear that has led to proximal humeral head migration and secondary osteoarthritis of the glenohumeral joint, ‘cuff tear arthropathy’.

medial muscle–tendon retraction and loss of elasticity of the structure. Options for defect closure include muscle tendon transfers and patch grafts (synthetic or xenografts), although the results of such procedures are less than satisfactory. A primary source of poor results, in this case, is the loss of contractility of the chronically retracted muscles, which undergo disuse atrophy and fatty infiltrative degeneration.

The majority of patients with massive irreparable tears complain of pain rather than loss of function. A successful treatment strategy is to repair, to the greater tuberosity, as much of the mobilised cuff that has retained adequate elasticity, which constitutes a partial repair, in combination with a minimal decompression. Good pain relief and some functional improvement are to be expected. A simple decompression without a partial repair may produce short-term pain relief, but has the potential for accelerated head migration and further erosion of the acromial bone stock.

Acute rotator cuff tears

Most tears of the supraspinatus result from degeneration and, as discussed above, will be associated with impingement symptoms. Occasionally, a large tear of the rotator cuff can result from trauma in the absence of any previous shoulder symptoms. These patients present soon after the event with profound weakness and loss of function but minimal pain. On examination, there is marked restriction of abduction, usually to less than 90°, with a characteristic hunching of the shoulder. This is due to elevation and rotation of the scapula to attempt to aid abduction. Diagnosis is confirmed by ultrasound or MRI, and early exploration and repair are indicated. Unlike the large degenerate cuff tears, the acute tear is usually repairable if surgery is carried out early. Often no decompression is necessary, as the front edge of the acromion is normal with no evidence of overhang. In middle-aged and elderly patients, an acute cuff tear can occur after shoulder dislocation, on the background of a pre-existent chronic degenerate tear (Summary box 34.6).

Summary box 34.6

Acute rotator cuff tears

- Present with little pain but profound weakness
- Early repair gives good results

Frozen shoulder

This is a description of a painful and stiff shoulder condition of varying aetiologies, some of which remain poorly defined and termed 'idiopathic'. The rotator interval between supraspinatus and subscapularis is affected, as is the shoulder capsule. The disease most commonly affects females in their fifth decade, and is more common in diabetics and patients with heart or thyroid disease. Summary box 34.7 gives a brief summary of the condition.

Summary box 34.7

Frozen shoulder

- Idiopathic or secondary to other defined pathologies
- Symptoms – pain followed by reduced shoulder motion
- Idiopathic usually in females in the fifth decade
- Spontaneous resolution reported in between 1 and 3 years
- Differential diagnoses include calcific tendinitis and rotator cuff tear

History and examination

Idiopathic frozen shoulder is characterised by spontaneous, often severe pain of sudden onset, and may follow minor trauma. Sleep is often disturbed, and the differential diagnoses include infection, fractures and rotator cuff tears. In the early stages, the shoulder is difficult to examine owing to pain but, as the disease progresses, the range of motion reduces, both actively and passively. Local tenderness is often felt anteriorly over the rotator interval. The pathognomonic sign of frozen shoulder is loss of external rotation, and this differentiates it from rotator cuff disease. Plain radiographs exclude other intra-articular pathology.

Clinical course

The clinical course of frozen shoulder can be divided into three stages as follows:

- Stage 1 – Painful phase. This can last for 2–9 months. The shoulder becomes increasingly painful, especially at night, and the patient uses the arm less and less. The pain is often very severe, and may be unrelieved by simple analgesics.
- Stage 2 – Stiffening phase. This can last for 4–12 months and is associated with a gradual reduction in the range of movement of the shoulder. The pain usually resolves during this period, although there is commonly still an ache, especially at the extremes of the reduced range of movement.
- Stage 3 – Thawing phase. This lasts for a further 4–12 months and is associated with a gradual improvement in the range of motion.

The clinical course runs over a period of 1–3 years, and the condition usually resolves without any long-term sequelae.

Treatment

Often no treatment is required, and the condition will resolve as described above. The range of motion may be slightly reduced compared with the unaffected side, but the vast majority of patients have no functional problems.

Treatment in the acute stage is pain relief. Corticosteroids may be tried but have variable effects, and should be avoided if imaging reveals a potentially repairable rotator cuff tear to be present. Active and passive mobilisation can be carried out if comfort allows, but aggressive/painful physiotherapy should be discouraged.

Surgery is usually reserved for prolonged stiffness affecting function, but can also produce good pain relief in the acute stage. Manipulation under anaesthetic may produce an increased range of motion. Arthroscopic distension of the joint with saline allows inspection of the shoulder before treatment. If these measures fail to produce any benefit, open release of the rotator interval can be carried out through an anterior approach, or preferably through an arthroscopic release.

Calcific tendinitis

This is a common disorder of unknown aetiology, which results in an acutely painful shoulder. Calcium is deposited within the supraspinatus, and it is thought that this may be part of a degenerative process or a consequence of a partial degenerative tear of the tendon. The differential diagnosis includes frozen shoulder, with both conditions occurring most commonly in middle-aged women.

History and examination

This pain is usually of rapid onset, often with no precipitating cause. In common with impingement, the pain is felt on the anterolateral aspect of the shoulder and is worse with activity, particularly overhead activities. The pain can be very severe and usually disturbs sleep. On examination, the shoulder is tender anterolaterally, and there is often some painful restriction of active, and sometimes passive, motion. External rotation will be possible, and this differentiates the condition from frozen shoulder.

The calcific deposits can be seen on plain radiographs (Fig. 34.11), lying within the supraspinatus tendon, inferior to the acromion and just medial to the tuberosity of the humerus. They can also be seen on ultrasound and MRI scans.

Treatment

Simple analgesia should be tried, together with rehabilitation. Calcific tendinitis usually responds to subacromial injection of corticosteroid, although a course of several injections may be necessary. The condition is often self-limiting, with resolution of the symptoms and resorption of the calcium.

Surgery

Resistant cases of calcific tendinitis are an indication for surgical treatment. Open excision of the calcific deposits can be carried out through a sabre incision, although arthroscopic subacromial decompression is a less invasive alternative. The calcific deposit can be debrided and removed and, if the remaining cavity is considerable, a simple closure can be performed.

Figure 34.11 Radiograph demonstrating calcific tendinitis.

The prognosis for calcific tendinitis is generally good. Summary box 34.8 summarises the condition.

Summary box 34.8

Calcific tendinitis

- Commonly of unknown aetiology
- Rapid symptomatic onset, usually in middle-aged women
- Plain radiography often reveals the calcific deposits
- The majority of cases are self-limiting
- Resistant cases may be helped by subacromial decompression and deposit removal

Arthritis of the shoulder

Rheumatoid arthritis

The glenohumeral joint is commonly involved in inflammatory arthritides, particularly rheumatoid arthritis, with up to one-third of these patients developing severe problems, prior to the introduction of modern disease-modifying agents. Initially, pain is related to synovitis, and this responds to medical management, including intra-articular steroid injection.

Impingement symptoms can also occur, either with or without a rotator cuff tear. These will respond to subacromial injection, but decompression may be indicated. Arthroscopic synovectomy can be carried out at the same time but, in general, open synovectomy is not indicated in the management of rheumatoid arthritis of the shoulder. Chemical synovectomy may be indicated for symptoms that are resistant to medical treatment, but this is not commonly performed for rheumatoid arthritis.

For advanced disease, glenohumeral arthroplasty is indicated, with very good relief of pain, but there is often little improvement in the preoperative stiffness, as this is more a function of the peri-articular soft tissues (Summary box 34.9).

Summary box 34.9

Shoulder problems in rheumatoid arthritis

- One-third of cases have glenohumeral joint involvement
- Impingement can lead to rotator cuff tears
- Arthroscopic synovectomy is symptomatically effective
- Glenohumeral joint arthroplasty improves pain, but motion to a lesser degree

Osteoarthritis

Osteoarthritis of the glenohumeral joint is either primary or, more commonly, secondary. Secondary arthritis is commonly post-traumatic (Fig. 34.12) or a result of end-stage rotator cuff disease, in association with a massive tear of the cuff and superior migration of the humeral head (see Fig. 34.10, p. 489).

Treatment

Medical management is the first line of treatment but, if unsuccessful, surgical options are indicated. The two surgical avenues of management are debridement or joint arthroplasty; realigning osteotomies, akin to the knee, have no proven benefit in the shoulder. Whereas shoulder debridement is less predictable for long-term symptomatic relief, both total shoulder replacement (Fig. 34.13) and hemiarthroplasty (Fig. 34.14), without glenoid replacement, have good results in correctly indicated patients. A standard total shoulder arthroplasty should only be carried out if the rotator cuff is intact. In most rheumatoid patients and all patients with cuff tear arthropathy, the cuff is deficient, and the surgical options include hemiarthroplasty, hooded glenoid total shoulder arthroplasty (Fig. 34.15) or a reverse polarity total shoulder arthroplasty (Fig. 34.16). Shoulder arthroplasty is an effective pain-relieving procedure, but is less predictable in restoring motion, especially above shoulder level motion.

Arthrodesis of the joint is an alternative in younger patients, especially with a history of sepsis or any neurological problem that could destabilise a joint replacement. The perioperative morbidity is higher, and 3–4 months of immobilisation are required for union to occur. The patient retains a moderate range of movement at the shoulder, as a result of motion at the scapulothoracic articulation (Summary box 34.10).

Figure 34.12 Post-traumatic arthritis with malunion of the proximal humerus, collapse of the humeral head and other features of osteoarthritis (subchondral sclerosis and osteophytes).

Figure 34.13 Total shoulder arthroplasty, for osteoarthritis, with an intact rotator cuff (from Kvitne, R.S. and Jobe, F.W. The diagnosis and treatment of anterior instability in the throwing athlete. *Clin Orthop* 1993, **291**: 107–23). With permission of the publisher.

Figure 34.14 Hemiarthroplasty in a patient with an intact rotator cuff and reasonable chondral surface on the glenoid. An oversized hemiarthroplasty is an option in the presence of a massive rotator cuff tear.

Figure 34.15 Hooded glenoid total shoulder arthroplasty for cuff-deficient arthropathy. The hooded glenoid resists superior migration of the humeral head, thereby allowing the deltoid to generate a centred rotatory torque and enabling the shoulder to be elevated and abducted.

Summary box 34.10

Shoulder osteoarthritis management

- Severe cases are treated by partial or total joint replacement
- If the rotator cuff is beyond repair, a standard total joint replacement is not an option
- Cuff tear arthropathy options are hemiarthroplasty, hooded glenoid or reverse polarity joint replacement
- Pain relief is predictably achieved, but range of motion improvement is less predictable
- Glenohumeral arthrodesis is an option in younger patients
- Post-arthrodesis motion is surprisingly good as a result of scapulothoracic motion

Acromioclavicular joint arthritis

Degenerative changes of the acromioclavicular joint are relatively common on plain radiographs and are often age related. Symptomatic disease usually manifests in males between 20 and 50 years of age and is frequently post-traumatic. Commonly, sports or manual occupations that load the upper limbs are implicated. The presence of inferior osteophytes implies the potential for impingement of the underlying rotator cuff.

History and examination

The pain is activity related and, unlike most causes of shoulder pain, is well localised, with the patient pointing to the acromioclavicular joint as the source of the pain. On examination, there is usually a bony abnormality, with prominence of the lateral end of the clavicle. This may be tender, and movement of the joint by depressing the clavicle while pushing up the humerus will

Figure 34.16 Reverse polarity total shoulder arthroplasty for cuff-deficient arthropathy. The glenosphere resists superior migration of the humerus, thereby allowing deltoid function.

reproduce the pain. Flexing and adducting the arm to place the hand behind the opposite shoulder will also produce pain. An intra-articular injection of local anaesthetic will confirm the joint as the site of the pain. If the symptoms are related to the inferior osteophytes, the pain is less localised, and impingement signs and symptoms are present.

Treatment

Intra-articular injection of corticosteroids usually produces some benefit, and a course of three injections is a standard course of treatment. If medical management fails, then surgery may be appropriate. The distal 0.5–1 cm of the clavicle is excised by an arthroscopic excision or open approach, with good relief of pain and no functional difficulties. In patients with predominantly impingement symptoms, arthroscopic debridement of the osteophytes can be carried out (Summary box 34.11).

Summary box 34.11

Acromioclavicular joint problems

- Usually secondary to either repetitive overload or trauma
- Inferior osteophytes can impinge on the underlying cuff
- Intra-articular local anaesthetic can aid diagnosis
- Intra-articular steroid injection is helpful in some cases
- Excision of the lateral end of the clavicle is curative if recalcitrant to conservative measures

Long head of biceps tendon rupture

A relatively common condition, predominantly in the middle to elderly age groups. The pathomechanics appears to involve abrasion of the tendon in the bicipital groove and is associated with rotator cuff tears. Most patients present with few symptoms, although they often seek advice acutely.

History and examination

Usually, the patient feels a sense of ‘something giving way’ in the front of the shoulder, and this sensation is often linked to a specific exertional event, e.g. lifting or pulling. The upper arm is

often bruised, and elbow flexion produces a swelling in the front and middle of the arm. The lump is initially tender and power is diminished (Fig. 34.17).

Treatment

In the vast majority of cases, the treatment is reassurance that the pain and bruising will resolve and that the power will improve over several months (Summary box 34.12).

Summary box 34.12

Proximal biceps tendon rupture

- Rupture of the long head is the commonest
- There is an association with rotator cuff pathology
- Surgery is rarely indicated
- A swelling remains but the power improves over several months

Instability of the glenohumeral joint

Traumatic dislocation of the shoulder is the commonest of all dislocations, with recurrent dislocations or instability being commoner age-related sequelae. A significant proportion (> 50%) of under 25-year-olds develop either recurrent subluxations or dislocations. A sub-group of shoulder instability patients dislocate their shoulders after relatively little force (atraumatic dislocation), while another sub-group is able to dislocate or sublux under their own volition (habitual dislocation). A careful clinical history, physical examination and plain radiographs (including lateral and axillary views) often accurately define the pathology in most cases.

Figure 34.17 Long head of biceps tendon rupture – an obvious change in upper arm shape is evident along with acute bruising on the lateral aspect.

Classification

There are many ways of classifying shoulder instability, based on the direction and degree of traumatic energy, as well as differentiating between subluxations and dislocations. There is a spectrum of instability, but three broad groups of instability can be considered (Summary box 34.13).

Summary box 34.13

Classification of dislocations

- Traumatic – unidirectional; surgery usually successful
- Atraumatic – multidirectional, painful; responds to surgery
- Habitual – voluntary with ligament laxity, painless; surgery usually contraindicated
- Remember – patients may have a combination of the above aetiologies

Recurrent traumatic instability

Predominantly unidirectional and commonly anteroinferior. There is a notable traumatic event initially, although less energy is required on subsequent occasions. The patient experiences apprehension during activities that place the humeral head at risk of displacing towards the vulnerable direction. The shoulder may sublux or dislocate, which may or may not require medically supervised reduction. On examination, there is a full range of motion; with forced abduction and external rotation, apprehension is elicited (Fig. 34.18). Other joints are usually normal. As discussed in the section on trauma, there is usually a Bankart defect, with detachment of the anteroinferior glenoid labrum and damage to the humeral head (Figs 34.19 and 34.20) and, if the instability causes functional difficulties, surgery is indicated. For anterior instability, repair of the Bankart defect, in addition to some tightening of the capsule, will produce good results in 90–95% of patients. This is carried out either through an open anterior deltopectoral approach or arthroscopically (Fig. 34.21). For recurrent posterior instability (which is uncommon), tightening of the posterior capsule is curative, through either an open or an arthroscopic approach (Summary box 34.14).

Summary box 34.14

Recurrent traumatic shoulder instability

- A traumatic event is initially noted
- Subsequent dislocations/subluxations become easier
- Commonest direction of instability is anteroinferior
- Normal range of motion but positive apprehension sign
- Surgical treatment repairs the labral lesion and tightens the capsule

Figure 34.18 Shoulder instability can be clinically tested with an apprehension test; the photograph demonstrates the test while the patient is supine, but the same test can be performed with the patient sitting. The arrow indicates the direction of humeral head instability in common anteroinferior instability.

Atraumatic instability

Although there may be an initiating event, this is often less traumatic, for example a fall climbing stairs rather than a sporting injury. In many cases, there is no initial injury, and the instability may occur in more than one direction. The shoulder usually subluxes rather than dislocates, and the patient can often self-reduce the shoulder. The subluxation is painful, and the patient cannot dislocate the shoulder voluntarily. On examination, generalised ligament laxity is commonly present, and the shoulder can often be subluxed inferiorly to produce a sulcus sign, with a lateral sulcus appearing beneath the acromion as the arm is pulled down. Apprehension tests are again positive, but often in more than one direction. Anterior and posterior drawing of the humeral head often allows laxity to be appreciated (Fig. 34.22).

Physiotherapy, by an experienced therapist, should be tried first in these patients. As well as muscle strengthening, re-education of the patient, and of the shoulder, is necessary, and specific muscle groups may need to be targeted.

Approximately half of patients will require surgery, and a capsular tightening procedure is carried out either through an anterior approach or arthroscopically. This is a successful procedure, but there is a higher failure rate than with patients found to have a Bankart defect. Arthroscopic capsular shrinkage appears not to have an independent role in such patients, although it may have an, as yet incompletely defined, adjunctive role to capsular plication.

Figure 34.19 Schematic representation of Bankart's lesions, which form a spectrum of pathology from minor labral detachment (B) to large detachments with glenoid rim fractures (bony Bankart; E).

Arthur Sydney Blundell Bankart, 1879–1951, Orthopaedic Surgeon, the Middlesex Hospital, London, England.

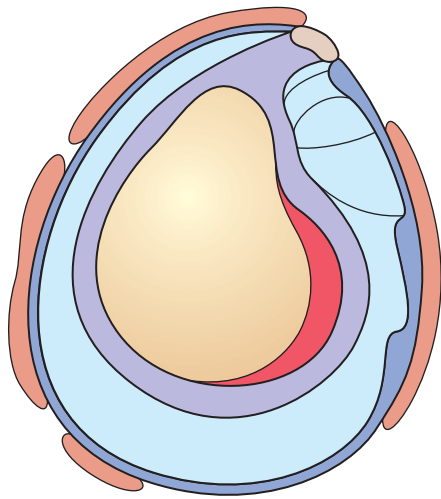

Figure 34.20 An end-on view of the glenoid labrum, demonstrating a labral detachment (red), with the rotator cuff muscles (brown), long head of biceps tendon and labrum (grey).

Habitual dislocation

This is a much smaller group of patients, but one that does not respond well to surgical treatment. The patient is able to sublux the shoulder at will, either anteroinferiorly (Fig. 34.23) or posteriorly (Fig. 34.24), and this is usually not painful. There is underlying joint laxity, which is usually generalised, and there is rarely a significant traumatic event. The patient may sublux the shoulder as a ‘party trick’ or for emotional or psychological reasons.

It is vital that these patients are assessed and managed by an experienced therapist. The patient must be educated to avoid subluxing the shoulder and shown exercises as appropriate. Biofeedback re-education of muscles is important. Surgery is associated with a high failure rate and should be avoided in the vast majority of cases. However, recalcitrant cases can be treated by temporary paralysis of the dislocating muscle groups with botulinum toxin, while the stabilising muscle groups are re-educated.

DISORDERS OF THE ELBOW

Tennis elbow (lateral epicondylitis)

This is the most common cause of elbow pain excluding traumatic conditions, and usually occurs in patients in their 30s to 50s. The aetiology is unknown in the majority of cases, but the

Figure 34.22 Generalised laxity can be appreciated by drawing the humeral head in anterior and posterior directions, and further confirmed by the sulcus sign.

condition commonly follows a period of overactivity, particularly unaccustomed activity that involves active extension of the wrist. The tendon of extensor carpi radialis brevis is most commonly involved and, at exploration, a partial muscle tear and chronic inflammatory tissue may be evident (Summary box 34.15).

Summary box 34.15

Tennis elbow

- Strenuous or overactivity may precede symptoms
- Anterodistal lateral epicondyle tenderness
- Resisted wrist extension is a reliable diagnostic test
- Local anaesthetic injection is diagnostically helpful
- Vast majority improve with supervised conservative management
- Open or arthroscopic release yields good results in recalcitrant cases
- Arthroscopic release also identifies associated pathology

History and examination

The patient complains of pain around the lateral epicondyle and in the back of the forearm with certain activities. There is not usually

Figure 34.21 An arthroscopic view of a detached labrum (a) followed by an arthroscopic repair (b). The red arrow indicates where the labrum has been re-attached to the rim of the glenoid. HH, humeral head.

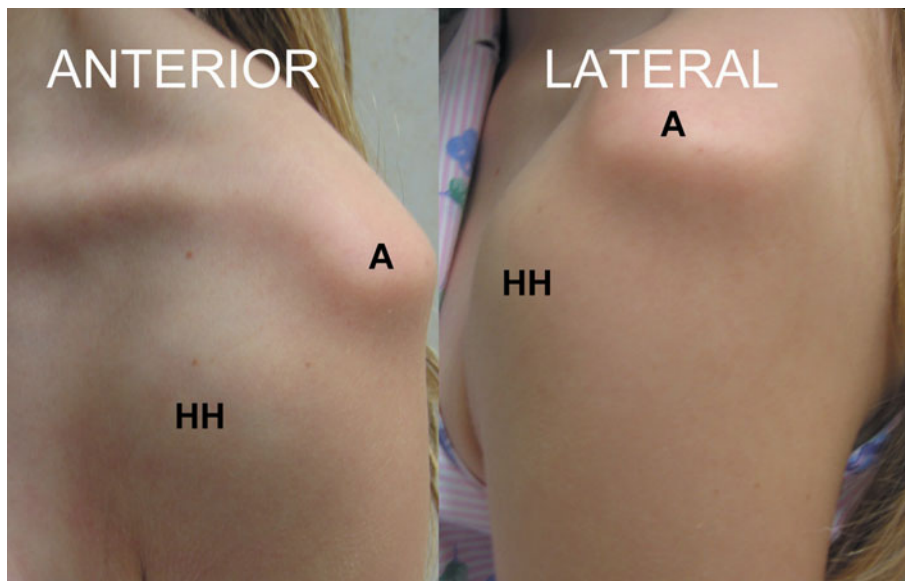

Figure 34.23 Anteroinferior habitual subluxation of the left shoulder in a 12-year-old girl. This was treated successfully with a combination of botulinum toxin to the pectoralis major muscle, biofeedback muscle re-education and a temporary anterior glenoid rim K-wire. A, acromion; HH, humeral head.

a history of trauma, but the patient may relate the onset to a period of unusual or strenuous activity. On examination, the patient is locally tender, which is commonly just distal and anterior to the lateral epicondyle rather than at the apex of the epicondyle itself. Forced palmar flexion and pronation (Fig. 34.25) or resisted wrist extension against resistance (Fig. 34.26) reproduces the pain. Pain with resisted middle finger metacarpophalangeal joint extension distinguishes the source as the extensor digitorum communis origin. The diagnosis is essentially a clinical one, aided by a local anaesthetic injection into the lateral epicondylar region. The need for ultrasound or MRI is minimal, as the vast majority are adequately diagnosed with clinical examination.

Treatment

The prognosis is generally good with most cases resolving without medical input, especially if the precipitating activity is avoided. Persistent cases can be aided with simple analgesia or a local injection of hydrocortisone, depending on severity, but repeated injections should be avoided. Other effective non-surgical measures include extensor mass stretching exercises and deep massage of the extensor mass, followed by cooling the elbow with ice packs. Open or arthroscopic surgery (Fig. 34.27) may be indicated occasionally, and local excision of the abnormal tissue will produce good results in 70–90% of patients.

Figure 34.24 Posterior habitual instability of the shoulder in a 14-year-old girl that completely responded to biofeedback muscle re-education; (a) reduced, (b) posteriorly subluxated.

Figure 34.25 Tennis elbow test 1. Pain is reproduced with wrist flexion and forearm pronation against resistance.

Figure 34.26 Tennis elbow test 2. Pain is reproduced with resisted wrist extension.

Golfer's elbow (medial epicondylitis)

This is less common and involves the flexor-pronator origin at the medial epicondyle. Ulnar nerve symptoms due to irritation or compression are part of the differential diagnosis, and treatment follows similar lines. If non-surgical management fails and surgical excision of the degenerate muscle origin is carried out, further imaging such as ultrasound or MRI is occasionally required, but this is essentially a clinical diagnosis.

Arthritis of the elbow

Rheumatoid arthritis

The elbow is commonly involved in rheumatoid arthritis, which can be a source of discomfort and functional limitation. Medical management is increasingly successful, but surgery is occasionally required. Radial head excision and synovectomy (open or arthroscopic) is effective for painful and restricted pro-supination, with good short-term results, although relapses are frequent. Elbow arthroplasty is a very effective modality for pain relief and functional restoration in end-stage disease (Fig. 34.28), with up to

Figure 34.27 Arthroscopic view of tennis elbow. Arrows highlight the visible pathology. (a) Capsular splits; (b) capsular partial rupture; (c) complete capsular and extensor carpi radialis brevis rupture. C, capitellum.

Figure 34.28 Typical end-stage rheumatoid arthritic destruction of the elbow joint, with characteristic erosion of the olecranon process and distal humeral columns.

Figure 34.29 A linked total elbow arthroplasty (Coonrad–Morrey) of the patient from Fig. 34.28. Of note is the lack of olecranon process and columns.

90% implant survival at 10 years (Fig. 34.29), with gross bony destruction. The functional outcomes are gratifying and of significant benefit to this group of debilitated patients (Fig. 34.30) (Summary box 34.16).

Summary box 34.16

Rheumatoid arthritis of the elbow

- Surgical management is less frequently required due to the success of medical treatment
- A painful rheumatoid radial head can be excised to improve pain and pro-supination
- End-stage elbow disease is well treated with a total elbow arthroplasty
- Elbow replacement surgery is technically challenging if little bone stock is present

Osteoarthritis

Primary osteoarthritis of the elbow is increasing in frequency, but most cases of arthritis are secondary to previous trauma, osteochondritis dissecans or congenital problems. The typical patient demographic is a 40- to 60-year-old male, working in a heavy manual occupation (Fig. 34.31). Pain is the primary problem, along with locking although, on examination, there will usually be some crepitus, pain with motion and some degree of fixed flexion deformity. The history and examination should concentrate on differentiating the pain of a degenerate joint, which is activity related and predictable, from that of sudden unexpected pain and locking, which suggests loose bodies within the elbow (Figs 34.32 and 34.33). In addition, ulnar nerve symptoms are more common in the arthritic elbow.

(b)

Figure 34.30 Final functional outcome of the patient in Fig. 34.28, 1 year after a Coonrad–Morrey linked total elbow arthroplasty.

Figure 34.31 Arthroscopic view of primary osteoarthritis (arrows) of the radiocapitellar joint in a young male labourer.

Figure 34.32 Plain radiographs of primary degenerative osteoarthritis of the elbow. White arrows, osteophytes.

Treatment

No treatment is required in most cases other than reassurance about the nature of the condition. Osteoarthritic elbows seldom deteriorate rapidly, and the symptoms often improve after retirement. For the patient who is unable to carry out normal activities, there are surgical procedures that alleviate symptoms but may not guarantee a return to heavy manual work. Debridement, with or without augmentation with hyaluronic acid supplementation, will alleviate painful symptoms and increase the range of motion in the earlier stages; loss of motion is rarely a major complaint. Interposition arthroplasty using tendon, fascia or cutis is an option, although the outcomes are less predictable. Prosthetic joint arthroplasty is better for a more predictable symptomatic relief, but patients wishing to return to a heavy manual profession should be precluded. Other options that are less acceptable but should be considered in certain situations are resection arthroplasty and arthrodesis.

Figure 34.33 Computerised tomography scans of primary degenerative osteoarthritis of the elbow. Arrows, loose bodies; arrow heads, osteophytes; white line, broken osteophyte.

In general, the results of elbow replacement for osteoarthritis are not as good as for rheumatoid arthritis, probably as a consequence of different lifestyles of the patients (Summary box 34.17).

Summary box 34.17

Elbow osteoarthritis

- Initial management – decrease forces across elbow
- Decrease activities, change occupation
- Joint-preserving measures include arthroscopic/open debridement
- When conservative measures fail, consider prosthetic arthroplasty in low-demand patients

Loose bodies

After the knee, the elbow is the second commonest site of symptomatic loose bodies. The most common cause is osteoarthritis but, in younger patients, osteochondritis dissecans is the usual cause. Most patients complain of sudden unexpected pain and locking of the elbow, and often they have to shake or manipulate the elbow to relieve it. Plain radiographs will confirm the diagnosis in 90% of cases, and further investigation is not necessary (Fig. 34.34). Arthroscopic removal (Fig. 34.35) is effective and, in the presence of mechanical symptoms, good results can be expected. The removal of loose bodies from a degenerate elbow in isolation

(a)

(b)

Figure 34.34 Radiograph of elbow loose bodies.

may not result in any lasting benefit, due to the degenerative symptomatology from the remainder of the joint (Summary box 34.18).

Summary box 34.18

Other common elbow problems

- Osteochondritis dissecans – occurs in teenage boys
Detached fragments can be repaired or removed
- Olecranon bursitis – usually chemical not septic
- Ulnar nerve compression – may present with numbness in the hand. May need to be decompressed

Osteochondritis dissecans

Osteochondritis dissecans is much less common in the elbow than in the knee, and usually affects the capitellum. Teenage boys are usually affected, and the condition is often related to sporting activities. The main symptoms are pain and swelling and, on

Figure 34.35 Loose bodies arthroscopically removed from the patient in Fig. 34.33.

examination, there is loss of full extension. Treatment is normally conservative, with a rest from sports, but arthroscopic removal may be required if the fragment detaches and the patient develops mechanical symptoms suggestive of a loose body.

Olecranon bursitis

Inflammation of the olecranon bursa is relatively common. The elbow is often very red, warm, swollen and painful, and a septic arthritis may initially be suspected. The signs and symptoms are, however, confined to the back of the elbow (Fig. 34.36), and movement within an arc of 30–130° is usually possible. The bursitis is usually chemical rather than infective, and management consists of rest, ice, anti-inflammatories and a compression dressing. If there is any suspicion of a penetrating wound, antibiotics should be administered, but formal drainage of the bursa should be avoided, unless purulent material is present.

Chronic bursitis can occur and may be associated with calcific nodules of the bursal lining (Fig. 34.37). When troublesome, surgical excision is beneficial.

Distal biceps tendon rupture

Rupture of the distal insertion of the biceps is an uncommon condition that usually occurs in younger patients, particularly after a

Figure 34.36 Olecranon bursa.

Figure 34.37 A very large chronic olecranon bursa, excised and its internal lining exposed, revealing a dense calcific component to the lining.

sporting injury. Again, pain and weakness are present but, unlike rupture of the long head, the weakness will not improve. Surgical repair is indicated in the demanding younger age groups, with good functional restoration (Fig. 34.38).

Ulnar nerve compression

This is the second commonest peripheral nerve entrapment after carpal tunnel syndrome. The most common sites of compression are around the elbow, especially if associated with a significant cubitus valgus angular deformity (Fig. 34.39): there are a number of other possible sites:

- the arcade of Struthers and the medial intermuscular septum – as the nerve passes into the posterior compartment of the distal humerus;
- medial epicondyle – particularly if osteophytes are present;
- cubital tunnel – as the nerve passes between the two heads of the flexor carpi ulnaris (Fig. 34.40).

A nerve palsy may also be due to a flexion or a valgus deformity of the elbow.

History and examination

Unlike carpal tunnel syndrome, compression of the ulnar nerve may not be painful, and the patient may present with weakness of the hand in association with paraesthesia. On examination, a positive Tinel's sign is usually present, particularly at the site of compression, and wasting (Fig. 34.41) and weakness of the intrinsic muscles of the hand are evident. Nerve conduction studies have an unpredictable diagnostic value in the earlier stages of the pathology, and are frequently no more informative than a good clinical examination. Plain radiographs are of value to screen for deformity, medial impinging osteophytes and medial epicondylar pathology.

Figure 34.41 Clinical signs of ulnar neuropathy. (a) Hypothenar eminence wasting; (b) interosseous muscle wasting.

Treatment

Despite the absence of pain, decompression of the nerve should be carried out. The nerve can be explored through an open or arthroscopic approach. Surgical options include simple decompression, decompression with partial medial epicondylectomy and anterior transposition. Transposition is usually necessary in cases of deformity or if the nerve is unstable after decompression. For most other situations, decompression without transposition is sufficient, provided all sites of possible compression have been explored.

Any paraesthesia should resolve, but the prognosis for the return of hand power should be guarded as the recovery is unpredictable.

Compression of both radial and median nerves at the elbow occurs, but this is much less common than ulnar nerve compression.

INFECTIONS OF THE UPPER LIMB

Osteomyelitis

Osteomyelitis of the upper limb is very uncommon in adults, unless there are specific predisposing factors such as penetrating wounds. As with other sites, staphylococci and streptococci are commonly implicated, although other organisms may be encountered in the immunocompromised patient. The treatment of osteomyelitis of the upper limb does not differ from that in other sites.

In children, osteomyelitis of the proximal humeral metaphysis can occur, but this is much less common than osteomyelitis of the proximal femur or around the knee.

Septic arthritis

In both adults and children, septic arthritis of the shoulder or elbow is uncommon. Arthroscopy is preferred to formal arthrotomy for washing out the shoulder. The elbow may be washed out arthroscopically or via a lateral Kocher-type approach.

Tuberculosis

The shoulder and elbow are relatively uncommon sites for tuberculosis (TB), but the incidence appears to be increasing (Fig. 34.42), and treatment is along conventional lines. Secondary degeneration can occur and may be difficult to manage. A previously infected joint is one of the few indications for shoulder arthrodesis, but the elbow presents a dilemma. Arthrodesis of the elbow is not a good procedure, and there is little information on the outcome of other methods of treatment after previous TB (Summary box 34.19).

Figure 34.42 Tuberculosis of the ulnar shaft in an Indian female, revealing a bony erosive lesion, which responded to conventional anti-tuberculous chemotherapy without surgery.

Emil Theodor Kocher, 1841–1917, Professor of Surgery, Berne, Switzerland.

Summary box 34.19

Sepsis in the shoulder and elbow

- Most commonly occurs following trauma
- Early diagnosis and aggressive treatment are important
- A treatment for sepsis is arthrodesis
- Elbow function after arthrodesis is mostly unacceptable

Tumours of the upper limb

Tumours are unusual around the elbow, but the proximal humerus is a relatively common site. It is the third most common site for both osteosarcomas and fibrosarcomas after the distal femur and proximal tibia. Treatment is along conventional lines. The shoulder is the second most common peripheral site after the proximal femur for chondrosarcomas, and the scapula body is also a common site. The principal method of treatment for chondrosarcomas is surgical excision, and this may be technically difficult around the shoulder. Subtotal excision of the scapula can be carried out with good preservation of function if the glenoid can be left. The humerus is also a relatively common site for lymphomas and Ewing's tumour. Treatment is, again, along conventional lines (Summary box 34.20).

Summary box 34.20

Tumours in the upper limb

- These are rare apart from metastases in the humerus
- The shoulder and upper humerus are a site for osteo-, fibro- and chondrosarcomas
- Common soft-tissue tumours of the hand include granulomas, inclusion cysts, ganglia and giant cell tumours of the tendon sheath (Fig. 34.43)

Benign and intermediate tumours such as osteochondromas, giant cell tumours and aneurysmal bone cysts are also relatively common. The proximal humerus is the most common site for unicameral bone cysts, which are thought to represent an abnormality of cells of the growth plate (Fig. 34.44). They commonly present as pathological fractures in children around the age of 10 years and affect boys more commonly than girls. The lesion may

Figure 34.43 Giant cell tumour (arrows) of the tendon sheath (magnetic resonance imaging).

James Ewing, 1866–1943, Professor of Oncology, Cornell University Medical College, New York, NY, USA, described this type of sarcoma in 1921.

Figure 34.44 Unicameral bone cyst (arrows) of the proximal humerus in a 12-year-old boy.

resolve after fracturing, but local medical treatment is often required. Benign soft-tissue tumours that are common are lipomas (Fig. 34.45) and fibromas (Fig. 34.46), with ganglia (Fig. 34.47) sometimes posing diagnostic challenges.

The humeral shaft is a common site for secondary deposits (Fig. 34.48), and intramedullary nailing may be required for pathological fracture or impending fracture, if the patient is fit for surgery. In the majority of cases, primary tumours are found in the breast or prostate, but secondary spread from the thyroid, lung, kidney and bowel can also occur.

HAND

Function

The hand is a complicated and highly sensate organ that is designed to manipulate the environment, and therefore has some prerequisites to function effectively (Summary box 34.21).

Summary box 34.21

Prerequisites for hand function

- Flexible and strong
- Sensitive and pain free
- Coordinated

The index finger works against the thumb, which acts as a post, in order to achieve a fine pinch grip, e.g. picking up a small object, whereas the little and ring fingers provide power grip, e.g. holding a hammer, and curl into the palm. The thumb presses against the side of the index finger for key grip and presses the tips of the index and middle fingers for chuck grip (holding a pen). All

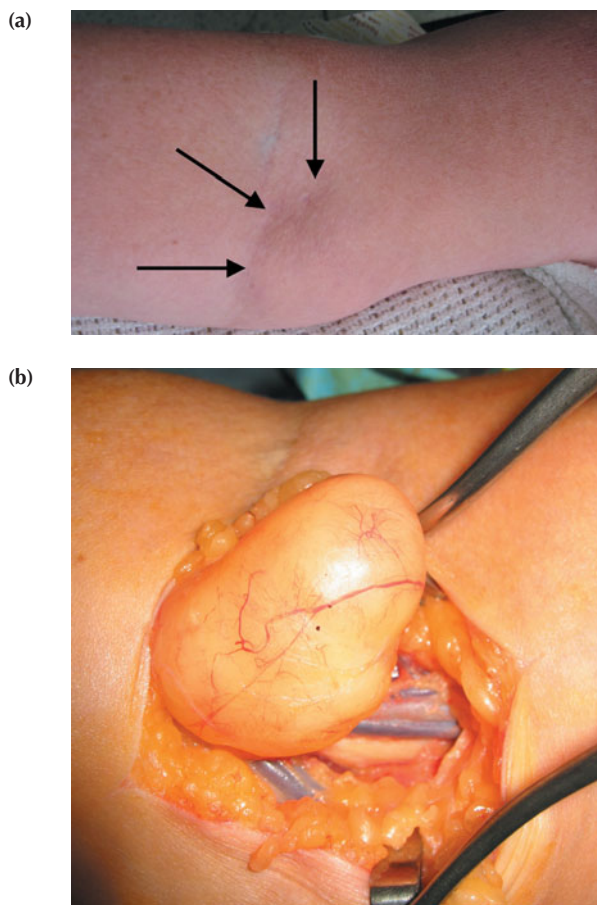

Figure 34.45 Antecubital lipoma (arrows), which presented with median nerve compression neuropathic symptoms. (a) Antecubital swelling; (b) lipoma defined with the underlying median nerve and brachial artery/vein.

the fingers curl for hook grip (holding a suitcase). A stable wrist is required to allow these hand functions (Summary box 34.22).

Summary box 34.22

The five functions of the hand

- Fine pinch, e.g. picking up a small object
- Power grip, e.g. holding a hammer
- Key grip, e.g. holding a key
- Chuck grip, e.g. holding a pen
- Hook grip, e.g. carrying a suitcase

Clinical history and physical examination

The initial clinical history should ascertain the patient's age, occupation and left or right handedness. An important aspect of assessment is the function and pain of the hand with a lesser importance placed on cosmesis, with care being taken to assess rotational malalignments of the digits (Fig. 34.49). Sensation and weakness are also specifically questioned.

Tendons

Examination should begin with inspection for deformity, scars, nodules, etc. Tendon function can be tested with the passive

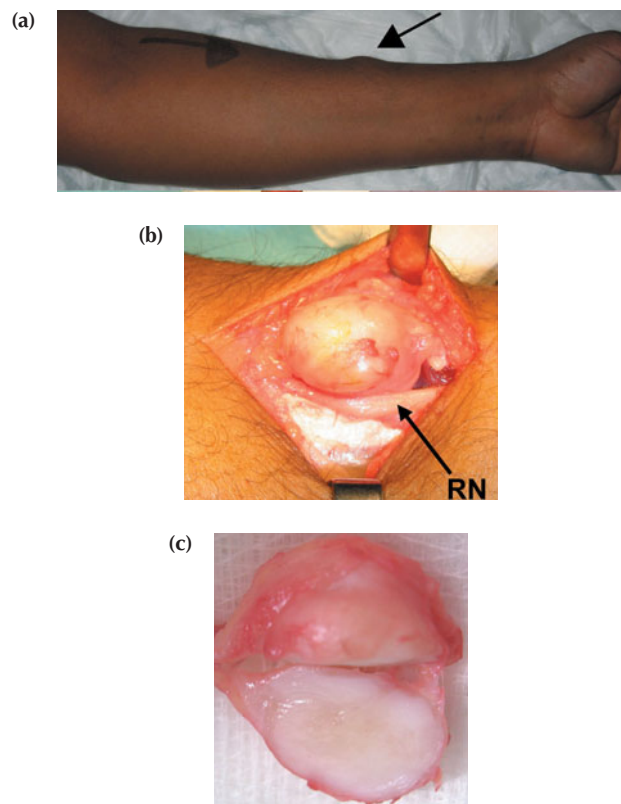

Figure 34.46 Fibroma of the forearm. (a) Swelling on the radial border of the mid-forearm, a firm but mobile swelling. (b) Fibroma defined with the underlying radial nerve, which was the source of the sensory neuropathy. (c) Fibroma bivalved revealing a dense fibrous interior.

tenodesis method: the wrist is moved from flexion to extension passively, normal function is demonstrated by the fingers curling into flexion with wrist extension and should open with wrist flexion. This motion arc should be smooth and coordinated, thereby establishing the function of each tendon.

Nerves

The neurological status of the hand should be assessed by sensation on each side of the digits (light touch and two-point discrimination). Tinel's test (nerve percussion that produces tingling) allows the examination of a compressed nerve or a nerve tip that is regenerating and advancing following an injury. Sweat gland function in the hand, assessed by passing a pen across the surface of a digit, can assess whether a nerve is intact, in which case the pen sticks to the skin, or severed, if the pen glides smoothly over the skin without resistance.

Circulation

The capillary refill time can be examined with nailbed compression and observing the time taken to reperfuse. Arterial supply by the radial and ulnar arteries can be tested with the Allen test: the patient elevates and tightly clenches the fist. The Allen test can identify whether both radial and ulnar arteries are intact. In this

Edgar van Nuys Allen, 1900–1961, Professor of Medicine, the Mayo Clinic, Rochester, MN, USA.

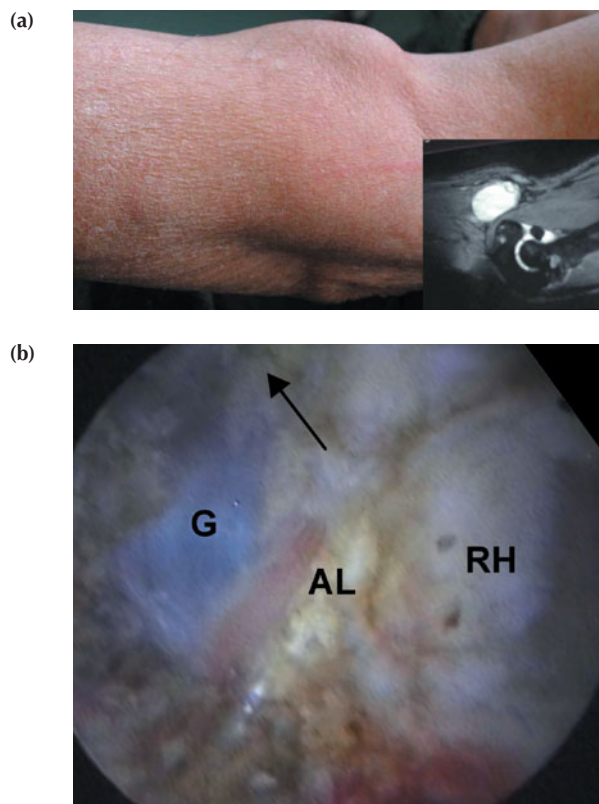

Figure 34.47 Antecubital ganglion (G) causing considerable elbow discomfort. (a) Antecubital soft and fluctuant swelling, with a magnetic resonance imaging inset revealing a fluid-filled mass. (b) Arthroscopic excision view revealing its close relationship to the annular ligament (AL) and radial nerve (arrow). RH, radial head.

test, the patient squeezes his or her hand to express the blood, and then both arteries are compressed by the examiner's fingers. The hand will be white. The examiner then releases one artery; if the hand does not 'pink up', that artery is occluded or divided. The test is repeated for the other artery. Compression of the fingernail will cause it to go white. On release of the examiner's finger, return of a normal pink colour within 2 s confirms a proper distal artery circulation (Fig. 34.50) (Summary box 34.23).

Summary box 34.23

Examination of the hand

- Tendons – passive tenodesis test for function
- Nerves – two-point discrimination for sensation
- Nerves – skin sweat test for autonomic nerve function
- Arteries – Allen's test for circulation

Investigations

The following are specific investigations for the hand and wrist: (1) electrophysiology provides data regarding nerve function and is helpful in carpal and Guyon's tunnel syndromes if the clinical picture is not conclusive; (2) MRI can be helpful to detect

Jean Casimir Felix Guyon, 1831–1920, Professor of Genito-urinary Surgery, Paris, France.

Figure 34.48 A pathological distal humeral shaft fracture through a secondary renal cell carcinoma deposit. This patient was not fit for surgery and hence was treated in a plaster cast.

Figure 34.49 Rotational malalignment of the little finger.

Kienböck's lunate and scaphoid fracture fragment vascularity; (3) radioisotope bone scans can be helpful in elusive cases of wrist pain for increased signals identifying areas of higher vascularity; (4) wrist arthroscopy can be a useful diagnostic aid for triangular fibrocartilage complex (TFCC) tears, carpal instabilities and arthritis.

Robert Kienböck, 1871–1953, Professor of Radiology, Vienna, Austria, described this condition in 1910.

Figure 34.50 Allen's test.

Hand treatment – basic principles

Prevent swelling and stiffness

Following injury, surgery or infection, the hand swells (Fig. 34.51), leading to an extended metacarpophalangeal joint and flexed interphalangeal joint position. This position can, if prolonged, lead to collateral ligament shrinkage; as the wrist swells, it tends to fall into a position of flexion, the metacarpophalangeal joints extend and the interphalangeal joints flex. This position becomes permanent as the collateral ligaments shrink and the oedematous tissues fibrose. The hand cannot then function properly. To avoid this, the following three principles should be observed:

- 1 *Elevation* in a high sling, without excess elbow flexion, which impairs venous drainage.
- 2 *Splintage*. The wrist should be splinted initially in the position of safety – the 'Edinburgh' position described by James is designed to avoid fixed flexion contractures. Dressings must not be too tight.
- 3 *Movement*. Rehabilitation should be planned to mobilise all joints as early as possible (Summary box 34.24).

John Ivor Pulsford James, 1913–2001, Professor of Orthopaedic Surgery, the University of Edinburgh, Edinburgh, Scotland.

Figure 34.51 Hand swelling following surgery is to be avoided.

Summary box 34.24

General principles of treatment

Avoid swelling and stiffness by:

- Elevation – to reduce swelling
- Splintage – to avoid contractures
- Movement – to pump away swelling and encourage suppleness

Many other basic principles apply to the surgical treatment of the hand and are listed in Summary box 34.25.

Summary box 34.25

Hand surgery principles

- Local anaesthetic or a regional blockade in most cases
- Arm or finger tourniquets
- Incisions should cross a flexor crease at 45° angles

Thumb ulnar collateral ligament

Gamekeeper's thumb is a chronic overuse stretching of the ulnar collateral ligament of the thumb. An acute form of this injury is the skier's thumb, radial hyperabduction of the thumb. Patients present with pain and instability of the thumb when attempting to maintain a power pinch grip between the thumb and index finger. Most stable sprains can be managed conservatively with 3–4 weeks of splintage. When unstable, the ulnar collateral ligament should be either repaired, if possible, or reconstructed with a suitable graft.

Triangular fibrocartilage complex

This is a structure that is in continuity with the dorsal and volar wrist capsules and primarily serves to stabilise the distal radio-

ulnar joint and acts as part of the proximal articulation of the triquetrum. It can undergo traumatic or degenerative tears, thereby presenting with ulna-sided wrist pain, and distal radio-ulnar instability. Diagnosis by magnetic resonance arthrography or diagnostic arthroscopy can effectively lead to repair of the traumatic tears and debridement of the ragged degenerative tears.

Infections

Most hand infections can be treated initially with elevation, static splintage and presumptive antibiotics. Surgical drainage may be necessary if pus is evident, and antibiotics should be altered in accordance with microbiological investigation of the pus. If swelling and inflammation settles, with or without surgical intervention, supervised motion is instigated to avoid stiffness (Summary box 34.26).

Summary box 34.26

Hand infections – treatment

- Elevation, splinting and antibiotics if no pus
- Surgical drainage if pus is present
- Tendon sheath pus needs irrigation
- Bites should be explored, cleaned and managed with broad-spectrum antibiotics
- All infections need early mobilisation once inflammation settles

Paronychia

Acute paronychia is the commonest hand infection, often due to inappropriate nail trimming or skin picking around the nail fold (Fig. 34.52). After initial inflammation, pus accumulates beside the nail and needs to be surgically released, with or without the excision of the outer quarter of the nail. Chronic paronychia appears over several weeks and is usually a fungal infection, unrelated to the acute form. It commonly occurs in patients whose hands are frequently immersed, and microscopy of scrapings and fungal cultures reveals the diagnosis. Management ranges from advice to keep the hand dry and the use of anti-fungal creams to nail fold surgery.

Pulp space (felon)

Pus trapped between the specialised fingertip septae causes intense fingertip pain, and may lead to terminal phalangeal bone infection, erosion and sequestrum formation. The last of these

Figure 34.52 Acute paronychia.

will need to be drained and debrided. A common differential diagnosis with small vesicles and crusts is the self-resolving herpetic whitlow, especially in dental workers, caused by the herpes simplex virus.

Flexor tendon sheath infection

The clinical presentation is of a swollen flexed finger, which is painful with passive motion and tender on tendon sheath palpation. If the infection, commonly by *Staphylococcus* or *Streptococcus*, is untreated, adhesions between the tendon and its sheath lead to a stiff and useless finger. Management is by early saline irrigation of the sheath, with a catheter passed into the sheath, with early motion once signs of inflammation resolve.

Bites

Animal or human bites can lead to infection and consequent loss of function, commonly due to *Staphylococcus*. Broad-spectrum antibiotics are generally effective. Wounds should be explored thoroughly, excised, washed out, damaged tendons repaired and splinted, and appropriate antibiotics commenced.

Other infections

Mycobacterial infections

Tuberculosis in the hand may involve the tenosynovium, joints or bone. The most dramatic form is the compound palmar ganglion, with synovial swelling, proximal and distal to the transverse carpal ligament. The diagnosis is made with a biopsy, and synovectomy and prolonged chemotherapy are the basis of treatment.

Pilonidal sinus

A hair implanted in the palm or web space can cause a recurrently infected cyst (Fig. 34.53), which should be excised.

Palmar space infections

The whole hand becomes swollen and tender, as pus collects on either side of the septum. Treatment is by incision and drainage and thorough washout of the wound.

Figure 34.53 Pilonidal sinus in a barber.

Web space infections

Pus can collect in the potential space surrounding the lumbricals, which pass from the palm, across the deep transverse metacarpal ligament into the extensor mechanism. The web space swells, and swelling tends to spread adjacent fingers apart. Pus is drained through a longitudinal incision over the web space.

Arthritis

Rheumatoid arthritis

Rheumatoid arthritis has many deforming and devastating effects and presents with the classic symptoms of morning stiffness, symmetrical arthritis, especially involving the hand, hand deformities and rheumatoid nodules. Further diagnostic criteria include seropositive rheumatoid factor and radiographic changes, e.g. erosive changes and periarticular decalcification (Table 34.1). Rheumatoid synovitis (pannus) destroys ligaments, tendons and joints, producing pain, deformity and loss of function. Zig-zag collapse is a typical rheumatoid feature, e.g. boutonnière (Fig. 34.54), swan neck (Fig. 34.55), and ulnar drift of the metacarpophalangeal joints with radial drift of the wrist. Simple activities of daily living, such as thumb pinch and opening jars, stress the weakened ligaments, thus producing greater deformities. Any treatment is primarily dictated by pain and disability, not deformity (Summary box 34.27).

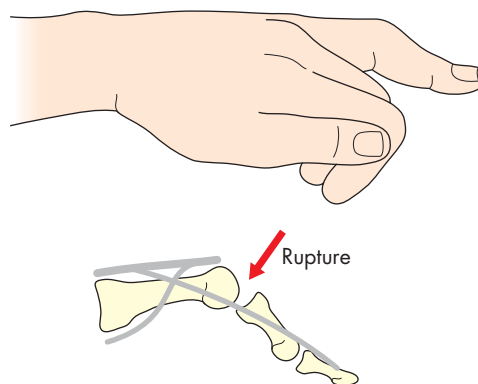

Figure 34.54 Boutonnière deformity.

Figure 34.55 Swan neck deformity.

Boutonnière is French for button-hole.

Table 34.1 Radiographic differences between rheumatoid and osteoarthritis

Rheumatoid arthritis	Osteoarthritis
Periarticular osteoporosis/ subchondral erosions	Subchondral sclerosis and cysts
Periarticular soft-tissue swelling	Less pronounced swelling
Joint space narrowing	Joint space narrowing
Marginal erosions	Marginal osteophytes
Joint deformity/malalignment	Less pronounced deformities
Ankylosis	Less common ankylosis

Summary box 34.27**Deformities in rheumatoid arthritis****Fingers**

- Swan neck deformity
- Boutonnière deformity
- Extensor tendon rupture
- Flexor tendon rupture
- Flexor synovitis

Metacarpophalangeal joints

- Flexion
- Ulnar deviation
- Subluxation, dislocation

Wrist

- Radial deviation
- Carpal supination
- Prominent ulnar head
- Extensor tenosynovitis

Management

Non-operative treatment is primarily directed at slowing progression and improving symptoms. Specific aids help patients to perform daily tasks, e.g. turning taps and opening jars, and splints improve symptoms during flare-ups, all of which serve to decrease further damage to weakened ligaments. The primary indications for operative treatment are: (1) pain relief; (2) functional improvement; (3) to prevent disease progression; and (4) cosmesis. In general, the hand and wrist should be treated after the shoulder and elbow, and the more reliable operations, e.g. wrist and thumb fusion, should be considered prior to less predictable operations, e.g. soft-tissue reconstructions, as discussed below.

- 1 Synovectomy can improve pain and increase function, even following tendon rupture, eliminate trigger finger and cure carpal tunnel syndrome in these patients.
- 2 Excision of the distal ulna may reduce the risk of extensor tendon rupture, protects the repair of ruptured extensor tendons and has a cosmetic benefit. Post-excision instability can be treated with soft-tissue stabilisation or ulna head arthroplasty.
- 3 Prosthetic arthroplasty of the wrist is relatively unpredictable, whereas metacarpophalangeal and interphalangeal joint replacement is more predictable for pain relief and functional improvement, with the proviso of functioning soft-tissue stabilisers, e.g. repairable/reconstructable collateral ligaments and tendons.

- 4 Arthrodesis of the wrist, thumb and some of the smaller joints provides good pain relief, and creates a stable axis against which other parts of the hand can function. For example, when the flexor pollicis longus tendon ruptures and is symptomatic, the most reliable solution is to arthrodesis the interphalangeal joint of the thumb.
- 5 Tendon reconstructions. Some ruptured tendons cause significant morbidity, often solved by either a local joint fusion or tendon transfer, e.g. extensor indicis transfer for an extensor pollicis longus rupture. Multiple tendon ruptures can be treated by creating a mass tendon action, with side-to-side tendon suture or multiple tendon transfers.

Osteoarthritis**Wrist**

The radiocarpal joint can develop primary or secondary osteoarthritis, e.g. after intra-articular trauma and infection (Fig. 34.56). Non-operative management begins with conservative measures, e.g. analgesia, splints, activity modification and activity aids. Operative management, following failed conservative treatment, includes wrist arthrodesis in 20° extension and radiocarpal arthroplasty, a much less predictable option than fusion. Specific and localised arthritis of the carpus, e.g. post-scapoid fracture or scapholunate disruption, can be managed with either fragment excision or limited arthrodesis. Pisotriquetral arthritis, with clinical tenderness and confirmed by a 30° supinated lateral radiograph (Fig. 34.57), can be treated with rest, splintage, corticosteroid injection or pisiform excision as a last resort.

Hand

Commonly affected are the distal interphalangeal (Heberden's nodes), proximal interphalangeal (Bouchard's) and the thumb carpometacarpal joints (Fig. 34.58). Symptoms rarely correlate with appearance or radiographic appearances. Affected joint arthrodesis eliminates pain at the expense of motion, but function is often well tolerated. Joint arthroplasty (Fig. 34.59) is an option

**Figure 34.56** Radiocarpal osteoarthritis.

William Heberden (Snr), 1710–1801, a Physician who practised first in Cambridge, and from 1748 in London, England, described these nodes in 1802.
Charles Jacques Bouchard, 1837–1915, Physician, Dean of the Faculty of Medicine, Paris, France.

Figure 34.57 Pisotriquetral arthritis (arrow).

Figure 34.58 Osteoarthritis of the hand.

in some cases, as is trapezial excision for basal thumb arthritis (Summary box 34.28).

Summary box 34.28

Wrist and hand osteoarthritis (management)

- Wrist arthrodesis – maintains acceptable function and improves pain
- Distal interphalangeal joint fusion – maintains acceptable function
- Excision of the trapezium – improves pain but decreases stability and reduces pinch strength

Figure 34.59 Proximal interphalangeal joint replacement.

Other arthritides

Gout

Gout commonly causes pain, joint redness and occasional tophi, and can be differentially diagnosed as septic arthritis. Serum urate and negative microscopic birefringence of joint aspirated sodium urate crystals are diagnostic.

Psoriasis

Psoriatic arthropathy of the hand and wrist is asymmetrical, with pitted nails and destructive radiographic features including a pencil in cup appearance.

Systemic lupus erythematosus

Systemic lupus erythematosus arthropathy is common in young females (15–25 years), with rheumatoid-like deformities, but without joint narrowing or erosions.

Dupuytren's contracture

An autosomal dominant trait with an association with Anglo-Saxon lineage, age, smoking, use of vibrating tools, pulmonary tuberculosis, epilepsy, acquired immunodeficiency syndrome (AIDS) and alcoholic cirrhosis. Clinical features include palmar nodules, skin puckering, cords of the palm and digits, flexion contractures of the digits, Garrod's knuckle pads [thickened skin on proximal interphalangeal joint (PIPJ) dorsum; Fig. 34.60]. Penile thickening and curvature (Peyronie's disease) and plantar

Baron Guillaume Dupuytren, 1777–1835, Surgeon, Hôtel Dieu, Paris, France, described this condition in 1831.

Sir Archibald Edward Garrod, 1857–1936, Regius Professor of Medicine, the University of Oxford, Oxford, England, described this condition in 1893.

Francois de la Peyronie, 1678–1747, Surgeon to King Louis XIV of France, and Founder of the Royal Academy of Surgery, Paris, France.

Figure 34.60 Garrod's knuckle pads.

thickening (Ledderhose's disease) are associations. Deformities that rapidly progress or are of functional consequence are indications for surgical correction. Surgical goals include deformity correction, protection of neurovascular bundles, which are often intricately entangled with the fibrous tissue, and skin coverage, often requiring Z-plasties (Fig. 34.61) (Summary box 34.29).

Summary box 34.29

Dupuytren's contracture

- Autosomal dominant inheritance (trait)
- Fibroblastic hyperplasia with resultant skin nodules, cords and deformities
- Management is surgical if rapidly progressive or functionally debilitating

Tendon disorders

Trigger finger

Triggering occurs in a finger or thumb when there is size disproportion between a flexor tendon and its sheath, often with a

Figure 34.61 Dupuytren's disease.

Georg Ledderhose, 1855–1925, a German Surgeon, described this disease in 1894.

nodule developing in the tendon (Fig. 34.62). Initial management is with a steroid injection into the sheath, followed by surgical tendon sheath release if non-responsive, with careful preservation of the digital nerves. Rheumatoid triggering may be due to synovitis or tendon nodules, and treatment is with synovectomy and excision of a slip of the flexor digitorum superficialis tendon without dividing the A1 pulley (Summary box 34.30).

Summary box 34.30

Trigger finger

- Flexor sheath thickening catches the flexor tendon/nodule
- Often painful with attempted straightening of the digit
- Initial management is with tendon sheath steroid injection
- Surgical release of the A1 pulley relieves the symptoms
- Paediatric trigger thumb and fingers frequently resolve spontaneously
- Rheumatoid triggering is treated by synovectomy, partial tendon excision, but sheath preservation

de Quervain's disease

This is believed to be an overuse pathology of the abductor pollicis longus and extensor pollicis brevis in the first dorsal wrist compartment, most common in middle-aged females, although pregnancy and inflammatory arthritides are also implicated. Dorsoradial wrist pain and tenderness, along with Finkelstein's test (pain with wrist and thumb ulnar deviation while the thumb is fully flexed), are diagnostic. Management ranges from non-steroidal anti-inflammatory analgesia, splintage and steroid injection to surgical release of the extensor retinaculum of the first compartment if the non-operative measures fail.

Neuropathies

Median nerve (carpal tunnel syndrome)

A common pathology presenting with painful wakening at night with tingling in the radial three and a half digits of the hand. There may also be weakness of the abductor pollicis brevis, leading to clumsiness with fine movements. Advanced cases may be observed to have thenar eminence wasting. Specific reliable clinical tests include: (1) Tinel's percussion over the carpal

Figure 34.62 Trigger thumb in a child.

Fritz de Quervain, 1868–1940, Professor of Surgery, Berne, Switzerland, described this form of tenosynovitis in 1895.

tunnel; (2) Phalen's test (reproduction of paraesthesia with full wrist flexion); and (3) carpal tunnel compression with full wrist flexion. Rarely does electrophysiological testing add to the clinical tests, but it is a good tool for tracking changes. Non-operative treatment modalities include night splintage of the wrist in extension and steroid injections into the carpal tunnel. Operative options serve to de-roof the carpal tunnel, thereby creating space for the nerve, without compression (Summary box 34.31).

Summary box 34.31

Carpal tunnel syndrome

- Night pain is common and relieved by shaking the hand
- Less common features are numbness and clumsiness
- Thenar wasting is an advanced sign
- Clinically, Tinel's and Phalen's tests are useful
- Electrophysiology is rarely useful beyond clinical tests
- Treatment options include splints, steroid injection and surgical decompression

Ulnar nerve (Guyon's tunnel syndrome)

Compression of the ulnar nerve due to ganglia, osteophytes or fractured hook of hamate can lead to hypothenar wasting (Fig. 34.63) and ulnar territory dysfunction, with preservation of dorsal sensation of the little finger and the ulnar half of the ring finger.

Kienböck's disease

Commonly thought to be an avascular phenomenon, the aetiology is unclear, but probably involves both ischaemia and micro-trauma of the lunate. A possible correlation with a negative ulnar variance (relatively short ulna) has been suggested. The pathological stages progress from sclerosis to collapse and, finally, arthritis. Clinical presentation with wrist pain and weakness can be positively diagnosed with plain radiographs and MRI scans; the latter are able to detect very early lesions before they are visible on radiographs (Fig. 34.64). Early-stage treatment is with wrist splintage, with analgesia, or radial shortening to reduce compressive forces, thereby potentially decreasing the risk of disease progression. Advanced stage disease may require limited fusion to alleviate pain.

Figure 34.63 Ulnar nerve neuropathy with hypothenar wasting (arrow).

George S. Phalen, Orthopaedic Surgeon, the Cleveland Clinic, Cleveland, Ohio, OH, USA.

Figure 34.64 Kienböck's disease.

Ganglion cysts

These are the commonest hand swellings, causing patient concern and occasional discomfort. They are commonest on the wrist dorsum, but can be on the volar surface (Fig. 34.65). Physical examination reveals a smooth, fluctuant, transilluminable swelling, most which resolve following aspiration or being 'hit with a large book'. Surgical excision aims to remove the whole ganglion, including its connection to the underlying joint/sheath. Patients should be informed regarding the possibility of recurrence.

Figure 34.65 Volar wrist ganglion (arrow).

Congenital differences

The true rate of congenital malformations is difficult to assess, but a fundamental has to be correct identification (Fig. 34.66), communication of the findings to the parents and child, and

management involving a multidisciplinary team. The classification by Swanson, later adopted by the International Federation of Societies of Surgeries of the Hand, is reproduced in Table 34.2.

Figure 34.66 Congenital deformities in the hand. (a) Thumb duplication. (b) Absent fourth ray with constriction ring of the fifth digit.

Table 34.2 Congenital malformations (hand and wrist)

A Defects in formation due to arrested development	(1) Transverse agenesis (2) Longitudinal agenesis (a) radial ray aplasia; (b) median ray aplasia; (c) ulnar ray aplasia (3) Thumb aplasia/hypoplasia
B Defects in differentiation/separation	(1) Syndactyly (2) Camptodactyly (3) Clinodactyly (4) Kirner's deformity (5) Radioulnar synostosis
C Duplications	(1) Supernumerary phalanges (2) Supernumerary digits (polydactyly) (Fig. 34.66)
D Excess development/hyperplasia	Macroductyly
E Insufficient development/hypoplasia	Thumb hypoplasia
F Constricting (amniotic) bands	Simple amniotic band syndrome
G Generalised skeletal anomalies	Marfan's, Turner's and Down's syndromes

LEARNING OBJECTIVES

To understand:

- The common problems affecting these regions in each age group
- The basic anatomy and biomechanics of the hip and knee
- The principles behind the treatment of each condition, be it conservative or surgical
- The basic concepts in joint replacement in terms of materials used, design features and methods of fixation
- The advances that have been made in the management of disorders of the lower limb and that modern surgical practice is still evolving
- The growing need for minimal access surgery and the move towards arthroscopy

THE HIP JOINT

Applied anatomy

The hip joint is a ball and socket joint formed by the head of the femur and the cup-shaped acetabulum. The femoral head and the acetabulum are covered with hyaline articular cartilage throughout, except at the fovea capitis on the femoral head and the base of the acetabulum (Fig. 35.1). The joint allows a considerable range of movement but is inherently stable because of its bony anatomy and the static and dynamic stabilisers. The static stabilisers are composed of the ligaments, the capsule and the labrum, whereas

the muscles running across the joint constitute the dynamic stabilisers. The joint is supported by the iliofemoral and pubofemoral ligaments anteriorly and the ischiofemoral ligament posteriorly. Another structure contributing to stability is the acetabular labrum, which is a triangular fibrocartilagenous structure attached to the rim of the acetabulum except at the base where it is replaced by the transverse ligament. The labrum helps in deepening the socket and also provides a negative suction effect in the joint, thereby enhancing stability. The ligamentum teres, which is attached to the acetabular notch and the transverse ligament and to the fovea capitis, may also have a role in providing stability to the joint. The short external rotator muscles posteriorly, the psoas muscle anteriorly and the abductors acting on the greater trochanter laterally are the dynamic stabilisers of the joint.

The femoral head derives its blood supply mainly from the retinacular branches of the medial circumflex femoral artery and there is a small contribution from the artery of the ligamentum teres (Summary box 35.1).

Figure 35.1 Anatomy of the hip joint.

Summary box 35.1

Anatomy

- The hip joint is a ball and socket joint
- It is stabilised by static and dynamic stabilisers
- Static stabilisers include the capsule, ligaments and labrum
- Dynamic stabilisers comprise the muscles acting across the joint
- Blood supply to the femoral head is mainly derived from the medial circumflex femoral artery

Biomechanics of the hip joint

Biomechanics is the study of the forces acting on the living body and involves both kinetic and kinematic analysis. Kinematics is the study of motion without reference to forces whereas kinetics

relates to the effect of forces on bodies producing motion. Kinematic analysis of the hip joint shows that it allows a large range of movement; average degrees of movement in each direction are summarised in Summary box 35.2.

Summary box 35.2

Range of movement in the hip joint

- Flexion – 115°
- Extension – 30°
- Abduction – 50°
- Adduction – 30°
- Internal rotation – 45°
- External rotation – 45°

Kinetic analysis reveals that forces as high as one and a half times body weight can be exerted across the hip joint during activities of daily living and this is primarily the result of contraction of muscles crossing the joint. The abductors, because of their insertion on the greater trochanter and the lateral side of the femur, help in supporting the pelvis when the patient stands on one leg and thereby form the basis of a Trendelenburg test (Fig. 35.2) (Summary box 35.3).

Summary box 35.3

Forces going through the hip joint

- Lifting leg from bed – one and a half times body weight
- Standing on one leg – three times body weight
- Running and jumping – 10 times body weight

Figure 35.2 Load on the hip joint when subject (weighing W) stands on one leg. Hopping increases the load from 4 to 10 W .

Friedrich Trendelenburg, 1844–1924, Professor of Surgery, Rostock (1875–1882), Bonn, (1882–1895) and Leipzig, Germany, (1895–1911).

Conditions affecting the hip joint

The pathological state of the hip joint in the paediatric age group and secondary to trauma is covered in Chapters 38 and 27 respectively. This chapter focuses on the acquired pathological conditions in the adult.

Avascular necrosis

Introduction and aetiology

Avascular necrosis (AVN) or osteonecrosis of the femoral head occurs because of an interruption in the blood supply to the femoral head, which causes bone death. This leads to collapse of the femoral head with degenerative changes setting in the joint eventually. It can be idiopathic or secondary to other pathology. The most common cause is trauma and, of the non-traumatic causes, excessive alcohol intake and the use of systemic steroids are the most common (Summary box 35.4).

Summary box 35.4

Aetiology of AVN of the femoral head

- Sickle cell disease
- Haemoglobinopathies
- Caisson disease
- Hyperlipidaemia
- Systemic lupus erythematosus
- Gaucher's disease
- Chronic liver disease
- Antiphospholipid antibody syndrome
- Radiotherapy
- Chemotherapy
- Human immunodeficiency virus
- Hypercoagulable states (protein C and protein S deficiency)

Clinical features

AVN of the femoral head usually occurs in men aged from 35 to 45 and is bilateral in over 50% of patients. The patient is frequently asymptomatic in the early stages of the disease process and therefore a high index of suspicion is required for initial diagnosis. However, as the disease progresses the patient may complain of an ache in the groin and clinical examination may reveal an effusion, a limp and limitation of movement.

Investigations
