Both of these methodologies complement one another in the detection and evaluation of structural rearrangements. This is because mate pair Sequencing enables more comprehensive detection of large structural rearrangements, and paired-end sequencing provides more detailed sequencing data filling in any gaps that may be present in the mate pair sequencing genome coverage, as well as being particularly useful in highly repetitive regions. When the data from each of these DNA sequencing methods is analyzed together it facilitates determination of: the genomic loci of structural rearrangements, the size of the rearrangements, the altered DNA sequence following each rearrangement, the genes involved in each rearrangement, and an estimation of the impact of each rearrangement. Together, this gives WGS methods an advantage of having unprecedented sensitivity and resolution of structural and mutational changes. However, it should be noted that mate-pair sequencing is technically challenging and that WGS for the detection of structural rearrangements in tumor samples is a costly and highly experimental approach at present and far from being used routinely.

When Specific Methods are Utilized

The methods used to identify structural rearrangements differ dependent on the size and type of rearrangements to be detected. For instance, standard cytogenetics and FISH are typically used for studying balanced structural rearrangements; whereas molecular cytogenetics, particularly Array-CGH and SNP arrays, are generally used for studying smaller unbalanced structural rearrangements. DNA sequencing methods are not commonly used to investigate structural rearrangements because they are too expensive and difficult to use routinely for this purpose.

Overall there is a need to develop better methods for detecting structural rearrangements in cancers, particularly for DNA sequencing approaches, because it is common for fewer methods to be utilized to detect structural rearrangements in cancer research and routine diagnostics, thus sacrificing important detail in exchange for cheaper, quicker and simpler analysis. Further, currently structural rearrangements are mainly detected using standard cytogenetics. This is mostly done in liquid tumors (i.e., fCML, AML, and ALL, not so much for chronic lymphocytic leukemia, multiple myeloma, nonhodgkin lymphoma, and hodgkin lymphoma). In most solid tumors structural rearrangements are not routinely characterized with the exception of sarcomas and some prostate and lung cancers. Lastly, it should also be acknowledged that there is only a limited resolution achievable by standard and molecular cytogenetic techniques. So even in those cancers where structural rearrangements are often investigated, there are probably many more small-scale structural rearrangements, especially small inversions or CNAs, that are not identified by these methodologies and are thus not routinely diagnosed.

Medical Implications From Studying Structural Rearrangements in Cancer

The primary objective of detecting and evaluating structural rearrangements in cancers is to use the results for clinical management, with the most important aim being the improvement of patient survival. Notably, there are many structural rearrangements that have produced beneficial medical implications, with the t(9;22) translocation and the resulting BCR/ABL fusion protein being a prime example.

Firstly, structural rearrangements can function as disease biomarkers in cancer diagnosis, where the presence of BCR/ABL fusion alongside histopathological features can be used to diagnose CML. In addition, structural rearrangements can be used as biomarkers

for other applications; for instance, the level of the BCR/ABL fusion transcript is used as a measurement to guide prognosis and treatment success, as well as influencing clinical decisions regarding disease management strategies.

Furthermore, the BCR/ABL fusion protein resulting from Philadelphia chromosomes exemplifies how researching structural rearrangements can improve anticancer therapies by enabling personalized treatment approaches. This is because BCR/ABL results in constitutive tyrosine kinase signaling, and small molecule inhibitors of tyrosine kinase activity of BCR/ABL fusion protein (e.g., Imatinib, Dasatinib, and Nilotinib) have been developed. In fact, these drugs have been so efficacious that they have reduced the number of CML cells until the point at which a patient is declared to be in molecular remission with no detectable BCR/ABL fusion transcript, and they have greatly increased the survival time of many CML patients. Presently, studies are underway to investigate whether tyrosine kinase inhibitor treatment in CML patients can be stopped when certain criteria are met. First results indicate that about 50% of the CML patients can be considered cured and remain in permanent remission even after tyrosine kinase inhibitor treatment has ceased. Thus the study of chromosomal structural rearrangements which started in the early 1970s with Janet Rowley's pioneering cytogenetic work and her discoveries of the t(9;22) and t(8;21) translocations have now resulted in the first permanent cures of a blood cancer without chemotherapy just using targeted therapies.

Conclusion and Prospective Vision

Future research will aim to resolve many of the unanswered questions surrounding structural rearrangements in cancer; such as, which regions of the genome are most susceptible to structural rearrangements, what the exact mechanisms are behind common structural rearrangements, why certain rearrangements are seen in some cancers but not others, and how often the presence of structural rearrangements results in cancer development… amongst many more. Further, future research will aim to increase the capacity of genetic and cytogenetic methods to detect structural rearrangements, and it is anticipated that such technological advancements especially cheaper and more accurate NGS techniques will enable the identification of many new structural rearrangements in cancers and further increase the understanding on the genetics and biology surrounding structural rearrangements. Additionally, methodological improvements alongside increased routine assessment of structural rearrangements, will also likely further enhance the medical implications of structural rearrangements in oncology clinics, perhaps in helping with faster and more efficient screening of such rearrangements in patients and facilitating the improvement of anticancer therapies through individualized medicine.

Introduction

Chronic lymphocytic leukemia (CLL) is a malignancy of $CD5^+$ B-cells characterized by the accumulation of small, mature-appearing neoplastic lymphocytes in the blood, bone marrow and lymphoid tissues, thereby resulting in lymphocytosis, marrow infiltration, lymphadenopathy and splenomegaly. The vast majority of CLL cases are thought to originate from monoclonal B-cell lymphocytosis (MBL), a precursor state that differs from CLL essentially by the concentration of circulating tumor cells. CLL is biologically and clinically very heterogeneous, with some patients never requiring any therapy and others displaying an aggressive course with limited response to therapy.

Definition

The World Health Organization (WHO) requires the presence of a CLL-type monoclonal B-cell population of $\geq 5 \times 10^9$/L in the peripheral blood for the diagnosis of CLL. Small lymphocytic lymphoma (SLL) is the same disease but the term SLL refers to cases with blood involvement of $< 5 \times 10^9$/L with documented nodal, splenic, or other extramedullary involvement. The WHO also defines monoclonal B-cell lymphocytosis (MBL) as the presence of the same type of B-cell population of $< 5 \times 10^9$/L in the absence of lymphadenopathy, organomegaly, or other extramedullary disease.

Epidemiology

CLL is the most prevalent form of leukemia. In the USA it is estimated that approximately 20,000 new cases will be diagnosed during 2017, representing the 1.2% of all new cancer cases in that country. The age-adjusted incidence rate is 4.7 cases per 100,000 men and women per year, with a clear difference between men (6.4 cases/year) and women (3.3 cases/year). In Europe, the incidence rate is similar (4.9 cases/year), with a similar sex distribution (5.9 for males and 4.0 for females). The median age at diagnosis is 70 years, while the median age at death is 80 years.

One of the most notorious epidemiological characteristic of CLL is its racial diversity. Within the USA, the incidence rate is highest in Caucasian males (6.8 cases/year) and females (3.6 cases/year) compared with African Americans (5.1 and 2.5 cases/year for males and females, respectively), while Asian Americans and Pacific Islanders have the lowest incidence (1.6 and 0.7 cases/year for males and females, respectively). For unknown reasons, the incidence of CLL is very low in the Far East, including China and Japan,

where it is estimated to occur at a frequency that is approximately 10% of that seen in Western countries. Genetic rather than environmental factors have been invoked for these differences, since Japanese who settled in Hawaii do not have a higher incidence than those living in Japan. The incidence of CLL is higher than expected among relatives of patients with the disease. Recent genome-wide association studies have identified common risk single nucleotide polymorphisms associated with sporadic CLL. The risk of CLL associated with each of these variants is however modest at best. Although families with CLL provide evidence for genetic susceptibility, no rare alleles of large effect have thus far been discovered.

Clinical Presentation

Patients with CLL usually are asymptomatic at the time of diagnosis. A small proportion of patients consult a physician because of painless swelling of lymph nodes, which may wax and wane, but does not disappear. $<5\%$ of patients present with the general symptoms including one or more of the following: (i) unintentional weight loss $\geq 10\%$of body weight within the previous 6 months; (ii) fevers of $>38\,^{\circ}C$ for ≥ 2 weeks without evidence of infection; (iii) drenching night sweats without evidence of infection; and (iv) extreme fatigue. In some patients, the disease presents with features of acquired immunodeficiency (e.g. infections), autoimmune phenomena such as hemolytic anemia, thrombocytopenia or pure red cell aplasia, or exaggerated reactions to arthropod stings or bites.

The most common finding on physical examination is lymphadenopathy, usually located in cervical, supraclavicular and axillary sites. The spleen may also be enlarged and, as is the case with enlarged lymph nodes, the splenomegaly is usually painless. Enlargement of the liver may also be rarely noted at diagnosis. In those cases, the liver is usually nontender and firm. Infiltration of the skin (leukemia cutis) is seen in $<5\%$ of cases. In contrast to other lymphoid malignancies, gastrointestinal and meningeal involvement are rarely seen in CLL.

Laboratory Abnormalities

The hallmark of the disease is an increased white blood cell count with a high percentage of small, mature-looking lymphocytes (i.e. lymphocytosis). The lymphocyte count is extremely variable, ranging from 10 to 200–300 $\times 10^9$/L. In patients diagnosed with CLL on routine analysis, anemia is found in $<10\%$ of the patients. Importantly, anemia is not always due to the infiltration of the bone marrow by the disease; other causes such as autoimmunity, iron, folic acid or vitamin B_{12} deficiency may account for it and should be investigated in all patients with anemia. Likewise, a marked thrombocytopenia (i.e. $<20 \times 10^9$/L) should raise the possibility of an immune origin, particularly in the absence of anemia. Hypogammaglobulinemia is frequent (30% of patients) and tends to worsen over the course of the disease. Serum immunofixation can demonstrate a monoclonal band, usually of the immunoglobulin M type, in around 10–15% of patients. A positive direct antiglobulin test is observed in around 5% of the patients at the time of diagnosis, with clinically apparent autoimmune hemolytic anemia being less frequent.

Morphology

Peripheral Blood and Bone Marrow

Before the advent of immunophenotyping, most chronic lymphoproliferative disorders (CLPD) with leukemic expression were diagnosed as CLL, but advances in the morphological evaluation of peripheral blood and lymphoid tissues, immunohistochemistry, flow cytometry, cytogenetics and molecular genetics have facilitated the differential diagnosis. Morphologically, leukemic CLL cells are characteristically small, mature-looking lymphocytes with scanty cytoplasm and a dense nucleus with clumped chromatin (Fig. 1). CLL cells are extremely fragile and can become partially broken during the preparation of blood smears; these cells are known as 'basket', 'smudge' of 'Gumprecht cells' which, although not specific, are typical of CLL (Fig. 1). Depending on the morphologic features of the tumor cells, two variants are recognized: typical and atypical CLL. In typical CLL $>90\%$ of leukemic lymphocytes have the previously mentioned morphology. In atypical CLL, an increased number of atypical cells (prolymphocytes, centrocytes, centroblasts, large stimutated cells, etc.) is observed in the lymphocyte differential count. Atypical CLL can be further subdivided in CLL with increased prolymphocytes (CLL/PL), when the percentage of prolymphocytes ranges from 11% to 55%, and CLL mixed cellularity, when the atypical lymphocytes represent $>15\%$ of all lymphocytes. CLL with atypical morphology is associated with trisomy 12 and it is often necessary to request additional tests to rule out other lymphoproliferative disorders.

Lymph Nodes and Bone Marrow

Neither bone marrow or lymph node histological examination is required for CLL diagnosis, but it may be useful in difficult or atypical cases. Involved lymph nodes show a characteristic morphological picture with a diffuse effacement of the architecture by a population of small lymphocytes with scant cytoplasm, round nuclei, clumped chromatin and absent nucleoli. In some cases, lymph nodes may be only partially involved by the disease, with tumor cells infiltrating the areas between reactive follicles or surrounding these follicles with a perifollicular pattern. Most lymph nodes have a variable number of pale areas called proliferation centers (formerly named pseudofollicles) (Fig. 2). These areas have a continuum of small to larger cells with broader cytoplasm and

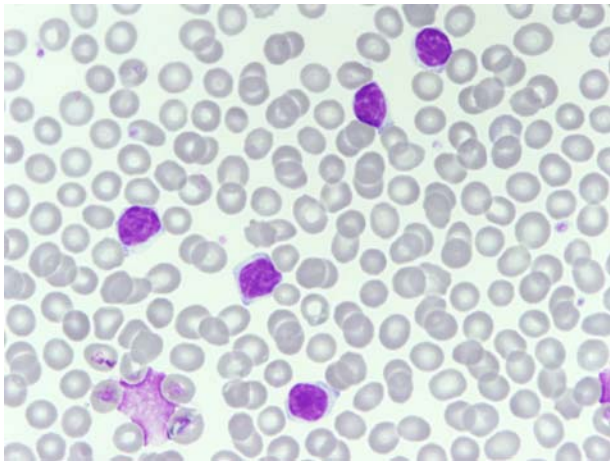

Fig. 1 CLL in peripheral blood. Peripheral blood smear showing increased number of small-sized lymphocytes with partially aggregated chromatin. Notice also one 'smudge' or 'Gumprecht' cell (May-Grünwald-Giemsa, $\times 1000$).

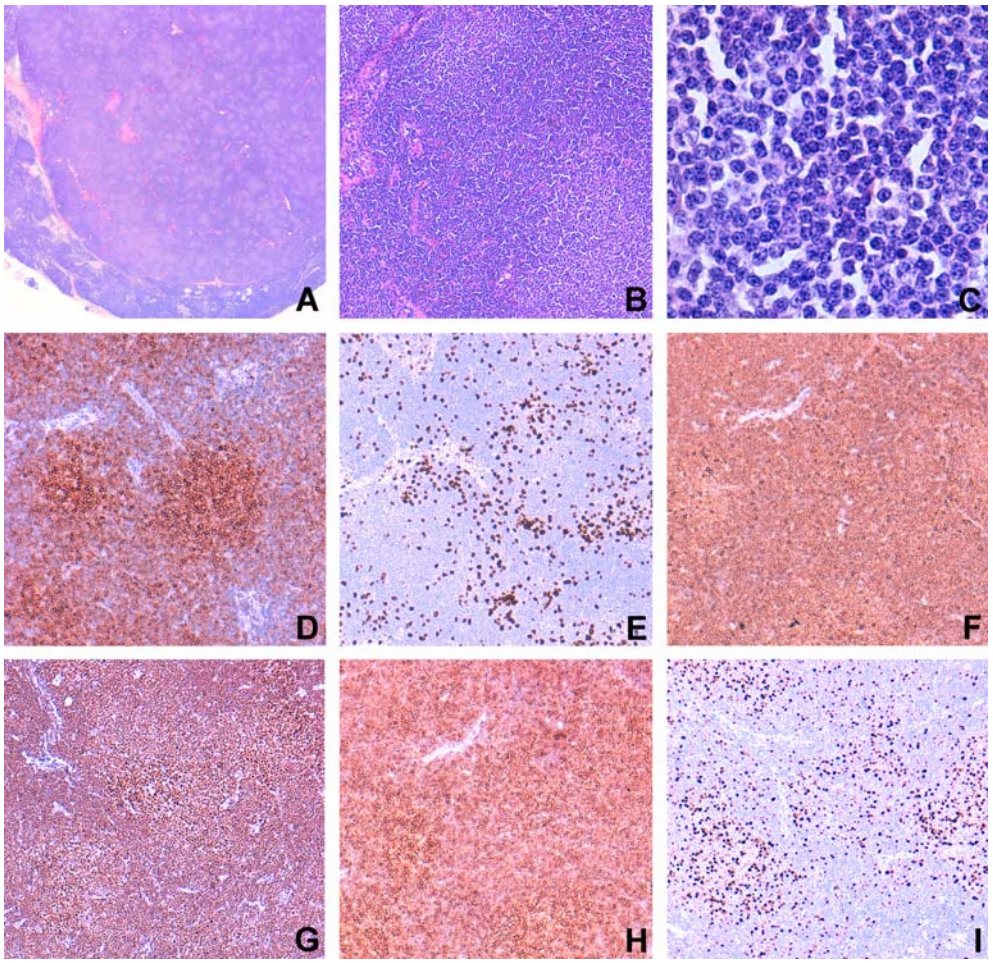

Fig. 2 CLL morphology and phenotype in a lymph node. (A) The lymph node at low power shows pale areas corresponding to proliferation centers (H&E, $2\times$); (B) The lymph node shows an effacement of the architecture by a diffuse proliferation of small cells (H&E, $10\times$); (C) The tumor cells are small with round nuclei, clumped chromatin and scarce cytoplasms. Occasional cells have larger nuclei with evident central nucleoli corresponding to prolymphocytes (H&E, $40\times$); (D) CD20 immunohistochemical staining shows the diffuse positivity of tumor cells, which is stronger in the cells of the proliferation centers; (E) CD3 is positive in infiltrating reactive T cells; (F) CD5, in contrast, is diffusely positive in tumor cells. Occasional cells with stronger staining correspond to infiltrating reactive T-cells that have a similar distribution as CD3 positive cells; (G) LEF1 is diffusely positive in CLL cells with a nuclear staining pattern; (H) CD23 is diffusely positive in CLL cells and it is stronger in the cells of the proliferation centers; I: The expression of the proliferation antigen KI67 is higher in tumor cells of the proliferation centers than in cells from diffuse areas.

round nuclei with central nucleoli corresponding to prolymphocytes and paraimmunoblasts. These proliferation centers are characteristic of CLL and not present in any other lymphoid neoplasms. A few mitotic figures are usually found in proliferation centers. In some cases, proliferation centers may be large, becoming confluent and occupying an area broader than a 20× field. They may have also a higher number of proliferating cells with a Ki67 index >40% and >2.4 mitosis per proliferation center. These cases have been called "accelerated" or "histologically aggressive CLL" and are associated with unfavorable genetic alterations. These patients usually have clinical manifestations of progressive disease and a clinical outcome that is intermediate between typical CLL and Richter's transformation.

The bone marrow is virtually always infiltrated by the same population of cells with interstitial, nodular and/or diffuse patterns. Proliferation centers are less common than in lymph nodes but may be seen in some cases. In the spleen, tumor cells tend to expand white pulp nodules, but may also infiltrate the red pulp. Proliferation centers may be seen, but are usually less prominent and frequent than in lymph nodes.

Immunophenotype

Flow Cytometry

Immunophenotyping is essential for the diagnosis of CLL. Immunophenotyping usually distinguishes B- from T-cell disorders, establishes the monoclonal nature of the proliferation by showing immunoglobulin light chain restriction and defines the characteristic profile of CLL cells. CLL cells are phenotypically very different from normal mature and precursor B-cells. Typically, their levels of surface immunoglobulin, CD20, CD22, CD79b, CD81, and FMC7 are low or absent compared to normal B-cells. They also co-express CD5, CD43, and ROR1, and overexpress CD23 and CD200 (Fig. 3 and Table 1). The differential antigenic expression between CLL and normal B-cells has allowed the design of flow cytometry tests able to quantify minimal residual disease with a sensitivity ≤0.01%.

Since there is no single marker exclusively expressed on CLL cells, a composite immunophenotype that integrates five markers into a scoring system helps distinguish CLL form other CLPD (Matutes score). In this score, one point is given for each of the following markers: (i) positive CD5 expression, (ii) positive CD23 expression, (iii) weak kappa/lambda chain expression, (iv) negative or weakly positive CD79b expression, and (v) negative FMC7 expression. Patients with CLL usually score of 4 or 5 points, while patients with other lymphoproliferative disorders usually score 0–2 points.

Beyond its diagnostic and therapeutic value, immunophenotypic analysis has been shown to be useful for the estimation of prognosis. Expression of CD38, ZAP70 and CD49d are all predictors for an unfavorable outcome in terms of treatment-free interval and overall survival. Although there is an overlap on the expression of these markers and the IGHV mutational status (see below), some studies have demonstrated that they have independent prognostic value. High sensitive flow cytometry assays, able to detect at least a CLL cell in 10.000 normal cells, are used to assess minimal residual disease in patients receiving intensive therapy and its presence is associated with a worse outcome.

Immunohistochemistry

Immunophenotype may be studied in tissues using immunohistochemical methods (Fig. 2). Tumor cells are diffusely positive for the mature B-cell markers CD20 and CD79a with coexpression of CD5 and CD23. CD20 and CD23 expression is stronger in cells

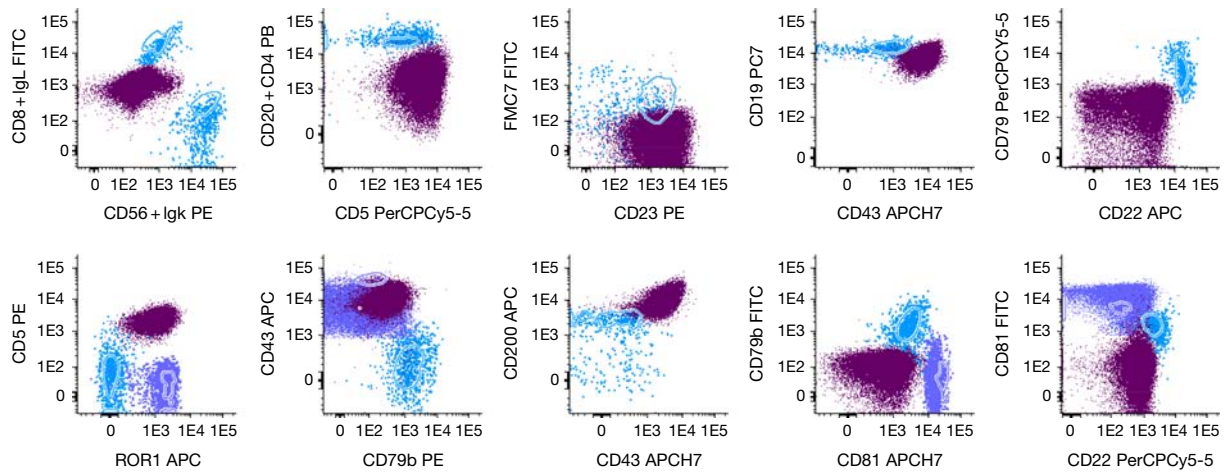

Fig. 3 Phenotypic profile of CLL cells in peripheral blood. Dot plots of B-cells from the peripheral blood and bone marrow of a patient with CLL stained with different combinations of antibodies. In each plot a countour showing the reactivity of the normal mature B-cells (*cyan*) or B-cell precursors (*light violet*) is depicted. CLL are painted in dark magenta, residual normal mature B cells in cyan and normal B-cell precursors in light violet.

Table 1 Immunophenotypic profile of B-cell lymphoproliferative disorders with leukemic expression

CLL, chronic lymphocytic leukemia; *MCL*, mantle-cell lymphoma; *LPL*, lymphoplasmacytic lymphoma; *B-PLL*, B-cell prolymphocytic leukemia; *FL*, follicular lymphoma; *HCL*, hairy-cell leukemia; *MZL*, marginal zone lymphoma.
[a]Indicates antigens included in the immunophenotypic score for CLL.

located in the proliferations centers (Fig. 2). The CD5 staining of neoplastic B-cells is weaker than that of T-cells, and this double intensity is helpful in identifying the tumor subpopulation. Proliferation centers contain numerous T-cells, most of which are $CD4^+$, and in some cases a fine network of dendritic cells. Cells in proliferation centers have increased expression of the proliferation-associated marker Ki67, co-expression of survivin and MUM1/IRF4. These cells may also express MYC protein, NOTCH1, and cyclin D1 in up to about 30% of cases, but they are not associated with the associated genomic alterations. TP53 protein expression may be found in >30% of the cells in CLL with *TP53* mutations. This finding may suggest the presence of mutations, but should not substitute cytogenetic or molecular tests.

Monoclonal B-Cell Lymphocytosis

In the absence of lymphadenopathy, organomegaly, cytopenias and clinical symptoms, the presence of up to 5×10^9/L monoclonal B-lymphocytes in blood is defined as monoclonal B-cell lymphocytosis (MBL). MBL represents a miscellaneous category ranging from patients with "low-count" clonal B-cell populations ($< 0.5 \times 10^9$/L), detected through general population studies, to patients with absolute "high-count" ($\geq 0.5 \times 10^9$/L) lymphocytosis that are referred for consultation. This is important because low count MBL has significant differences from CLL, an extremely limited, if any, chance of progression, and, until new evidence is provided, does not require routine follow-up outside of standard medical care. In contrast, high-count MBL requires routine follow-up, and has very similar biomarkers as early stage CLL. MBL is classified into three categories on the basis of phenotype: (1) CLL-type, when the cells have the typical CLL phenotype; (2) atypical CLL-type, when the clonal cells have strong CD20 and/or surface immunoglobulin, while CD23 may be negative; (3) non–CLL-type, which is considered when clonal cells are CD5 negative and usually have a stronger expression of CD20 and surface immunoglobulins. In atypical-CLL and non-CLL-type MBL, additional cytogenetic and molecular studies are recommended to rule out other leukemic lymphoid neoplasms, particularly mantle cell lymphoma and splenic marginal zone lymphoma.

The prevalence of MBL is closely associated with the sensitivity of the flow cytometry test used. Initial studies using basic B-cell panels revealed that the MBL prevalence was 0.6%, but this figure reached 5–12% in adults over 60 years when a more complex and sensitive flow cytometry test was used. The highest reported prevalence of CLL-like MBL occurs in first-degree relatives of CLL patients. Studies in both the UK and USA showed a high prevalence of CLL-like MBL (13.5–18%) in individuals with a family history of CLL who had normal blood counts. Indeed, a fourfold increased prevalence of MBL was observed in families with a genetic predisposition to CLL compared to the general population.

High-count MBL and early stage CLL seem to share the same immune system perturbation and in particular the increased risk of infections. Conversely, it has been reported that patients with MBL frequently have a personal history of pneumonia, meningitis and even infectious episodes among their siblings or children, suggesting that exposure to infectious agents may trigger immune events leading to MBL. High-count MBL does not always progress to CLL, a phenomenon that occurs in only 1–2% cases per year, but disease progression may occur over time and therefore lifelong monitoring is recommended for these cases, similar to what is current practice for patients with early stage CLL.

Another important question is whether all CLL cases are preceded by MBL or if some CLL cases develop de novo. To address this question, a study evaluated 77,469 healthy adults who were enrolled in a US Cancer Screening Trial. Among 45 participants who

were subsequently diagnosed with CLL during the study and had a prediagnostic peripheral blood sample available, MBL was present in 44 (98%) patients, suggesting that virtually all CLL cases are preceded by MBL.

Although confirmatory studies are necessary, the concept of tissue-based MBL of CLL type is in discussion as there is a subset of cases with lymph node involvement by CLL cells that do not appear to have a significant rate of progression. In one retrospective study, lymph nodes with CLL/SLL in which proliferation centers were not observed and patients in whom lymphadenopathy was <1.5 cm based on computed tomography scans were the best candidates for this new diagnostic category of tissue-based MBL.

Richter's Transformation

Richter's transformation (RT) represents the development of an aggressive lymphoma, most commonly a diffuse large B-cell lymphoma in a patient previously (or simultaneously) diagnosed with CLL. The diagnosis needs to be substantiated through the biopsy of a lymph node or another lymphoid tissue. Rarely, RT presents in peripheral blood or bone marrow smears in the form of large immunoblasts with reticular chromatin, prominent nucleoli and basophilic cytoplasm admixed with small CLL lymphocytes. In this context, immunophenotyping is equally important as these cells tend to have a CLL phenotype with minor deviations. RT is reported to occur in 3–5% of patients with CLL, with a 10-year-cumulative incidence of around 10%. Clinical and laboratory clues that should raise the possibility of RT include sudden worsening of the general status, appearance of B symptoms, enlarging lymph nodes or spleen and dramatically increasing serum lactate dehydrogenase. Risk factors predicting for the development of RT are high CD38 expression, unmutated and stereotyped IGHV genes and presence of *NOTCH1* mutations. In 80% of cases, the transformation occurs in the CLL clone, which usually acquires *TP53*, *CDKN2A*, and *MYC* abnormalities and/or increased number of chromosomal alterations. The prognosis of these patients is poor. In the remaining 20% of patients, the large-cell lymphoma arises in a CLL-unrelated B-cell clone, and these patients have a similar prognosis compared with patients with de novo diffuse large B-cell lymphoma.

There are infrequent cases ($<1\%$) of CLL transformation into Hodgkin's lymphoma. The disease predominates in older men and the most common histological subtype is mixed cellularity. Most cases originate in CLL with mutated IGHV genes and are Epstein-Barr virus (EBV) positive. The diagnosis of Hodgkin's lymphoma requires the presence of diagnostic cells associated with an appropriate microenvirontment of reactive T and inflammatory cells. Some CLL cases may have isolated Reed-Sternberg cells, frequently EBV positive, but without this microenvirotnment. These cases should not be diagnosis as Hodgkin's lymphoma. The presence of EBV-positive Reed-Sternberg cells or Hodgkin's lymphoma may be associated with treatments including fludarabine.

Differential Diagnosis with Other Lymphoproliferative Disorders

Usually, the diagnosis of CLL is straightforward after the morphologic evaluation of peripheral smears and determination of the leukemic phenotype by flow cytometry. However, other chronic lymphoproliferative disorders (CLPD) with leukemic expression can have overlapping morphological and immunophenotypical features and in those cases genetic and molecular tests can be useful in the differential diagnosis.

Morphology

CLL with atypical morphology is characterized by a variable percentage ($>10\%$) of atypical lymphocytes (e.g. prolymphocytes, lymphoplasmacytoid cells, centrocytes, centroblasts or activated lymphocytes) resembling other lymphoid neoplasms such as follicular lymphoma, mantle cell lymphoma, lymphoplasmacytic lymphoma and marginal zone lymphoma. The presence of $>55\%$ prolymphocytes in the blood arbitrarily separates CLL from B-cell prolymphocytic leukemia, a completely separate disorder.

In lymph nodes the presence of proliferation centers is very characteristic of CLL. However, in the few cases in which these structures are absent the differential diagnosis may need to be established with other small B-cell lymphomas. Atypical CLL cells infiltrating lymph nodes may have irregular nuclei that suggest mantle cell lymphoma. Some CLL cases may have residual reactive germinal centers without mantle zones similar to those seen in mantle cell lymphoma. The expression of LEF1 and lack of cyclin D1 would facilitate the CLL diagnosis.

Immunophenotyping

Immunophenotyping of peripheral blood cells is necessary to make the differential diagnosis (**Table 1**). The characteristic phenotype of CLL is shown in **Figs. 2** and **3**. The dim expression of B-cell markers and the coexpression of CD5 are infrequent in other CLPD. The positivity of CD10 helps to distinguish CLL from follicular lymphoma as it is negative in the former and usually positive in the latter. The expression of CD43 and overexpression of CD23 and CD200 may provide further information in the differential diagnosis of CLL and other CLPD. For instance, these three antigens tend to be negative or dimly expressed in MCL, another $CD5^+$ CLPD. CD200 is a glycoprotein belonging to the Ig superfamily and this antigen is being considered as a target for therapy in

$CD200^+$ tumors, including CLL, but also in rheumatoid arthritis and other autoimmune disorders. The differential diagnosis with lymphoplasmacytic lymphoma is sometimes difficult as it could express a CLL-like phenotype. The analysis of the plasma cell compartment and molecular tests may be useful. Finally, the receptor tyrosine-like orphan receptor one (ROR1) is an embryonic glycoprotein highly and specifically expressed on the membrane of malignant, but not normal B-cells. In particular, ROR1 is highly expressed in CLL and hairy-cell leukemia, intermediately expressed in mantle-cell lymphoma and diffuse large B-cell lymphoma and scarcely expressed in follicular lymphoma. Moreover, ROR1 expression in CLL patients is not influenced by therapy. In contrast, normal B-cells have no significant expression of ROR1. Several studies are currently testing the diagnostic and therapeutic use of monoclonal antibodies targeting this molecule.

Cytogenetics and Molecular Biology

In contrast with what is observed in lymphoma, reciprocal balanced chromosomal translocations are rare in CLL. Indeed, fluorescent in-situ hybridization (FISH) tests investigating the presence of t(11;14)(q13;q32), leading to cyclin D1 rearrangement, are useful for distinguishing CLL from mantle-cell lymphoma. Since CLL does not display specific chromosomal aberrations, cytogenetics and FISH are generally performed for prognostic purposes. Chromosomal deletions and amplifications can be detected in up to 90% of patients. The most frequent genetic abnormalities in patients with CLL are del13q14 as isolated abnormality (14–60% of cases), del11q22-q23 (10–32%), trisomy 12 (11–18%), del 17p13 (3–27%) and del6q (2–9%), depending on the time-point at which the study is performed, and whether or not the disease is resistant to therapy. These structural abnormalities will be discussed in detail in the following section.

Similarly, CLL is not characterized by specific gene mutations. *MYD88* L265P mutation is detected in near all lymphoplasmacytic lymphoma and in only 3% of CLL. In the appropriate clinical, morphological and phenotypic context, the determination of *MYD88* L265P mutation is useful in the differential diagnosis of CLL and this type of lymphoma.

Genetics of CLL

Immunogenetics

CLL can be divided into two main subsets with different clinical behavior based on the presence or absence of mutations in the variable region of the immunoglobulin genes, reflecting the stage of normal B-cell differentiation from which they originate. CLL cells expressing unmutated IGHV genes (uCLL) arise from B-cells that have not undergone differentiation in germinal centers. CLL cells with mutated IGHV (mCLL) originate from post-germinal center B-cells. Of note, these IGHV mutations occur in normal B-cells during an immune response to antigens and should not be considered pathological. Patients with uCLL typically have a more aggressive disease than those with mCLL in terms of time to first treatment, overall survival and also progression-free survival after therapy.

Another interesting aspect of CLL immunogenetics is that the repertoire of immunoglobin molecules produced by CLL patients in general is considerably more limited than that of normal controls, reflecting the biased use of certain IGHV genes that have restricted somatic mutation and limited junctional and heavy–light chain combinatorial diversity. Moreover, in one third of patients the tumor expresses immunoglobulin 'stereotypes', which are stretches of the variable region that can also be identified in the immunoglobulins produced by the CLL cells of other patients. This limited immunoglobulin diversity provides compelling evidence that CLL cells are selected based on the binding activity of their surface immunoglobulin, which plays a crucial part in its pathogenesis. There are hundreds of stereotyped subsets, each defined by a unique VH CDR3 motif, and are classified as major (containing 20 or more sequences) or minor subsets. As of today, 19 different major subsets have been identified, representing 41% of al stereotyped cases and 12% of all CLL cases. Examples are subset #1, which is defined by the IGHD6–19 and IGHJ4 genes, subset #2 (IGHV3–21) and subset #4 (IGHV4–34). Interestingly, these subsets have different clinical characteristics. For instance, patients from subset #4 have a very indolent clinical course, even better than that of patients carrying del13q14, while patients from subsets #1 and #2 have a very aggressive disease with a prognosis similar to patients with *TP53* aberrations.

Structural Abnormalities

The importance of structural abnormalities in the outcome of patients with CLL is well established. Initial efforts were made using conventional chromosome banding analysis (CBA), but this technique is able to identify abnormalities in only 50% of patients, probably due to the low mitotic rate of CLL cells. These results were consistently improved with the advent of FISH so that, with a relatively low number of probes, genomic aberrations can be found in 80% of patients. In view of these results, FISH became the gold-standard method for cytogenetic assessment and has remained so to date even though it only evaluates specific genomic regions and not the entire genome. In parallel, the results of CBA could be improved when tumor cells were incubated with novel mitogens (e.g. DSP30 and IL2), which are capable of detect aberrations in 80% of patients, including 20–35% of those who have "normal" FISH results. Moreover, single-nucleotide polymorphism (SNP)-arrays also interrogate the entire genome and could be a suitable alternative to FISH for detecting deletions or amplifications. SNP-arrays do not detect balanced rearrangements (e.g. translocations), but these are rare in CLL. Irrespective of the technique used, the most common structural aberration in patients with CLL are:

- Del13q14, which is present in 50–60% of cases. This deletion, affecting the microRNAs miR15-a and miR16–1, reduces the expression of these genes, which are implicated in the regulation of apoptosis and the cell cycle. In addition, translocations involving 13q14 with a variety of chromosomal partners are also relatively frequent and generally disrupt the miR15-a/miR16–1 locus as well. When del13q14 is the only cytogenetic aberration, it is usually associated with early, non-progressive disease and favorable prognosis.
- Trisomy 12 is generally considered the second most frequent aberration in patients with CLL, occurring in 15–20% of patients, although the gene involved remains unknown. It often appears as a unique cytogenetic alteration but it can also be associated with others. Importantly, both del13q14 and trisomy 12 are nowadays associated with a favorable/intermediate prognosis and considered early CLL-founding events, since they are usually present in most tumor cells. Trisomy 12 is associated with atypical morphology and immunophenotype (e.g. FMC7 positivity, CD23 and CD43 negativity, strong surface immunoglobulin, CD20 and CD22 expression). It is also associated with *NOTCH1* mutations, particularly when trisomy 12 is not part of a complex karyotype.
- Deletions of chromosome 11q22-q23 may imply loss of the *ATM* and/or *BIRC3* function. They are usually identified in younger, male patients with bulky lymphadenopathy and aggressive disease. The disease is usually less responsive to conventional monotherapy and tends to relapse early. It is statistically associated with the presence of *SF3B1* mutations.
- Del17p13 alters the function of the *TP53* gene. Most patients with 17p deletion also have *TP53* mutations on the other allele, but 2–5% of patients present mutations of *TP53* in absence of del17p13. Both del17p13 and *TP53* mutations are associated with progressive disease resistant to conventional therapy, although there is also some degree of heterogeneity. In about a third of cases, *ATM*, *TP53* and *BIRC3* genes are inactivated by either point mutations or mutations plus copy number neutral loss of heterozygosity. Both del11q22-q23 and del17p13 are initially subclonal events that expand over time as a function of their proliferative advantage or environmental pressures (e.g. therapy).
- Novel candidate CLL driver genes recently identified in regions of copy number alterations (CNA) as detected by SNP arrays are *ZNF292* (6q15 loss), *SP140*/*SP110* (2q37 loss), *SMARCC1*/*SETD2* (3p21 loss), *NFKB2* (10q24 loss) and *MGA* (15q15.1 loss).

Since these structural abnormalities may coexist, a hierarchical model was devised in which patients are assigned to one of the following groups (from unfavorable to favorable prognosis): (i) del17p13; (ii) del11q22-q23 in the absence of del17p13; (iii) trisomy 12 in the absence of del17p13 or del11q22-q23; and (iv) isolated del13q14. Patients without any of the previous abnormalities have a prognosis that is intermediate between those with trisomy 12 and those with del13q14. However, this and other models combining chromosomal alterations and mutations need to be confirmed in larger cohorts of patients.

Genomic complexity, either defined as complex karyotype by CBA or increased CNA by SNP arrays has been consistently associated with adverse clinical outcome. Genomic complexity frequently co-exists with *TP53* disruption and modulates the poor prognosis of the latter. More recently, extreme genomic complex alterations called chromothripsis have been identified in 2–3% of patients. In chromothripsis focal regions of the genome undergo extensive chromosome fragmentation and reorganization causing structural genomic complexity which is also associated with *TP53* disruption and poor outcome. It has also been associated with *SETD2* inactivation, a gene that has been shown to cooperate with chromosomal aberrations in other types of leukemia.

Translocations are rare in CLL, but cases of t(14;19)(q32;q13) involving the immunoglobulin heavy chain gene and BCL3 loci, or even t(14;18)(q32;q21), involving the immunoglobulin heavy chain locus and BCL2, have been observed. Of note, the use of novel mitogens has increased the detection of chromosomal abnormalities as detected by conventional cytogenetics.

Mutations in Coding Regions

All cancers arise as a result of somatically acquired changes in the tumor cell genome. This does not mean, however, that all these abnormalities are involved in cancer development and, indeed, it is likely that some make no contribution at all. It is, therefore, of utmost importance to distinguish 'driver' from 'passenger' mutations. Driver mutations are causally implicated in oncogenesis, confer growth advantage and are positively selected by the microenvironment of the tissue in which the cancer arises. Passenger mutations are not selected, do not confer growth advantage and therefore do not contribute to cancer development. Passenger mutations are found within cancer genomes because somatic mutations without functional consequences often occur during cell division by different mechanisms. Thus, any given cell acquiring a driver mutation will already harbor innocuous passenger mutations within its genome, which will be carried along and therefore will be present in all tumor cells. In general, CLL is a very heterogeneous disease from a genomic point of view, in clear contrast to other diseases such as hairy cell leukemia and Waldenström's macroglobulinemia, where *BRAF* and *MYD88* mutations, respectively, are almost diagnostic.

The advent of next generation sequencing (NGS) techniques together with potent bioinformatic pipelines has fuelled cost- and time-effective studies of cancer genomes. The first NGS-based study performed in patients with CLL was the whole genome sequencing (WGS) of four patients including two uCLL and two mCLL cases. This study identified *NOTCH1*, *MYD88*, *XPO1* and *KLHL6* as potential CLL drivers, a hypothesis that was validated by targeted sequencing of additional samples. The results from this study and those from an independent cohort confirmed the role of *NOTCH1* activating mutations as a CLL driver. Moreover, *NOTCH1* mutations are more common in uCLL compared to mCLL, and associated with resistance to rituximab therapy, shorter survival and high risk of transformation to aggressive lymphoma (RT). *MYD88* mutations, on the other hand, had been previously observed in a proportion of cases of diffuse large B-cell lymphoma and virtually all cases of WM. In CLL, *MYD88* mutations are associated with young age, mCLL and a normal life expectancy. Finally, the role of *XPO1* mutations remains unclear due to the

low frequency at which it appears in CLL patients (< 2%), even though selective protein inhibition appears promising for the treatment of CLL and other malignancies.

This initial study has ben followed by whole genome and exome sequencing (WES) of larger cohorts comprising around 1000 patients in total. These studies confirmed the role as CLL drivers of previously described genes (e.g. *TP53* and *ATM*) but also revealed other recurrently mutated genes not previously reported, including *SF3B1*, *CHD2*, *POT1*, *FBXW7*, *DDX3X* and *BIRC3*. In one cohort, thirty-six significantly mutated genes were identified together with 23 additional genes that were either significantly mutated in one subgroup (uCLL or mCLL), had truncating mutations, or were infrequent but had been described in other malignancies. The most recurrently mutated genes were *NOTCH1* (12.6%), *ATM* (11%), *SF3B1* (8.6%), *BIRC3* (8.8%), *CHD2* (6%), *TP53* (5.3%) and *MYD88* (4%). Novel CLL drivers were also identified, including *ZNF292*, *ARID1A*, *ZMYM3* and *PTPN11*, and also less frequent mutations in well-known oncogenes (*KRAS* and *NRAS*), tumor suppressor genes (*CDKN1B* and *CDKN2A*) and transcription factors (*IKZF3*). In the other cohort, 44 recurrently mutated genes and 11 recurrently CNAs were identified. Some examples, not included in the previous list, are: *MGA* (3.2%) and *FUBP1* (1.7%), both of which modulate MYC expression together with *PTPN11*; *MAP2K1* (2%), which belongs to the MAPK-ERK pathway together with *KRAS*, *NRAS* and *BRAF*; and *RPS15* (4.3%), a component of the S40 ribosomal unit. *SF3B1* mutations cause aberrant splicing of specific genes and are more frequent in patients with aggressive disease. Other candidate genes such as *POT1* and *CHD2* have been further validated as bona fide CLL drivers by functional studies. Truncating mutations in *DDX3X* or *BIRC3* have been associated with refractoriness to therapy and adverse outcome.

Globally, these mutations could be grouped into eight main signaling pathways: B-cell receptor signaling (*MYD88*, *IRAK1*, *TLR2*, *IRF4*, *CARD11*), cell cycle regulation (*PTPN11*, *KRAS*, *NRAS*, *BRAF*, *CDKN1B*, *CDKN2A*), apoptosis (*TP53*, *BAX*), DNA damage response (*ATM*, *TP53*, *POT1*, *CHEK2*), chromatin remodeling (*ARID1A*, *SETD1A*, *ZMYM3*, *IKZF3*, *ASXL1*, *CHD2*), NF-kB signaling (*TRAF3*, *BIRC3*, *NFKB2*), NOTCH signaling (*NOTCH1*, *FBXW7*), and RNA metabolism (*MGA*, *ZNF292*, *SF3B1*, *RPS15*, *DDX3X*, *XPO1*, *FUBP1*).

Mutations in Noncoding Regions

The role of non-coding mutations in cancer pathogenesis is starting to emerge after decades of controversy. A recent WGS study of CLL found recurrent mutations in two regions of interest. The first was located in the 3′-UTR of *NOTCH1* in 2% of patients, suggesting that in about 20% of CLL tumors with *NOTCH1* mutations, these are located in non-coding regions. The mutations create new splicing sites and result in the deletion of the protein's PEST domain, thus increasing its stability in a similar way as previously described for the typical p.P2514fs*4 mutation. The second mutational region was found in 8% of patients and is located in a small intergenic region of chromosome 9p13. Several functional studies confirmed that this region contains an active enhancer for *PAX5*, a critical transcription factor for B-cells whose locus is located 330 kilobases away from this region. Remarkably, tumor cells with this mutation had a significantly reduced protein expression of *PAX5* compared to wild-type CLL or even normal B-cells. Subsequent studies revealed that this mutation is also present in other lymphoid malignancies such as diffuse large B-cell lymphoma and follicular lymphoma, raising the possibility that *PAX5* enhancer mutations might constitute driver events contributing to the development of these tumors.

Genomic Evolution

As most tumors, CLL is composed of a variety of subclones with diverse genomic aberrations. These subclones may evolve differently over the years in response to intrinsic (microenvironment) or extrinsic (therapy) pressures in a process that has been termed "clonal evolution". The first evidence of clonal evolution in CLL came from studies using FISH and SNP arrays. However, it was the digital quantification allowed by NGS that confirmed and extended this concept. According to these studies, the so-called "clonal" mutations are found in all or almost all tumor cells and probably constitute founder alterations (e.g. trisomy 12, del13q14, *MYD88* mutations), whereas "subclonal" mutations are probably acquired over the course of the disease (e.g. mutations in *TP53*, *ATM*, *SF3B1*, *NRAS*) and their prevalence correlates with the number of treatments received by the patient. In line with this, direct pairwise relationships have identified that, for instance, del11q22-q23 or trisomy 12 usually precede the acquisition of *ATM* and *NOTCH1* mutations, respectively. Of note, therapy may eradicate dominant clones and select subclones containing driver mutations, which would eventually propel disease progression and treatment refractoriness in most cases. Clonal evolution can be, however, very heterogeneous, including dominant clones that remain stable over time, but also subclones that switch dominance before and after treatment. Of special interest, several studies have shown that small subclones carrying *SF3B1* mutations may evolve without treatment pressure and become the dominant tumor population at progression. In this regard, ultra-deep NGS analysis allows for the detection of very small subclones harboring these mutations (down to 0.3% of all tumor cells), which are invisible by traditional Sanger sequencing and non-detected in previous WGS/WES studies. In one study, patients with small *TP53* mutated subclones only detectable by NGS had the same poor outcome compared to patients with clonal *TP53* mutations detected by Sanger sequencing. The same approach was applied to other recurrently mutated genes (*NOTCH1*, *SF3B1*, *BIRC3*, *POT1*, *XPO1*, etc.), and the same conclusion was reached: subclonal mutations in these genes may have prognostic impact in CLL. In contrast, for some genes the proportion of tumor cells carrying the mutation is prognostically relevant. As such, a number of studies have revealed that high-frequency *NOTCH1* mutations shorten patients' survival, whereas low-frequency mutations do not. Moreover, ultra-deep targeted NGS using a panel of 28 genes plus SNP arrays, all molecular tests performed after one simple DNA extraction, were able to identify

one driver abnormality in 86% of patients with the disease (almost as high as what you would achieve using WES or WGS). All together, these results have led to the progressive incorporation of NGS panels in the prognostic evaluation of patients with CLL.

A great example of how different subclones may evolve depending on therapy comes from the expanding role of ibrutinib in CLL. Ibrutinib is a Bruton tyrosine kinase inhibitor that has been approved for patients with relapsed/refractory CLL and also for those with *TP53* disruption. Shortly after this agent was introduced into the CLL therapeutic armamentarium, several studies revealed that relapse on this agent is predominantly due to acquired mutations in the *BTK* or in the *PLCG2* gene, the enzyme immediately downstream of BTK. Of note, clinical resistance is preceded by a prolonged period of asymptomatic expansion of *BTK*- or *PLCG2*-mutated clones, suggesting that, perhaps, these patients could be switched to alternative agents before the patient develops refractory disease or even Richter's transformation.

Gene Expression (Transcriptome)

More than a decade ago, microarray gene expression profiling (GEP) studies were crucial for the characterization of the different gene signatures observed in patients with CLL. These seminal studies were responsible, among many other things, for the identification of ZAP70 expression as one of the best surrogate markers for IGHV mutational status; or ROR1 as one of the most CLL-specific surface antigens. Subsequent GEP studies were also of utmost importance in the delineation of the cellular origin of CLL and characterization of the different anatomic compartments of the disease. However, the transcriptional landscape of CLL at high resolution has remained elusive until the development of novel technologies for deep RNA sequencing such as RNAseq. Using this technology, global transcriptome signatures were identified, including transcriptional elements such as transposable elements, long non-coding RNAs and pseudogenes, all of which are by definition invisible to GEP microarrays.

Epigenomic Profile

The advent of NGS and genome-wide methylation arrays has recently allowed investigators to explore the whole genome methylation pattern of CLL and normal B-cell subsets. CLL cells harbor a global hypomethylation in gene bodies, which correlates imperfectly with gene expression. Moreover, there is a striking correlation between the methylation pattern of uCLL and normal naïve B cells, and also between mCLL and normal memory B cells. These results supported the idea that naïve B-cells could potentially be the cell of origin of uCLL, whereas mCLL arises from memory B-cells, a conclusion also reached by an independent research group using gene expression profiling and similar genome wide methylation analysis. In addition, the authors could classify CLL patients according to their methylation profile into 3 groups with a distinct clinical outcome: naïve B-cell like, intermediate and memory B-cell like. These 3 groups had different IGHV mutational status, IGHV usage and other molecular characteristics such as *NOTCH1* and *SF3B1* mutations, and their diverse prognostic impact was validated in two independent cohorts.

Integrating Genomic, Epigenomic and Transcriptomic Data

In the last decade, NGS technology has provided scientists with a wealth of information that requires careful interpretation. For instance, WGS revealed that each patient with CLL or MBL tends to bear from 240 to 5416 point base substitutions or small insertions/deletions, yielding an average of 0.87 mutations per megabase. This mutation rate is low compared to melanoma or lung carcinoma, but in agreement with previous estimates of less than one mutation per megabase for leukemias. Moreover, there are marked differences in the genomic and epigenomic pattern according to the tumor subtype (uCLL vs. mCLL), thus reflecting the molecular mechanisms implicated in their respective development. The number of mutations (excluding the immunoglobulin loci) is higher in mCLL than in uCLL even though the number of driver mutations is significantly lower in the former compared with the latter. In other words, mCLL accumulates a significantly higher proportion of passenger mutations, and not necessarily driver mutations, as they pass through the germinal centre. Indeed, the proportion of mCLL cases with at least one driver mutation identified is 83% compared to 96% for uCLL cases. Equally, CLL and MBL patients have a comparable number of mutations, but a significantly different number of driver mutations, which is consistent with the notion that progression from MBL to CLL is generally determined by the increasing accumulation of driver alterations.

On the other hand, NGS and SNP arrays have identified a variety of CLL drivers associated with adverse prognosis. Interestingly, apart from having specific driver genes mutated, what confers a particularly dismal prognosis to patients is their accumulation, so that an increasing number of driver alterations correlates with a progressively shorter time to first treatment and overall survival. Moreover, epigenomics and genomics are clearly linked in CLL. The three epigenetic subgroups defined according to the methylome appear to have a distinct genomic profile as well. Patients from the naïve B-cell like subgroup generally had a higher tumor burden at diagnosis, as measured by beta$_2$-microglobulin, and almost exclusively unmutated *IGHV* genes, with preferential use of the VH1–69 gene. Phenotypic markers linked with adverse outcome, such as high CD38, ZAP70 or CD49d expression were more frequent in this subgroup, and this also applies to some genomic aberrations such as trisomy 12, del11q22–23 and *NOTCH1* and *ATM* mutations. In contrast, patients included in the memory B-cell like subgroup were portrayed as bearing mutated *IGHV* genes in almost all cases (frequently the VH4–34 gene) together with the absence of poor prognostic markers. Interestingly, though, patients categorized as 'intermediate', also have specific genomic aberrations. These patients, apart from having an intermediate outcome, bear unmutated *IGHV* genes in 22% of cases and, when they are mutated, the mutation rate is low (median 4%) compared to the memory B-cell like subgroup (median 7%). These tumors preferentially use the IGHV1–18, IGHV3–21 and IGHV3–23 genes and the incidence of

SF3B1 and *MYD88* mutations is remarkably high compared to the naïve B-cell like or memory B-cell like subgroups, thus confirming that this subset of patients deserves being separated from the other two subsets.

Applying this Knowledge into Current and Future Medical Practice

Since a good proportion of patients with CLL have a normal life expectancy, and clinical trials have not shown to date any advantage for initiating treatment in asymptomatic patients, the gold-standard of care for the majority of patients at diagnosis is careful observation without therapy. Once the disease becomes symptomatic, patients are usually treated with DNA-damaging agents such as fludarabine, cyclophosphamide or chlorambucil in combination with monoclonal antibodies (i.e. chemoimmunotherapy). More recently, BCR inhibitors such as ibrutinib or idelalisib, or BCL2 antagonists such as venetoclax, have been added to the treatment armamentarium after promising results obtained in clinical trials. Despite these advances, CLL remains incurable with current therapeutic options and new agents are desperately needed for patients with high-risk disease.

New genomic developments could improve patient outcome in two ways: (1) allowing for a more precise prognostic estimation and, (2) identifying novel therapeutic targets. The first aspect has already been put into practice in a variety of publications evaluating the prognostic value of these new driver genes in combination with classical markers, and also as predictors of response to therapy. Examples of these are:

- Patients with *TP53* abnormalities are unlikely to respond to conventional chemotherapeutic agents and clearly benefit from the use of ibrutinib or idelalisib. Indeed, both agents have been approved by the European Medicines Agency for patients with CLL and *TP53* disruption (del17p13 or TP53 mutations).
- Patients with *NOTCH1* mutations do not benefit from the addition of rituximab to the FC (fludarabine plus cyclophosphamide) backbone, which still remains the gold standard frontline therapy for younger and fitter patients.
- Patients harboring *SF3B1* and *NOTCH1* mutations have very short progression-free survival after chemoimmunotherapy (i.e. rituximab, fludarabine and cyclophosphamide), probably suggesting that they should be considered for inclusion into appropriate clinical trials whenever possible.
- Both complex karyotype and del17p13 are associated with disease progression on ibrutinib, suggesting that markers that predict poor prognosis with standard therapies also confer risk with novel therapies, albeit a delayed risk. Moreover, as previously mentioned, disease progression on ibrutinib is very frequently preceded by the emergence of *BTK*- or *PLCG2*-mutated clones.
- Patients with mCLL devoid of *TP53* abnormalities or del11q22–23 obtain very good responses and a very prolonged progression-free survival with conventional chemoimmunotherapy (i.e. fludarabine, cyclophosphamide and rituximab).

The second important message from NGS studies is that the prognostic value of these aberrations is not only evident when they are detectable using conventional Sanger sequencing, but also when they are only present in very small subclones, which could change the way we approach molecular studies in our daily practice. The uncovering of intra-tumor heterogeneity and the description of the Darwinian process of clonal evolution leading to the expansion of resistant subclones upon therapy, initially proposed by Nowell in 1976, could change the way we approach CLL therapy. Indeed, half of all driver mutations are subclonal, and the clone composition remains stable over time for most untreated patients, probably owing to the slow growing capacity of CLL cells. In contrast, however, most patients requiring therapy experience a clonal evolution characterized by the expansion of highly fit clones and, perhaps, conventional therapy should be combined with agents targeting the subclonal driver(s) that could potentially expand upon disease relapse. In this regard, genomic studies have identified a number of pathways that could be potential targets for therapeutic intervention:

- B-cell receptor (BCR) signaling: The importance of BCR signaling in CLL biology is well established since all B-cells require these signals for their survival and proliferation. As such, pharmacological inhibition of several proteins downstream the BCR (Syk, BTK, PI3K) is remarkably effective in this disease. Some of these genes (i.e. BTK and PLCG2) may acquire mutations upon BTK inhibition. Moreover, point mutations affecting key molecules belonging to this and other tightly related pathways (e.g. Toll-like receptors) have also been identified (*MYD88*, *IRAK1*, *TLR2*, *IRF4*, *CARD11*). As already stated, the BTK inhibitor ibrutinib and the PI3K inhibitor idelalisib have approved for therapy of patients with CLL.
- Cell cycle regulation: CLL cells overexpress a variety of cyclins and cyclin-dependent kinases, mostly through BCR activation, but also through point mutations in cyclin-dependent kinase inhibitors (*CDKN1B*, *CDKN2A*) and other similar molecules (*PTPN11*). Pharmacological inhibition of cyclin-dependent kinases has been tested in CLL with mixed results, mostly due to safety concerns (not lack of efficacy), but novel oral inhibitors (e.g. palbociclib) have been approved in solid tumors and hold promise for CLL. Furthermore, the MAPK/ERK pathway is disrupted in a proportion of patients with CLL, with mutations identified in *KRAS*, *NRAS*, or *BRAF*. Interestingly, specific inhibitors of *BRAF* or *MEK* have been already approved for a number of solid tumors and could be of interest. Also, multikinase inhibitors of the MAPK/ERK pathway, such as sorafenib, have showned a remarkable anti-CLL activity in vitro.
- Apoptosis: As in most malignancies, CLL cells try to evade apoptosis either by disrupting DNA damage response (mutations in *ATM*, *TP53*, *POT1*, or *CHEK2*), disrupting pro-apoptotic molecules (mutations in *BAX*) or overexpressing anti-apoptotic molecules (BCL2 or MCL1). Over the past years, several BCL2 inhibitors have been developed and one of them, venetoclax, has remarkable efficacy in CLL, including patients with *TP53* and *ATM* disruption and has been already approved by the US Food and Drug Administration for the treatment of CLL.

- NOTCH signaling: This pathway is involved in cell-fate decisions during development through its nuclear translocation and transcription of target genes including *HES1* and *MYC*. In CLL, NOTCH1 is constitutively expressed thereby promoting apoptosis evasion and cell survival. In some patients, this is due to *NOTCH1* mutations which stabilize the protein. Some agents, called gamma-secretase inhibitors, are able to induce apoptosis in vitro and inhibit the constitutive Notch activation that is characteristic of *NOTCH1*-mutated CLL cells. Moreover, MYC itself could be a potential target thanks to the novel Bromodomain and Extra-Terminal motif (BET) protein inhibitors, which are currently being investigated in many different lymphoid malignancies.
- RNA metabolism: The identification of mutations in the spliceosome-RNA processing machinery (*SF3B1*, *RPS15*, *DDX3X*) has led to the development of spliceosome modulators. These agents induce selective cytotoxicity of CLL cells in vitro when compared with normal lymphocytes or cells from other B-cell malignancies.
- NF-kB signaling: The NF-kB signaling pathway is an important therapeutic target since it is constitutively activated in CLL through the canonical and alternative (non-canonical) pathways. In some patients this is due to point mutations (*TRAF3*, *BIRC3*, *NFKBIE*) or structural abnormalities (*NFKB2*), and pharmacological blockade of this pathway (e.g. using proteasome inhibitors or direct IKK inhibitors) leads to anti-CLL activity in vitro. Moreover, BET inhibitors block downstream oncogenic NF-kB-driven transcriptional programs in in vitro and in vivo lymphoma models. Of note, TRAF3 serves as a negative regulator of the non-canonical NF-kB signaling pathway and targets NIK for constant ubiquitination and degradation. As a result, *TRAF3*-mutated tumors result in non-canonical NF-kB activation through NIK overexpression and, indeed, NIK has emerged as a very attractive target for therapy.

Conclusions

CLL is the most common leukemia in adults in the developed world. The diagnosis of CLL requires the phenotypic analysis of tumor cells. Small lymphocytic lymphoma is the same disease with tissue involvement and low tumor cell counts in peripheral blood. Morphology and immunophenotype are the initial, and usually sufficient, diagnostic investigations. In cases with morphological atypical features, additional tests such as molecular genetics and/or histology are required to confirm the diagnosis. Some other markers, such as CD38 and ZAP70 expression, are also useful for prognostic purposes. A monoclonal population immunophenotypically identical to that found in CLL or other CLPD can be detected in up to 3–10% of healthy people. However, only those with 'high-count' MBL behave as early stage CLL and need to be clinically followed, while avoiding cumbersome and anxiety-triggering medical examinations in those with minute ('low-count') monoclonal populations.

Regarding the genetics of the disease, several research groups have discovered significant prognostic associations coupled with new driver genes and signaling pathways whose role in cancer was previously unknown or poorly understood. Massive scale epigenomics and transcriptomics have supplied the foundations for the cellular origin of the disease, and recent studies have uncovered non-coding mutations as drivers for the disease. We are now in a position to compose a fully integrated model of biological factors that could be assimilated into daily practice, even though the list of genes that should be evaluated remains undefined. Moreover, some drivers could be targeted pharmacologically, even when present at subclonal level, thus avoiding clonal selection and disease refractoriness. This outburst of genomic knowledge is just starting to expand into the clinic, but in the coming years, as our understanding broadens and ongoing technological innovation propels new achievements, we will certainly learn how to apply it in our daily practice.

Definition and Classification

Chronic myelogenous leukemia (CML), *BCR-ABL* positive (ICD-O code: 9875/3) is a myeloproliferative neoplasm that originates from an abnormal pluripotent bone marrow stem cell and is consistently associated with the *t(9;22)(q34.1;q11.2)* reciprocal chromosomal translocation which generates the *BCR-ABL1* fusion gene located on the so called Philadelphia (Ph) chromosome. The *BCR-ABL1* is found in all myeloid lineages as well as in some lymphoid cells and endothelial cells.

CML, *BCR-ABL* positive is also called CML, Philadelphia chromosome positive; CML, *t(9;22)(q34;q11)*; chronic granulocytic leukemia, Philadelphia chromosome positive; chronic granulocytic leukemia, *t(9;22)(q34;q11)*; chronic granulocytic leukemia, *BCR/ABL*; and chronic myeloid leukemia.

Epidemiology and Risk Factors

Burden

CML accounts for 15%–20% of adult leukemias. It affects 1–2 individuals per 100,000 annually, with a slight male predominance. The incidence increases with age: the disease is rare in children (<0.1 case per 100,000 population) and is most frequent in the elderly (over 2.5 cases per 100,000). No significant geographical variations in the CML incidence have been reported, however patients in areas of lower socioeconomic status tend to be younger at disease onset.

CML which has reached the blast phase used to be associated with a dismal outcome. However, with the introduction of targeted therapies and more accurate monitoring methods, the 10-year survival rates for CML patients have risen to approximately 80%–90%.

Etiology and Risk Factors

The etiology of CML is largely unknown. Except for acute radiation exposure (such as in atomic bomb survivors), no environmental or lifestyle factors have been identified. There seem to be no familial predisposition, either.

Presentation and Diagnosis

The natural clinical course of untreated CML consists of two or three phases: chronic phase (CP) and blast phase (BP; also called blast crisis) which are usually—but not always—separated by accelerated phase (AP; sometimes also called acute phase because of its resemblance to acute leukemia).

Most patients are diagnosed in CP which usually has an insidious onset. Nearly 50% of newly diagnosed CP-CML cases are asymptomatic and are discovered incidentally with abnormally high white blood cell (WBC) counts at routine blood testing and/or with splenomegaly at physical examination. Common findings at presentation are nonspecific fatigue, malaise, night sweats, and weight loss, and they may occur long after the disease onset. Loss of energy and reduced exercise tolerance may appear during CP after several months. Many patients have symptoms related to enlargement of the spleen, with about half of the patients presenting with palpable splenomegaly. The enlarged spleen may encroach on the stomach and cause early satiety and decreased food intake leading to weight loss. Spleen infarction may manifest as "gripping" pain in the left upper abdominal quadrant. Splenomegaly may also be associated with a hypermetabolic state manifesting as low-grade fevers, excessive sweating, and chronic fatigue. The spleen size usually correlates with the peripheral blood granulocyte counts (the largest spleen in patients with the highest WBC counts). Hepatomegaly, usually asymptomatic, may also occur but it is less common. It usually results from the extramedullary hematopoiesis occurring in the spleen. Visual changes, seizures, cerebral or myocardial infarctions, and priapism may occur in patients with extremely high WBC counts (over 300,000 cells/μL) as manifestations of leukostasis (abnormal WBC clumping) and hyperviscosity. The retina may show papilledema, venous obstruction, and hemorrhages on funduscopy.

Untreated CP-CML inevitably progresses to blast crisis (via AP or without it) within 3–5 years. About 5% of patients are diagnosed in AP or BP (without a recognized CP). Bleeding, petechiae, and ecchymoses are frequently prominent symptoms of AP-CML. Fever is usually associated with infections. Bone pain and fever, very large spleen, and/or increased bone marrow fibrosis are common harbingers of the blast phase. Typical symptoms of the blast crisis are due to increasing anemia, thrombocytopenia, basophilia, a rapidly enlarging spleen, and failure of the usual medications to control leukocytosis and splenomegaly.

The initial workup consists of a physical examination, including palpation of the spleen and the liver, and a complete blood count (CBC) with a differential and a chemistry profile. Patients should also be tested for infections with hepatitis viruses.

CML can usually be diagnosed based on the peripheral blood findings combined with the detection of the Philadelphia chromosome and/or the BCR/ABL1 fusion protein and transcript using cytogenetic and molecular techniques (fluorescence in situ hybridization (FISH) with dual *BCR/ABL1* probes and reverse transcriptase polymerase chain reaction (RT-PCR), respectively). Bone marrow aspiration is necessary to obtain sufficient material for karyotyping and morphological evaluation which allow to determine the CML phase. For patients diagnosed with advanced-phase disease (AP or BP), flow cytometry to determine the cell lineage and mutational analyses are recommended. In a majority of patients, bone marrow biopsy is not necessary for diagnosis. However, it remains an important alternative in case of atypical peripheral blood findings or when a cellular aspirate cannot be obtained.

The major initial finding at the blood test is neutrophilic leukocytosis, with neutrophil left shift (increased proportion of immature neutrophils) and WBC counts commonly exceeding 30,000 cells/μL at diagnosis. Mild eosinophilia and basophilia are often present already in CP and increase with the disease progression to advanced phases. Increased platelet levels (thrombocytosis) are common at presentation, with the counts that may exceed 1,000,000 cells/μL. Thrombocytopenia is uncommon in CP. Other laboratory abnormalities include hyperuricemia which reflects high bone marrow cell turnover, as well as markedly elevated serum vitamin B-12–binding protein correlated with the degree of leukocytosis (this protein is synthesized by granulocytes).

At cytogenetic and molecular analyses, the *BCR-ABL1* fusion is found in all myeloid lineages as well as in some lymphoid cells and endothelial cells, in all CML phases. The presence of additional chromosomal abnormalities in Ph-positive cells ("clonal evolution") is associated with the disease progression to AP and/or BP. Of note, very low levels of *BCR-ABL1* transcripts are detected in approximately 30% of healthy individuals, with an incidence which increases with age. The risk of developing CML is extremely low in these individuals and they do not require treatment.

Disease progression manifests with a declining performance status, constitutional signs such as fever and weight loss, recurrent bone pain, and symptoms related to increasing anemia, thrombocytopenia, basophilia, increasing WBC counts with increasing proportion of blasts, and enlarging spleen. The disease status should be reevaluated in this setting.

The clinical and morphological boundaries between different CML phases are not very sharp, and the diagnostic criteria may vary between different centers. In particular, some investigators insist that a cut-off of 30% (and not 20% as defined by the World Health Organization, WHO) sets the boundary of the blast crisis, and this threshold has been used in many clinical trials, including those which led to the approval of tyrosine kinase inhibitor (TKI) therapy for treatment of CML patients. However, using either of the two cut-offs does not seem to have any prognostic significance for BP-CML patients. The diagnostic criteria for the three CML phases defined by WHO are summarized in **Table 1**. As the established hematological/cytogenetic criteria, in particular in AP-CML patients, are not sufficient for accurate prognostication, provisional criteria of response to therapy (mainly treatment with TKIs) have been proposed. They seem to improve the prognostic utility of the established hematological/cytogenetic criteria but this remains to be clinically validated.

Table 1 Diagnostic criteria for different chronic myelogenous leukemia (CML) phases as defined by the World Health Organization (WHO)

Chronic phase (CP) CML	*Accelerated phase (AP) CML*	*Blast phase (BP) CML*
	Established hematological/cytogenetic criteria	
The presence of the Philadelphia chromosome and/or the BCR/ABL1 fusion protein or transcript confirmed by cytogenetic and molecular techniques		
<10% of blasts in the bone marrow or peripheral blood WBC	10% < blasts <20% in the bone marrow or peripheral blood WBC; Persistent thrombocytopenia (platelets $<100 \times 10^9$/L) or thrombocytosis (platelets $>1000 \times 10^9$/L) unresponsive to therapy; Increasing WBC count and spleen size unresponsive to therapy; Cytogenetic evidence of clonal evolution (the presence of additional chromosomal aberration in Ph-positive cells); 20% or more basophils in the peripheral blood* Large clusters or sheets of small abnormal megakaryocytes associated with marked reticulin or collagen fibrosis in biopsy specimens presumptive of AP diagnosis; usually associated with one of the above-listed criteria	At least 20% of blasts in the bone marrow or peripheral blood WBC; Extramedullary blast proliferation (e.g., osteolytic bone lesions or lymphadenopathy); Large foci or clusters of blasts in bone marrow biopsy
	Provisional response-to-TKI therapy criteria	
	Hematological resistance (i.e. failure to achieve a complete hematological response) to the first TKI treatment Any grade of resistance to two sequential TKI treatments Occurrence of two or more new mutations in the *BCR-ABL1* fusion gene during TKI therapy	

TKI, tyrosine kinase inhibitor; *WBC*, white blood cells.
*The presence of any of these criteria confirms the diagnosis.

Pathology and Genetics

Pathology

CML is characterized by the clonal expansion of terminally differentiated myeloid cells originating from a leukemic stem cell. The peripheral blood smear in CML patients shows a typical leukoerythroblastic blood picture, with circulating immature cells from the bone marrow. Alkaline phosphatase (ALP) in granulocytes is virtually absent and stains very low or negative by immunohistochemistry.

In chronic phase CML, bone marrow specimens show hypercellularity with marked granulocytic proliferation and a maturation pattern similar to that found in the normal blood, including expansion at the myelocyte stage. There is no significant dysplasia. Blasts usually account for <5% of the bone marrow cells (diagnostic criterion for the CP-CML: < 10% blasts). A substantially decreased proportion of erythroid precursors is usually observed. Up to 50% of cases show moderate to marked megakaryocytic proliferation, with normal or slightly decreased megakaryocyte counts. Megakaryocytes are smaller than normal and have hyposegmented nuclei ("dwarf megakaryocytes") but they are not true micromegakaryocytes like those observed in myelodysplastic syndromes. Eosinophil and basophil counts are usually elevated, and pseudo-Gaucher cells are common. This is often observed in bone marrow biopsy sections as a thicker layer of immature granulocytes around the bone trabeculae (5–10 cells compared to 2–3 cells in samples from healthy individuals). In 30%–40% of cases, increased megakaryocyte counts correlate with moderate to marked reticulin fibrosis which may also be associated with splenomegaly. Infiltration of the red pulp cords in the spleen by granulocytes, both mature and immature, leads to the spleen enlargement. A similar infiltrate can be observed in hepatic sinuses and portal areas. In most cases, blasts have a myeloid phenotype. Lymphoid blasts may also be seen but some data suggest that the presence of any lymphoblasts, whether in CP or AP, may predict an imminent lymphoblastic BP rather than a myeloid blast crisis.

The expression of CD7 on CD34-positive cells in CP-CML has been suggested to be an adverse prognostic factor, whereas the presence of a normal CD34-positive stem cell population which do not express abnormal markers (such as CD7, CD56, or CD11b) predicts a better response to TKI treatment.

The disease progression is associated with increasing numbers of circulating blasts, increasing numbers of abnormal megakaryocytes, and the occurrence of dysplasia. In accelerated phase, dysplastic changes may be observed in any of the myeloid lineages. Clusters of small megakaryocytes (including micromegakaryocytes similar to those observed in myelodysplastic syndromes) may appear and may be associated with significant reticulin and/or collagen fibrosis which is best visible in biopsy sections. The proportion of blasts is increased (diagnostic AP-CML criterion: 10% < blasts <20%), which can be highlighted by immunohistochemical staining for CD34.

In a majority of BP-CML cases (up to 70%), the blast lineage is myeloid, with blasts displaying a phenotype which is indistinguishable from that of acute myeloid leukemia. The lineage may include neutrophilic, monocytic, megakaryocytic, basophilic, eosinophilic, and/or erythroid blasts in any combination. Most of the remaining cases of blast crisis (20%–30%) are lymphoid, in which the blasts (lymphoblasts) usually have immunophenotypic characteristics of pre-B cells or have biphenotypic features (myeloid and B lymphoid). Megakaryocytic or undifferentiated blast crises may occur in up to 10% of patients. Sequential lymphoblastic and myeloblastic crises have also been reported. The blast lineage may be morphologically obvious. However, the blasts are often primitive and antigens of more than one lineage are frequently expressed. Therefore, cytochemical analysis and immunophenotyping (preferably using flow cytometry) of the blasts are recommended. Extramedullary blast proliferations may be of myeloid, lymphoid, or mixed phenotype. Sheets of blasts occupying focal but substantial areas of the bone marrow (e.g., an entire intertrabecular space) visible in marrow biopsy specimens strongly suggest BP diagnosis even if the rest of the bone marrow suggests CP.

Genetics

The defining genetic characteristics of CML is the *t(9;22)(q34.1;q11.2)* reciprocal chromosomal translocation. This translocation fuses sequences of the breakpoint cluster region (*BCR*) gene on chromosome 22 with regions of the Abelson murine leukemia (*ABL1*) gene on chromosome 9, generating the Philadelphia chromosome *der(22)t(9,22)* harboring the fused *BCR-ABL1* oncogene. About 5%–10% of patients have variant translocations which involve another (third) chromosome or even two extra chromosomes in addition to chromosomes 9 and 22, or a cryptic translocation of chromosomes 9q34.1 and 22q11.2. The *BCR-ABL1* fusion gene is present in all cases and can be detected by FISH and/or RT-PCR. However, the cryptic fusion is not detectable by routine cytogenetic analysis.

Depending on the site of the chromosome 22 breakpoint and the size of the resulting fused gene, different fusion proteins are produced, impacting the phenotype of the disease. In a majority of CML patients, the breakpoint is in the major BCR (M-BCR) region, spanning exons 12–16 and resulting in the production of an abnormal p210 BCR-ABL1 fusion protein with an increased tyrosine kinase activity. In rare cases, the breakpoint occurs in the μ-BCR region (exons 17–20), generating a gene encoding for a larger p230 fusion protein. Patients with this translocation may show prominent neutrophilic maturation and/or conspicuous thrombocytosis. Breaks in the minor breakpoint region (m-BCR; exons 1–2) resulting in the production of a short p190 protein (frequent in Ph-positive acute lymphocytic leukemia) are very rare in CML and are associated with increased monocyte counts, resembling chronic monomyelocytic leukemia. However, low p190 transcript levels may be detected in up to 90% of CML patients due to alternative *BCR* splicing.

The BCR-ABL1 fusion oncoprotein has an increased tyrosine kinase activity and plays a central role in the CML pathogenesis. It promotes cell growth and replication, and inhibits apoptosis, by constitutively activating targets in several signaling pathways, including the JAK/STAT (cell growth and differentiation), PI3K/Akt (cell metabolism), and the Ras/MEK pathway. This influences leukemogenesis by creating a cytokine-independent cell cycle with aberrant apoptotic signals in response to cytokine withdrawal. The chromosomal translocation leading to the *BCR-ABL1* fusion and the production of a hyperactive tyrosine kinase is believed to be both necessary and sufficient to initiate CP-CML. As leukemic hematopoiesis in CP-CML, with the exception of the very primitive leukemic stem cells, is dependent on the tyrosine kinase activity the disease is easily controllable by tyrosine kinase inhibitors. However, subclones of leukemic progenitor cells resistant to TKIs may emerge with time. These clones usually carry additional point mutations in the *BCR-ABL1* gene which prevent the binding of the TKI to its target by changing the amino acid sequence of the target tyrosine kinase domain. Second- and third-generation TKIs have been developed to overcome this acquired resistance to the initial TKI treatment (see section "**Management and Therapy**"). *BCR-ABL1* copy number gains may also confer resistance to TKIs.

Disease progression from CP to advanced phase (AP or BP) is associated with clonal evolution. Other chromosomal abnormalities (in addition to the Ph-chromosome which persists) appear in approximately 80% of patients entering AP or BP. These may include the so-called major route karyotypic abnormalities: an additional or double Ph-chromosome, isochromosome 17q, and gains (usually trisomies) of chromosomes 8 or 19. The presence of these abnormalities at diagnosis is usually associated with a worse prognosis.

The molecular bases of the transformation are poorly known. AP and BP have similar molecular characteristics, suggesting that the bulk of genetic changes occurs at transition from CP to AP-CML. Mutations in a number of genes encoding epigenetic regulators (e.g. *ASXL1*, *EZH2*, and *TET2*), proteins involved in cytokine signaling (e.g. *JAK2*), transcription factors (e.g. *RUNX1* and *SETBP1*), and those encoding cell-cycle regulators (e.g. *CDKN2A*, *TP53*, and *MYC*) have been reported. However, genome-wide analysis data are missing and the role of these mutations in the transformation is neither elucidated, nor established. Activation of the β-catenin signaling enhancing the self-renewal activity of granulocyte-macrophage progenitor cells has been suggested as one of the key events in the evolution towards blast crisis. Hyperactivation of the hedgehog signaling through SMO overexpression may also play a role.

An important issue in understanding the pathogenesis and clinical course of CML is the persistence of leukemic stem cells (LSCs). These cells are not eliminated by currently available TKI treatments which have a strong antiproliferative effect in LSCs but induce only modest levels of apoptosis. Quiescent LSCs are particularly resistant to TKI-induced apoptosis. Since several studies have shown that TKIs do inhibit kinase activity in LSCs, the resistance of these cells to TKIs seems to be BCR-ABL1-independent. Various intracellular regulatory mechanisms which contribute to CML LSC maintenance despite medication have been proposed. These include in particular the JAK/STAT, NF-kB, and β-catenin signaling pathways as well as the cell-cycle regulators: Myc, p53, and SIRT2. Further studies are needed to understand the comprehensive network of interactions between different molecules and pathways, and potentially refine targeting of future therapies.

Management and Therapy

CML management is a model example of a successful implementation of targeted therapies into clinical practice. With the introduction of tyrosine kinase inhibitors (TKIs) as the mainstay of CML treatment, the prognosis of CML patients has substantially improved, with the survival rates approaching those of the general population. In particular, CP-CML has become relatively easy to control by medication. BP-CML, however, remains to be associated with a poor prognosis.

The response of CML patients to therapy is defined at three levels: hematological, cytogenetic, and molecular level. In other words, CML treatment aims at hematological, cytogenetic, and molecular remission of the disease. The hematological remission is defined as normalization of CBC and physical examination findings (in particular reversing splenomegaly and hepatomegaly if they were present). Cytogenetic remission means no Philadelphia chromosome-positive cells detected by cytogenetic methods, whereas molecular remission is defined as no *BCR-ABL1* fusion transcripts detected by RT-PCR. However, with the increasing sensitivity of the molecular detection methods, the definition of the latter may become somewhat confusing and requires precise definitions of the detection cut-offs. Moreover, as current therapies fail to eliminate clones of leukemic stem cells which give rise to relapse, it has been suggested that obtaining prolonged treatment-free remission rather than complete disease eradication (as measured on a molecular level) should be set as a goal of CML therapy.

Several TKIs are available for the treatment of CML patients. The first TKI which was approved for the primary treatment of CML patients was imatinib mesylate (imatinib; Gleevec®). Imatinib competitively interferes with ATP binding to the kinase domain of the ABL kinase, thus preventing phosphorylation of tyrosine residues on its substrates. Imatinib generics also exist but their efficacy has been questioned.

Second-generation TKIs were initially developed for the treatment of patients resistant to imatinib. These include dasatinib (Sprycel®), nilotinib (Tasigna®), and bosutinib (Bosulif®). Dasatinib and bosutinib inhibit both SRC and ABL kinase activity, whereas nilotinib is an imatinib analogue. All the three agents induce a more rapid and deeper molecular response than imatinib. However, their impact on overall survival rates is only marginally better than that of imatinib and they are associated with more severe toxicities. Dasatinib and nilotinib are approved by the US Food and Drug Administration (FDA) also for the primary treatment of CP-CML patients, while bosutinib is approved for treatment of any phase CML patients who are resistant or intolerant to other TKI therapies, including imatinib.

A third-generation TKI, ponatinib (Iclusig®), was developed to specifically target *BCR-ABL1* with the *T315I* mutation which confers high-level resistance to imatinib and all second-generation TKIs. Surprisingly, it was found to be clinically effective against BCR-ABL1 with any mutation arising during treatment with other TKIs and it induces the highest response rates after failure of any second-generation TKI treatment. However, it is associated with severe toxicities, in particular cardiovascular complications (including fatal myocardial infarctions and heart failure) even in patients without known cardiovascular risk factors, and severe hepatotoxicity.

Acquired resistance to TKIs which develops during treatment, at least in part due to point mutations in the *BCR-ABL1* gene (see section "**Genetics**"), is a recurrent problem in the management of CML patients. CML with the most common mutations which appear under imatinib treatment can be effectively treated by some of the second-generation TKIs. The *V299 L* and *F317I BCR-ABL* mutations confer relative resistance to dasatinib, the *V299 L* mutation to bosutinib, and the *Y253H*, *E255V/K*, and *F359 V/C* mutations make the leukemic cells resistant to nilotinib. The *T315I* mutation confers high resistance to all of the TKIs but the third-generation drug ponatinib.

Management of CP-CML

The choice of the first-line TKI treatment for the CP-CML patients is based on the risk score, patient's age, comorbidities and ability to tolerate therapy which are weighed against the toxicity profile of the potential TKI treatment.

Risk stratification of patients newly diagnosed with CP-CML is usually performed using either the Sokal, or Hasford (Euro) scoring system. The Sokal scoring takes into account patient's age, spleen size, platelet count, and the proportion of blasts in the peripheral blood. The Hasford system additionally includes the eosinophil and basophil counts in the peripheral blood. The European Treatment and Outcome Study (EUTOS) score which takes into account the percentage of basophils and eosinophils in the blood and the spleen size seems to be more accurate. However, its predictive value has not yet been validated in clinical trials and many clinicians prefer to use the other scores, even if they were validated with older treatments (chemotherapy) and not with TKIs.

Intermediate- and high-risk patients have been shown to have higher rates of molecular response and lower risk of disease progression when treated with second-generation TKI therapy. Therefore, dasatinib, nilotinib, or bosutinib (depending on the national clinical guidelines and health policies by country) are the first-degree recommendation in these patients. Imatinib remains an alternative in case of clinically significant intolerance to these treatments. Imatinib is also frequently the frontline treatment of choice for low-risk CML patients, even though in some countries second-generation TKIs are preferred, after a careful consideration of the toxicity profiles. Dasatinib or bosutinib may be preferred in patients with a history of arrhythmias, heart disease, pancreatitis, or hyperglycemia, whereas for patients with a history or lung disease or deemed to be at risk of developing pleural effusions, nilotinib or bosutinib may be the best options.

Cytopenias (anemia, neutropenia, and thrombocytopenia) resulting from hematological toxicity of TKI treatments are managed with transient interruptions of the TKI therapy and dose modifications. These controlled treatment pauses should not be confused with patient-decided nonadherence to therapy which may lead to undesirable clinical outcomes. Patients should be educated that

any treatment interruptions should be done only under strict medical control and that their adherence to therapy is of critical importance. Frequent follow-up visits and monitoring of response to treatment are also helpful to this effect.

Monitoring response to primary TKI treatment is key to planning further therapy. Assessing molecular response using the so-called response milestones quantitatively defined by levels of *BCR-ABL1* transcripts detectable with RT-PCR at defined time points following the treatment is highly recommended. International Scale (IS) has been proposed to standardize molecular monitoring across different laboratories. Patients who do not meet thus defined response milestones following primary therapy, are treated with adequate second-line treatment. Patients with appropriate response to the primary treatment used to be deemed to continue the treatment indefinitely. However, the possibility to stop the primary TKI treatment in a subset of patients achieving deep molecular response has been recently widely debated. Based on results of some clinical studies, the US National Comprehensive Cancer Network (NCCN) expert panel states that TKI discontinuation is feasible, preferably in a clinical trial setting, in some carefully selected patients who achieved deep molecular remission and maintained it for at least 2 years.

Myelosuppressive agents, which used to be the mainstay of treatment to convert CML patients from uncontrolled to normalized presentation, are now used exclusively to reduce WBC counts and in CP-CML patients with hyperleukocytosis and to alleviate acute symptoms of leukostasis, hyperviscosity, and tissue infiltration while waiting for a molecular confirmation of the CML diagnosis and definitive treatment. The most common of the myelosuppressive agents is hydroxyurea, an inhibitor of deoxynucleotide synthesis. WBC counts can also be rapidly and safely lowered by leukapheresis using a cell separator.

Management of Advanced Phase (AP or BP) and Relapsed CML

Advanced phase disease, especially blast crisis, has an adverse prognosis. The prognosis of patients who progressed from CP-CML to advanced-CML while on TKI treatment is particularly poor.

TKI therapy is the recommended first-line treatment for all patients with a de novo diagnosed AP-CML and BP-CML. Imatinib induces favorable hematological and cytogenetic response rates in these patients. Dasatinib, nilotinib, bosutinib, and ponatinib may have an activity in imatinib-resistant CML or in imatinib-intolerant patients. Treatment regimens combining TKI therapy with chemotherapy, such as imatinib with decitabine or cytarabine-based chemotherapy, have been shown to be effective in AP-CML patients by some studies, however the sample sizes were small. Combining imatinib or dasatinib with HyperCVAD regimen (alternated cycles of hyperfractionated cyclophosphamide/vincristine/adriamycin/dexamethasone and high-dose methotrexate/cytarabine) is also effective in patients with lymphoid blast crisis, in particular when followed by allogeneic hematopoietic stem cell transplantation (HSCT).

An alternative for patients with CML resistant to multiple TKIs and for those with the *T315I* mutation is omacetaxine. Being an inhibitor of RNA synthesis, its activity is not affected by mutations in the *BCR-ABL1* gene. Omacetaxine (Synribo®) is approved for treatment of CML patients who have not responded to at least two TKIs. It can also be used as a bridge to HSCT in patients who do not respond to or tolerate any of the TKIs. However, omacetaxine is not equally popular in clinical practice in all Western countries.

Allogeneic HSCT, while no longer used for CP-CML patients, remains the appropriate first-line treatment for the rare patients who present with BP-CML and for those with the *T315I BCR-ABL1* mutation or other mutations in the fused gene which confer resistance to all TKIs, as well as for the extremely rare patients intolerant to all currently available TKIs. It is also often recommended as a second-line treatment in other advanced-phase CML patients.

The prognosis of CML patients who have progressed to advanced-phase disease while on TKI therapy for CP-CML is considerably worse than of those with a de novo advanced-phase CML. Allogeneic HSCT (if possible) and enrolment in a clinical trial are the recommended options for these patients. A treatment with an alternate TKI (a TKI that was not used in previous treatments) or with omacetaxine (if used) is beneficial as a "bridge" to HSCT. TKI in combination with chemotherapy used for acute lymphocytic leukemia or steroids is recommended for patients with BP-CML, whether myeloid or lymphoid, whereas chemotherapy regimens used in acute myeloid leukemia are suitable for CML patients with myeloid blast crisis only. In patients with lymphoid BP, central nervous system involvement may occur. It should be managed according to the standards for acute myeloid or lymphoblastic leukemia. Of note, TKI therapy has not been optimized for patients with central nervous system involvement. Dasatinib may be the best choice as it has been reported to cross the blood-brain barrier.

Donor lymphocyte infusion (DLI) as well as imatinib treatment induce durable molecular response in patients with CML who relapsed following allogenic HSCT. Some studies have suggested that combining these two treatments is even more effective. However, overall, better response rates are obtained in patients who relapsed in chronic phase than in those relapsing in advanced phase. The data on the use of other TKIs for treatment of relapsed CML are still limited. Interferon alfa may be used in combination with TKIs for treatment of refractory cases.

Pediatric CML

CML is rare in children and no specific clinical guidelines exist. Many pediatric oncologists follow the guidelines designed for adults, even though clinical manifestations and host factors in children are different. So far, imatinib and dasatinib are the only TKIs approved for the primary treatment of children with CML by FDA. There is little data on the safety and efficacy of other TKIs in children. The use of risk scores has not been validated in childhood CML patients, either, and their use to guide treatment decisions is not recommended.

Prospective Vision

The key to increasing the proportion of CML patients achieving durable treatment-free remission is understanding and overcoming the resistance of leukemic stem cells to the existing treatments. Several potential molecular targets other than the BCR-ABL1 kinase have been identified, including members of the JAK/STAT and p53 pathways, Wnt signaling molecules as well as epigenetic modulators. Among those, the efficacy of inhibiting the JAK2 kinase, a downstream target of the BCR-ABL1 kinase, with ruxolitinib is currently under investigation in clinical trials. Targeting inflammatory signaling also seems a promising direction. Identification, isolation and precise molecular characterization of leukemic stem cells that persist after primary TKI treatment using single-cell technologies, so far remaining a challenge, would help to identify other potential targets.

Definitions

Carcinoma of the colon and rectum (colorectal carcinoma, CRC) is a malignant neoplasm which originates in the large bowel and invades through the muscular mucosae into the submucosa. Over 90% of CRCs are adenocarcinomas.

Presentation and Diagnosis

Most CRCs are located in the sigmoid colon and rectum but a proportion of CRCs located more proximally increases with age. Two-thirds of colorectal cancers occur in the left colon and one-third in the right colon, although women more often develop right-sided tumors. About 20% of CRCs develop in the rectum.

Patients commonly present with hematochezia and anemia due to bleeding from the tumor. Right-sided colonic lesions are often asymptomatic. Most typical symptoms—if they appear—include dull and ill-defined abdominal pain, bleeding, and symptomatic anemia causing weakness, fatigue, and weight loss. Left-sided lesions commonly result in changes in bowel habits, bleeding,

gas pain, decrease in stool caliber, constipation, and colonic obstruction. In some cases, only distant metastases, in particular those to the liver, cause the initial symptoms in which case patients present with some liver dysfunction.

Colonoscopy is currently the gold standard to detect colonic polyps and CRC. It allows to observe the mucosal surface of the entire large bowel and has a high sensitivity for detecting cancer and all classes of precancerous lesions. It also has an advantage of a single-session diagnosis and treatment, and—together with the fecal immunochemical test (FIT)—is the cornerstore of screening for CRC. Detection of non-protruding lesions can be improved by using contrast dyes (chromoendoscopy) or confocal endoscopy. In addition, other electronic image enhancement techniques, such as narrow band imaging (NBI), autofluorescence imaging (AFI), I-scan, and flexible spectral imaging color enhancement (FICE), have been shown to improve the accuracy of polyp characterization but their added value to the detection of polyps is still being evaluated.

Capsule colonoscopy has been approved by the US Food and Drug Administration (FDA) for imaging the proximal colon in patients with previous incomplete colonoscopies and more recently for patients who need colorectal imaging but who are not candidates for colonoscopy or sedation. As it is non-invasive, it allows to avoid the risks associated with colonoscopy, such as perforation or bleeding. However, the bowel preparation is more extensive than for colonoscopy.

Computed tomography (CT) colonography (CTC; sometimes also called virtual colonoscopy) has replaced double-contrast barium enema for colorectal imaging. It has been shown to achieve high levels of colonic polyp detection. However, it has limitations in detection of flat and serrated lesions, and it is less sensitive than colonoscopy for detecting polyps smaller than 1 cm. Moreover, associated radiation exposure is usually viewed as a disadvantage of this technique.

Biopsies of all suspicious lesions should be taken for pathological evaluation. This can be done during colonoscopy or using CT-guided fine-needle aspiration (FNA).

Cross-sectional CT imaging, magnetic resonance imaging (MRI), and transrectal ultrasonography may be used to assess the depth of tumor invasion and the possibility of regional and distant metastases. Chest, abdomen, and pelvis CT or MRI with contrast may identify small lung, liver, or intraperitoneal metastases. Positron emission tomography (PET) is also used to determine whether an anatomic lesion of unclear origin is malignant and to assess the spread of the disease.

Management and Therapy

The only universally accepted potentially curative treatment for colorectal cancer is surgery. It frequently follows an endoscopic removal (snare polypectomy, endoscopic mucosal resection, or submucosal dissection) and a pathological review of a primary malignant colonic polyp. In patients with invasive cancer in a pedunculated or sessile polyp (adenoma), no additional surgery is required provided that the polyp has been completely resected and has favorable histological features (low grade, no angiolymphatic invasion and negative margins). However, colectomy should be considered in patients with a completely resected sessile polyp with unfavorable histological features even if the resection margins are clear.

Patients presenting with resectable invasive CRC require a complete staging workup, with the pathological tissue review, total colonoscopy, complete blood counts and chemistry profile, carcinoembryonic antigen (CEA) levels, and baseline CT scans of the chest, abdomen, and pelvis. Elevated preoperative CEA levels indicate that CEA may be used as a prognostic marker for post-operative surveillance as metastases of primary tumors associated with elevated CEA are also likely to give elevated CEA measurements. However, variable specificity and sensitivity of this approach remains a major limitation. Endoscopic ultrasound (EUS) significantly improves the preoperative assessment of the depth of invasion of large bowel tumors, and especially rectal tumors. A combination of EUS to assess rectal tumor extent and digital rectal examination (DRE) to determine mobility should enable precise planning of surgical treatment and identifying patients who may benefit from preoperative chemoradiation. Transrectal biopsy of perirectal lymph nodes can often be taken with EUS guidance. MRI with concomitant administration of rectal contrast might be superior to EUS in the identification of perirectal lymph node metastases.

Curative surgery should excise the tumor with wide margins and maximize regional lymphadenectomy so that at least 12 lymph nodes are available for pathological evaluation. For resectable non-metastatic colon cancer, the preferred surgical procedure is colectomy with *en bloc* removal of regional lymph nodes. The extent of colectomy is defined by the tumor location. It should be such that both the portion of the bowel and the arterial arcade containing regional lymph nodes be resected. Other nodes should also be removed or at least biopsied. In order to be curative, the resection should be complete, including removal of all involved lymph nodes. Obstructing tumors in the right colon are usually managed by primary resection and primary anastomosis. Obstructing tumors in the left colon may be managed with initial decompression (proximal colostomy) or stent insertion followed by resection of the tumor and deferred closure of the colostomy. Recent trends, however, favor extending resection and primary anastomosis to include obstructing tumors in the transverse, descending, and even sigmoid colon.

For rectal tumors, several surgical approaches are possible. Transanal excision is sufficient for selected small low-grade tumors without lymph node involvement. Transanal endoscopic microsurgery (TEM) may facilitate tumor excision through the anus for lesions that can be properly identified in the rectum and some data suggest that it may be associated with better outcomes than transanal excision. In both cases, appropriate tumor margins should also be removed. In all other cases, more invasive transabdominal resection is performed. Depending on the tumor localization, this may be low anterior resection (LAR), proctectomy with total excision of the mesorectum (TME) and coloanal anastomosis, or abdominoperineal resection (APR). TME involves an en bloc removal of the mesorectum, including associated vascular and lymphatic structures, fatty tissue, and mesorectal fascia with the tumor.

Minimally invasive approaches may be alternatives to both open colectomy and invasive surgical excision of rectal tumors. Laparoscopic colectomy has been shown to be equally effective as a staging and therapeutic approach, while shortening the hospital stay and reducing the use of pain medication. Robotic colectomy, even though more expensive and more time-consuming, may also offer substantial advantages.

For patients who have unresectable tumors or are medically unfit for surgery, chemotherapy or chemoradiation is recommended, possibly with the goal of converting the lesion to a resectable state. Patients with resectable high-stage colonic disease (T4 tumors) may be given pre-operative neoadjuvant therapy in an attempt to downstage the tumor. For rectal cancer patients, pre-operative radiotherapy or chemoradiation have been shown to be beneficial.

Adjuvant chemotherapy is recommended for post-surgical patients with stage III (lymph node involvement) or high-risk stage II disease. A number of combined regimens have been and are being tested in clinical trials. The combinations that have shown most clinical benefit in stage III patients and are currently most commonly used are the following: 5-fluorouracil (5-FU) and leucovorin (LV) with oxaliplatin (FOLFOX), bolus 5-FU/LV with oxaliplatin (FLOX), and capecitabine with oxaliplatin (CapeOX, also called XELOX or CAPOX). However, given the plethora of constantly evolving incoming data, there is no international consensus so as to the best regimens. In the same line, the panel of the US National Comprehensive Cancer Network (NCCN) clearly endorses the concept that including CRC patients for treatment in clinical trials should have a priority over therapies considered standard or generally accepted.

The use of adjuvant therapy in stage II patients is more controversial. Some trials have shown that stage II patients with high levels of microsatellite instability (MSI-H) or a deficiency in the expression of mismatch repair proteins (MMRs) are less likely to benefit from adjuvant therapy with fluoropyrimidine alone as well as from 5-FU therapy following surgery than those with low MSI (MSI-L) or those being microsatellite-stable (MSS). However, other studies have shown that the MSI is of a purely prognostic value and does not predict response to treatment. A number of genetic assays depicting characteristic molecular signatures of the tumors have also been designed in an attempt to identify patients at high risk of recurrence. However, their added predictive value for selecting patients more likely to benefit from adjuvant therapy has not been established and none of these tests is currently recommended for routine use by clinical guidelines. Awaiting more clinical trials, the current clinical practice is to offer adjuvant therapy only to selected high-risk patients with stage II disease. The NCCN panel lists FOLFOX, FLOX, and capecitabine with or without oxaliplatin as possible choices, however with 2a category of evidence strength and no preference for any of these options.

Metastases are frequent in CRC patients, with about 85% appearing within 3 years and nearly all within 5 years from initial surgery. The most common metastasis site is the liver, followed by the lungs. 80%–90% of metastatic CRC patients develop unresectable liver metastases (more often metachronous than synchronous). For patients with resectable metastases, surgical resection remains the standard of care, usually combined with perioperative systemic therapy. If resection is not possible, image-guided ablation or stereotactic body radiation therapy (SBRT) are reasonable options. Numerous systemic treatment regimens combining previously mentioned chemotherapeutics with biological agents, like inhibitors of vascular endothelial growth factor (VEGF; e.g., bevacizumab) or endothelial growth factor receptor (EGFR; e.g., cetuximab), are applied in the treatment of both advanced and disseminated metastatic disease, many of them with promising results. However, identifying and validating molecular biomarkers that would allow to reliably stratify patients according to their responsiveness to particular treatment combinations is clearly the need for the future clinical practice.

Glossary

Adenoma Benign epithelial neoplasm of the colorectum, frequently presenting as a polyp.
Aberrant crypt focus Focus of colorectal mucosa with disturbance of crypt architecture, earliest stage of carcinogenesis.
APC Adenomatous polyposis coli gene.
BRAF v-Raf murine sarcoma viral oncogene homolog B.
Chromosomal instability (CIN) Pathway of colorectal cancer development characterized by chromosomal changes (loss, gain or rearrangement).
Colonoscopy Endoscopic examination of the mucosa of the colon.
CpG island methylator phenotype (CIMP) Colorectal cancer characterized by high frequency of gene promoter CpG island methylation.
CTNNB Gene encoding β-catenin.
Desmoplastic Cancer type characterized by extensive development of(fibrous) tumor stroma.
Exophytic Cancer growth type characterized by expansion into the lumen of the affected organ.
Hyperchromasia Characteristic of high basophilic staining intensity of cancer cell nuclei.
KRAS Proto-oncogene corresponding to the oncogene first identified in Kirsten rat sarcoma virus and encoding a p21 GTPase.
Microsatellite instability (MIN) Pathway of colorectal cancer development characterized by high gene mutation rate, as reflected in instability of microsatellite DNA.
Mismatch repair DNA repair mechanism targeting correcting errors of DNA replication.
Mitotic activity Measure of cellular growth activity of a cancer.
MLH1 DNA mismatch repair gene mutL homolog 1.
MSH2 DNA mismatch repair gene mutS homolog 2.
MSH6 DNA mismatch repair gene mutS homolog.
Morphotype Histopathological variant of a cancer.
MUTYH Gene encoding MYH glycosylase, which is involved in the repair of DNA.
NRAS Neuroblastoma RAS viral oncogene homolog.
NSAID Non-steroidal anti-inflammatory drug.
NTRK1 Gene encoding neurotrophic receptor tyrosine kinase.
PD1 Checkpoint protein on T cells blocking them from being activated.
PD-L1 Activating ligand for PD1.
PIK3CA Gene encoding phosphoinositide-3-kinase, a tyrosine kinase receptor.
Pleomorphism Variation is size and shape of cancer cells.
PMS2 DNA mismatch repair gene postmeiotic segregation 2.
Polypectomy Endoscopic removal of colorectal polyp.
Polyp Tumefaction in the shape of a pedunculated mass.
Polyposis Condition characterized by the occurrence of multiple polyps in the colorectum.
POLE DNA polymerase epsilon.
POLD1 DNA polymerase delta1.
pTEN Gene encoding the phosphatase and tensin homolog protein.
SMAD4 Mothers against decapentaplegic homolog 4, gene encoding a signaling molecule in the TGF-β pathway.
TGF-β pathway Signaling pathway triggered by the TGFbeta1 receptor.
TP53 Tumor associated gene.
Wnt pathway Signaling pathway triggered by activation of the frizzled receptor.

Definition

Colorectal cancer is the term used for a malignant epithelial neoplasm in the colon or the rectum. As a rule, this is an adenocarcinoma. Even though the term colorectal cancer suggests that adenocarcinoma of the colorectum is a single disease entity, in reality,

the term covers a variety of conditions differing in etiology, biological behaviour, treatment and prognosis. Colorectal suggests that carcinomas of the colon and of the rectum are similar and effectively in terms of morphology and molecular mechanisms involved this is true. However, the therapeutic approach of rectal cancer differs significantly from that of colon cancer, primarily due to the quite different anatomical setting of the rectum (as it is embedded in the floor of the minor pelvis with genitourinary organs in close proximity). Furthermore, it has become clear that cancer in the right colon (cecum, ascending colon) is different in terms of molecular characteristics and response to targeted treatment from that in the left colon (from the splenic flexure down). Most colorectal cancers are sporadic, but about 20% of colorectal cancers arise in the context of a familial syndrome or as a complication of inflammatory bowel disease, and these cancers have distinct characteristics. Colorectal cancer is one of the most closely studied cancer types and the different signaling pathways involved in the development of colorectal cancer have been elucidated and their association with diagnosis, treatment and outcome clarified. This has resulted in the recognition that colorectal cancers develop in different patterns, which are known as the chromosomal instability (CIN), microsatellite instability (MIN), and CpG island methylator phenotype (CIMP) pathways. Results of recent molecular profiling studies have clearly established molecular and genetic heterogeneity of colorectal cancer beyond these established categories.

Burden

Colorectal cancer is among the most frequent of human cancers with an estimated 1.4 million new cases of CRC occurred worldwide in 2012, representing about 9.4% of all new cancers. Globally, in women colorectal cancer is the third most frequent cancer (after cancer of the breast and uterine cervix) and in men the fourth (after cancer of the lung, prostate, and stomach). However, the age-standardized incidence varies >25-fold around the world. In well-developed industrialized countries of North America, Europe, Australia, New Zealand, and Japan the incidence is around 40–60 per 100,000, but this is much lower in Africa and most Asiatic countries.

A striking difference exists between high and low incidence countries in the average age at which colorectal cancer is diagnosed (Fig. 1). In high incidence countries around 5% of cases are diagnosed before the age of 40 while in low incidence countries, rates in this age category as high as 35% have been reported. There is a trend for the incidence rate in low incidence countries to increase, while in high incidence countries the incidence is stable (in Europe) or even decreasing (North America). Of note, among immigrant populations from low incidence countries to a high incidence country the incidence rate has shown a rapid increase towards that of the newly adopted country. This is an important argument in favor of environmental factors as etiological agents in colorectal cancer.

In the US, the burden of colorectal cancer has shown a decrease, both in terms of incidence and death rate (the latter from 28 deaths per 100,000 in 1975 to 14 per 100,000 in 2013). The incidence showed a similar reduction (by almost 50%). In European countries, in the same period colorectal cancer mortality increased for men (about 5%) but decreased (by 15%) for women. However, between European countries significant differences exist. Among men and in women in countries like Austria, Switzerland and the United Kingdom the reduction in mortality was even as high as 30% while in the Netherlands this was about 15%, but in central and eastern European countries mortality rates remained stable. Overall, reduction in mortality rate seems to be most convincing in high resource countries where specialized care and screening services such as endoscopy are available.

Screening for colorectal cancer is done through the fecal occult blood test, which has a reasonable sensitivity but low specificity. Colonoscopy is increasingly advocated, as colonoscopic polypectomy in principle would allow eradication of the disease. Molecular testing for disease-specific DNA abnormalities in feces or in the blood is under development, but not yet routinely applied. Likewise, hopes are high that screening might be feasible through "liquid biopsies," testing peripheral blood for the presence of abnormal (tumor) DNA or RNA or circulating tumor cells. Promising data have been obtained in an experimental setting but confirmation in clinical trials is still pending.

Risk Factors

Environmental Factors

Numerous epidemiological studies have documented risk factors for colorectal cancer. A high incidence is consistently observed in affluent "Western" populations with a diet rich in calories and animal fat and a sedentary lifestyle. This translates into obesity, meat consumption, smoking and alcohol consumption as important risk factors which are potentially amenable to improvement. Immigrants from low-incidence populations to a high incidence population have consistently shown an increase in incidence rate. Various factors, such as dietary consumption of fruits, vegetables and whole grains, dietary supplements such as calcium and vitamin D, prolonged use of nonsteroidal anti-inflammatory drugs, estrogen replacement therapy in women and physical activity are associated with lower incidence rates. Molecular pathways underlying these epidemiological associations have not been elucidated. This is a rather complex issue as in dietary factors macro- and micronutrient-composition of foodstuff and methods of food preparation are variables not easy to assess. In addition, hormonal effects and genetic characteristics differ between individuals. A noticeable exception is the effect of NSAID's. Large trials have been conducted to study the effect of these drugs on the incidence of colorectal adenoma, the precursor lesion of colorectal cancer, and effective chemoprevention using cyclooxygenase inhibitors has been documented. Other prevention strategies, such as increased fiber content of the diet and reduced intake of fat, have shown less convincing effects.

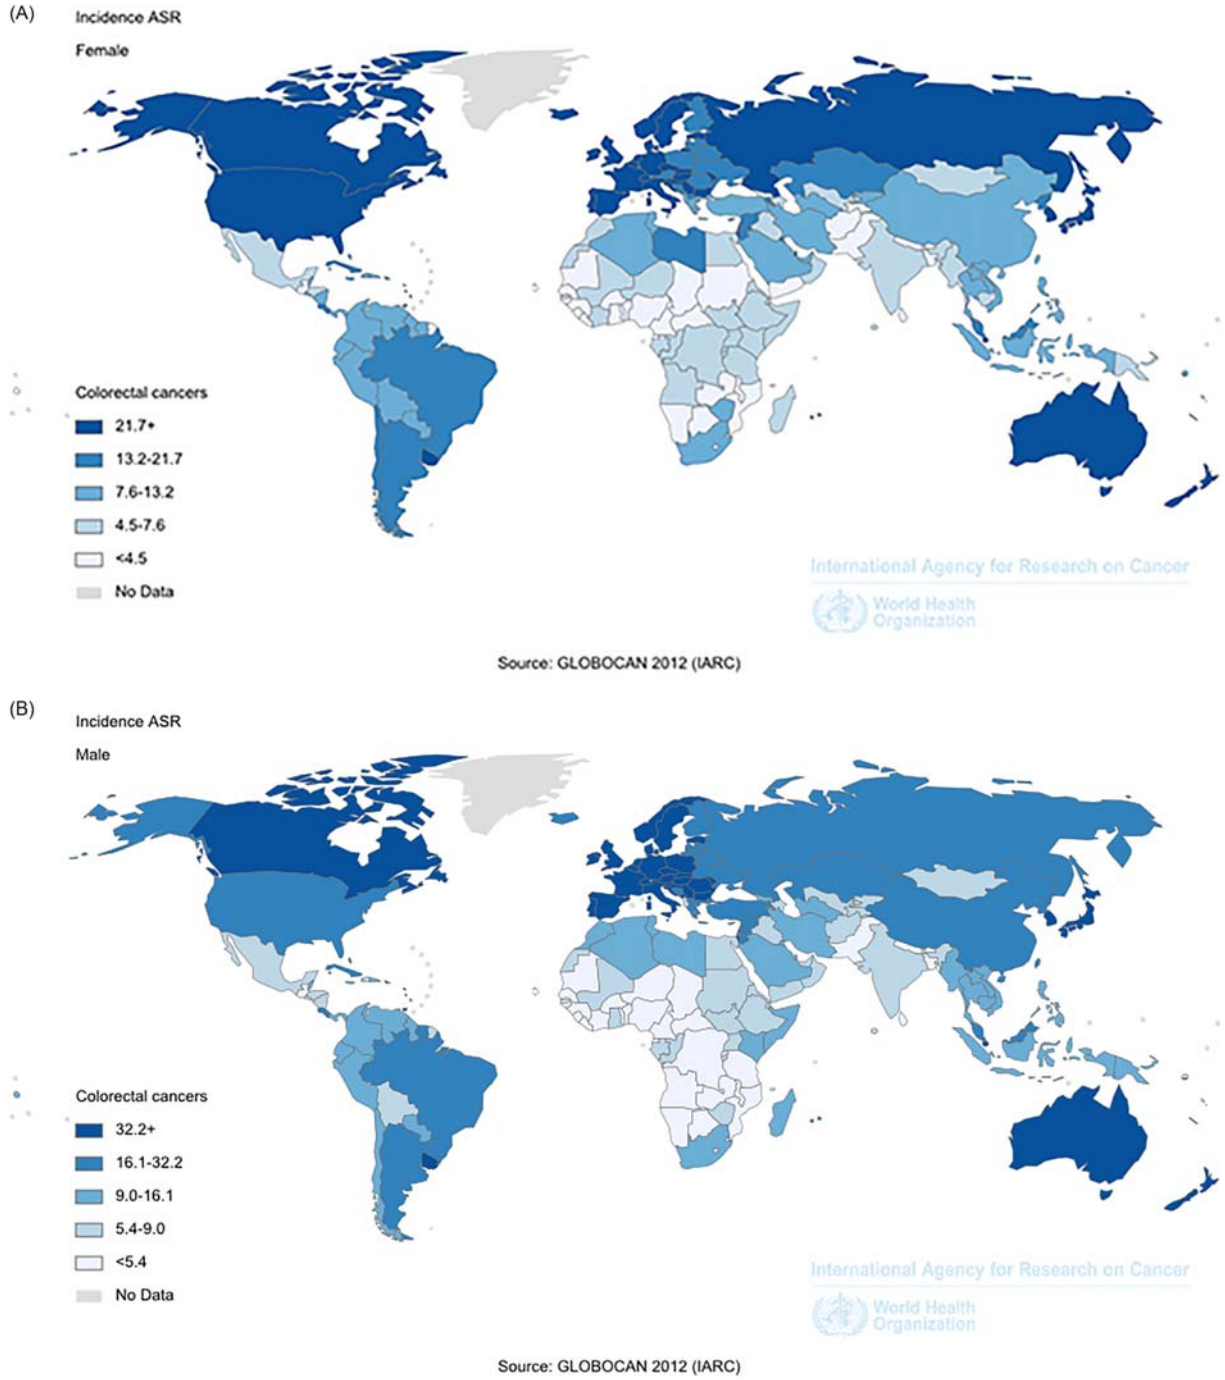

Fig. 1 Global incidence of colorectal cancer per gender (A) Females; (B) Males. Source: Globocan, 2012, http://globocan.iarc.fr.

Genetic Factors

More specific risk factors for colorectal cancer are genetic abnormalities, responsible for the different forms of familial colorectal cancer. These include familial adenomatous polyposis and its variants, Lynch syndrome, MUTYH-associated polyposis, DNA Polymerase-E or D1 deficiency related colorectal cancer and Peutz-Jeghers syndrome. Identification of the genetic abnormalities responsible for these syndromes has provided detailed insight into the molecular pathogenesis of colorectal cancer. Present understanding of the development of colorectal cancer indicates that colorectal cancer can develop along several distinct pathways: the chromosomal instability (CIN) pathway, the microsatellite instability (MIN) pathway and the CpG island methylator (CIMP) pathway. These will be discussed in detail in the paragraph on molecular pathology and genetics.

Chronic Inflammation

Chronic inflammatory bowel disease, notably when longstanding and active, has been recognized as a risk factor for colorectal cancer. This is more important for ulcerative colitis than for Crohn disease. It is assumed that DNA damage due to oxygen radicals in the context of active inflammation is involved. Chronic inflammation in the context of diverticular disease does not carry an increased risk for colorectal cancer.

Other Risk Factors

Although to some extent anecdotal, therapeutic pelvic irradiation and ureterosigmoidostomy have also been associated with colorectal cancer.

Pathology

Macroscopy

In general, early colorectal cancers will be found as a sign of progression in a precursor lesion, as a rule a pedunculated adenomatous polyp (Fig. 2). Size and architecture of these polyps can suggest malignancy: large adenomatous polyps of villous architecture (Fig. 3) are more frequently associated with malignancy and hence are called "high risk."

Advanced colorectal cancers most often present either as an exophytically growing mass or as a mass deeply infiltrating the bowel wall which tends to result in stenosis. The surface of both is often ulcerated. The exophytic growth pattern is most frequently encountered proximal to the splenic flexure (Fig. 4) while infiltrating stenosing cancers predominate in the distal colon and rectum. This is of significance notably in the rectum, as the proximity of urogenital organs carries a risk of invasion. These patterns often overlap as cancers which initially grow exophytically invariably will progress to infiltrate into the bowel wall.

Histology

Precursor Lesions

Carcinomas develop from adenomas, in what has become universally known as the "adenoma-carcinoma" sequence. Molecular studies have shown that in adenomas inactivation of the APC/Wnt pathway parallels that observed in colorectal carcinoma. In the adenoma-carcinoma sequence, genome abnormalities accumulate, responsible for the progression of the lesion to invasive cancer. Adenomas are defined as benign, premalignant epithelial proliferations of which the architecture reflects that of the normal colonic mucosa. They can be predominantly composed of glandular structures and then are called tubular (Fig. 2). Tubular adenomas are most frequently pedunculated, although when small may present as circumscript, slightly elevated patches of the mucosa, so-called flat adenomas. Villous adenomas have a multiple leaf-like architecture and are often sessile (Fig. 3). Tubulovillous adenomas have a mixture of both architectural patterns. Microscopically, adenomas contain glandular or crypt-like structures are composed of crowded hypercellular epithelium, the cells of which show varying degrees of hyperchromasia, pleomorphism and

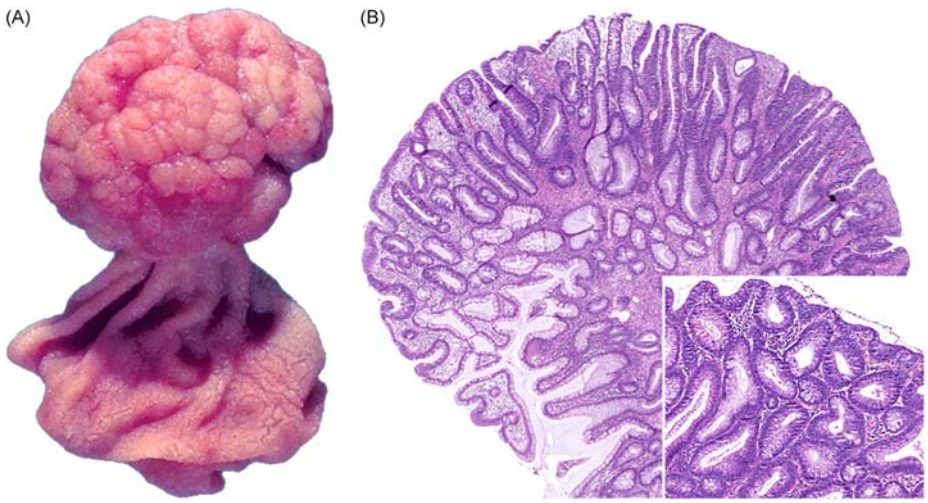

Fig. 2 Characteristic aspect of an adenomatous polyp (tubular adenoma) of the colon. (A) Gross image. Note the pedunculated architecture and slightly lobular surface. (B) Microscopic image. The basis of the stalk is covered with a relatively normal mucosa. In the head of the polyp the glandular architecture is disturbed. At higher magnification (insert) the dysplastic character of the epithelium can be discerned.

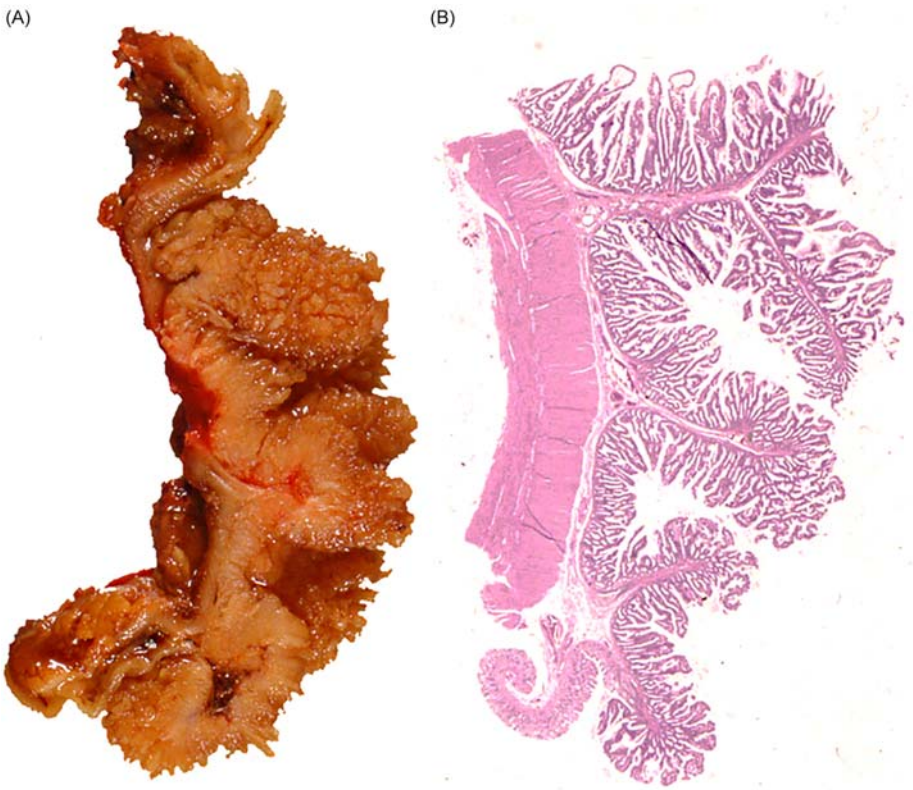

Fig. 3 Characteristic aspect of a villous adenoma. (A) Gross image. The adenoma has a broad ("sessile") implantation in the underlying mucosa. (B) Microscopic image. Note the villous (finger-like)architecture.

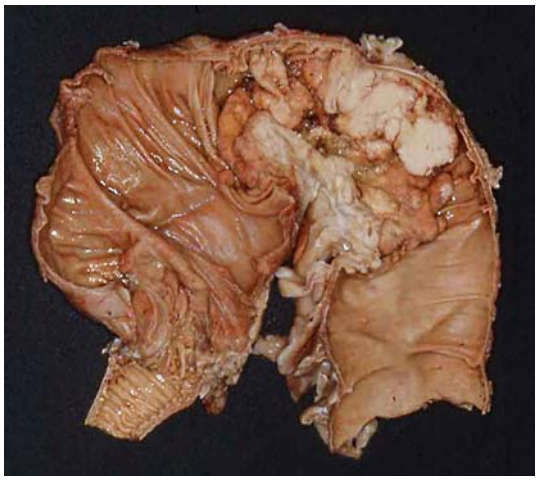

Fig. 4 Colon adenocarcinoma in the cecum of a patient with Lynch syndrome. Note voluminous exophytic growth into the lumen.

mitotic activity. The degree of epithelial cell crowding, nuclear hyperchromasia, mitotic activity and loss of glandular architecture determine dysplasia grade, which goes from low to high on a gradual scale. Adenomas larger than 1 cm and/or high grade and/or of villous architecture are called advanced as they are associated with a 3–5 fold increase in the risk of carcinoma. When in an advanced adenoma an area of high-grade dysplasia shows invasive growth that is limited to the lamina propria (e.g., no invasion of the submucosa) this is called intramucosal carcinoma. Risk of lymph node metastasis remains low as the lamina propria does not contain lymph vessels. Once invasion of the submucosa has developed the lesion is diagnosed as a colorectal carcinoma. It is important to underline that of all adenomas only about 10% would ever progress to a carcinoma.

A relatively recently defined adenomatous lesion is the so-called sessile serrated adenoma or polyp. As the term indicates, these lesions are sessile and occur more frequently in the right colon. The term serrated describes their microscopic appearance: composed

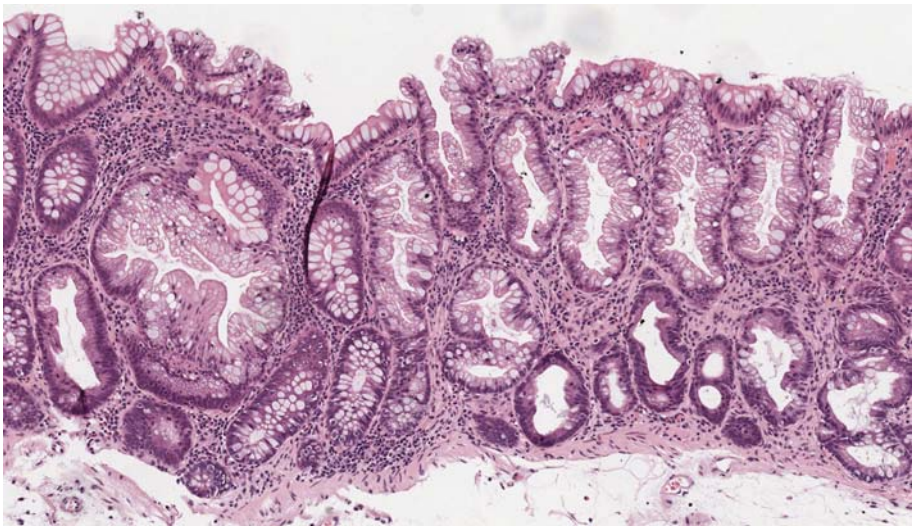

Fig. 5 Microscopic image of a sessile serrated adenoma. The basic architecture of this lesion is crypt-like, but the bases of the glands/crypts show architectural changes (dilation, lateral extension) as well as goblet cell differentiation deep down in the crypts.

of dilated crypts with a serrated (sawtooth-like) architecture of the epithelium and a tendency to branch towards the bottom of the crypt (Fig. 5). The term adenoma is justified by the clonal nature of the epithelial proliferation, as reflected in shared molecular abnormalities (high frequency of promoter methylation, loss of mismatch repair competency, *BRAF* mutation), even though the microscopic appearance of the epithelium is not dysplastic, which is why some insist that these lesions should not be called adenoma. It has become clear that sessile serrated adenomas do carry an increased risk of colorectal carcinoma, even though the risk is lower than that of conventional adenomas and time to progression is longer. For patients with (a) sessile serrated adenoma(s), surveillance as for conventional adenomas is advised. Sessile serrated adenomas rarely occur as a polyposis syndrome (sessile serrated polyposis). This goes along with a significantly higher risk of development of a colorectal carcinoma. Its molecular basis has not (yet) been clarified. Progression of a sessile serrated adenoma towards carcinoma passes through a phase of epithelial dysplasia, rather like that in conventional adenoma.

Another adenoma morphotype is that of traditional serrated adenoma. This is the least frequent of colorectal adenomas. Its architecture tends to be villous. The villous structures are covered with an epithelium that is usually mildly dysplastic with patches of epithelial cells with strikingly eosinophilic cytoplasm and thin elongated (penicillate) nuclei. A characteristic feature is an occurrence of "ectopic crypts": crypt-base like structure emerging from the epithelial lining of the villi.

Adenomas can be removed by endoscopic polypectomy. Theoretically, endoscopic surveillance with the removal of polyps would prevent the development of colorectal carcinoma. Large studies have shown that colonoscopic surveillance reduces colorectal cancer risk and mortality by as much as 70%.

Adenocarcinoma

Once a focus of high-grade dysplasia in any type of adenoma has invaded through the muscularis mucosae into the underlying submucosa, the lesion is classified as an adenocarcinoma. There is some discussion as to what exactly can be regarded as evidence of invasive growth in its initial phase. By definition, invasive growth starts with a breach in the epithelial basement membrane, but this is not a useful histological criterion as it is difficult to visualize and discontinuous basement membranes can also be seen in inflammatory conditions. Often, a "desmoplastic" stromal reaction is used as criterion. A more molecularly defined criterion is evidence of epithelial-mesenchymal transition, which characterizes most forms of invasive growth. Architectural criteria are also used, notably the existence of cribriform growth. Altogether, frank invasive growth is easy to identify for example, when tumor cell clusters are found in the submucosa. Early invasive growth, however, can be difficult to recognize. Frank invasive growth occurs in two patterns: "pushing" with sharp edges of tumor cell fields, and diffusely infiltrating which is frequently accompanied by tumor cell "budding," the occurrence of clusters of fewer than five tumor cells in the invasive front. The pattern of invasion has some prognostic value: diffuse infiltration with tumor cell budding is associated with poorer prognosis.

Several morphotypes of adenocarcinoma commonly are seen (Fig. 6). Most often the carcinoma has a glandular architecture, which is called well or moderately well differentiated. A solid growth pattern is called poorly differentiated. Some carcinomas show areas of mucinous differentiation, when this exceeds 50% of the tumor volume the carcinoma is called "mucinous." Occasionally a carcinoma can be composed (almost) entirely of signet ring cells, this is called a signet ring cell carcinoma. What has emerged recently is the importance of a high number of tumor-infiltrating lymphocytes (TIL), often in combination with clusters of dense follicle-like lymphocytic infiltrate around the tumor. Carcinomas with mucinous differentiation and poorly differentiated carcinomas with a solid growth pattern often contain a high number of TIL, tend to be more frequent in the right colon and mismatch repair

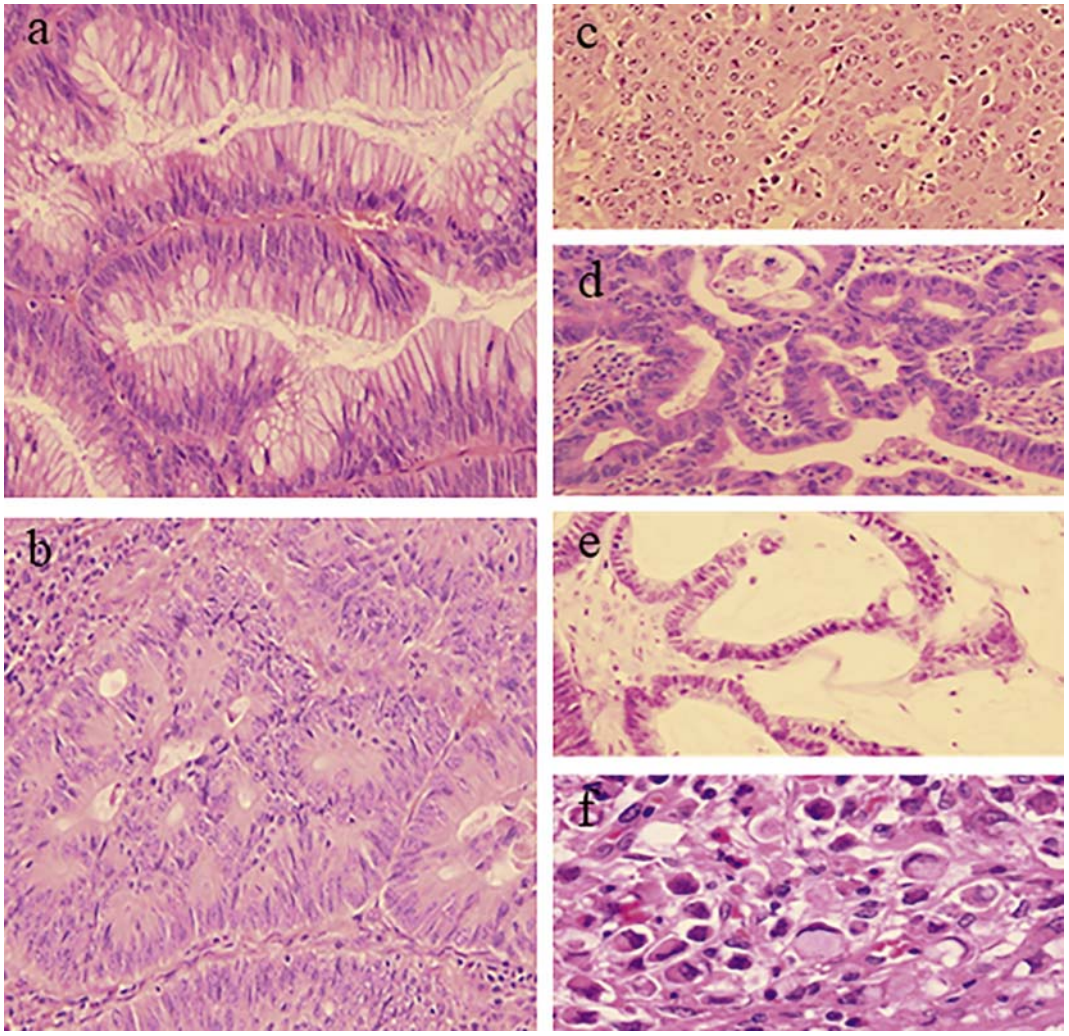

Fig. 6 Histological spectrum of colorectal cancer. Grading is as low grade (A) or high grade (B), the latter characterized by strong architectural and cytonuclear atypia. Solid tumors (C) tend to be infiltrated by lymphocytes and are associated with deficient mismatch repair, as are mucinous tumors (E). Other morphotypes are serrated (D) and signet ring-cell type (F).

deficient. Conversely, mismatch repair competent tumors tend to have a glandular growth pattern, often with areas of cell debris ("dirty necrosis"), and lack TIL. Colorectal carcinomas, however, display notoriously heterogeneous morphology and for a diagnosis of mismatch repair deficient (microsatellite instable) carcinoma, some form of molecular analysis needs to be undertaken.

Grading

Traditionally, colorectal adenocarcinomas are graded in three grades: well, moderately well and poorly differentiated. In grading, architectural as well as cytonuclear features are taken into account. Architectural features pointing towards high grade are the loss of epithelial polarity, loss of gland formation and cribriform growth pattern (Fig. 6A and B). Cytonuclear features include high nuclear pleomorphism and high mitotic activity, which is almost invariably accompanied by significant necrosis. Grading is somewhat subjective and relatively poorly reproducible. Nonetheless, grading is significantly associated with prognosis. Tumor grade is included in the list of parameters taken into consideration in deciding whether or not a stage 2 cancer will require adjuvant postoperative treatment.

Extension and Staging

Adenocarcinomas of the colorectum progress by invasion into the bowel wall. The depth of invasion determines the T-stage (Table 1). Metastasis will be initially to locoregional lymph nodes. Distant metastases occur most frequently in the liver. In

Table 1 TNM classification based staging of colorectal carcinoma

Stage grouping	*Tumor*	*Node*	*Metastasis*	*5y overall survival (%)*
Stage I	T1, T2	N0	M0	>90
Stage IIa	T3	N0	M0	85
Stage IIb	T4	N0	M0	65
Stage IIIa	T1, T2	N1, N2	M0	85
Stage IIIb	T3, T4	N1, N2	M0	60
Stage IV	any T	any N	M1	10

Overall survival data are approximations. T1 tumor limited to the submucosa; T2 tumor infiltrating into the muscularis propria; T3 tumor infiltrating into the subserosal fat; T4 tumor penetrating the serosal membrane and/or infiltrating an adjacent organ. N0 no lymph node metastasis; N1 metastasis in 1–3 regional lymph nodes; N2 metastases in four or more regional lymph nodes, M1 metastases in any distant organ.

advanced stages, metastases can be found in almost any organ. In a clinical context, stage grouping is practiced facilitating decisions on therapy. Stage grouping is explained in Table 1. Stage determines prognosis as well as the therapeutic approach, notably as regards the need for adjuvant therapy.

Molecular Pathology

Colorectal cancer is a classic example of stepwise progression, initially developing as an aberrant crypt focus, passing on to a still benign adenoma, and ultimately progressing to an invasive adenocarcinoma with the capacity to metastatic spread. The cell of origin most likely is a crypt base stem cell, from which a clone of aberrant transformed cells arises through the accumulation of multiple genetic abnormalities. The key signaling pathway affected in colorectal cancer is the Wnt pathway through inactivating mutation of *APC*, activating mutation of *KRAS* and subsequent mutation of *TP53* and genes in the TGF-β pathway (notably *SMAD4*) which confer invasive and metastatic capacity (Fig. 7). As discussed in the paragraph on pathology, many subtypes of colorectal cancer can be distinguished, differing in morphology, genetic background, molecular profile, clinical behavior and response to therapy. We will discuss the three main pathways involved, their relationship to familial colorectal cancer syndromes and how molecular pathology impacts on clinical decision making.

The Chromosomal Instability (CIN) Pathway

The prototypical pattern of the development of colorectal cancer is along the chromosomal instability (CIN) pathway, which represents about 85% of sporadic colorectal cancers. Chromosomal instability is reflected in a high number of allelic losses and gains, including recently discovered chromosomal translocations involving the *NTRK1* gene. CIN cancers have a relatively low gene point mutation rate, contrary to mismatch repair deficient microsatellite instable colorectal cancers. CIN colorectal cancers almost invariably carry a mutation in the Wnt pathway genes *APC* (70%) or *CTNNB1* (30%). KRAS mutations, usually in codons 12 and 13, occur in 45% of cases and constitutively activate the MAP-kinase/ERK signaling pathway which renders them insensitive to

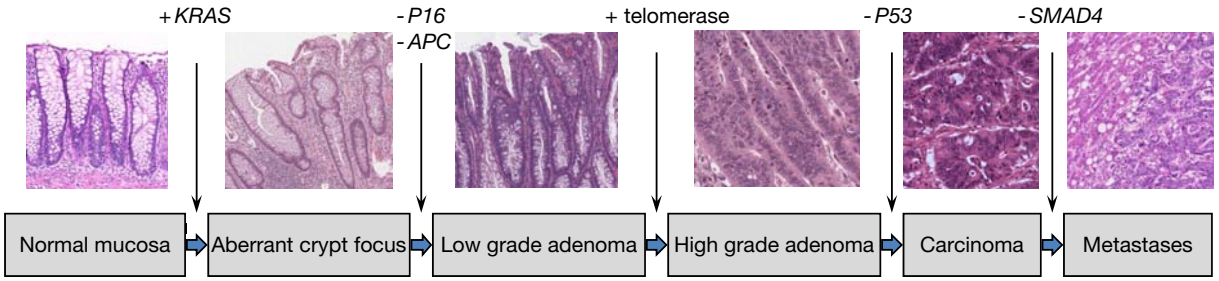

Fig. 7 The classical adenoma-carcinoma sequence of the development of colorectal cancer (after Vogelstein), which follows a CIN pattern of carcinogenesis. The initial lesion is called aberrant crypt focus and is characterized by a slight disturbance of crypt architecture and cytonuclear atypia of crypt cells. These often carry an activating (+) *KRAS* mutation. When an inactivating (−) *APC* mutation occurs epithelial dysplasia (as is shown in the second panel) ensues and an adenoma develops. Low grade adenomas are mostly small and tubular with little cytonuclear and architectural features of dysplasia. Upon telomerase activation (+) high grade features emerge: larger size, villous architecture and high grade cytonuclear features (loss of polarity, nuclear pleomorphism, mitotic activity). Progression towards invasive carcinoma is often accompanied by a *TP53* mutation and progression towards by further molecular events, such as inactivation of SMAD4 (−). Adapted from Bosman, F.T. (2014). World Cancer report 2014, In: Stewart, B.W., Wild, C.P. (eds.) ISBN 978–92–832-0429-9. Page 392. IARC publications. With permission from the publisher.

anti-EGFR therapy. *TP53* mutations are found in 70% of cases. In advanced colorectal cancer loss of SMAD4 (which functions downstream of the TGF-β2 receptor) occurs, which confers poor prognosis. Evidence emerging from The Cancer Genome Atlas (TCGA) studies has added to these classical molecular events >20 genes that are frequently mutated, including *ARID1A, SOX9 and FAM123B/WXT*.

In aberrant crypt foci, small patches of mucosa in which regular crypt architecture is disturbed, mutations in *KRAS* or *APC* gene are found. Aberrant crypt foci with an *APC* mutation are morphologically dysplastic, which signifies progression towards adenoma. Subsequent telomerase is activated, which confers unlimited lifespan and ultimately *TP53* mutation is acquired which is associated with progression from low grade to high-grade adenoma. The TGF-β pathway, including the SMAD family, is involved in the progression from a non-invasive adenoma to an invasive carcinoma. This is illustrated in **Fig. 7**.

The Microsatellite Instability (MIN) Pathway

Around 15% of colorectal carcinomas are characterized by microsatellite instability. This is a result of a deficient DNA mismatch repair system. This corrects mismatches (single base mismatches or short deletions or insertions) that have occurred during DNA replication. When this does not function, mutations accumulate and mismatch repair deficient cells effectively are hypermutated. This is reflected in the variable length of microsatellite repeats, hence the term microsatellite instability. Microsatellite instability can be visualized using a set of defined microsatellite sequences, which are almost invariably affected (the mononucleotides BAT25 and BAT26, and the dinucleotide repeats D2S123, D5S346, and D17S250). Mismatch repair deficiency is due to loss of function of one of the proteins that make up the effector complex of this system: MLH1, MSH2, MSH6, and PMS2. This can be due to a mutation of one of the responsible genes. Most cases of MSI colorectal carcinoma, however, are due to promoter methylation of MLH1 which silences expression of the gene. Patients with Lynch syndrome carry a germ-line mutation of one of the mismatch repair genes. Loss of function of these proteins can be visualized using immunohistochemical staining (**Fig. 8**). This is the most frequently used test approach for mismatch repair deficiency. Sporadic MSI cancers show a relatively high frequency of *BRAF* gene mutations, which are almost invariably of V600E type.

Morphologically, MSI cancers also follow an adenoma-carcinoma sequence. Precursor adenomas may be of the conventional type but more often of the sessile serrated type with dysplasia. The ensuing carcinomas are more often located in the right colon, show mucinous or medullary histology and a host response characterized by a high number of TIL. It is assumed that the hypermutated state of these cancers induces numerous cancer-cell related neoepitopes, which evoke a strong host immune response. MSI

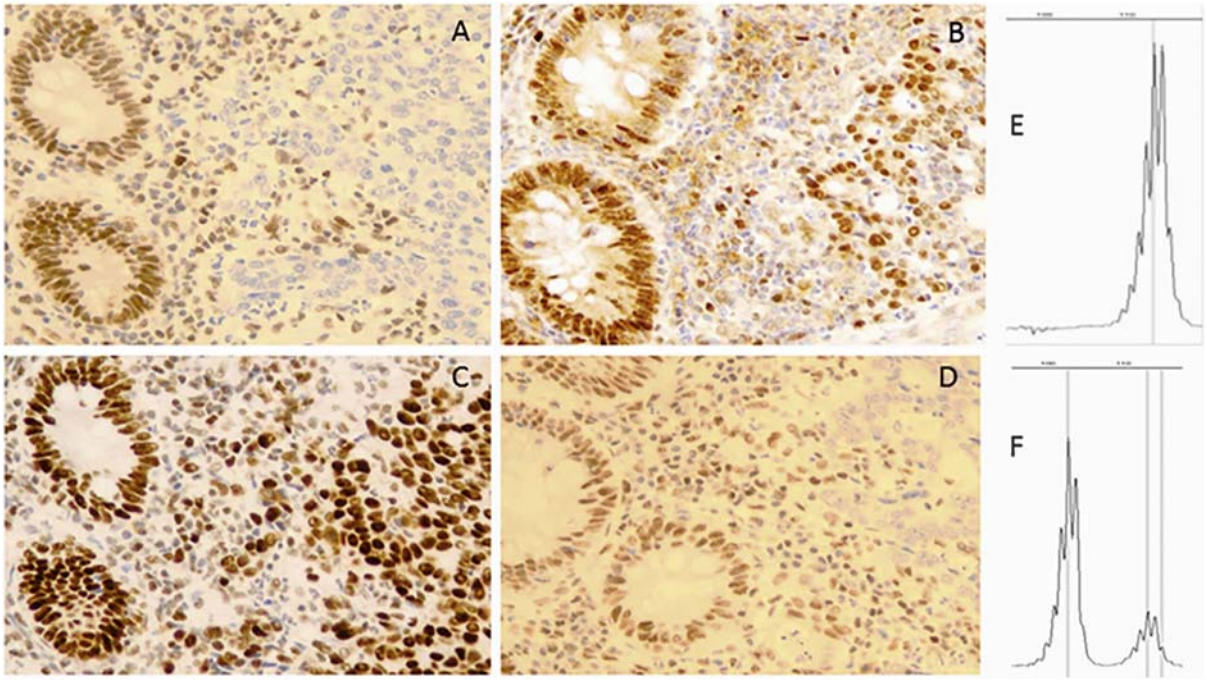

Fig. 8 Mismatch repair deficiency analysis using immunohistochemistry panels (A–C) and microsatellite instability. Immunohistochemical staining for MLH1 (A) and PMS2 (D) shows loss of expression (note nuclear staining of normal cells surrounding the cancer cells). MSH2 and MSH6 (panel B and C) show nuclear staining of cancer cells reflecting normal expression. Panels E and F show microsatellite analysis of a MS stable tissue sample (E) showing a single peak for the microsatellite marker (BAT26) whereas the existence of two peaks (F) indicates microsatellite instability. From Bosman, F. and Yan P. (2015). Molecular pathology of colorectal cancer. *Polish Journal of Pathology* **65**, 257–266. https://doi.org/10.5114/pjp.2014.48094.

cancers have a better prognosis than microsatellite stable (MSS) cancers but tend to be less responsive to 5-Fluorouracil, the standard chemotherapeutic drug used for colorectal cancer (adjuvant) treatment. Recent developments are quite exciting in that MSI cancers (not only colorectal cancers) appear to be highly sensitive to immune-checkpoint (PD1) blocking therapy, which potentially changes completely the treatment of advanced colorectal carcinoma.

The CpG Island Methylator Phenotype (CIMP) Pathway

This pathway is also known as the "serrated pathway," as it closely associated with the development and progression of sessile serrated adenomas (Fig. 9). It shows significant overlap with the microsatellite instability pathway. It is assumed that the earliest molecular event is promoter hypermethylation affecting a wide variety of genes (hence the term CpG island methylator phenotype) early on affecting MLH1 with microsatellite instability as a result, which then facilitates the accumulation of additional genetic abnormalities. In most cases, the *BRAF* gene is mutated (typically the V600E mutation). In more advanced stages of the pathway additionally affected genes correspond to those involved in the CIN pathway.

Colorectal Carcinoma in the Context of inflammatory Bowel Disease (IBD)

Inflammatory bowel disease is the generic term used to cover two specific entities: Crohn's disease and ulcerative colitis. Ulcerative colitis is a chronic inflammatory disease of the colon and/or rectum and in most cases restricted to the mucosa and submucosa. Crohn's disease is also a chronic inflammatory disease but can affect any part of the gastrointestinal tract although most commonly the terminal ileum. The pattern of the inflammatory reaction can be quite similar to that of ulcerative colitis but in a significant proportion of Crohn's disease cases, the inflammation is granulomatous. Inflammation extends through all layers of the bowel wall which may lead to stenosis through fibrosis but also perforation and formation of fistulae. Both conditions have a pattern of extra-intestinal manifestations. Important in this context is that in both conditions longstanding active disease is associated with increased risk of large bowel cancer or (in Crohn's disease) small bowel cancer. In this setting, carcinoma develops through a "dysplasia-carcinoma" sequence. The transcription factor NF-κB provides the link between inflammation and carcinogenesis, as it induces expression of the pro-inflammatory mediators COX-2 and TNF-α, which both play a role in colorectal carcinogenesis. Genome abnormalities in colorectal carcinoma in the context of IBD are similar to those in sporadic CRC but *TP53* mutations often occur early. *APC* mutations are less frequent.

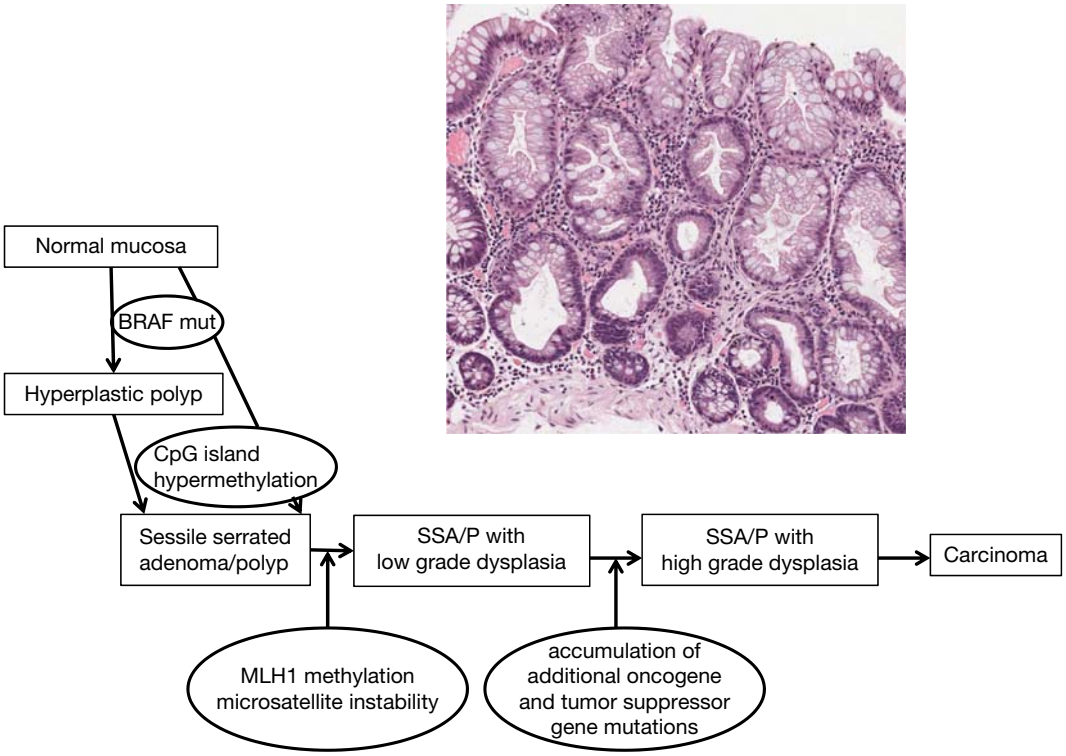

Fig. 9 Molecular pathway involved in the development of sessile serrated adenomas, which largely corresponds to the CIMP pathway. From Bosman, F.T. (2013). Molecular pathology of colorectal cancer. In: Chung, L., Eble, L.N. (eds.) Molecular surgical pathology. New York: Springer, pp. 1–16. ISBN 978–1–4614-4899-0.

Colorectal Cancer Genetics: Familial Colorectal Cancer Syndromes

About 20% of all colorectal carcinomas occur in a familial context: more family members are affected than would be expected by chance. An individual in a family with one or more cases of colorectal cancer has a two to sixfold chance to be affected by this cancer, depending on the number of affected family members. However, in only half of such families can a familial cancer syndrome be identified. Genome-wide association studies have pinpointed a variety of chromosomal loci and single nucleotide polymorphisms, associated with increased colorectal cancer risk. These might be less (if at all) penetrant or represent variants of which the effect depends on gene-environment interactions. For a substantial proportion of familial colorectal cancer cases, therefore, the genetic background still needs to be resolved.

Consequently, about 10% of all colorectal carcinomas arise in the context of a known familial cancer syndrome. Their number gradually increases. The first discovered syndrome is familial adenomatous polyposis coli. A later discovery was non-polyposis hereditary colon cancer or Lynch syndrome. More recent is the MutYH associated polyposis or MAP syndrome and a recently discovered syndrome is associated with DNA polymerase E/D1 deficiency. Other rare polyposis syndromes with increased colorectal cancer risk exist (e.g., Peutz-Jeghers syndrome, juvenile polyposis syndrome and Cowden syndrome).

Familial Adenomatous Polyposis

About 1% of all colorectal cancers occur in the context of familial adenomatous polyposis, of which the Gardner syndrome is a variant. The syndrome is characterized by the development early in life of an increasing number (between hundreds and thousands) of adenomatous polyps in the colon characteristically in the second decade of life (**Fig. 10**) If untreated these will progress to colorectal cancer; mean age of colorectal cancer diagnosis in FAP patients is 39 years. Extracolonic manifestations include adenomas in the stomach and the proximal duodenum, which can progress to carcinoma, and fundic gland polyps in the stomach. FAP-associated benign lesions are desmoids, lipomas, fibromas, sebaceous and epidermoid cysts in the skin, skeletal osteomas, dental abnormalities and congenital hyperplasia of the retinal pigment epithelium (known as CHRPE). Less common extracolonic malignancies are malignant neoplasms of the thyroid, brain, adrenal, hepatoblastoma in the liver and pancreaticobiliary tumors. The syndrome is caused by an autosomal dominantly inherited mutation of the adenomatous polyposis (*APC*) gene on chromosome 5. The APC protein plays a crucial role in the Wnt signaling pathway: in a normal cell it binds β-catenin (which is also integrated into the E-cadherin-catenin cell-adhesion complex) which will be then be degraded in the proteasome. Loss of APC results in accumulation of β-catenin, which migrates to the nucleus with transcription factor activity, promoting transcription of genes of which the protein products stimulate growth, such as MYC and cyclin D1 (**Fig. 11**).

In the context of FAP, >400 different mutations have been reported in the *APC* gene. Different mutations are associated with different phenotypes and distinct genotype-phenotype associations have emerged, as listed in **Table 2**. Most important are the mutations reported in exons 3, 4, 6, and 15 in association with attenuated FAP. In attenuated FAP fewer adenomatous polyps are found and colorectal cancer tends to develop at a more advanced age. Upper gastrointestinal lesions are associated with mutations in exon 15 and those beyond codon 1400. Mutations beyond codon 1444 are associated with the presence of desmoid tumors and those in codons 767–1513 with osteomas. Thyroid cancers are mostly seen with mutations in exons 1–15 and CHRPE's with mutations in exons 9–15 (**Table 3**).

The Gardner syndrome was first described before the discovery of the FAP syndrome or the *APC* gene. It refers to a FAP subtype with numerous gastrointestinal polyps in combination with other neoplasms including osteomas, desmoid tumors, epidermoid cysts and also dental anomalies. *APC* mutations in Gardner syndrome occur in a region encoding for the β-catenin-binding site of the protein. The use of the term Gardner syndrome is discouraged, as it clearly constitutes one of the subtypes of FAP.

The MUTYH-Associated Polyposis (MAP) Syndrome

Patients with the MUTYH-Associated Polyposis (MAP) syndrome have a FAP phenotype but lack a mutation in the *APC* gene. It is estimated that about 2% of colorectal cancers occur in the context of this syndrome. MAP is an autosomal recessive disorder caused

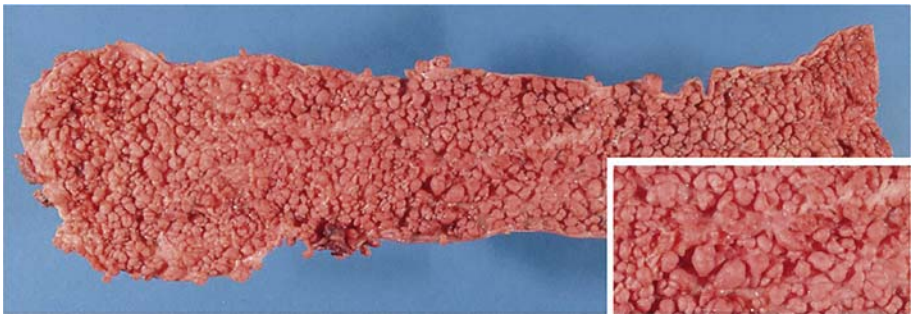

Fig. 10 Colon mucosa from a patient with familial adenomatous polyposis. The mucosa is diffusely seeded with polyps varying in size. Inset shows higher magnification.

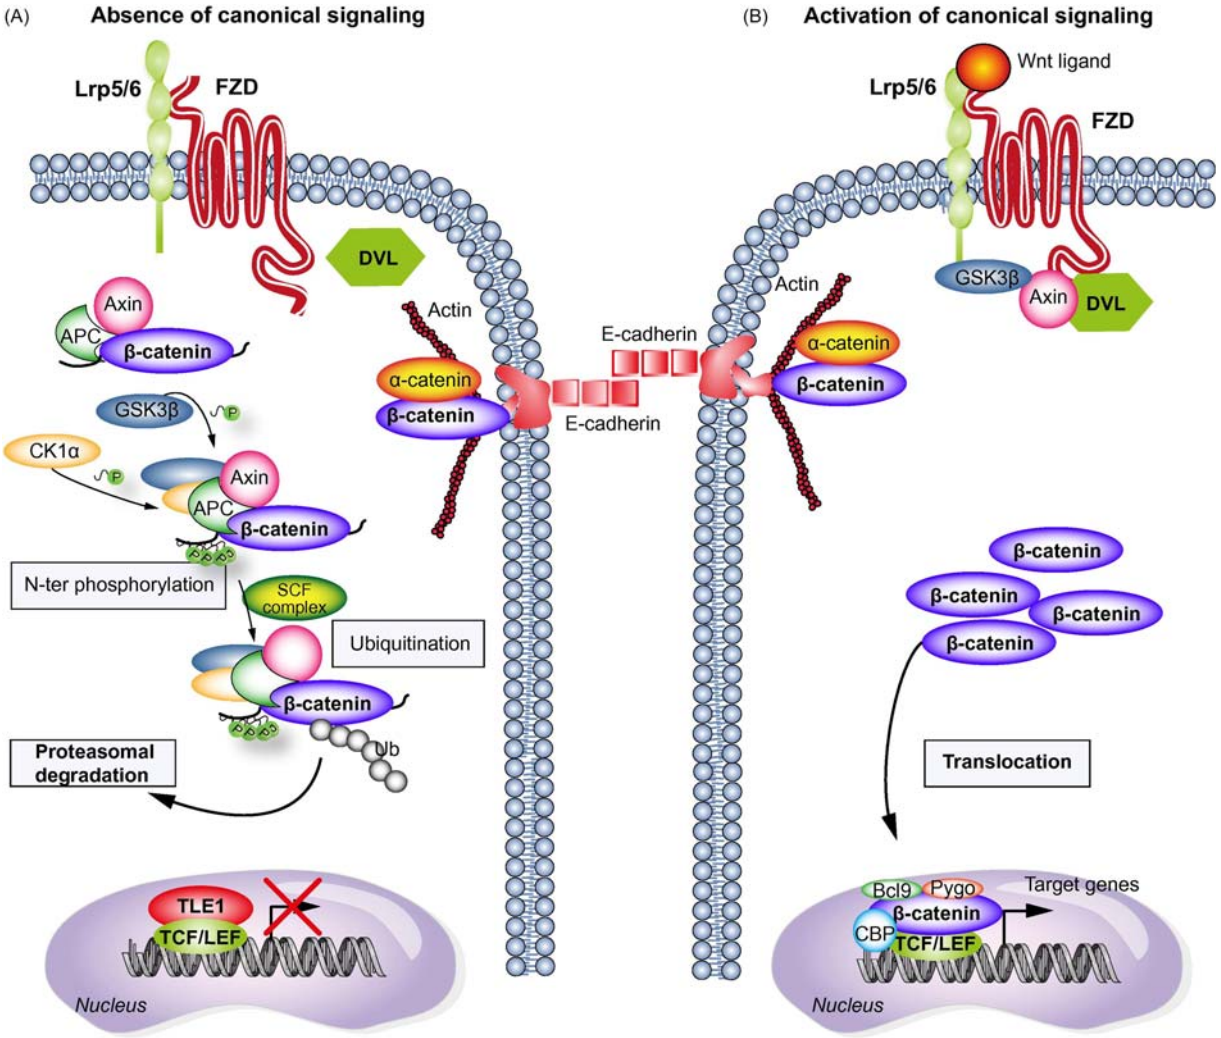

Fig. 11 Schematic representation of the canonical Wnt pathway in the absence (A) or presence (B) of a signaling event. In the absence of signaling β-catenin forms a complex initially with axin and APC, downstream completed with GSK3β and CK1α, which results in ubiquitination of β-catenin and ultimately its degradation. A proportion of β-catenin participates in the e-cadherin/catenin cell-adhesion complex. In the presence of a signaling event (B) β-catenin is not degraded, translocates to the nucleus where it forms a transcription factor in complex with, among others, TCF/LEF, pygopus and Bcl9, activating expression of target genes. From https://www.google.nl/search?q=wnt+pathway&source=lnms&tbm=isch&sa=X&ved=0ahUKEwjo0pX1sv_XAhVsC8AKHW8hCggQ_AUICigB&biw=1920&bih=925#imgrc=PUdZ-3WdhmeWRM.

Table 2 Genotype-phenotype associations for extracolonic manifestations in familial adenomatous polyposis (FAP) and attenuated familial addenomatosis (aFAP)

Syndrome phenotype	*Genotype*	*Characteristics*
FAP	Numerous different mutations reported (over 400)	Frequent extracolonic manifestations
FAP with		
Desmoid tumors	Mutations beyond codon 1444	
Duodenal polyposis	Mutations in exon 15, beyond codon 1400	
CHRPE	Mutations in exons 9–5	
Osteomas	Mutations in codons 767–1513	
Thyroid cancer	Mutations in exons 1–15	
aFAP	>35 mutations described (exons 3, 4, 6, 9, and 15; introns 3 and 9)	Other tumor types and desmoid tumors are less frequent Patterns of extracolonic manifestations not associated with specific mutations Often duodenal polyposis No CHRPE's

Table 3 Familial polyposis syndromes with polyp characteristics and responsible gene

Syndrome	*Polyp characteristics*	*Gene responsible*
Autosomal dominant		
Lynch syndrome	Few adenomatous polyps	*MLH1, MSH2, MSH6, PMS2*
Familial adenomatous polyposis	Numerous adenomatous polyps	*APC*
Polymerase proofreading-associated polyposis	Multiple mostly adenomatous or serrated polyps	*POLE, POLD1*
Peutz-Jeghers syndrome	Hamartomatous polyps also in upper GI tract	*LKB1/STK11*
Juvenile polyposis syndrome	Multiple hamartomatous polyps	*SMAD4/BMPR1A*
Cowden syndrome	Multiple adenomatous, hamartomatous or inflammatory polyps	*pTEN*
Autosomal recessive		
MUTYH associated polyposis syndrome	Multiple adenomatous or serrated polyps	*MUTYH*

by biallelic mutations in the Mut Y homolog (MUTYH) gene, located on chromosome 1p. The gene encodes a protein with an important function in the DNA base excision repair pathway. MAP syndrome resembles familial adenomatous polyposis in that multiple adenomatous polyps of the colorectum develop, with a very high lifetime risk of colorectal cancer. The number of adenomas ranges from very few to hundreds and therefore MAP resembles attenuated familial adenomatous polyposis. Extracolonic manifestations occur, including duodenal adenomatous polyps and adeno(carcino)mas, CHRPE's and breast cancer.

Hereditary Non-Polyposis Colon Cancer or Lynch Syndrome

About 3% of cases of colorectal cancers occur in the context of hereditary non-polyposis colon cancer or Lynch syndrome, the most common hereditary colorectal cancer predisposition syndrome. Lynch syndrome patients carry an 80% lifetime risk of developing colorectal cancer. Cancer occurs also in other organs, including (in decreasing order of frequency) in the endometrium, ovary, duodenum, urinary tract, stomach, pancreas, biliary tree, and brain. Lynch syndrome is autosomal dominant and is caused by mutations in one of the DNA mismatch repair genes mutL homolog 1 (*MLH1*) on chromosome 3p21, mutS homolog 2 (*MSH2*) on chromosome 2p16, mutS homolog 6 (*MSH6*) on chromosome 2p16 and postmeiotic segregation 2 (*PMS2*) on chromosome 7p22. The most frequent (about 80%) are *MLH1* and *MSH2* mutations. In the mismatch repair protein complex, which altogether is composed of seven DNA mismatch repair proteins (in addition to those previously mentioned *MLH3*, *MSH3* and *PMS1*), these work sequentially to initiate repair of DNA mismatches, base mismatches or small insertions or deletions that occur during DNA replication. MLH1 deficiency is relatively frequent in cancer, not through a mutation of the gene but through epigenetic silencing by methylation of the *MLH1* promoter. MSH2 deficiency can also occur through gene-silencing by transcriptional read-through of *TACSTD1*, a gene directly upstream of *MSH2* and encoding the Ep-CAM protein. Because of a germline deletion of the last exons of *TACSTD1*, its transcription is extended into *MSH2* with functional loss of MSH2 activity.

Around 15% of colorectal cancers are MisMatch Repair deficient (dMMR) and these characteristically show microsatellite instability (MSI), increased variability in length of the nucleotide repeats that occur throughout the genome. The large majority of these dMMR cancers show epigenetic silencing of MLH1 through promoter methylation. Only patients with a germline mutation in one of the MMR genes have the Lynch syndrome phenotype. Not all replication errors due to MMR are pathogenic. Mutations are significant when they occur in key genes in processes such as cell proliferation, apoptosis or DNA repair, with functional significance in the context of cancer development. MSI is detected through analysis of a consensus set of gene markers frequently affected by dMMR (the mononucleotides BAT25 and BAT26, and the dinucleotide repeats D2S123, D5S346, and D17S250) which show variations in length in MSI. When three or more markers are unstable this is designated as MSI-H(igh). dMMR can also be detected through immunohistochemical staining of the four MMR genes mentioned above. Loss of staining for one of the proteins qualifies the case as MSI (**Fig. 8**). In case of MLH1 loss, the *MLH1* gene might be mutated or, alternatively (and most frequently) silenced through promoter methylation. To diagnose such a case as sporadic or Lynch syndrome, the methylation status of the promoter needs to be assessed. When non-methylated the patient will be further screened for *MLH1* mutation. *BRAF* mutation status can be considered a surrogate marker, as in Lynch syndrome-associated colorectal cancer *BRAF* mutation is exceptionally rare. dMMR cancers are hypermutated: they show a very high frequency of gene point mutations and significantly fewer chromosomal rearrangements and allelic imbalances. While of colorectal cancers about 15% is MSI, this is much more frequent in gastric and esophageal cancer, non-small cell lung cancer and squamous cell carcinoma of head and neck. This has gained clinical significance recently as MSI cancers have been found to respond to immune checkpoint blocking therapy (PD1/PD-L1 inhibitors): the PD1 inhibitor Pembrolizumab was approved for recurrent solid tumors, regardless of the histological tumor type.

In Lynch syndrome, the dMMR colorectal cancers develop through an adenoma-carcinoma sequence with adenomatous polyps as precursor lesions. However, even though polyps may be multiple, they are never sufficiently numerous to call the condition polyposis. Common characteristics of (Lynch syndrome-associated and sporadic) dMMR colorectal cancers are typical localization in the right colon, mucinous or medullary histotype, and a striking lymphoid host reaction, partly as TIL's and partly as peritumoral

secondary lymphoid follicles. The prognosis is better than that of mismatch repair competent cancers, but mismatch repair-deficient cancers respond less well to adjuvant chemotherapy. Therapeutic options have changed significantly with the discovery of their response to immune-checkpoint blocking drugs.

DNA-Polymerase Epsilon/D1 Deficiency Syndrome

As with the three syndromes described above only a fraction of the familial cases of colorectal cancer could be explained, the search has been on to further identify inherited risk factors, through whole genome sequencing combined with linkage disequilibrium studies in families with multiple colorectal adenomas and early-onset colorectal cancer.

Such studies identified germline mutation of the DNA-polymerase epsilon and D1 gene (*POLE* and *POLD1*) as a new autosomal dominant syndrome with high-penetrance predisposition to colorectal cancer. The exonuclease domain of the protein has proofreading activity and removes wrongly incorporated nucleotides during DNA replication. Mutations in the part of the gene encoding for this domain result in lack of fidelity of DNA replication. The ensuing hypermutated phenotype contributes to tumorigenesis. The associated syndrome is called polymerase proofreading-associated polyposis. In families with germline *POLE* mutations, a predisposition for multiple adenomas and early-onset is characteristic but neoplasms in endometrium, ovary, brain, pancreas, small intestine and skin (melanoma) have also been reported. *POLD1* mutations also predispose carriers to multiple colorectal adenomas and carcinoma and in addition endometrial and breast cancer. The phenotype associated with polymerase proofreading-associated polyposis is not fully defined yet and will be further detailed as more families with this syndrome are identified.

Consensus Molecular Subtypes (CMS) of Colorectal Cancer, Tumor Microenvironment and the Immune Response

In recent years a series of independent publications proposed sub-classifications of colorectal cancer based upon molecular criteria, varying from expression profiles to genome aberrations. These classifications shared certain characteristics in approach and resulting classification but were far from identical. To resolve this conundrum an international consortium composed of the groups responsible for the original publications worked out a gene expression-based classification system, which is now known as the "consensus molecular subtypes" (CMS) of colorectal cancer. This classification distinguishes four CMSs of colorectal cancer. Characteristics of CMS1 are MSI, mutations of *BRAF*, infiltration with TIL composed of Th1 cells and cytotoxic T-lymphocytes and activation of immune evasion pathways. CMS2 tumors are characterized by high chromosomal instability (CIN) and activation of Wnt and MYC pathways. In the CMS3 category, *KRAS* mutations are frequent, and metabolic pathways are disrupted. Finally, CMS4 tumors show a strong desmoplastic reaction along with high expression of mesenchymal genes and angiogenesis in which activation of the transforming growth factor beta (TGF-β) plays a central role. The biological significance of molecular subtyping initially was supported by a difference in prognosis between the subtypes, notably with poor prognosis for CMS4. Between the four CMS's significant differences in the tumor microenvironment have been reported with high numbers of cytotoxic T-lymphocytes and macrophages in CMS1 and 4. In contrast, in CMS4 (myo)fibroblast proliferation and collagen deposition are higher than in the other CMS's. These differences go along with different patterns of expression of chemokines, mediators of inflammation, genes involved in regulation of the immune response and of angiogenesis. With the stellar increase of interest in immunotherapy, a strong focus has developed on quantifying infiltrating immune cells which has become known as the immunoscore. However, understanding the role of the tumor microenvironment in biology and clinical behavior of colorectal cancer will require the comprehensive study of other cellular and molecular players.

Prognostic and Predictive Biomarkers

Colorectal cancer patients are stratified according to prognostic parameters in view of eventual adjuvant chemotherapy. Central in this exercise remain the classical TNM stage parameters tumor extension (T) and lymph node metastasis (N). As these lack in precision (**Table 1**), more accurate parameters are proposed almost monthly. Most of these, however, do not hold up in subsequent validation studies and presently beyond TNM, (lymph)vascular invasion is reported as a rule and tumor budding as a sign of invasive activity might be added in the near future. In MSS cancers the small subgroup with the *BRAF* V600E mutation have a particularly poor prognosis. *KRAS* mutations status has no prognostic significance for overall survival of stage II/III patients, but does predict poor prognosis in advanced (stage IV) cases. MS status has gained in importance as MSI-H cancers have a better prognosis, even though they might respond less favorably to chemotherapy. Other prognostic factors have not made it into daily clinical practice. Recently published tests such as Oncotype DX (multiplex RT-PCR based) and Coloprint (array-based) might provide additional prognostic value, but this needs to be independently validated.

As predictive biomarker, *KRAS* mutation status has become essential, notably for advanced colorectal cancer as *KRAS* mutated carcinomas do not respond to anti-EGFR therapy. The responsible mechanism is the position of KRAS downstream of EGFR in the MAPK pathway. Constitutive activation of KRAS renders approaches, blocking the upstream activity of EGFR, ineffective (**Fig. 12**). Of note, no *KRAS* mutated but also only about 40% of *KRAS* wild-type colorectal cancers respond to anti-EGFR treatment. This indicates that *KRAS* mutation status does identify a subset of non-responders but does not predict who will respond. More recently, the status of other genes involved in the pathway, including *PIK3CA*, *BRAF*, *NRAS*, and *pTEN* has been found to improve predictive

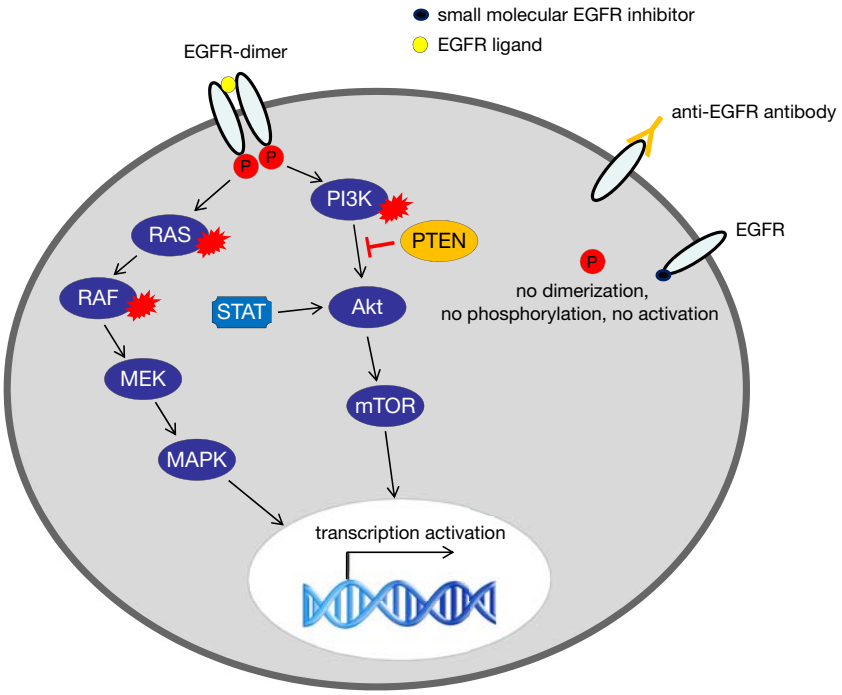

Fig. 12 Schematic representation of MAPK/mTOR signaling downstream of EGFR activation, and its role in insensitivity of KRAS mutated colorectal cancer for anti-EGFR treatment. Upon binding of an EGFR ligand to its receptor, EGFR dimerizes, phosphorylates and activates the signaling pathways. This can be inhibited by an anti-EGFR antibody or by a small molecular inhibitor. A mutation in *KRAS*, *RAF* or *PI3K* activates the pathway downstream of EGFR, thus circumventing EGFR inactivation. From Bosman, F. and Yan P. (2015). Molecular pathology of colorectal cancer. *Polish Journal of Pathology* **65**, 257–266. https://doi.org/10.5114/pjp.2014.48094.

power, but as yet unidentified genes are likely to be involved. MSI status identifies a subgroup of colorectal cancer patients with a high chance of favorable response to immunotherapy, notably PD1/PD-L1 blocking.

Prospects

For pathologists and for clinicians alike, heterogeneity of colorectal cancer remains a challenge. Which mechanisms are responsible for morphological heterogeneity? How can cancers that are histologically indistinguishable and in the same stage behave differently in terms of recurrence and response to chemotherapy? Some progress has been made with the introduction of molecular parameters and new molecular subtyping holds promise. However, this will have to be validated through molecular annotation of large series of colorectal cancers with detailed follow-up data. This will have to be repeated in connection with the emergence of new therapeutic targets and prognostic and predictive biomarkers.

An exciting field is the host response to the growing tumor cells, which creates the tumor micro-environment. It has become clear that the characteristics of the immune response of the host, in terms of the type, location and density of tumor infiltrating lymphocytes in combination with their functional molecular orientation, which together determine the immune contexture, have a significant impact on tumor progression and response to therapy. It will be essential to collect longitudinally samples from tumors before and after treatment, as they progress in recurrent or metastatic sites, as circulating tumor cells or circulating tumor DNA, to improve our understanding of the dynamics of tumor evolution and progression under therapy. Molecular analysis of such samples will clarify which (sub)clones exist in the primary tumor, which of these manage to gain access to the circulation and/or develop into a metastasis and how they respond to the selection pressure exerted by systemic therapy. Detailed knowledge of such tumor dynamics will ultimately allow the development of what has become known as "precision medicine," to improve outcome of patients with colorectal cancer.

Copy Number Variations in Tumors

Tao Huang, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai, China

Glossary

Biomarker An easy-to-measure indicator of the disease status or subtype.
Copy number variation The number of copies within a genome region is different from the normal number of copies, 2.
Pan-cancer Diverse tumor types that share similar cancer features yet show different characteristics.
Targeted sequencing Resequencing of an isolated region of genome.
Whole genome sequencing The sequencing of the complete DNAs within an organism.

Human is a diploid organism with two copies of alleles for autosomal and pseudo autosomal genes. If there are no longer two copies, CNV (copy number variation) happens. When there are more than two copies, it is called gain or amplification. When there are less than two copies, it is called loss or deletion. CNVs are very common in diseases, especially in tumors when the biological systems dysfunction on multiple levels. CNV is usually the upstream change that triggers the cascade of signaling chaos and therefore can be the driver of disease. In tumors, CNV is found to be a very good biomarker for subtyping and survival prognosis. And it is helpful for understanding tumorgenesis and how mutations happen and in which order.

In this review, we will introduce the latest computational methods for CNV detections, especially the challenges of tumor CNV detection, and how to use the CNV data to investigate the mechanisms of several major types of cancers.

The Computational Methods for NGS Based CNV Detection

With the rapid development of next-generation sequencing (NGS) technology, CNV detection becomes easier and many computational methods have been proposed. The difficulties of NGS based CNV detection are filtering the noise, determining the region of CNV and estimating the copy numbers. The most widely used CNV software include PennCNV, CNVkit, and CNVtools, GISTIC and others. CNVkit is highly recommended for targeted sequencing.

To summary the principles underlying these software, there are several approaches: read-depth based methods, paired-end mapping based methods, split-read based methods and sequence assembly based methods. The four methods for CNV detection are shown in Fig. 1. The first three methods need to map the reads onto the reference genome while the last methods need to assemble the sequence from the beginning.

 https://doi.org/10.1016/B978-0-12-801238-3.65047-X

The Read-Depth Based Methods

The read-depth based methods are most intuitive and straightforward. These methods analyze the read depth at each position of the genome and find the differences across regions. It assumes that the read depth and copy number are positively correlated. This is generally correct, since the reads are randomly generated and should cover the genome without bias. Therefore, when a region is amplified or deleted, the reads within that region will change accordingly. But it is observed that the GC content can significantly affect the read depths. Usually, the region with extremely high or low GC content will have fewer reads. Another disadvantage of read depth methods is that the region with a lot of repeats tend to have more mapped reads since the mapping software could not assign the read onto the right region. This problem will become more serious when the length of reads is short. The simple but not perfect solution is to only consider the uniquely mapped reads or assign such reads onto a randomly chosen region. CNVnator is a representative CNV detection software that uses read-depth approaches.

The Paired-End Mapping Methods

The paired-end mapping methods need to break the DNA sequence into fragments with fixed length and then sequencing from both ends. Since the reads are paired, the mapped position of two reads within a pair can provide important information of the genome structure. It can not only detect CNV but also structural variation. When the distance between the mapped positions of two reads from a read pair is significantly short or long, this read pair is discordantly mapped and indicates CNVs between them. By clustering such discordantly mapped read pairs, the CNV regions and copy numbers can be detected. BreakDancer is one of the software that use paired-end mapping approaches.

The Split-Read Based Methods

The split-read based methods split the reads into smaller fragments and map the split fragments onto reference genome. To analyze the break point of the read with fragments that are mapped onto different regions, the CNV position can be accurately detected and the position can be as accurate as one base pair. If two fragments form one read are mapped onto two positions with a gap, it indicates a deletion between these two positions. If one fragment from a read can be mapped but the other fragment from this read can't be mapped, it indicates an insertion. How to split the reads is difficult to decide. To try more split methods means more computational time. And if the length of the original read is short, it will be difficult to split them and expect the even smaller fragments can be mapped onto the genome correctly. One of the split-read based software is Pindel. Generally speaking, the split-read based methods are slower.

The Sequence Assembly Based Methods

The sequence assembly based method does not require a reference genome and does not do mapping. It assembles the genome de novo and then detect the CNVs by analyzing the assembled genomes. Since the whole genome assembly is quite difficult, it usually does de novo assembly and local assembly to generate sequence clusters and compares with close reference genomes. Similar as read-depth based methods, the assembly based methods performs poorly at genome regions with many repeats. Velvet is a representative software that uses assembly based methods.

The Challenges of Tumor CNV Detection

Although there are already many software for CNV detections, it is still difficult to perform CNV detection for tumor samples. The main challenge is that the tumor samples usually are not pure tumor cells and include normal cells. This will contaminate the tumor sample and make the CNV detection from NGS data difficult. Even with careful selection to make sure the samples are from tumor, the heterogeneity of tumor cells is still troublesome. Single cell sequencing may be a good solution for this problem. But the small amount of DNA in single cell sequencing makes the sequencing procedure and analysis challenging. We need to distinguish the duplication during PCR, low coverage due to the small amount of DNA and actual CNVs.

Second challenge is that most methods assume that the genome is stable and most regions are diploid. But in tumor samples, it is quite common to have large structural variation and aneuploidy on a genome wide scale. Such systematic errors may cause great bias for CNV detection. It is better to detect structural variations before detecting CNVs for tumor samples. The contamination with normal cells, tumor heterogeneity, and tumor aneuploidy are very common in tumor samples and will make the CNV detection difficult.

The CNVs Contribute to Tumor Initiation and Progression

With the accumulation of more and more CNV data, several CNV databases have been built, such as CNVD and SCAN. And large tumor CNV datasets, such as TCGA (The Cancer Genome Atlas) and METABRIC (Molecular Taxonomy of Breast Cancer International Consortium), have been released.

Various pathological CNVs have been identified to be associated with tumor initiation and progression. For example, CNVs of well-known breast cancer genes *BRCA1* and *BRCA2*, are observed in breast cancer patients and suggest that the CNVs contribute to breast cancer. We will discuss the functions of CNVs in several major cancers.

CNVs in Breast Cancer

We downloaded the GISTIC processed TCGA breast cancer (BRAC) CNV data and METABRIC breast cancer data. The CNV status were quantified as "−2" for homozygous deletion, "−1" for heterozygous deletion, "0" for diploid, "1" for low-level gain, and "2" for high-level amplification. In TCGA and METABRIC breast cancer dataset, the most common deep deletion genes were *CSMD1*, *MYOM2*, *CDKN2A*, *DLGAP2*, *ERICH1*, *PTEN*, *RPL23AP53*, *ZNF596*, *ARHGEF10*, *CDKN2B*, and *KBTBD11*; the most frequent high-level amplification genes were *TRPS1*, *MYC*, *CASC8*, *LINC00536*, *PVT1*, *CCAT1*, *EIF3H*, *MIR1205*, *MIR1208*, and *TMEM75*. In breast cancer, gene amplification is more common than deletion. The frequencies of amplification and deletion in TCGA and METABRIC breast cancer datasets were shown in Fig. 2.

In Fig. 3, we plotted the top three deletion genes, *CSMD1*, *MYOM2*, *CDKN2A*, and the top three amplification genes, *TRPS1*, *MYC*, *CASC8*, in TCGA and METABRIC breast cancer dataset. It can be seen that the frequencies of the top amplification genes were much higher than the top deletion genes. The top amplification genes were consistently amplified in two datasets while the top deletion genes were deleted in most samples but amplified in a small proportion of other samples.

To investigate the CNV consistency in breast cancer, we plotted the amplification and deletion frequencies in both TCGA and METABRIC breast cancer dataset in Fig. 4. It can be seen that although the deletion frequencies of *CSMD1*, *MYOM2*, and *CDKN2A* were high in both TCGA and METABRIC, there were considerable large proportions of breast cancer samples from both TCGA and METABRIC with amplification of these genes. For top amplification genes *TRPS1*, *MYC* and *CASC8*, there were no deletions in 3253 TCGA and METABRIC breast cancer patients.

The CNV status of genes were reported to be associated with breast cancer stages, overall survival and disease-free survival. More specifically speaking, the breast cancer patients with deletions of *C20orf46* and *SCUBE2* had shorter overall survival time. And the

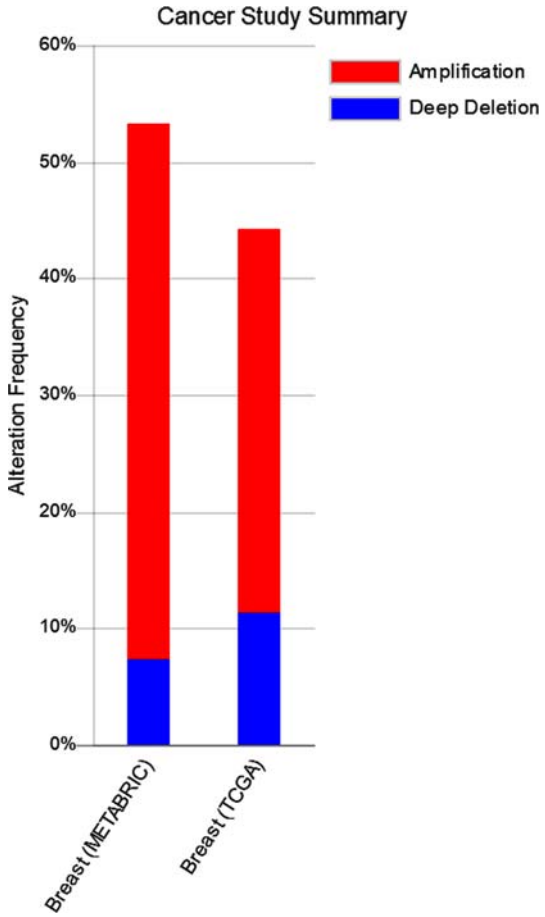

Fig. 2 The frequencies of amplification and deletion in TCGA and METABRIC breast cancer datasets. In breast cancer, the amplification is more common than deletion.

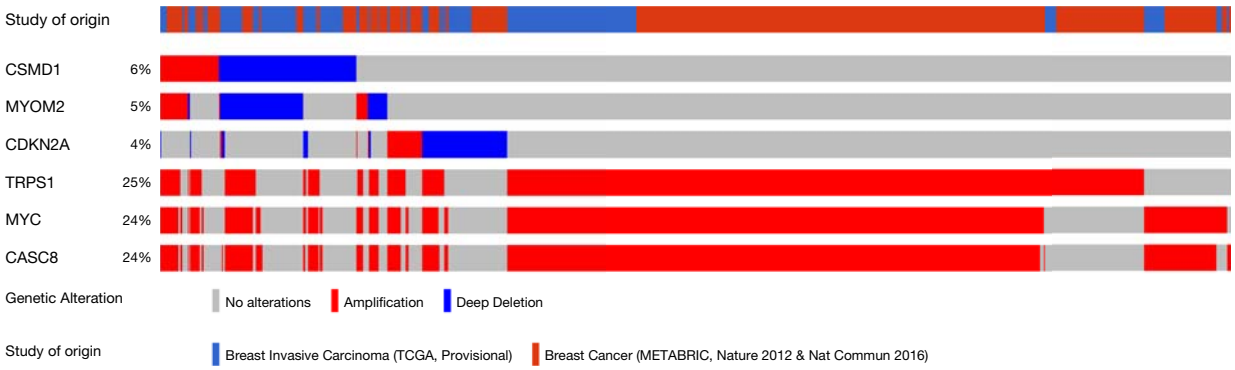

Fig. 3 The OncoPrint of the deletion genes, CSMD1, MYOM2, CDKN2A and the amplification genes, TRPS1, MYC, CASC8, in TCGA and METABRIC breast cancer dataset. CSMD1, MYOM2, CDKN2A were the top three deletion genes and TRPS1, MYC, CASC8 were the top three amplification genes. The patients without CNVs of these genes were not shown.

gain of *ZFP14*, *GSTM2*, and *JAK1* tended to have bad effect on overall survival while the loss of *PDGFRA* tended to have good effect on extend the overall survival. The loss of *PDGFRA* can not only extend survival time, but also postpone breast cancer recurrence. The gain of *ZFP14* and *LCE3C* will significantly accelerate breast cancer recurrence.

CNVs are not only biomarkers for breast cancer subtyping or prognosis prediction, but also useful for understanding how breast cancer begins and in which temporal order the mutations occur. With the oncogenetic tree model, the chronological CNV mutation timeline can be inferred. The general mutation orders of key driver genes in breast cancer were as follows: the *ERBB2* CNV mutation happened first, then the copy numbers of *AKT2*, *KRAS*, PTEN, and *CCND1* became abnormal and the mutation changes of *PIK3CA* happened after the changes of *KRAS*.

The CNV pattern of breast cancer varies a lot in different patients. Age is an important factor. For example, the prevalence of *PIK3CA* CNV in young breast cancer patients under 45 years old was much smaller than its prevalence in elderly patients over 70 years old. The prevalence of *TP53* mutations was the highest in patients between 46 and 69 years old. The mutation of *GATA3* only occurred in young patients under 45 years old but not in old patients while the mutations of *CDH1* were only found in patients over 45 years old. Another factor is ethnicity. For example, the amplification of 3q26.1 was detected in Chinese breast cancer patients but not in other populations.

CNVs in Lung Cancer

Non-small cell lung cancer (NSCLC) is the most common subtype of lung cancer and it includes adenocarcinoma and squamous cell carcinoma. In a CNV array dataset of over 200 lung adenocarcinoma patients and about 100 lung squamous cell carcinoma patients, 266 discriminative CNV probes were identified. They were able to classify the adenocarcinoma patients and squamous cell carcinoma patients nearly perfectly. They were from pathways, like hsa04310 Wnt signaling pathway, hsa04510 Focal adhesion, and hsa04512 ECM-receptor interaction. They located in the chromosome regions of 2q34, 10p15, 18q11, 3q26, 8p23, 3p21, 3q27, 22q12, Xq13, 2q36, 10p11, and 10p12. The CNV pattern of lung adenocarcinoma and squamous cell carcinoma are very significantly different.

There are many published array-based CNV signatures. Will these signatures still be useful if the NGS is used? To investigate this, we selected 20 CNV genes that can classify the adenocarcinoma patients and squamous cell carcinoma patients and mapped these genes on TCGA lung adenocarcinoma and TCGA lung squamous cell carcinoma dataset. The OncoPrint of the 20 CNV signatures derived from array data in the NGS based TCGA lung adenocarcinoma and TCGA lung squamous cell carcinoma dataset was shown in Fig. 5. It can be seen that the array-based CNV signatures can still classify the NGS lung adenocarcinoma and lung squamous cell carcinoma samples correctly. The genes *ESRRG* and *FZD8* were amplified more often in lung adenocarcinoma; *CD69* was deleted more frequently in lung adenocarcinoma. In lung squamous cell carcinoma, *TP63*, *NAALADL2*, *SOX2*, *BCL6*, *DGKG*, *DLG1*, *IL1RAP*, *LPP*, *LRRC15*, *MED12L*, *NLGN1*, *PAK2*, *PLSCR1*, *PLSCR2*, *TNIK*, *USP13*, and *ZIC4* were amplified more frequently. The array-based results and the NGS-based results were consistent. These results proved that the accumulated CNV array signatures can be adopted in the NGS-based methods.

The CNV is not just an adenocarcinoma or squamous cell carcinoma biomarker, but also indicates drivers for dysfunctions of multiple levels in lung cancer. By integrating CNV with gene expression, microRNA expression, DNA methylation in TCGA squamous cell lung carcinoma dataset, a whole genome wide integrative regulatory network can be constructed using regression model. The CNV of *FSCB*, *TCL6*, *MECOM*, *BCHE*, *ANO9*, *FBXO17*, *AGAP2*, and *C9orf53* were found to be the key drivers of the gene expression, microRNA expression, DNA methylation dysfunctions associated with lung squamous cell lung carcinoma. There have been many reports of how CNV affects gene expression through dosage effects. The regulatory roles of CNV in the integrative network of lung squamous cell lung carcinoma confirmed that CNV could regulate gene expression with dosage effect.

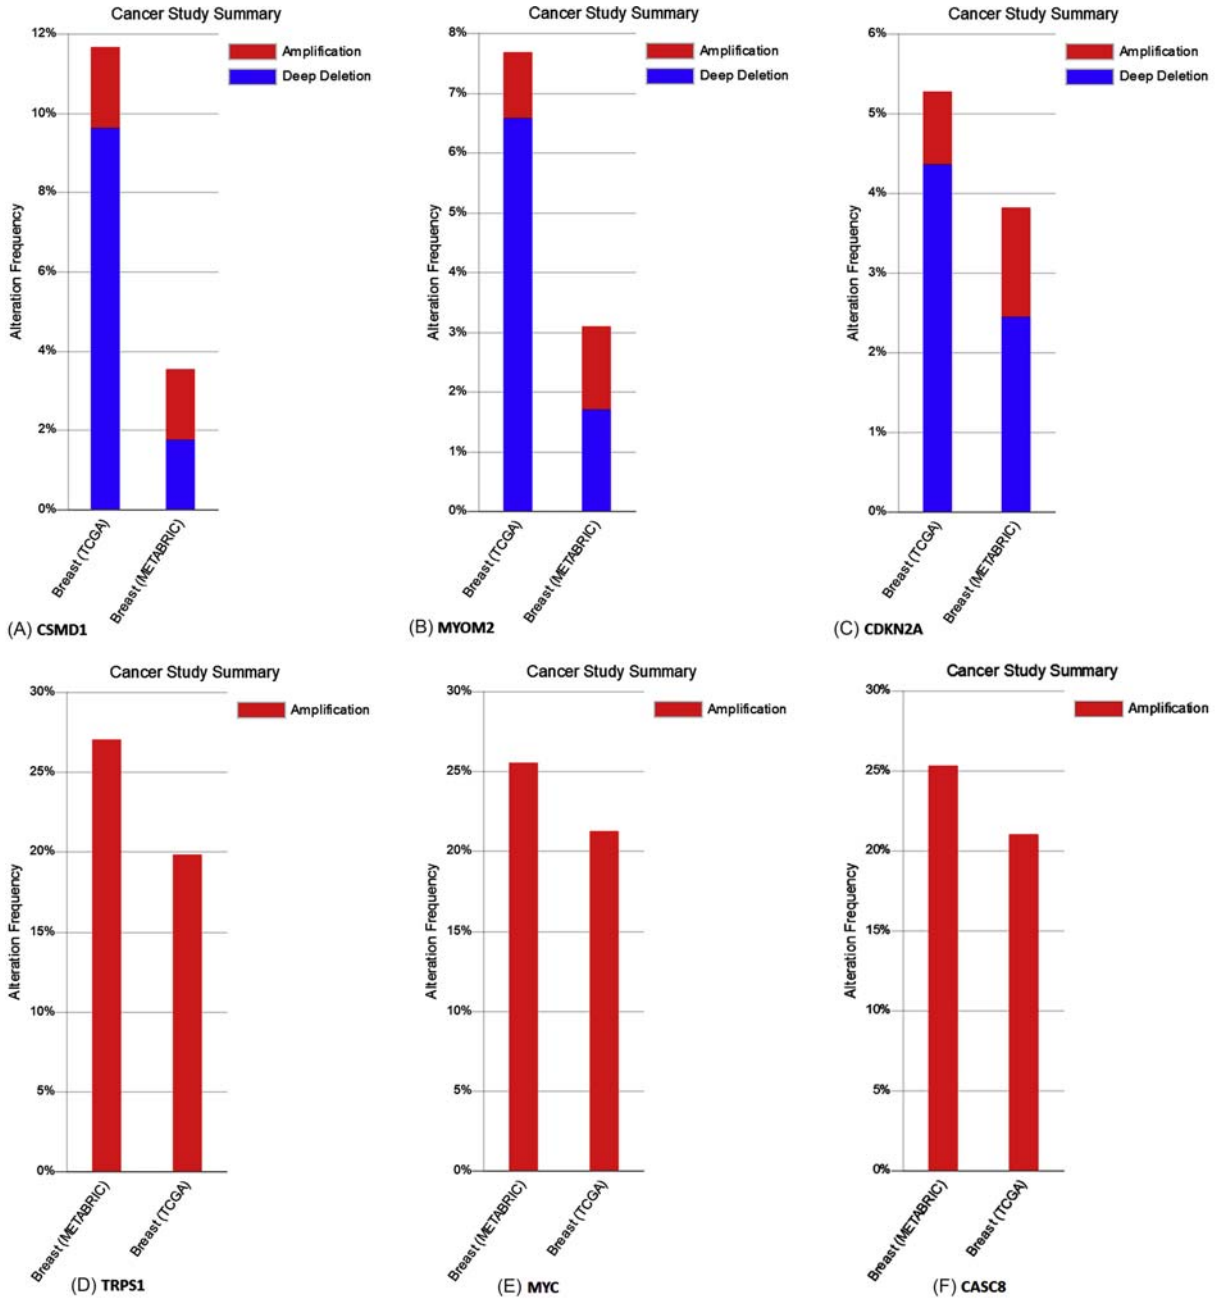

Fig. 4 The amplification and deletion frequencies of CSMD1, MYOM2, CDKN2A, TRPS1, MYC, and CASC8 in TCGA and METABRIC breast cancer dataset. The amplification and deletion frequencies of CSMD1 (A), MYOM2 (B), CDKN2A (C), TRPS1 (D), MYC (E), and CASC8 (F) in TCGA and METABRIC breast cancer dataset.

CNVs in Colorectal Cancer

In TCGA colon and rectal cancer dataset, the CNVs were measured using Affymetrix SNP 6.0 arrays. Meanwhile the methylation, microRNA and mRNA were quantified with Illumina HumanMethylation27 BeadChip, Agilent miRNA-Seq and Illumina RNA-Seq, respectively. The regulatory effect of CNV, methylation and microRNA on mRNA levels can be modeled as a linear regression. Based on how well the CNV, methylation and microRNA data can predict the gene expression level, the CNV-regulated genes, the methylation-regulated genes and the microRNA-regulated genes can be identified. The functions of these genes were investigated. It was found that the CNV-regulated genes have very different functions compared with the methylation-regulated genes and the microRNA-regulated genes. This finding indicates that the CNV is a unique regulator of gene expression.

Based on the TCGA colorectal cancer dataset, the CNVs prefer to regulate genes of cellular macromolecule metabolic process, gene expression, macromolecule modification, cellular protein modification process, protein modification process, transferase

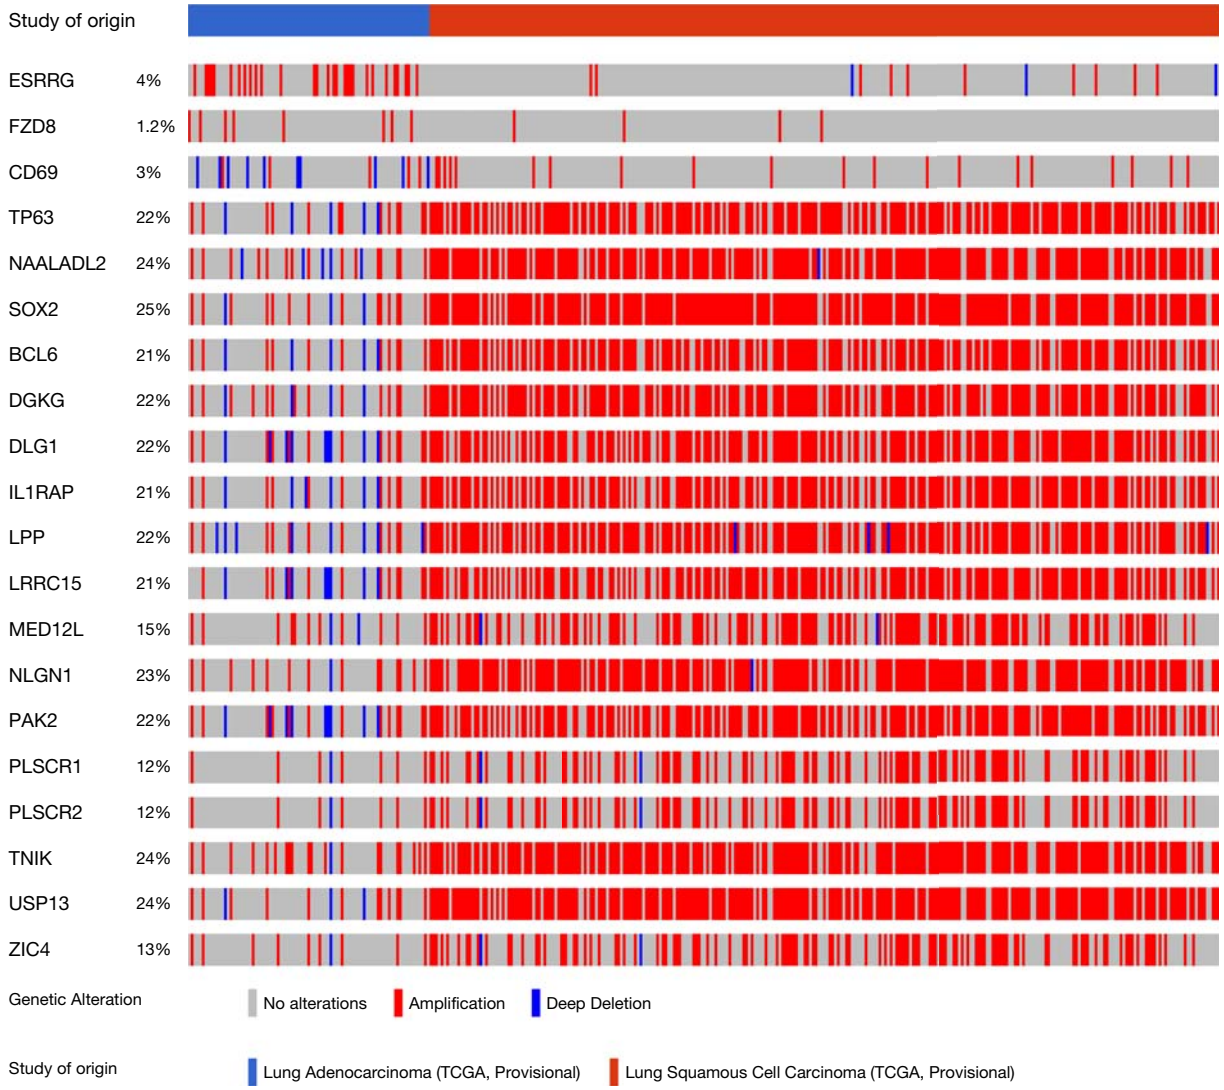

Fig. 5 The OncoPrint of the 20 CNV signature derived from array data in the NGS based TCGA lung adenocarcinoma and TCGA lung squamous cell carcinoma dataset. The array based CNV signature can still classify the NGS lung adenocarcinoma and lung squamous cell carcinoma samples correctly.

activity, transferring phosphorus-containing groups, protein kinase activity, phosphotransferase activity, and alcohol group as acceptor. The CNV-regulated genes are not like the methylation-regulated genes which are mostly from anatomical structure morphogenesis, immune system process, regulation of multicellular organismal process, response to external stimulus and calcium ion binding, or the microRNA-regulated genes that are enriched onto single-organism process, single-organism cellular process, biological regulation, protein binding, receptor activity, signal transducer activity, molecular transducer activity, and signaling receptor activity.

Through regulating key genes in colorectal cancer, CNV plays important roles for prognosis. For example, the CNV of *UQCRB* is a prognostic predictor for colorectal cancer. The receiver operative characteristic curve (AUC) of *UQCRB* CNV gain was 0.891. The CNVs of *CHD8*, *CD47*, and *RERG*, *ARHGDIB* are associated with colorectal cancer risk. The CNV of *TNFRSF10C* is associated with colorectal cancer metastasis. Similarly, there are also population specific CNVs in colorectal cancer. It was reported that the *ZNF217* and *CYP24A1* tend to be gained simultaneously in Chinese colorectal cancer patients.

CNVs in Pan-Cancer

The TCGA dataset is a large multi-omics dataset with about 30 types of cancers. The CNVs of 19 genes (*RPS15*, *IL17RC*, *CUL2*, *SMPD3*, *MIR4703*, *CDKN2A*, *RFFL*, *CTBP2*, *MMD2*, *SEMA6A*, *ZFPM1*, *CDC25A*, *ZMYND11*, *KBTBD6*, *CELF5*, *EGFR*, *PIGL*, *ZNF503-AS1*, *RBFOX1*) were found to be able to classify six major cancer types in TCGA: BRCA (breast invasive carcinoma),

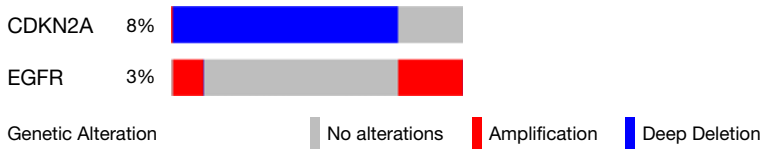

Fig. 6 The OncoPrint of CDKN2A and EGFR in MSK-IMPACT. Within the MSK-IMPACT cohort which included over 10,000 patients and over 360 types of cancers, 8% of them had CDKN2A deep deletion and 3% of them had EGFR amplification. The patients without CNVs of these two genes were not shown.

COAD/READ (colon adenocarcinoma/rectum adenocarcinoma), GBM (glioblastoma multiforme), KIRC (kidney renal clear cell carcinoma), OV (ovarian serous cystadenocarcinoma) and UCEC (uterine corpus endometrioid carcinoma). The accuracy of the 19-gene CNV signature was over 75%.

Another large pan-cancer CNV dataset is MSK-IMPACT in which over ten thousand cancer samples were included but only over four hundred genes were measured. The OncoPrint view of CNV will show how broadly CNV happens in cancer and how different their CNV pattern are. In Fig. 6, we plotted the OncoPrint of two genes from the 19 gene CNV signature discovered from TCGA dataset, *CDKN2A* and *EGFR*. Within the MSK-IMPACT cohort which included over 10,000 patients and over 360 types of cancers, 8% of them had *CDKN2A* deep deletion and 3% of them had *EGFR* amplification.

The Clinical Applications of CNVs in Tumors

As we discussed above, the CNV patterns were different in tumor and normal samples, different tumor subtype samples, tumor patients with different drug response, tumor patients with different survival time. CNV is an important biomarker. Unlike gene expression which can be easily disturbed and shows randomness, CNV is more robust and stable. Since it is known that the normal copy number for human is 2, it doesn't require complicated normalization baselines like gene expression based methods, such as RT-PCR, microarray or RNA-Seq. All these characteristics of CNV make it a perfect tumor signature.

In clinical practice, the targeted NGS-based CNV panels are widely used and highly reproducible. In a study with one cohort of 391 samples and another cohort of 2375 samples, 37 unique CNV events were detected by nine targeted NGS panels with 100% sensitivity. This assessment of CNV applications in clinical laboratory testing shows how reliable CNV biomarkers are.

There are many commercial CNV panels. For example, NanoString Technologies has an nCounter® v2 Cancer Copy Number Assay which includes 87 common tumor CNV genes, such as *AKT*, *BRCA*, *ERBB2*, *MYC*, *PIK3CA*, and *PTEN*. This panel can be used for formalin-fixed, paraffin-embedded (FFPE) samples. ArcherDX, Inc. has a comprehensive thyroid and lung (CTL) kit that can detect common oncogenic CNV drivers in lung cancers. NGeneBio Co., Ltd. also has a lung cancer kit called LUNGaccuTest™ that can easily detect lung cancer CNVs.

Unlike whole genome CNV analysis, the CNV panel analysis focus on a small set of genes but requires much higher accuracies since the results will directly affect the clinical practice, such as how to treat the cancer patients. Among the open source software, CNVkit is designed for targeted DNA sequencing and is a good choice for panel CNV data analysis. Of course, there are commercial software that are designed for specific platforms. For example, the NanoString platform has nCounter® Digital Analyzer.

Overall, CNV can be a great biomarker for tumors. It can be applied for tumor subtyping, drug response prediction, survival time prediction. If we can choose the right genes based on genome-wide CNV investigation, the targeted CNV panel can be easily designed and applied. We believe that more and more CNV applications in tumor diagnostics will be developed and applied.

Prospective Vision

The CNV analysis becomes more and more widely used. There are two big challenges. One is the CNV analysis in single-cell and ctDNA (circulating tumor DNA). When the amount of DNA is small or the genome is incomplete, the CNV measurements will become difficult and we must adjust these effects to distinguish actual copy number deletion and artificial low DNA fractions in a specific region. Another challenge is the integrative analysis of CNV with other multi-omics data. The CNV is only one level of data in the complex system of cancer which involves dysfunctions at almost all levels of regulation including SNP, CNV, methylation, mRNA, microRNA, lncRNA (Long non-coding RNA), circRNA (Circular RNA), protein, PTM (post-translational modification), and metabolites. We should not only study them on each level, but also integrate them and get a systems level picture of how tumors develop and progress.

Glossary

DNA methylation The addition of methyl groups from the methyl group donor *S*-adenosyl-L-methionine onto carbon five of cytosine residues in DNA resulting in the formation of 5-methylcytosine. This enzymatic reaction is carried out by DNA methyltransferases and occurs preferentially at CpG sequences in most tissues.

DNA demethylation The loss of 5-methylcytosine from DNA resulting in replacement of 5-methylcytosine with cytosine. Demethylation can occur passively by continuing DNA replication in the absence of DNA methyltransferases, or actively, by TET protein-mediated oxidation of the methyl group of 5-methylcytosine.

Epigenetics The study of mechanisms that cause changes in gene expression based on chromatin-linked events that do not involve direct changes in the DNA sequence.

IDH Isocitrate dehydrogenase, an enzyme of the tricarboxylic acid (TCA) cycle that provides the TET enzyme cofactor alpha-ketoglutarate.

TET proteins Ten-Eleven-Translocation (TET) proteins are 5-methylcytosine oxidases that oxidize the methyl group of 5-methylcytosine leading to sequential formation of 5-hydroxymethylcytosine, 5-formylcytosine and 5-carboxylcytosine.

TDG Thymine DNA glycosylase, an enzyme that was initially reported to remove thymine from T/G mispairs. TDG has strong activity to excise 5-formylcytosine and 5-carboxylcytosine from DNA. The resulting abasic site is processed by base excision repair. After TET-initiated 5-methylcytosine oxidation and base excision repair involving TDG, the outcome of these reactions is DNA demethylation.

Introduction

5-Methylcytosine (5mC) is an enzymatically produced modified cytosine base that has been known to exist in mammalian DNA for about 70 years. These decades of research have provided important clues as to its presumed functional role but there is no complete understanding yet. Numerous correlative studies have shown that the presence of 5mC at gene control elements such as promoters and enhancers is not compatible with gene expression. 5mC can directly interfere with binding of transcription factors. This modified base is often associated with inactive, repressed chromatin characterized by lack of histone acetylation. In some genomic regions, 5mC tends to co-exist with nucleosomes methylated at lysine 9 of histone H3 (H3K9me3), for example at repetitive DNA regions, or with nucleosomes methylated at lysine 36 of histone H3 (H3K36me3), when found in gene bodies. One major role of 5mC seems to be the suppression of unwanted gene activity, in particular its presence is thought to ensure the silenced state of retroviral and repetitive elements in the genome. This function could be described as aiming to reduce transcriptional noise genome-wide leaving unmethylated genomic regions as recognizable landmarks associated with active genes.

A surprising discovery in the field was made in 2009 when two research groups reported that 5mC is not the only modified base in mammalian genomes. An oxidized form of 5mC, 5-hydroxymethylcytosine (5hmC) was detected initially in embryonic stem cells and in certain types of neurons in the brain. The levels of 5hmC in brain tissue can be quite substantial and may represent up to 1% of all cytosines, being equivalent to a quarter to a third of all 5mC in neuronal cell types. In most other tissues, the levels of 5hmC range from about 005% to 0.2% of all cytosines, which is about 20–80 times lower than the levels of 5mC. Predominantly, 5hmC occurs at CpG dinucleotides. Like 5mC, which is a product of DNA methyltransferase activity, 5hmC is produced enzymatically. Mammalian genomes encode three evolutionary conserved proteins that can catalyze the conversion of 5mC to 5hmC by enzymatic oxidation. They are named TET1, TET2, and TET3. This name comes from the fact that TET1 was initially described as a gene involved in a translocation in leukemia involving chromosomes 10 and 11 (*T*en-*E*leven-*T*ranslocation 1, or TET1). The enzymatic reaction involves the transfer of molecular oxygen to the methyl group and requires the cofactors alpha-ketoglutarate (αKG), Fe^{2+} and ascorbate, the latter being important to preserve the 2+ state of iron (Fig. 1).

Although 5hmC is a modified DNA base that can be readily detected and quantitated by antibody-based assays or by mass spectrometry-based approaches in tissue samples, in vitro studies with purified TET proteins showed that the reaction does not stop at the 5hmC base, but can proceed to create 5-formylcytosine (5fC), and 5-carboxylcytosine (5caC) (Fig. 2). However, in cultured cells or in tissues, the latter oxidation products are only barely detectable suggesting that they are either not effectively produced in vivo or that they are eliminated rapidly. One plausible pathway to process 5caC bases would be a decarboxylation reaction leading instantaneously back to unmodified cytosine (Fig. 2). Decarboxylation of 5caC does not occur spontaneously to a significant extent. So far, decarboxylase activity has not been demonstrated as an enzymatic function of TET proteins, and 5caC DNA decarboxylase enzymes have not been identified. Instead, it was shown that 5fC and 5caC can be removed from DNA by the base excision repair (BER) pathway initiated by thymine DNA glycosylase (TDG). This enzyme was previously known

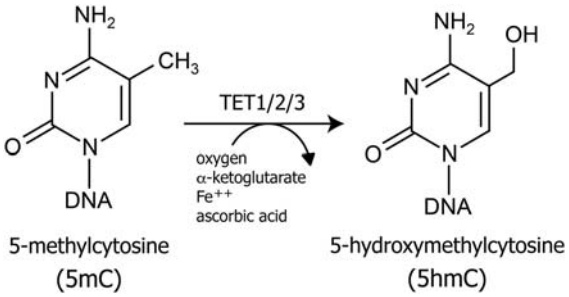

Fig. 1 Formation of 5-hydroxymethylcytosine by TET protein catalytic activity. The TET enzymes oxidize 5-methylcytosines at CpG sequences in DNA. They require oxygen, alpha-ketoglutarate, Fe^{2+} and ascorbic acid as cofactors.

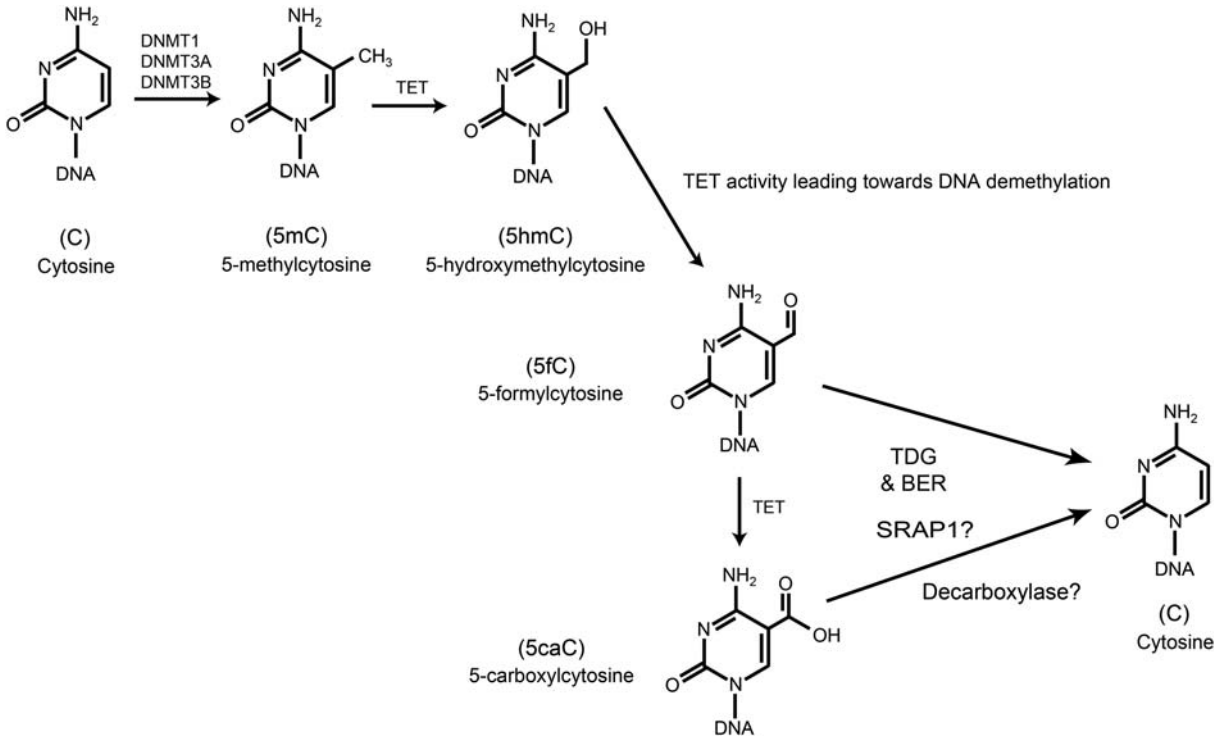

Fig. 2 Sequential enzymatic oxidation of 5-methylcytosine by TET proteins results in DNA demethylation. The TET enzymes oxidize 5mC to 5hmC, 5fC and 5caC at CpG sequences in DNA. 5hmC is observed as a relatively stable DNA base in cells. When 5hmC undergoes further oxidation, the pathway proceeds towards DNA demethylation via base excision repair that removes 5fC and 5caC from DNA. A 5caC decarboxylase is hypothetical and has not yet been identified.

to remove thymine from T/G mispairs in DNA, which are formed by spontaneous hydrolytic deamination of 5mC. This TDG-initiated DNA repair step seems to be important for cellular survival and genome integrity inasmuch as 5fC and 5caC are capable of arresting the progression of RNA and DNA polymerases on templates containing these oxidized bases. An alternative pathway for removal of 5caC bases that uses the SRAP1 autopeptidase-endonuclease has recently been described. It is still not well understood under what physiological conditions the TET-initiated 5mC oxidation pathway proceeds from 5hmC to the higher oxidized forms of 5mC resulting in complete elimination of the modified base (Fig. 2).

The biological role of 5hmC (and of 5fC and 5caC) as specific signaling marks rather than them simply being intermediates in an active DNA demethylation process has also been discussed. Several candidate proteins that may interact with oxidized 5mC bases have been identified using a mass spectrometry-based screening approach. However, the biological roles of these proteins when recognizing oxidized 5mC bases are not understood.

The first indication that the 5mC oxidation pathway may play an important role in tumorigenesis came from the discovery of common mutations in the *TET2* gene in hematological malignancies. We will discuss these mutations as well as other genetic and epigenetic changes in tumors that affect the balance between 5-methylcytosine formation and 5-methylcytosine removal (DNA demethylation).

TET2 Mutations

Around the same time when 5-hydroxymethylcytosine and the TET enzymes that produce this base modification were first reported, an analysis of hematological malignancies uncovered frequent mutations in the coding sequence of the *TET2* gene. This comprehensive analysis of *TET2* in over 400 hematopoietic tumor samples revealed *TET2* somatic mutations in 7.6% of myeloproliferative neoplasms, 42% of chronic myelomonocytic leukemia (CMML) and in 12% of acute myeloid leukemia (AML) cases analyzed. Many additional studies confirmed the prevalence of TET2 mutations in AML, myelodysplastic syndrome (MDS) and in CMML. However, TET2 mutations are uncommon in solid tumors as revealed by numerous cancer genome sequencing studies. The *TET2* mutations in hematological tumors are generally point mutations or deletions that lead to a lack of a functional protein, for example by truncation mutations or by point mutations in the catalytic domain. In many cases, one wildtype TET2 allele remains intact. The TET2 mutations are considered early events in the malignant transformation process. They also occur at low frequency during normal aging leading to clonal hematopoiesis.

Tet2-deficient mouse models also show an expansion of myeloid progenitor cells leading to the accumulation of pre-leukemic cell clones and the development of myeloid malignancies resembling CMML, MPD-like myeloid leukemia, and MDS, similar to the human disease. Somewhat surprisingly, the same human hematopoietic malignancy may harbor mutations in *TET2* and in the DNA methyltransferase gene *DNMT3A*. Such a finding suggests that TET2 and DNMT3A may have different genomic targets that are affected differentially by functional inactivation of either epigenetic enzyme. Mutation of both *Tet2* and *Dnmt3a* in mouse models leads to more severe phenotypes than single mutations of these genes. It is likely that TET2 loss of function, even when only partial, will lead to an imbalance of the methylation–demethylation cycle and one expectation is that CpG methylation at TET2-targeted loci should be increased. However, published studies have shown both a predominant loss and a predominant gain of methylation in tumors harboring TET2 mutations. One reason for the seemingly disparate finding may be that the tumors analyzed carry additional mutations in other epigenetic modifier genes (e.g., *DNMT3A*, *EZH2*) and it is difficult to judge the impact of a single mutation on genomic methylation patterns.

Ascorbic acid is an important co-factor for TET activities. Many standard cell culture media lack ascorbic acid, which could be one explanation for the extremely low levels of 5hmC generally found in cells propagated in tissue culture. Treatment of TET2-deficient cells with vitamin C enhances 5-hydroxymethylcytosine formation and suppresses human leukemic cell colony formation and leukemia progression. This effect is likely mediated by activation of TET3. TET2 and TET3, although they may also have unique gene targets, are believed to function redundantly in many tissues.

Mutations in TET1 and TET3

TET1 and *TET3* are rarely mutated in human tumors and no such mutations were identified in an initial screening of a variety of hematological malignancies. According to the COSMIC database, *TET1* is found mutated in a few percent, generally less than 5% of the cases of endometrial, stomach and intestinal tumors. *TET3* mutations are only found very rarely in solid or hematological tumors. Although *TET2* is expressed at high levels in cells of the hematopoietic system partially explaining its frequent mutation in hematological diseases, it is unknown why TET1 and TET3 are rarely affected by mutations in other tumor tissues.

IDH1 and IDH2 Mutations

Isocitrate dehydrogenases are NAD(+)- or NADP(+)-dependent enzymes that catalyze the conversion of isocitrate to alpha-ketoglutarate by oxidation and decarboxylation reactions. These enzymes are associated with the tricarboxylic acid (TCA) cycle. Mutations at specific amino acids of IDH1 were initially found in human brain cancers including astrocytomas, oligodendrogliomas and some glioblastomas. They are most common in lower grade gliomas (grade II or grade III). Mutations in IDH1 or IDH2 are also seen in acute myeloid leukemias, cholangiocarcinomas and in chondrosarcomas. The most common IDH1 mutations affect an amino acid within the active site of the protein and changes codon 132 from arginine to histidine. The change results in a gain of function producing a neomorphic enzyme that produces 2-hydroxyglutarate instead of alpha-ketoglutarate. Indeed, 2-hydroxyglutarate accumulates to high levels in IDH1-mutant cells. The theory proposes that 2-hydroxyglutarate is a competitive inhibitor of a number of alpha-ketoglutarate-dependent dioxygenase enzymes. In fact, the 2-hydroxyglutarate metabolite was shown to inhibit TET enzymatic activities leading to a defect in 5mC oxidation and thus to an accumulation of 5mC at genomic location that would normally be targeted by TET activities. As a result, IDH1-mutant gliomas are characterized by an overabundance of hypermethylated CpG islands (also called CpG island methylator phenotype or "CIMP"). In some instances, these hypermethylation events, for example when occurring at promoters of genes, will lead to silencing of the linked gene. One other class of dioxygenase enzymes that are effectively inhibited by 2-hydroxyglutarate are the large group of alpha-ketoglutarate-dependent histone lysine demethylases of the JmjC-domain family. The effect of IDH1 mutation will be an increase of the methylated state of different lysines on histone tails, for example, resulting in a potential dysregulation of gene expression. Since many lysine demethylases may be affected simultaneously, the disruption of the epigenetic state at specific gene loci is expected to be complex.

IDH1 or IDH2 mutations are relative early occurrences in glioma pathogenesis. They are a very common event in lower grade gliomas occurring in up to 80% of astrocytomas and oligodendrogliomas. Different molecular pathways seem to follow IDH1/2

mutations during tumor progression. These events include the loss of chromosomes 1p and 19q and the acquisition of *TERT* promoter mutations in oligodendrogliomas and mutations of *TP53* and *ATRX* in astrocytomas. On the other hand, mutation or amplification of the epidermal growth factor receptor gene (*EGFR*) occur rarely in IDH1-mutant brain tumors but are common in IDH1-wildtype primary glioblastomas. Mutations in IDH1/2 and TET2 do not co-occur in AML suggesting that the same downstream targets may be impacted by these mutations and that inhibition of TET2 activity by 2-hydroxyglutarate is indeed a key mechanism in disease pathogenesis.

Succinate and Fumarate

Two successively operating mitochondrial enzymes of the TCA cycle, succinate dehydrogenase (SDH) and fumarate hydratase (FH) show heterozygous mutations in their genes that cause predispositions to two types of inherited cancer syndromes. SDH mutations are linked to paraganglioma (PGL) and phaeochromocytoma and FH mutations predispose to leiomyomatosis and renal cell carcinoma. Mutation of these enzymes will lead to accumulation of their substrate metabolites, succinate and fumarate and dysregulation of metabolic pathways. Similar to 2-hydroxyglutarate, these metabolites are also competitive inhibitors of alpha-ketoglutarate-dependent dioxygenases, that is, lysine demethylases, 5-methylcytosine oxidases and prolyl hydroxylases. These events will likely lead to perturbations of epigenetic states of DNA and histones. However, these two genes are rarely mutated in other types of cancers.

General Loss of 5-Hydroxymethylcytosine in Human Solid Tumors

When viewed across the broad spectrum of multiple types of solid tumors, mutations in TET2, IDH1/2, FH, and SDH are still relatively rare and frequently occur in only a few tumor types such as gliomas and AML. The vast majority of human tumor specimens do not contain these aberrations. However, in 2011 it was discovered that the major product of 5mC oxidase activity, 5hmC, is strongly depleted in all solid tumors analyzed. These tumors included cancers of the lung, breast, colon, liver, pancreas, prostate, melanoma and several others. When quantitated with sensitive techniques such as liquid chromatography coupled with tandem mass spectrometry, the extent of 5hmC depletion in tumors can reach 80%–90%. This degree of loss of 5hmC is much greater than the loss of 5mC, which often is only in the range of 10%–30% in tumors when compared to corresponding normal tissue. Therefore, loss of 5hmC during tumorigenesis does not simply reflect the loss of its precursor, 5mC.

The loss of 5hmC may occur as an early event in carcinogenesis. For example, the loss is seen as a consequence of exposure of rodent liver to a nongenotoxic carcinogen, phenobarbital. Currently, it is unknown if other carcinogenic substances may also impair 5hmC maintenance in normal cells.

Loss of 5hmC, as monitored by immunocytochemistry or immunofluorescence staining, is characteristic of malignant lesions and may be useful as a biomarker for cancer. For example, when used for assessing the malignant potential of melanocytic lesions in the skin, benign nevi show strong staining for 5hmC but this staining is lost in primary or metastatic malignant melanomas. Interestingly, this modified base is also reduced in proliferating normal tissue including, for example intestinal crypt stem cell compartments.

The mechanisms that lead to a general depletion of 5hmC in tumors are not well understood and multiple pathways are probably involved. It has been known from earlier in vitro studies that the presence of 5hmC, in place of 5mC, on a parental DNA strand is incompatible with DNA methyltransferase 1 (DNMT1) activity that normally copies symmetrical methylation patterns at CpG sites shortly after DNA replication. This lack of DNMT1 activity on 5hmC-containing substrates leads to a loss of both 5mC and 5hmC in replicated daughter strand DNA molecules. However, in malignant tissue the global loss of 5hmC is much greater than the loss of 5mC so that other or additional mechanisms need to be invoked. A general reduction of *TET* gene expression, TET protein levels or TET enzymatic activity in tumor versus normal cells is one likely explanation. However, gene expression data from The Cancer Genome Atlas (TCGA) does not confirm a loss of *TET* gene expression across multiple tumor entities. To the contrary, *TET* gene expression levels are often increased in tumors. TET protein levels have rarely been measured in primary matched tumor-normal tissues and neither have their activities. There is also the possibility that there is reduced availability of co-factors in tumor tissues. For example, levels of ascorbic acid may be reduced in tumor patients or more specifically, in their tumor tissues. Metabolic reprogramming is a widespread phenomenon in tumor cells (e.g., the Warburg effect). As one possibility, the availability of the cofactor alpha-ketoglutarate may be limited in tumors. Equally important could be the maintenance of a correct balance between the dioxygenase enzyme cofactor alpha-ketoglutarate and their inhibitors such as succinate and fumarate. All three of these compounds are part of the TCA cycle and even subtle disturbances in the ratios of these metabolites may affect TET enzymatic activities. These parameters would need to be assessed systematically in normal and in tumor tissue.

One other unresolved issue is whether the depletion of 5hmC in cancer is perhaps only a consequence of tumor formation or enhanced cell proliferation or whether these changes have a causative role in tumorigenesis. There are not many studies that have addressed these issues other than those based on inactivation of *Tet* genes. *Tet2* inactivation in mice leads to an expansion of clonal hematopoiesis and emergence of premalignant clones as discussed earlier. Reintroduction of active TET2 into a melanoma cell line with low 5hmC levels led to suppression of melanoma growth and increased tumor-free survival in mice. Interestingly, combined loss of *Tet1* and *Tet2* in mice promotes B cell tumors, but not myeloid malignancies. However, germline deletion of *Tet2* in combination with acute loss of *Tet3* leads to a rapid, progressive leukocytosis, which developed within a few weeks into aggressive myeloid leukemia in 100% of the gene-targeted mice. These combinations of *Tet* genotypes are not usually found in human tumors;

however, the data leave open the possibility that other mechanisms of TET protein inactivation may occur and may be critically involved in human cancers as well.

Perturbation of DNA Methylation Patterns as a Consequence of Defective 5mC Oxidation

If one considers the state of methylation at a CpG-rich target to be the result of a balance between de novo methylation and DNA demethylation initiated by TET proteins, then the expectation is that loss of TET activity will shift that balance towards 5mC. These predictions have generally proven to be correct in experimental systems in which one or more *Tet* genes have been disabled. For example, genome-wide mapping of 5hmC has shown that enhancers are enriched for this modification. The results imply that certain TET proteins may be targeted to enhancers and that they are critically involved in regulating enhancer DNA methylation and thus the enhancer's accessibility and function. Indeed, when *Tet2* was deleted in embryonic stem cells, extensive loss of 5hmC occurred at enhancers and this loss was accompanied by DNA CpG hypermethylation at the same enhancer sequences. Combined loss of all three *Tet* genes in mouse embryonic stem cells inhibits their differentiation potential. These studies further revealed that promoters became hypermethylated upon loss of TET activities and this loss led to a deregulation of genes implicated in embryo development and differentiation. In mouse embryos, loss of all three Tet genes leads to a gastrulation defect also involving hypermethylation of normally demethylated critical gene control elements.

In patient samples, the contribution of TET2 mutations to DNA hypermethylation patterns is more difficult to appreciate because of the simultaneous occurrence of a number of other epigenetic modifier mutations in the same malignant cell populations. Cases of myeloproliferative neoplasms with TET2 mutations tend to show not only decreased levels of 5hmC but also distinct sets of hypermethylated genes. Hypermethylation of enhancers has also been reported for human AML cases with TET2 mutations. Therefore, similar as in mouse ES cells, loss of TET2 function in human hematopoietic and other somatic stem cells may be associated with a phenotype of enhancer hypermethylation and dysfunction that may contribute to the formation of leukemias and other malignancies (Fig. 3).

It is also conceivable that the global loss of 5hmC in solid tumors, which occurs by unknown mechanisms, will lead to DNA hypermethylation of regulatory gene sequences. At a global level, the extent of 5hmC loss does not seem to correlate with the number of DNA hypermethylation events observed in a tumor. Whether loss of 5hmC formation at specific sites (e.g., in regions flanking promoters or near enhancers) will lead to DNA hypermethylation of the same targets is more difficult to assess. It requires genome-wide high-resolution mapping of 5hmC in normal and tumor tissues, but single base mapping of 5hmC in mammalian genomes is still prohibitively expensive. Some of the initial studies using these approaches suggest that the presence of 5hmC is indeed negatively correlated with DNA methylation changes.

Prospective Vision

Perturbation of DNA methylation patterns in tumors, a phenomenon known for several decades, includes broad, genome-scale DNA hypomethylation and localized DNA hypermethylation at CpG-rich sequences. The loss of 5-hydroxymethylcytosine in

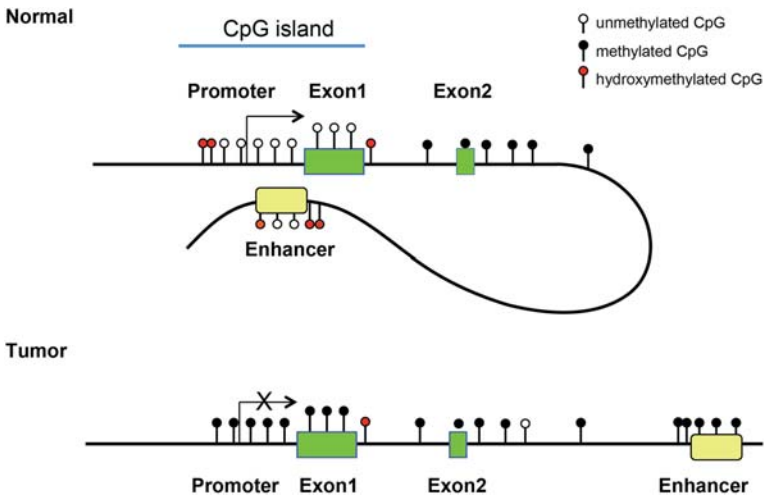

Fig. 3 Model for changes of 5hmC and 5mC in cancer. The diagram shows a hypothetical gene. Unmethylated CpG-rich sequences at enhancers and promoters in normal cells are protected from aberrant de novo methylation by TET-protein-catalyzed removal of erroneously introduced 5mC. In this scenario, TET-mediated 5mC oxidation leads to conversion of 5mC back to cytosine. Open circles, unmethylated CpG sequences; *black circles*, methylated CpG sequences (5mC), red circles, hydroxymethylated CpG sequences (5hmC). Loss of 5hmC near promoters and enhancers may be accompanied by de novo methylation of gene control elements in tumors.

tumors greatly exceeds the extent of the loss of 5-methylcytosine. This loss is not limited to tumors carrying mutations in *TET* genes or in *IDH* genes but occurs across a broad spectrum of malignancies. There is a need to understand the mechanisms of 5hmC loss since this process may be mechanistically linked to tumorigenesis. It is also tempting to speculate that there is an intrinsic connection between 5hmC perturbation and the changes in 5mC that are observed in tumors. Targeted genetic studies in mice will be needed to dissect the tissue-selective roles of specific *TET* gene inactivation in cancers other than those of the hematopoietic system. Manipulation of co-factor pathways relevant for TET protein function will also be required to understand the role of altered metabolism in the imbalance of DNA methylation and DNA demethylation pathways during tumor formation. Diagnostic assays assessing the DNA methylation status of a few specific genes are already in use for clinical tests with the goal of early cancer detection and patient management. Since widespread changes in 5hmC are also a ubiquitous characteristic of tumor genomes, similar assays analyzing 5hmC patterns in tissue or blood DNA samples could be developed for aiding cancer detection and diagnosis.

Diabetes and Cancer

Rachel Dankner, Sheba Medical Center, Tel Hashomer, Israel; Sackler Faculty of Medicine, School of Public Health, Tel Aviv University, Tel Aviv, Israel; and The Feinstein Institute for Medical Research, Manhasset, NY, United States

Introduction

Diabetes is a chronic progressive metabolic disease, defined by hyperglycemia. Diabetes is considered a worldwide epidemic. The world prevalence of diabetes for all ages is expected to double to 4.4% from the year 2000 to 2030. This means that by the year 2030 there will be 366 million people with diabetes living in the world. Older age is an important risk factor and the increase in the proportion of people >65 years of age across the world is an important reason for future projections on diabetes prevalence. Obesity is another important factor and given the increasing prevalence of obesity, it is likely that these figures provide an underestimate of future diabetes prevalence. Diabetes is more prevalent in men, but there are more women with diabetes in the world due to women's greater life-expectancy.

In his landmark article, published in Science in 1956, Otto Warburg linked metabolism with cancer. In the decades since, numerous epidemiological studies have demonstrated links between diabetes and cancer. Several publications during the year 2009 suggested that treatment with the insulin analogue, glargine, may increase the risk of cancer incidence. These studies, together with criticisms of them, raised interest in the relationship between diabetes and cancer, which went well beyond the use of glargine. In December 2009, representatives from American and European diabetes and cancer organizations met and produced a consensus report. This document supported associations of diabetes with increased risk of certain cancers, and corroborated cancer as a complication of diabetes. Hyperglycemia, hyperinsulinemia, adiposity, subclinical inflammation, and diabetes treatment were all identified for their involvement in the relationship between the two diseases. More research was called for to elucidate the mechanistic relationships between the diseases, as well as the effects of diabetes medications on carcinogenesis. Since the issuance of the consensus report, the publication of observational and clinical studies supporting associations between diabetes and cancer has soared. In this article we will first present the epidemiological evidence for associations between diabetes and all-site as well as site-specific cancers. Next, we will present possible mechanisms that may underlie associations of diabetes with cancer in general, as well as with a number of specific sites. Glucose lowering medications (the term used in this article for anti-diabetes drugs) will be discussed as possible confounders in the association of diabetes with cancer, as well as causative factors for carcinogenesis. We have tried to take a critical approach and urge our readers to do the same.

The Epidemiological Evidence

Epidemiological studies investigating associations of diabetes with cancer incidence or mortality are abundant. Diabetes is an exposure that cannot be imposed on study participants; thus, randomized controlled trials (RCTs) cannot be conducted to examine its association with cancer. Here, we present studies published since 2013, with an emphasis on systematic reviews and well-designed observational studies. Most of the meta-analyses conducted described considerable heterogeneity among included studies; and many lacked adjustments for potentially confounding factors. More recent studies more often adjusted for potentially confounding variables and some of them employed time-dependent approaches, which accounted for the date of diabetes diagnosis and assessed cancer incidence from only a certain period thereafter.

All-Site Cancer

Estimated population attributable fractions (PAFs) for diabetes, as well as for high body mass index (BMI, >25 kg/m^2) to cancer incidence in the year 2012 were published for 12 cancers, for 175 countries, with stratification by age and sex. Overall, the contribution of diabetes was estimated as 2%. However, higher PAFs were calculated for cancers of the liver (14.5%), pancreas (12.8%), gallbladder (7.8%), and colorectum (2.9%) in men; and for the liver (15.8%), pancreas (12.6%), endometrium (10.8%), gallbladder (7.4%), colorectum (2.8%), and breast (2.2%) in women. The overall estimated PAF for high BMI was calculated as 3.9%, almost twice that of diabetes. During the 10–32-year lag (starting in 1980–2002 and spanning to 2012) between exposure to diabetes or high BMI, a disproportionate number of those with high BMI evidently converted to diabetes, and this may have further contributed to their risk for cancer incidence, thus indicting BMI as a double whammy. Substantial differences were observed across geographical regions, supporting possible effects of factors other than diabetes and overweight. Though not investigated in that study, these could include differences in genetic susceptibility, in fetal and childhood nutrition and growth, in the detection and treatment of diabetes, and in lifestyle factors including nutrition and physical activity.

Most meta-analyses have reported positive associations of diabetes with cancer, yet some have only included a small number of cancer cases. A cohort of 2.3 million individuals followed for 11 years, using a time-dependent approach and a 2 year lag after diabetes diagnosis, reported hazard ratios (HRs) for all-site cancer of 1.42 (95% confidence interval (CI): 1.38, 1.46) in diabetic women and 1.33 (95%CI: 1.29, 1.36) in diabetic men, after adjusting for age, ethnic group, sociodemographic status (SES), and BMI. Several additional population-based studies have reported positive associations of diabetes with all-site cancer incidence. In studies

that stratified by sex, associations were generally stronger in women, but this is apparently due in large part to the lower incidence of prostate cancer reported for diabetic men, as well as to the increased risks of female-specific cancers. For non-sex-specific cancers, risks were generally similar between men and women. Potentially confounding factors were considered to varying degrees. The vast majority of studies that distinguished the type of diabetes, investigated type 2 (T2D). Higher risks of cancer were generally found for T2D than type 1 diabetes (T1D).

Site-Specific Cancers

In this section, we discuss meta-analyses of associations between diabetes and site-specific cancers, presented alphabetically, as well as a number of selected observational studies.

Bladder cancer

Differences between the sexes have been reported, with some studies finding a risk of bladder cancer in diabetic women and not men, and others finding the risk only in diabetic men and not women. Smoking may attenuate the risk. A number of studies have found an increased risk of bladder cancer, only or predominantly, during the first year following diabetes diagnosis. Such findings support the possibility that increased medical surveillance may explain observed associations of diabetes with bladder cancer. Nonetheless, a large historical population study, with a 2-year lagged analysis since diabetes diagnosis and 11 years follow up found a 35% increased risk in men and 70% in women, after adjusting for age, SES, and smoking.

Brain cancer

Brain cancer incidence was reported as 28% increased in diabetic women and 52% increased in diabetic men at 2–11 years after diabetes diagnosis.

Breast cancer

Several, but not all studies on the matter have shown an association of diabetes with an increased risk of breast cancer. However, these findings may not be relevant to Asian, Hispanic and African American populations, and this may be due, at least in part, to differences in mean body weight and fat distribution between populations. A large population study showed a 21% increased risk of breast cancer in postmenopausal, but not premenopausal women at 2–11 years after diabetes diagnosis and after adjustments for BMI, SES, ethnicity, and parity (HR = 1.21 95%CI 1.12, 1.30). A number of studies have shown that the association of diabetes with breast cancer may depend on the type of breast cancer. Triple-negative breast cancer tumors and estrogen receptor negative tumors have been associated with increased risk.

Cancer of unknown primary

Cancers of unknown primary (CUP) are metastatic malignant tumors for which the primary tumor is not identified; the prognosis of these cancers is generally very poor. Tobacco smoking is the only established risk factor for CUP. An association of diabetes with increased risk of CUP has been reported, particularly when the metastasis was to the liver and respiratory systems.

Colorectal cancer

Several studies have reported an association of diabetes with increased risk of colorectal cancer, in the range of 21%–26%. Some have found differences in risk between the sexes. A large population study with a time-dependent analysis reported 44% increased HR in women and 53% in men, for the 2–11 years after diabetes diagnosis, controlling for BMI. Another time-dependent analysis found an association of longer duration of obesity with increased risk of colorectal cancer, after adjusting for age, sex, smoking, alcohol consumption, and statin use in the previous 6 months. That study did not find an assocition with coloretal cancer of diabetes treatment stage; the latter was assessed as 90-day intervals of treatment with insulin or with one or more non-insulin glucose lowering medications alone or in combination. Some studies have shown differences in colon cancer risk, according to the location of the malignancy. However, the data are inconclusive, as both proximal and distal cancer have been found to be of greater risk.

Endometrial cancer

Several studies have found an association of diabetes with increased risk of endometrial cancer, which did not always remain statistically significant after adjusting for BMI.

Esophageal cancer

A number of studies have found a positive association of T2D with the risk of esophageal cancer; however, this association appears not to present in Asian populations. Male sex is a risk factor for esophageal cancer.

Gallbladder cancer

Several studies have found an increased risk of gallbladder cancer, similarly in men and women with diabetes, and independent of BMI, smoking, and a history of gallstones. Though, the possibility arises of confounding by alcohol consumption, the association was shown to persist in a study conducted in Israel, where alcohol consumption is not considered an important confounding factor.

Gastric/stomach cancer

Most, but not all studies on the matter have found an association of diabetes with gastric cancer. This risk may differ between the sexes, and may be particularly strong in East Asian populations.

Head and neck cancers

Associations of T2D with increased incidence of oral cancer, oropharyngeal cancer, and nasopharyngeal cancer have been reported, compared to non-diabetic individuals, matched by sex, age, obesity, and a number of comorbidities.

Liver cancer

Considerable evidence has accumulated for an association of diabetes with liver cancer, which appears to be stronger in non-Asian than Asian populations. Tobacco smoking and increased BMI, but not alcohol, have been identified as confounding factors. The association remains strong, even after excluding the first 2 years after diabetes diagnosis.

Lung cancer

Several studies have shown a robust association of diabetes with increased risk of lung cancer, particularly among women. However, the risk may be lower in Asian populations.

Ovarian cancer

Data seems conclusive for an association of diabetes with ovarian cancer, though the strength of the association varies between studies. Higher risks were found in studies published later and conducted outside of the United States or Europe, in studies that did not adjust for BMI or smoking status, and for T1D than T2D. An elevated risk of ovarian cancer was found to persist in diabetic women after adjustment for parity and the exclusion of women who had hysterectomies.

Pancreatic cancer

The pancreas, together with the liver, is directly responsible for glucose metabolism and insulin secretion. Thus, if diabetes is indeed associated with cancer via its metabolic pathways, the association would be expected to be the strongest in these organs. Indeed, the incidence of pancreatic cancer has consistently been shown to be elevated in the diabetic population. The population attributable fraction of diabetes to pancreatic cancer was found to be 13.5% and the BMI adjusted 2–11-year risk reportedly three times greater in the incident diabetic than in the non-diabetic population. The increased risk of pancreatic cancer is strong, even after excluding the first 2 years following diabetes diagnosis; and was shown to remain significant even after 20 years, and after adjusting for BMI and smoking.

Prostate cancer

Several studies have reported a lower risk for prostate cancer among men with than without diabetes, in both T1 and T2 diabetes. The risk appears to be lower in Europeans and Americans, and higher in Asians.

Thyroid cancer

The data are not conclusive regarding an association of diabetes with thyroid cancer, neither for men or women.

Site-specific cancers—summary

As the evidence presented here shows, considerable differences were found between studies for associations of diabetes with several types of cancer. While confounding factors and differences in study design likely account for some of the differences observed, real differences seem to exist between populations, and between the sexes.

Pathophysiology and Mechanisms Relevant to the Association of Diabetes With Cancer in General

Four main explanations are possible for the associations observed between diabetes and cancer; the relevance of these explanations differ among cancer types. Causality is the relationship by which the pathology of diabetes disease increases the risk of cancer. Since diabetes is diagnosed by hyperglycemia, we will consider direct cause as an effect of hyperglycemia on cancer risk. A second explanation for the associations observed between diabetes and cancer relates to shared risk factors. Insulin resistance and hyperinsulinemia, obesity, chronic inflammation, oxidative stress and alterations in sex hormones evidently comprise a metabolic milieu that predisposes to diabetes and that is conducive to cancer (Fig. 1). Shared lifestyle factors: physical inactivity, poor nutrition, smoking and excessive alcohol intake, as well as genetic susceptibility, may impact such metabolic milieu. A third possible explanation for the observed relationship between diabetes and cancer is reverse causality, in which the cancer pathology precedes the diabetes, and may even be the cause for hyperglycemia, though cancer is diagnosed only after diabetes. A fourth possibility is a spurious association, perceived due to biases or confounding factors, rather than a causal association between the diseases. We will discuss each of the four possible explanations for the observed associations between diabetes and cancer, considering cancer as a single entity. We will then present specific mechanisms by which diabetes may increase the risk of cancer, as pertains to specific cancers.

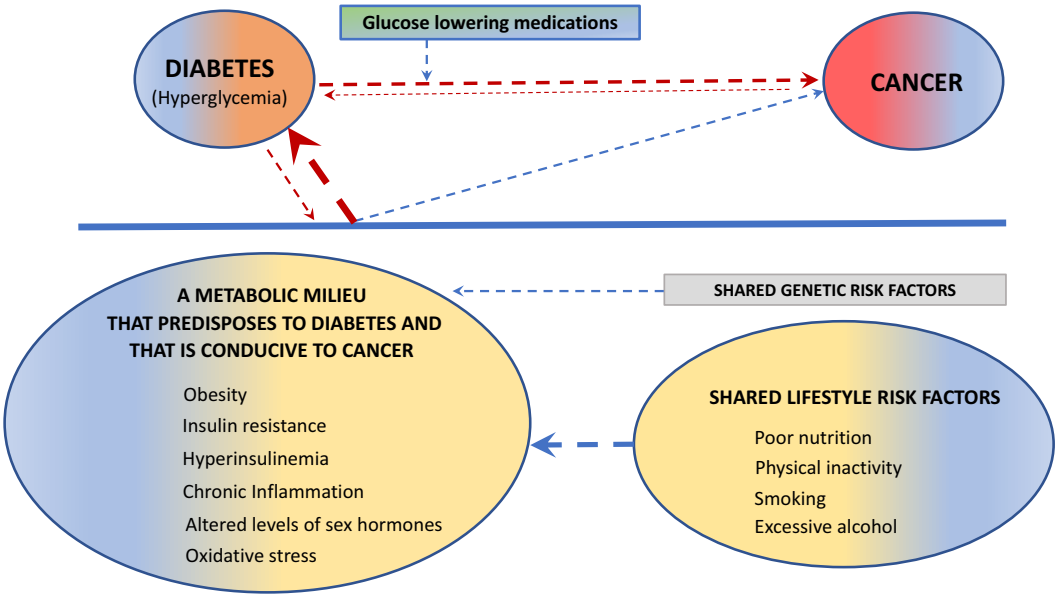

Fig. 1 The association of diabetes with cancer. The lines are *dotted* to indicate that the relationships are suspected and not verified, as they are based on observational studies. The thicker the line, the more evidence is currently available in support of the relationship.

Diabetes as a Risk Factor for Cancer

Distinguishing the impact on cancer of hyperglycemia from influences of pathophysiological conditions that accompany diabetes may be complex. The Warburg effect describes how irreversible damage to cell respiration leads some normal cells to become more proficient in using glucose for anaerobic glycolysis; these cells convert to highly proliferating undifferentiated cancer cells. However, this supposition does not infer that an increased supply of glucose, that is, hyperglycemia, promotes the development of cancer. Nonetheless, fatless hyperglycemic mice were shown to develop more aggressive tumors than normoglycemic mice. While this model neutralized the effect of obesity, it did not exclude hyperinsulinemia. Among diabetic mice that were insulin deficient, increased tumor growth was not observed. Taken together, while glucose is evidently essential for tumor growth, hyperglycemia in itself does not necessarily increase such growth. Still, knowledge accumulated since Warburg's publication has substantiated the perception of cancer as a metabolic disorder.

A number of publications have described direct effects of hyperglycemia on tumorigenesis. In nonmalignant human breast cancer cells, increased glucose uptake activated known oncogenic signaling pathways. Further, elevated glucose was shown to enhance the signaling of WNT/β-catenin in cancer cells, and this regulates cell proliferation and survival. In a mouse model, the glucose transporter GLUT1 was demonstrated as necessary for mammary tumorigenesis. Hyperglycemia was shown to promote features associated with cancer stem cells in premalignant and malignant pancreatic ductal epithelial cells, by activating signaling of the cytokine TGF-β.

Hyperglycemia promotes low-grade inflammation; and inflammatory processes are part of the etiology of cancer. Chronic hyperglycemia causes irreversible glycation and oxidation of proteins and lipids in the extracellular matrix; this results in the formation of advanced glycation end-products (AGE). Interactions of AGE and their receptors (RAGE) increase the generation of reactive oxygen species (ROS) in adipocytes, thus inhibiting glucose uptake and stimulating insulin resistance. Extracellular matrix glycation and RAGE activation may promote tumor growth by damaging proteins and DNA; this provides a link for the association between diabetes and cancer. Further evidence of an effect of elevated glucose on tumorigenesis by means of inflammation is the demonstration of increased phosphorylation of p38 MAPK, an essential kinase for inflammation, in pancreatic tumors from diabetic animals and in pancreatic cancer cells treated with high glucose.

The balance between oxidative and redox reactions in tumorigenesis is apparently complex. Along this line, James Watson, the Nobel prize winner, proposed that deficiencies rather than excesses in reactive oxygen species (ROS) may be the basis of diabetes and cancer, as well as other chronic diseases. He referred specifically to an insufficiency of the endoplasmic reticulum to generate the oxidative redox potential necessary to form the disulphide bonds that stabilize active proteins. Taken together, disruptions in oxidative or redox systems may link between diabetes and cancer.

Poorly controlled diabetes may perpetuate a pro-inflammatory state that may precede hyperglycemia, as will be detailed further below. The demonstration of higher levels of ROS among diabetic individuals with poorer glycemic control supports a role of hyperglycemia in pro-inflammation and oxidative stress. Further, poor glycemic control was found to be associated with serum gamma-glutamyltransferase and high sensitivity C-reactive protein levels, which are markers of inflammation. Nonetheless, individuals with poor glycemic control may tend to have more acute hyperinsulinemia, which is known to be associated with

pro-inflammatory effects and oxidative stress, as discussed below. This exemplifies the difficulty in distinguishing the effect of hyperglycemic from other pathophysiological components of diabetes.

The epidemiological evidence is inconclusive regarding a possible association of glucose control and the risk of cancer. While some studies have shown positive associations with any or site-specific cancers, others found no association. However, these studies generally did not consider factors that are relevant to the clinical manifestations and treatment of diabetes.

Studies on metabolic status in populations without known diabetes are not confounded by glucose lowering medications. Increased overall cancer risk has been reported in individuals without known diabetes yet with elevated HbA1c levels, as well as in diabetic patients. However, the great differences between cancer sites that have been reported for associations of HbA1c and cancer risk, highlight the importance of investigating cancer sites separately, in regard to associations with glycemia.

Shared Risk Factors Between Diabetes and Cancer

In individuals with diabetes, a number of factors interact with each other, generally before the diagnosis of diabetes; and separately or in combination, they may promote malignancy. While these factors are related to the development of diabetes, due to their precedence, we will consider them as entities shared by diabetes and cancer, rather than as the basis for a direct causal relationship between diabetes and cancer.

Obesity

Obesity is a major risk factor for both diabetes and cancer. Links between obesity and diabetes are complex and not fully understood; while most persons with T2D are obese, most obese persons do not have T2D. Certain cancers have long been associated with obesity. Already in 1980, endometrial cancer was found to be associated with excess body weight in postmenopausal women; and with increased levels of estradiol (E2) and decreased levels of sex hormone-binding globulin (SHBG). Among individuals with T2D, associations have been demonstrated of excess body weight with all cancer and with a number of site-specific cancers.

Adipocyte (fat) cells are central to energy storage, and particularly responsive to insulin. In addition to their metabolic role, adipocytes serve as endocrine cells that secrete a wide variety of hormones, among them cytokines, including tumor necrosis factor-alpha (TNF-α); steroid hormones, including estrogen; and adipokines, including leptin and adiponectin. Abnormal secretion of these hormones provides a link of obesity with diabetes and cancer. Obesity is associated with increased leptin and decreased adiponectin levels; these changes in endocrine function appear to have a role in cancer development. Insulin, estrogens, and TNF-α stimulate the release of leptin. Adiponectin regulates glucose metabolism, increases insulin sensitivity, and reduces the production of inflammatory cytokines.

Insulin resistance and hyperinsulinemia

Obesity, particularly abdominal obesity, leads to insulin resistance; insulin resistance can also contribute to obesity, and is a precursor of T2D. Insulin resistance is followed by compensatory hyperinsulinemia; this leads to beta cell compensation, which increases insulin production, resulting in hyperinsulinemia. The association between hyperinsulinemia and cancer was first hypothesized in relation to colon cancer; and was based on the recognition that similar factors are involved in hyperinsulinemia and colon cancer risk: namely, obesity, and abdominal obesity in particular; physical inactivity; and a low fiber, high sugar diet; the latter raises insulin levels by increasing the rate of blood glucose elevation and the blood glucose load. A number of epidemiological studies have substantiated the relationship between hyperinsulinemia and cancer. Moreover, factors related to hyperinsulinemia such as C-peptide, a biomarker of pancreatic insulin secretion and serum insulin growth factor (IGF)-1 were found to be associated with increased cancer risk.

A number of mechanisms have been proposed for the contribution of insulin resistance and hyperinsulinemia to cancer development. In addition to the metabolic effects of insulin and IGF, these hormones, together with their receptors and signal transduction networks, are recognized to have mitogenic effects. The binding of insulin receptor isoform A (IR-A) to IGF-II was described to result in mainly mitogenic effects; whereas, the binding of the same isoform to insulin results in mainly metabolic effects. Increased expression of IR-A has been detected in thyroid, colon, and breast tumors. Hyperinsulinemia impairs downregulation of insulin receptors in cancer cells; and affects signaling pathways of insulin and IGF-1, as well as plasma-free amino acid profiles; such activities may promote the development of both cancer and diabetes. Insulin and IGF-1, separately and in combination, increased cell proliferation and decreased apoptosis in colon cancer cells; and activated extracellular-signal regulated kinase 1/2 and c-Jun N-terminal kinase. All these activities are considered to contribute to the development of colon cancer.

Data of cancer incidence among individuals with T1D can help discriminate the roles of hyperglycemia and hyperinsulinemia, since only hyperglycemia and not hyperinsulinemia presents in T1D. A study of five nationwide diabetes registrars in European reported higher incidence of cancers of the stomach, liver, pancreas, endometrium and kidney in persons with T1D, compared to the general population; yet the rates were lower than for persons with T2D. These data support a role for hyperglycemia in cancer incidence, yet infer that other factors are evidently involved.

Effects of hyperglycemia and hyperinsulinemia may be additive or even synergistic. For example, the pro-inflammatory effect of hyperinsulinemia and hyperglycemia positively interact. Further, both hyperglycemia and hyperinsulinemia promote DNA

damage; and this has been proposed as a link in the relationship between diabetes and cancer: the mutations generated from DNA damage can lead to carcinogenesis. Disruptions in circadian rhythms that regulate metabolic processes has also been attributed a role in carcinogenesis.

Altered concentrations of sex hormones

Hyperinsulinemia affects concentrations of endogenous sexual hormones, and this may contribute to the development of both diabetes and cancer. High levels of insulin in the blood decrease the hepatic synthesis of SHBG, which leads to increased circulation of E2. Studies in both sexes have reported an inverse association of T2D with SHBG; and a positive association with E2. In women, elevated E2 has been shown to be associated with breast, endometrial, ovarian, and cervical cancers.

Oxidative stress and inflammation

While hyperglycemia induces oxidative stress, which causes insulin resistance that results in hyperinsulinemia, as described above, hyperinsulinemia also contributes to oxidative stress and low-grade inflammation. Associations are well established of pro-inflammatory agents with diabetes, as well as with several types of cancer. Apparently, in reciprocal relationships of chronic inflammation with both diabetes and cancer, inflammation may precede or be induced by diabetes and its associated conditions, as well as precede or be induced by oncogenic changes.

A number of mediators between insulin resistance and inflammation have received attention for their potential as links between diabetes and cancer. Elevated lactate promotes insulin resistance and inflammation, and has thus been coined "an interaction hub between diabetes and cancer." Similarly, the adipokine, chemerin, has been identified as a link between diabetes and cancer due to its involvement in inflammation and insulin resistance. Specifically, chemerin activates an inflammatory response, which increases oxidative stress in adipose tissue and thus contributes to insulin resistance. Further evidence for inflammation as a mediator in the link between diabetes and cancer is the reported association of increased concentration of growth differentiation factor 15 (GDF-15) with cancer, among individuals with type 2 diabetes. The stress responsive cytokine GDF-15 was found to be increased in individuals before type 2 diabetes diagnosis, yet not to be an independent predictor of diabetes. In addition, considerable evidence has accumulated for a role of the nuclear receptor transcription factor peroxisome proliferator activated receptor-γ (PPARγ) at the crossroad of obesity, diabetes, and several cancers. PPARγ is involved in the regulation of insulin and adipokine production and secretion; and of inflammatory pathways and differentiation. Thiazolidinediones, including rosiglitazone and pioglitazone, are synthetic ligands of PPARγ, which are used for the treatment of diabetes and whose pathways have been suggested to have potential benefit in the development of cancer therapies.

Genetically predisposing factors

Genetic factors may have both direct and indirect effects on the relationship between diabetes and cancer. Single nucleotide polymorphisms (SNPs) that were identified from genome-wide association studies as related to T2D, were associated with increased risk of a number of cancer types in diverse populations. Genetic factors may also affect the relationship between diabetes and cancer indirectly, by affecting shared predisposing factors. Along this line, the evidence does not support an independent relationship of the fat mass and obesity-associated (FTO) gene variant with cancer risk. Nonetheless, this variant may affect diabetes and cancer risk by its effect on obesity.

Lifestyle factors: diet, physical activity, alcohol consumption, smoking

A number of lifestyle factors have been identified as risk factors for both diabetes and cancer; and, as such, may contribute to obesity, as well as to other aspects of the metabolic milieu conducive to cancer, described above and depicted in **Fig. 1**.

Poor nutrition can contribute to imbalances in oxidation/redox systems, which can contribute to pro-inflammatory processes; and these, as discussed above, may increase risks of chronic illnesses including diabetes and some types of cancer. The role of diet in cancer development is particularly important to colorectal cancer, due to changes in the gut microbiota. Among the dietary factors that may be involved in the association between gut microbiota and the development of colorectal cancer are obesity, dietary patterns, and the consumption of red meat, sulfur, and fiber.

Evidence is robust for the benefit of physical activity to both primary and secondary prevention of chronic diseases, including diabetes and cancer. Among individuals with diabetes, cancer incidence was increased among those reporting low levels of physical activity (<2 h weekly), as well as among those who were overweight or obese, but not among those reporting high levels of physical activity (≥ 2 h weekly). According to James Watson's hypothesis, the benefit of physical activity to diabetes and cancer, as well as to other chronic diseases is in creating redox potential; specifically, the generation of ROS that oxidize free sulfhydryl groups of cysteine into the disulphide bonds that stabilize physiologically active proteins.

Elevated hazard ratios for diabetes and cancer were reported among women with a 20% increase in energy consumption; and decreased risks among women with a 20% increase in activity-related energy expenditure. Further, decreased risks of 25%, 14%, and 21% for diabetes, breast cancer, and colon cancer, respectively, were reported for individuals who were highly active (total weekly activity ≥ 8000 metabolic equivalents (METs)) compared with inactive individuals (<600 METs). Physical activity may affect breast cancer risk through biological pathways that involve adiposity, sex hormones, insulin resistance, adipokines, and chronic inflammation.

Several studies have reported an association of moderate alcohol consumption with a reduced risk for diabetes. However, some data have shown such association only for women. An association of occasional heavy drinking with an increased risk of diabetes

was also reported in women. Associations have been found of moderate alcohol consumption with increased risk of breast cancer and male colorectal cancer; and of light alcohol consumption with a reduced risk of lung cancer in both men and women.

Several studies have reported an association of cigarette smoking, including passive smoking with T2D. The cancer population attributable risk of smoking has been estimated as 20%, that is, the elimination of smoking could reduce one-fifth of all cancers. Up to one-third of cancer deaths has been estimated as preventable from smoking cessation; this includes the effect of passive smoking.

Reverse Causality

Reverse causality is a possible explanation for associations between diabetes and certain types of cancer. In a study of new users of diabetes medications, patients with upper gastrointestinal cancers (esophageal, stomach, pancreatic, liver cancers) were more likely than patients with other cancer diagnoses to have initiated insulin use during the 6 months prior to the cancer diagnosis. This supports the possibility of reverse causation, that is, that upper gastrointestinal cancers promoted diabetes, rather than the converse. To account for reverse causality, studies of the relationship between the two diseases have often excluded from analysis the early period, ranging from 3 months to 2 years, following the diabetes diagnosis.

Biases and Confounding Factors Relevant to the Exploration of the Relationship Between Diabetes and Cancer

A main difficulty in assessing the relationship between diabetes and cancer is the difficulty in identifying and mitigating the biases that may arise. In addition to biological mechanisms and shared risk factors, factors that are often not considered may influence the relationship between the diseases; these include: the duration and latency periods of both diseases, competing risks such as cardiovascular disease; glucose lowering medications, confounding by indication and cancer screening.

Since both diabetes and cancer may have long latency periods, their dates of diagnosis are somewhat arbitrary. Changes in glucose levels, and in insulin sensitivity and insulin secretion have been documented 3–6 years prior to the diagnosis of diabetes. For cancer subtypes, latency periods vary greatly, and should be considered in the determination of associations with diabetes. While not always a reflection of true biological disease onset, the dates of diagnosis of diabetes and cancer are important disease parameters, which generally reflect the initiation of treatment; the latter affects disease progression and possibly risks of other diseases.

Immortal time bias occurs from an inadequate definition of the follow up time of the exposed group, which ignores the period prior to diabetes diagnosis, thus implying that the study outcome, that is, cancer incidence, cannot occur during that period. The period before diabetes was diagnosed should not be ignored or attributed to the exposed arm, but rather to the unexposed group. This bias dilutes the strength of diabetes association with cancer risk towards the null hypothesis of no association.

Detection bias or ascertainment bias arises due to differences between persons with and without diabetes in cancer screening and surveillance; such differences may vary according to population. For example, United States and Israeli studies showed higher rates of screening among diabetic than non-diabetic men for colorectal cancer and for prostate cancer; however, in Korea, a lower rate of cancer screening was reported among people with than without diabetes; and a lower rate of screening for breast and cervical cancer was reported among Spanish women with than without diabetes. Several studies have shown particularly elevated cancer diagnoses during the first months, and up to 2 years following diabetes diagnosis, which could be due to increased cancer surveillance, as well as to reverse causality.

Detection/surveillance bias may be especially relevant to cancers of the thyroid and prostate, which have relatively long latency periods. For these cancers, particularly, symptoms of the diagnosed cancer may not present during a patient's lifetime; thus, the detection may be considered as an overdiagnosis, and the ensuing treatment may actually have negative consequences on physical and mental health, despite the cancer being asymptomatic. Detection bias can be mitigated in research by excluding from analysis an initial period, usually of up to 2 years following diabetes diagnosis, and adjusting for screening procedures.

Mechanisms Relevant to the Association of Diabetes With Certain Site-Specific Cancers

In addition to the mechanisms described above, which may increase cancer risk in any organ, several site-specific mechanisms affecting particular organs have been described; some of them are described below.

Colorectal Cancer

Disturbances in luminal factors may contribute to the increased risk of colorectal cancer in diabetic individuals; such factors include altered bile acid metabolism, delayed colonic transit, compositional change in gut microbiota, and reduction in the intestinal mucus barrier. Gut microbial dysbiosis has been reported in persons with T2D. NLRP6 inflammasomes have been reported to disrupt metabolism by altering gut microbiota and also to contribute to tumorigenesis. Various energy sensing pathways have been suggested to specifically link T2D with colorectal cancer. In addition, both diabetes and poor nutrition were shown to be independent and additive risk factors for colorectal cancer.

Endometrial Cancer

Estrogen and insulin have been shown to exhibit a synergistic effect in the development of type 1 endometrial carcinoma.

Liver Cancer

T2D is associated with increased incidences of a number of liver diseases that are associated with hepatocellular cancer (HCC); among them, hepatitis B virus infection, which accounts for more than half of HCC cases; hepatitis C virus infection, which contributes to 25% of HCC cases worldwide; and both alcohol-induced liver disease and nonalcoholic fatty liver disease, and their progression to HCC. In addition, excessive alcohol consumption is a risk factor for both T2D and HCC, and a synergistic interaction of alcohol, diabetes and hepatitis on HCC has been observed.

Prostate Cancer

While several studies have reported a lower risk for prostate cancer among diabetic men, a number of investigations have suggested that screening strategies may affect the association. In an Israeli study, the screening rate for the prostate-specific antigen (PSA) was 10% higher among diabetic than non-diabetic men, PSA positivity (>4 μg/L) was 20% lower, and only low-moderate grade, not high-grade tumors were decreased in diabetic men. These findings suggest that lower reported risks of prostate cancer in diabetic men may be due to lower PSA levels compared to non-diabetic men, rather than to a lower actual risk. In concurrence, a large Australian study identified a history of diabetes, as well as a number of socioeconomic and health system factors, such as frequency of visits to primary care physicians, as factors that affect rates of PSA testing. The possibility that a lower rate of prostate cancer screening among Asian than European men may explain, at least in part, the increased risk of prostate cancer in Asian diabetic men and decreased risk in European diabetic men needs investigation.

Thyroid Cancer

T2D as well as other metabolic diseases may increase the risk of thyroid cancer by affecting the level of thyroid stimulating hormone, iodine deficiency, chronic autoimmune thyroiditis and estrogen-dependent signaling.

Glucose Lowering Medications and Cancer Risk

Although diabetes is an exposure that cannot be imposed on study participants; glucose lowering medications are such an exposure and can be studied in RCTs with cancer as an outcome. Since mainly diabetic patients use these medications, separating effects of the disease from effects of the treatment is challenging. Phase-3 RCTs, as well as observational studies, provide evidence to this paradigm, each with its inherent methodological limitations. The pharmacologic treatment of T2D changes with increasing hyperglycemia, the indication of disease severity. Recommendations for the treatment of T2D consist of first-line treatment with metformin, followed by the successive addition of other oral glucose-lowering medications, or insulin, as needed to maintain glucose control, which is measured by the HbA1c level. T1D is treated by insulin, sometimes with the addition of oral glucose-lowering medications. Diabetes progression, together with its complications, the increased cancer risk over time, and the sequential nature of diabetes treatment and its combinations, makes it difficult to disentangle associations of diabetes pharmacotherapy and cancer risk.

The biases discussed above regarding all investigations of diabetes and cancer are also relevant to observational studies on glucose lowering medications. In addition, a number of parameters are particularly relevant to investigations of medications, among them: precise classification of drug exposure: dosages, duration and continuity. Factors such as increased hyperglycemia and the time of initiation of treatments are especially challenging to the investigation of associations of glucose lowering medications with cancer risk. Thus, disease severity may be a confounder between the glucose lowering medication investigated and cancer risk, a phenomenon called "confounding by indication." This bias is particularly relevant to non-randomized studies of diabetes therapies; whereby, for example, patients on metformin and insulin are compared, without considering that generally, metformin is a first-line treatment, and insulin is administered at a later stage when oral agents do not sufficiently reduce hyperglycemia. Another example arises in observational investigations of dose response relationships, when patients are stratified according to cumulative time under treatment or cumulative dose. However, such an approach may be confounded by disease severity, disease duration, and survival bias. Proper adjustments and using a time dependent statistical approach can attenuated these methodological limitations.

Adjustment for disease duration and the use of statistical methods like propensity scoring or instrumental variables can overcome, to some extent, lack of randomization and fundamental differences in the compared treatment groups, but they do not account for unmeasured confounders. In addition, while time varying variables: factors like HbA1c level, BMI and disease duration affect the selection of glucose lowering medications over the course of the disease, treatments also affect HbA1c levels and BMI. Associations of BMI and HbA1c with cancer risk may therefore confound the true association between glucose lowering medications and cancer. Not accounting for competing risks between diseases can result in a selection bias, as for example happens when

a diabetic patient dies due to another cause before treatment initiation. Excluding this patent from the analysis will result in immortal time bias. Time-dependent analysis, which accounts for the timing of changes in medications, can mitigate biases that arise in this context. In addition, such approach can overcome a differential misclassification bias, such as when patients are classified as using a medication of interest throughout the study period even though they may have used it only for a portion of the period. Referring unexposed person-years to the exposed group dilutes the magnitude of the association towards the null, and the investigated medication may even appear to show a protective effect with cancer, as often happens with metformin.

Glucose lowering medications are divided into classes according to their mechanism of action on various organs and tissues (Fig. 2). The diversity of these classes of medications reflects the complexity of diabetes as a multi-organ metabolic disease. The classes of medications can be categorized into: *insulins* (human and analogs); *insulin secretagogues* (including sulphonylureas, meglitinides, GLP-1 agonists, and DPP-4 inhibitors); *insulin sensitizers* (including biguanides and thiazolidinediones); and other medications, which at present include glucose absorption disrupters acting in the intestine (alpha-glucosidase inhibitors) and glucose reabsorption disrupters acting in the kidneys (SGLT2 inhibitors). Deciphering the association between glucose lowering medications and cancer risk can help elucidate the mechanisms underlying the diabetes cancer association. For example, findings that sulfonylureas and exogenous insulin are positively associated with cancer risk, and medications that decrease insulin resistance such as metformin and perhaps thiazolidinediones negatively associated with cancer risk, are congruent with a role of hyperinsulinemia in cancer risk.

Insulin

Insulin remains the most potent glucose-lowering agent. However, weight gain and risks of hypoglycemia may accompany improved glycemic control. In addition, all insulins to some extent act as a growth stimulating factor, raising concerns regarding their potential contribution to tumorogenicity. Since 2009, several studies have investigated cancer risks of insulin analogues (Aspart, Determir, Glargine, Glulisine, and Lispro), compared to human insulin. The insulin analogue glargine was associated with an increased risk of breast cancer risk in a number of observational studies that were later criticized for methodological flaws. RCTs have generally not found insulin treatment of any type to be associated with increased cancer risk, though some case-control and cohort studies showed increased risk. Further, the CARING five-country cohort study did not find consistently higher risk for 10 cancers following 5 or more years use of insulin glargine or insulin detemir compared to human insulin. A dose-response increased breast cancer risk was shown in women 40 years and older who used glargine compared to Hagedorn (NPH); this risk was evident only after 6 or more years of use. However, concerns that arise from the study's methodology are confounding by indication and differential misclassification of the outcome due to the screening policy for breast cancer in England. While there is no compelling

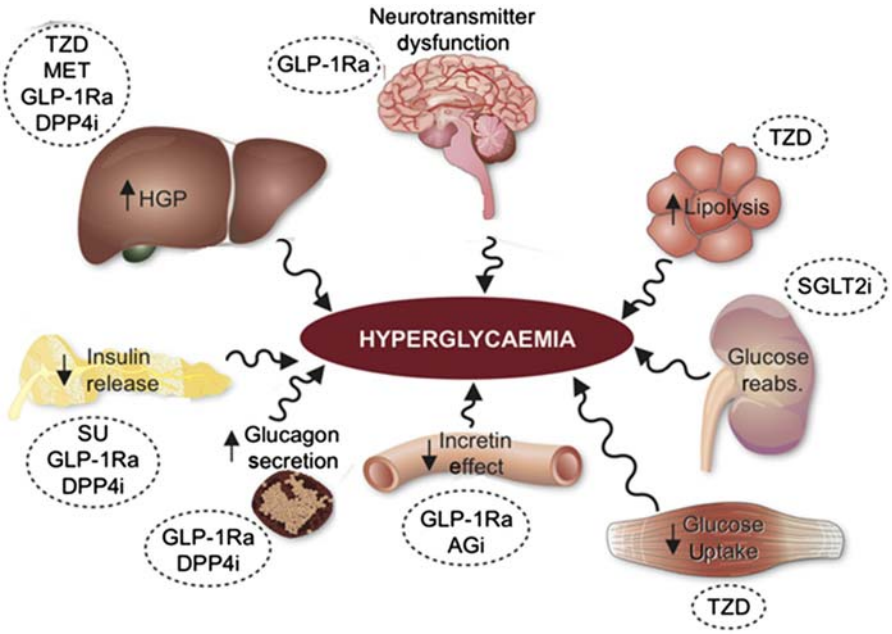

Fig. 2 Site of action of glucose-lowering medications on target organs and tissues contribution to hyperglycemia. Site of action of glucose-lowering medications on target organs are shown in the dotted circles. Contribution of different tissues to hyperglycemia is indicated by the direction of the small arrows indicating the direction of change in function of the organs in diabetes. HGP, hepatic glucose production; GLP-1Ra, GLP-1 receptor agonists; TZDs, thiazolidinediones; DPP4i, DPP4 inhibitors; SGLT2i, SGLT2 inhibitors; SU, sulfonylureas; AGi, α-glucosidase inhibitors. Adapted from Impact of glucose-lowering drugs on cardiovascular disease in type 2 diabetes. European Heart Journal 2015, **36**(*34*), 2288–2296. https://doi.org/10.1093/eurheartj/ehv239.

evidence that any clinically available insulin analogue or human insulin increases breast cancer risk, insulin might induce breast tumor progression by upregulating mitogenic signaling pathways.

Sulfonylureas

Sulfonylureas have been used to treat T2DM patients since the 1960s, although their use has declined with the emergence of new glucose lowering medications. Their main mechanism of action is to enhance insulin secretion by β-cells; the resultant hyperinsulinemia overcomes, in part, insulin resistance in liver and muscle, and leads to decreases in blood glucose and HBA1c. In vitro studies demonstrated that sulfonylureas accelerate β-cell failure, a process that was shown in an in vivo study to be reversible. Their main side effect is increasing the risk of hypoglycemia. Several observational studies of sulfonylureas have found an increased cancer risk, but such association is not evident in RCTs. Differences in cancer risk between types of sulfonylureas have been reported and warrant further research.

Metformin

Metformin, a biguanide, has been in use for over 50 years and its safety profile is well known. Metformin's glucose lowering effect is most probably confined to the liver and gut: reduction in hepatic glucose production and modest weight loss due to an anorectic effect and gastrointestinal side effects (diarrhea, abdominal discomfort, and flatulence). While not completely clear, the glucose lowering mechanism of metformin apparently involves inhibition of mitochondrial complex I, which increases the AMP/ATP ratio and leads to activation of the energy sensor Adenosine Monophosphate (AMP)-Activated Protein Kinase (AMPK). A direct anticancer mechanism of metformin may involve AMPK-independent and AMPK-dependent effects; while reductions in blood glucose, hyperinsulinemia, and IGF-1 level are possible indirect effects. Already in 2005, the first study to report an association between glucose lowering treatment and cancer suggested a protective effect of metformin. Numerous observational studies have reported a protective effect of metformin on all-site or specific cancer risk; however, those that accounted for biases were less likely to report such. Moreover, RCTs have generally not shown an association between metformin and cancer incidence. The metformin protective effect reported in observational studies has been claimed to result from time-related biases, as discussed above, and from overlooking aspects of the natural history of T2D. Several studies that accounted for time-related biases reported metformin not to be associated with a decreased risk of prostate, lung, colorectal, breast, or pancreas cancers. A number of clinical trials are in the process of investigating a protective effect of metformin on breast cancer risk in overweight or obese women. Metformin is thought to have antineoplastic activity directly via the modulation of cancer stem cell energy pathways, and indirectly by reducing hyperinsulinemia and glycemic levels. Clinical trials in prostate cancer patients are in process, with metformin as an additive to treatment arms, to examine a possible benefit in cancer survival.

Thiazolidinediones

The thiazolidinediones (TZDs, pioglitazone and rosiglitazone) are insulin sensitizers that activate peroxisome proliferator-activated receptors-γ (PPAR-γ). TZDs induce insulin secretion, preserve β-cell function, and improve insulin sensitivity. RCTs have generally shown no association of TZDs with all-site cancer; though some case-control and cohort studies have shown a protective effect. In December 2016, the U.S. Food and Drug Administration (FDA) re-issued a drug safety communication to the labelling information, having concluded that use of pioglitazone may be linked to an increased risk of bladder cancer. In France the drug has been removed from the market altogether. An analysis of close to 3 million individuals from several cohort and RCT studies showed higher risk of pioglitazone for bladder cancer for European populations, larger cumulative drug dose and longer use. Observational studies have generally not shown a significant association of bladder cancer with ever pioglitazone users compared with diabetic patients who had never used it, although an increased risk for bladder cancer may be possible after longer than 1-year exposure to pioglitazone.

Meglitinides

Meglitinides (repaglinide, mitiglinide and nataglinide) are insulin secretagogues that can cause weight gain and hypoglycemia. The evidence shows no association between Meglitinide use and all-site cancer risk.

Alpha-Glucosidase Inhibitors (AGIs)

AGIs (acarbose, miglitol, and voglibose) impede the breakdown of complex carbohydrates in the gastrointestinal tract, thus slowing carbohydrate absorption and reducing postprandial hyperglycemia. AGIs also increase plasma GLP-1 levels. Treatment with AGIs is usually associated with weight loss. RCTs have not shown an association between AGIs and cancers.

Dipeptidyl Peptidase-4 Inhibitors

Dipeptidyl peptidase-4 inhibitors (DPP4i) block the degradation of GLP-1, glucose-dependent insulinotropic polypeptide GIP, and other peptides, including brain natriuretic peptide. This class of drugs has a modest effect in reducing HbA1c and no effect on body

weight. Early concerns about an increased risk of acute pancreatitis and pancreatic cancer associated with DPP4i use have, for the most part, been refuted in more-recent studies. However, laboratory findings have raised concern that DPP4i can accelerate tumor metastasis. Numerous RCTs have shown no association between DPP-4is and cancer risk.

Incretins

The incretins, (GLP-1 receptor agonists—GLP-1RAs) mimic the action of endogenous glucagon-like peptide-1 (GLP-1). They enhance glucose homeostasis through: stimulation of insulin secretion; inhibition of glucagon secretion; direct and indirect suppression of endogenous glucose production; and delayed gastric emptying. The result is suppression of appetite, decreased post-prandial hyperglycemia, and enhanced insulin sensitivity secondary to weight loss. Laboratory studies suggest GLP-1RAs signaling promotes intestinal growth, and may promote colonic tumorigenesis. Several RCTs have reported no association of GLP-1RAs with cancer risk; a number of them specifically investigated the risk of pancreatic cancer. The possibility arises for a decreased risk of pancreatic cancer following long-term use of incretin therapies. GLP-1 analogues were demonstrated not to increase breast cancer incidence compared to DPP-inhibitors. The incretin therapies GLP-1 and Exendin-4 were shown to inhibit migration and promote apoptosis of human ovarian cancer cells, thus supporting the potential for a protective effect of these therapies on cancer risk.

Sodium-Glucose Co-Transporter-2 Inhibitors

Sodium-glucose co-transporter-2 inhibitors (SGLT2i) (dapagliflozin) represent the newest class of oral glucose lowering agents approved for the treatment of T2D in the United States and Europe. Inhibition of the SGLT2 transporter leads to increased urinary glucose excretion, resulting in a decline in plasma glucose concentrations. Due to their unique mechanism of action, the SGLT2i can be combined with all glucose-lowering medications, including insulin. The evidence shows no association of dapagliflozin with cancer risk. Long term RCTs are needed to rule out an association with bladder or urethral malignancies.

Glucose Lowering Medications—Summary of the Evidence

Meta-analyses from systematic reviews of observation studies (cohort and case control studies) showed increased risk for insulin and sulfonylureas, and a protective effect for metformin and TZDs. However, meta-analyses of RCTs showed no increased cancer risk conferred by any glucose lowering medication. We note that RCTs published to date on the association between glucose lowering medications and cancer risk were not designed for this purpose but were conducted to demonstrate cardiovascular safety and HbA1c reduction efficacy. These trials included diabetic patients with a specific risk profile to address their designated purposes; thus, some lacked statistical power to investigate cancer risk due to a short length of follow up or a small sample size. Further, since metformin, which is often used as the comparator or as background therapy, is the first-line oral therapy for type 2 diabetes, its comparison with other therapies that could be of lower clinical safety and effectiveness would be unethical. While meta-analyses overcome problems of small sample size, they are still subject to the limitations inherent in each of the included studies. Moreover, high heterogeneity between studies can reduce the validity of the findings.

To date, no study was published that accounts for the full complexity of diabetes disease, which exposes patients to sequentially changing treatments. Glucose lowering medications potentially act both as confounders and as causative factors in the association between diabetes and cancer. Thus, a research implication is that glucose lowering medications may confound associations of diabetes with cancer risk less than previously thought. A temporal association is consistently demonstrated between diabetes and cancer, which is not explained by glucose control or by glucose lowering medications. A clinical implication is that cancer risk need not be considered in the selection of diabetes treatments, in most circumstances. Still, the possibility that metformin, and perhaps also TZDs, may reduce cancer risk seems worthy of further investigation.

Concluding Remarks

Associations of diabetes with cancer risk are well established. Explanations are abundant and vary according to cancer type. Diabetes is evidently temporally associated with cancer risk directly, by means of hyperglycemia; as well as indirectly by means of shared risk and predisposing factors. Accounting for the numerous factors that can confound the association between the diseases and the potential biases is challenging and must be addressed. The evidence does not support causality of glucose lowering medications on cancer risk.

Introduction

Diet plays a key role in the prevention of chronic diseases including cancer. Cancer is one of the leading cause of death accounting for 8.2 million deaths globally (International Agency for Research on Cancer, 2014). Cancer rates vary across geographical regions and population migration studies observed a 20-fold variation in rates (Rastogi et al., 2008; Ziegler et al., 1993; King et al., 1985) suggesting that environmental factors including diet play may be important contributors. Historically there is evidence supporting a role of diet in carcinogenesis from observations by Peyton Rous who, in Rous (1914) found that food restriction in mice reduced tumor metastasis (Rous, 1914), while in the 1920s obesity was found to be associated with greater cancer mortality and in the 1930s high plant food consumption was suggested to be protective in cancer development (Stocks et al., 2009). Doll and Peto (1981) estimated that approximately 35% of cancer deaths could be avoided by dietary modifications (Doll and Peto, 1981) and this seems to be confirmed by more recent epidemiological studies (McCullough and Giovannucci, 2004; Willett, 1995). Generally, high calorie diets as well as high consumption of red and processed meat are linked to increased cancer risk whereas high vegetable and fruit intake, particularly citrus fruit and vegetables from the brassica family, are consistently found to be protective against cancer development (Kushi et al., 2012; Pan et al., 2012; Santarelli et al., 2008; Willett, 1995; Bosetti et al., 2012; Turati et al., 2015b). There is a paucity of data from clinical trials of diet in cancer patients owing to the challenges and high costs of such trials. Below sections targeting nutrients, selected food groups and dietary patterns are discussed.

Dietary Carbohydrates and Glycemic Index

Amongst dietary compounds, carbohydrates have been implicated in the etiology of cancer at various sites (Franceschi et al., 1997; Giovannucci, 1995; Augustin et al., 2002) while sources of carbohydrates such as whole grains have been found to reduce cancer mortality in many studies and have been included in the guidelines for breast cancer recurrence of the American Cancer Society (Runowicz et al., 2016). In a recent meta-analysis published in 2016 of ten large international epidemiological studies showed that higher consumption of whole grains compared to low or no consumption reduced cancer mortality by 12% (Zong et al., 2016). This suggest that not all dietary carbohydrates are the same and some may give protection while others increase risk. Specifically it has been proposed that the extent of the blood glucose rise produced by carbohydrates and captured by the glycemic index (GI), may play a differential role in cancer development (Augustin et al., 2002). The GI is a ranking of carbohydrate foods based on the ability to raise blood glucose concentration by the food ingested (Jenkins et al., 1981). In equicarbohydrate amounts, low GI foods increase blood glucose levels mildly while high GI foods result in larger rises in blood glucose and insulin (Jenkins et al., 1981). Hyperglycemia and hyperinsulinemia have been suggested to increase cancer risk. McKeown-Eyssen (1994) and Giovannucci (1995) independently suggested that blood glucose and insulin may be important factors promoting malignant transformation and tumor growth. Indeed hyperglycemia, both fasting and postprandial, and even at concentrations below the diabetes threshold have been associated with a higher risk of cancer incidence and death independent of body weight (Jee et al., 2005; Stattin et al., 2007; Stocks et al., 2009) and cancer site (Crawley et al., 2014). A meta-analysis showed that blood glucose concentration above 110 mg/dL (6.11 mmol/L), increased risk of all cancers by 32% compared to glycemic concentrations below 110 mg/dL (6.11 mmol/L) (Crawley et al., 2014). Fasting blood glucose $\geq$140 mg/dL ($\geq$7.8 mmol/L) was associated with significantly higher (23%–29%) death rates from major cancer sites including colorectum, liver and pancreas, compared with blood glucose concentration $<$90 mg/dL ($<$5.0 mmol/L) (Jee et al., 2005). Furthermore, hyperglycemia can enhance cancer progression and promotion (Li et al., 2015), and in a dose–response meta-analysis it was shown that every 10 mg/dL (0.56 mmol/L) increase in blood glucose concentration corresponded to a 15% increased risk of pancreatic cancer (Liao et al., 2015). Reducing hyperglycemia pharmacologically by use of antihyperglycemic medications (e.g., metformin, acarbose) (Noto et al., 2012; Tseng et al., 2015) and consuming low GI diets instead of high GI diets has shown benefits in reducing the risk of major cancers especially colorectum, breast and endometrium (Augustin et al., 2001; Barclay et al., 2008; Turati et al., 2015a; Choi et al., 2012). Some evidence may also suggest reduced colorectal cancer recurrence (Meyerhardt et al., 2012). The mechanisms involved in increasing risk of cancer with high GI foods may include at least two pathways, hormonal and oxidative stress.

Potential Mechanisms

Regarding whole grains these carbohydrate foods are rich in dietary fiber, vitamins, minerals and phytochemicals which are protective against chronic diseases (Slavin, 2003). Dietary fiber down-regulates inflammation, probably through the production of short chain fatty acids, particularly butyrate and propionate, when fiber is fermented in the colon by gut microbiotia. There are however other mechanisms of action beyond fiber which have been suggested and include (Fardet, 2010). Furthermore, dietary fiber may reduce insulin resistance by decreasing the rate of carbohydrate absorption and increasing insulin-like growth factor binding protein 3 concentrations. These mechanisms are explained further below in relation to the dietary GI.

Insulin-like growth factor—1 (IGF-1)

High GI foods induce higher glycemic and insulinemic responses and insulin is known to have growth promoting and proliferating effects (Giovannucci, 2003; Kaaks and Lukanova, 2001) and to affect recurrence in breast cancer patients (Goodwin et al., 2002). Insulin is able to bind to the insulin-like growth factor (IGF)-1 receptor and produce the cascade of reactions typically seen with IGF-1 activation. IGF-1 is a peptide, similar in molecular structure to insulin, produced mainly by the liver in response to growth hormone, but can be synthesized by almost any tissue in the body (Olivecrona et al., 1999). IGF-1 is the primary circulating growth factor in the IGF system, comprising of other IGFs and their binding proteins, regulating cellular proliferation, differentiation and apoptosis. Meta-analyses of recent studies confirm previous reports regarding elevated serum levels of IGF-I to be associated with an increased risk of colorectal cancer (Chi et al., 2013; Rinaldi et al., 2010), breast cancer (Endogenous et al., 2010) and prostate cancer (Rowlands et al., 2009). Studies in healthy people of low versus high GI diets and changes in circulating IGF-1 and its binding proteins suggest that low GI diets beneficially affect the IGF-1 axis and therefore may lead to an environment that is less conducive to tumor growth compared to high GI foods (Brand-Miller et al., 2005; Runchey et al., 2012).

Oxidative stress

Damage to DNA by reactive metabolites has been widely accepted as a major cause of cancer (Ames and Gold, 1991; Beckman and Ames, 1997; Halliwell, 2007). Oxidative stress can activate a variety of transcription factors leading to the expression of over 500 different genes, including those for growth factors, inflammatory cytokines, chemokines, cell cycle regulatory molecules, and anti-inflammatory molecules (Reuter et al., 2010). Activation of these pathways via oxidative damage has been implicated in the initiation, promotion, and progression of a normal cell into a tumor cell (Reuter et al., 2010; Valko et al., 2007). Consumption of high glycemic index foods have been suggested to increase oxidative stress through formation of free radicals that are capable of damaging biological molecules and hence initiating abnormal cell growth through gene mutation. Hyperglycemia contributes to increased oxidative stress through an incremental generation of reactive oxygen species (ROS) during the mitochondrial oxidative metabolism of carbohydrates which depletes antioxidant defenses (Brownlee, 2005; Ceriello et al., 1998; Title et al., 2000). Reducing the GI of a meal using acarbose has been shown to significantly reduce markers of oxidative stress in individuals with impaired glucose tolerance (Inoue et al., 2006; Monnier et al., 2006; Quagliaro et al., 2005). Compared to a high GI diet, consumption of a low GI diet was associated with an increased plasma total antioxidant capacity in overweight and obese men (Botero et al., 2009) and with a lower marker of oxidative stress in overweight and obese women (Arikawa et al., 2015).

Conclusions and Future Directions

Despite population differences in dietary habits and carbohydrate intakes low GI diets seem to protect from cancer risk compared to high GI diets particularly for specific cancer sites: colorectum (WHS study) (Higginbotham et al., 2004), breast (ORDET and EPIC studies) (Sieri et al., 2007; Romieu et al., 2012) and endometrium (NBSS and NHS studies) (Silvera et al., 2005; Cui et al., 2011).

Populations who could benefit the most from consuming low GI diets may be those characterized by a high prevalence of overweight and/or obesity since the strongest associations have been found in people with higher body weight (Coleman et al., 2014; Franceschi et al., 2001) and this is possibly due to the underling insulin resistance in people who are overweight or obese which would result in higher insulin responses for the same dietary GI rank. In an environment characterized by sedentary behavior, overeating and obesity, higher circulating blood glucose as a result of high GI food consumption, could represent a greater burden for an already stressed metabolism caused by obesity and lack of physical activity. Lowering the GI of foods may therefore be particularly relevant in affluent societies and in countries with high consumption of dietary carbohydrates as in the Mediterranean region (Favero et al., 1997; Slimani et al., 2002; Wirfalt et al., 2002). Regarding prevention of cancer recurrence (secondary prevention), the guidelines for cancer survivors by the American Cancer Society include foremost maintenance of a healthy body weight, engaging in physical activity and consuming a healthy diet which are consistent with guidelines for cancer prevention and heart disease prevention (Kushi et al., 2012). There is no mention of carbohydrate quality beyond whole grains, with regards to longer survival. At present, there is a lack of clinical trial investigating low GI diets in secondary cancer prevention. Nevertheless, when summarizing the mechanistic evidence linking glycemia and insulinemia to carcinogenesis and the evidence from primary prevention studies, there is a general support for cancer protecting effects of lower fluctuations of blood glucose and insulin (Rock et al., 2012) and hence potentially for low GI diets. Considering the longer survival of people diagnosed with cancer and therefore their

potential risk of developing or worsening other chronic conditions such as diabetes, the inclusion in cancer guidelines for a preference of low GI whole grains and low GI carbohydrates in general would be a sensible decision.

Plant Based Proteins and Cancer

Plant based dietary patterns have been associated with reduced risk of developing several chronic diseases, including cancer. Consistent with these findings, guidelines support dietary patterns lower in animal-based foods and higher in plant-based foods, emphasizing beans/legumes including soy, whole grains, nuts/seeds, and vegetables, namely sources of plant protein (USDA, 2010; USDA, 2015; Kushi et al., 2012; Schüz et al., 2015). From a global standpoint, production of plant-based proteins is considered to have lower environmental burden, land and water requirements coupled with fewer greenhouse gas emissions, as well as having a lower financial cost compared with animal-based proteins (Pimentel and Pimentel, 2003; Reijnders and Soret, 2003). These reasons, along with concerns for animal welfare, likely explain the increasing interest in the potential of using plant-based protein sources. The following focuses on cancer morbidity and mortality related to plant compared with animal protein consumption, summarizing available evidence and considering implications for future research.

Plant Based Protein Sources

Plant-based proteins can be found in a variety of food sources, including soy beans and other legumes, nuts/seeds, whole grains containing gluten (e.g., seitan) as well as other vegetables although the amounts are usually small (USDA Food Composition Database, 2018). In Europe and the United States, cereals are the principal contributors to plant protein intake providing 40%–70% of plant protein. However, animal products are still the main source of dietary protein providing between 55% and 71%, depending on the country, with red meats contributing 16%–35% to animal protein intake (Halkjaer et al., 2009; Phillips et al., 2015; Camilleri et al., 2013).

Evidence for Plant Based Protein Compared to Animal Protein and Cancer Risk

Numerous studies have assessed the impact of animal protein consumption on various types of cancer, however, few have focused specifically on cancer and consumption of plant protein. Evidence regarding carcinogenic or anticarcinogenic effects of plant compared with animal protein is mixed. Yet, protein is not consumed in isolation, but as part of a food matrix. Thus, in epidemiological studies, it can be difficult to attribute any observed benefit solely to protein as the finding may be due to other nutrients found in the food source. As well, findings from observational studies may be confounded since individuals consuming a more plant-based diet may also tend to participate in "healthier" lifestyle behaviors, such as being a nonsmokers, consuming less alcohol, having a lower body weight, being more physically active, and/or consuming a generally healthier diet, all of which may contribute to decreased cancer risk (Tharrey et al., 2018; Davey et al., 2003). Due to these limitations the following will focus on research where protein was explicitly the nutrient of interest in the comparison of animal and plant based dietary exposures. Much of the available evidence for plant protein compared to animal protein in relation to specific cancers pertains to colorectal and breast cancers. In a meta-analysis of observational studies on colorectal cancer risk, comprising 21 studies and 8187 cases, showed no evidence of significance between dietary animal protein or vegetable protein intake (Lai et al., 2017). The association between dietary protein sources and breast cancer risk was assessed in a meta-analysis of 46 prospective cohort studies (60,615 cases and 2,749,307 participants, with a mean follow-up of 3.9–65 years). Findings indicated higher total red meat, fresh red meat, and processed meat intake were risk factors for breast cancer, whereas evaluation of plant protein sources showed soy protein exhibited a protective association, and nuts (peanuts and tree nuts) had no adverse association. In terms of cancer mortality, animal and plant protein intake has been prospectively examined in US health professionals (121,700 women and 51,529 men) followed for up to 32 years with repeated measures of dietary intake. Animal and plant protein consumption comprised 14% (9%–22%) and 4% (2%–6%) of total energy intake, respectively. Plant protein was inversely associated with cancer mortality when age was taken into account, however, when the model was further adjusted for dietary and lifestyle factors, such as smoking status, body mass index and physical activity, this relationship disappeared (Song et al., 2016).

Potential Mechanisms of Action: Plant vs. Animal Proteins

The mechanisms involved require further investigation. Proposed potential mechanisms relate to: (1) the reduction and/or displacement of animal protein intake with plant protein and (2) the food matrix within which plant protein tends to be contained. In reducing animal protein intake it is suggested there would be a subsequent reduction of the carcinogenic byproducts from consumption of red meats, such as heterocyclic amines and polycyclic aromatic hydrocarbons formed during high temperature cooking (Steck et al., 2007; Zheng and Lee, 2009). Animal protein is also a source of fat and heme iron, which have been implicated

in the production of oxidative stress and inflammation, where experimental data suggest oxidative stress and inflammation have a pro-carcinogenic role in cancer development (Farvid et al., 2014; Fonseca-Nunes et al., 2014; Hedlund et al., 2008; Negre-Salvayre et al., 2010; Samraj et al., 2015). Plant protein is found in food matrices that tend to include dietary fiber and antioxidants, thus possibly playing a role in cancer protection by lessening the negative effects of inflammation, insulin resistance and hyperinsulinemia by reducing IGF-1 concentrations, as well as oxidative damage. Additionally, plant foods are known to contain antioxidants, including vitamin C, vitamin E, and carotenoids, yet many plant proteins and peptides have also been identified as novel antioxidant agents, and are thought to contribute to carcinogenic protection by interfering with oxidative damage to DNA, lipids, and proteins (Lu et al., 2010; Zhang et al., 2010; Xue et al., 2009).

Conclusions and Recommendations and Future Directions

It is important for overall population health to continue to support dietary patterns with lower animal-based foods and higher plant-based foods (USDA, 2010; USDA, 2015; Kushi et al., 2012; Schüz et al., 2015). Cancer specific recommendations still require further research, yet, at this time it appears that consumption of plant-based proteins do not have adverse results thus supporting their intake. Higher quality research is recommended, differentiating cancer types and investigating cancer mortality rates for high versus low vegetable protein consumption.

Soy Foods and Cancer

Over the years epidemiological studies have consistently shown health benefits of soy foods related to the prevention of chronic diseases, including cancer (Messina, 2010). Of particular interest for human health are soy isoflavones, bioactive compounds in soybeans, that have shown anticancer properties due to their estrogen-like activity, as well as their ability to modulate cell cycle, apoptosis, differentiation, proliferation, and cell signaling (Rizzo and Baroni, 2018). Breast cancer incidence rates are lower in soy food consuming countries such as Asian populations (Pisani et al., 1999). Asian epidemiologic studies show that higher soy consumption is associated with an approximate one-third reduction in breast cancer risk (Chen et al., 2014). Opposite, in last decades, as Westernization of Asian cultures has occurred, breast cancer rates among Asian populations have steadily increased. In 1995 the "early intake" hypothesis emerged, in animal models, that exposure to soy isoflavones early in life reduce breast cancer risk (Lamartiniere et al., 1995a, b, 2000). Data from epidemiological studies indicate that higher soy intake early in life, such as during childhood and/or adolescence, is associated with 25%–60% reductions in risk (Wu et al., 2002; Shu et al., 2001; Lee et al., 2009). The "early-intake" hypothesis could also explain discrepancies in epidemiologic data from different countries. The estrogen-like activity of isoflavones by soybeans is at the base of data reporting soy isoflavones adversely affect the prognosis of breast cancer patients. Results from animal studies indicate that isoflavones activity stimulates the growth of existing mammary tumors (Ju et al., 2001; Allred et al., 2001; Helferich et al., 2008). However, results from in vitro and animal studies are controversial and not in line with human studies. The European Prospective Investigation into Cancer and Nutrition Study cohort (EPIC) reported no increase in cancer risk with higher soy isoflavone intake (Zamora-Ros et al., 2013). Regarding the association between soy food intake in breast cancer patients, clinical and prospective epidemiological data clearly show that soy consumption after breast cancer diagnosis was associated with reductions in breast cancer recurrence and beneficial effects were similar in Asian and non-Asian populations (Guha et al., 2009; Caan et al., 2011; Shu et al., 2009; Kang et al., 2010; Zhang et al., 2012). A meta-analysis of five cohort studies showed that soy isoflavones intake might be associated with lower recurrence in ER negative, ER+/PR+ breast cancer (Chi et al., 2013). Furthermore, it is reported that exposure to soy isoflavones was associated with reduced mortality and reduced cancer recurrence also in women with ER(+) and ER(−) breast cancer (Messina, 2016a, b; Shu et al., 2009). Results from in vivo studies shown that isolated isoflavones possibly interfere with the efficacy of tamoxifene, an antiestrogen prescribed to women with ER+ tumors (Ju et al., 2008; Jones et al., 2002), whereas other studies in humans report benefits of combined soy food intake and tamoxifen therapy use on the inhibition of breast cancer growth improving pharmacological efficacy (Kang et al., 2010; Nechuta et al., 2012).

As for breast cancer, prostate cancer incidence varies throughout the world and it appear higher in Western countries than in the Asian population. Specifically, the higher soy food intake in Asian population is associated with as much as a 50% reduction in prostate cancer risk (Zhang et al., 2016) even if prostate cancer has a lower incidence rate in Asian population and this phenomenon has been linked to difference in intestinal bacteria responsible for conversion of daidzein to equol in the gut (Akaza, 2012). Clinical studies indicate that isoflavone exposure has beneficial effects in prostate cancer patients (Messina et al., 2006; Kwan et al., 2010; Ide et al., 2010). A recent meta-analysis supports the existing evidence which indicates that the total soy food intake is associated with reduced prostate cancer risk (Applegate et al., 2018). Nevertheless, some studies reported controversial results on the effects of soy on prostate cancer (Bosland et al., 2010; Fleshner et al., 2011). Differences in study designs limit the implications of results.

The European Food Safety Agency (EFSA) commented on the possible association between the intake of isoflavones and adverse effect on sex-hormone responsive tissues (such as breast and endometrium), after reviewing 25 clinical studies and concluded that

35–150 mg per day of isoflavones from supplements do not adversely affect the endometrium (EFSA Panel on Food Additives and Nutrient Sources added to Food ANS, 2015). No effect of oral isoflavone supplementation on endometrial thickness overall was found in a meta-analysis of 23 randomized controlled trials in peri- and postmenopausal women (Liu et al., 2016). Moreover, data from a meta-analysis of 10 observational studies found that dietary soy isoflavones from soy beans and soy foods were inversely associated with endometrial cancer risk, and the protective effects were found for both Asian and non-Asian populations.

Evidence reported from a meta-analysis of 17 epidemiologic studies (including case-control and prospective cohort studies) revealed that soy isoflavone consumption, particularly with soy foods/products, was significantly associated also with reduced risk of colorectal cancer in Asian populations (Yu et al., 2016). Another meta-analysis of prospective studies showed higher isoflavone intakes significantly decreased the risk of stomach and lung cancer while nearly significantly decreased the risk of breast and colorectal cancer (Grosso et al., 2017).

Mechanisms of Action

Many biological explanations have been proposed for the cancer protective effects of soy foods (Grosso et al., 2017). Soy isoflavones play a competitive role with endogenous estrogens for binding of estrogen receptors (ERs) and stimulate cell proliferation (Trock et al., 2006; Taylor et al., 2009; Guha et al., 2009). Isoflavones act as weak ER agonists or antagonists, depending on the cell type and estrogen environment (Larkin et al., 2008). ER agonist/antagonist properties of isoflavones have been widely studied and because of their tissue-selective effects isoflavones are classified as selective ER modulators. Soy may act as an ER antagonist (Dorjgochoo et al., 2011) and soy isoflavones intake was associated with protective effects in both ER− and ER+ breast cancer patients (Chi et al., 2013).

The mechanisms by which soy intake may improve the prognosis of breast cancer patients is not obvious, taking into account also data showing a lack of effect of isoflavones on breast cancer markers. To date, neither soy protein nor isoflavones supplements seem to affect markers of breast cancer including mammographic density and breast cell proliferation (Hooper et al., 2010; Wu et al., 2015; Sartippour et al., 2004; Palomares et al., 2004; Cheng et al., 2007; Khan et al., 2012). Different mechanisms have been proposed to explain the role that isoflavones may play in prostate cancer prevention and modulation. Clinical and animal studies report that isoflavones are able to inhibit metastasis (Xu et al., 2009; Jin et al., 2013). Also, cell-based studies show that phytoestrogens exert a chemopreventive effect through binding ERβ, expressed in prostate epithelial cells, regulating genes that control cell cycle and apoptosis (Applegate et al., 2018; Mahmoud et al., 2014).

Several mechanisms for the protective role of early isoflavone exposure have been proposed (Messina and Hilakivi-Clarke, 2009). The protective effect of early isoflavone exposure may be related to isoflavones ability to impact mammary gland development, changing cells in ways that make them permanently less likely to be transformed into cancer cells. Early life exposure to phytoestrogens has been demonstrated to impact mammary gland development through accelerated terminal end bud differentiation. Furthermore, many similarities between the protective effect of early isoflavone exposure and early pregnancy have been observed (De Assis et al., 2011; Rahal and Simmen, 2011; Mishra et al., 2011).

Soy isoflavones also act independently of ER activity exhibiting antiproliferative, antioxidant and antiinflammatory properties in vitro and in vivo (Guha et al., 2009; Rizzo and Baroni, 2018; Zaheer and Humayoun Akhtar, 2017). Isoflavones act as antioxidants and reduce the long-term cancer risk by preventing DNA damage. Genistein in particular is a potent antioxidants and it seems to increase the production of SOD which removes free radicals from cells (Zaheer and Humayoun Akhtar, 2017).

Isoflavones interact with epigenetic modifications, such as hypermethylation of tumor suppressor genes. In vitro studies have demonstrated that phytoestrogens act on chromatin and modify transcription through the demetylation and acetylation of histones in breast cancer cell lines (Dagdemir et al., 2013; Zaheer and Humayoun Akhtar, 2017; Grosso et al., 2017).

Conclusions and Recommendations

Evidence indicates that soy foods, mainly by virtue of their isoflavones content, as having a number of health benefits. Despite the many benefits, soy foods have not been embraced by the medical community. Mainly the estrogen-like properties of isoflavones has led to concerns that soy may exert untoward effects in some subpopulation (e.g., postmenopausal women), increasing breast cancer risk and getting worse the prognosis of breast cancer patients. As a result, clinicians treating breast cancer patients frequently caution them to either avoid soy foods or use them in moderation. However, evidence published over the past decades indicates the safety of isoflavones exposure with respect to breast and endometrial cancer. The position of AICR and WFRC are that soy foods are safe and even beneficial if consumed by women with a breast cancer diagnosis (American Institute for Cancer Research (AICR); World Cancer Research Fund International (WCRF). In 2015, after a literature evaluation, EFSA concluded that isoflavones do not adversely affect the breast, uterus and thyroid (the three organs that were investigated) in *peri* and postmenopausal women (EFSA Panel on Food Additives and Nutrient Sources added to Food ANS, 2015). Clinical studies did not support the hypothesis of an increased risk of breast cancer and supplementation with 150 mg/day of soy isoflavones (up to 30 months) of had no adversely effect on endometrial thickness and in the uterus (EFSA Panel on Food Additives and Nutrient Sources added to Food ANS, 2015).

As suggested by the early hypothesis, it could be reasonable to encourage young women to consume one serving per day of soy foods because epidemiological data suggest it may be protective. However, the consumption of a variety of soy foods, such as soy flour and tofu, should be encouraged rather than purified forms of phytoestrogens. A moderate consumption of soy foods, such as one to two standard servings daily of soy foods (one serving averages approximately 25 mg isoflavones) is not links to increased breast cancer risk.

Future Directions

Although soy and isoflavones offer health benefits to humans, controversial results from different studies have raised doubts about the validity of such health claims. More studies are therefore needed to clarify the controversial results. Nutraceutical values of soybean, including isoflavone content of soy foods, can vary considerably due to the soybean type, cultivar and food processing.

Labeling of soy foods with isoflavones concentrations could be a helpful information for consumers and scientists. Dietary guidelines for soy foods and soy isoflavones consumption may improve cancer prevention and management.

Dietary Fats

Dietary fats include oils, butter and lard. They are composed of a 3-carbon backbone to which fatty acids are attached. Fatty acids are formed by long, short or medium hydrocarbon or aliphatic chain linked to a carboxylic acid end. The aliphatic chain of fatty acids can present double or single bonds between their carbon molecules, indicating unsaturated fats or saturated fats (SFA), respectively. Fatty acids with one double bound are called monounsaturated fats (MUFA), while polyunsaturated fats (PUFA) are fatty acids with more than one double bound. A type of unsaturated fat that occurs in small amounts in nature are trans-unsaturated fatty acids, with one or more of their double bonds in the "trans" rather than the common "cis" configuration. Cholesterol is not a fat but an organic molecule of the sterol family (similar to wax) and it is not used for calorie production hence it is not oxidized. Fats and oils are most abundant lipids in nature. They represent the major component of storage fat or adipose tissue in the human body and the major contributor to energy intake in diet. The fatty acids profile in serum and tissues reflects the composition of dietary fats. Fat-rich foods are formed by SFA (with no double-bond), MUFA (e.g., oleic acid) and PUFA ($n-3$, $n-6$ fatty acids, e.g., linolenic acid, omega 3 fatty acids). SFAs are found in dairy products such as butter, cream, cheese and milk, in meat and certain plants (e.g., palm oil, coconut oil). Dietary sources of MUFAs are olives, rapeseed, peanuts, sesame and safflower oil. Specific types of fish contain abundant levels of $n-3$ PUFAs, such as eicosapentaenoic acid (EPA) and docosahexanoic acid (DHA). Linoleic acid (LA, $n-6$ PUFAs) is present in oil of safflower, grape seed, hemp, corn, wheat germ, cotton-seed and soybean, while α-linoleic acid (ALA, $n-3$ PUFAs) is in flaxseed, walnuts, some vegetables and canola oils (Burdge, 2004). Trans-fatty acids are found especially in dairy products and meat, but in high amounts in baked foods (biscuits, crackers, cookies, etc.) and margarines. Cholesterol dietary sources are mainly egg yolk, organ meat, shrimp, squid and shell.

Dietary Fats and Cancer Prevention

Many studies have suggested that a high consumption of fat through diet is related to an increased incidence of breast, colon, pancreatic and prostate cancer (Othman, 2007). Independently from type of fat, excess dietary fat intake has been associated with cancer recurrence (Dal Maso et al., 2008; McEligot et al. 2006; Vernieri et al. 2018). However, when intervention studies with low fat diets were conducted in the USA no effect on primary (Prentice et al. 2006) or secondary prevention of breast cancer were observed (Pierce et al. 2007) unless the dietary change involved weight loss (Chlebowski et al. 2006).

Saturated Fatty Acids

Direct associations between SFAs intake and risk of breast cancer in postmenopausal breast cancer have been found but not in premenopausal women (Cao et al., 2016; Xia et al., 2015). Higher intakes of total fat and SFAs compared to lower intakes were associated with higher risk of breast cancer subtypes, in particular ER and PR positive breast cancer (Sieri et al., 2014). When investigating exposure to SFA consumption and mortality incidence, a recent meta-analysis of four studies found 50% higher risk of breast cancer mortality in the highest compared to the lowest SFA intakes.

In colorectal cancer total fat and SFAs did not show any significant associations in an Asian population (Zhong et al., 2013) but in a large European population SFA was directly and significantly associated with colorectal cancer risk (May-Wilson et al. 2017). A meta-analysis of endometrial cancer studies and dietary fat a 45% increased risk was found in case-control studies only (Zhao et al., 2016a, b). Evidence from observational studies (both case-control and prospective) indicate that there is no apparent relationship

between SFAs and pancreatic cancer risk. Case-controls study on prostate cancer and dietary fats shows that high consumption of SFAs was associated with a higher aggressiveness of prostate cancer (PC) which seemed to be related mainly to the SFA effects on serum cholesterol levels. Other studies confirmed a role of dietary cholesterol on PC aggressiveness (Allott et al., 2017; Mensink et al. 2003; Platz et al., 2006; Platz et al., 2009).

Monounsaturated Fat (MUFA)

Most recent epidemiologic evidence has shown that foods rich in MUFAs could reduce breast cancer risk (Pelucchi et al., 2011) but others do not support these results. High versus low consumption of MUFAs to SFAs ratio was associated with a significantly reduced risk of colorectal cancer in three case–control studies (Rosato et al., 2016). Inverse associations were observed between MUFAs and endometrial cancer risk in cohort studies, while nonsignificant associations were observed in case-control studies (Zhao et al., 2016b). No significant relationship between MUFAs and pancreatic cancer risk were observed in cohort studies (Yao and Saturated, 2015) and conflicting results were seen for prostate cancer.

MUFAs are found both in vegetable oils especially olive oil and canola oil but also in meat. This could explain the heterogeneity of results in international studies particularly between North American populations with high meat to olive oil intakes and Mediterranean populations who tend to consume larger amounts of olive oil and less meat. Indeed, when investigating vegetable oil and olive oil a protection is seen in breast cancer risk of 12% and 26%, respectively, in a meta-analysis of cohort and case-control studies (Xin et al. 2015). This protection was supported by results of the PREDIMED clinical trial conducted in Spain where the arm consuming higher extra virgin olive oil showed a 68% reduction in breast cancer risk after 4 years of intervention compared to the control group (Toledo et al. 2015).

Polyunsaturated Fat PUFA

Numerous studies (epidemiological, clinical, animal model and in vitro) confirm a preventive role of $n-3$ PUFAs in different types of cancer sites, including breast, colon and prostate (Berquin et al., 2008; Huerta-Yépez et al., 2016) while high dietary intake of $n-6$ PUFAs could increase risk of cancer development (Lawrence, 2013). In vitro and in vivo recent studies indicate positive association between $n-3$ PUFAs and cancer risk (Sawada et al., 2012), moreover data from epidemiologic studies confirm a protective role of this type of fats on cancer risk (Huerta-Yépez et al., 2016). Colorectal cancer is most widely developed in populations who consume a Western diet which is characterized by high fat and are especially rich in $n-6$ PUFAs particularly arachidonic acid (AA) which is associated with cancer promotion (Huerta-Yépez et al., 2016). Overall, $n-3$ PUFAs fats and fish may have positive effects on carcinogenesis and lower risk of colorectal cancer (Hall et al., 2008; Ronco et al., 2010). Results from meta-analysis indicate that high intakes of PUFAs was associated to reduced risk of pancreatic cancer, especially in case-control studies but not clearly in prospective studies while a high $n-6/n-3$ PUFA ratio was correlated with higher risk of high-grade prostate cancer (Williams et al., 2011). In recent meta-analysis, consumption of foods rich in $n-3$ PUFAs such as marine fish, EPA and DHA, was associated with lower risk of breast cancer (Yang et al., 2014). Meta-analysis on endometrial cancer risk indicate a relationship between intake of fish and lower risk of cancer in European studies (Hou et al., 2017). Results from prospective cohort studies confirm the benefit of $n-3$ PUFAs on breast cancer incidence (Zheng et al., 2013) which may be due to improvements in immune system for EPA/DHA in supplementation studies (Paixão et al., 2017).

Trans-Fatty Acid

Intakes of commercially produced trans-fatty acid are associated with several diseases, including several types of cancers (Thompson et al., 2008; Mozaffarian et al., 2006; Stender and Dyerberg, 2004). Data from correlational studies on trans-fatty acid intake and breast cancer indicate a positive correlation between intake and risk in premenopausal women (Hu et al., 2011) but studies on ruminant-derived trans-fatty acids do not confirm this association (Kolahdouz Mohammadi et al., 2017). However trans fatty acids in ruminants are different than those in industrial products, they are 10-fold lower in concentration and the position of the double bond is located on different carbons. Only few studies observed direct associations between intakes of trans-fatty acids and colon cancer or prostate cancer (Hu et al., 2010).

Cholesterol

Dietary cholesterol is found only in animal foods. There is an increased evidence of an important role of dietary cholesterol in increasing breast cancer risk (Li et al., 2016) and this may be due partly to the cholesterol metabolite, 27-hydroxycholesterol, which has estrogenic activity increasing proliferation of ER+ breast cancer cells (Nelson et al., 2013). High dietary cholesterol may also increase risk of pancreatic (Chen et al., 2015) and colorectal cancers in some studies (Järvinen et al., 2001; Lee et al., 2009), but not all (Nagata et al., 2001) and of endometrial and prostate cancers (Allott et al., 2017).

Mechanisms of Action

Potential mechanisms of dietary fats in the etiology of cancer include pathways linked to excess adiposity, reactive oxygen species (ROS), hyperinsulinemia, adipokine secretion and other key mechanism of inflammation which could induce an environment favorable to tumor growth (Austin et al., 2011; Sung et al., 2011). Dietary fats affect eicosanoids synthesis which are involved in the inflammatory cascade which in turn may stimulate cancer growth (Larsson et al., 2004; Escrich et al., 2011). ROS production is linked to higher consumption of dietary fat and induce oxidative stress that may promote carcinogenesis (Kang, 2002, Baracos et al., 2004). Fatty acids regulate transcription and expression of genes influencing cancer (Jump, 2004; Mandal et al., 2010). Different fatty acids can differently induce cell growth, proliferation, differentiation and motility of cancer cells (Zadra et al., 2013; Navarro-Tito et al., 2008). $N-3$ PUFAs for example reduce inflammation and seem to be protective against tumor growth (Schley et al., 2005).

Guidelines and Recommendations

The recommendations are to limit the intake of red meat and processed meats as much as possible since they are rich sources of SFA, AA, cholesterol and increase inflammation. It is important to avoid excess dietary fat which would lead of positive energy balance and therefore to overweight and obesity. The preferred sources of fats linked to better health and lower cancer risk are MUFA and PUFAs (ACS, American Cancer Society; WCRF, World Cancer Research Fund International).

Cruciferous Vegetables and Related Sulphoraphane

Cruciferous vegetables are part of the Brassica genus of plants and include arugula, broccoli, Brussels sprouts, cabbage, cauliflower, kale, turnip greens and mustard, among others. Cruciferous vegetables have been associated with protection against a range of cancers (AICR'S Foods That Fight Cancer—Broccoli and Cruciferous Vegetables; NIH—Cruciferous Vegetables and Cancer Prevention). They are a rich source of carotenoids (beta-carotene, lutein, zeaxanthin), vitamins C, dietary fiber and a major source of glucosinolate-derived bioactive compounds which have been shown to have anticarcinogenic properties. Glucosinolates are present in almost every member of Cruciferae family and these sulfur-containing compounds are responsible for the pungent aroma and bitter flavor that distinguish cruciferous vegetables from other vegetables (Verhoeven et al., 1996; Higdon et al., 2007). Chemically, glucosinolates are composed of thiohydroximate-*O*-sulfonate group linked to glucose, and an alkyl, aralkyl, or indolyl side chain (R) (Agerbirk and Olsen, 2012). Glucosinolates (Glucoraphanin) undergo hydrolysis upon contact with the enzyme myrosinase, which is present within plant tissues, and they form biologically active compounds such as indoles (indole-3-carbinol) and isothiocyanates (sulforaphane) that have well known anticarcinogenic properties in in vitro and animal studies (Bosetti et al., 2012; Zhang et al., 1992). Isothiocyanates (ITCs) in plants have antibacterial and antifungal activity and provide important protection from insect and herbivore attack (Rosa et al., 1997).

Glucoraphanin glucosinolate is found in the vacuoles of intact plant cells and it is spatially separated from myrosinase, which is in the cytoplasm cells. After cell rupture, induced by chewing during human consumption or by tissue damage during freezing, thawing, and chopping of edible plants, glucoraphanin comes into contact with myrosinase and is converted into sulforaphane and sulforaphane nitrile.

Raw vs Cooked

Storage, processing and cooking can change ITCs formation from glucosinolate and affect the cruciferous vegetables anticancer activity (Barba et al., 2016; Jones et al., 2010). Intake of raw cruciferous vegetables provides two to nine times the amount of ITCs in humans compared with similar intakes of their cooked counterparts (Rouzaud et al., 2004; Getahun and Chung, 1999; Conaway et al., 2000; Shapiro et al., 1998). Studies demonstrated that inverse association between cruciferous vegetable intake and cancer risk appear to be stronger with raw vegetable consumption than with their cooked counterparts. It is notable that ITCs may be largely reduced by cooking procedures due to heat-inactivating myrosinase, reducing the formation of sulforaphane (Rouzaud et al., 2004; Getahun and Chung, 1999; Conaway et al., 2000). Human intestinal microflora also possess myrosinase activity and is able to partially hydrolyze ingested glucosinolates, but studies have shown that isothiocyanate exposure after the consumption of cooked cruciferous vegetables is 60%–90% less than that after the ingestion of raw cruciferous vegetables (Rouzaud et al., 2004; Getahun and Chung, 1999; Conaway et al., 2000; Shapiro et al., 1998). Among thermal processing, steaming is preferred over boiling because glucosinolates can leach into the boiling water and because the action of myrosinase at internal temperatures exceeding 70°C is inhibited (Jones et al., 2010).

Freezing at −20°C is one way to preserve the content of nutrients and improve health benefits of cruciferous vegetables. Freezing at −20°C resulted in the formation of more sulforaphane of broccoli sprouts which was probably due to the enhancement of

myrosinase activity and to the damage caused by ice crystals that brings glucoraphanin into contact with myrosinase (Guo et al., 2015). However, freezing at −20°C and −40°C had a negative impact on the ascorbic acid content in broccoli leading to the enhancement of myrosinase activity (Guo et al., 2015).

Evidence That Cruciferous Vegetables Can Reduce Cancer Risk

There is substantial evidence from human studies that cruciferous vegetable consumption may reduce the risk of several common cancer (IARC 2004, WCRF/AICR 2007; Verhoeven et al., 1997; Turati et al., 2015).

Prostate Cancer

A meta-analysis of 13 studies found that high intakes of cruciferous vegetables were associated with the decreased risk of prostate cancer (Liu et al., 2012). Cohort studies have examined a wide range of daily cruciferous vegetable intakes and found little or no association with prostate cancer risk (Schuurman et al., 1998; Giovannucci et al., 2003; Key et al., 2004). However, some case-control studies have found that people who ate greater amounts of cruciferous vegetables had a lower risk of prostate cancer (Kolonel et al., 2000; Jain et al., 1999).

Colorectal Cancer

Results from cohort studies have generally found no association between cruciferous vegetable intake and colorectal cancer risk (McCullough et al., 2003; Flood et al., 2002; Michels et al., 2000). Two meta-analysis reported consistent findings on the protective effects of cruciferous vegetables for colorectal cancer suggesting that intake of cruciferous vegetables may reduce the risk of colorectal cancer in humans (Wu et al., 2013; Tse and Eslick, 2014). In an updated report from the World Cancer Research Fund and the American Institute for Cancer Research (WCRF/AICR), dietary fiber intake, including cruciferous vegetables, has been upgraded as a convincing protective dietary factor for CRC (WCRF Colorectal cancer).

Breast Cancer

Data from a meta-analysis of 13 studies suggest that cruciferous vegetables consumption may reduce the risk of breast cancer with a significantly reduced risk in postmenopausal but not in premenopausal women (Liu and Lv, 2013). Despite strong evidence of a protective role of cruciferous vegetables in breast cancer in animal and in in-vitro studies, data in human studies are often inconsistent. Some epidemiological studies reported no association (Smith-Warner et al., 2001) or a weak association with breast cancer risk (Zhang et al., 1999). No evidence of association between cruciferous vegetables consumption and breast cancer prognosis has been observed in breast cancer patients (Nechuta et al., 2013; Peng et al., 2017).

Overall

Significant reductions of colorectal and breast cancer risk in subjects consuming cruciferous vegetables at least once a week (compared to non-consumers) were reported from an analysis of a large network of case-control studies while no significant associations were seen in prostate cancer risk (Bosetti et al., 2012). Similar findings have been reported from a systematic review of Mediterranean countries (Turati et al., 2015).

Mechanisms

Similar to other plants, cruciferous vegetables contain various protective compounds including dietary fiber, several antioxidants and vitamins (i.e., carotenoids, polyphenols, vitamin C, and folate) (IARC 2004; Verhoeven et al., 1997; Higdon et al., 2007). In addition, cruciferae are rich unique sources of glucosinolates whose major breakdown products (indoles and ITCs) have shown anticarcinogenic properties. Indoles and ITCs may protect against cancer by modulating Phase I and Phase II enzymes, inhibiting carcinogenesis, stimulating cell cycle arrest and apoptosis, and by reducing inflammation and angiogenesis (Navarro et al., 2011; Lenzi et al., 2014).

Dietary Fiber

Cruciferous vegetables are good sources of dietary fiber which may play a protective role in colorectal cancer (Aune et al., 2011).

Mechanisms Modulating Estrogen Receptor-α Expression

There is strong evidence from cell and animal experiments of a preventive role of cruciferous vegetables in breast carcinogenesis by regulating the expression of estrogen receptor, altering the metabolism of estrogen, or suppressing cyclooxygenase 2 (COX-2) (Lin et al., 2017; Fowke et al., 2000; Kang et al., 2009). The chemopreventive effect of indole-3-carbinol on breast cancer may be linked to its ability of decreasing estrogen receptor-α expression (Bosetti et al., 2002; Fowke et al., 2000). Indeed indole-3-carbinol are able to bind to the estrogen receptor (ER), repressing ER signaling, downregulating the expression of estrogen-responsive genes (Meng et al., 2000) and thus preventing the development of estrogen-dependent cancers including breast, endometrial and cervical cancers. Besides indole-3-carbinol also ITCs can modulate expression of sex hormones and their receptors. ITCs function as ERα disruptors to abrogate mitogenic estrogen signaling in ER-positive breast cancer cells, which provides a molecular explanation for the growth inhibitory function of ITCs in breast cancer development, and a rational for further exploration of ITCs as chemopreventive agents for human mammary carcinogenesis. (Kang et al., 2009).

GST Polymorphism and Colorectal Cancer

Several studies have investigated the different capacity of individuals to metabolize and eliminate glucosinolate byproducts of hydrolysis and this theory may help explain the differential health benefits of cruciferous vegetables (Lampe and Peterson, 2002; Lin et al., 1998). Approximately half of the population lacks GSTM1 (a variant of glucosinolate enzymes) due to gene deletion (Lin et al., 1998) and the homozygous deletion of GSTM1 gives rise to the null phenotype in which there is no expression of GSTM1 protein. The hypothesis is that individuals with the null genotype of GSTM1 or GSTT1 polymorphisms would have less conjugation activity, and thus permitting ITCs to remain biologically active potentially providing greater protection against cancer (Cotton et al., 2000). Findings from a meta-analysis suggest a positive correlation between glucosinolate polymorphism and the protective effects of cruciferous vegetables consumption against colorectal cancer risk in individuals with a single null GSTT1 genotype (Tse and Eslick, 2014).

Epigenetic Modulation

Cruciferous vegetables may have epigenetic properties modulating cancer prevention. Most cancers are characterized by the overexpression of histone deacetylases and DNA methyltransferases, and the mis-expression of micro RNAs. Sulforaphane and indole-3-carbinol from cruciferous vegetables may regulate micro RNAs and inhibit histone deacetylases and DNA methyltransferases (Royston and Tollefsbol, 2015).

Recommendations

Dietary Guidelines generally recommend consuming a variety of vegetables each day because of their different content of bioactive compounds (USDA Choose my Plate). Usually cruciferous vegetables fall into the "dark-green vegetables" category. It is suggested to eat cruciferous vegetables as part of a healthy diet and to prefer eating them raw or after steaming and that sulforaphane appears to be an effective and safe chemopreventive molecule and a promising tool to fight cancer (Lenzi et al., 2014).

Pro-Inflammatory Vegetables: Is There Any Evidence?

High plasma levels of C reactive protein (CRP) are expression of chronic inflammatory status and are associated with poor prognosis of tumors. The inflammatory cytokines are released into the blood by the tumor and by the tumor-associated macrophages, their presence in the blood and the presence of high levels of CRP may indicate that the tumor is more aggressive.

It is a common belief that the Solanaceae plants (tomatoes, eggplants, peppers, and potatoes) may increase inflammation however there seems to be a lack of evidence (Berrino, 2016). In order to keep inflammation low, it is preferable to consume a diet rich in plant foods such as vegetables, fruit and whole grains with some omega-3 fats (flaxseeds, soybeans, wild herbs). Evidence of a possible association between the intake of tomatoes and tomato juice and inflammation has given mixed results: reduction in CRP levels in some studies (Jacob et al., 2008) or no significant change in CRP and other inflammatory mediators in others (Blum et al., 2007). Furthermore, isolated lycopene supplementation has not shown antiinflammatory effect (Markovitis

et al., 2009). Tomatoes, eggplants, peppers, and potatoes are rich the glycoalkaloids α- solanine and α—chaconine which are plants' natural defenses. These compounds however may stimulate the formation of polyamines, metabolites that induce cell proliferation, reduce immune defenses against tumors and promote metastatic migration of tumor cells and angiogenesis (Soda, 2011).

Supplements: Soy Isoflavones

Soy isoflavones are phytochemical compounds that are found in soybeans. These bioactive compounds are also known as phytoestrogen because of their chemical structure similar to animal endogenous estrogens which allows them to bind to the estrogen receptor (Setchell, 1998; Cabot, 2003). Mean isoflavone intake among adults range from 30 to 50 mg/day in Asian countries consuming traditional soy foods whereas is less than 3 mg/day in United States, Canada and Europe (Goodman-Gruen and Kritz-Silverstein, 2001; Bai et al., 2014; Van Erp-Baart et al., 2003; Van der Schouw et al., 2005).

Soy isoflavones occur mainly as glycosides form, bound to a sugar molecule (Murphy et al., 2002). After food fermentation during processing or gut digestion the sugar moiety is hydrolyzed, thereby allowing absorption to occur (Rowland et al., 2003). Breaking of this glycosidic bond leaves the isoflavones in their simple aglycone form (Murphy et al., 1999, 2002; Yamabe et al., 2007; Otieno et al., 2007). It is still not clear whether the effects are due only to the aglycone or its glucosidic portion or both. Soy isoflavones occur mostly in the form of genistein, daidzein and glycitein which account for approximately 50%, 40%, and 10%, respectively, of the total soy isoflavones content (Murphy et al., 2002).

Some human studies reported a wide inter-individual variability in isoflavones metabolism (Jackson et al., 2011) which depends primarily on intestinal flora polymorphisms (Moon et al., 2006; Nechuta et al., 2012a,b). Some individuals host intestinal bacteria that convert the isoflavone daidzein into the isoflavonoid equol (Jackson et al., 2011; Setchell, 1998; Setchell and Clerici, 2010) and this may explain some of the discrepancies in results seen for the health effects of soy foods in human studies (Bolca et al., 2007). It has been suggested that individuals with equol-producing intestinal bacteria may benefit from soy food consumption more than those without (Setchell et al., 2002; Setchell and Clerici, 2010; Setchell, 1998).

Sources

Plants synthetize isoflavones through environmental stresses, such as infections or paucity of nutrients (Lozovaya et al., 2005). Also, different climatic conditions and different cultivation practices lead to variable bean dimension as well as isoflavone content (Howitz and Sinclair, 2008). Isoflavones content can vary depending on temperature and soil moisture. During plant growth, the highest isoflavone concentrations occurring at low temperatures and high soil moisture (Rizzo and Baroni, 2018). Isoflavones are contained in different legumes, such as soy, kidney beans, navy beans, red clover and Japanese arrowroot called kudzu, but only soy beans and soy foods provide the main dietary sources of isoflavones in the human diet (Messina, 1999; Mazur et al., 1998). Soy foods include traditional Asian foods such as tofu, soy milk, tempeh and edamame.

Each gram of soy protein in soybeans and traditional soy foods is associated with approximately 3.5 mg of isoflavones (Messina et al., 2006a,b,c). One serving of a traditional soy food, such as 100 g of tofu or 250 mL soymilk, typically provides about 25 mg isoflavones. In 1999 USDA in conjunction with Iowa State University created a database providing data on the isoflavone (including daidzein, genistein, glycitein and total isoflavones) content of selected food items (USDA).

Health Effects

Beneficial effects have been associated with soy consumption, some of which may depend on phytoestrogen content (Rizzo and Baroni, 2018; Messina et al., 2006a,b,c). Epidemiological studies in Asian countries showed that a traditional diet rich in phytoestrogens was associated with a lower risk of chronic diseases and report on possible benefits in hormone-dependent prostate cancer (Applegate et al., 2018; Zuniga et al., 2013), colon cancer (Yu et al., 2016; Grosso et al., 2017a,b), breast and ovarian cancers (Loibl et al., 2011; Magee et al., 2004; Patisaul and Jefferson, 2010; Peeters et al., 2002; Grosso et al., 2017a), endometrial cancer (Zhong et al., 2018) and stomach cancer (Grosso et al., 2017b).

Some common potential mechanisms of action through which isoflavones could exert protective effects in carcinogenesis have been reported. Isoflavones are structurally similar to 17β-estradiol, the primary endogenous estrogen (Tham et al., 1998; Guha et al., 2009). These molecules play a competitive role with endogenous estrogens for binding to ERα and ERβ although they have lower estrogenic potency compared to estradiol (Breinholt and Larsen, 1998). Isoflavones possessed mixed ER agonist and antagonist properties, depending on the cell type and concentration of estrogen present in the surroundings (Larkin et al., 2008). It has been suggested that soy isoflavones may act as selective tissue estrogenic activity regulators and selective estrogen receptor modulator also with different mechanisms than direct receptor interactions (Nilsson and Gustafsson, 2002; Meegan and Lloyd, 2003; Riggs and Hartmann, 2003; Smith and O'Malley, 2004). ERα and ERβ display distinct expression patterns in men and women, thus phytoestrogens do not exert their activity as classical estrogen agonists (Matthews and Gustafsson, 2003; Hooper et al.,

2009). For example, the ability of genistein to bind to ERβ may be a key factor in the inhibition of prostatic carcinogenesis but other mechanisms include cellular proliferation, apoptosis and differentiation (Mahmoud et al., 2014). Indeed, in addition to ER-depending activity, anticancer effects of soy have been largely ascribed to isoflavones which can modulate cell cycle, apoptosis, differentiation, proliferation and cell signaling (Messina et al., 2006a,b,c; Zhou et al., 1999; Vitale et al., 2016). Soy isoflavones, as a polyphenol subclass, also act exhibiting antioxidant, anti-proliferative and anti-inflammatory properties in vitro and in vivo (Tham et al., 1998; Guha et al., 2009; Patel et al., 2001).

Newly discovered anticarcinogenic mechanisms of action of phytoestrogens include epigenetic modifications. In breast cancer cell lines phytoestrogens modulated chromatin transcription through epigenetic modifications such as methylation and acetylation of histones (Dagdemir et al., 2013; Grosso et al., 2017a,b).

A protective action of soy isoflavones during the cancer promotion phase may explain the reduced breast cancer risk and reduced recurrence in Asian women exposed to soy since infancy.

In 1995 the "early intake" hypothesis emerged showing that early isoflavone exposure may be protective against breast cancer in adulthood in animal studies. This effect may be related to isoflavones ability to impact on mammary gland development, changing cells in ways that make them permanently less likely to be transformed into cancer cells. Animal studies and epidemiological evidence support this hypothesis (Russo et al., 2005; Brown et al., 2010; De Assis et al., 2011; Rahal and Simmen, 2011; Mishra et al., 2011).

Concerns

The estrogen-like properties of isoflavones have been a concern suggesting it may increase estrogenic activities and thus cancer cell proliferation particularly in those who already had breast cancer. This concern stems mainly from animal studies where pharmacological doses of isoflavones were able to stimulate the growth of existing tumors in athymic ovariectomized mice implanted with estrogen-sensitive human breast cancer (Messina, 2016). However clinical and epidemiological studies in humans indicate that isoflavone exposure is safe for all women and it improves the prognosis of breast cancer patients (Grosso et al., 2017a,b; Rizzo and Baroni, 2018). This may be due partly to the selective nature of isoflavones in binding to estrogen receptors and to their other anticancer properties mentioned above. In 2015, after a comprehensive and multiyear evaluation of the literature, the European Food Safety Authority (EFSA) concluded that in postmenopausal women, intakes of 35–150 mg per day of isoflavones from food supplements do not adversely affect sex hormones-responsive tissues such as breast and utero after 2.5 years of treatment (EFSA Panel on Food Additives and Nutrient Sources added to Food ANS, 2015). Data from this systematic review does not support the hypothesis of an increased risk of breast cancer nor of an effect on mammographic density or proliferation marker Ki-67 expression (Wu et al., 2015). Moreover, higher isoflavone intakes in breast cancer patients were associated with reduced mortality and cancer recurrence in women with ER (+) and ER(-) breast cancer (Shu et al., 2009) and no contro-indications have been observed for women under treatment with tamoxifeen or anastrozole, two antihormonal drugs commonly used to treat breast cancer (Guha et al., 2009; Nechuta et al., 2012a,b; Kang et al., 2010).

Recommendations

Up to three servings/day (up to 100 mg/day of isoflavones) as consumed by Asian populations for thousands of years do not seem to be associated to increased breast cancer risk (American Institute for Cancer Research, AICR). Considering one serving averages about 7 g of protein and 25 mg isoflavones, a moderate soy isoflavone consumption is achieved with 1–2 standard servings daily of soybeans or soy foods.

Green Tea and Green Tea Extracts (GTEs)

Next to water, tea is the beverage most widely consumed worldwide, consisting of an infusion or decoction made from the leaves of a woody plant, *Camellia sinensis* (L.) Kuntze, belonging to the family Theaceae. The varieties of tea, derived from the leaves of the same plant, are created through different treatments and have different degrees of enzymatic oxidation of polyphenols by polyphenol oxidase (fermentation). Green tea is a nonoxidized nonfermented product which has similar phenolic compounds to unprocessed tea leaves. To preserve the polyphenols present in green tea, the leaves are arranged on bamboo surfaces and are exposed to the sun for a few hours, then they are steamed (Japanese Style Green Tea) or heated dried (Chinese Style Green Tea) to inactivate enzymes involved in the modification of polyphenols. Drying phases are alternated with folding or rolling allowing water to evaporate. When the leaves are well dried they are ready to be refined (dust and debris are eliminated) and packaged (Kosinska and Andlauer, 2014). The most common polyphenols present in green tea are catechins: (-)-epigallocatechin-3-gallate (EGCG) ≅ 59% of total catechins, (-)-epigallocatechin (EGC) (≅ 19%), (-)-epicatechin-3-gallate (ECG) (≅ 13.6%), (-)-epicatechin (EC), (+)-catechin (C), (-)-gallocatechin gallate (GCG) (≅ 6.4%) and glycosylated flavonols (Lin et al., 2008). They contribute to a higher antioxidant capacity of green tea and its sensory properties. Green tea products are also available as highly concentrated extracts (GTEs) for reconstituted tea drinks (in liquid and powdered forms) or supplements.

Recently, the EFSA ANS Panel provided a scientific opinion on the safety of green tea catechins from dietary sources including food supplements and infusions as a result of concerns about the possible hepatotoxicity, concluding that the catechins contained in green tea infusion and reconstituted drinks are risk-free. However, there is evidence from interventional clinical trials that intake of doses above 800 mg EGCG/day as a food supplement, may be a health concern due to increased serum transaminases (EFSA, Opinion 2018).

Previously peculiar to Asia, green tea is now gaining popularity in Western countries because its consumption seems to be linked to health benefits, especially for its potential anticancer effects in primary and secondary prevention (Cabrera et al., 2006) and in cancer therapy (Lecumberri et al. 2013). Several preclinical evidences have shown that EGCG is a multipotent chemopreventive and anticancer agent in vitro and in various animal models (Fujita et al., 1989; Fujiki and Suganuma, 2002; Gupta et al., 2001; Yamane et al., 1995; Yang et al., 2009; Yiannakopoulou, 2014). The mechanisms involved include inhibition of NF-kB signaling, protection from intracellular oxidation and DNA damage and apoptosis in tumor cells (Roy et al., 2010; Sadava et al., 2007). However, in contrast to the consistent results in in vitro and animal models, results from human studies are mixed (Johnson et al., 2012; Yuan, 2013). Two high quality systematic reviews assessed the link between green tea consumption and the risk of incidence, mortality and recurrence of all cancer types (Bohem et al., 2009; Sturgeon et al., 2009). The authors concluded that despite the associations between green tea consumption and decreased risk for some cancers, the overall evidence is limitated in quantity and quality. In intervention studies an inhibitory role of oral supplementation of green tea on a precancerous lesion of the oral cavity was shown (Li et al., 1999). A limited moderate to strong evidence has been investigated for lung cancer and seem inversely associated with green tea intake among never smokers but not among smokers, probably due to the potential confounding effect of smoking that cancel out the potential protective effect of green tea (Zhong et al., 2001). In prostate cancer, observational studies do not support a role of tea intake in reducing risk but some phase II clinical trials suggested that green tea catechins may have chemopreventive properties against prostate carcinogenesis (Bettuzzi et al., 2006).

The role of green tea infusion on cancer of the liver, colorectal and breast is not yet clear. However, two case control studies investigated the role of genotypes and suggested that differing angiotensin converting and folate metabolism activity genotypes in women probably play a role in the risk reduction of breast cancer with green tea (Inoue et al., 2008; Yoan et al., 2007).

A field to be investigate is the interaction between green tea/GTEs supplementation and cancer drug treatments. Studies showed an interference between green tea supplementation and the chemotherapy drug Bortezomib (Golden et al., 2009) and Sunitinib (Ge et al., 2011).

Until now, very little research has been done on the use of green tea or green tea extracts in treating cancer. Phase I and II trials of daily oral somministration of a green tea extract to patients with a chronic lymphocytic leukemia, who did not take any other treatment, showed that the number of leukemic cells and the size of their lymphones were reduced in a third of the participants (Shanafelt et al., 2009, 2013). More evidence is needed to confirm these preliminary results. At present there is no conclusive evidence that green tea helps to prevent or treat cancer in people because the number of studies especially randomized controlled trials are lacking and studies conducted thus far have utilized different amounts and types of green tea in different settings which makes it difficult to compare results.

Mediterranean Diet

The traditional Mediterranean diet represents the dietary pattern of the Mediterranean countries in 1960s (Kromhout et al., 1989; Sofi et al., 2008; Sofi et al., 2013). The traditional Mediterranean diet is characterized by a high intake of vegetables, legumes, fruits, nuts, unprocessed cereals and extra virgin olive oil as the main source of fat, it is also characterized by a low intake of saturated fats, meat and poultry, moderately high intake of fish, moderately low intake of dairy products and ethanol, mainly wine and generally during meals (Willett et al., 1995; Sofi et al., 2014). The Mediterranean diet contributes to the intake of important vitamins and phytochemicals including β-carotene, vitamins B, C, and E, folic acid, polyphenols and it contains on average: 55%–60% carbohydrates (80% complex carbohydrates and 20% simple sugars mainly from fruit), 10%–15% proteins (40% plant protein), and 25%–30% fats (mainly monousaturated fat from olive oil). The traditional Mediterranean diet received a great attention in the 1970s by the American physiologist Ancel Keys who lived for many years in Southern Italy and conducted the Seven Countries Study, the first major epidemiological study to investigate the relationship between diet and lifestyle in cardiovascular disease across countries and cultures (Menotti et al., 1989; Serra-Majem et al., 2006). This study suggested that the Mediterranean diet is protective against cardiovascular disease and cancer (Ferro-Luzzi and Branca, 1995). Numerous epidemiological studies showed that the Mediterranean diet is associated with a risk reduction of overall mortality, cardiovascular disease incidence and mortality, total cancer incidence and mortality, 25% reduction in colorectal cancer, 15% in breast cancer, and 10% in prostate, pancreas and endometrial cancers (Bloomfield et al., 2016).

Mediterranean Diet in Breast Cancer

High adherence to Med Diet has been shown to reduce incidence and recurrence of breast cancer (Bloomfield et al., 2016). A large European observational study supports a protective role of the Med Diet and its components in breast cancer risk (Buckland et al.,

2013). In international studies outside the Mediterranean basin, reductions in breast cancer risk have been observed with higher consumption of components of the Med Diet such as dietary fiber, low glycemic index carbohydrates, whole grains, fruit and vegetables and dietary marine $\omega - 3$ (Farvid et al., 2016; Kushi et al., 2012; Nicodemus et al., 2001; Zheng et al., 2013). The intervention study PREDIMED (Prevención con Dieta Mediterránea), showed that a Spanish Med Diet supplemented with at least 20% of calories as extra virgin olive oil reduced the incidence of breast cancer by 68% after 4.8 years (Toledo et al., 2015). Possible mechanisms seem to be linked to reduced inflammation, higher antioxidant, antiproliferative and apoptosis-inducing properties of specific compounds present in vegetables, fruit, nuts, extra virgin olive oil and fish, flavonoids such as polyphenols present in olive oil and red wine, dietary fiber and vitamin C present in vegetables and fruit, lignans in whole grains and seeds, monounsaturated fat and squalene in olive oil, and omega-3 fatty acids in fish (Dussaillant et al., 2016; Jing et al., 2013) improving insulin sensitivity and decreasing insulin-like growth factors (Barnard et al., 2006; Breneman and Tucker, 2013). In addition the antioxidant content in extra virgin olive oil (Carruba et al., 2006) may decrease endogenous estrogens, increase sex-hormone binding globulin levels (Wu et al., 2009), neutralize free radicals, prevent DNA damage and reduce oxidative stress (Mitjavila et al., 2013; Visioli et al., 2004). These results are confirmed also by the DIANA-5 study (Diet and Androgens) (Villarini et al., 2012).

Mediterranean Diet in Colorectal Cancer

The Med diet seems to be implicated also in a decreased risk of colorectal cancer although some studies are discordant. It seems that the positive effects of the Med Diet are more evident for the distal colon rather than the proximal colon (Donovan et al., 2017). Possible mechanisms are the antinflammatory effects as reported by preclinical studies. In vitro studies attributed this effect to the phenolic fraction and $\omega - 3$ content of olive oil and partly also to oleic acid, polyphenols from grapes, red wine, fruits and vegetables (Llor et al., 2003). Other studies assess that butyrate, produced from fiber by microorganisms in the gut, contribute to the oncoprotective effect. Future studies will focus on the role of the Med diet on epigenetic regulation and on changes of the microbiome as means of reducing colorectal cancer risk.

Mediterranean Diet in Prostate Cancer

Approximately 10% of the incidence of prostate cancer can be prevented following a traditional Mediterranean dietary pattern (Capurso and Vendemiale, 2017), reducing risk by 4% (Bloomfield et al., 2016). Possible protective compounds may be flavonoids in fruit and vegetables which exert antiinflammatory, antioxidant, antimutagenic and antiproliferative activities (Vance et al., 2013). Important is the antioxidation ativity of lycopene from tomatoes which modulate inflammatory mechanisms of carcinogenesis (Gann et al., 1999; Graff et al., 2016). Numerous studies are also investigating the antiflammatory action of $\omega - 3$ derived from fish in prostate cancer prevention and progression (Thompson et al., 2014; Aucoin et al., 2017).

Mediterranean Diet in Endometrial Cancer

Evidence associating endometrial cancer risk and specific dietary components are limitated. Howewer a 10% protection was found with the highest adherence to the Med Diet (Schwingshackl et al., 2017). Bioactive compounds and fiber of vegetables and fruit, as well as monounsatured fatty acid of extra virign olive oil, seem to modulate the estrogen levels and the inflammatory response. (Bravi et al., 2009; Filomeno et al., 2015; Lampe, 1999; Bandera et al., 2007; Fortner et al., 2017; Wang et al., 2011; Rose, 1990).

Mediterranean Diet in Pancreatic Cancer

Studies on the association between the Med Diet and pancreatic cancer are scanty and discordant. Howewer some studies suggest a protection of 10% for an high adherence to the Med Diet (Trichopoulou et al., 2000) possibly due to the high consumption of vegetables and fruit because of vitamin C, D, E, and K, folate and phenolic compounds (Larsson et al., 2006; Nothlings et al., 2007; Rossi et al., 2012; Trichopoulou et al., 2000; Buckland et al., 2013; Giacosa et al., 2013; Davis-Yadley and Malafa, 2015).

Guidelines and Future Perspectives

Scientific evidence supports healthy benefits of Mediterranean dietary pattern in primary and secondary prevention for the most common types of cancer. The World Cancer Research Fund (WCRF) and the American Institute for Cancer Research (AICR), based on scientific evidence, including the European code against cancer, provided lifestyle recommendations aimed to reduce the incidence and recurrence of the most common cancers worldwide. The recommendations are to avoid sugared beverages and processed

meat and to limit calorie-dense and salty food, alcoholic beverages and red meat. The central recommendation is to "Eat mostly food of plant origin, with a variety of nonstarchy vegetables and of fruit every day and with unprocessed cereals and/or pulses within every meal". these recommendations are at the base of the Med diet characteristics.(WCRF/AICR, 2007, www.iarc.it).

Fasting and Intermittent Fasting Diet

In the last decades a range of dietary interventions have gained considerable popularity for the prevention and treatment of age-related diseases, including cancer. Calorie restriction (CR) as well as fasting regimens are both dietary interventions of reduced caloric intake without malnutrition and have demonstrated a wide range of beneficial effects potentially able to prevent cancer and increase the efficacy of cancer therapies (Varady and Hellerstein, 2007; Mattson et al., 2017; Buono and Longo, 2018). Calorie restriction (CR) is a term commonly used to refer to a 20%–40% reduction in caloric intake without malnutrition (e.g., with an adequate micronutrient intake) (Mirzaei et al., 2016; Varady and Hellerstein 2007). As CR is not well tolerated by cancer patients and contraindicated for those at risk of weight loss, cachexia and sarcopenia, other caloric restricted approaches have been investigated, such as intermittent fasting (IF) which may be more suitable (Varady and Hellerstein, 2007; Rizza et al., 2014)

Fasting refers to a complete absence of food intake. The fasting period for the organism is a time for standby and repair in order to harvest energy when food becomes available (Longo and Panda, 2016). Alternate cycle of feeding and fasting are at the base of fasting physiology. Fasting can be administered at various time frames and can be repeated many times. Both reducing daily energy intake and restricting the time of food intake to a few hours may trigger the fasting physiology (Longo and Panda, 2016). IF comprises different forms of fasting including alternate day fasting (ADF), periodic fasting (PF), time-restricted feeding (TRF) and Ramadan fasting (Longo and Mattson, 2014; Varady, 2016). ADF regimens generally involve a 24-h fast followed by a 24-h non-fasting period (Horne et al., 2015). PF only requires participants to fast two or more consecutive days per week, every 2 or more weeks (Hutchison and Heilbronn, 2016). TRF requires individuals to confine the period of food intake to a set period of time during the day, for example an 8-h feeding window where all food is consumed between 10:00 am and 6:00 pm (Rothschild et al., 2014). The Islamic ritual of Ramadan fasting is a form of time-restricted feeding, where food consumption is only permitted during the night time (Mazidi et al., 2015).

Evidence in Cancer

Data from epidemiological and experimental studies suggest that calorie intake, the timing of food intake (e.g., fasting cycles), and dietary composition (e.g., protein, aminoacid, fat, mineral, vitamin and phytochemical intakes) are implicated in the pathogenesis of chronic diseases, including common types of cancer (Fontana et al., 2010; Mattson, 2005; Eyre et al., 2004).

Chronic CR provides both beneficial and detrimental effects as well as major compliance challenges, whereas different fasting regimens, without malnutrition, are emerging as interventions with the potential to be widely used to prevent and treat cancer (Patterson and Sears, 2017; Buono and Longo, 2018; Lee et al., 2012b; O'Flanagan et al., 2017).

First experiments in animal models demonstrated that fasting exerts a protective effect against DNA damage and promotes longevity (Longo and Fontana, 2010; Varady and Hellerstein, 2007). IF reduces the incidence of spontaneous tumors (Berrigan et al., 2002; Descamps et al., 2005), while PF can delay cancer progression as effectively as chemotherapy in animal models (Lee et al., 2012b). No data are available on the effects of IF on cancer rates in humans. Surrogate evidence that IF may reduce cancer risk can be derived from its effects on cancer risk factors. For example, most studies of ADF show benefits in weight reduction (Tinsley and La Bounty, 2015) and weight control is associated with a reduced risk of cancer (Renehan et al., 2008). IF has a beneficial effect on insulin resistance and diabetes which are cancer prognostic factors (Goodwin et al., 2015). Some studies have investigated the effect of fasting on the effectiveness of cancer therapy. Preliminary studies in 10 cancer patients fasted voluntarily during their chemotherapy and showed a decrease in the range of self-reported common side effects caused by chemotherapy compared to when they were on a standard diet (Safdie et al., 2009; Raffaghello et al., 2010b).

Mechanisms

CR and fasting have been shown to promote stress resistance as well as longevity in a wide variety of animal models. These dietary regimens affect cellular metabolism and growth by down regulating conserved nutrient-signaling proteins and by activating stress resistance transcription factors (Fontana et al., 2010). Metabolic and molecular antitumorigenic mechanisms of CR are well established. Accumulating data have showed that CR tumor suppressive effects are mediated by enhanced apoptosis, modulation of systemic signals such as IGF-1, insulin, metabolic and inflammatory pathways, and reduced angiogenesis (O'Flanagan et al., 2017; Fontana et al., 2010). Indirect evidence suggests that CR and fasting regimens may share common mechanisms. To date no data from human studies on the effect of IF or PF in cancer prevention are available. However their effect on reducing IGF-1, insulin and glucose levels, and increasing IGFBP1 and ketone body levels could generate a protective environment that reduces DNA damage and carcinogenesis, while at the same time creating hostile conditions for cancer and pre-cancerous cells (Longo and Mattson 2014). Elevated circulating IGF-1 is associated with an increased risk of developing several cancers (Chan et al.,

2000; Giovannucci et al., 2000) and individuals with severe IGF-1 deficiency caused by growth hormone receptor deficiency, rarely develop cancer (Guevara-Aguirre et al., 2011; Shevah and Laron, 2007). Findings in IGF-1 deficient subjects suggest that fasting may protect from cancer by reducing cellular and DNA damage but also by enhancing the programmed cell death of precancerous cells (Guevara-Aguirre et al., 2011). However, the effect of IF on IGF-1 levels in human studies has been variable. Some studies reported no changes in IGF-1 with weight loss due to intermittent fasting (Harvie et al., 2011), and others showed an increase in both IGFBP1 and IGFBP2 (Harvie et al., 2011; Fontana et al., 2010; Thissen et al., 1994). It is well established that a positive energy balance, as well as an increasing adiposity contributes to an increased risk of developing several types of cancer, including cancer of the colon, breast, prostate, endometrium, pancreas, liver and kidney, whereas weight loss lowers risk (Longo and Fontana, 2010; Calle and Kaaks, 2004).

Evidence demonstrates the important role of dysregulation in signal transduction and metabolic pathway in tumor initiation and progression. Cancer cells are characterized by an abnormally high level of glucose requirements necessary to produce the glycolytic ATP, as well as by accumulation of a variety of mutations (e.g., the IGF-1 receptor) (Buono and Longo, 2018) making them potentially sensitive to the changes in growth factors and circulating nutrients. Furthermore, a differential stress resistance (e.g., cell mechanism used during fasting to protect normal cells but not cancer cells from chemotherapy) and differential stress sensitization (e.g., cell mechanism used during fasting to preferentially kill cancer cells and other damaged cells in combination with chemotherapy or other cytotoxic agents) of fasting conditions in normal and cancer cells have been showed in in vitro and animal models (Buono and Longo, 2018; Raffaghello et al., 2008). Fasting conditions can be protective in normal cells because they are capable of adapting to starvation (Raffaghello et al., 2008) whereas cancer cells are characterized by inability to adapt to multi-stressed environments (Cheng et al., 2014; Lee et al., 2012b).

Future Directions

Several epidemiological studies clearly demonstrated that diet plays an important role in the initiation, promotion and progression of many common cancers (Kushi et al., 2006; Renehan et al., 2010). To date, there are no specific guidelines on the type of nutrition for each cancer type or cancer stage. According to the American Cancer Society, cancer patients receiving chemotherapy should increase calorie and protein intake (Doyle et al., 2006).

Findings from in vitro and animal studies have reported beneficial effects of combined fasting regimens with the standard-of-care pharmacotherapy. Dietary interventions mimicking CR can also be viewed as adjuvant anticancer strategies to be combined to standard cancer therapy (chemotherapeutic agents, ionizing radiation, and drugs with specific molecular targets). Clinical studies on the potential use of dietary treatments alongside conventional treatments are ongoing however the preliminary evidence suggests that these approaches may be a valid integrated therapy in cancer patients.

Dietary Factors and Cancer*

Isabelle Romieu, National Institute of Public Health, Cuernavaca, Mexico; and Emory University, Atlanta, GA, United States

Glossary

Case control study An epidemiological study in which the participants are chosen based on their disease or condition (cases) or lack of it (controls) to test whether past or recent history of an exposure is associated with the risk of disease.

Cohort study An epidemiological study of a group of people whose characteristics are recorded at recruitment, followed for a period of time during which the outcomes of interest are noted. Differences in the likelihood of a particular outcome are presented as the relative risk comparing one level of exposure to another.

Confidence interval A measure of uncertainly in an estimate usually reported as 95% confidence interval.

Dietary fiber Constituents of plant cell walls that are not digested in the small intestine. Non-starch polysaccharides are a consistent feature and are fermented by colonic bacteria to produce energy and short chain fatty acids including butyrate.

Fatty acids A carboxylic acid with a carbon chain of varying length, which may be either saturated (no double bonds) or unsaturated (one or more double bonds).

Meta-analysis The process of using statistical methods to combine the results of different studies.

Pooling In Epidemiology, a type of study where original individual-level data from two or more original studies are obtained, combined and reanalyzed.

Randomized controlled trial (RCT) A study in which a comparison is made between one intervention (often a treatment or prevention strategy) and another (control). Groups are randomized to one intervention or the other, so that any difference in outcome between the two groups can be ascribed with confidence to the intervention.

Relative risk (RR) The ratio of the rate of the disease or death among people exposed to a factor, compared to the rate among the unexposed.

Introduction

Interest in the cause and prevention of cancer arose from the observation that cancer rates vary greatly between countries and are correlated to dietary factors, and that nutrition can modify cancer incidence in animals. Furthermore, ecological studies showing correlation between dietary habits and cancer incidence and mortality, and migrant studies on changing rates with change in diet and life style, have stimulated research on the role of diet in cancer prevention. To provide more specific information on human cancer, many retrospectives case-control studies, some prospective cohort studies and a few randomized controlled trials (RCT) have been conducted. The most extensive review of the existing evidence on diet and cancer has been conducted by the World Cancer Research Funds/American Institute for Cancer Research (WCRF/AICR) (2007) and the continuous update project (CUP/WCRF). Lifestyle recommendations for cancer prevention were drawn up on the basis of nutrition-related factors judged to be convincingly or probably causally related to cancer, according to predefined criteria for judging the strength of the evidence regarding causality. Results from the most recent evaluations on the association between dietary factors and alcohol consumption and major cancers are presented in Table 1. According to the recommendations, a healthy diet for cancer prevention is a diet (1) that allows a person to be as lean as possible without being underweight; (2) is rich in fruit, vegetables, whole grains and pulses; (3) contains low amounts of red meat; (4) does not contain processed meats; (5) limits salt intake; (6) avoid sugary drinks, and limits intake of calorie-rich foods. A healthy diet also limits consumption of alcoholic drinks. In this article we address the mechanisms involving nutritional factors in cancer development, and the challenges in studying these associations, then we present and discuss the most recent evidence on the link between dietary factors and cancer development.

Main Mechanisms Involving Nutritional Factors in Cancer Development

Excessive caloric intake results in weight gain and ultimately obesity, which in turn is associated with an increased risk of several cancers (colorectal, endometrium, kidney, esophagus, postmenopausal breast, gallbladder, pancreas, gastric cardia, liver, ovary, thyroid, meningioma, multiple myeloma, and advanced prostate cancers). Many experimental studies have shown that calorie restriction suppresses the carcinogenic process. The interactions between cellular energetics in cancer cells and the systemic metabolic changes associated with obesity are emerging as critical drivers of obesity-related cancer. In obesity, alterations occur in

↓↓↓, convincing decreased risk; ↓↓, probable decreased risk; ↓, limited-suggestive evidence decreased risk.
↑↑↑, convincing increased risk; ↑↑, probable increased risk; ↑, limited-suggestive evidence increased risk.
AICR/WCRF evidence stratification.
Convincing: Evidence strong enough to support causal relationship. Evidence from more than one study type, data from at least two cohort studies, no unexplained heterogeneity between studies with regard to the presence or absence of an association, good quality studies where random or systematic error are unlikely, presence of a dose–response relationship, and strong and plausible experimental evidence.
Probable: Evidence from at least two cohort studies or at least five case-control studies, no unexplained heterogeneity between studies with regard to the presence or absence of an association, good quality studies where random or systematic error are unlikely, evidence of biological plausibility.
Limited-suggestive: Evidence is too limited to permit a probable convincing judgment but there is evidence of a direction of effect. Evidence from at least two cohort studies or at least five case-control studies, some evidence of biological plausibility, and the direction of the effect is generally consistent.
Limited-no conclusion: evidence limited in number of studies or yielding inconsistent results.
[a]For unmarked items there is limited evidence and no conclusion could be drawn.
[b]Include evidence for saturated fat for pancreas.
[c]Includes evidence for stomach (noncardia).
[d]Includes evidence from total dairy, milk, cheese and dietary calcium intakes for colorectum.
[e]Includes evidence on foods containing carotenoids for oropharynx (mouth, pharynx, larynx), foods containing beta-carotene for esophagus; foods containing vitamin C for esophagus and stomach (cardia).
[f]Includes evidence on foods containing carotenoids for oropharynx (mouth, pharynx, larynx) and breast (pre and postmenopausal); foods containing beta-carotene for esophagus; foods containing vitamin C for esophagus; stronger effect on ER− breast tumors.
[g]Includes evidence for foods containing carotenoids for oropharynx (mouth, pharynx, larynx) and breast (stronger effect for ER− tumors). Includes evidence on foods containing beta-carotene for esophagus and lung. Increased risk for lung derived from studies using beta-carotene supplements.
[h]Based on evidence for alcohol intake up to 30 g/day (about two drinks a day). There is insufficient evidence for intake >30 g/day.

circulating levels of insulin and insulin-like growth factor-1 (IGF-1); adipokines, such as leptin and adiponectin; inflammatory factors; several chemokines; lipid mediators, and vascular-associated factors. Each of these factors has a putative role in the development and progression of cancer as well as several other chronic diseases including cardiovascular disease and type 2 diabetes.

In addition, nutrition influences inflammatory and immune responses, and this has led to the development of the "dietary inflammatory index" and the use of the term immune-nutrition. Obesity is strongly linked to chronic inflammation and to immunologic abnormalities with fewer cytotoxic CD8 + T cells and natural killer cells, while fasting has been associated with antiinflammatory effects. These factors may influence cellular processes and lead to the accumulation of the well-established hallmarks of cancer cells: reprogrammed energy metabolism, sustained proliferative signaling, increased chronic inflammation, increased genome instability, enabled replicative immortality, enhanced angiogenesis, activated processes related to invasion and metastasis, and resistance to growth suppressors, cell death inducers, and immunoregulators. A growing body of evidence indicates that lowering the energy density (the amount of energy in a particular weight of food) of diet can reduce caloric intake. Energy dense diets contain less fiber-rich foods, and are usually high in fats, processed starch, and added sugars. Sugar-sweetened soft drinks play an important role in the development of obesity.

Nutrition can also cause oxidative stress, augment a cascade of molecular reactions in cells and alter the metabolism of tissues. Overnutrition may generate free radicals and subsequently elevated oxidative stress and ROS-mediated modulation of various molecular pathways and chronic inflammation. Some nutrients have been linked to an increase in oxidative stress response. Carbohydrates quality can influence the plasma level of glucose and insulin resistance, leading to the formation of free radicals by an imbalance in the ratio of NADH to NAD and by non-enzymatic glycation increased by glucose in cells. Fatty acids appear to affect differentially the cancer risk, in particular through inflammatory pathways. The cyclo'oxygenase-2 (COX-2) enzyme can convert omega-6 FAs into prostaglandin E2, a proinflammatory cytokine, which enables angiogenesis and cell proliferation, whereas prostaglandin E3 is produced from omega-3 FAs with the help of COX-2 which does not facilitate mitogenic angiogenesis. The ratio between omega-6 and omega-3 polyunsaturated fatty acids (n-6 PUFAs and n-3 PUFAs) could therefore play an important role.

Fatty acids could also act through other mechanisms. In breast cancer, "de novo" lipogenesis through the action of the stearoyl-CoA desaturase-1 (SCD-1) has been suggested to increase cancer risk. Trans fatty acids are used in industrial processed sweet and salty foods and have been associated to alterations in metabolic and signaling pathways, higher circulating levels of lipids, systemic inflammation, endothelium dysfunction and possibly increased visceral adiposity, body weight and insulin resistance.

Vitamins and minerals such as carotenoids, folate, vitamin C, D, E, and B6 and selenium might reduce cancer through preventive oxidative damage, affecting immune response, inhibiting cell proliferation, inducing cell-cycle arrest, and maintaining DNA methylation. Similarly, phytochemicals such as polyphenols are natural antioxidants modulating intracellular ROS levels resulting into epigenetic alterations of essential genes in tumorigenesis. Flavonoids compounds have been linked to an anticancer activity. Isoflavone possesses a well-characterized anti-estrogenic activity; acts in intracellular steroid metabolism and has antiangiogenic, antiproliferative and proapoptotic activities in tumor cells. Lignans (enterolactone) are strong antioxidant and antiinflammatory substances.

Some food compounds can act as *direct mutagens and carcinogens*. In processed red meat, haem iron is nitrosylated, because curing salt contains nitrate or nitrite leading to the synthesis of nitroso compounds that are mutagenic and potential carcinogens. In red meat, haem iron may act by catalyzing the formation of nitroso compounds and of lipid oxidation end products such as 4-hydroxynonenal. Heterocyclic amines and polycyclic aromatic hydrocarbons are formed when cooking food at high temperatures for a long time, or exposed to a direct flame such as a barbecue. In addition, various single-nucleotide polymorphisms involved in the metabolism of these potential carcinogens may modulate the association of carcinogens formed in meat with cancer risk.

Sodium chloride is a food preservative used in processed foods. In animal experiments, salt intake facilitates gastric Helicobacter pylori colonization, one of the main predisposing factors for stomach cancer development, and induces mucosal damage. It may also promote or enhance the effect of nitroso-compounds and other carcinogens.

Dietary fiber from plant foods can reduce the risk of cancer by several mechanisms. Dietary fiber stimulates bacterial anaerobic fermentation in the large bowel with production of short-chain fatty acids, acetate, propionate, and butyrate, shown to reduce cell proliferation and induce apoptosis. Dietary fiber may also protect against colorectal cancer by reducing the transit time of the intestinal content. Dietary fiber interferes with the enterohepatic circulation of oestrogens and experimental studies in mice have shown that soluble fiber can reduce mammary tumor growth, angiogenesis and metastasis. In addition, fiber-rich foods are important sources of phytoestrogens, estrogen-like plant compounds that may modulate the risk of hormone-dependent cancers, especially breast cancer.

Carbohydrates and carbohydrate quality could influence carcinogenesis by affecting insulin resistance and plasma levels of insulin and glucose and level of insulin-like growth factor-1. In addition to increased oxidative stress, elevated circulating insulin level could promote carcinogenesis either directly by stimulating the production of insulin receptors, or indirectly by suppressing insulin growth factor binding protein 1 and 3 affecting the bioavailability of insulin growth factor-1.

Folate, originating mainly from green leafy vegetables and fruits, is an important B vitamin. Folate is a critical factor in the network of biochemical reaction referred to as "one-carbon metabolism" together with other B vitamins (B2, B6, B12) that plays critical role in DNA methylation and DNA synthesis, and in turn, facilitates the cross-talk between genetic and epigenetic processes. Thus, the 1-carbon metabolism can impact both genetic and epigenetic pro-carcinogenic processes, and these biologic roles potentially make folate and other related B vitamins important in cancer prevention. However, serum folate has been inconsistently associated with DNA methylation. The effect of diet on epigenetics could be indirect by modulating chronic inflammation, an important factor associated to epigenetic changes and cancer risk.

Despite its central function in maintaining DNA integrity, the role of folate in cancer prevention seems to be affected by folate status and the timing of folate administration. In particular, data from a supplementation study suggest that folate administrated prior to the existence of preneoplastic lesions can prevent tumor development, whereas provision of folate once early lesions are established appears to increase tumorigenesis. In addition, other factors may impact the relationship between folate intake and cancer risk, such as alcohol intake, and polymorphisms in methylenetetrahydrofolate reductase (*MTHFR*), which codes for a key 1-carbon metabolizing protein. Further, the impact of folate may be related to the tumor type, and other B vitamin namely vitamin B2, B6, B12 that serve critical cofactors for several pivotal enzymes in 1-carbon metabolism.

Activation of the vitamin D pathway with calcitriol, the active component of vitamin D, or its analogues reduced tumor development and growth in numerous animal models. Calcitriol acts by binding to the vitamin D receptor (VDR) and by functioning via both genomic and nongenomic pathways to regulate target gene expression. Calcitriol has been shown to have antiproliferative, prodifferentiation and antiinflammatory and immunomodulating activities.

Alcohol dinking has been classified as carcinogenic to humans (Group 1) by the International Agency for Cancer Research. Ethanol in alcoholic beverages and acetaldehyde associated with the consumption of alcoholic beverages have also been classified as carcinogenic to humans (Group 1). Overall, there is no consistent difference in cancer risk between different types of alcoholic beverages. While the mechanisms of alcohol carcinogenesis are not fully understood, several mechanisms have been suggested: the direct carcinogenicity of ethanol and its metabolites; the interplay with folate metabolism regulated in part by methylenetetrahydrofolate reductase (MTHFR); impact on endocrine and growth factor pathway leading to an increased levels of androgen and estrogen; impacts on bioactive lipids metabolism including lipoperoxidation and generation of free-radical oxygen species, all of which would be further modulated by use patterns and genetic and environmental factors.

The human microbiota is a very diverse ecosystem composed of a large number of microorganisms (close to 100 trillion). Nutrition plays a pivotal role in the regulation of the bacterial community in the gut. Excess intake or imbalance in micro or macronutrients have deleterious effects. Microbiota interacts with the host via direct contact through surface antigens or via soluble molecules which are produced by the microbial metabolism. Most of the data on the link between microbiota and cancer is derived from intestinal tumor models in mice that suggest a causal role for bacterial diversity and community changes. Patients with colorectal cancer and polyposis show dysbiosis, or altered diversity of microbiota supporting the search for tumor-promoting or tumor-protectives species. Bacterial species such as enterogenic *Bacteroides fragilis* could confer protumorigenic properties. Microbiota can also affect the risk of cancer through its metabolic activity and functions. For example, the metabolism of fiber is a critical one for colorectal cancer. A reduction in butyrate levels has been associated with tumorigenesis in mouse models with oncogenic K-ras activation. Metagenomic analyses have consistently shown a reduction of butyrate producers in colorectal cancer patients. In addition, the host genotype may interact with diet to alter the diversity and function of the microbiota in the gut.

Challenge in Diet–Cancer Research

Foods are naturally complex and provide numerous bioactive substances that can act individually or synergically to influence processes such as cell differentiation, apoptosis and hormonal regulation of cellular functions. However, demonstrating relationship between diet and cancer risk in epidemiological studies and intervention, has been challenging because of the potential for bias and random misclassification in both exposure and disease.

Study Design

Prospective cohorts are least susceptible to bias, yet require very large sample size, long term follow-up and good ascertainment of cases. Randomized controlled trials (RCTs) of dietary change or supplements provide the highest level of evidence on diet–cancer relationship. However, adherence to the intervention and sufficient change in nutritional intake are needed to detect an effect. In addition, dietary effects are likely to differ based on baseline nutritional status, and volunteers who participate in dietary intervention are likely to be more health-conscious. Dietary or nutritional supplement interventions are usually conducted over a few years which is a brief period relative to the long latency of most cancers. Therefore, depending on the proposed mechanism of action, the timing of the intervention might affect the outcome. Finally, it is becoming more evident that early life exposure and exposure during infancy and adolescence might impact the risk of cancer later in life. Greater growth/stature is a risk factor common to many cancers, including breast, ovary, endometrium, kidney, testicular, colon, and rectal cancer, and malignant melanoma, non-Hodgkin's lymphoma, and leukemia. Studying the relevant period of exposure becomes an important challenge, and focusing only on exposure in adulthood may obscure an association.

Dietary Assessment

Food frequency questionnaire (FFQs) have been mostly used to assess dietary intake in cancer studies. Being self-administered, FFQs are considered easy to use with practical application in cohort studies. Accuracy of dietary assessment is obtained through validation studies using different methods of assessment (e.g., 24-h report or 24-h recall) and assessment of biomarkers in blood and urine samples measuring recovery biomarkers such as urinary nitrogen, potassium and sodium in order to calibrate FFQ data. In addition, concentrations of biomarkers correlated to intake of food or food group are available such as carotenoids, vitamin E or fatty acids and

can be used to validate a FFQ. Direct measurement of blood biomarkers has the advantage of integrating the bioavailability of the nutrients and not relying on reported food intake and food composition tables so improving dietary assessment. Recently, high-throughput technologies developments have provided tools to improve dietary assessment. Metabolomics, by measuring the full profile of small molecules metabolites in biological samples such as saliva, blood and urine, can improve our knowledge of metabolic pathways relevant to diet–cancer relationship. Moreover, because nutritional epidemiological studies rely on self-reported dietary assessment methods subject to recall bias and measurement error, and because objective biomarkers do not exist for all nutrients and foods, metabolomics can be a promising technique for objectively identifying dietary biomarkers and dietary patterns.

Cancer Phenotype

The biology of cancer has shown heterogeneity within and across different organ sites and a number of carcinogenic pathways are involved through various genetic mutations; therefore, tumors originating within the same organ site are often etiologically different and are likely to be associated with different risk factors. For example, in the pooling project of prospective studies on diet and cancer, the intake of fruit and vegetables had a consistent protective effect on estrogen receptor negative (ER−) tumors, but not on estrogen receptor positive (ER+) breast cancer across 20 cohorts. It is therefore important to classify adequately tumor subtypes.

Early Life Exposure

Diet in early life can affect markers of adolescent growth and development such as age at menarche, age at peak height growth velocity, and peak height growth velocity. This association has implications for chronic diseases such as breast cancer which has some risk factors stemming from adolescent growth and development, in particular because the breast has not yet completed cell differentiation. Several longitudinal studies have shown that the intake of animal protein in young girls has been associated to earlier age at menarche, while vegetable protein has been associated to a later onset of menarche. Animal protein intake has also been related to faster growth and higher attained height. Higher peak height growth velocity and early age at menarche each increase the risk of breast cancer.

Data on the contribution to breast cancer risk of childhood and adolescent dietary exposure is little documented. Soy intake particularly in childhood has been related to lower risk of breast cancer. Data from the ongoing Nurses 'Health study II (NHS II), a large cohort study of young US nurses 24 to 44 years of age, suggest that meat intake and fatty diet during adolescence are related to an increase of premenopausal breast cancer. A significant linear association was observed with every additional 100 g of red meat consumed per day during high school (20% increase in risk; Relative risk (RR) = 1.10 95% CI = 1.00–1.43). Fat intake in the highest quintile (142 g/day) was associated with a 35% increase in risk when compared to fat intake in the lowest quintile (105 g/day) (RR = 1.35 95% CI = 1.00–1.81). Fiber intake during adolescence was also related to the risk of breast cancer; women in the highest quintiles (27.8 g/day) had 24% less risk of premenopausal breast cancer than women in the first quintile (18.2 g/day) (RR = 0.76 95% CI = 0.58% 1.00%). Higher total fruit intake during adolescent independently of fruit intake in adulthood was also associated to a reduced risk of premenopausal breast cancer. In addition, consumption of fish, fruit and vegetables during adolescence has been associated with a reduced risk of colorectal adenomas, a precursor lesion of colorectal cancer.

"Prudent" dietary pattern, characterized by high intake of vegetables, fruits, legumes, fish and poultry, during adolescence was inversely associated with premenopausal breast cancer. Similar results were observed by scoring higher on the Alternative Healthy Eating Index (AHEI) and the association appeared to be stronger for ER−/progesterone receptor-negative (PR−) tumors. High consumption of fish, fruit and vegetables during adolescence was associated with a reduced risk of colorectal adenomas. This association is plausible since dietary fiber can modify the composition of the gut microbiota to metabolize and reduce circulating estrogen. In addition to reducing the risk of early cancers, prevention efforts that begin in early life may also provide important benefits much later in life by shifting the long-term trajectory of risk accumulation.

The importance of the timing of exposure during adolescence is further emphasized by the adverse effect of alcohol consumption. Adolescent alcohol consumption is directly related to the risk of premalignant and invasive breast cancer in prospective cohort studies. In NHS II, alcohol consumption between menarche and first full-time pregnancy (FFTP) was associated with an 11% increased risk per 10 g/day (1 drink) in breast cancer (RR = 1.11 95% CI = 1.00–1.23) and a 16% increase in benign breast disease (RR = 1.16 95% CI = 1.02–1.32). In addition, a stronger effect was observed with binge drinking pattern. In the European prospective investigation into cancer and nutrition (EPIC), a large multicenter European cohort, alcohol intake was associated with both pre- and postmenopausal breast cancer. However, breast cancer risk was stronger among women who started drinking prior to FFTP. An increase of 10 g of alcohol/day was related to an 8% (RR = 1.08 95% CI = 1.02–1.14) increased risk of ER− tumors in women who start drinking prior to FFTP, while no association could be detected among women who start drinking after FFTP.

Association of Adult Diet and Cancer in Population Studies

Fat

Among dietary factors, fat has received the greatest attention due to strong international correlations with rates of several cancers common in developed countries. However, prospective studies have consistently shown little relationship of fat intake with breast

cancer risk. Some epidemiological studies indicate that, rather than total fat intake, subtypes of fatty acids could be more determinant and diversely affect breast cancer risk; although, overall findings to date are conflicting. Epidemiological data on biomarkers of exposure to fatty acids and breast cancer risk are also limited. A meta-analysis of prospective studies has suggested a protective effect of n-3 PUFAs on breast cancer risk. One prospective study showed a significant association between high blood levels of industrial trans-fatty acids (ITFA) and increased risk of breast cancer. However, in general prospective studies have not shown clear associations between patterns of fatty acids and risk of breast cancer, overall and by hormonal receptor status. In two large RCT of low-fat diet, there was no significant effect on risk of breast cancer.

Prospective studies of colon cancer have also not supported the positive relationship with fat intake suggested by international comparison of cancer rates. Prospective studies of dietary fat and prostate cancer are fewer but do not generally support the relation with total or specific types of dietary fats. Intake of saturated fatty acids has been related to an increase in pancreatic cancer. In a recent meta-analysis including 5 cohort studies, an 11% increase in pancreatic cancer incidence per 10 g saturated fatty acid per day (RR = 1.11 95% CI = 1.01–1.21) was observed while no consistent results were observed for total fat intake. Studies of lung cancer have found inconsistent evidence of an association with total fat.

Red and Processed Meat

Numerous studies have shown an association between high intake of processed meat (such as ham, bacon, sausage and hot dogs), red meat (mainly beef, pork and lamb) and colorectal cancer. Processed meat has been classified as carcinogenic to human by the International Agency for Research on Cancer (IARC) (group 1) while red meat has been classified as probably carcinogenic to human (group 2A). A meta-analysis including 10 cohort studies has shown significant dose–response relationship and concluded to an18% increase (RR = 1.18 95% CI = 1.10–1.28) per 50 g/day of processed meat intake and a 17% increase (RR = 1.17 95% CI = 1.05–1.31) per 100 g/day of red meat. Processed meat cured with nitrite contains high content of nitroso compounds (NOCs), potent carcinogenic agent in animal experiment, and nitrosylated haem iron potential carcinogenic to human. Carcinogens formed during the cooking of meat heterocyclic aromatic amines (HAAs), polycyclic aromatic hydrocarbon, and benzopyrene have provided conflicting results, in part because of the difficulty in assessing dietary carcinogen intake. However, interaction between specific phenotypes of *N*-acetyltransferase 2 (NAT2) (rapid, intermediate or slow acetylation), and enzyme requires for the bioactivation of HAAs, and the risk of colorectal cancer has been observed. Red and processed meat intake has also been linked to stomach, pancreatic cancer and overall cancer mortality. Although consumption of meat during midlife or later has not been associated with risk of breast cancer, a positive association has been seen with intake in adolescent and early adult life. Studies on red meat and the risk of prostate cancer have been limited and results are inconsistent.

Salt Intake

Animal and human studies supported the cocarcinogenic effect of salt on gastric cancer through synergic action with Helicobacter pylori infection, in addition to some independent effects such as increase in the rate of cell proliferation and of endogenous mutations. Salt intake may also promote or enhance the carcinogenic effect of nitroso compounds. The epidemiologic evidence is consistent across studies investigating the intakes of salt, pickle vegetables, dry fish and other salty foods.

Dairy Products

Higher consumption of milk and dairy products have been associated with lower risk of colon cancer with a decreased risk of 13% (RR = 0.87; 95% CI = 0.83–0.90) per 400 g/day. Dairy products were not associated with rectal cancer. This protective effect is probably due to the calcium content, lactic-acid producing bacteria and potentially lactoferrin, vitamin D and short chain fatty acid butyrate. In contrast, higher consumption of dairy products has been associated with increased risk of total prostate cancer in many studies (RR = 1.07 95% CI = 1.02–1.12 per 400 g/day). The fat component of milk does not appear to account for these associations.

Fruits, Vegetables, Pulses and Phytochemicals

Higher intake of essential nutrients and other biological active constituents of plants have reduced cancer incidence in laboratory animals. However, the potential protective effect of fruit and vegetables against cancer observed in case control epidemiological studies has not been strongly supported in cohort studies and is limited to some cancers. Fruit and vegetable intakes have been inversely associated to cancer of the mouth, pharynx and larynx in a large consortium of case-control studies. Fruit and vegetable intake have also been inversely associated with oesophageal squamous cell carcinoma in a large meta-analysis (31 studies). The evidence for fruit intake and stomach cancer has been confirmed in a meta-analysis of 22 cohort studies showing that individual with lower fruit intake were at higher risk of stomach cancer and an association with citrus fruit was confirmed in a further meta-analysis of prospective cohort studies. A 13% reduction of gastric cancer according to the intake of citrus fruit when comparing highest to lowest intake was observed (RR = 0.87, 95% CI = 0.76–0.99). The effect was stronger for cardia gastric cancer than noncardia gastric cancer. This association was later confirmed in cohort studies based on plasma vitamin C. For vegetables, no association with stomach cancer was observed, but allium vegetables (garlic, onions and shallots) showed a protective effect in a large meta-analysis.

Lung cancer is the most common cancer death and fruits and vegetables containing carotenoids and other antioxidants have been hypothesized to decrease lung cancer risk. Data from large meta-analysis of cohort studies report a protective effect of fruits and vegetables on lung cancer risk. When comparing highest versus lowest intake, a 18% decrease risk was observed for fruit intake (RR = 0.82 95% CI = 0.76–0.89) and 8% decrease for vegetable intake (RR = 0.92 95% CI = 0.87–0.97). The effect was stronger in current smokers. For each increase of 100 g/day an inverse dose response was observed for vegetables (RR = 0.94 95%CI 0.89–0.98 and fruits (RR = 0.92, 95% CI = 0.89–0.95). Vegetable intake has been associated to a small decreased risk of colorectal cancer (2% decrease; RR = 0.98, 95% CI = 0.96–0.99 per100g/day). No effect was observed for rectal cancer. Intake of fruits was not related to the risk of colorectal cancer. For breast cancer, results from the pooling of large cohort studies have shown an inverse association between vegetable intake and ER− breast cancer (18% decrease, RR = 0.82 95% CI = 0.74–0.90 comparing highest vs. lowest vegetable intake). No protective effect was observed in ER+ tumors. Recent data from the EPIC study suggest a protective effect from vegetable fiber on breast cancer risk.

Whole Grain and Cereal Fiber

Whole grain is rich in fiber, phytochemicals, B vitamins and other active substances, while refined cereals retain almost only the starchy endosperm when the germ and bran are removed. The majority of studies focused on gastrointestinal cancers. Most of the evidence is related to the association of whole grain intake and colorectal cancer. Whole grain intake has been associated with a 7% decreased risk of colon cancer (RR = 0.83 95% CI = 0.78–0.89) per 90 g/day; no effect was observed for rectal cancer in a meta-analysis (4 studies). Association with other gastrointestinal cancer, genitourinary cancers (prostate and renal cancers), breast and endometrium and neck cancers are inconsistent.

Cereal fiber intake has been associated to a decreased risk of colorectal cancer with a decreased risk of 9% (RR = 0.91 95% CI = 0.88–0.94) per 10 g/day intake. This was confirmed by results from the large prospective EPIC study (RR = 0.89 95% CI = 0.82–0.97 per 10 g/day). For other gastrointestinal cancers data are sparse and inconclusive. No effect has been observed on genitourinary cancers. For head and neck cancer there is suggestion of a protective effect. For breast cancer a borderline protective effect has been observed cereal fiber.

Carbohydrate, Glycaemic Index, and Glycaemic Load

Cancer with potential links to diabetes leading to an increased risk include bladder cancer, breast cancer, colorectal cancer, endometrial cancer, liver cancer and pancreatic cancer while prostate cancer could possibly be lower among diabetic individuals. Many factors influence how rapidly carbohydrates are digested and absorbed and hence what their glycaemic and insulinemic effects will be. Refined carbohydrate such as pure sugar is rapidly absorbed. This physiologic response of carbohydrates can be quantified by the glycaemic index (GI), which compares the plasma glucose response to specific foods with that induced by the same amount of a standard carbohydrate source, usually white bread or pure glucose. The GI is therefore a measure of carbohydrate quality. However, both the quality and quantity of dietary carbohydrates need to be considered in relation to metabolic effects; the glycaemic load (GL) of a specific food, calculated as the product of GI and the amount of dietary carbohydrates in a food item, has been proposed as a global indicator of the glucose response and insulin demand induced by a serving of food. A recent meta-analysis of prospective studies reported a significant positive association between GI and GL and total diabetes-induced cancers risk; the pooled multivariable-adjusted RR of the overall diabetes related cancer risk when comparing the highest versus the lowest levels of GI and GL were 1.07 (95% CI = 1.04–1.11) for GI and 1.02 (95% CI = 0.96–1.08) for GL. For colorectal cancer a borderline positive association between GI and colorectal cancer risk was observed when comparing the highest with the lowest category of intake (RR = 1.08; 95% CI = 1.00–117). No significant association was observed between GL intake; for endometrial cancer risk no significant association was observed with GI intake while GL intake was significantly associated with a 21% greater risk of developing endometrial cancer compared with the lowest category of intake (RR = 1.21 95% CI = 1.07–1.37); for breast cancer RR comparing the highest with the lowest category were 1.06 (95% CI = 1.01–1.10) for GI and 1.04 (95% CI = 0.97–1.11) for GL. No association with GI or GL were observed for pancreatic and prostate cancers while data were very sparse for liver and bladder cancers (only 1 study for each) and no conclusion could be made.

Polyphenols and Food Containing Polyphenols

Polyphenols/flavonoids

Polyphenols are a large and diverse family of phytochemicals widely consumed by humans. Food sources for major classes of polyphenol include berries, citrus fruits, leafy vegetables, tea and chocolate, soybean and legumes for flavonoids; tea, berries, wine, fruits, vegetables and coffee for phenolic acid; and sesame seeds, whole grains, vegetables and olive oil for lignans.

Flavonoids are the most studied subgroup of polyphenols with regard to cancer risk. In recent epidemiological studies, total flavonoid intake has rarely been associated with a reduction in cancer risk. However, isoflavones, whose main dietary source is soy foods, plausibly reduce the risk of colorectal, breast, and prostate cancers, especially in Asian countries. Soy consumption during childhood and adolescence might be the most relevant period and only studies in Asian populations have evaluated this association. In Western countries, the greatest potential is from the intake of tea catechins, although evidence is limited and still controversial for colorectal, breast, and prostate cancers. Other flavonoids require much more extensive study in relation to major cancers,

especially in prospective studies. In brief, epidemiological evidence for a protective effect of polyphenol intake upon cancer risk remains weak. It should be kept in mind that many in-vitro studies have administered pharmacological doses of polyphenols in nonglycosylated form rather than as metabolites. Lignans are converted to the estrogen-like compounds enterolactone and enterodiol during digestion and could affect breast cancer.

Coffee and caffeine

Coffee is among the most commonly consumed beverage worldwide and has been associated to human health effects. Several beneficial compounds are present in coffee including antioxidants polyphenols (phenolic acid). Meta-analysis of coffee consumption have shown reduced risk in several cancers including endometrial, colon, liver, prostate, pancreatic and gallstone when comparing highest versus lowest consumption. However, to date, evidence of a probable protective effect is only observed for liver and endometrial cancers.

Vitamins and Minerals

Folate and B vitamins

Among epidemiological studies that explore the relation between folate intake and the risk of developing cancer, the evidence has been most compelling for colorectal cancer. In a meta-analysis of cohort studies, the resulting summary risk estimate for high versus low dietary folate intake has shown a marginal decreased risk of 8% when comparing the highest to the lowest intake (RR = 0.92, 95% CI = 0.81–1.05). The protective effect was larger for colon cancer (RR = 0.75, 95% CI = 0.57–0.99). This result was confirmed by a large prospective study with a 30% lower risk of developing colorectal cancer among subjects with the highest versus lowest dietary folate intake (RR = 0.81, 95% CI = 0.52–0.97). The protective effect is more pronounced in moderate to heavy consumers of alcohol, a known inhibitor of folate metabolism. A role of folate in colorectal carcinogenesis is supported by the association between a genetic polymorphism in MTHFR, and enzyme involved in folate metabolism and risk of colorectal cancer.

Epidemiological studies on the association between folate intake and breast cancer risk have provided mixed results. Results from a meta-analysis showed no significant association between dietary folate intake and breast cancer risk (pooled RR = 0.95, 95% CI = 0.87–1.03); however higher folate intake may reduce breast cancer risk for those with high alcohol intake. Results from prospective studies also suggest a U-shaped relationship for the dietary folate intake and breast cancer risk. Women with daily dietary folate intake between 153 and 400 mcg showed a significant reduced breast cancer risk compared with those <153 mcg, but not for those >400 mg. These results were further confirmed in the EPIC study in which, a 14% reduction in breast cancer risk was observed when comparing the highest with the lowest dietary folate tertiles in women having a high (>12 alcoholic drinks/week) alcohol intake (RR = 0.86, 95% CI = 0.75 to 0.98). There is no clear evidence for a significant association between blood folate levels and breast cancer risk.

A protective role for adequate folate status in other cancers is not compelling but there are some observations implying a protective role for adequate folate intake in oropharynx, esophagus, stomach, pancreas lung, cervix neuroblastoma and leukemia.

Vitamin D

Vitamin D is mostly synthesized in the skin by ultraviolet B radiation while dietary intake and supplements also contribute to overall vitamin D status. Several cancers have been associated with low sun exposure, in particular colorectal and breast cancers. An inverse association has also been observed between prediagnostic circulating serum 25-hydroxyvitamin D (25(OH)D) levels and risk for colorectal cancer. In a meta-analysis an inverse association of colorectal cancer risk was observed with dietary vitamin D (RR per 100 IU/day = 0.95, 95% CI = I 0.93–0.98; range of intake (midpoints) 39–719 IU/day) and serum/plasma 25-(OH)D (RR = 0.96, 95% CI = 0.94–0.97 per 100 IU/L; range 200–1800 IU/L). However, the association has been less consistent for other cancer types. In a recent large meta-analysis, the pooled RR of breast cancer for the highest (>500 IU/day, mean) versus lowest categories of vitamin D intake (<148 IU/day, mean) was 0.95 (95% CI = 0.88–1.01). The pooled RR of breast cancer for the highest (>31 ng/ml, mean) versus lowest categories of 25(OH)D blood levels (<18 ng/ml, mean) provided similar results. Several lines of evidence suggest that effects of vitamin D may be stronger for cancer mortality than for incidence. Cancer patients with higher prediagnostic 25(OH)D have lower risks of dying from prostate, colorectal and breast cancer.

Carotenoids

Carotenoids and retinol are considered biomarkers of fruits and vegetables intake, and have important antiinflammatory and antioxidant properties. In a meta-analysis of prospective studies of blood concentrations of carotenoids and retinol, and lung cancer risk, blood concentrations of α-carotene, β-carotene, total carotenoids, and retinol were significantly inversely associated with lung cancer risk or mortality. The summary RR was 0.66 (95% CI = 0.55–0.80) per 5 μg/100 mL of α-carotene, 0.84 (95% CI = 0.76–0.94) per 20 μg/100 mL of β-carotene, 0.66 (95% CI = 0.54–0.81) per 100 μg/100 mL of total carotenoids, and 0.81 (95% CI = 0.73–0.90) per 70 μg/100 mL of retinol. In stratified analysis by sex, the significant inverse associations for β-carotene and retinol were observed only in men and not in women. Carotenoids have also been linked to a decreased risk in cancer of the oropharynx. A systematic review and meta-analysis of cohort studies of dietary intake and blood concentrations of carotenoids and breast cancer risk reported stronger associations with blood concentrations than with dietary estimates, probably because the measurement error in the dietary assessment of carotenoid intake from fruits (such as mango, orange, tangerine, melon, papaya) and vegetables (such as carrots, pumpkin, tomato, kale, sweet potato) may have attenuated associations with breast cancer risk. Of

the six dietary carotenoids assessed, only intake of β-carotene was significantly associated with a reduced breast cancer risk (RR = 0.95 95% CI = 0.91–0.99; per 5000 mg/day). In contrast, blood concentrations of total carotenoids, β-carotene, α-carotene, and lutein were inversely associated with breast cancer risk. In a recent report, an inverse association between plasma carotenoids and risk of premalignant breast diseases was found in younger women, consistent with inverse associations reported for invasive breast cancer suggesting that carotenoids may play a role in breast cancer early development. The relative levels of the different types of carotenoids are important to take into account as well as a potential influence from other lifestyle factors.

Alcohol

The association between alcohol drinking and the risk of various cancers has been evaluated in a large number of case controls and cohort studies. Alcohol consumption has been convincingly associated to the cancer of the oral cavity, pharynx, larynx, esophagus, colorectal, liver (hepatocellular carcinoma) and female breast cancers. For the majority of these cancers, the association appears mostly linear. Among nonsmokers, reported RRs for oesophageal squamous cell carcinoma and laryngeal cancer range from no effect for light intake (1 drink per day or 10–12 g of ethanol) to a threefold increase (RR = 3.09, 95% CI = 1.75–5.46) for high intakes (4 or more drinks/day). Risks for oropharyngeal cancer are as high as fivefold increase (RR = 5.04, 95% CI = 4.49–6.50) in high intake. The combined exposure to alcohol drinking and tobacco smoking results in a synergistic effect which enhances the risk of these neoplasms up to 14-fold, among heavy-smokers and heavy drinkers (4 or more drinks/day).

Summary effect estimates for colorectal cancer are about 11% (RR = 1.11, 95% CI = 0.90–1.38) at one drink per day (corresponding to 10–12 g of ethanol) and 40% (RR = 1.41, 95% CI = 1.16–1.72) at more than four to five drinks per day. Associations of alcohol consumption with hepatocellular carcinoma are generally found at high intakes with significant increased risks of about 30%–40% at consumption levels >40 g/day. For breast cancer, the risk increases by 5% for premenopausal breast cancer (RR = 1.05, 95% CI = 1.02–1.08) and by 9% for postmenopausal breast cancer (RR = 1.09, 95% CI = 1.07–1.12) per 10 g/day of ethanol. While studies on binge drinking and cancer risk are still sparse and a standardized measure of exposure is lacking, the available evidence shows that the risk is increased between 33% (RR = 1.33, 95% CI = 1.11–1.59, for monthly binge drinking) and 55% (RR = 1.55, 95% CI = 1.07–2.26, for weekly binge drinking). For other cancers sites, kidney, bladder, stomach, ovary, small intestine, Hodgkin and non-Hodgkin lymphoma, ampulla of Vater, pancreas and thyroid, the evidence is considered "not conclusive".

Vitamin and Mineral Supplementation

The role of vitamin and mineral supplements in cancer prevention has been examined in both prospective and RCTs. Trials of beta-carotene and other single supplements, including vitamin E and selenium have not shown benefits. In some studies, adverse effects were observed: an increased risk of lung cancer with beta-carotene in heavy smokers and an increased risk of prostate cancer with high doses of vitamin E. In trials using combinations of multiple vitamins and mineral at lower doses than those in single supplements, a reduction in cancer rates has been seen in a Chinese population with multiple nutrient deficiencies as well as a decrease in overall mortality after 10 years follow up. However, no effect on overall and specific mortality was observed after 20 years follow up. Recent reports from the Physicians' Health Study (PHS) II, a RCT of daily multivitamins among US physicians, found fewer total cancers in multivitamin recipients, but no effect on overall mortality. Overall supplements with multivitamins and minerals are likely to be beneficial in populations with multiple nutrients deficiency but not in well-nourished individuals.

Randomized controlled trials of folic acid conducted among individuals with previously resected colonic adenomas provide conflicting results. Supplements of folic acid (with dose varying from 0.5 to 5 mg/day) did not reduce recurrent adenomas as a whole, while among subjects with lowest plasma folate a marginal reduction was observed. In one trial an increased risk of recurrent adenoma was seen. These results suggest that an adequate amount of folate intake is protective compared to an inadequate intake, but supplementation of those who are already folate-replete conveys no additional protection against colorectal cancer.

Total calcium intake is consistently associated with a reduction of colorectal cancer in observational studies. Recent results of large prospective studies (NHS and PHS) report a decreased risk of colon cancer when comparing high versus low intake ($\geq$1400 vs. <600 mg) (RR = 0.78, 95%CI = 0.65–0.95). In subjects reporting the use of calcium supplementation, a protective effect against colorectal cancer has been observed. However, trials have shown a protective effect of calcium supplementation on colorectal adenomas, a precursor of colorectal cancer, but not against colorectal cancer itself.

Several lines of evidence suggest that effects of vitamin D may act on cancer incidence and mortality. A meta-analysis of RCTs conducted over 2–7 years of duration, showed that vitamin D supplementations had little effect on total cancer incidence (400–1100 IU/day) (RR = 1.00, 95% CI = 0.94–1.06, comparing the intervention vs. the control groups) but significantly reduced total cancer mortality (400–833 IU/day, summary RR = 0.88, 95% CI = 0.78–0.98). In addition recent review and meta-analysis of RCTs suggested that vitamin D supplementation is not associated with a reduced risk of breast cancer.

Dietary Patterns

Dietary patterns are defined as the quantities, proportions, variety or combinations of different foods and beverages in diets, and the frequency with which they are habitually consumed.

The dietary pattern has gained considerable attention because nutrients and foods are eaten in combination and may interact; therefore, the evaluation of intake pattern provides a better understanding and is more readily available for dietary recommendations. The impact of dietary pattern on health outcomes including cancer has been reviewed recently to define the dietary guideline for American 2015–2020.

Approaches to derive dietary patterns

Several methods have been used to define dietary patterns. The first method is based on an "a priori index" based on a set of dietary recommendations for a healthy dietary pattern. An individual index/score is derived by comparing and quantifying their adherence to the criterion food/nutrient component of the index. Examples of dietary quality scores include: The Healthy Eating Index (HEI)—2005 and 2010, the Alternate HEI (AHEI) and updated AHEI—2010, the Recommended Food Score (RFS), the Dietary Approaches to Stop Hypertension (DASH) score, the Mediterranean Diet Score (MDS), and the Alternate Mediterranean Diet Score (aMed) (for a review see **USDA, 2015**). The second method of dietary pattern assessment is through data-driven approaches "some posteriori", such as cluster, factor analyses of other statistical methods to define specific patterns and link these patterns to a health outcome such as cancer. Generally, the dietary patterns investigated are a prudent or healthy dietary pattern (high in vegetables and/or fruits, poultry, fish, low-fat dairy and/or whole grains) as compared to the Western diet or so-called unhealthy diet (red or processed meats, refined grains, sweets and/or high-fat dairy).

The cancer sites that have been most investigated include colorectal, breast, lung and prostate. The scientific evidence has been classified as convincing, moderate and limited. For colon/rectal cancer, moderate evidence indicates an inverse association between dietary patterns that are higher in vegetables, fruits, legumes, whole grains, lean meats/seafood, and low-fat dairy, and moderate in alcohol; and low in red and/or processed meats, saturated fat, and sodas/sweets relative to other dietary patterns. Conversely, diets that are higher in red/processed meats, French fries/potatoes, and sources of sugars (i.e., sodas, sweets, and dessert foods) are associated with a greater colon/rectal cancer risk.

For breast cancer, moderate evidence indicates that dietary patterns rich in vegetables, fruit, and whole grains, and lower in animal products and refined carbohydrates, are associated with a reduced risk of postmenopausal breast cancer. The data regarding this dietary pattern and premenopausal breast cancer risk point in the same direction, but the evidence is limited due to fewer studies.

For lung cancer, limited evidence from a small number of studies suggests a lower risk of lung cancer associated with dietary patterns containing more frequent servings of vegetables, fruits, seafood, grains/cereals, and legumes, and lean versus higher fat meats and lower fat or nonfat dairy products. However, for lung cancer as well as prostate cancer no conclusions can be drawn due to the small number of studies and the wide variation in study design, dietary assessment methodology and prostate cancer outcome ascertainment.

Inflammatory dietary index

Chronic inflammation has been linked to alteration of cellular processes and carcinogenesis. Evidence also shows that diet plays a central role in the regulation of chronic inflammation. The dietary inflammatory index DII has been developed to categorized the inflammatory (anti or pro) potential of individual foods and nutrients based on an extensive review of literature. Higher score indicates a more proinflammatory diet while a lower score indicates a more antiinflammatory diet. For example, the Mediterranean diet characterized by high consumption of plant foods, whole grain products, vegetables, fruits, nuts and legumes and regular intake of fish and seafood, low intake of red and processed meat and high-fat dairy products, olive oil and moderate alcohol consumption (preferably red wine taken with meals) has been linked to antiinflammatory proprieties. A recent meta-analysis including 24 studies reports that highest versus lowest DII categories are associated to a 25% overall increase of cancer incidence (RR = 1.25 95% CI = 1.16–1.35) and a 67% higher cancer mortality (RR = 1.67 95% CI = 1.13–2.48). For each of the cancer studies (colorectal, breast and lung) higher DII was related to a high incidence of cancer. The DII provides a useful summary measure of total inflammatory potential of multiple food items and can inform cancer prevention efforts.

Future in the Field

Cancers are increasingly seen as metabolic diseases; however, the contribution of metabolic dysfunction to the onset or development of cancer remains poorly understood. Recently developed technologies including metabolomics and deep DNA sequencing have become major tools to explore the metabolism of cancer cells. Hundreds to thousands of metabolites can now be measured simultaneously in bio specimens and give a highly detailed picture of metabolites profiles in tumor tissues and biofluids. The metabolome—the sum of low molecular-weight metabolites at a given time—is the most fundamental biochemical indicator of biological systems and an indicator of both genetic and environmental conditions. Identification of metabolites and metabolic pathways can improve our understanding on the mechanisms of carcinogenesis and related nutritional factors. In addition, both the modulating effect of diet on epigenetics and the connection between diet and the microbiota are fields of intense research as potential mechanisms of action on cancer development.

DNA Methylation Changes in Cancer: Cataloguing

Tibor A Rauch, Rush University Medical Center, Chicago, IL, United States
Gerd P Pfeifer, Center for Epigenetics, Van Andel Research Institute, Grand Rapids, MI, United States

Glossary

Bisulfite sequencing Bisulfite treatment of DNA converts cytosine residues to uracil, but 5-methylcytosine residues are unaffected, which reveals the methylation status of the region of interest at the single nucleotide level.

CpG island (CGI) Genomic regions with a high frequency of CpG dinucleotides, usually over 200 base pairs in length.

DNA methylation Addition of methyl-groups to cytosines, predominantly in the context of CpG dinucleotides.

Genome-wide DNA methylation profiling Analysis of the methylation status of CpGs in the regions of interest or in the whole genome.

High-throughput (or next-generation) sequencing Millions of DNA strands are sequenced in parallel, eliminating the need for fragment-cloning before nucleotide sequence determination. It provides single-nucleotide resolution.

Microarray (DNA chip) A laboratory tool (a microscope slide) that carries thousands of regions of the investigated genome, including promoters, CGIs and any nonrepetitive loci of the genome.

Restriction endonucleases Specific enzymes that cleave DNA into fragments at specific recognition sites. DNA cleavages can be affected by the methylation status at the recognition site.

Introduction

DNA methylation is an epigenetic process that converts cytosines, chiefly at CpG dinucleotide sequences, into their methylated state. The reaction is carried out by three catalytically active mammalian DNA methyltransferases, DNMT1, DNMT3A and DNMT3B. All of these enzymes are required for survival in mice pointing to a critical role of DNA methylation in development and cellular physiology. 5-methylcytosine, when occurring in gene regulatory sequences is generally associated with gene inactivity and loss of methylation can occur when genes become activated.

The first carcinogenesis-associated DNA methylation (i.e., 5-methylcytosine [5mC]) changes were described in the early 1980s when global DNA hypomethylation in tumors was observed. Several years later, the first gene-specific hypermethylation events were detected in tumor samples. Hypermethylation commonly affects CpG island sequences, which in some cases, may be associated with silencing of well-studied tumor suppressor genes such as CDKN2A or MLH1. Since then, a number of differentially methylated regions have been described in the context of all types of cancer. Some types of tumors, even different malignancies originating in the same tissue or organ, can be distinguished by their unique DNA methylation profiles. Tumor classification based on the methylation profile of numerous sequences within the tumor when compared to the corresponding normal tissue has only become possible after sufficiently sensitive genome-scale approaches for methylation analysis had been developed. This field has moved from conducting single gene analysis or scanning of a few selected genes to obtaining overviews of the changes occurring genome-wide (i.e., the "methylome").

To identify altered DNA methylation at the genome scale, a large number of approaches have been developed. The currently employed DNA methylome mapping methodologies can be traced back to three major principles, including DNA methylation-sensitive restriction endonucleases, sodium bisulfite modification of genomic DNA and DNA methylation-specific antibodies or proteins (Table 1). In the last 15 years, significant developments have been made in genome-wide DNA methylation profile analysis, whereby the methods are based on coupling the aforementioned three principle-based approaches with various microarray or next-generation sequencing (NGS) platforms.

Table 1 Commonly used methods for genome-scale analysis of DNA methylation and DNA hydroxymethylation profiles

Genome-wide DNA methylation profiling approaches		
DNA methylation sensitive endonuclease-based methods	Biological affinity-based methods	Sodium bisulfite treatment-based methods
Differential methylation hybridization	Methylated DNA immuno-precipitation (MeDIP)	BS-sequencing (targeted and whole genome)
HELP assay	MDB-Seq	RRBS
MCAM	MIRA	Infinium assay
	hMeDIP (5hmC)	TAB-Seq (5hmC)
	T4-BGT-assisted (5hmC)	Ox-BS-Seq (5hmC)

The methods discussed in this article are subdivided into restriction enzyme-based, biological affinity-based approaches and sodium bisulfite-dependent techniques.

 https://doi.org/10.1016/B978-0-12-801238-3.65057-2

The recent discovery of 5-hydroxymethylcytosine (5hmC), the first in a series of oxidative products leading to active demethylation of 5mC, in mammalian DNA challenged almost all previously used DNA methylation (i.e., 5mC) mapping methods because they could not distinguish between 5mC and 5hmC bases. Thus, by employing "classical" 5mC-mapping technology, one needs to be careful if the goal is to distinguish between these two bases. Indeed, 5mC and 5hmC have completely different biological functions with 5hmC being often associated with active genes or their control elements and 5mC being linked to repressed or silent chromatin. This can be particularly critical in cases of investigating tissues where high levels of 5hmC are present, for example, in neurons of the brain. Accordingly, new techniques were developed for selective detection of the two closely related cytosine residues. In this article, we will present the most frequently used genome-wide DNA methylation profiling methods that can be effectively employed for cataloguing DNA methylation changes in tumors.

Methylation-Sensitive Restriction Endonuclease-Based Methods

This family of methylome mapping techniques relies on restriction endonucleases that have a different sensitivity towards the methylation status of cytosine residues at the cleavage site. Accordingly, the methylation status of cytosine determines the actual restriction endonuclease digestion pattern, which reflects the level of DNA methylation of the investigated genomic region. A number of the originally applied methods, including methylation-specific digital karyotyping (MSDK), methylation-sensitive representational difference analysis (MS-RDA), methylation-sensitive restriction fingerprinting (MSRF) and restriction landmark genomic scanning (RLGS), are not used very widely anymore. However, at least two of these techniques are still being used; the HELP assay (HpaII tiny fragment enrichment by ligation-mediated PCR) and the methylated CpG island amplification coupled to microarray (MCAM) method. Both methods employ adapter ligation and PCR amplification steps after the digestion of chromosomal DNA with methylation-specific enzymes. The PCR amplified and labeled fragment pools are hybridized to microarray platforms or the corresponding amplicons are sequenced by one of the available NGS platforms. Here, we present MCAM, which employs SmaI (methylation sensitive) and XmaI (methylation insensitive) restriction endonuclease pairs (Fig. 1). The unmethylated cleavage sites can be cut with the SmaI enzyme, generating blunt ended fragments. A second digestion with the XmaI enzyme can cut the methylated cleavage sites as well and generate sticky ends for the subsequent adapter ligation. PCR amplification and fluorescent labelling of amplicons is followed by hybridization of labeled fragments onto microarray platforms carrying CpG-rich regions, including promoters and CpG islands.

The main drawback of the methylation sensitive enzyme-based profiling methods is the uneven occurrence of SmaI/XmaI cleavage sites in the genomes. Consequently, a significant number of potentially interesting genomic regions, such as promoters and CpG islands, cannot be investigated because of the lack of this particular cleavage site. Numerous enzyme pair combinations have been used to overcome the described limitations, but all of them have reduced genomic coverage, which partly explains why the methylation sensitive enzyme-based approach has been less popular recently.

Recent studies have revealed that the DNA base N6-methyladenine (6 mA), previously considered to be a prokaryote-specific epigenetic modification, also occurs in higher organisms including mammals. This base can be mapped using restriction enzymes that are inhibited by 6 mA within the cleavage site, affinity-based approaches using 6 mA-specific antibodies, or by single molecule sequencing that distinguishes between 6 mA and other bases.

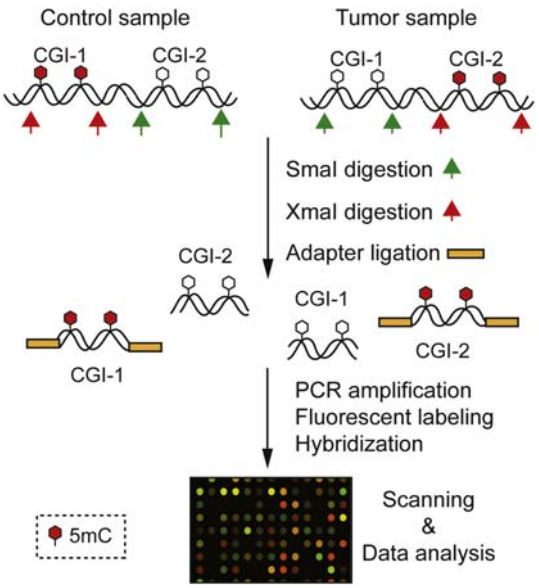

Fig. 1 The main steps of methylated CpG island amplification coupled to microarrays (MCAM). A detailed description of the method is provided in the text. *Arrows* point to *Sma*I and *Xma*I cleavage sites.

Biological Affinity-Based Methods

High affinity towards methylated DNA is the principle of these genome-wide DNA methylation-profiling techniques. Methylated DNA fragments can be affinity-purified by using either 5mC-specific antibodies or methyl-CpG-binding domain (MBD) proteins that specifically bind to methylated DNA sequences. Consequently, DNA fragments containing methylated CpG sites are effectively captured by these proteins (i.e., antibodies or MBDs) and can be selectively extracted and enriched. Using these approaches, methylation profiles can be generated with a resolution of approximately 100 base pairs, similar to chromatin immunoprecipitation (ChIP)-sequencing.

Methylated DNA Immunoprecipitation (MeDIP)

MeDIP first utilizes a 5mC-specific antibody to capture methylated DNA fragments after nonspecific fragmentation of genomic DNA (i.e., by sonication) (Fig. 2). Next, the immunoprecipitated DNA fraction and the input (nonenriched) genomic DNA can be labeled with different fluorescent dyes (e.g., Cy5 and Cy3) and cohybridized onto microarray platforms. The ratio of the fluorescent intensity of the two dyes reflects the methylation status of the region of interest. The main limitations of the MeDIP method are that single-stranded (denatured) DNA is needed for analysis and the quality of anti-5mC antibodies can be variable. MeDIP is compatible with NGS (MeDIP-seq), which provides much higher coverage than microarray-coupled technologies.

MBD Protein-Based Affinity Pull-Down Methods

A relatively small family of proteins including MBD1, MBD2, MBD3, MBD4 and MeCP2, possess a very similar methyl-CpG-binding domain. With the exception of human MBD3, each of these proteins is capable of binding specifically to methylated 5mC containing DNA. An affinity column-based method was initially developed, which employed the methyl-CpG binding domain of MeCP. However, it was recently demonstrated that MeCP2 could also bind to 5hmC with good affinity and therefore may not effectively discriminate between 5mC and 5hmC bases. This indiscriminative nature of MeCP's MBD can compromise the accuracy of methylation profile mapping. However, the other MBD proteins' recombinant MBD fragments can be fused to affinity tags (e.g., His- or GST-tag) and be used for capturing the methylated DNA fraction from genomic DNA fragment pools. These fragments can then be analyzed, as done earlier using microarrays or, more recently, by employing NGS.

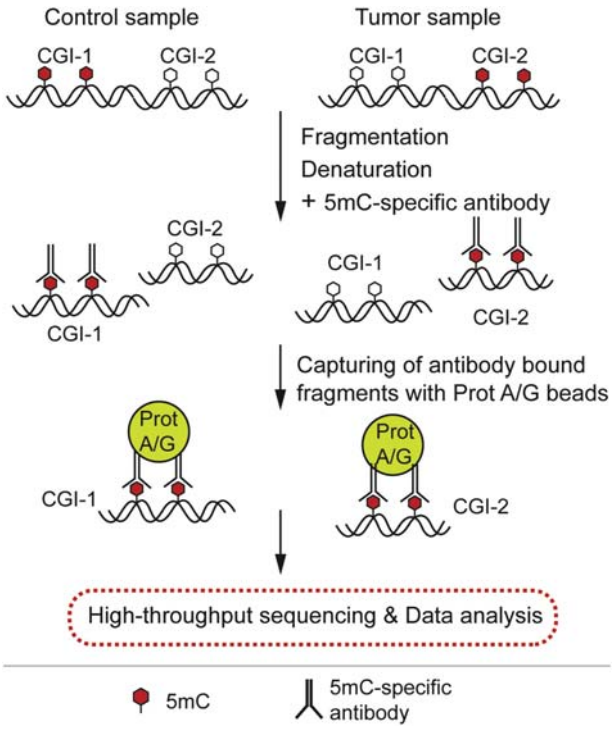

Fig. 2 Methylated DNA immunoprecipitation sequencing (MeDIP-seq). The detailed description is provided in the text.

Methylated-CpG Island Recovery Assay (MIRA)

MBD2b, the shorter isoform of MBD2, has the highest affinity to methylated DNA and can form heterodimers with other MBD proteins via its C-terminal coiled-coil domain. One of its interacting partners is MBD3L1. MBD3L1 has no DNA binding domain itself, but can act as a hetero-dimerization partner and then bind to methylated DNA. There is no dependence on DNA sequences other than that it requires a minimum of two methylated CpGs in the captured fragment. The MBD2b/MBD3L1 heterodimer complex has a higher affinity to methylated DNA templates than MBD2b alone, a feature that is harnessed in the methylated-CpG island recovery assay (MIRA) (Fig. 3). Bacterially expressed recombinant GST-MBD2b and His-MBD3L1 proteins are mixed and incubated with the fragmented genomic DNA. The heterodimer complex captures methylated DNA fragments, which are then purified, PCR amplified, labeled and analyzed on microarray platforms (MIRA-chip). The MIRA-enriched methylated fraction can be also coupled with NGS platforms (MIRA-seq). MIRA can reliably be performed on a few hundred nanograms of genomic DNA. The MIRA technique was used to profile DNA methylation patterns at a resolution of 100 base pairs in the entire genome of human B lymphocytes, providing one of the first mammalian "methylome" data sets.

Affinity-Based 5hmC Mapping Methodologies

Discovery of 5hmC in mammalian genomic DNA demanded new technologies that could distinguish between 5hmC and 5mC bases. For this purpose, two biological affinity-based methods were developed.

The hMeDIP approach is based on a 5hmC-specific antibody that has been used for immunoprecipitation of DNA sequences harboring 5hmC residues. This method is similar to the detailed MeDIP technique, except that the employed high affinity antibody is specific for 5hmC in single-stranded DNA (Fig. 2).

Another method(s) requires the specific modification of 5hmC using T4 bacteriophage-derived β-glucosyltransferase (T4-BGT), which can transfer a modified glucose moiety to the hydroxyl group of 5hmC. Glucosylated 5hmC residue carrying fragments can be enriched by using a specific protein (e.g., Jbp1) or can be further modified to be suitable for biotin-streptavidin pull-down (Fig. 4). NGS is conducted on the enriched fractions to annotate the genomic locations of 5hmCs. The best resolution that can be achieved by these methods is about 100 bp, which is determined by the size fragmentation and by the employed NGS platform.

Sodium Bisulfite Treatment-Based Methods

The previously discussed genome-wide DNA methylation mapping techniques provide valuable information regarding the locations of 5mC and 5hmC residues, but they also have several obvious drawbacks, including the relatively low resolution of mapping,

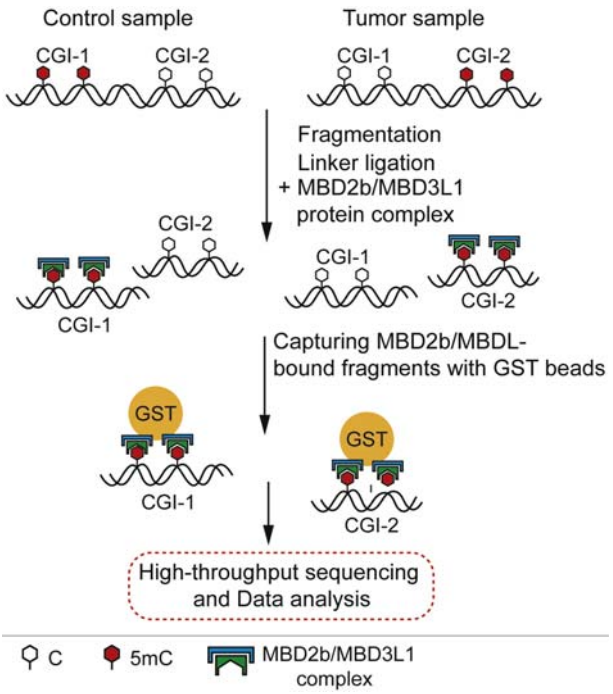

Fig. 3 Methylated-CpG island recovery assay (MIRA-seq). Please see text for detailed description of this methodology.

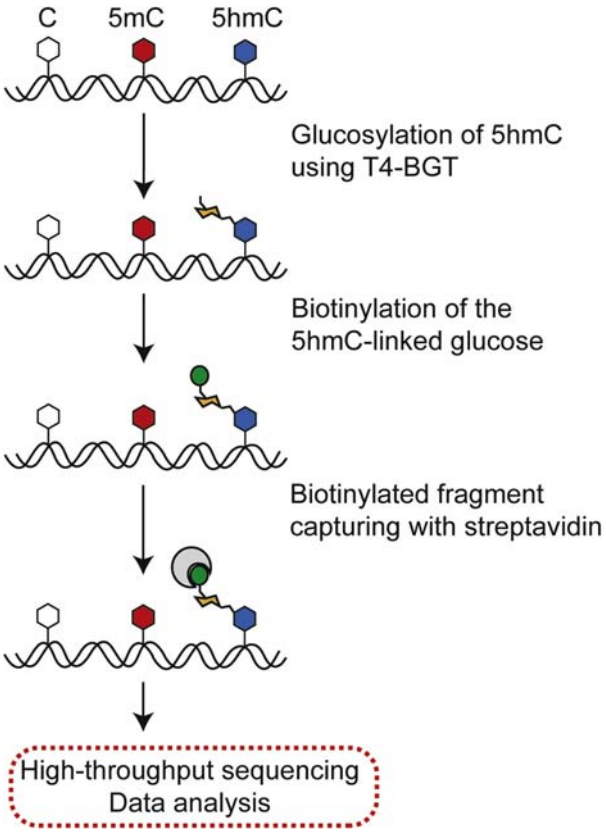

Fig. 4 Mapping of 5-hydroxymethyl cytosine (5hmC) in the genome. Detailed description is provided in the text.

and that the number of the modified nucleotides cannot be identified at the single nucleotide level. Bisulfite treatment-based profiling approaches overcome these issues inasmuch as they provide single base resolution and modified cytosine residues are countable within single molecules. Bisulfite sequencing is based on the premise that unmodified cytosine and 5mC showing different sensitivity towards sodium bisulfite treatment. Sodium bisulfite provokes deamination of cytosine and turns it into uracil, but 5mC is resistant to bisulfite-induced deamination. Thus, bisulfite treatment introduces specific changes in the DNA sequence, which depends on the methylation status of cytosine residues. Whole-genome bisulfite sequencing (WGBS) consists of several main steps: NGS library preparation, high-throughput sequencing of NGS libraries, and data analysis. NGS library preparation is a multi-step process that involves the fragmentation of genomic DNA followed by adapter ligation, bisulfite conversion and amplification using adapter-specific PCR primers. The actual nucleotide sequence analysis is conducted by using Roche 454, Illumina, or ABI/SOLiD platforms. Finally, the collected sequencing reads are aligned to "computationally bisulfite-converted" model genomes and the actual methylation status of all cytosines is revealed. Although WGBS is a powerful method that provides the most complete genome-wide DNA methylation profiling data, the associated high cost of sequencing still limits its widespread application (about $ 2000–4000 per sample). Therefore, a related method, the reduced representation bisulfite sequencing (RRBS) (Fig. 5), was developed, which is a cost-effective alternative to WGBS, although only 85% of CpG islands and 60% of promoters can be investigated. In RRBS, genomic DNA is digested with MspI, a methylation-insensitive endonuclease, which is followed by adapter ligation and fragment size selection. Adapter-ligated fragments in the several hundred bp size range are isolated and subjected to bisulfite conversion. Bisulfite-treated samples are PCR amplified and sequenced. RRBS is frequently employed when high-throughput and low-cost DNA methylation profiling is desired, such as in clinical applications. The method is very sensitive and requires low input allowing the analysis of limited numbers of cells.

Infinium Methylation Bead Arrays

The Illumina Infinium methylation assay is a company-developed platform that provides quantitative array-based measurement at the single-CpG-site level (Fig. 6). The assumption behind this experimental design (i.e., focusing on a single CpG in a particular region of interest) is that neighboring CpGs are usually (but not always) at similar methylation states. The monitored CpG sequences are selected from promoter regions, first exons, gene bodies and 3'UTRs. The flagship of this methylation platform has been the Infinium 450 k methylation assay, which could be used for detecting the methylation status of ~480,000 CpG of

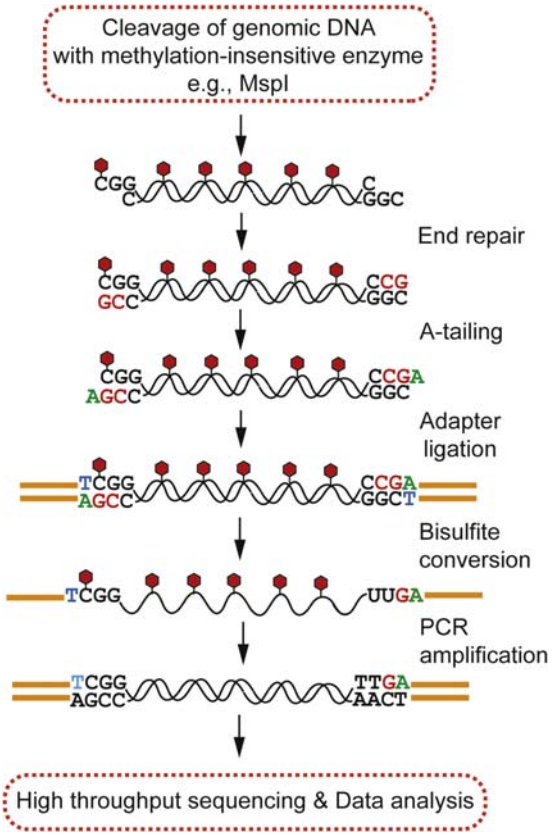

Fig. 5 Reduced representation bisulfite sequencing (RRBS). *MspI* cleavage enriches genomic fragments from CpG islands and other CpG-rich regions. See text for details.

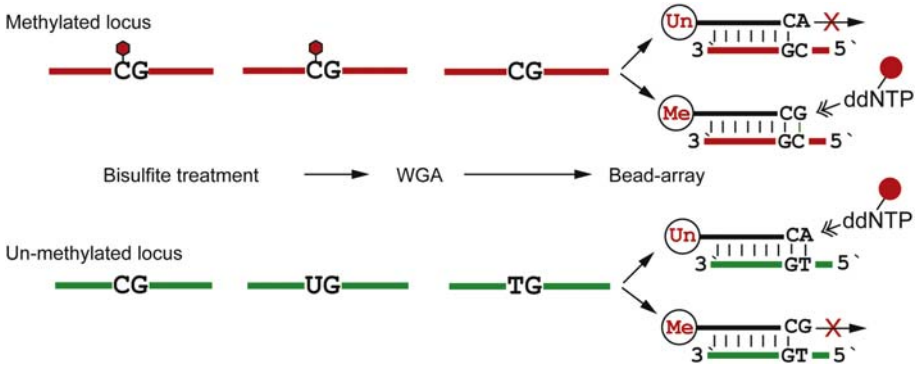

Fig. 6 Infinium 450 k methylation bead-array.The detailed description is provided in the text.

the human genome. An improved version of this platform, the EPIC array, is suitable to methylation profiling of ~850,000 CpG sites. The EPIC array now covers 99% of RefSeq gene promoters, 95% of CpG islands, many distant enhancers and miRNA promoters. However, the coverage of the large number of enhancers in mammalian genomes is still limited. Genomic DNA is bisulfite-treated and amplified, employing a special DNA polymerase (Phi29) with very low error rate. Whole genome amplification is carried out and the product of this reaction is enzymatically fragmented and applied to the Infinium chip (bead array). On the chip, there are two bead types for each CpG site per locus. Each bead type is attached to a single stranded 50-mer DNA oligonucleotide that differs in sequence only at the 3′ end, which corresponds to the investigated cytosine at CpG sequences. The bisulfite converted and denatured DNA can hybridize to either the methylation-specific probe or the nonmethylation probe, and in a single-base extension reaction, labeled dideoxynucleotides can be incorporated. Through conducting appropriate labelling and

scanning, the methylation status of the particular CpG site can be determined. This methylation bead array technology is now used very commonly in basic research and clinical settings.

5hmC Mapping at Single Nucleotide Level

Soon after the discovery of 5hmC in mammalian genome, it was realized that the conventional bisulfite treatment cannot be used directly for identifying 5hmC, since both bases are resistant to this treatment. Thus, such methodologies have been developed that can distinguish between these two closely related nucleotides. Currently, there are two available methods that can be used for unambiguous identification of 5hmC at single-base resolution.

TET-Assisted Bisulfite Sequencing (TAB-Seq)

The TET enzymes catalyze the oxidative demethylation of 5mC in a stepwise manner. The TETs convert 5mC to 5hmC, then 5-formylcytosine (5fC), and then 5-carboxylcytosine (5caC). It is thought that 5fC and 5caC are then converted to unmodified C by base excision repair initiated by thymine DNA glycosylase (TDG). In TAB-seq (Fig. 7. left panel), 5hmC is first protected from further oxidation by using T4-BGT enzyme that transfers a glucose moiety to the hydroxyl group of 5hmC. Next, DNA is treated with recombinant TET1 enzyme or its catalytic domain that oxidizes the 5mC to 5caC, while leaving the glucosylation-protected 5hmC intact. Subsequent bisulfite treatment converts unmodified C and 5caC residues to uracils that can be read as T after sequencing. Accordingly, any C-containing reads at CpG sequences in the resulting sequence can be interpreted as a direct readout of 5hmC.

Oxidative Bisulfite Sequencing (OxBS-Seq)

In OxBS-Seq (Fig. 7. Right panel), first, 5hmC is oxidized to 5fC by employing a strong oxidizing agent (KRuO4). KRuO4 treatment of DNA leaves 5mC and unmodified C residues intact. Unlike 5mC and 5hmC, 5fC is sensitive to bisulfite-induced deamination; thus, subsequent bisulfite-treatment converts the 5fC to uracil. Next, the KRuO4 and bisulfite treated DNA is subjected to NGS. In OxBS-Seq, T reads in the resulting sequence can be either originating from 5hmC or from unmodified C. Therefore, OxBS-Seq and conventional BS-Seq must be run parallel and, by comparing the two sequences, 5hmC can be identified. The

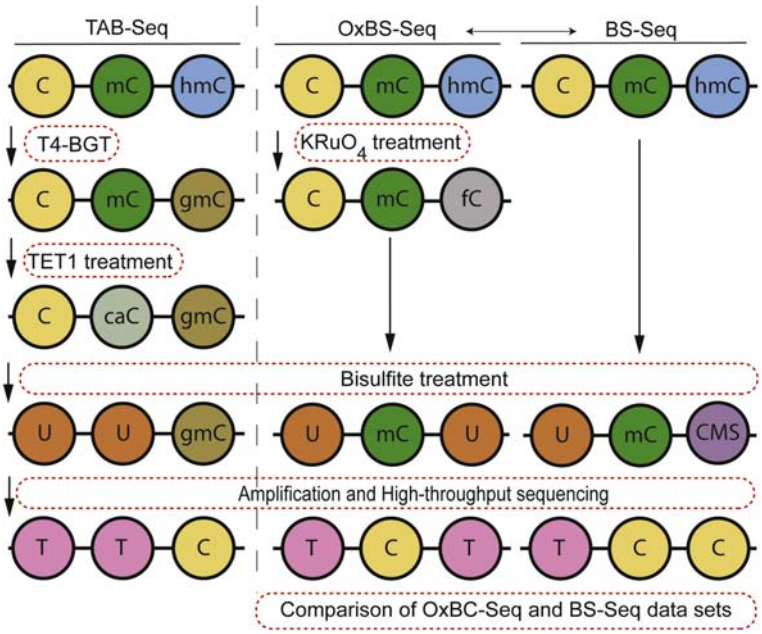

Fig. 7 TET-assisted bisulfite sequencing (TAB-seq) and oxidative bisulfite sequencing (OxBS-Seq). *Left panel* depicts TAB-seq, *right panel* describes the main steps of OxBS-Seq. OxBS-Seq displays 5mC only and requires a comparison to standard BS-seq, which shows the sum of 5mC and 5hmC. A detailed description of these approaches is provided in the text. *caC*, 5-Carboxylcytosine; *CMS*, cytosine-5-methylsulfonate; *gmC*, glucosylated 5-hydroxymethylcytosine; *hmC*, 5-hydroxymethylcytosine; *mC*, 5-methylcytosine.

disadvantage of OxBs-Seq that it displays 5hmC only indirectly, but the advantage is that this methodology does not require recombinant TET protein.

Prospective Vision

Epigenome-focused studies have already made remarkable progress towards exploring carcinogenesis-involved genes, pathways and mechanisms. It is quite predictable that DNA profiling techniques will receive more and more applicability and credit in clinical diagnostics. Application of high-throughput technologies can contribute to better cancer management in multiple ways: (i) by exploring cancer-specific epigenetic biomarkers, these methods can help in early tumor detection and prognosis, (ii) by monitoring and evaluating the efficacy of therapies, and (iii) by revealing novel "druggable" targets. The method of choice depends on multiple factors, including the number and complexity of the investigated regions, the depth of the required information (i.e., single base resolution is needed, or lower resolution is sufficient). Cost may have a decisive role as well. It is expected that the technological development of high-throughput approaches will continue, which might allow for more cost-effective analysis. The currently employed DNA profiling techniques are multistep and still time-consuming methodologies. New technologies, such as nanopore sequencing, are on the horizon; they allow eliminating PCR amplification and fluorescent labelling from the protocol. Nanopore sequencing has the potential to discriminate between the four canonical DNA bases and their oxidized derivatives.

In summary, efficient cataloguing of cancer-associated DNA methylation changes has more than academic significance inasmuch as it can provide novel inroads to diagnosis and choice of treatment options.

DNA Methylation Changes in Cancer: Mechanisms

Hideyuki Takeshima and Toshikazu Ushijima, National Cancer Center Research Institute, Tokyo, Japan

Glossary

CpG island CpG sites are observed less often than expected in the genome. However, there are clusters of CpG sites, and such a cluster is named as a CpG island. If a CpG island is located at a promoter region, its DNA methylation can strongly repress transcription of its downstream gene.

CpG island methylator phenotype (CIMP) In some cancers, a large number of CpG islands are simultaneously methylated, and such a phenotype is designated as the CpG island methylator phenotype. CIMP can be associated with specific cancer pathophysiology, such as patient prognosis and drug sensitivity.

DNA methylation DNA modification that occurs at the 5th position of the cytosine residue (5-methylcytosine, 5-mC) within a CpG dinucleotide (CpG site).

DNMT Enzymes that can catalyze DNA methylation are collectively designated as DNA methyltransferases (DNMTs), and DNMTs can be classified into two classes, de novo type (DNMT3A and DNMT3B) and maintenance type (DNMT1). DNMT3A and DNMT3B are mainly involved in the establishment of DNA methylation status during early embryogenesis. DNMT1 is mainly involved in the maintenance of DNA methylation status at DNA replication.

TET An enzyme that can catalyze the conversion of 5-mC to 5-hydroxymethylcytosine (5-hmC), 5-formylcytosine (5-fC), and 5-carbocylcytosine (5-caC). 5-hmC, 5-fC, and 5-caC are removed by base excision repair. Therefore, TET enzymes are critical for the DNA demethylation process.

Introduction

DNA methylation is involved in various biological processes, such as embryogenesis, tissue differentiation, genomic imprinting, and inactivation of the X chromosome. At the same time, DNA methylation status can be altered by exposure to various environmental stimuli, and alterations of DNA methylation status are deeply involved in development and progression of human cancers.

Regulation Mechanism of DNA Methylation

DNA methylation is present at the 5th position of the cytosine residue (5-methylcytosine, 5-mC) within a CpG dinucleotide (CpG site) (Fig. 1). DNA methylation status is established during early embryogenesis by de novo type DNA methyltransferases (DNMTs), DNMT3A and DNMT3B. Once DNA methylation status is established, it is accurately transmitted upon somatic cell division (DNA replication) by maintenance DNMT (DNMT1) (Fig. 2).

At the same time, DNA demethylation can take place at specific biological periods in preimplantation embryos and primordial germ cells. Biochemically, 5-mC can be converted to 5-hydroxymethylcytosine (5-hmC), 5-formylcytosine (5-fC), and finally 5-carboxylcytosine (5-caC) by tet methylcytosine dioxygenase (TET). These modified bases are removed by the action of a DNA repair pathway, namely base excision repair (BER), and unmethylated cytosine is incorporated (Fig. 1).

Changes of DNA Methylation in Cancers

Regional Hypermethylation

DNA methylation status is altered in cancer cells, and the alteration is generally classified into two types; regional hypermethylation and global hypomethylation (Fig. 3). Regional hypermethylation, also called aberrant DNA methylation, represents increased DNA methylation of a CpG island (a cluster of CpG sites) unmethylated in normal cells. Aberrant DNA methylation of a promoter CpG island completely represses transcription of its downstream gene (methylation-silencing) (Fig. 4A), and can be involved in repression of various tumor-suppressor genes, depending upon cancer types. *RB* gene is repressed in many types of cancers, including retinoblastomas and pituitary adenomas, *CDKN2A* also in a variety of cancers, *BRCA1* gene predominantly in breast and ovarian cancers, *CDH1* gene in gastric and breast cancers, *MLH1* gene in colorectal, gastric, and lung cancers, and *RASSF1A* gene in various cancer types, such as breast and lung cancers.

In addition to tumor-suppressor genes, aberrant DNA methylation can be present at promoter CpG islands of thousands of genes. Most of such genes are not transcribed in corresponding normal tissues (as described in section "Aberrant DNA Methylation Induction by Environmental Stimuli"). Since these genes are considered not to be functional in normal tissues, their aberrant DNA methylation is not considered to be "driver methylation" but "passenger methylation".

 https://doi.org/10.1016/B978-0-12-801238-3.65058-4

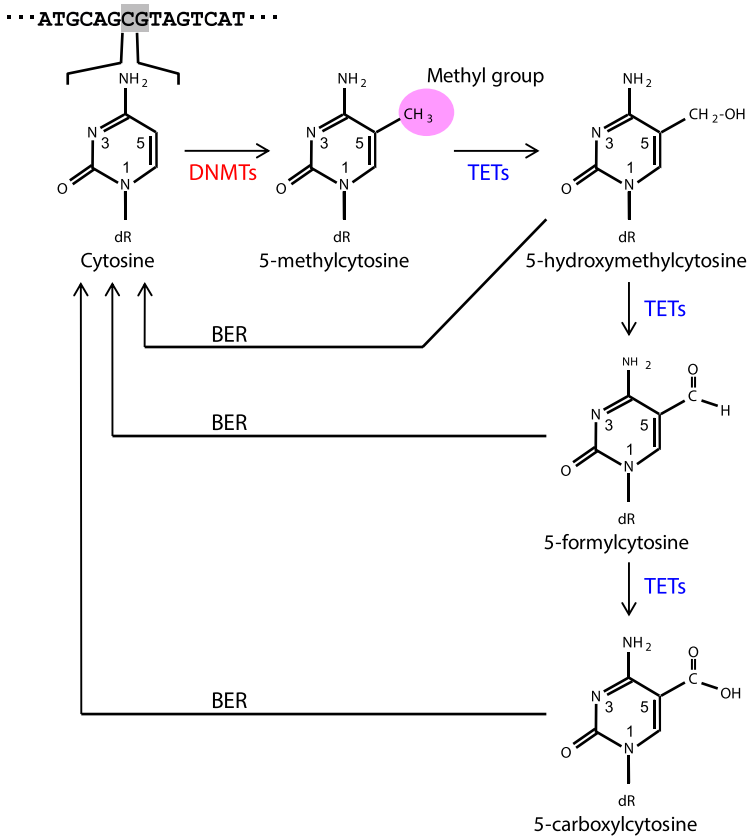

Fig. 1 DNA methylation and demethylation. DNA methylation is present at the 5th position of the cytosine residue (5-methylcytosine, 5-mC) within a CpG dinucleotide (CpG site). 5-mC can be converted to 5-hydroxymethylcytosine (5-hmC), 5-formylcytosine (5-fC), and finally 5-carboxylcytosine (5-caC) by tet methylcytosine dioxygenase (TET). These modified bases are finally removed by base excision repair (BER).

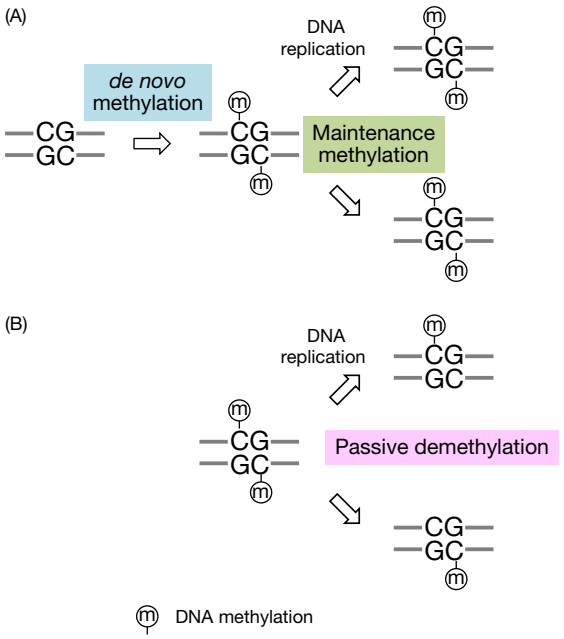

Fig. 2 Maintenance of DNA methylation. Once DNA methylation status is established, it can be accurately transmitted, even after cell division by maintenance DNMT (DNMT1) (A). When maintenance methylation is inhibited, passive DNA demethylation takes place (B).

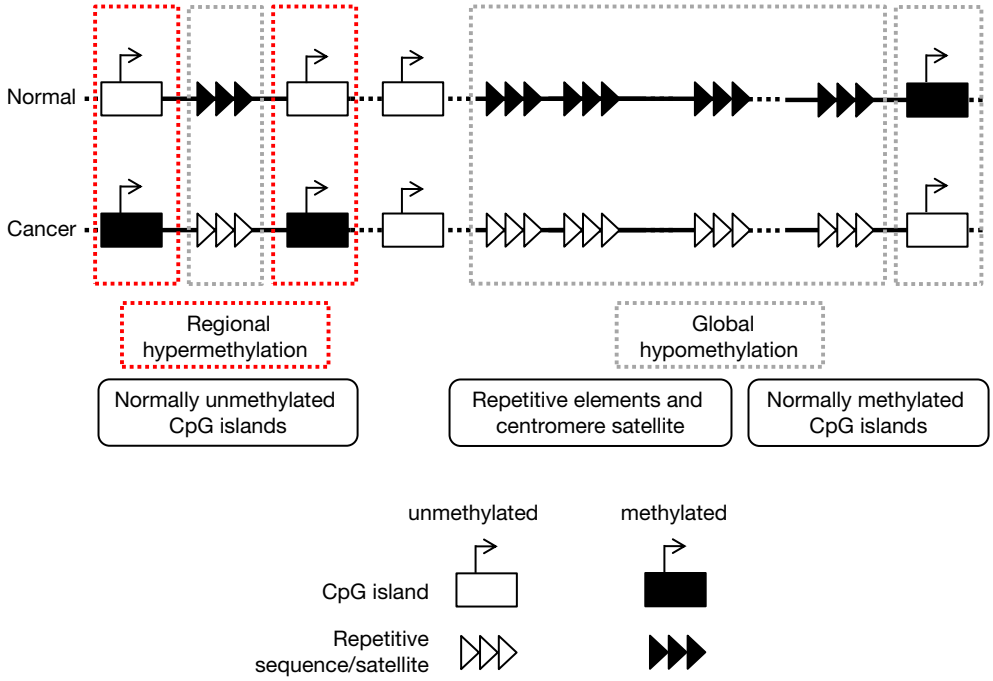

Fig. 3 Alterations of DNA methylation in cancer cells. They are generally classified into two types, namely regional hypermethylation and global hypomethylation. Regional hypermethylation represents increased DNA methylation of a CpG island unmethylated in normal cells. Global hypomethylation represents decreased 5-mC content in genomic DNA, due to mainly demethylation of repetitive sequences highly methylated in normal cells.

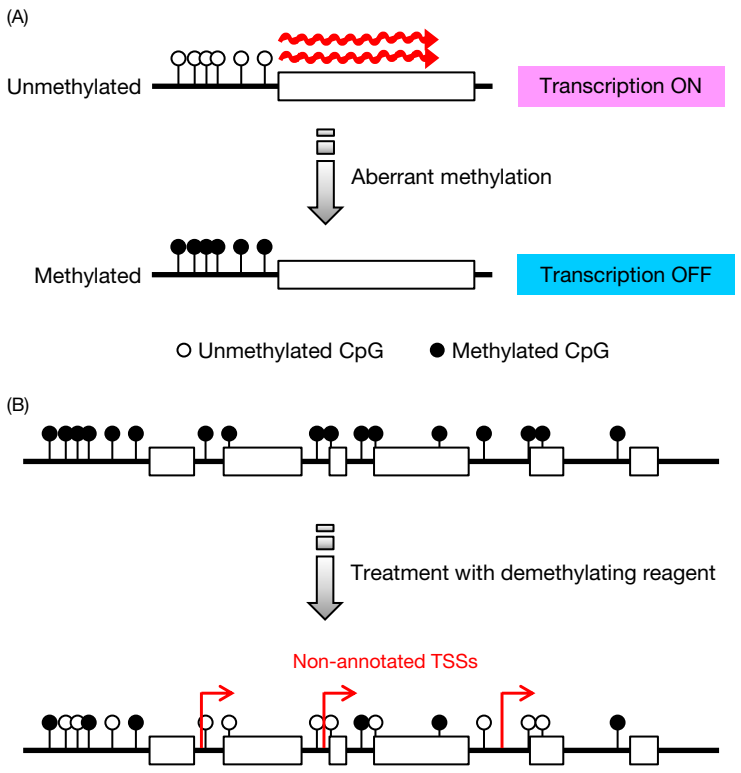

Fig. 4 Regulation of gene transcription by DNA methylation. (A) Repression of gene transcription by aberrant DNA methylation. Aberrant DNA methylation of a promoter CpG island completely represses transcription of its downstream gene (methylation-silencing), and can be deeply involved in the repression of various tumor-suppressor genes. (B) Generation of aberrant transcripts by DNA hypomethylation. Treatment of cells with a DNA demethylating reagent induced aberrant transcripts from thousands of non-annotated transcription start sites via demethylation of a gene body.

Global Hypomethylation

Global hypomethylation represents decreased 5-mC content in genomic DNA (Fig. 3), mostly due to demethylation of repetitive sequences (retrotransposons, Alu and LINE, and centromeric satellite DNA, α-satellite) highly methylated in normal cells. Global hypomethylation can lead to elevation of mutation rates, thus is involved in chromosomal instability. In addition, hypomethylation of promoter CpG islands of normally methylated genes can lead to their activation, including cancer-testis antigens, such as *MAGE-A1* and *NY-ESO-1*. Activation of oncogenes by hypomethylation has been proposed, but may need more robust analysis.

Recently, it has been reported that treatment of cells with a DNA demethylating agent induces aberrant transcripts from thousands of treatment-induced non-annotated transcription start sites (TSSs) via demethylation of the gene body (Fig. 4B). These aberrant transcripts can generate aberrantly truncated proteins, which are potentially involved in the dysregulation of cellular functions and immunogenicity. Global hypomethylation in cancer cells is proposed to lead to induction of such aberrant transcripts.

CpG Island Methylator Phenotype

A large number of CpG islands can be simultaneously hypermethylated in a cancer, and such status is referred to as the "CpG island methylator phenotype (CIMP)". The presence of cancers with the CIMP was first reported in colorectal cancers. Subsequently, cancers with the CIMP have been reported in various types of cancers, such as gastric cancers, glioblastomas, hepatocellular carcinomas, lung cancers, neuroblastomas, and renal cancers.

The CIMP is associated with specific cancer pathophysiology, such as patient prognosis and drug sensitivity, depending upon cancer types. In colorectal cancers, the CIMP is associated with old age, right-side location, and female patients. The association between the CIMP and patient prognosis in colorectal cancers is controversial, and associations with both good prognosis and poor prognosis have been reported. In neuroblastomas, the prognosis of patients with the CIMP is much poorer than those without. The predictive power of the CIMP is stronger than that of *MYCN* amplification, a clinically utilized prognostic marker. In lung cancers and renal cell carcinomas, the prognosis of patients with the CIMP is also poorer. In contrast, in glioblastomas and breast cancers, the prognosis of patients with the CIMP is better than that without.

As for the mechanisms of how the CIMP is induced, there had not been known. However, *IDH* mutations in glioblastomas and *SDH* (succinate dehydrogenase) mutations in gastrointestinal stromal tumors were recently shown to be causal for the CIMP. In contrast, an association between the CIMP and a *BRAF* mutation has been known for a long time in colorectal cancers, but its causal role has not been demonstrated.

Expression Changes of DNA Methylation Machineries in Cancers

Genes Involved in DNA Methylation

All the three DNMTs have been shown to be up-regulated in various types of cancers, such as breast cancers, colorectal cancers, and liver cancers. Therefore, the upregulation of DNMTs is a possible mechanism of aberrant DNA methylation induction. In addition, UHRF1 (Np95), which is required for maintenance of DNA methylation, is also upregulated in lung cancers and bladder cancers, and may be involved in aberrant methylation induction.

Genes Involved in Histone Modification

Expression changes of epigenetic machineries other than those directly involved in DNA methylation status have also been reported in various types of cancers. EZH2, a methyltransferase of histone H3 lysine 27 (H3K27), is upregulated in various types of cancers, such as prostate cancers, breast cancers, bladder cancers, gastric cancers, lung cancers, and liver cancers. The upregulation is often associated with aggressive phenotypes, such as the presence of metastasis and poor prognosis.

It is known that genes aberrantly methylated in cancer cells are frequently marked with trimethylation of H3K27 (H3K27me3) in their corresponding normal cells (as described in section "Aberrant DNA Methylation Induction by Environmental Stimuli"). Therefore, changes of H3K27me3 status by EZH2 upregulation may be possibly involved in aberrant DNA methylation induction.

Genetic Alterations of DNA Methylation Machineries in Cancers

Genes that Methylate DNA

Cancer genome analysis has revealed that various genes encoding epigenetic machineries are mutated, depending upon cancer types (Fig. 5). As for the genes that methylate DNA, DNMT3A mutations, mainly located within its C-terminal catalytic domain, especially at Arg882 (such as R882C, R882S, and R882H), have been reported in acute myeloid leukemia (AML). However, it had been unclear whether these *DNMT3A* mutations are a gain-of-function mutations or not (a loss-of-function mutations). Initially, it was reported that the *DNMT3A* mutations caused the reduction of its enzymatic (DNA methylation) activity, and were considered as loss-of-function mutations. This reduction of enzymatic activity was shown to lead to hypomethylation of *HOXB* cluster genes, critical genes for leukemogenesis.

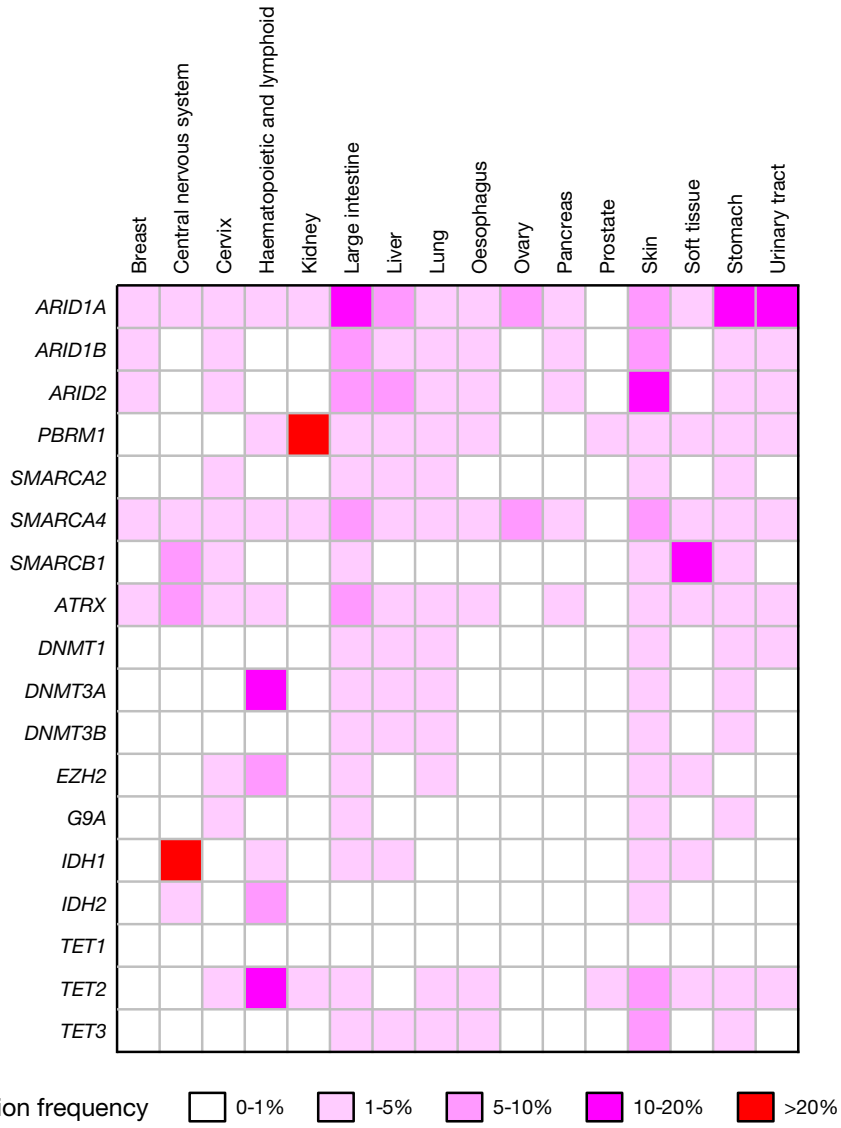

Fig. 5 Genetic alterations of genes encoding epigenetic machineries. Cancer genome analysis has revealed that various genes encoding epigenetic machineries are mutated in cancers. As for the genes involved in addition of DNA methylation, *DNMT3A* mutations mainly located within its C-terminal catalytic domain have been reported in AML. As for the genes involved in removal of DNA methylation, *TET2* mutations have been reported in several hematological cancers. Also, mutations of isocitrate dehydrogenase, *IDH1* and *IDH2*, whose gain-of-function product can inhibit TET activity has been reported in glioblastoma and AML. Therefore, mutations of these genes are considered to be involved in aberrant DNA methylation induction. Mutation frequencies were obtained from COSMIC (Catalogue of Somatic Mutations in Cancer; http://cancer.sanger.ac.uk/cancergenome/projects/census/).

Afterwards, gain of function by the *DNMT3A* mutation was also reported. R882H mutant DNMT3A protein, but not its wild-type protein, was shown to interact with polycomb repressive complex 1 (PRC1), which is involved in gene repression by inducing H3K27me3. In cells with the DNMT3A R882H mutation, myeloid differentiation-related genes, such as *Cebpa*, *Cebpe* and *PU.1*, are down-regulated, independently of DNA methylation. As for the other DNMTs, genetic alterations have not been documented.

Genes that Demethylate DNA

Mutations of genes encoding isocitrate dehydrogenase (IDH1 and IDH2) have been reported in glioblastoma and AML. IDH mutation is a typical gain-of-function mutation, and confers a novel enzymatic activity to convert α-ketoglutarate (α-KG) to (*R*)-2-hydroxyglutarate (2-HG) in addition to the impairment of its original enzymatic activity (conversion of isocitrate to α-KG). This oncometabolite, 2-HG, produced by mutant IDH protein inhibits the enzymatic activities of TET proteins. The accumulation of 5-mC by reduced TET activities is considered to be one of the molecular mechanism of aberrant DNA methylation induction.

In addition, *TET2* is known to be mutated in several hematological cancers, and the 5-hmC levels are reduced in the bone marrow of patients with *TET2* mutations. In solid tumors, 5-hmC levels are also reduced in several cancer types, such as melanoma, liver cancers, and lung cancers. *TET2* and *TET3* are actually mutated in these solid tumors, especially for *TET2* (Fig. 5). Therefore, *TET2* and *TET3* mutations are considered to be involved in aberrant DNA methylation induction.

Genes Related to Other Epigenetic Mechanisms

Epigenetic machineries involved in histone modifications are also mutated in cancers. Among various histone modifications, H3K27me3 in normal cells is known as a premark of aberrant DNA methylation induction (as described in section "Aberrant DNA Methylation Induction by Environmental Stimuli"). In lymphoma, *EZH2* is mutated predominantly at tyrosine641 (such as Y641H, Y641N, and Y641S). This mutation enhances histone methyltransferase activity of EZH2, and disturbs cellular H3K27me3 status. In addition, inactivating mutations of UTX (KDM6A), an H3K27 demethylase, have been reported in AML, colorectal cancers, and esophageal squamous cell carcinomas (ESCCs). Activation of an H3K27 methylase and inactivation of an H3K27 demethylase can affect H3K27me3 status, and thus these alterations are potentially involved in aberrant DNA methylation induction.

Genes Related to Chromatin Remodeling

A chromatin remodeling factor, such as SWI/SNF, is composed of multiple components, and regulates gene transcription via changing nucleosome occupancy. Genes encoding SWI/SNF components are frequently mutated in various types of cancers, and these mutations are considered to disrupt SWI/SNF functions, which is likely to lead to the alterations of nucleosome occupancy. The presence of nucleosome can protect genomic DNA from DNA methylation catalyzed by de novo type DNMTs, DNMT3A, and DNMT3B. Therefore, there is a possibility that SWI/SNF mutations might be one of the possible mechanisms of aberrant DNA methylation induction.

Aberrant DNA Methylation Induction by Environmental Stimuli

Inducers of Aberrant DNA Methylation

Aberrant DNA methylation can be detected not only in cancer cells but also in normal cells, even far before cancer development. As for the inducers of aberrant DNA methylation, aging has been known for a long time (Table 1). DNA methylation levels of genes encoding estrogen receptor in human colonic tissues were initially shown to increase, depending upon age. It has also been shown that some infectious agents can induce aberrant DNA methylation in various tissues. In the stomach, DNA methylation levels are up to 300-fold higher in people infected with *Helicobacter pylori* (*H. pylori*), an almost exclusive cause of gastric cancers, than those without. Also in the liver, aberrant DNA methylation is induced in people infected with hepatitis C virus (HCV). In addition, some chemicals (smoking) and a hormone (estrogen) are also reported to induce aberrant DNA methylation.

Aberrant DNA methylation can be accumulated in normal tissues for a long time. The degree of accumulation of aberrant methylation, namely methylation burden, is closely correlated with risk of cancer development in the stomach, esophagus, and mammary glands. This strongly indicates that the accumulation of aberrant DNA methylation in normal tissues leads to the formation of an epigenetic field for cancerization (epigenetic field defect), an apparently normal tissue but predisposed to carcinogenesis

Table 1 Inducers of aberrant DNA methylation

Inducing factors	*Tissues*
Aging	Colon
Bacterial infection	
Helicobacter pylori	Stomach
Viral infection	
Hepatitis B virus	Liver
Hepatitis C virus	Liver
Epstein-Barr (EB) virus	Stomach
Papillomavirus	Uterine cervix, Oropharynx
Parasitic infection	
Liver fluke	Bile duct
Schistosoma	Bladder
Smoking	Esophagus
Hormone	
Estrogen	Mammary epithelium (under the culture condition)

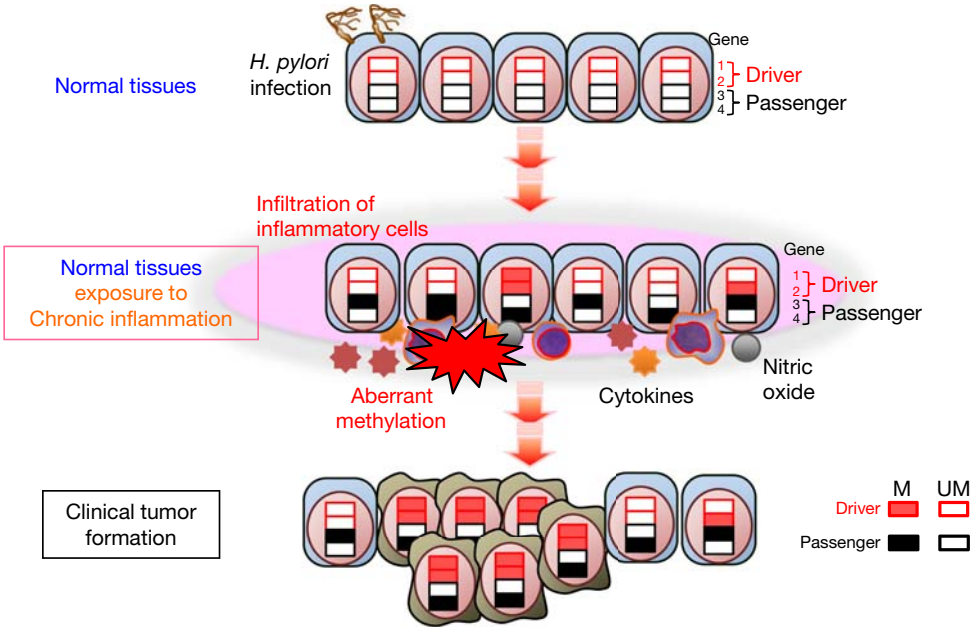

Fig. 6 Formation of an epigenetic field for cancerization. Aberrant DNA methylation can be detected not only in cancer cells but also in normal cells, even far before cancer development. It affects both driver and passenger genes. The accumulation of aberrant DNA methylation in normal tissues is associated with increased cancer risk, and produces a field for cancerization, a normal tissue predisposed to carcinogenesis.

(Fig. 6). The measurement of the degree of methylation burden is useful for cancer risk prediction, and the usefulness has been demonstrated even clinically for gastric cancer.

Importance of Chronic Inflammation in Aberrant DNA Methylation Induction

Chronic inflammation is especially important in aberrant DNA methylation induction. Suppression of chronic inflammation in the stomach of Mongolian gerbils by the administration of cyclosporin A (an immunosuppressant) markedly inhibited methylation induction while it did not affect colonization of *H. pylori*. This clearly showed that chronic inflammation, but not the *H. pylori* itself, is important for aberrant DNA methylation induction.

Mechanism of Target Gene Specificity

Aberrant DNA methylation is induced at specific genes, depending upon tissues and possibly methylation inducers. In gastric tissues, some genes are methylated at a high incidence (susceptible to methylation induction) in individuals with *H. pylori* infection while others are not (Fig. 7). As for the mechanism of the target gene specificity, methylation-susceptible genes were shown to have low transcription levels in normal cells. Then, it was also shown that genes aberrantly methylated in cancer cells are pre-marked by H3K27me3 in their corresponding normal cells (Fig. 8A). Further, methylation-resistant genes had high levels of RNA polymerase II (Pol II) binding at their nucleosome free regions (NFRs), even if they are not transcribed (Fig. 8B). Exposure to chronic inflammation can also induce an increase of H3K27me3 levels, which eventually leads to induction of aberrant DNA methylation (Fig. 8C). Tumor-suppressor genes can be silenced by aberrant DNA methylation, despite their high levels of Pol II binding at their NFRs in normal cells.

Perspective: Clinical Applications of Aberrant DNA Methylation

Aberrant DNA methylation can be utilized for cancer diagnosis and therapy. Measurement of aberrant DNA methylation specifically present in cancer cells can be utilized for cancer detection. The presence of such methylation can be measured using specimens that can be obtained with minimal invasion (tumor-derived cell-free DNA, cfDNA) or without invasion (urine, sputum, and stool). Measurement of DNA methylation in cancer biopsy specimens can be utilized for the prediction of cancer pathophysiology, such as drug sensitivity and patient prognosis. Measurement of DNA methylation in normal cells can be utilized for risk prediction of cancer development.

Aberrant DNA methylation can be removed using DNA demethylating drugs. Now two drugs, azacytidine (5-azacytidine) and decitabine (5-aza-2′-deoxycytidine), are clinically utilized for treatment of myelodysplastic syndrome (MDS) and a part of acute

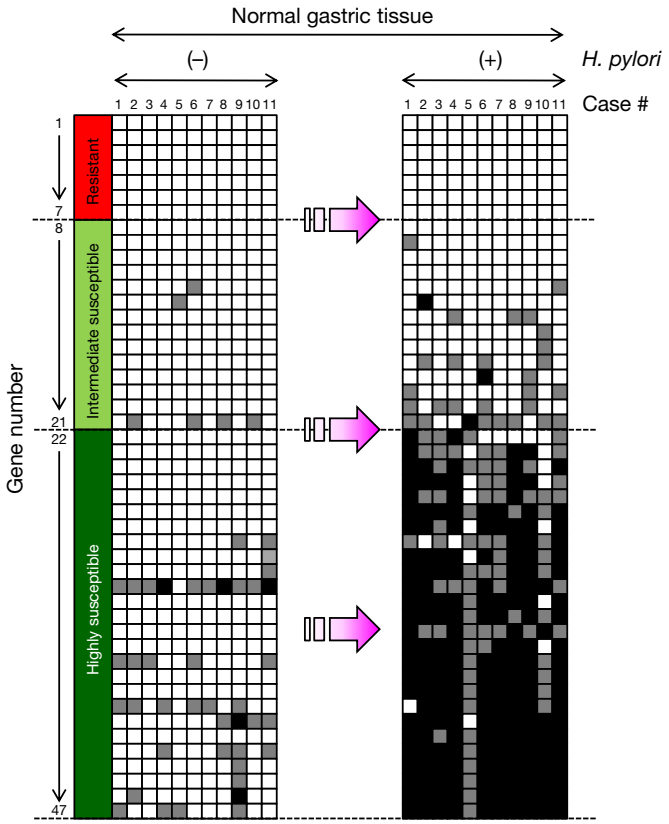

Fig. 7 Target gene specificity of aberrant DNA methylation induction. Aberrant DNA methylation is induced at specific genes, depending upon tissue types and possibly methylation inducers. For example, in gastric tissues, some genes were consistently methylated in different individuals exposed to *H. pylori*-triggered chronic inflammation (*Green*, highly susceptible to methylation induction) while the others were resistant (*Red*, resistance to methylation induction). Modified from Nakajima et al. *International Journal of Cancer* **124**, 905–910, 2009.

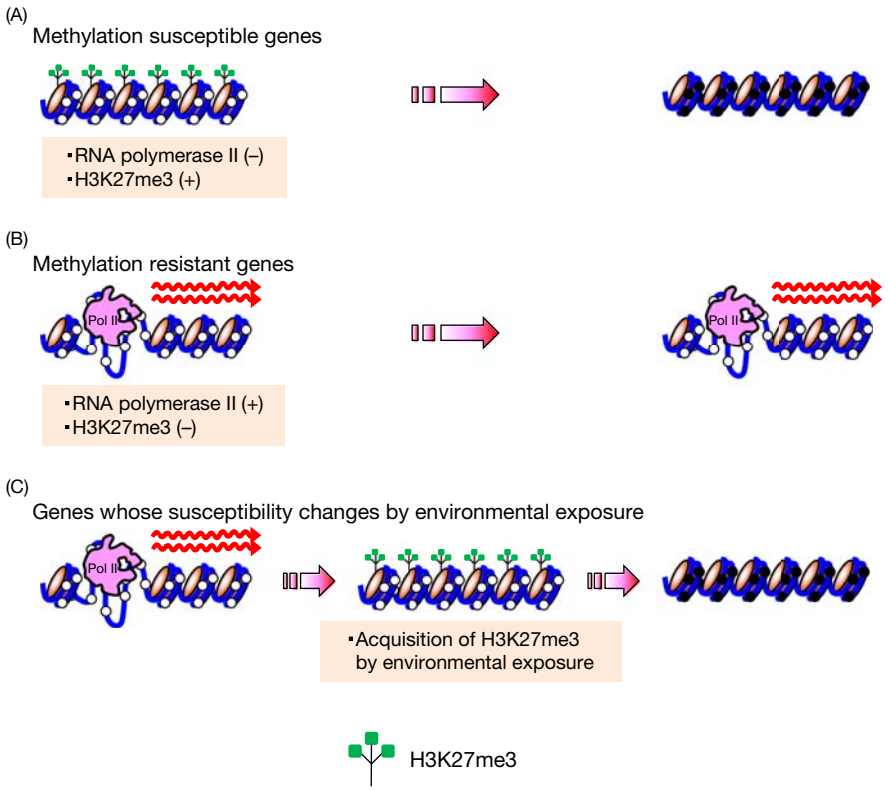

Fig. 8 Mechanisms of target gene specificity of aberrant DNA methylation induction. Genes aberrantly methylated in cancer cells are pre-marked by H3K27me3 in their corresponding normal cells (A). In contrast, methylation-resistant genes show high levels of RNA polymerase II (Pol II) binding at their nucleosome free regions (NFRs), even if they are not transcribed (B). Exposure to specific environmental factors can also induce an increase of H3K27me3 levels at a relatively early stage of the exposure, and this leads to aberrant DNA methylation after prolonged exposure (C).

myeloid leukemia (AML). Clinical trials for solid tumors are also being conducted, especially by focusing on a combination of a DNA demethylating drug and conventional chemotherapy (or another epigenetic drug). For example, a combination of azacytidine and entinostat (a histone deacetylase inhibitor) was shown to be effective for at least some patients with recurrent metastatic non-small cell lung cancers. Also, the efficacy of a combination of decitabine and carboplatin has been reported for carboplatin-resistant ovarian cancers, and a combination of decitabine and panitumumab (an anti-EGFR antibody) for metastatic colorectal cancers.

Epilogue

Recent development of technologies for genome-wide DNA methylation analysis revealed DNA methylation profiles in cancer cells that can be potentially used for diagnostic purposes. As inducers of aberrant DNA methylation, genes encoding epigenetic machineries are mutated and have altered expressions in cancers. The role of chronic inflammation is well known, and may be useful as a target of cancer prevention. Further efforts are required to deepen our understanding and to accelerate clinical applications of the findings in aberrant DNA methylation.

DNA Mismatch Repair: Mechanisms and Cancer Genetics☆

William J Graham V, Christopher D Putnam, and Richard D Kolodner, Ludwig Institute for Cancer Research, San Diego Branch, La Jolla, CA, United States

Glossary

Deletion Loss of a segment of DNA from a chromosome, sometimes part of a gene or an entire gene(s).

Frameshift mutation Type of mutation in a gene resulting from insertion or deletion of additional base pairs, usually 1 or 2, that changes the reading frame of the gene downstream from the mutation.

Heterodimer Protein complex consisting of two different proteins.

Heterozygous Having two different alleles of a gene.

Homozygous Having two identical alleles of a gene.

Immunohistochemistry A method to detect the presence of a specific protein in a tissue sample using protein-specific antibodies.

Mispair DNA nucleotides paired in non-Watson–Crick base pairs. For example, G-T rather than the correct G-C or A-T.

Mutation A change in the original DNA sequence.

Neoantigen A newly formed antigen due to a mutation in a gene that results in the expression of a new protein sequence that is not present in normal tissues.

Template strand The strand of DNA used by a DNA polymerase as instructions to build a new DNA strand with the same information as the template.

Introduction

Mispaired DNA bases can occur as a result of misincorporation of incorrect nucleotides by DNA polymerases during DNA replication. DNA mismatch repair (MMR) is a conserved mechanism that corrects both base–base mispairs (G-T rather than G-C, for example) and small insertion/deletion loops that are caused by DNA polymerase slippage. The MMR machinery first recognizes the mispair and then excises the DNA strand containing the mispaired base followed by filling in the resulting single stranded gap in the DNA. Critically, MMR identifies the newly synthesized DNA strand and only targets this strand for excision and resynthesis. If repair was targeted to the template strand or if repair failed to occur before the next round of DNA replication, the mispaired base would result in a mutation (Fig. 1).

MMR is a major pathway for suppressing DNA replication errors. Defects in MMR result in increased cellular mutation rates, which means that MMR-defective cells accumulate mutations at higher rates than cells with functional MMR. Increased numbers of mutations and increased mutation rates have been observed in many cancers. The "mutator phenotype hypothesis" posits that increased mutation rates drive tumor evolution. These mutations can directly activate proto-oncogenes or inactivate tumor suppressor genes to initiate tumorigenesis as well as increase growth advantages of tumor subclones during cancer progression. Consistent with the predictions of this hypothesis, several cancer predisposition syndromes including Lynch syndrome (also called hereditary non-polyposis colorectal cancer or HPNCC) and biallelic MMR deficiency are caused by inherited mutations in MMR genes. It is also known that somatic MMR defects can underlie the development of sporadic cancers.

This article reviews our current understanding of MMR pathways and the proteins involved, while highlighting some major remaining questions in the field. Additionally, the cancer predisposition syndromes caused by inherited MMR defects and the occurrence of MMR defects in sporadic cancers are discussed. It should be noted that MMR also acts on (1) mispaired bases that are the result of chemical damage to DNA and (2) mispared bases that occur in the heteroduplex DNA intermediates formed during recombination, and MMR acts to prevent recombination between divergent but highly homologous DNAs as well as playing roles in somatic hypermutation and meiotic recombination; however, these aspects of MMR are not discussed in this article.

Mechanism of MMR

Scope and Comments on Nomenclature

Much of the early work on MMR mechanisms was performed using *Escherichia coli* as a model system. However, the MMR pathways of *E. coli* and other closely related Gammaproteobacteria have a number of mechanistic differences compared to the MMR pathways

☆*Change History:* November 2017. William J. Graham V, Christopher D. Putnam, and Richard D. Kolodner updated the text and references to this article. This article is an update of Richard D. Kolodner, and Hernan Flores-Rozas, Mismatch Repair: Biochemistry and Genetics, in Encyclopedia of Cancer (Second Edition), edited by Joseph R. Bertino, Academic Press, 2002, Pages 179–185.

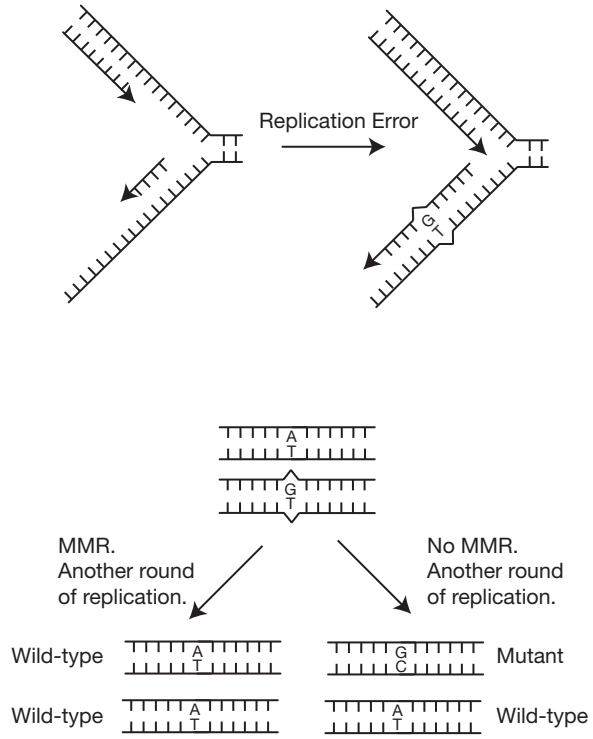

Fig. 1 Model for the formation and repair of mispaired based during DNA replication.

Table 1 Eukaryotic MMR proteins

H. sapiens/M. musculus	*S. cerevisiae*	*E. coli*	*Function in MMR*
Mispair recognition			
MSH2-MSH3	Msh2-Msh3	MutS	Mispair recognition protein. Msh2-Msh3 is also called MutSβ, and Msh2-Msh6 is also called MutSα. See text for more details
MSH2-MSH6	Msh2-Msh6		
Accessory factors			
MLH1-PMS2	Mlh1-Pms1	MutL	Mispair activated endonuclease that also recruits downstream proteins. In some bacteria, MutL does not have an endonuclease activity. Also called MutLα
MLH1-PMS1	Mlh1-Mlh2		Accessory factor for MMR acting through an unknown mechanism. Also called MutLβ
MLH1-MLH3	Mlh1-Mlh3		Can substitute for *S. cerevisiae* Mlh1-Pms1 in some cases. Acts primarily in resolution of meiotic crossovers. Also called MutLγ
Excision reaction			
EXO1	Exo1	[a]	5′ → 3′ dsDNA[b] exonuclease that excises DNA around the mispair
Resynthesis reaction/accessory proteins			
PCNA	PCNA	β Clamp	DNA polymerase processivity factor and required for activating the Mlh1-Pms1 (*S. cerevisiae*)/MLH1-PMS2 (*H. sapiens*) endonuclease and for DNA Pol δ
RFC	RFC	γ complex	Loads the β clamp/PCNA onto DNA
RPA	RPA	SSB	ssDNA[b] binding protein that acts in the excision and resynthesis reactions
DNA Pol δ	DNA Pol δ	[c]	DNA polymerase that resynthesizes excised DNA
DNA Pol ε	DNA Pol ε	[c]	Another DNA polymerase that can act during MMR
Ligase I	Ligase I	DNA ligase	Seals any nicks in the DNA

[a] *E. coli* uses a different excision mechanism involving a DNA helicase and one of four different ssDNA-specific endonucleases.

[b] dsDNA, double-stranded DNA; ssDNA, single-stranded DNA.

[c] *E. coli* uses DNA polymerase III, which is most analogous to DNA polymerase δ because of the requirement of the β clamp/PCNA processivity factor.

of eukaryotes and other bacteria, even though a number of MMR proteins are highly conserved between different organisms. Therefore, we will only discuss eukaryotic MMR proteins and mechanisms in this article. See **Table 1** for a list of the known *Saccharomyces cerevisiae* and human MMR proteins and their relationship to the known *E. coli* MMR proteins. The discussion of these proteins will focus on the human proteins and use the names of the human proteins as much as possible. However, MMR proteins and their function are the same in *S. cerevisiae* and human, and since studies of *S. cerevisiae* MMR have contributed enormously to our understanding of MMR mechanisms the discussion below will also draw upon insights developed through the study of *S. cerevisiae* MMR.

MutS-Related Proteins

Eukaryotes possess three homologs of bacterial *mutS* that encode proteins known to function in MMR: *MSH2*, *MSH3*, and *MSH6*. The protein products of these genes form two heterodimeric complexes, MSH2-MSH3 (also called MutSβ) and MSH2-MSH6 (also called MutSα), which have slightly different, but partially redundant roles in recognizing mispairs (Fig. 2). Base–base mispairs are primarily recognized by MSH2-MSH6, although MSH2-MSH3 can recognize a small number of these mispairs, and MSH2-MSH3 is solely responsible for recognizing large insertion/deletions. In contrast, both complexes act in the repair of small insertion/deletions, which are the most common type of DNA replication errors. Because of this partial redundancy and the importance of MSH2-MSH6 in base–base mispairs, MSH2-MSH6 appears to play a larger role in the suppression of mutations than MSH2-MSH3. Consequently deletion of *MSH3* causes only a small increase in mutation rates compared to deletion of *MSH6*. However, disruption of *MSH2* results in completely defective MMR and much higher mutation rates than disruption of either *MSH6* or *MSH3* because *MSH2* encodes a common subunit in both complexes.

The MSH2-MSH6 and MSH2-MSH3 mispair binding proteins have two composite ATP binding/hydrolysis sites. Binding of ATP, hydrolysis of ATP, and release of ADP at these sites modulates the interaction between these proteins and DNA as well with downstream MMR factors. The nucleotide-free and ADP-bound forms of MSH2-MSH6 and MSH2-MSH3 can bind to mispairs and induce a dramatic bend in the DNA at the site of the mispair. Remarkably, the structures of these complexes with mispair-containing DNAs has revealed that mispairs are recognized in a specific manner, such as the recognition of the thymidine base in a T:G mispair, which indicates that the orientation of mispair binding by MSH2-MSH6 or MSH2-MSH3 cannot be the source of strand-specificity for the downstream steps of MMR. In contrast, the ATP-bound form of these proteins cannot bind mispaired bases. Moreover, ATP binding by mispair-bound MSH2-MSH6 and MSH2-MSH3 triggers a conformational change whereby the proteins convert to a sliding clamp that releases from the mispair, eliminates the bend in the DNA, and slides along the DNA. ATP binding by MSH2-MSH6 and MSH2-MSH3 is also required for the recruitment of the MutL homolog complexes; however, some mutant versions of Msh2-Msh6 in *S. cerevisiae* are competent for recruitment but not sliding, suggesting that these two ATP-dependent states are not identical.

MutL-Related Proteins

Eukaryotes encode four genes related to bacterial *mutL* that encode proteins that act in MMR: *PMS1* (*MLH2* in *S. cerevisiae*), *PMS2* (*PMS1* in *S. cerevisiae*), *MLH1* and *MLH3*. The protein products of these genes form three heterodimeric complexes, MLH1-PMS2 (Mlh1-Pms1 in *S. cerevisiae*; also called MutLα), MLH1-PMS1 (Mlh1-Mlh2 in *S. cerevisiae*; also called MutLβ) and MLH1-MLH3 (also called MutLγ).

MLH1-PMS2 is the major MutL-related protein complex that functions in MMR. Mispair bound MSH2-MSH6 and MSH2-MSH3 recruit and load MLH1-PMS2 onto DNA (Figs. 2 and 3). There is evidence that either multiple molecules of MLH1-PMS2 are recruited per molecule of MSH2-MSH6 (or MSH2-MSH3) or that MLH1-PMS2 has a longer residence time on DNA than MSH2-MSH6 or MSH2-MSH3. Moreover, structural and single molecule studies suggest that MLH1-PMS2 may also form a clamp on the DNA. It should be noted that the MSH2-MSH6 sliding clamp is not required for MLH1-PMS2 recruitment, suggesting that sliding clamp formation and MLH1-PMS2 recruitment may represent different aspects of ATP binding-induced conformational changes. MLH1-PMS2 is an endonuclease that makes single strand breaks in DNA, and this activity is essential for MMR. Its endonuclease activity, which can be observed under a number of different reaction conditions, is highly activated in the presence of

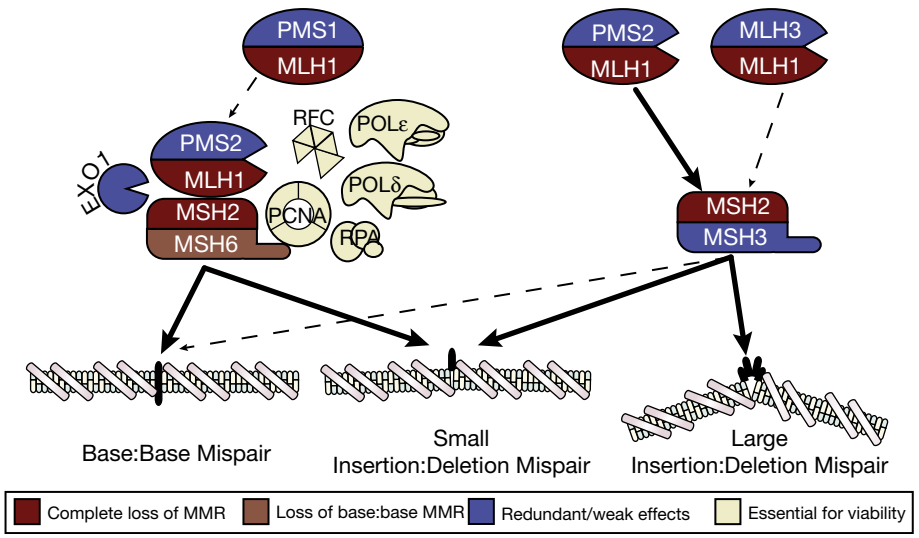

Fig. 2 Illustration of the known MMR proteins and their specificity for different mispaired bases.

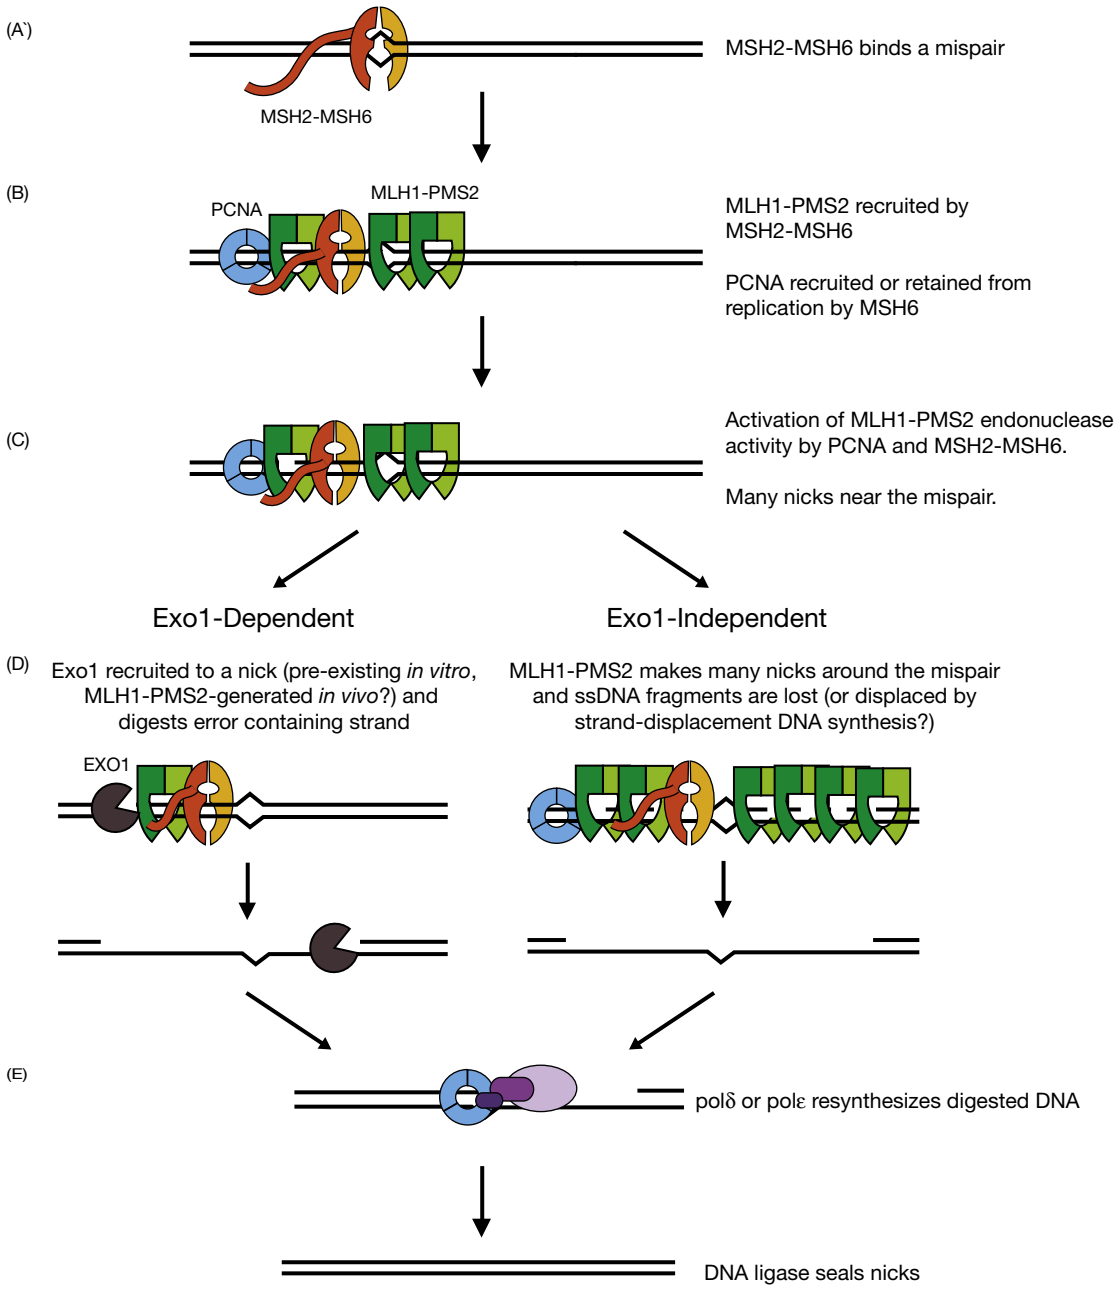

Fig. 3 Models for the mechanisms of Exo1-dependent and Exo1-independent MMR reactions.

MSH2-MSH6 or MSH2-MSH3, the proliferating clamp nuclear antigen (PCNA), replication factor C (RFC) and ATP on mispaired base containing DNA substrates that also contain a single strand break. Under these reaction conditions, MLH1-PMS2 makes single strand breaks (called nicks) only in the DNA strand that contains the pre-existing nick, although the mechanisms by which nicking is directed to the pre-nicked strand under these conditions are not yet understood. It is still unknown how eukaryotic systems distinguish between the newly synthesized and template strands to target MMR to the newly synthesized strand; however, it has been suggested that because the newly synthesized DNA strands can contain differing levels of nicks and PCNA may remain on the DNA after replication it may mark the newly replicated strand by an unknown mechanism and that PCNA-dependent strand-specific nicking by MLH1-PMS2 might then play a role in initiating strand-specific MMR.

The MLH1-MLH3 heterodimer is less important for MMR than MLH1-PMS2. Genetic studies in *S. cerevisiae* suggest that the MLH1-MLH3 heterodimer plays a small role in MMR that is partially redundant with that of MLH1-PMS2, and studies in mice support this idea (Fig. 2). Like PMS2, MLH3 contains an endonuclease active site; however, biochemical studies have not yet been able to demonstrate that MLH1-MLH3 has a mispair-dependent nicking activity like that of MLH1-PMS2. Other studies

have demonstrated that the major function of MLH1-MLH3 is in the resolution of meiotic crossing over intermediates and that the MLH1-MLH3 endonuclease may cleave Holliday junction recombination intermediates.

In contrast, less is known about the role of MLH1-PMS1. PMS1 does not appear to have an endonuclease active site like that of PMS2 or MLH3. In *S. cerevisiae*, Mlh1-Mlh2 (human MLH1-PMS1) can be recruited to DNA containing mispaired bases by both Msh2-Msh6 and Msh2-Msh3. Deletion of *S. cerevisiae MLH2* does not cause a mutator phenotype except under conditions of reduced Pms1 expression (human PMS2). These results suggest that the human MLH1-PMS1 complex functions in MMR as an MLH1-PMS2 accessory protein, though its exact function in this regard is unknown.

Identification of Other MMR Proteins

Exonuclease 1 (EXO1) was first implicated in MSH2-dependent MMR because it was identified as an MSH2-interacting protein. EXO1 was later found to interact with MLH1 through a peptide in EXO1 called a MIP (for MLH1 interacting peptide) box. EXO1 is a 5′ to 3′ dsDNA exonuclease that can also cleave branched DNA molecules. Considerable data support the idea that EXO1 functions in the mispair excision step of MMR under some conditions and that the interaction between EXO1 and MSH2 increases the extent of excision by EXO1 in response to a mispair. In contrast, the role of the interaction between EXO1 and MLH1 is less clear. Genetic studies show that loss of EXO1 only causes weak MMR defects, suggesting that other mechanisms for DNA strand excision during MMR must exist. Other exonucleases proposed to function in MMR are the endo/exonuclease FEN1/RAD27 and the 3′ to 5′ editing exonuclease functions of DNA polymerases δ (DNA Pol δ) and epsilon (DNA Pol ε); however, a role for these exonucleases in the excision step of MMR has not yet been definitively established. A combination of in vitro MMR reconstitution studies, genetic studies and studies of the MLH1-PMS2 endonuclease established a role for DNA Pol δ, DNA Pol ε, replication protein A (RPA), PCNA and RFC in MMR. Finally, recent studies identified WDHD1 and MCM9 as MSH2-interacting proteins; however, a role for these proteins in MMR has not been definitively established.

Reconstitution of MMR In Vitro

A number of insights into MMR mechanisms have been obtained through in vitro reconstitution studies using different combinations of proteins to catalyze MMR reactions. Two types of mispair-dependent excision/repair reactions have been reconstituted with human and *S. cerevisiae* proteins. In the first type of reaction, a combination of one of the mispair recognition factors MSH2-MSH6 or MSH2-MSH3, EXO1, DNA Pol δ, the single-stranded DNA binding protein RPA, PCNA and the PCNA loading factor RFC catalyze the repair of a circular mispaired substrate containing a single strand break (called a nick) on the 5′ side of the mispair. In this reaction, the mispair recognition factors stimulate excision by Exo1 from the nick past the mispair to produce a gap that is filled in by DNA Pol δ, PCNA, and RFC to repair the mispair. DNA Pol ε can substitute for DNA Pol δ in this first type of MMR reaction, although PCNA and RFC are no longer required under these conditions. In a second type of reaction, a combination of MSH2-MSH6 or MSH2-MSH3, MLH1-PMS2, EXO1, DNA Pol δ, RPA, PCNA and RFC promotes the repair of a circular mispaired substrate containing a nick on the 3′ side of the mispair. In this reaction, the MLH1-PMS2 endonuclease is activated in a mispair-dependent fashion by a combination of MSH2-MSH6 or MSH2-MSH3, PCNA and RFC to generate DNA nicks 5′ to the mispair. Once 5′-nicks are formed, repair appears to occur as observed in the 5′-nick directed MMR reactions. DNA Pol ε can substitute for DNA Pol δ in this second type of MMR reaction, although PCNA and RFC are still required due to their role in activating the MLH1-PMS2 endonuclease.

MMR can also occur in the absence of EXO1; however, our knowledge of EXO1-independent MMR mechanisms is not as well developed as it is for EXO1-dependent MMR. Several potential mechanisms have been suggested based on the results of biochemical and genetic studies. Biochemical reconstitution studies have shown that a combination of MSH2-MSH6, MLH1-PMS2, DNA Pol δ, RPA, PCNA and RFC can promote the repair of a circular mispaired substrate containing a nick on the 3′ side of the mispair. In this reaction, the MLH1-PMS2 endonuclease makes DNA nicks 5′ to the mispair and strand displacement synthesis by DNA Pol δ from the 5′ nick removes the nicked DNA strand from the 5′ nick to the 3′ nick, thus repairing the mispair. It should be noted that as yet there is no definitive genetic evidence supporting this mechanism. It is also unclear how this mechanism would work on the leading strand of the replication fork as nicks on the leading strand are much less frequent than nicks on the lagging strand, and human DNA Pol ε reportedly cannot support this reaction. A combination of biochemical, genetic and cell biology experiments showed that Exo1-independent MMR requires hyper-activation of the MLH1-PMS2 endonuclease leading to the hypothesis that iterative nicking of the DNA by MLH1-PMS2 may play a role in Exo1-independent MMR. Further study will be required to elucidate the mechanisms of Exo1-independent MMR.

Unanswered Questions About MMR Mechanisms

A model for eukaryotic MMR can currently be sketched out (**Fig. 3**); however, multiple steps remain speculative and are derived primarily from genetic inferences or are implicated primarily by biochemical reconstitution experiments that have not been verified in vivo. But even this model does not answer some important mechanistic questions. In order for MMR to prevent mutations that occur as a result of replication errors it must: (1) detect individual mispairs among a vast excess of normal basepairs even though the mispair binding proteins only have a modest selectivity for binding mispairs relative to base pairs; (2) target MMR to the newly synthesized DNA strand; and (3) complete MMR before the next round of DNA replication. A complete picture of how these steps are accomplished is not yet available.

Mispaired bases occur at very low frequencies and must be recognized and repaired in the presence of a vast excess of correct base pairs. However, MSH2-MSH6 and MSH2-MSH3 have only a 10–20 fold higher affinity for mispairs relative to their affinity for base pairs, suggesting there may be some mechanism to amplify the signal of the mispair. The conversion of MSH2-MSH6 and MSH2-MSH3 to sliding clamps allows additional molecules of these proteins to bind the mispair and then track along the DNA, which could be part of the mechanism by which the mispair signal is amplified to trigger repair in vivo. Another possible aspect of signal amplification may have been revealed by the formation of cytological *S. cerevisiae* Mlh1-Pms1 (human MLH1-PMS2) foci containing multiple molecules of *S. cerevisiae* Mlh1-Pms1 (human MLH1-PMS2) as a MMR intermediate. If the recruitment of MLH1-PMS2 protein involves a cycle of ATP hydrolysis by MSH2-MSH6 (or MSH2-MSH3), mispair re-recognition, and ATP binding, then the small energetic difference between mispairs and fully base paired DNA will be amplified.

The mispair binding proteins, MSH2-MSH6 and MSH2-MSH3, are known to colocalize with the DNA replication machinery where they function as mispair detectors for MMR. This colocalization is mediated by the interaction between MSH2-MSH6 (or MSH2-MSH3) and PCNA and is required for MMR under some conditions. Consistent with this, MMR is also temporally coupled to DNA replication during S-phase. Other mechanisms for coupling MMR to DNA replication likely exist but have not yet been definitively established; one possible mechanism is the reported interaction between MSH2-MSH6 and an S-phase specific chromatin modification through the deterostome-specific N-terminal PWWP domain of MSH6, although further studies of this possible mechanism are needed. S-phase coupling of MMR to DNA replication proteins during the S-phase in which the mispair occurred provides a potential mechanism for enhanced mispair recognition by MMR proteins and would be expected to ensure that mispairs are recognized and repaired before the next round of DNA replication.

It is less clear how MMR is targeted to newly replicated DNA strands. The unusual property of the MSH2-MSH6 (or MSH2-MSH3) and PCNA-dependent MLH1-PMS2 endonuclease that targets its endonuclease activity to nicked DNA strands is intriguing in this regard, as the newly replicated DNA strands, particularly the lagging DNA strand, would be expected to be marked by both nicks and PCNA. Key unresolved questions are: (1) what are the biochemical and structural mechanisms that phase MLH1-PMS2 to target it to nicked DNA strands; and (2) why would additional nicking actually be needed for MMR given that pre-existing nicks, particularly on the lagging strand, should be substrates for EXO1-mediated excision of mispairs. This potential strand recognition mechanism seems less applicable to MMR on the leading strand given the much lower density of nicks and PCNA that are expected on the leading strand. It has also been suggested that nicking at ribonucleotides that are misincorporated during DNA replication could provide a strand specificity signal, although this seems unlikely as defects that eliminate RNAseH2, the enzyme that would make these nicks, do not cause an MMR defect. Further investigation of the mechanisms of strand specificity during MMR are clearly needed.

MMR Defects and Cancer

Lynch Syndrome

A large number of hereditary cancer syndromes have been identified. Among the earliest of these to be described is Lynch syndrome (also called hereditary non-polyposis colorectal cancer, or HPNCC), which was first documented in the literature by Aldred Scott Warthin in 1913. Lynch syndrome is an autosomal dominant disorder characterized by inheritance of susceptibility to develop early onset cancers relative to sporadic cancers of the same type. Colorectal and endometrial cancers are the most common type of cancer associated with Lynch syndrome, other cancers are also associated with Lynch syndrome including ovarian, stomach, urological tract, small bowel, and hepatobiliary system and pancreatic, breast, prostate, brain (usually glioblastoma) and adrenocortical cancers have also been reported. At least two variants of Lynch syndrome have been reported. Muir–Torre syndrome is a variant of Lynch syndrome that is characterized by the presence of sebaceous neoplasms and/or keratoacanthomas in conjunction with the other cancers associated with Lynch syndrome. Turcot syndrome is characterized by an association between colorectal cancer and brain tumors and is due to either Lynch syndrome or familial adenomatous polyposis.

Linkage studies originally mapped Lynch syndrome to two loci, one on chromosome 2p and a second on chromosome 3p. The tumors from the patients analyzed in these studies showed an unusual phenotype—striking instability of mononucleotide and dinucleotide repeat sequences due to the accumulation of frameshift mutations in these sequences that are ubiquitous in the human genome, often referred to as microsatellite instability high or MSI-H. This phenotype was known to be caused by MMR deficiency in *E. coli* and *S. cerevisiae* and led to the initial demonstration that Lynch syndrome is caused by inherited heterozygous mutations in the MMR genes *MSH2* and *MLH1*. While *MSH2* and *MLH1* mutations are the most common cause of Lynch syndrome, candidate gene studies demonstrated that mutations in *PMS2* and *MSH6* are also present in Lynch syndrome, but at lower frequencies. Carriers of heterozygous *PMS2* mutations tend to have a milder phenotype relative to *MSH2* or *MLH1* carriers, including a lower frequency and later onset of cancer whereas carriers of heterozygous *MSH6* mutations often have a predominance of endometrial cancer. Convincing evidence for mutations in other MMR genes in Lynch syndrome is lacking. *MSH2* or *MLH1* are the only MMR genes in which mutations completely eliminate MMR, providing an explanation for the high prevalence of *MSH2* or *MLH1* defects in Lynch syndrome. In contrast, *MSH6* is partially redundant with *MSH3* and *PMS2* is partially redundant with *MLH3*, and hence defects in *MSH6* and *PMS2* cause partial MMR defects providing a possible explanation for their lower prevalence in Lynch syndrome.

Lynch syndrome was originally diagnosed using clinical criteria but is now diagnosed using both clinical criteria and molecular diagnostics, with the results from molecular diagnostics studies leading to a broadening of the clinical definition of Lynch

syndrome. There are presently three clinical criteria for Lynch syndrome, the Amsterdam criteria, the Amsterdam II criteria, and the Bethesda criteria (Table 2). The Amsterdam criteria primarily focused on a family history of colorectal cancer along with age of diagnosis. The Amsterdam II criteria, sometimes called the "Modified Amsterdam Criteria" included Lynch syndrome-associated cancers and tumor pathology in addition to colorectal cancer in the criteria for diagnosis of Lynch syndrome. Finally, the Bethesda criteria allowed for inclusion of smaller pedigrees, different Lynch syndrome-associated cancers, early age of diagnosis, multiple tumors and the presence of microsatellite instability in colorectal cancer resulting in a broader clinical definition of Lynch syndrome. The broader the definition of Lynch syndrome used, the more likely patients with MMR defects will be identified, but larger numbers of patients without MMR defects will be included in the cases identified.

Modern molecular and genetic testing methods have augmented and to some extent replaced clinical criteria for diagnosing Lynch syndrome. Testing of tumors from individuals suspected to have Lynch syndrome for MSI-H using accepted microsatellite markers and testing for loss of expression of MSH2, MSH6, MLH1 or PMS2 using immunohistochemistry (IHC) can effectively identify patents with candidate MMR defects; these approaches are often used to initially screen patients for potential MMR defects. It should be noted that *MSH6* defects can result in a less striking MSI-H phenotype with greater mononucleotide repeat instability than dinucleotide repeat instability compared to that caused by *MSH2*, *MLH1* or *PMS2* defects due to the redundancy between *MSH6* and *MSH3*. If abnormalities, such as loss of expression of an MMR gene or MSI-H, are observed or no data from tumor analysis is available for a suspected Lynch syndrome patient, then genetic testing for germline alterations focusing on the relevant genes is recommended. Genetic testing for *MSH2*, *MSH6*, *MLH1* or *PMS2* defects involves complete gene sequencing and analysis for the presence of deletion mutations and genome rearrangements affecting these genes and can also involve testing for *EPCAM* gene deletions that result in silencing of MSH2 expression and *MLH1* epimutations that result in silencing of MLH1 expression. Identification of a defect in an MMR gene constitutes a positive diagnosis of Lynch syndrome.

Biallelic Mismatch Repair Deficiency Syndrome (BMMR-D)

BMMR-D, also called constitutional MMR deficiency (CMMR-D), is a rare cancer susceptibility syndrome characterized by tumors of the gastrointestinal tract, skin lesions, brain tumors, leukemias and lymphomas, and rarely endometrial cancers usually occurring within the first two decades of life. BMMR-D is often connected to consanguinity, with over 50% of known cases coming from consanguineous families. Additionally, patients do not always have a family history of Lynch syndrome-like cancers. BMMR-D

Table 2 Clinical criteria for diagnosing Lynch syndrome

*Amsterdam I criteria**

A positive diagnosis of Lynch syndrome requires at least three relatives with colorectal cancer (CRC) and the presence of the following five criteria:

1. One relative must be a first degree relative of the other two
2. CRC must be present in two successive generations
3. One case of CRC must have been diagnosed when the patient was <50 years old
4. Familial adenomatous polyposis (FAP) has been eliminated as a possibility
5. Pathological examination has verified the tumors

*Amsterdam II criteria**

A positive diagnosis of Lynch syndrome requires at least three relatives diagnosed with a Lynch syndrome associated cancer (CRC, cancer of the endometrium, small bowel, ureter, brain, hepatobiliary tract, skin, stomach, or renal pelvis) and the presence of the following criteria:

1. One relative must be a first degree relative of the other two
2. Cancer must be present in two successive generations
3. One case of Lynch syndrome associated cancer must have been diagnosed when the patient was <50 years old
4. FAP has been eliminated as a possibility
5. Pathological examination has verified the tumors

*Revised Bethesda Guidelines for testing colorectal tumors for microsatellite instability (MSI)***

Because MSI-H is a hallmark of MMR deficient tumors, the Bethesda Guidelines suggest tumors from patients with suspected Lynch syndrome should be tested for MSI in the following situations:

1. If the patient is diagnosed with CRC at <50 years old
2. If the patient has synchronous, metachronous CRC, or other Lynch syndrome associated tumors at any age
3. If a patient of <60 years of age is diagnosed with CRC with MSI-H histology
4. If at least one first-degree relative is diagnosed with CRC or a Lynch syndrome related tumor at <50 years old
5. If at least two first- or second-degree relatives are diagnosed with CRC or a Lynch syndrome related tumor at any age

Information in this table was adapted from the following publications:

*Vasen, H. F. A., Watson, P., Mecklin, J-P., and Lynch, H. T. and the ICG-HNPCC. New Clinical Criteria for Hereditary Nonpolyposis Colorectal Cancer (HNPCC, Lynch Syndrome) Proposed by the International Collaborative Group on HNPCC. *Gastroenterology.* 116:1453–1456 (1999).

**Umar, A. et al. Revised Bethesda Guidelines for Hereditary Nonpolyposis Colorectal Cancer (Lynch Syndrome) and Microsatellite Instability. *J. Natl Cancer Inst.* 96: 261–268 (2004).

is caused by inheritance of two defective alleles of *MSH2* or *MLH1*, or more rarely, *PMS2*, and a small number of cases have been found to have homozygous *MSH6* defects. Genetic testing for BMMR-D generally follows the strategy used for Lynch syndrome; however, unlike Lynch syndrome, tumors of BMMR-D patients often do not present with MSI-H and consequently MSI-H is not a reliable method of diagnosing BMMR-D.

Sporadic Cancer

A variable fraction of many different types of sporadic cancers including some inflammation-associated colon cancers have MSI-H suggestive of an MMR defect; however, sequencing of MMR genes from these tumors rarely identified MMR gene defects. Biallelic *MLH1* promoter methylation and subsequent silencing of *MLH1* expression is recognized as the mechanism for inactivation of MMR in the majority of these sporadic MSI-H tumors. Approximately 20% of sporadic colorectal cancer is MSI-H and has *MLH1* promoter methylation, and *MLH1* promoter methylation is the primary cause of sporadic MSI-H endometrial cancers as well as other MSI-H sporadic cancers. Sporadic cancers with epigenetic silencing of *MLH1* are also frequently associated with activating mutations in the *BRAF* gene, which encodes a serine/threonine protein kinase in the mitogen-activated protein kinase (MAPK) pathway; *BRAF* is far less frequently mutated in Lynch syndrome. Why there is a relationship between the genetic and epigenetic alterations in these tumors is currently not understood. Analysis of sporadic cancers for MMR defects involves testing tumors for MSI-H and loss of expression of MMR genes by IHC followed by testing for *MLH1* promoter hypermethylation in those cases where there is loss of MLH1 or PMS2 expression; note that loss of MLH1 expression usually results in coordinate loss of expression of its partner protein, PMS2.

Causes and Treatment of MMR-Defective Cancers

Mutation of *MSH2* or *MLH1* or epigenetic silencing by hypermethylation of the *MLH1* promoter are the most common causes of total MMR defects, while mutation of *MSH6* causes an incomplete defect in MMR due to the partial redundancy of the MSH2-MSH6 and MSH2-MSH3 complexes. Regardless of the exact inherited defect present, it is clear that Lynch syndrome and other MMR related cancer predisposition syndromes result from loss of function mutations that cause partial or total defects in MMR and that early in the development of the cancer, the wild-type allele of the MMR gene in question is also lost, resulting in an MMR defect. Sporadic cancers that are MMR defective are also driven by early loss of MMR, primarily due to biallelic methylation, and hence silencing, of the *MLH1* promoter. Loss of MMR or reduction of MMR efficiency increases the rate of accumulating mutations in MMR-defective cells. This mutator phenotype increases the probability of the cells accumulating mutations that inactivate tumor suppressor genes or activate proto-oncogenes, which would then increase the rate of tumorigenesis. Tumorigenesis is well-known to be driven by the accumulation of mutations that inactivate tumor suppressor genes or activate proto-oncogenes, although due to the unique signature of mutations that arise due to MMR defects (e.g., high rates of frameshift mutations), the spectrum of defects in proto-oncogenes and tumor suppressor genes differs between MMR defective cancers and MMR proficient cancers of the same tissue types.

MMR defects can also cause resistance to chemotherapeutic drugs. For example, the standard treatment of colon cancer with fluorouracil-based compounds is less effective in MMR-defective tumors. Another example is that MMR-deficient malignant gliomas become resistant to the DNA methylating agent temozolomide. In the case of DNA damaging agents like temozolomide and possibly agents like fluorouracil that are incorporated into DNA, MMR can act on the damaged DNA, which contains lesions such as O^6-methylguanine-thymine mispairs, and induce apoptosis, or programmed cell death, in response to the drug. How MMR induces apoptosis is not clear; current hypotheses suggest that the MMR machinery either provides a direct signal for apoptosis or mediates a futile cycle of repair, which indirectly triggers apoptosis. Regardless, in the absence of MMR, this apoptotic response is defective, resulting in a reduced response to chemotherapeutic drugs. It is also possible that this reduced apoptotic response under conditions of normal cell growth may also contribute to the development of cancer, although studies in mutant mice have shown that this is not the major driver of the development of MMR-defective cancers.

Of critical importance is the development of effective treatments for MMR defective cancers. Some studies suggest that MMR defective colorectal cancers may be more sensitive to irinotecan and that MMR defective cells may be more sensitive to oxidative damage to DNA when the major pathways for oxidative DNA damage repair have been inhibited. Strikingly, MMR defective cancers appear to be highly responsive to immunotherapy, and MMR defects may provide a biomarker for responsiveness to immunotherapy. The FDA recently approved pembrolizumab, which is an antibody that inhibits the PD-1 immune checkpoint, for use against MSI-H or MMR deficient tumors. Pembrolizumab appears to work by allowing T cells in the adaptive immune system to recognize and eliminate cancer cells expressing neoantigens that arise in MMR-defective tumors due to the increased mutational burden of these tumors. Remarkably, the approval of pembrolizumab for MSI-H tumors is the first time a drug has been approved against a biomarker rather than against tumors derived from a specific tissue.

Summary

MMR is a conserved pathway that repairs base–base mismatches and small insertion/deletions caused by misincorporation errors during DNA replication. The MMR pathway works through mispair detection by the partially redundant complexes MSH2-MSH6 and MSH2-MSH3, followed by recruitment of downstream proteins that excise the error-containing DNA strand and resynthesize it

correctly. Two sub-pathways of MMR exist: the EXO1-dependent pathway that relies on DNA excision by EXO1, and a less well characterized EXO1-independent pathway. Defects in MMR lead to greatly elevated mutation rates that in turn can drive carcinogenesis. Lynch syndrome is a common hereditary cancer predisposition syndrome caused by heterozygous MMR defects that is most often characterized by early onset colorectal cancers and many other types of cancer. Another, rarer, cancer predisposition syndrome, BMMR-D is caused by homozygous MMR defects and results in a number of types of early onset cancers. The most common causes of these syndromes defects in *MSH2* or *MLH1*, both of which cause total MMR defects; less common causes are defects in *MSH6* and *PMS2*. MMR defective sporadic cancers of many types have also been characterized and are primarily due to silencing of the *MLH1* gene. The increased mutation rate caused by defective MMR increases the probability of inactivating mutations in tumor suppressor or proto-oncogenes, leading to increased development of cancer. Identifying MMR defects in patients has important implications for cancer surveillance in affected families and for cancer treatment, both in terms of avoiding drugs that MMR defective tumors are resistant to and using new treatments that may effectively target MMR defective tumors.

Glossary

Advance care planning Ongoing process of information exchange between health care providers and patients that enables individuals to make plans about their future health care consistent with their values, beliefs, and goals.
Advance directive An advance directive, ideally in the form of a legal document, provides specific direction to health care professionals about what actions to take when a person is no longer able to make and/or communicate their own health care choices.
Hospice care A philosophy of care that focuses on the relief suffering in all of its domains and supports for terminally ill patients and their loved ones.
Medical order for life sustaining therapy Used to issue a nonhospital DNR (do not resuscitate) and DNI (do not intubate) order, and must be honored by emergency medical services personnel, home care services personnel, hospice personnel, and hospital emergency services personnel. Physicians may also use the form for any patient in any setting to issue any orders for life-sustaining treatment.
Palliative care Approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems.

Introduction

Despite treatment advances, for many cancer is a lethal disease. Ensuring that patients and families have high-quality end of life care is integral to good cancer care. Communication about end of life preferences as well as high-quality symptom management, both physical and psychosocial, allows for the best quality of life through end of life. A palliative care team and/or a hospice team can provide expertise in assessing goals and ensuring appropriate symptom management at the end of life. Additional special topic areas that impact patients and families at the end of life include decisions regarding fluid and nutrition, and in some cases discussions around physician aid in dying (PAD), and palliative sedation.

Communication About Prognosis and End of Life Preferences

A life-limiting cancer diagnosis has a tremendous impact on both a patient and their family. As patients approach end of life they are often thinking through what is most important to them and planning forward with the time that they have remaining. A review of prognosis, a discussion of end of life preferences and documentation, and review of key medical and legal documents can help ensure that patients are receiving care that is in alignment with their wishes.

A Conversation About End of Life and Advance Care Planning

Advance care planning is the ongoing communication process by which patients make decisions about future health care needs. A diagnosis of cancer can expedite the need for advance care planning, as well as end of life discussions with medical providers. However, only in a minority of cases, do oncologists have these discussions early in a patient's clinical course. As a result, families have limited information to plan for end of life care and often receive intensive care (such as chemotherapy, hospitalizations, and intensive care admissions) at the end of life. Research demonstrates that early conversations regarding prognosis, goals, and end of life preferences improve the likelihood that patients and their families will receive high-quality end of life care.

The ideal setting for conversations around goals of care and end of life is in the ambulatory setting. This allows for a multidisciplinary approach and provides access to psychosocial and palliative care resources well in advance of an acute change or unexpected deterioration when patients may no longer have capacity to be involved in their own medical decisions. Susan Block, MD, a palliative care physician, has presented a simple framework for eliciting goals of care and end of life preferences. She asks four questions.

"Do you understand your prognosis? What are your fears about what is to come? What are your goals as time runs out? What trade-offs are you willing to make?"

These prompts can be a springboard for physicians to start difficult end of life conversations with their patients.

"Do you understand your prognosis?": **it** allows physicians to ascertain whether patients understand how much time they may have. While there is always uncertainty that underlies prognosis, physicians can provide data within a range that can increase accuracy and provide a framework for patients to consider their future. For example, physicians can frame time remaining as "years," "months to years," "weeks to months," "days to weeks" or "hours to days." The use of a range, rather than a specific amount of time, allows for uncertainty to coexist with information that can be helpful for patients and families to plan forward. It also allows for physicians to admit that they too do not know for sure, but can provide the best information within the scope of their medical knowledge. Prognosis is becoming even less clear with the advent of new therapies including immunotherapy and targeted agents that may improve prognosis dramatically, even when patients are clinically doing poorly and appear to be close to the end of life. With this in mind, a frequent dialogue, especially with each treatment change, can be helpful for both patient and provider. As patients move closer to the end of life, physicians can use physical cues and symptoms to help increase their prognostic accuracy. Common physical signs that end of life is approaching include increased fatigue leading to more time in bed, decreased appetite, progressive muscle wasting, and eventually decreased consciousness (**Table 1**).

"What are your fears about what is to come?" While many believe that a diagnosis of cancer immediately conjures up images of death and dying, what often troubles patients and families more than the prospect of death is suffering associated with end of life. Studies have shown that patients worry about symptoms at the end of life, such as pain and nausea. Additionally, they often have social concerns including how their loved ones will cope, whether they will be a burden to their families over time, and how finances will be managed. Finally, most confront spiritual questions around meaning and hope. An open-ended question around fears and worries can allow for meaningful discussions that will both guide medical treatment, lead to appropriate psychosocial and/or spiritual support, and provide the patient and family essential reassurance. A recent patient's most troubling fear was not his own illness, but concern about what would become of his wife, suffering from end-stage dementia, when he passed away. Early discussions with family that included planning for his wife's future provided the patient great relief and allowed him to face the dying process peacefully.

"What are your goals as time runs out?": Dr. Paul Kalanithi, a neurosurgeon who recently passed away due to metastatic cancer, wrote "The path forward would seem obvious if only I knew how many months or years I had left. Tell me three months, I'd just spend time with my family. Tell me one year, I'd have a plan (write that book). Give me 10 years, I'd get back to treating diseases." Goals change with a change in prognosis. While there is uncertainty in these discussions, asking this question supports a shared dialogue on what are the most pressing and important goals in the setting of limited time. Keeping these goals front and center helps ensure that treatment recommendations take into consideration and allow patients to do what is most important to them.

"What tradeoffs are you willing to make?": Ideally, treatment provides patients with more time and good quality of life. However, as illness progresses, this balance frequently shifts and treatment may prolong time at the cost of adverse effects on quality of life. Finally, there is a time point when treatment has little or no benefit with regard to time or quality of life. Early and continued discussions on potential trade-offs between treatment, survival and quality of life help physicians make treatment recommendations that are consistent with a patient and family's values and goals. One example is a gentleman in clinic whose main hobby was building model trains. This was a source of great joy for him, which he shared with his friends and grandchildren. When discussing treatment options, it became quite clear that any treatment with a significant risk of neuropathy posed an unacceptable risk to his quality of life. For him, it was important to continue building trains, even if that meant a decrease in longevity.

An essential conversation that incorporates these four questions provides guidance for patients, families, and medical teams and allows patients to focus on what is most important to them with the time they have remaining.

Advance Directives and Medical Order for Life-Sustaining Treatment

The process of advance care planning, through ongoing conversations between family and medical providers, is a critical building block to inform documents detailing medical interventions desired by the patient approaching end of life. These forms often

Table 1 Common symptoms at end of life

Prognosis	*Symptoms*
Weeks to months	Anorexia, fatigue, withdrawal from loved ones, muscle wasting, increasing time in bed
Days to weeks	Increased fatigue, confusion, restlessness, congestion, increased anorexia, hallucinations, secretions, variation in blood pressure, heart rate and respiratory rate, decreased urinary output
Hours to days	Irregular breathing, increased restlessness, cool blotchy extremities, weak pulse, decreased urine output, increased secretions
Minutes to hours	Gasping breathing, no awakening

include a legal document called an advance directive and a medical form that details choices around life-sustaining treatments (sometimes called a POLST (physician order for life-sustaining treatment) or a MOST (medical order for scope of treatment)).

Advance directives are a legal document that details how patients would want to be cared for if they are in a life-limiting situation and unable to convey their wishes. For example, patients may designate whether they would want life-prolonging interventions such as intubation or cardiopulmonary resuscitation. Patients can also designate a health care surrogate, a person who would make decisions on their behalf if the patient is no longer able to communicate. Advance care planning has been shown to decrease intensive care at the end of life and improve hospice utilization. It is important to note that the advance directive is a legal document and not a medical order. Medical personnel, for example, cannot follow the advance directive in the field.

A medical order for life-sustaining treatment known as either a POLST, MOLST (Medical/Physician Orders for Life Sustaining Treatment) or a MOST (Medical Orders for Scope of Treatment) specifies treatments that a patient would or would not want if he/she were to become seriously ill. Medical personnel must follow these orders. A medical order for life-sustaining treatment should be completed by patients who have made clear decisions about life-sustaining interventions and who have a serious illness that may lead to death within the subsequent year.

Each country has different legal and medical requirements regarding documentation of patient and family wishes at the end of life. The advance directive and the medical order for life-sustaining treatment are two common examples. The most crucial component is the conversation that occurs between family members and the medical team. Subsequent documentation can help to make this information available for others through the medical and legal record.

Symptoms at the End of Life

Physical symptoms commonly associated with advanced illness at the end of life include pain, dyspnea, delirium, secretions, and constipation. Patients may also struggle with psychological symptoms, most notably, anxiety, and depression. When possible clinicians can rely on patient history for symptoms at the end of life. However, as consciousness wanes, nonverbal cues are crucial to assessing symptoms. **Table 1** describes common physical symptoms and signs at the end of life. Optimal palliative or hospice care at the end of life focuses on relief of both physical and psychological symptoms.

Pain

Pain is a common and feared symptom at the end of life with a prevalence of 40%–50%. With this in mind, it is important to do regular assessments of pain. A numerical scale from 0 to 10 can be used to rate pain with a score of zero connoting no pain, and of 10 connoting severe pain. If patients are no longer verbal, using nonverbal cues (such as facial grimace, moaning, and restlessness) can provide cues that patients are in pain. Tylenol or antiinflammatories can be used to treat low levels of pain (0–3); can be given orally if the patient is able to swallow or rectally, if not. For moderate to severe pain, opioids and nonopioids in combination or opioids alone are recommended at the dose that adequately controls the pain. Specific considerations for the selection of analgesics, the route of administration, and drug dose and interval at the end of life include the patient's ability to swallow, body mass distribution, and organ dysfunction.

At the end of life, patients are often no longer able to swallow. Oral opioids at equianalgesic doses can be delivered via the transdermal, sublingual, buccal, rectal, subcutaneous, or intravenous route. Long-acting medications may be converted to equianalgesic doses that are delivered via a transdermal route or rectally. While these medications can also be converted to equianalgesic doses intravenously or subcutaneously, the least invasive and simplest means of delivery is preferred. Short-acting opioids may be converted to a concentrated liquid solution. For patients who have an enteral feeding tube, pain medications may be delivered via this route. However, it is important to note that long-acting opioids should never be crushed for administration via a feeding tube, as the total dose will be delivered rapidly (as if short acting). Finally, compounding pharmacies can make opioid suppositories or enemas. In the hospice setting, the subcutaneous route is frequently utilized to deliver concentrated doses of medications in low volumes (2–3 mL/h) when noninvasive options are not possible or inadequate for the needed total dose. See **Table 2** for common formulations and routes of opioids. As patients develop greater muscle wasting and weight loss, they may be less able to absorb medications that require fat for absorption (e.g., fentanyl). Additionally, as patients near end of life, kidney and liver function decline. Based on the metabolism of the prescribed analgesics, discontinuation of long-acting medications is recommended to avoid an unanticipated increase in blood drug concentration. Short-acting opioids, prescribed as needed, are safer as it is difficult to determine the correct dose and drug interval when metabolic function is actively declining. This approach requires continued evaluation of pain but is less likely to cause side effects such as sedation and delirium due to accumulation of opioid metabolites.

Adjuvant analgesics may also require rotation as patients decline. Patients who have a significant neuropathic component to their pain may benefit from rotation to methadone due to its effect on the *N*-methyl-D-aspartate (NMDA) receptor, a receptor that modulates neuropathic pain. Patients receiving antiinflammatory agents as a component of their pain regimen may need to be switched to a steroid such as dexamethasone. Steroids, while not recommended for long-term use due to side effects (proximal muscle wasting, mood disorders, abdominal pain, etc.), are potent antiinflammatory agents and helpful for short-term use. Dexamethasone can be given as a single daily dose once steady-state plasma levels are achieved, easier than the twice daily or three times

Table 2 Opioid equianalgesic doses and formulations

Medication	*Equianalgesic dosing Oral administration(PO)/Intravenous (IV)*	*Available formulations and direction*
		Short acting/long acting
Morphine	30 mg PO/10 mg IV	Oral, buccal, sublingual, rectal, intranasal, intravenous, intrathecal, epidural
		Short acting/long acting
Oxycodone	20 mg PO/not available	Oral
		Short acting
Hydromorphone	7.5 mg PO/1.5 mg IV	Oral, intravenous, rectal, subcutaneous, epidural, intrathecal
		Short acting and long acting
		Short acting—oral trans mucosal, nasal, and buccal
Fentanyl	Varies/50–100 μg IV	Long acting—transdermal
		Short acting
Tramadol	50–100 mg PO/not available	Oral
		Short acting/long acting
Oxymorphone	10 mg PO/1 mg IV	Oral, suppository, intravenous

Table 3 Common adjuvant medications for pain control and starting doses

Medication	*Indication*	*Starting doses/routes*
Acetaminophen and anti-inflammatories	Acetaminophen	4000 mg in 24 h (PO or IV)
Indications—bone pain, inflammation	Ibuprofen	2400 mg in 24 h (PO)
	Naproxen	1000 mg in 24 h (PO)
	Indomethacin	75–150 mg in 24 h (PO)
	Celecoxib	300 mg in 24 h (PO)
	Ketorolac	30–60 mg IV then 15–30 mg IV every 6 h
Bisphosphonates	Pamidronate	60–90 mg IV every 1–2 months
Indication—bone pain	Zoledronic acid	4 mg IV every 1–2 months
Antidepressants	Nortriptyline	10–25 mg daily (oral)
Indication—neuropathic pain	Desipramine	10–25 mg daily (oral)
	Venlafaxine	75 mg (oral)
	Duloxetine	30 mg (oral)
Antiepileptics	Gabapentin	100 mg three times daily (oral)
Indication—neuropathic pain	Pregabalin	50 mg three times daily (oral)

a day dosing of most oral nonsteroidal antiinflammatory agents. Table 3 provides a list of common adjuvant analgesics used for pain as well as the common indications for their use.

Continued pain assessment is essential to ensure patients have adequate pain relief. A palliative care team and/or hospice team is a helpful resource for making decisions about needed interventions for symptom control and for recommendations regarding which medications require adjustment or discontinuation as patients come closer to the end of life.

Nonpharmacologic approaches to pain include physical techniques such as physical therapy, assist devices, and massage. Physical therapists are helpful in deciding which techniques may be most beneficial based on the patient's clinical status and cognitive function. Additionally, for patients who are still alert and responsive, cognitive behavioral interventions such as breathing exercises, mindfulness, and spiritual practices may contribute to pain control. Finally, complementary approaches such as acupuncture, reiki, homeopathic, or ayurvedic treatments can be quite useful for the treatment of cancer pain. A thoughtful patient and family history may identify nonpharmacologic approaches that have previously been useful to the patient for symptom control. Reminding families of these techniques can empower families to help care for their loved ones.

Dyspnea

Dyspnea is described as the feeling of difficulty or distressed breathing, of "air hunger." Up to 70% of patients with cancer experience dyspnea at the end of life. Dyspnea is a subjective experience and may occur in the absence of pulmonary findings or objective changes in oxygenation or respiratory rate. The evaluation of dyspnea for patients with advanced cancer begins with a discussion about prognosis and the patient's desire to undergo evaluation for potential reversible causes. For the patient who has a prognosis of months and is out of bed close to 50% of the time (WHO Performance Status of 2–3) assessment for, and treatment of, potentially reversible causes of dyspnea is reasonable if consistent with the patient's goals. Common causes of dyspnea include bronchospasm, hypoxia, and anemia. Treating the underlying cause in this situation is appropriate via inhalers, oxygen, or transfusions. However, as

patients decline further, the burden of evaluation and treatment may be unacceptable. In addition, the underlying etiology of the dyspnea may no longer be reversible. In this case, the backbone of treatment is opioids. Opioids may decrease the feeling of air hunger by decreasing the ventilatory response to hypercapnia, through a decrease in preload and pulmonary congestion secondary to opioid-related vasodilation, a change in central perceptions or by decreasing opioid-related anxiety. The exact mechanism is unknown. The initial dose of opioids for the treatment of dyspnea is lower than that used for treating pain. An initial dose of just 1–2 mg of intravenous morphine or 5 mg of oral morphine may improve symptoms. Inhaled opioids (e.g., using a nebulized solution) have been evaluated for treatment of dyspnea, with mixed results. Much like for pain, a continuous symptom requires around the clock medication. Opioids may be delivered as an intravenous infusion or orally, depending on the patient's overall status and site of care. When dyspnea is accompanied by anxiety, the addition of benzodiazepines may further decrease the sensation of shortness of breath. Although oxygen is frequently prescribed for dyspnea, oxygen is only of use if hypoxia is a major contributor to the dyspnea. Nonpharmacologic treatments include relaxation, breathing training, facial cooling (via a fan), changes in position, and a decrease in ambient temperature.

Delirium

Delirium is a disturbance in consciousness that may occur suddenly or over hours to days and is characterized by cognitive dysfunction, emotional disturbances, and disorganized behavior. Symptoms tend to wax and wane and are often most severe at night and in settings unfamiliar to the patient. There are three types of delirium: hyperactive, hypoactive, and mixed. The hyperactive type is generally the easiest to recognize as patients present with agitation and restlessness and may experience rapid mood changes and hallucinations. Hypoactive delirium is underrecognized, especially in patients with advanced illness. The primary symptoms of this type of delirium, drowsiness, lethargy, and decreased engagement with the environment, may be misconstrued as progressive decline from the underlying cancer. Mixed delirium has symptoms of both of the prior types and the symptoms may fluctuate rapidly. Delirium occurs in up to 80% of patients at the end of life and may be reversible. Potential causes of delirium include hypoxia, infection, fever, uncontrolled pain, organ dysfunction, brain metastases, medication changes, constipation, urinary retention, or dehydration. Much like many symptoms in patients with advanced illness, the first consideration is determination of the balance between the burden of assessment to identify the underlying cause and its treatment and the patient's prognosis. Reversible causes should be evaluated and treated as appropriate for the patient's goals. A reversible cause is not always identified even when a work-up is undertaken.

Terminal delirium, or terminal restlessness, is a hyperactive delirium that occurs in some dying patients. It is sometimes called the "difficult road to death" and is generally associated with a prognosis of hours to days. Terminal delirium is an exceedingly distressing experience for families. Like all delirium, symptoms are managed aggressively to promote patient and family comfort. Family members caring for a patient with delirium have an increased risk of anxiety. However, education of family members on how to best care for their loved one, as well as continued emotional support via hospice, palliative care, and other professional caregivers can mitigate the negative effects of delirium on both patients and their loved ones.

Pharmacologic interventions for delirium include antipsychotic agents such as haloperidol, olanzapine, and quetiapine. Benzodiazepines, such as lorazepam, are not front-line therapy, because they may lead to paradoxical increase in agitation, especially in the elderly. However, they can be used with caution in conjunction with antipsychotic agents, when sedation is warranted and in the setting of irreversible delirium which may be more resistant to standard therapy (Table 4). Nonpharmacologic interventions include reorientation to the environment, reduction in stimulating factors, and improving sleep.

Constipation and Bowel Management

Constipation, a common symptom at the end of life, has a prevalence of 40%–80% and is a source of patient and family suffering. Causes of constipation are pharmacologic, metabolic, neurologic, and structural (Table 5). Additionally, decreased physical activity and changes in diet at the end of life frequently exacerbate constipation.

Table 4 Medications to manage delirium-titrate dose to effect

Typical antipsychotics	*Starting dose*	*Routes*
Haloperidol	0.5–2 mg every 2–12 h	PO, IV, SC
Chlorpromazine	12.5–50 mg every 4–6 h	PO, IV, SC, PR
Atypical antipsychotics		
Respiradone	0.5 mg daily	PO
Olanzapine	2.5–5 mg daily	PO
Seroquel	25 mg daily	PO
Anxiolytics/sedatives		
Lorazepam	0.5–2 mg q 4 h	IV, PO, SL, PR
Midazolam	0.5–1 mg/h	IV
Propofol	10 mg bolus ➔ 10 mg/h	IV

Table 5 Common causes for constipation at the end of life

Pharmacologic	Antacids, antiepileptics, cancer chemotherapeutic drugs, anticholinergics, antiparkinsonian, antidepressants, diuretics, opioids, neuroleptics, antitussives
Metabolic	Dehydration, hypercalcemia, diabetes, hypokalemia, uremia, hypothyroidism
Neurologic	Cerebral tumors, spinal cord or nerve involvement
Structural	Tumor mass, strictures, painful ano-rectal conditions
Functional and diet	Decreased oral intake, inactivity, sedation

Table 6 Approach to treatment of constipation

First line treatment ➔ combination of a softener (polyethylene glycol, or lactulose) and a stimulant (senna)
↓
No improvement in symptoms ➔ rectal suppository and enema, consider a peripheral acting opioid antagonist (in patients who are taking opioids) such as methylnaltrexone
↓
No improvement in symptoms ➔ manual evacuation, consider further diagnostic evaluation, discussion of goals of treatment

For patients who are taking in fluids and/or solids, an evaluation of constipation begins with a detailed history of the patient's oral intake and diet, bowel habits, recent medication changes, and other new symptoms. The physical examination can readily rule out fecal impaction and can provide clues to other potential causes including spinal cord compression or malignant bowel obstruction, for example. For patients who are still passing bowel movements, but less frequently or with greater difficulty because of hard stool, combining a stool softener with a motility agent is most effective. Use of a combination of agents is important in the end of life setting, since many of these patients do not have normal bowel contractility either due to physical inactivity or from side effects of medications. As a result, a stool softener alone may not enable patients to expel the stool. Ducosate is one widely available stool softener. Laxatives are categorized by their mechanism of action as lubricants (e.g., mineral oil), hyperosmotic agents (e.g., polyethylene glycol and magnesium citrate), or stimulants (senna and dulcolax). Specifically for opioid-induced constipation, peripheral opioid antagonists such as methylnaltrexone may be effective in relieving constipation but are expensive and require subcutaneous administration (Table 6).

As for most symptoms, prevention is generally easier than treatment. A daily oral regimen of stool softeners, with or without a stimulant, is sufficient to prevent constipation. However, if constipation is refractory to an escalating oral regimen, the addition of agents by rectum (suppository or enema) is indicated. Enemas introduce fluid into the rectum and intestine and stimulate a bowel movement via this mechanism. Suppositories may produce their effect as hyperosmotic agents, increasing intraluminal water and softening stool or as a stimulant.

Secretions

In the last hours of life, patients may develop noisy, and gurgling respirations; commonly known as the "death rattle." This "rattle" occurs due to the patient's inability to expectorate or swallow secretions. The "rattle" results from the air passing through the secretions pool with respirations. This is a symptom that is associated with a very short survival, generally hours to days. While these audible respirations are not thought to cause distress or discomfort for patients, the sounds are frequently disturbing for family members and caregivers. Initial treatment is nonpharmacologic and includes repositioning and decreasing fluid intake (if being delivered intravenously). Occasionally, oropharyngeal suctioning is attempted, but is not likely to be effective, since the secretions are usually much deeper than can be reached by the suctioning device. The backbone of pharmacologic interventions is anticholinergic agents, such as hyoscine, atropine, scopolamine, and glycopyrrolate. There is limited data to support one agent over the other, though it appears that earlier intervention results in better outcome regardless of which of these agents is initiated. Glycopyrrolate is often preferred in patients who are conscious since it does not cross into the central nervous system. Medications can be given via multiple routes: transdermal (e.g., a scopolamine patch), sublingual/oral (e.g., atropine), or as an IV infusion. Scopolamine often takes 4–8 h to work, supporting the need to initiate treatment as soon as symptoms begin.

It is often difficult to control secretions at the end of life. Most often, patients who develop audible secretions are no longer conscious and are unlikely to be distressed. Families benefit from support, education, and reassurance that their loved one is not likely suffering.

Psychological Symptoms

Depression and Anxiety

The prevalence of depression at the end of life is between 25% and 75%. Risk factors for depression include a prior history of depression, prior suicide attempts, social stresses, family history of depression, as well as poorly controlled symptoms. Depression causes

suffering, reduces quality of life, impairs the ability to find meaning, and may shorten survival. Patients at the end of life can be screened for depression with a simple screening tool. The PHQ-2 instrument for depression screening asks the following questions: over the past 2 weeks, how often have you been bothered by any of the following?

1. Little interest or pleasure in doing things.
2. Feeling down depressed or hopeless.

This tool has a sensitivity of 91% and a specificity of 86% based on the studies of patients with cancer receiving palliative care. For patients who are depressed it is important to screen for suicide. Asking the question, "Are you having suicidal thoughts?" is a good starting point and is an entry for asking more detailed questions regarding plan and intent. Treatment of depression includes pharmacologic and nonpharmacologic approaches. Pharmacologic approaches are diverse and can include selective serotonin reuptake inhibitors (SSRIs), serotonin, norepinephrine reuptake inhibitors, tricyclic antidepressants, or stimulants. The choice of medication should be based on prognosis and comorbid conditions. Many of the first-line antidepressants, such as the SSRIs, take 4–6 weeks to be effective and are only be useful for patients with a relatively long prognosis. For those patients closer to the end of life, a low-dose stimulant such as methylphenidate or modafinil may be appropriate for hypoactive symptoms. For patients with agitated depression, a neuroleptic such as risperidone may be a good choice. An option for patients with sleep difficulties or weight loss is mirtazapine, which has a relatively short time to efficacy and may also improve sleep and stimulate weight gain. Tricyclic antidepressants may be a good option for patients with pain and depression (**Table 7**).

Anxiety is quite common at the end of life and can affect patients both physically and psychologically. It can present as agitation, restlessness, insomnia, hyperventilation, or panic disorder. Management of anxiety at the end of life is primarily through the use of benzodiazepines. Short-acting drugs, such as alprazolam, are useful for acute symptoms, but for patients with a longer duration of symptoms, a longer acting benzodiazepine, such as clonazepam, is recommended.

Nonpharmacologic therapies are effective for anxiety and depression for some patients. For patients who are able to be out of bed for a proportion of each day, a gentle exercise program or yoga may improve mood. As patients become less mobile, they may benefit from structured counseling and interventions such as cognitive behavioral therapy and mindfulness-based stress reduction. Finally, existential and spiritual distress at the end of life may require spiritual care. Palliative and hospice care teams routinely provide chaplaincy and for others, religious counselors may be available.

Palliative Care and Hospice

Palliative care and hospice teams provide symptom management and end of life care. Palliative care is defined as "an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other

Table 7 Medications for management of depression and anxiety at end of life

Medication	*Starting dose*	*Time to onset*	*Side effects*	*Other benefits*
Selective serotonin reuptake inhibitors		4–6 weeks	GI	
Citalopram	10 mg		Insomnia, agitation	
Escitalopram	5 mg			
Fluoxetine	5 mg			
Fluvoxamine	25 mg			
Paroxetine	10 mg			
Sertraline	12.5 mg			
Serotonin–norepinephrine reuptake inhibitors		4–6 weeks	GI distress,	Neuropathic pain
Venlafaxine	75 mg		Insomnia, agitation	
Duloxetine	10 mg			
Tricyclic antidepressants		2–3 weeks	Sedation	Pain
Nortryptline	10 mg		Anti-cholinergic	
Amitryptiline	25 mg		Insomnia, agitation	
Despiramine	10 mg		Cardiac arrhythmia	
Imipramine	25 mg		Weight gain	
Doxepin	10 mg		Orthostatic hypotension	
Stimulants		1–2 days	Cardiac arrhythmia	Fatigue
Modafinil	100 mg		Agitation	
Ritalin	10 mg			
Noradrenergic and specific serotonin inhibitor				
Mirtazapine	7.5 mg	1–2 weeks	Drowsiness, weight gain	Weight gain, sleep
Dopamine–norepinephrine reuptake inhibitors		1–2 weeks	Weight gain, insomnia agitation,	Activating agent
Wellbutrin	75 mg		GI distress	

problems, physical, psychosocial and spiritual" (WHO). The integration of palliative care early in a patient's care has been shown to improve mood and quality of life. Early integration has also been shown to improve the quality of end of life care with a reduction in chemotherapy use, hospitalizations, and intensive care. The American Society of Clinical Oncology (ASCO) guidelines recommend the integration of palliative care at diagnosis for all patients with a metastatic or recurrent cancer diagnosis and/or a high symptom burden.

Palliative care can be provided by a patient's primary providers (i.e., oncologist and primary care doctor) or by a specialist palliative team or a hospice team. Scope of practice includes symptom management, goals of care discussions and support, and end of life care. A specialist palliative care team is interdisciplinary and generally includes a physician, a nurse, a social worker, and a chaplain. The team works together to create a unified plan with the patient and family that takes into account their medical, social, psychological, and spiritual needs.

Patients usually transition from palliative care to hospice care when their prognosis is less than six limited and they are no longer receiving disease-modifying therapies. Hospice care, like palliative care, is provided by an interdisciplinary team. Hospice recognizes the patient and family as the unit of care. Hospice can provide end of life care both in a patient's home and in a facility. The focus is on symptom management and quality of life.

Special Topics

Hydration and Nutrition at the End of Life

Several studies have examined the role of artificial nutrition at the end of life. A Cochrane meta-analysis concluded that there is insufficient evidence to recommend artificial nutrition at the end of life. Additionally, enteral feeding requires invasive procedures with risk of infection, bleeding, and pain, as well as complications of feeding such as diarrhea, aspiration, and electrolyte abnormalities. Parenteral feeding also has unique risks including infection, glucose control abnormalities, hepatic dysfunction, volume overload, and cholecystitis. With these risks in mind, artificial nutrition is not recommended at the end of life.

Artificial hydration is more controversial than feeding; some proponents believe that it may help with delirium at the end of life. However, there are recognized risks from hydration at the end of life, including volume overload, ascites, and pulmonary edema. If hydration is to be prescribed, low volumes are recommended with the goal of relieving symptoms, rather than delivering a set amount of fluid. Continuous hydration is generally not recommended.

At the end of life, patients often do not feel hungry, so it is appropriate to provide food and fluid based on the patient's desires. This is often called "pleasure feeding" and may involve small quantities offered at frequent intervals. If patients are having difficulty with swallowing, patients still benefit from frequent mouth care (keeping the oral cavity moist and clean) since xerostomia is a troubling symptom for patients with advanced illness. Discontinuation of oral intake by patients is a major source of emotional distress for families. Families may feel as if they are starving their loved one. It is important to reassure families that loss of appetite is an expected symptom of advanced disease. Providing suggestions to families of activities, other than feeding, with which they can demonstrate their love may be helpful. Alternate family activities might include massage, reading together, games, or legacy projects. Support and education by the hospice or palliative care team can be very reassuring for patients and families.

Palliative Sedation

The emancipation principle of palliative care states that one should "spare no scientific or clinical effort to free dying persons from twisting and racking pain that invades, dominates and shrivels their consciousness and leaves them no psychic or mental space for the things they want to think and say and do before they die." While most symptoms are able to be controlled, there are situations at the end of life when patients' symptoms become refractory, where further invasive or noninvasive approaches are incapable of providing adequate relief, are associated with excessive morbidity, or cannot provide relief in a tolerable time frame. In these situations, palliative sedation may be considered to relieve suffering at the end of life.

Palliative sedation is a procedure that utilizes sedative medications, in a supervised setting, to reduce the awareness of intolerable suffering by a terminally ill patient who has a very limited prognosis (hours to days). If palliative sedation is being considered, involvement of a multidisciplinary team is recommended. A hospice or palliative care team will evaluate the patient and consider any potential remaining opportunities for symptom control to ensure that reversible causes of discomfort have been addressed. If no alternative approaches or treatments are identified, informed consent is obtained for palliative sedation from the patient or health care surrogate. The consent discussion includes an overview of the patient's general condition, acknowledgment that prior treatments have not successfully controlled symptoms, current prognosis, rational for palliative sedation, recommended medications to achieve sedation, potential alternatives, expected effects of sedation, and risks of sedation. If a patient is unable to give consent, and there is no health care proxy available, it is the physician's responsibility to use all measures needed (including sedation), to relieve suffering.

The medications commonly used in this setting are anxiolytics and barbiturates. Sedating medications are delivered intravenously and titrated to symptom relief. Neuroleptics may be used for patients with delirium. Opioids are continued, in addition to the sedation, for patients with pain.

Care for the family and the medical team taking care of the patient are imperative during the palliative sedation procedure. Family often finds comfort in being with their loved ones, but may need reassurance that sedation is an acceptable course of action.

Family also benefits from knowing what to expect as the process proceeds. The medical team also often requires reassurance. Health care providers may feel like they are inadvertently "killing" the patient. They may express personal distress and struggle with a decision to move forward with palliative sedation. Education for staff and debriefing at team meetings may provide much needed support for staff.

PAD and Euthanasia

PAD refers to the provision of a prescription of a lethal dose of medication by a physician for a terminally ill, competent person who intends to use the medication to end his or her own life. The practice has been legalized in several countries and in several states in the United States. In most cases, there is a protocol that patients must undergo to confirm the terminal nature of their illness, competence of the patient, and lack of coexisting psychiatric illness.

Euthanasia refers to the administration of a lethal dose of medication by a physician to a patient to relieve suffering. This is legal in only a few countries such as the Netherlands, Belgium, Luxembourg, and Colombia. Generally, euthanasia is considered for competent and conscious patients who have severe symptoms and terminal illness.

In both of these settings, the intent of PAD or euthanasia is to end life. This is quite different from palliative sedation, where the primary intent is to relieve suffering.

Conclusion

End of life support begins with thorough conversations regarding patient and family goals of care and documentation of wishes. The involvement of a multidisciplinary team such as a palliative care team or a hospice team can ensure that patients receive appropriate symptom management throughout their end of life experience. In special situations, patients may access PAD and/or euthanasia. All patients deserve the best quality of life possible through the end of life, with intensive symptom control and care for the family.

Prospective Vision

Care for patients at the end of life is an area of great interest as people continue to live longer and often live with comorbid illness. Novel therapeutics, such as immunotherapy and targeted therapy, are changing the landscape of cancer and bring forward the potential of caring for cancer as a chronic rather than life-limiting illness. The financial toxicity for patients at the end of life will only become more challenging, as patients live longer and often have to devote more financial resources toward their health care. A new system of health care delivery with a focus on prevention and interventions that improve quality of care, in addition to longevity, will be critical moving forward.

Endometrial Cancer: Pathology and Genetics

Ben Davidson, Oslo University Hospital, Oslo, Norway; and University of Oslo, Oslo, Norway

Epidemiology

Endometrial cancer, consisting predominantly of endometrial carcinoma (EC), is the 6th cancer in incidence in women worldwide. However, this malignancy is not among the 10 most common causes of cancer mortality globally, and ranks 10th in developed countries. This reflects the fact that endometrial cancer predominantly affects women in developing countries, where access to medical treatment is better. Additionally, most uterine corpus carcinomas are diagnosed at earlier stage and consist of grade 1–2 endometrioid carcinomas, tumors that are less aggressive compared to carcinomas in other organs. Disease incidence is increasing in developed countries, including both Europe and the United States.

Risk factors which predispose to development of endometrial cancer include obesity, diabetes, nulliparity, history of colon/breast carcinoma, ovulatory failure, exposure to endogenous or exogenous estrogen and tamoxifen treatment. Oral contraceptive use confers protection. Exposure to endogenous or exogenous estrogen may result from hormone-producing tumors, such as sex cord stromal tumors of the ovary, and from medical administration of estrogens, for example, in patients with polycystic ovary syndrome, respectively (Rahaman et al., 2017). Increased exposure to estrogen primarily affects type I carcinomas (see below).

Genetics

Several genetic syndromes are associated with increased risk for developing EC, accounting in total for 6% of EC cases, the most common of which is Lynch syndrome. Lynch syndrome, which also predisposes women to colon cancer, ovarian cancer and other malignancies, is inherited in an autosomal dominant manner which is caused by mutation in one of the mismatch repair (MMR) genes *MLH1*, *MSH2*, *MSH6*, and *PMS2*, or the epithelial cell adhesion molecule gene *EPCAM*, which regulates the expression of *MSH2*. Over 50% of women affected by the syndrome will present with a gynecological cancer. The risk for developing EC is in the range of 15%–60% depending on the gene involved.

Cowden syndrome is caused by mutation in the tumor suppressor gene *PTEN* (phosphatase and tensin homolog), and is associated with an up to 28% risk for developing EC, as well as high risk for developing breast, renal and thyroid cancer. Other syndromes that are more rarely implicated in EC include Li-Fraumeni syndrome, in which the *TP53* gene is mutated, Peutz-Jeghers syndrome, in which patients carry mutation in the tumor suppressor gene *STK11*, and PPAP, polymerase proofreading-associated polyposis, in which the *POLD1* and *POLE* genes, encoding subunits of DNA polymerases δ and ε, respectively, are mutated (Spurdle et al., 2017; Ring et al., 2017). Recently published recommendations advocate screening of all patients with newly diagnosed EC for Lynch syndrome using MMR immunohistochemistry (IHC) (Randall et al., 2017).

Morphology

The 2014 WHO classification of EC includes the following entities (Kurman et al., 2014):

Endometrioid carcinoma (EEC).
Mucinous carcinoma (MC).
Serous carcinoma (SC).
Clear cell carcinoma (CCC).
Neuroendocrine tumors (low-grade and high-grade).
Mixed cell adenocarcinoma.
Undifferentiated carcinoma.
Dedifferentiated carcinoma.

The detailed morphology of each tumor is discussed in the WHO classification, as well as in several other recent publications (Lax, 2017; Hanley et al., 2017). Briefly, EC consist of cells that resemble endometrial glands, occasionally with a papillary growth pattern, and a variable degree of atypia. They are graded 1–3 based on the percentage of tumor which has a solid growth pattern (**Fig. 1** A and B). Secretory changes (**Fig. 1**C) and squamous metaplasia may be seen. MC has >50% component with mucinous differentiation. SC have high-grade atypia and grow in glandular, papillary or solid pattern, with scalloping of the inner aspects of the glandular structures (**Fig. 1**D). CCC consists of overtly atypical cells with high-grade nuclei and clear or eosinophilic cytoplasm, often with hobnailing, growing in tubolocystic, solid or papillary architecture (**Fig. 1**E). Mixed tumors are not uncommon and should contain at least 5% of each component in order to be diagnosed as such. Carcinomas in which all cells combine two histological phenotypes, most often endometrioid and serous, additionally occur. Undifferentiated carcinomas are high-grade tumors which cannot be assigned to any of the above-mentioned histotypes, whereas in dedifferentiated carcinomas a component of grade 1–2 EEC can be identified (**Fig. 1**F and H). Carcinosarcomas (CS), previously perceived to be mesenchymal tumors, are now classified as mixed epithelial-mesenchymal tumors, but widely accepted to originate from high-grade carcinomas (**Fig. 1**I and J).

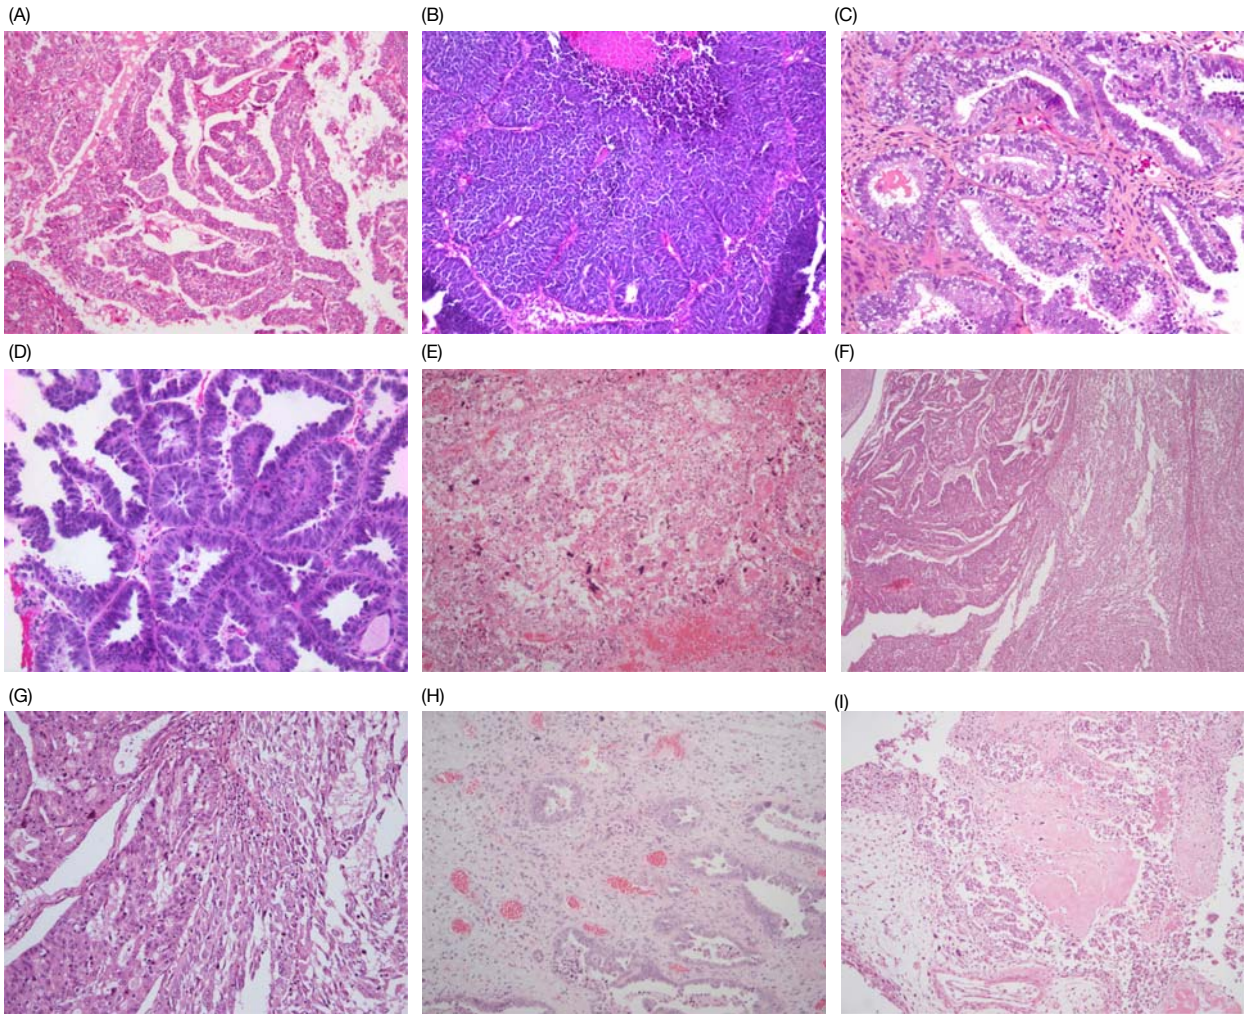

Fig. 1 Morphology. (A) Grade 1 endometrioid carcinoma. (B) Grade 3 endometrioid carcinoma. (C) Grade 1 endometrioid carcinoma with secretory features. (D) Serous carcinoma. (E) Clear cell carcinoma. (F and G) Dedifferentiated carcinoma. (H and I) Carcinosarcoma.

EC has been classically divided into type I and type II tumors. Type I EC consists of EEC, is estrogen-dependent, accounts for the majority of EC, is often associated with endometrial hyperplasia, and has relatively good prognosis. Type II tumors include non-endometrioid carcinomas (NEEC), that is, SC and CCC, which are clinically aggressive tumors, and are estrogen-independent, often developing in an atrophic endometrium. Activation of distinct molecular pathways has been identified in each of these groups (see below) (Yeramian et al., 2013; Matias-Guiu and Davidson, 2014; Murali et al., 2014). While some authors perceive CS as a distinct entity which should be excluded from the carcinoma category (Vaidya et al., 2006; Amant et al., 2005), there is a clear rationale in including these tumors in the type II group, given their cellular origin (Piulats et al., 2017).

While this dichotomous classification of EC holds true in most cases, it has its limitations. As discussed above, mixed tumors do occur. Additionally, some grade 1–2 EEC (G1EEC, G2EEC) are clinically aggressive. Finally, the relatively indolent clinical course of so-called type I tumors is limited to G1EEC and G2EEC. Grade 3 EEC (G3EEC) are recognized as clinically aggressive tumors, although the issue of whether they are as aggressive as SC and CCC has not been conclusively settled (Hamilton et al., 2006; Alkushi et al., 2010; Boruta et al., 2004; Park et al., 2013; Ayeni et al., 2013; Soslow et al., 2007; Voss et al., 2012).

In addition to the difficulty in assigning a clinically inclusive category for all EEC, there are also challenges in the differential diagnosis of the various EC histotypes. G3EEC and SC may have solid growth pattern and high-grade atypia, and SC may have a predominantly glandular growth pattern, leading to sub-optimal inter-observer reproducibility even among experts (Gilks et al., 2013), although several characteristics in distinguishing these tumors from each other have been published (Soslow, 2013; Clement and Young, 2004; Bartosch et al., 2011).

Difficulties may occasionally arise also in the differential diagnosis of SC from G1EEC and G2EEC, as well as in deciding whether the presence of tumor cells with clear cytoplasm truly represents CCC. In view of the overlapping morphology, ancillary methods, including both immunohistochemical staining for marker expression and molecular techniques have been frequently applied in order to reach a more conclusive diagnosis.

Immunohistochemical Markers

No single marker is by itself is able to differentiate between EEC, SC, and CCC. Consequently, panels of variable size and content have been assessed by different authors, and the choice of panels in everyday practice is similarly heterogeneous. Markers which have been tested in EC typing include p53, p16, estrogen receptor (ER), progesterone receptor (PR), monoclonal CEA (mCEA), PTEN, the MMR proteins hMLH1, hMSH2, hMSH6, and hPMS2, the insulin-like growth factor II (IGF-II) mRNA-binding protein family (IMP; IGFBP) members IMP2 and IMP3, Ki-67, β-catenin, the intestinal mucosal protein TFF3, The *ARID1A* protein product BAF250A, hepatocyte nuclear factor-1β (HNF1β), napsin A and high-mobility group AT-hook 2 (HMGA2) (Bartosch et al., 2011; Reid-Nicholson et al., 2006; Yemelyanova et al., 2009; Zheng et al., 2008; Li et al., 2007; Zhang et al., 2011; Mhawech-Fauceglia et al., 2010, 2013; Schlosshauer et al., 2002; Allo et al., 2014; McCluggage et al., 2012; Bárcena and Oliva, 2011; Fadare and Liang, 2012). Results have often been variable for markers tested by several groups.

In the most comprehensive of these studies, Han et al. analyzed the diagnostic role of 12 proteins, including ER, PR, p16, p53, Ki-67, PTEN, β-catenin, vimentin, IMP3, TFF3, ARID1A, and HNF1β in this differential diagnosis. Expression of TFF3, ARID1A loss and β-catenin expression had a specificity of 100%, but relatively low sensitivity (37%, 33%, and 7%, respectively) in diagnosing G3EEC. p53, p16 and IMP3 stained 94%, 80%, and 63% of SC compared to 26%, 11%, and 11% of G3EEC, respectively. The combination of ER, PR, p16, p53, vimentin, PTEN and IMP3 was 100% concordant with morphology, whereas the combination of ER, p16, and p53 was the most informative when applying a 3-marker panel (Han et al., 2013).

The author's preferred markers in the differential diagnosis between SC and EEC are p16, p53, PTEN, and WT1, despite the fact that the latter is often only focally expressed in uterine SC. ER and PR may be used as adjuncts, but have lower discriminating power. ARID1A, HNF1β, and napsin A are useful when CCC is a differential diagnosis. However, loss of ARID1A and nuclear expression of HNF1β may be seen in other histotypes, particularly in EEC. Examples of immunostains are shown in **Fig. 2**.

Molecular Analyses

In addition to differences in their morphology and marker protein expression profile, the different histotypes of EC have a unique molecular signature. Comparative analyses of type I and II EC, the latter with a focus on SC, have shown that EEC often has mutations in *PTEN*, *KRAS*, *PIK3CA*, *CTNNB1*, *ARID1A*, and *FGFR*, as well as microsatellite instability (MI), whereas type II tumors more often carry mutations in *TP53*, *PIK3R2*, and *PPP2R1A* and amplifications of *PIK3CA*, *CCND1*, and *CCNE1* (Yeramian et al., 2013). The possibility to use these differences in molecular profile for diagnostic purposes has been assessed by different groups. McConechy et al. found the use of a 9-gene test, including *ARID1A*, *PPP2R1A*, *PTEN*, *PIK3CA*, *KRAS*, *CTNNB1*, *TP53*, *BRAF*, and *PPP2R5C* to be useful in classifying EC (McConechy et al., 2012), and the validity of this signature was further assessed in a follow-up study with correlation to morphology and IHC profiles (Hoang et al., 2013).

The use of DNA ploidy as an ancillary technique with a diagnostic and prognostic role in EC has been advocated by some authors, and has recently been applied in several studies (Werner and Salvesen, 2014; Nastic et al., 2017; Proctor et al., 2017). However, this method has failed to gain widespread acceptance and is not in use in most institutions.

The fact that dividing all EC into type I or type II tumors is an oversimplification was further highlighted by the Cancer Genome Atlas (TCGA) study, an integrated genomic, transcriptomic and proteomic characterization of 373 EC, including 307 EEC, 53 SC and 13 mixed tumors. Somatic copy number alterations (SCNA) divided the studied tumors into four clusters, of which clusters 1–3 consisted almost entirely of EEC, divided by SNCA rates and 1q amplification, the latter associated with worse progression-free survival (PFS). Most SC and mixed tumors clustered in cluster four with a small number (36) of EEC, the majority of which were G3 EEC, and this group was characterized by extensive copy number alterations, few DNA methylation changes, low ER/PR levels, and frequent TP53 mutations, as well as MYC, ERBB2, and CCNE1 amplifications. This group had the worst survival. The majority of EEC had frequent mutations in PTEN, CTNNB1, PIK3CA, ARID1A, ARID5B, and KRAS, but few copy number alterations or TP53 mutations, whereas a smaller group of EC had increased mutation frequency and hotspot mutations in POLE. The latter group, consisting mainly of G3EEC, had excellent prognosis. Based on the combination of somatic nucleotide substitutions, microsatellite status (stability vs. instability; MSS vs. MSI) and SCNAs, EC were classified into four categories: POLE ultramutated, microsatellite instability hypermutated, copy-number low, and copy-number high (Cancer Genome Atlas Research Network et al., 2013).

Several follow-up studies based on the TCGA study have been published in recent years. Meng and co-workers analyzed 53 G3EEC, 25 SC, 16 CCC and 5 dedifferentiated carcinomas for the presence of *POLE* mutations by Sanger sequencing. *POLE* mutations were found in 8/53 (15%) G3EEC, of which only one had deficient MMR, but none of the other entities, and none of the patients with *POLE*-mutated tumors had disease progression (Meng et al., 2014).

Analysis of the morphology of these 8 *POLE*-mutated tumors and 8/17 *POLE*-mutated tumors from the TCGA cohort showed that the majority of these tumors had high-grade architecture and nuclear grade, as well as high mitotic counts. While all tumors except one had areas of endometrioid morphology, many tumors showed morphological heterogeneity and ambiguity. Many were rich in tumor-infiltrating lymphocytes and/or peri-tumoral lymphocytes. The majority of tumors had *PTEN*, *ARID1A*, and *KRAS* mutations (Hussein et al., 2015).

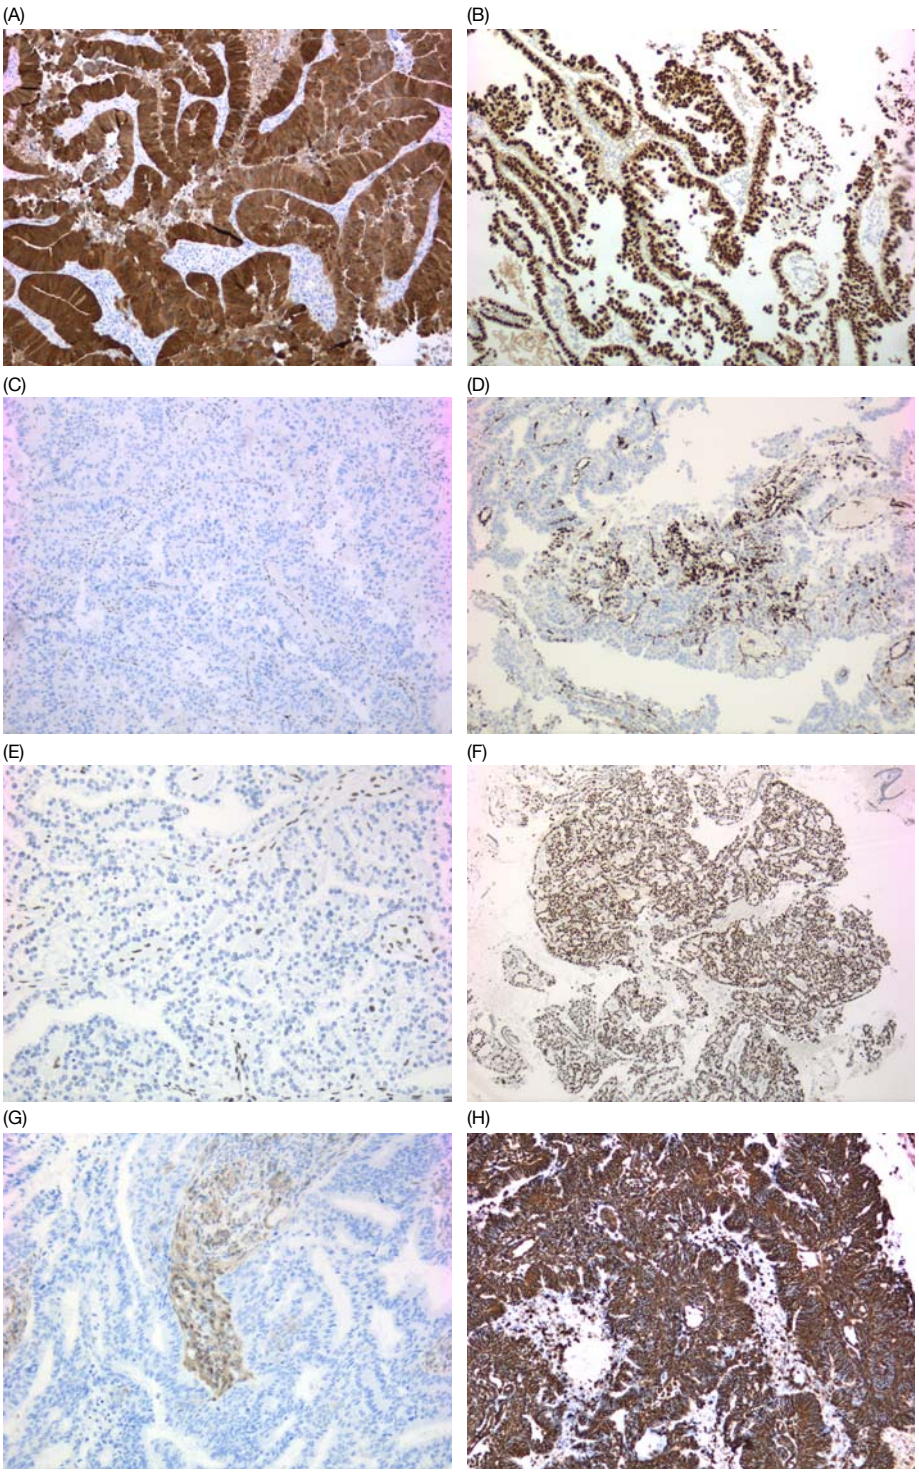

Fig. 2 Immunohistochemistry. (A) p16 staining in serous carcinoma. (B) Aberrant p53 (overexpression) in serous carcinoma. (C) Aberrant p53 ("null" pattern) in serous carcinoma. (D) WT1 stain in serous carcinoma. (E) Loss of ARID1A in clear cell carcinoma. (F) HNF1β stain in clear cell carcinoma. (G) Loss of PTEN in endometrioid carcinoma. (H) Vimentin expression in endometrioid carcinoma. (I) Focal CEA expression in endometrioid carcinoma. (J and M) Mismatch repair (MMR) proteins. Loss of MLH1 (J), intact MSH2 (K) and MSH6 (L), loss of PMS2.

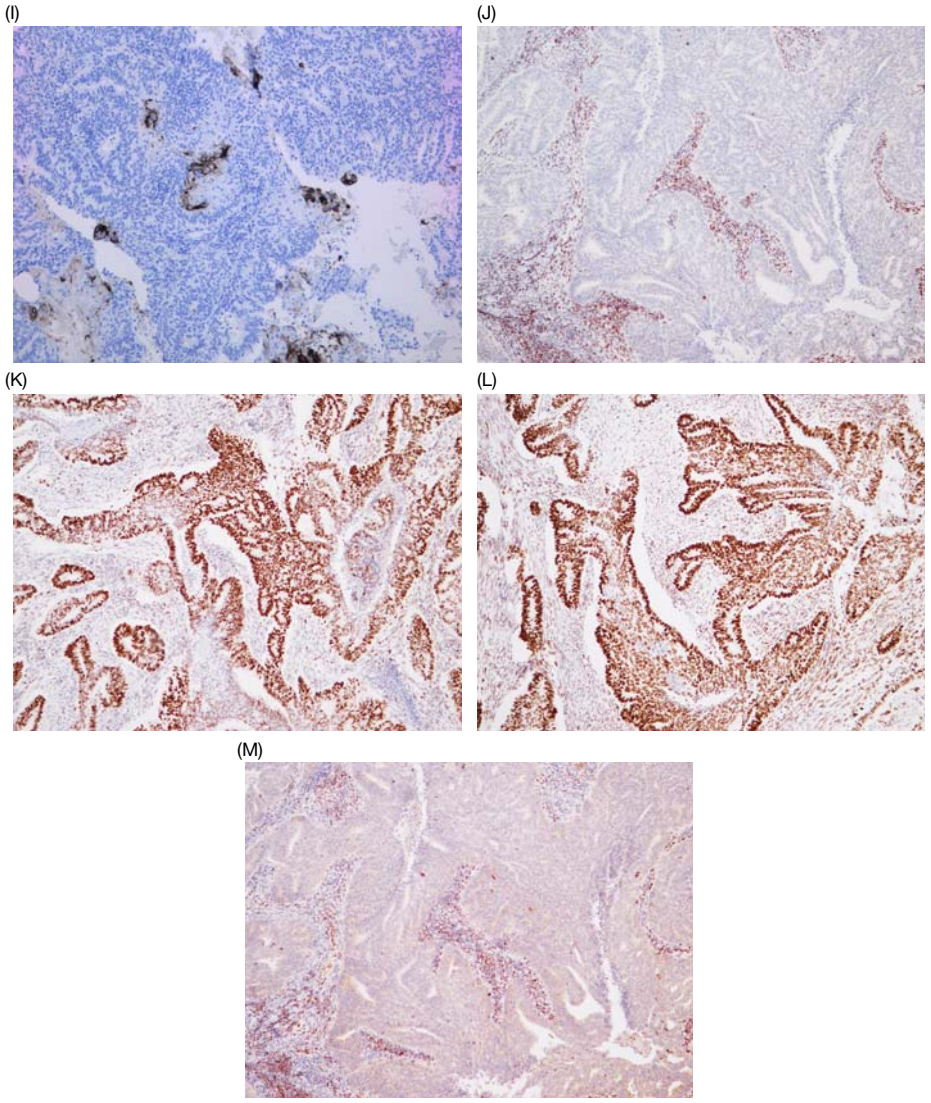

Fig. 2 (*continued*).

Billingsley et al. analyzed 544 EEC and found *POLE* mutations in 30 of them (5.6%). *POLE* mutations were more frequent in younger patients (< 60 years). However, no association with MS status or with PFS was observed. Association with longer overall survival (OS) was observed, but was lost in multivariate analysis (Billingsley et al., 2015).

Talhouk and co-workers analyzed 143 EC, including 119 EEC and 24 serous/mixed EC and found that MMR and p53 status by immunohistochemistry, combined with POLE mutation status, strongly correlate to clinicopathologic parameters and provide independent additional prognostic information (Talhouk et al., 2015). The usefulness of this classification was recently reproduced in analysis of 319 new EC cases (215 EEC, 104 non-EEC), in which this 3-marker combination was independently associated with OS, PFS and disease-specific survival (DSS) in multivariate analysis (Talhouk et al., 2017).

In an additional study related to this 3-paramter classification system, 151 EC were divided into *POLE*-mutated, MMR-deficient, p53 wildtype (wt) and p53 abnormal and morphologically classified by seven gynecologic pathologists into G1-2EEC, G3EEC, MC, SC, CCC, dedifferentiated carcinoma, CS, mixed carcinoma and other. Consensus among all seven pathologists was highest for p53 wt tumors (90%), intermediate for *POLE*-mutated and MMR-deficient tumors (65% and 58%, respectively) and lowest for abnormal p53 cases (39%). A large number of EEC and SC failed to fall in into the p53 wildtype (wt) and p53 abnormal categories, respectively, highlighting the need for ancillary techniques in this differential diagnosis (Hoang et al., 2017). The difficulties in reconciling the morphological and the genomic differential diagnosis of EEC and SC was highlighted in another study, in which inter-observer agreement between two gynecologic pathologists was better for copy-number low tumors than for the other TCGA categories (Hussein et al., 2016).

Schultheis et al. performed an in-depth analysis of *TP53* mutations in 228 EC from the TCGA dataset. Mutations were found in 64 (28%) tumors, were more frequent in SC compared to EEC (88% vs. 15%, respectively) and were associated with poor survival.

No association between the type of *TP53* mutation (i.e., missense, frameshift, or nonsense) and tumor type was found. However, TP53 hotspot mutations were more common in SC than in EEC. Somatic frameshift or nonsense "null mutations" that result in negative p53 protein expression and are diagnostically more challenging than overexpression were found in 22% of the mutated tumors (Schultheis et al., 2016).

Two other genes that are central in the biology of EC are *ARID1A* and *CTNNB1*.

ARID1A is member of a family of chromatin remodelers belonging to the polymorphic BRG-/BRM-associated factor (BAF), the Switch/Sucrose Non-Fermentable (SWI/SNF) complex, and Polybromo-associated BAF (PBAF). Mutations in genes belonging to these complexes have been found in >20% of cancers. *ARID1A*, a tumor suppressor located on chromosome 1p36.11, is the most commonly mutated among these genes, with mutations reported in various carcinomas, most frequently in ovarian CCC (50% of tumors) and in uterine and ovarian EEC (30%–40% of tumors), as well as Burkitt lymphoma, medulloblastoma and neuroblastoma. Mutations are typically nonsense or frameshift and result in loss of expression of the ARID1A (a.k.a. BAF250A) protein (Hodges et al., 2016; Takeda et al., 2016; Bitler et al., 2015; Gounaris and Brenton, 2015). Analysis of 190 high-grade EC, including 82 G3EEC, 88 SC, 10 CCC and 10 mixed tumors, showed loss of BAF250a, the protein product of ARID1A, in 55 (29%) tumors, the majority of which were G3EEC. BAF250a loss was significantly associated with MMR protein loss and intact p53. BAF250a loss was significantly associated with better PFS in the entire cohort, but only MMR and p53 status was informative of survival in separate analysis of G3EEC and SC. Analysis of the TCGA data showed that *ARID1A* mutations were negatively associated with *TP53* mutations and unrelated to MMR gene mutations (Allo et al., 2014).

The Wnt/β-catenin signaling pathway is deregulated in 10%–45% EC, mainly EEC, via inactivating mutations in the *CTNNB1* gene encoding β-catenin, or epigenetic regulation of the Wnt pathway (Dellinger et al., 2012). Liu and co-workers performed unsupervised clustering of gene expression profiling of 271 EEC from the TCGA series and identified four clusters that were statistically significantly associated with tumor stage, grade, MSI status and the three mRNA clusters characterized in the TCGA study. Clusters III and IV contained most of the G3ECC and stage III–IV tumors, while clusters I and II consisted mainly of G1-2EEC and stage I–II tumors. Cluster II cases were enriched for *CTNNB1* exon 3 mutations (87%; 47/54) of these mutations were significantly associated with Wnt/β-catenin signaling activation. In G1-2EEC tumors, high expression levels of *CTNNB1*, *MYC*, and *CCND1* was associated with poor OS. This clustering into four groups was confirmed in an independent dataset (Liu et al., 2014).

The role of epigenetic regulation of gene expression is now recognized as central in cancer biology, and this topic has recently been reviewed in two comprehensive papers by Bartosch et al. (2017a,b). Promoter hypermethylation has been reported for hormone receptors, *MLH1*, *MGMT*, *CDKN2A* (encoding p16) and molecules belonging to the phosphatidylinositide 3-kinase (PI3K), mitogen-activated protein kinase (MAPK), fibroblast growth factor (FGF) and WNT pathways. Hypomethylation has been less frequently studied, but has been reported for *PAX2*, *S100A4*, *PARP1*, *BMP*, *BORIS*, and *14-3-3 sigma* (Bartosch et al., 2017a).

Wentzensen et al. analyzed 148 EC and 23 normal endometria for methylation profile using 1500 probes for 807 genes. A total of 114 CpG sites on 37 genes that had significant differences in methylation at a cut-off of $P \leq 10^{-7}$ were identified. Eight genes (*ADCYAP1*, *ASCL2*, *CDH13*, *HS3ST2*, *HTR1B*, *MME*, *NPY* and *SOX1*) chosen for validation were confirmed to be discriminators between the two sample types in analysis of a second series of 69 EC and 40 normal endometria, as well as based on the TCGA data. HTR1B and SOX1 were shown to effectively differentiate SC from normal endometrium (Wentzensen et al., 2014).

Other molecules involved in epigenetic regulation of EC are those modifying histones, including histone acetyltransferases (HATs), histone deacetylases (HDACs), histone methyltransferases (HMTs), and histone demethylases (HDMs). Several of these molecules have been shown to be differentially expressed in EC compared to normal endometrium, and members of all four classes, including the HDACs members HDAC1, HDAC2 and Sirtuin 1 (SIRT1), the HAT Elongator complex protein 3 (ELP3), the HMT Enhancer of zeste homolog 2 (EZH2), and the HDM Lysine-specific histone demethylase 1 (LSD1), have been associated with aggressive behavior in EC. A large number of microRNA have also been shown to be deregulated, both over- and under-expressed in EC (Bartosch et al., 2017b).

The TCGA project has focused on molecular characteristics of EEC and SC, leaving the genomic characterization of CCC less explored. In a recent paper, DeLair and co-workers studied 32 pure CCC, including 16 FIGO stage I and 16 FIGO stage III or IV tumors, using IHC and massively parallel sequencing targeting of 300 cancer-related genes. Uterine CCC were shown to be a heterogeneous group which includes tumors that may be molecularly classified in all four TCGA groups. By IHC, abnormal protein expression of p53, ARID1A and at least one MMR member, most commonly MSH6, was found in 11 (34%), 7 (22%), and 6 (19%) tumors. At the molecular level, two ultramutated tumors with *POLE* mutation were found, while the remaining cases harbored *TP53* (46%), *PIK3CA* (36%), *PPP2R1A* (36%), *FBXW7* (25%), *ARID1A* (21%), *PIK3R1* (18%), and *SPOP* (18%) mutations, many of them in hotspot locations. *CCNE1* and *ERBB2* amplification and *DAXX* homozygous deletion was found in 5/28, 3/28, and 3/28 analyzed tumors, respectively. Based on the observed heterogeneity, the authors questioned the validity of classifying all CCC as high-grade/type II tumors (DeLair et al., 2017).

CS constitute 4.3% of uterine cancers and are highly aggressive tumors with a high recurrence rate of 37% and 5-year survival at 65% or less even at FIGO stage I. Current treatment has not led to major improvements in the outcome of patients with this malignancy (Cherniack et al., 2017).

A comprehensive molecular analysis of 57 uterine CS was recently published (Gibson et al., 2016). The most frequent mutations found were in *TP53*, detected in 91% of tumors. Additional mutations were detected in the PI3K pathway genes *PIK3CA* (35%), *PTEN* (19%), and *PIK3R1* (11%). *PTEN* and *TP53* mutations co-existed in 8/11 tumors harboring the former. Other mutated genes included *FBXW7* (28%), *PPP2R1A* (28%), *CDH4* (18%), *KRAS* (12%), *ARID1A* (12%), *RB1* (11%), *ARHGAP35* (11%), *ZBTB7B*

(11%), *SPOP* (7%), and *U2AF1* (4%). The majority of these genes, though not all, have been previously shown to be mutated in EC. Analysis of RNA sequencing data showed kinase-domain gene fusions in *NUP210-MAST1*, *CENPP-WNK2*, and *DDX6-ALK* in three tumors. Gene amplifications were observed in *TERC* (3q26.2), *FGFR3* (4p16.3), *MYC* (8q24.21), *KAT6A* (10q22.2), *MDM2* (12q15), *ERBB2* (17q12), *CCNE1* (19q12), *BCL2L1* (20q11.21), and RIT1 (1q22). A 76-gene signature was used to assign an epithelial-to-mesenchymal transition (EMT) score. Proteomics analysis was not informative with respect to clustering of tumors.

Prediction, Prognosis and Targeted Therapy

The difficulty in classifying EC based on morphology, IHC and molecular analysis owes to remarkable heterogeneity both across histological types and within morphologically similar tumors, as well as the existence of tumors combining the features of more than one histotype. Further complicating this issue is the observation that approximately half of the genetic changes observed in metastatic EC are not present in the primary tumor (Gibson et al., 2016). This heterogeneity has in turn limited the ability to identify predictive and prognostic markers that are reproducible and to identify therapeutic targets for this cancer. Consequently, at present no molecule is approved as therapy target for patients with EC, with the exception of hormone receptors.

In addition to clinicopathologic parameters, numerous biomarkers have been reported to have a prognostic role in EC at the protein and/or molecular level, including ER and PR, PTEN, Stathmin, L1CAM, β-catenin, molecules in the PI3K and MAPK pathway, vascular endothelial growth factor (VEGF), POLE, p53, epidermal growth factor receptor (EGFR), HER2, FGFR2, MSI/DNA repair, DNA ploidy (Matias-Guiu and Davidson, 2014; Werner and Salvesen, 2014; Binder and Mutch, 2014; Buhtoiarova et al., 2016; McAlpine et al., 2016). Candidate predictive markers, of which many are also targetable molecules, include ER and PR, Stathmin, L1CAM, HER2, the PI3K and MAPK pathways, KRAS, EGFR, FGFR and VEGF, as well as metabolic treatment using metformin and modulation of the microenvironment, including the immune response (Hoang et al., 2013; Binder and Mutch, 2014; Buhtoiarova et al., 2016; McAlpine et al., 2016; Lheureux and Oza, 2016; MacKay et al., 2017; Morice et al., 2016). Clinical trials focusing on some of these targets are discussed in several of these publications (Lheureux and Oza, 2016; MacKay et al., 2017; Eritja et al., 2017).

Two biomarkers of interest which have not been discussed in this article in the context of molecular changes, but are of interest at the protein level, are Stathmin and L1CAM. These are discussed below as examples of potentially targetable molecules in EC.

Stathmin (a.k.a. oncoprotein 18/Op18, LPA18 or metablastin) is a 149 amino acid microtubule-destabilizing phosphoprotein which mediates its effect via sequestration of free tubulin or induction of mitotic catastrophe. Stathmin has been reported to be expressed in many cancers, in which it has generally been associated with aggressive clinical behavior (Belletti and Baldassarre, 2011; Biaoxue et al., 2016a,b).

Stathmin expression is associated with aggressive clinical behavior and activation of the PI3K pathway in EC (Salvesen et al., 2009), and Stathmin expression was reported to be a better marker of PI3K pathway activation than AKT or p-AKT in this cancer (Trovik et al., 2010). In a follow-up study with a total of 1076 patients, Stathmin expression was significantly related to non-endometrioid histology, high grade, and aneuploidy, independently predicted lymph node metastasis, and was significantly associated with poor disease-specific survival (Trovik et al., 2011). Stathmin expression was further shown to be related to poor response to paclitaxel both in vitro and in clinical specimens (Werner et al., 2014). Stathmin expression was recently reported to be associated with shorter PFS and OS in the GOG-177 cohort of 69 patients, particularly in patients who received adriamycin/cisplatin only (Reyes et al., 2017). Conversely, in a recent multi-parameter analysis of 460 EC (10.8% cases not informative for Stathmin), Stathmin expression was not significantly related to survival (Karnezis et al., 2017).

L1CAM is a 200–220 kDa transmembrane glycoprotein belonging to the immunoglobulin (Ig) supergene family that is involved in development of nervous system via regulation of neuronal migration. L1CAM has in recent years been reported to be expressed in different cancers, including various carcinomas, melanoma and gastrointestinal stromal tumor (GIST) and is informative of clinical outcome in several of them (Altevogt et al., 2016). The possibility of targeting L1CAM has been assessed in several experimental models (Grünberg et al., 2005; Gast et al., 2008).

L1CAM was shown to be overexpressed in SC and CCC compared to EEC and its expression in the latter group, observed in 78/272 tumors, was related to poor survival. L1CAM expression was further showed to be related to absence of ER, PR and E-cadherin and development of EMT (Huszar et al., 2010). This was reproduced in a multicenter study of 1021 stage I EC, the majority of which were EEC, in which L1CAM was a strong predictor of relapse and death of disease (Zeimet et al., 2013). Similar results were observed in pooled analysis of EC ($n = 865$) from two randomized controlled trials (PORTEC-1 and -2) (Bosse et al., 2014). In a multicenter study by the ENITEC consortium, in which 1199 EC were analyzed, L1CAM was expressed in of 93/935 (10%) stage I EEC, 28/160 (18%) advanced-stage EEC, and 78/104 (75%) non-endometrioid tumors. L1CAM expression was significantly associated with advanced stage, nodal involvement, high grade, non-endometrioid histology, lymphovascular space invasion, and distant recurrence in the entire cohort, and with poor survival in patients with EEC (van der Putten et al., 2016). Similarly, analysis of 805 EC, in which 121 tumors (15%) were L1CAM-positive, demonstrated significant association with advanced stage, high grade, non-endometrioid histology, lymphovascular space invasion, cervical stromal invasion, positive peritoneal cytology and age >65 years, as well as poor disease-specific survival in patients with EEC, which was confirmed in a Cox multivariate analysis (Pasanen et al., 2016). L1CAM was additionally reported to be associated with the p53 abnormal molecular subtype based on the ProMisE classification, as well as with poor survival, in the study by Karnezis et al. (2017). In contrast, L1CAM was not significantly

associated with the risk of relapse or death of any cause in a recent analysis of 388 stage I EEC, although L1CAM was significantly associated with risk of relapse in patients who were not treated with chemotherapy (Smogeli et al., 2016).

A cut-off at 50% rather than 10%, as has been used in the above-mentioned studies, has recently been proposed in order to identify high-risk EC patients (Van Gool et al., 2016).

Prospective Vision

The majority of EC can be cured by surgery. While this group consists predominantly of G1-2EEC, it is evident that not all so-called type II EC are truly clinically aggressive cancers. At the same time, some so-called type I EC do recur, of which some prove lethal. Major improvements in our understanding of this cancer have been made in recent years, mainly based on highly informative molecular analyses, particularly the TCGA study. Difficulty in reconciling the morphologic heterogeneity of EC with expression patterns by IHC and molecular heterogeneity nevertheless remains, a fact which makes the identification of a widely-accepted diagnostic panel which correlates with clinical behavior highly desirable. Whether this will be a limited assay, such as the ProMisE approach, or a more comprehensive assay, such as the 53-gene signature suggested by Dai and co-workers (2016), remains to seen, although it is likely that the former, or a comparable assay, will be adopted for practical reasons. Analyses of biomarker expression, with the aim of applying targeted therapy, are likely to benefit from the identification of patient sub-groups with tumors that express the target proteins and in which these proteins have a clinical role. As in other cancers, large multi-institutional studies are a cornerstone of this research and its clinical implementation.

Enhancers in Cancer: Genetic and Epigenetic Deregulation

Kaixiang Cao and Ali Shilatifard, Northwestern University, Chicago, IL, United States

Glossary

Bromodomain A protein domain of about 110 amino acid residues that binds acetylated lysine. Bromodomain-containing proteins can bind acetylated histones and recruit transcription regulators to modulate gene expression.

Chromatin immunoprecipitation (ChIP) A technique used to determine the localization of a protein of interest to specific DNA sequences in vivo. In combination with high-throughput sequencing (ChIP-seq), it can be used to study the genome-wide distribution of proteins of interest.

Chromosome conformation capture (3C, 4C, and Hi-C) Molecular biology methods for studying chromatin looping and the three-dimensional structure of chromatin in vivo.

CRISPR/Cas9 A genome editing method derived from a prokaryotic immune system called CRISPR (Clustered Regularly Interspersed Palindromic Repeats). By delivering the RNA-guided Cas9 nuclease and a guide RNA into cells, specific DNA sequences could be targeted by Cas9 to generate double strand break.

Enhancer hijacking A process in cancer where the repositioning of inter- or intra-chromosomal enhancers to a close proximity of proto-oncogenes leads to the activation of these genes.

Global run-on sequencing (GRO-seq) An assay aiming to study the position and amount of nascent RNA associated with transcriptionally engaged RNA polymerase II (RNA Pol II) in a genome-wide fashion. This method is often used to investigate the promoter-proximal pausing of RNA Pol II in cells but it is also a sensitive method for detecting eRNA transcription.

Genome-wide association study (GWAS) An analysis method that compares single nucleotide polymorphisms (SNPs) in people with and without certain traits to help understand the relationship between genetic variants and diseases.

Single nucleotide polymorphism (SNP) A type of genetic variation which represents a difference in a single nucleotide located at a specific position in the genome. Although most SNPs have little effects on human health, some are highly associated with pathogenesis.

YEATS domain A protein domain of about 80–120 amino acids that binds acetylated lysine. Unlike the bromodomain, the YEATS domain is found in only a handful of proteins in humans.

Introduction

Enhancers are regulatory noncoding DNA sequences that can activate genes across a long distance. The coining of the term "enhancer" came from the finding that a segment of SV40 DNA could activate the β-globin gene 200-fold on a recombinant plasmid in HeLa cells. Subsequently, functional studies in model organisms including fruit-flies and mice demonstrated that enhancers were critical regulators of organismal development through spatiotemporal gene expression and specification of cell identity. Genome-wide studies, using recently developed next generation sequencing techniques, have revealed that enhancers are omnipresent in the human genome and harbor distinct epigenetic features. In addition, the capacity to carry out functional studies of enhancer function is growing enormously due to advancements in genome engineering using tools such as CRISPR/Cas9.

Transcriptional deregulation of proto-oncogenes and tumor suppressor genes is integral to the transition from healthy cells to malignancy as they acquire cancer hallmarks. An emerging theme is that mutation, aberrant methylation, or genomic rearrangement of enhancers drives transcription deregulation in human malignancies, suggesting that therapies addressing enhancer malfunction will benefit treatment regimens. In this article, we discuss the mechanisms of enhancer mediated transcription regulation and the different ways through which enhancer malfunction leads to cancer.

Enhancer Biology

Features of Enhancers

Enhancers such as those in the locus control region (LCR) of the human β globin gene are able to drive the expression of genes across a long distance. Located 60 kilobases (kb) upstream of the human β globin gene, the LCR of β globin contains five DNase I hypersensitive sites (HS), and controls the expression of the five genes in the β globin locus during embryonic development. Mutations in the LCR can lead to thalassemia, a disease characterized by insufficient hemoglobin function. In general, the temporal and spatial regulation of tissue specific genes is driven by enhancers. For example, the ordered expression of the homeotic (Hox) genes are controlled through a cohort of enhancers located upstream and downstream of their gene clusters during development. The

orientation of the enhancers does not seem to be critical for transcription activation but their localization in particular local chromatin environments can regulate their activity.

Traditionally, the identification and characterization of enhancers have been very challenging, as the noncoding DNA in which they typically reside takes up more than 97% of the human genome. The recent development of genome-wide sequencing techniques such as global run-on sequencing (GRO-seq) and chromatin immunoprecipitation sequencing (ChIP-seq) reveals that active enhancers produce transcripts called enhancer RNA (eRNA). Furthermore, deep sequencing indicates that enhancers are characterized by DNase I hypersensitivity and DNA hypomethylation.

Core histone modifications mark the activity of enhancers in specific cell types and tissues. Active enhancers are marked by mono-methylation at lysine 4 and acetylation at lysine 27 of histone H3 (H3K4me1 and H3K27ac), while poised enhancers are decorated with H3K4me1 and tri-methylation at lysine 27 of histone H3 (H3K27me3). Bioinformatics analyses of ChIP-seq studies have led to the identification of groups of closely spaced enhancers variably named transcriptional initiation platforms (TIPs), stretch enhancers, or more commonly super-enhancers. Super-enhancers are characterized by the enrichment of master transcription factors, a high level of occupancy of the Mediator complex, and they are comprised of $\sim$10 kb genomic regions on average. Super-enhancers are found to be associated with key cell identity genes but not housekeeping genes. Super-enhancers have been identified near oncogenes such as *c-Myc* and *TAL1* in cancer cells but not normal cells, suggesting that tumors acquire super-enhancers at oncogenes during pathogenesis. Super-enhancers overlap with many previously characterized LCRs, indicating that it is possible that these extended regulatory regions are clusters of regular enhancers. Do individual enhancers within a super-enhancer region have synergistic effects on nearby genes? To answer this question, the α-globin regulatory region, a typical super-enhancer, has been carefully analyzed. Individual deletion of the five enhancers in the α-globin super-enhancer demonstrated that the enhancer elements act in an additive manner. None of the five enhancers were solely responsible for the activation of the α-globin gene, and the effect of compound deletion was similar to that of the additive results of single-enhancer deletions. This suggests that individual enhancers in one super-enhancer region may work independently from each other. However, in other cases, enhancers in a cluster may work as "shadow enhancers," a term used to describe the discovery of seemingly functionally redundant enhancers in *Drosophila* for genes that already have known enhancers. In mammals, two "shadow enhancer" like regulatory elements are present in the HoxA gene cluster, with the removal of either enhancer having little effect whereas deletion of the two enhancers significantly impairs HoxA gene activation. It is likely that the "shadow enhancer" mechanism is frequently utilized to guarantee the well-regulated expression of important genes during development.

Enhancer-Promoter Communication

How do cis-regulatory elements located several 100 kb away from a promoter regulate their target genes? A series of experiments using DNA fluorescence in situ hybridization (FISH) and chromosome conformation capture (3C) derived techniques revealed that promoters and their regulatory elements form long-range loops that are correlated with transcription levels of the loop-associated genes. Enhancer-promoter loops can be formed prior to gene activation and remain stable in different development stages. Such preformed loops may be necessary for the genes to be turned on, however, it is difficult to experimentally prove the importance of loop formation as genetic perturbation of contact points or depleting cells of factors promoting looping are likely to have secondary effects. To solve this issue, Deng and colleagues artificially recruited GATA1 cofactor LDB1 to silent loci in erythroid cells and found forced looping could activate genes independently of GATA1, suggesting that enhancer-promoter communication per se drives transcription.

CTCF and cohesin are essential for the formation and stabilization of enhancer-promoter loops (**Fig. 1**). CTCF was initially characterized as an insulator binding factor that blocks the enhancer-promoter interaction if placed between the two elements. However, recent studies indicate that CTCF is also enriched at the boundaries of topologically associated domains (TADs), the building units of the three-dimensional (3D) chromatin structure, and over-represented at the border of sub-TAD regions, suggesting a possible role of CTCF in maintaining long-range interactions and genome architecture. Indeed, rapid depletion of CTCF resulted in a dramatic loss of chromatin loops. Interestingly, the orientation of CTCF binding sites (BSs) seem to be important for the formation of long-range loops, which are preferably formed between convergently oriented CTCF BSs.

Cohesin is a complex of proteins that forms a ring-like structure that is important for sister chromatid cohesion during mitosis, physically interacts with CTCF, and colocalizes with CTCF on the genome, suggesting that CTCF and cohesin cooperate to regulate long-range loops. As with CTCF, rapid depletion of cohesin subunits leads to dissolution of chromatin loops. Cohesin interacts with the Mediator complex and recruits Mediator to enhancers not bound by CTCF. Such recruitment is thought to maintain enhancer-promoter interactions and therefore is important for cell fate determination.

Transcription Factors Modulate Enhancer Activity

The activity of an enhancer is directly controlled by the transcription factors (TFs) and epigenetic modifiers bound to it. Therefore, the TFs' expression levels and binding patterns determine the tissue specific expression of developmental genes. However, enhancers harboring binding motifs of cell-type specific TFs may not be bound by these TFs, as the local chromatin environment, such as a TF binding site being embedded within a nucleosome, or residing within heterochromatin, can limit the accessibility of these proteins to enhancer elements. Unlike general TFs, pioneering TFs such as FoxA, GATA, PU.1, and Oct4 can directly bind their preferred sequences even when embedded within a nucleosome, and are therefore thought to play important roles in recruiting cofactors

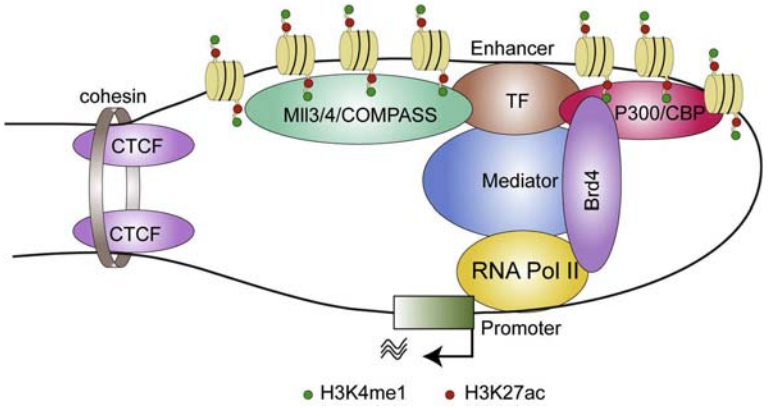

Fig. 1 A model of transcription activation through chromatin looping and enhancers. The interaction between CTCF and cohesin facilitates the formation of chromatin loops . Transcription factors (TF) such as pioneering TFs bind to enhancers and recruit epigenetic modifiers Mll3/4/COMPASS and P300/CBP, which deposit H3K4me1 and H3K27ac respectively at enhancer nucleosomes. Chromatin decompaction at enhancers and histone modifications allow the recruitment of the Mediator complex and chromatin binding proteins such as Brd4, which further assembles basic transcription machineries at the gene promoter and activates transcription.

to decompact chromatin, establish long-range interactions between promoters and enhancers, and activate specific gene expression patterns.

Enhancer-binding TFs regulate gene expression partly through their interactions with the Mediator complex, which is central to the transcription initiation and elongation of RNA polymerase II (RNA Pol II) (Fig. 1). The large protein complex has an impact on basic transcription machineries such as the preinitiation complex (PIC), RNA Pol II pausing factors, and transcription elongation factors. The 26 subunits of Mediator interact with various enhancer-binding TFs such as nuclear receptors, P53, and Myc. We refer readers to the review by Allen and Taatjes on the role of the Mediator complex in transcription regulation for further reading. Mediator appears to have an important role in enhancer-promoter interaction. The Mediator complex interacts with cohesin and colocalizes with cohesin at enhancers. Mediator and cohesin are more enriched at short-range chromatin loops smaller than 100 kb, suggesting that the formation of the short-range looping events depends on the Mediator complex. Depletion of Mediator component Med12 leads to a reduction of looping efficiency as indicated by FISH. It is worth noting that depletion of the Mediator complex would impair both enhancer activity and RNA Pol II initiation at promoters, thus whether the loss of promoter-enhancer interaction is driven by reduction in transcription activity or directly by Mediator depletion is unclear.

Epigenetic Enzymes and Enhancers

Enhancer-associated epigenetic marks are deposited by a specific group of enzymes. In *Drosophila* and mammals, Trr, Mll3, and Mll4 are the enzymes responsible for depositing H3K4me1 at enhancers (Fig. 1). In yeast, all three states of H3K4 methylation (H3K4me1, H3K4me2, and H3K4me3) are implemented by Set1, which is the catalytic core of the large histone methyltransferase complex named "COMplex of Proteins ASsociated with Set1" (COMPASS). COMPASS is also present in higher eukaryotes with three *Drosophila* homologs, named Set1, Trx, and Trr. In mammals, Set1A (KMT2F) and Set1B (KMT2G) are homologs of Drosophila Set1, Mll1 (KMT2A), and Mll2 (KMT2B) are homologs of Trx, and Mll3 (KMT2C) and Mll4 (KMT2D) are homologs of Trr. Genetically removing each COMPASS leads to embryonic lethality in mice, each with distinct phenotypes, suggesting that this family of H3K4 methyltransferases is critical, and that each member of the COMPASS family plays distinct roles during mammalian development. Such variability may be attributed, in part, to the functional differences of mammalian COMPASS in catalyzing H3K4 methylation in vivo.

Set1A/COMPASS and Set1B/COMPASS are mainly responsible for the bulk level of H3K4me2 and H3K4me3. Mll1/COMPASS contributes to promoter and intergenic H3K4me2 and H3K4me3 in a context dependent manner, while Mll2/COMPASS regulates H3K4me3 at a subset of enhancers and at promoters of a specific group of genes called bivalent genes in mouse embryonic stem cells (mESCs). Mll3/COMPASS and Mll4/COMPASS deposit H3K4me1 at enhancers in most cell types. A number of proteins such as TFIID, BPTF, and CHD1 are able to bind H3K4 methylation, however whether H3K4 methylation functions through these binding proteins is poorly studied. Intriguingly, several lines of evidence indicate that the COMPASS family of methyltransferases has both catalytic and noncatalytic functions. It is conceivable that large protein complexes like COMPASS may recruit factors required for enhancer activation. Indeed, the histone demethylase UTX, which targets H3K27 methylation, is a subunit of both Mll3 and Mll4 COMPASS. The simultaneous methylation at H3K4 and demethylation at H3K27 may have additive effects on opening chromatin and activating transcription. In addition, the H3K4 demethylases LSD1, KDM5C, and KDM5D are found to be localized at enhancers in specialized contexts, where they function to repress enhancers, thus providing an additional layer for regulating gene expression.

The active enhancer mark H3K27ac is catalyzed by the histone acetyltransferases P300 and CBP in vivo. Histone acetylation is thought to decompact chromatin as it neutralizes the negative charge of DNA and loosens histone DNA interactions to expose DNA to TFs and RNA Pol II. Apart from relaxing chromatin, histone acetylation can be recognized by bromodomain proteins and YEATS domain proteins, leading to a profound impact on downstream transcription regulation (Fig. 1). BRD4, one of the BET (bromodomain and extra terminal domain) family members, binds the transcription elongation complex P-TEFb to enhance transcription. The YEATS domain proteins AF9 and ENL are components of another transcription elongation complex named super elongation complex (SEC) that also contains P-TEFb. SEC is required for the rapid induction of transcription in response to environmental and developmental cues. Therefore, perturbing these binders of histone acetylation may help rectify the deregulated transcription program in cancer.

The poised enhancer mark of H3K27me3 is implemented by polycomb repressive complex 2 (PRC2). Initially characterized at bivalent promoters in mESCs, H3K27me3 is correlated with transcriptional repression. It has been proposed that the canonical PRC1 complex recognizes H3K27me3, modifies histone H2A with ubiquitination on lysine 119 (H2A119ub), and causes chromatin compaction as well as transcriptional silencing. Other evidence indicates that PRC2 recruitment and H3K27me3 placement may depend on a non-canonical PRC1 that lacks the H3K27me3 recognition module. In summary, although the functions of epigenetic marks at enhancers are not fully understood at this time, it is evident that the further elucidation of how epigenetic enzymes are recruited to enhancers will greatly facilitate the understanding of enhancer biology, and how its misregulation leads to transcription deregulation in cancer.

Long Noncoding RNAs and eRNAs in Modulating Enhancer Activity

Although only 3% of the human genome contains protein-coding sequences, many noncoding DNA regions are transcribed to generate so called noncoding RNA (ncRNA). Two types or noncoding RNAs, eRNA and long noncoding RNA (lncRNA), have been heavily studied in enhancer biology. eRNAs are unspliced, non-polyadenylated, and bidirectionally transcribed from enhancer DNA, while lncRNAs are spliced, polyadenylated, and transcribed from canonical promoters. Transcription from cis-regulatory regions, such as the LCRs of β globin, MHC class II, and human growth hormone (hGH), were discovered long before the era of next generation sequencing. Transcription from the hGH LCR is important as demonstrated by the insertion of a RNA Pol II termination element in the LCR leading to attenuation of transcription of its downstream gene. Genome-wide analysis of RNA Pol II ChIP-seq and RNA-seq data revealed that indeed Pol II resides on many enhancers throughout the genome and that eRNA production precedes the activation of the adjacent protein-coding gene, suggesting a potential instructive role of eRNA on the transcription of its target genes. Furthermore, depletion of eRNAs has been shown to lead to downregulation of expression of nearby genes in several different cases. Multiple models have been proposed to explain the mechanisms underlying the functions of eRNA, including the in *trans* model where eRNA recruits co-activators such as the Mediator complex to activate nearby genes, and the in *cis* model where eRNA traps transcription factors such as YY1 to the enhancer locus to keep chromatin accessible and active.

It is reported that there are over 58,000 lncRNA genes in the human genome. Most of the known functions of lncRNA are involved in nuclear structure, chromatin interactions, transcription regulation, and RNA processing. For the roles of lncRNA in normal biological processes and cancer, we refer readers to the review by Long et al. for further reading. In addition to the function of the lncRNA transcript, the lncRNA promoter-proximal and genic regions are often found to contain enhancer elements. The *cis* versus *trans* effects of lncRNAs are hard to discern as the transcription activity at the locus of a lncRNA gene may be required for the expression of nearby genes, while the lncRNA transcript could be dispensable, as has been shown for the *Lockd-Cdkn1b* locus, as well as the *Uph-Hand2* locus. Future studies that combine genome-wide screening and locus-specific studies, including deletion of genomic segments, forced induction of premature transcription termination, and targeted degradation of the transcript, will shed new light on the functions of lncRNAs and their genomic loci in transcription regulation.

Genetic Changes in Enhancers Lead to Cancer

Mutations such as point mutations, amplifications, deletions, insertions, and rearrangements of enhancer sequences have been associated with many types of cancer. Many of these mutations lead to misregulation of proto-oncogenes and tumor suppressor genes, which drive oncogenesis and tumor progression. Below, we discuss examples of these types of enhancer mutations in cancer.

Enhancer Hijacking

The first example of enhancer hijacking was described in Burkitt lymphoma where the proto- oncogene *c-Myc* on chromosome 8 is translocated near to an enhancer at the immunoglobulin heavy chain (IgH) locus on chromosome 14, resulting in the overexpression of *c-Myc*. Subsequently, similar translocation of the *Bcl2* gene proximal to the *IgH* enhancer have been reported by several groups, suggesting that the overexpression of proto-oncogenes by enhancer hijacking could be a general mechanism of lymphomagenesis. In recent years, enhancer hijacking has been observed in various types of cancers including medulloblastoma, neuroblastoma, leukemia, lung cancer, and colorectal cancer.

In general, genome rearrangements that lead to enhancer hijacking have two types of structure (Fig. 2): (1) interchromosomal translocations that juxtapose an enhancer to a proto-oncogene, such as the *Myc-IgH* translocation in Burkitt lymphoma, or the

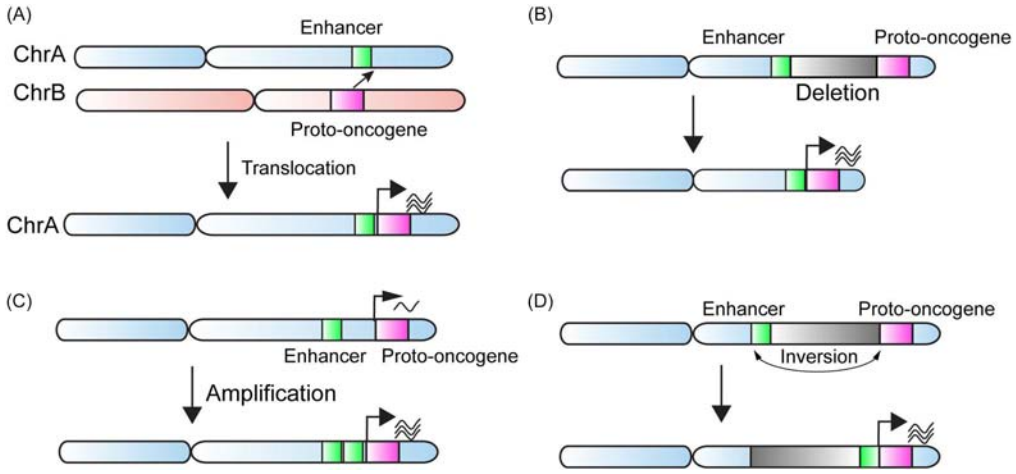

Fig. 2 Inter-chromosomal and intra-chromosomal rearrangements in cancer cells lead to enhancer hijacking. (A) Inter-chromosomal translocation juxtaposes an enhancer to a proto-oncogene and drives its expression. (B–D) Enhancers activate proto-oncogenes through intra-chromosomal deletion (B), amplification (C), and inversion (D).

Bcl2-IgH translocation in follicular lymphoma; (2) intrachromosomal rearrangements, including deletion, duplication, and inversion of genomic regions, which can bring an enhancer to the proximity of a proto-oncogene, as in the case of the *Gata2* enhancer translocation that activates *Evi1* to drive acute myeloid leukemia (AML), and the *Ddx31* enhancer's translocation to drive *Gfi1b* expression in medulloblastoma. Recent findings that CTCF binding sites are frequently mutated in cancer, and that somatic mutations in boundaries of topological domains are enriched in cancer, shed new light on how enhancers can be hijacked through the alteration of chromatin architecture. Hypermethylation at a CTCF BS in *IDH* mutant gliomas leads to loss of insulation between topological domains and aberrant activation of the proto-oncogene *PDGFRA* by a constitutive enhancer. In 293T cells, mutating CTCF BSs at domain boundaries found to be deleted in T-ALL, resulted in ectopic interactions between *TAL1* and *LMO2* genes and distal enhancers to increase the expression of these two proto-oncogenes. Interestingly, tandem duplication of the *IGF2* locus in colorectal cancer samples creates a de novo topological domain containing a super-enhancer with the duplicated *IGF2* gene, causing *IGF* upregulation. Both improvements in the detection of genome rearrangements and future studies to understand the mechanisms of the rearrangement, will advance our understanding of the degree to which enhancer hijacking contributes to oncogenesis.

Mutation of Enhancers in Cancer

Mutations in enhancer sequences include point mutations, insertions, small deletions, and focal amplifications. These mutations are found in many cancers and can result in upregulation of proto-oncogenes or inactivation of tumor suppressor genes. Point mutations in an enhancer may affect TF binding to the enhancer. cis-Regulatory regions of proto-oncogene *c-Myc* have been heavily studied, which has led to the identification of cancer-related single nucleotide polymorphisms (SNPs). For example, the SNP rs6983267, located within a TCF binding motif at an enhancer of *c-Myc*, has tight association with colorectal cancer and prostate cancer. The risk region loops to the *c-Myc* gene and it is highly occupied by TCF7L2, whose binding to the mutated enhancer is linked to the activation of *c-Myc* and carcinogenesis. At least 17 cancer-associated SNPs, including rs6983267, have been identified in the noncoding regions of the 8q24 locus. These SNPs in enhancers could play a role in regulating enhancer activity, chromatin looping, and c-Myc expression in colorectal cancer, breast cancer, ovarian cancer, prostate cancer, chronic lymphoblastic leukemia, and B-cell lymphoma. Apart from the 8q24 locus, the SNP rs339331, located at the *Rfx6* enhancer, strengthens the binding of HoxB13 to the enhancer in prostate cancer, leading to overexpression of Rfx6. SNP rs9383590, found at the *Esr1* enhancer, affects the recruitment of GATA3 to the enhancer in breast cancer, altering the activity of the enhancer as well as promoter-enhancer interactions. On the other hand, the SNP rs2168101, located within a super-enhancer of *Lmo1*, leads to abrogation of GATA3 binding and reduced H3K27ac levels at the super-enhancer, and is associated with decreased expression of *Lmo1* in neuroblastoma. These data suggest that a single mutation can modulate the activity of a large cluster of enhancers to drive oncogenesis. Although the improvement in genome-wide association studies (GWAS) has identified increasing numbers of risk related SNPs in noncoding regions, it is worth noting that whether these SNPs have causative effects on the expression of proto-oncogenes is largely unknown. Future studies that endogenously mutate these SNPs in cancer cells, for example, using CRISPR/Cas9, will elucidate the functional relevance between enhancer SNPs and cancer.

Similar to point mutations, small insertions in cis-regulatory elements have been found to be very frequent in various cancer types including T-ALL, breast cancer, neuroblastoma, lung cancer, colorectal cancer, melanoma, glioblastoma, B-cell lymphoma, and pancreatic cancer. Insertions could alter the activity of enhancers to activate proto-oncogenes, or reduce the expression of tumor suppressors. In T-cell acute lymphoblastic leukemia (T-ALL), genome-wide sequencing reveals a 2–18 bp insertion upstream of the

proto-oncogene *TAL1* in patient-derived cell lines. The insertion creates a binding site for the transcription factor MYB, thereby activating a super-enhancer that drives the overexpression of *TAL1*. Importantly, when the insertion is deleted by CRISPR/Cas9-guided genome engineering, H3K27ac at the super-enhancer was diminished and *TAL1* expression was drastically reduced. Similar insertions and regulatory mechanisms have been found at the *LMO2* super-enhancer, where MYB and TAL1 ectopically bind to the altered enhancers to drive expression of *LMO2* in T-ALL.

In addition to insertions that create novel TF binding sites, enhancers can be focally amplified such that their activity is significantly increased to upregulate a proto-oncogene. Focal amplifications have been found at different enhancers of *c-Myc* in AML, T-ALL, lung adenocarcinoma, and endometrial carcinoma. A statistical study of copy number variation in 29 tumor types found 55 focally amplified noncoding regions, six of which contain super-enhancers, including those regulating *Klf5*, *USP12*, *PARD6B*, and *c-Myc* expression. The amplified *c-Myc* super-enhancer has increased physical contact with *c-Myc*, indicating that focal amplification not only increases the activity of enhancers but also strengthens the enhancer-promoter communication. Further inhibition of enhancer activity by CRISPR inhibition and deletion of enhancer elements demonstrate that the transcription activity at the amplified enhancers is required to turn on the *c-Myc* gene.

It is noteworthy that although enhancers are frequently mutated or hijacked in tumor samples and cancer cell lines, there is not enough evidence to prove a causal relationship between enhancer mutation and oncogenesis. Enhancer mutations clearly contribute to the misregulation of oncogenes and tumor suppressor genes but their functions need to be further tested to determine which ones are true cancer drivers.

Epigenetic Alteration at Enhancers Leads to Cancer

Transcription factors and chromatin modifiers play important roles in enhancer malfunction as many of these molecules control a large cohort of enhancers and genes in specific cell types. In this section, we will focus on the major enhancer regulators and their roles in enhancer misregulation and oncogenesis.

Mll3 and Mll4/COMPASS in Cancer

Mll3 and Mll4, the major enzymes placing H3K4me1 at enhancers, are central for enhancer activity (refer to Sze and Shilatifard for further reading). Importantly, a cancer genome sequencing study by Lawrence et al. found that Mll3 and Mll4 are among the most frequently mutated genes across more than 20 cancer types. Human Mll3 is 4911 amino acids in length and Mll4 contains 5537 amino acids. Despite their large size, Mll3 and Mll4 only harbor a few known functional domains including PHD domains, which can bind histones or other proteins, and a SET domain which catalyzes H3K4 methylation. As the cancer-related mutations of Mll3 and Mll4 are distributed throughout the two proteins, it is likely that these methyltransferases lose their physiological functions during tumorigenesis either through loss of chromatin recruitment or loss of methyltransferase activity. Such loss-of-function may lead to enhancer deactivation, oncogenesis, and cancer progression. Observations in mice null for the SET domain of Mll3 support a tumor suppressor role of Mll3/COMPASS with half of the Mll3 SET-deleted mice developing urothelial tumors within 4 months after birth. Furthermore, the tumorigenic process is shortened in a p53 heterozygous background, suggesting that Mll3/COMPASS plays a role in DNA damage repair. Such a notion is consistent with the role of Mll4/COMPASS in maintaining genome stability as Mll4 mutant cells show increased DNA damage and mutation rates. The tumor suppressor role of Mll4/COMPASS has also been shown during mouse B cell development and in a mouse model of lymphomagenesis. Deletion of Mll4 early in B cell development leads to increased germinal center formation, upregulation of cell cycle regulators, and increased proliferation of B cells. In addition, depletion of Mll4 cooperates with Bcl2 to accelerate lymphomagenesis. Mechanistically, many of the follicular lymphoma and diffuse large B cell lymphoma-associated Mll4 mutations impair the methyltransferase activity of Mll4/COMPASS, and Mll4 deletion results in reduced H3K4 methylation at enhancers of tumor suppressor genes in B cell lymphoma.

Enhancer activation of tumor suppressor genes may be a general mechanism for the role of Mll3/Mll4/COMPASS in repressing cancer development; nevertheless, multiple lines of evidence suggest that these enhancer regulators play pro-cancer roles in different contexts. For example, Mll4 deletion leads to impairment of hematopoietic stem cells (HSCs) repopulation in vivo. Moreover, in contrast to its tumor suppressor role in B cell lymphoma, Santos et al. have found that Mll4 can facilitate Mll1-AF9 leukemia, with deletion of Mll4 leading to increased oxidative stress and DNA damage in the Mll1-AF9 leukemia cells, which led to increased myeloid differentiation. In breast cancer cells, gain-of-function (GOF) P53 mutant proteins bind to the promoters of Mll1 and Mll4 to activate their transcription, which leads to increased levels of H3K4 methylation and transcription of proto-oncogenes such as Hox genes. Interestingly, depletion of Mll1 or inhibition of Mll1 activity impairs the growth of P53 GOF breast cancer cells but has no effect in P53 WT breast cancer cells. Although the function of Mll4 in P53 GOF breast cancer cells was not investigated, the upregulation of Mll4 by GOF P53 mutants suggests that enhancer activation through Mll4 may participate in promoting the tumorigenicity of these cells. The oncogenic role of Mll4/COMPASS in ER-positive breast cancer cells was further demonstrated in the PI3K-AKT pathway, where AKT inhibits Mll4 activity, which leads to decreased ER recruitment. PI3Kα inhibition resulted in a more active Mll4, suggesting that the therapeutic efficacy of PI3Kα inhibitors in ER-positive breast cancer can be enhanced by Mll4 inhibition. Mll3 may also have an oncogenic role in breast cancer cells, as the pioneering TF FoxA1 can recruit Mll3 to activate enhancers in ER-positive breast cancer, while depletion of Mll3 results in loss of H3K4me1 at enhancers, reduced ER induced-gene expression, and decreased ER-triggered cell growth.

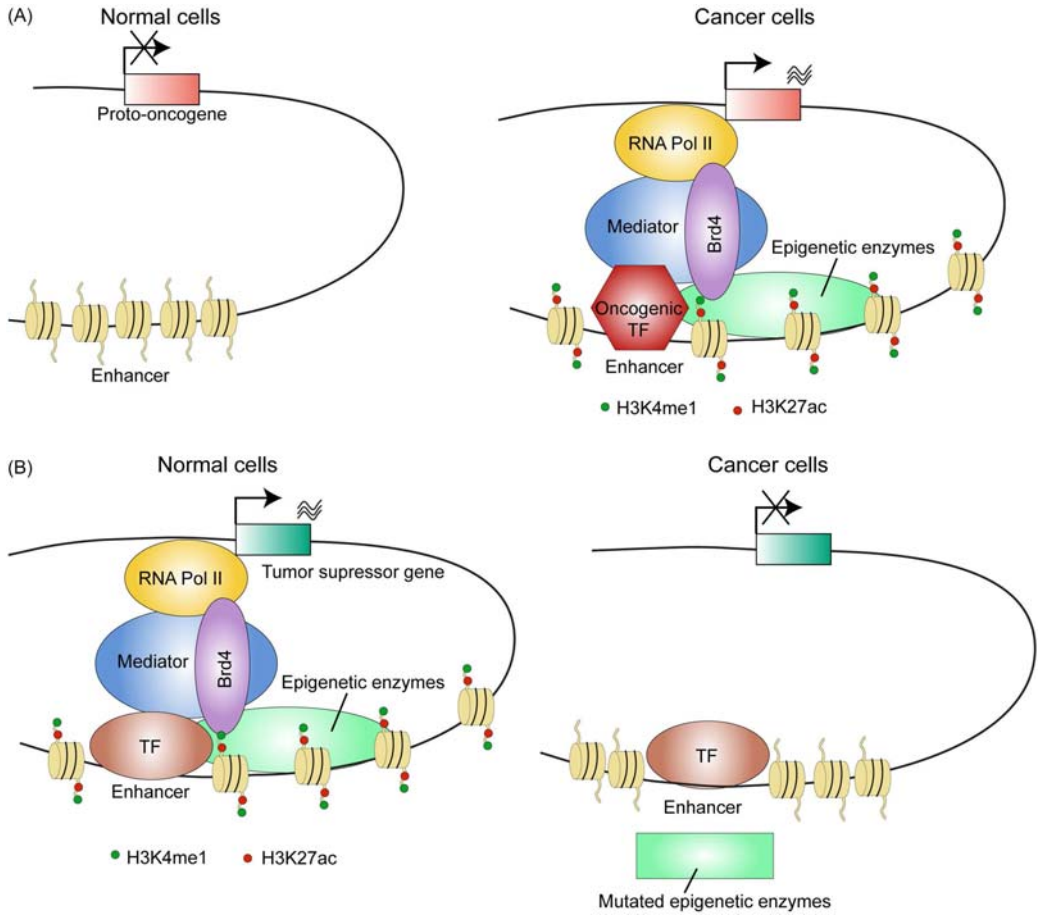

Fig. 3 Oncogenic and tumor suppressing roles of epigenetic enzymes. (A) A model of oncogenic functions of epigenetic modifiers. In cancer cells, oncogenic transcription factors could recruit epigenetic enzymes such as Mll3/4/COMPASS and P300/CBP to the enhancers of proto-oncogenes. Chromatin is decompacted, nucleosomes are modified with H3K4me1 and H3K27ac, and proto-oncogenes are activated. (B) A model of tumor suppressing functions of epigenetic modifiers. In cancer cells with loss-of-function mutations of Mll3/Mll4 or P300/CBP, the chromatin at enhancers of tumor suppressor genes cannot be modified and enhancers are not accessible to basic transcription machineries, leading to transcription repression of these genes.

What factors determine if Mll3/Mll4/COMPASS function as oncogenes or tumor suppressors? It is possible that Mll3 and Mll4 can acquire gain-of-function somatic mutations to drive enhancer activation of downstream proto-oncogenes or tumor suppressor genes. On the other hand, loss-of-function mutations in Mll3 and Mll4 may lead to deactivation of proto-oncogenes or tumor suppressor genes (Fig. 3). We suspect that the transcription factors that recruit Mll3/Mll4/COMPASS in specific cell types are critical for the functions of these important enhancer regulators. Future studies characterizing the consequence of COMPASS mutations in specific types of cancer in combination with studying the recruitment mechanisms of COMPASS will be helpful to solve this challenging question.

The Role of UTX in Cancer

UTX/KDM6A is one of the components of Mll3/Mll4/COMPASS, and it is also highly mutated in multiple cancers, including AML, T-ALL, colorectal cancer, glioblastoma, lung cancer, pancreatic cancer, bladder cancer, and renal carcinoma. The mutation rate of UTX in cancer is higher in its JmjC domain, which is the domain responsible for its demethylase activity, suggesting that the enzymatic function of UTX is important during tumorigenesis. Indeed, tumor-suppressor roles of UTX are supported by studies of fibroblast proliferation and hematopoiesis. Depletion of UTX causes increased proliferation in human fibroblasts, while UTX overexpression leads to a reduction in proliferation. Deletion of UTX, however, led to enlarged spleens, myeloid dysplasia, and chromosomal aberrations of bone marrow cells in female mice. Moreover, two recent studies from independent groups found that UTX acts as a tumor suppressor in T-ALL. Bone marrow transplantation of UTX-deleted and NOTCH1-overexpressing HSCs resulted in an increased leukemic blast number in peripheral blood, aggravated leukemia cell filtration, and downregulation of tumor suppressor genes. In a different NOTCH1-overexpressing transplantation model, depletion of UTX by shRNA accelerated T-ALL development and led to repression of tumor suppressors with increased H3K27me3 levels. Thus, like Mll3 and Mll4, the

function of UTX in cancer seems to be context dependent. Interestingly, UTX was reported to play an oncogenic role in TAL1-positive but not in TAL1-negative T-ALLs. It was further shown that inhibition of UTX activity by small molecule GSK-J4 kills TAL1-positive T-ALLs in vitro and in xenograft models. The pro-tumor roles of UTX was also observed in glioblastoma stem cells (GSCs) tolerant to receptor tyrosine kinase (RTK) inhibitors. In comparison with naive GSCs, these so called persister-like GSCs had upregulated levels of lysine demethylases and exhibited a genome-wide redistributed H3K27me3 profile. The growth rate of persister-like GSCs but not naive GSCs was drastically reduced by UTX deletion and H3K27 demethylase inhibition, highlighting an oncogenic role of UTX in persister-GSCs.

UTX protein gets degraded when Trr is depleted in *Drosophila* cells, indicating that the integrity of Trr/COMPASS is required for UTX stability and that it is possible that there is little free UTX outside of Trr/COMPASS. However, how much Trr/Mll3/Mll4/COMPASS function depends on UTX during animal development and tumorigenesis is largely unknown. The simultaneous methylation of H3K4 and demethylation of H3K27 by Mll3/Mll4/COMPASS may be required for enhancer activation, but since the function of UTX is dependent on Mll3 and Mll4, the loss-of-function (LOF) of UTX may not generate as severe phenotypes as LOF of Mll3 and Mll4. Indeed, Mll4 null mice die before E9.5, whereas many UTX null male mice are viable and fertile. It is worth noting that UTX has a male-specific paralog UTY, which lacks demethylase activity. Similar to UTX, UTY also co-immunoprecipitated with Rbbp5, indicating that UTY could be part of Mll3/Mll4/COMPASS. Interestingly, male mice null for both UTX and UTY die in utero, suggesting a non-catalytic function of UTX that remains elusive.

The Functions of P300/CBP and Acetylation Readers in Cancer

As pervasive histone acetyltransferases, P300 and CBP are implicated in almost every aspect of transcription. P300/CBP are highly mutated in bladder urothelial carcinoma, endometrial carcinoma, head and neck squamous cell carcinoma, and lung squamous cell carcinoma based on cancer genome sequencing studies. They are considered tumor suppressors based on a series of early studies. The first evidence of tumor suppressor functions for P300/CBP came from studies of Rubinstein-Taybi syndrome (RTS), a rare genetic disorder characterized by broad thumbs, toes, facial abnormalities, and mental retardation, which is likely driven by heterozygous LOF mutations in CBP or P300. Patients with RTS have an increased likelihood to develop cancer, including AML, non-Hodgkin lymphoma, and neuroblastoma, suggesting that P300/CBP LOF contributes to tumorigenesis. Furthermore, mice with CBP haploinsufficiency develop hematologic malignancies. Interestingly, loss of heterozygosity of CBP was observed in tumors dissected from CBP heterozygous mice, and chimeric CBP or P300 null mice develop hematological tumors that are exclusively derived from the CBP or P300 mutant cell population, further supporting a tumor suppressor role of CBP. It was later shown that reintroduction of WT P300 in cancer cell lines lacking normal P300 resulted in suppression of cell growth, while expressing P300 in P300 WT cells had a minimal effect on growth rate. The interactions of P300/CBP with tumor suppressing transcription factors such as BRCA1 may explain their anti-tumor role, as these tumor suppressing TFs could recruit P300/CBP to activate downstream tumor suppressor genes. Recent identification of inactivating mutations in P300/CBP in B-cell lymphoma and relapsed ALL further support their tumor suppressor roles. Indeed, CBP haploinsufficiency cooperates with BCL2 deregulation to drive B-cell lymphomagenesis in vivo, consistent with its LOF mutation in B-cell lymphoma.

Like Mll3/4 COMPASS, P300/CBP plays an oncogenic role in some contexts. Both the MOZ-CBP fusion protein produced by a recurrent translocation in the M4/M5 subtype of AML, and the Mll-CBP fusion protein found in therapy-related myeloproliferative disease, are potential oncogenic proteins which induce malignancy. In colorectal cancer cells after DNA damaging, P300 deletion leads to a more stable P53 level, increased apoptosis, and decreased tumor size in a xenograft model. In some cases, the activity of P300/CBP can be augmented by oncogenic proteins to activate other oncogenes. For instance, the kinase IKKα was reported to phosphorylate CBP and enhance its activity such that NFκB-mediated gene expression is increased while P53-mediated genes are repressed due to the preference of phosphorylated CBP's binding to NFκB over P53. In another scenario, P300 can acetylate the AML1-ETO fusion protein in acute myelogenous leukemia, which enhances the oncogenic capability of the fusion protein. Importantly, inhibition of P300/CBP activity can block AML1-ETO induced leukemogenesis, indicating an oncogenic function of P300 in this context.

In recent years, the role of lysine acetylation binding proteins such as the bromodomain and extra terminal (BET) domain family of proteins and YEATS domain containing proteins are intensively studied in cancer and other diseases. There are four members of BET domain family: BRD2, BRD3, BRD4, and BRDT. Except for BRDT which is expressed in testis, BRD2–4 are ubiquitously expressed and play a role in a series of biological processes including TF recruitment, chromatin remodeling, transcription elongation, and cell proliferation. In NUT midline carcinoma, a very aggressive squamous cell epithelia cancer, *BRD4* and sometimes *BRD3* are translocated to the gene *NUTM1* on chromosome 15, producing the NUT-BRD fusion protein, which drives cell growth, potentially through a feed-forward cycle involving recruitment of P300 to enhancers by the NUT part and binding to acetylated histones by the BRD4 portion.

RNAi screens revealed that BRD4 depletion inhibits AML growth and suppresses Myc regulated genes, indicating that Myc could be a downstream target of BRD4 in AML. Using a proteomic strategy, an independent study identified that BET proteins interact with the PAF complex (PAFc) and super elongation complex (SEC), both of which are involved in regulating transcription elongation, and found that inhibition of BET proteins can specifically inhibit the growth of Mll-fusion leukemia, potentially through suppressing the expression of *Bcl2*, *CDK6*, and *Myc*. In addition, Myc suppression by BRD4 inhibition has been observed in different types of cancer including multiple myeloma and lymphoma.

Recent genome-wide CRISPR screens identified that the YEATS domain protein ENL is required for the proliferation of Mll-fusion leukemia and the degradation of ENL attenuates the recruitment of SEC to oncogenes such as *Myb*, *Meis1*, *Hoxa10*, and *Myc*. Similarly, an independent study showed that ENL depletion reduces AML proliferation in vitro and in a xenograft model, which led to reduced RNA Pol II recruitment to oncogenes. Importantly, the interaction between the YEATS domain of ENL and histone acetylation is crucial for ENL's function. Furthermore, BET protein inhibition and mutation of the ENL YEATS domain had an additive effect on AML proliferation and progression, suggesting that the recruitment through binding acetylated histones is critical for tumor growth, and that inhibition of this binding could be further investigated for drug development in cancer therapy.

The Role of CTCF and Cohesin in Cancer

CTCF and cohesin are key to the establishment and/or maintenance of chromatin loops and TAD structure. The LOF of CTCF or cohesin in cancer may cause activation of oncogenes through altering chromatin loops (Fig. 4). CTCF is frequently mutated in endometrial carcinoma, head and neck squamous cell carcinoma, and breast cancer. More than half of the known missense CTCF mutations in cancer are located in its zinc fingers (ZFs), suggesting that the DNA binding capability of CTCF is impaired in cancers harboring these mutations. Tumor specific mutations in the ZF regions of CTCF disrupt CTCF's recognition toward its binding sites and result in the CTCF dependent transcription in reporter assays, suggesting a tumor suppressor role of CTCF. Moreover, overexpression of CTCF in B-cell lymphoma leads to apoptosis, downregulation of *c-Myc* oncogene, and upregulation of P53 target genes. CTCF's role in tumor suppression is further demonstrated in vivo using CTCF hemizygous knockout mice, which have a significantly higher chance to succumb to different types of cancer including uterine tumors, T cell lymphoma, and B cell lymphoma by 100 weeks of age in comparison to their WT counterparts. Furthermore, CTCF hemizygous knockout mice have accelerated development of Kras-driven lung cancer. The tumor suppressor function of CTCF may be due to its role in DNA double-strand break (DSB) repair as CTCF is recruited to the sites of DSB, and depletion of CTCF causes delayed kinetics of DSB repair. In summary, although CTCF's tumor suppressor role is well established, whether CTCF LOF leads to oncogenesis primarily through disrupting chromatin looping and chromatin structure is largely unknown.

Cohesin is frequently mutated in both solid tumors and hematological malignancies. Among all the cohesin complex subunits, the cohesin subunit STAG2 is the most mutated in tumors including bladder cancer, Ewing sarcoma, myelodysplastic syndrome (MDS), and AML. STAG2 mutations in glioblastoma, Ewing Sarcoma, and melanoma mostly lead to truncation of the protein. Depletion of STAG2 in the colorectal cancer cell line HCT116 leads to defects in sister chromatid cohesion while targeted correction of the endogenous mutant STAG2 in glioblastoma cells restores sister chromatid cohesion and reduces genome instability. The role of cohesin in leukemia has been reported by several independent studies. Viny and colleagues conditionally knocked out cohesin subunit Smc3 in mouse HSCs and found that Smc3 hemizygous knockout mice have increased HSC self-renewal and succumb to AML much earlier than WT mice when carrying the *Flt3-ITD* allele. Mullenders and colleagues generated shRNA mouse models in which cohesin subunits RAD21, STAG2, and SMC3 were respectively depleted and demonstrated that cohesin depletion skews HSC differentiation and leads to myeloproliferative neoplasms in aged animals. Mazumdar and colleagues took a different approach, making mutants of cohesin subunits found in AML and overexpressing them in leukemia cell lines and primary human hematopoietic stem and progenitor cells (HSPCs). They found that cohesin mutants have dominant negative functions as they impair myeloid differentiation, increase serial replating of human HSPCs, and enforce the expression of stem cell genes. All three studies found that chromatin accessibility was altered upon depletion of cohesin or expression of mutant cohesin subunits, suggesting that genome architecture may be altered by cohesin LOF in AML with cohesin mutations. On the other hand, Galeev et al. and Fisher et al. identified cohesin in an RNAi screen as a modifier of hematopoietic self-renewal and differentiation. Interestingly, depletion of Hoxa7 or Hoxa9 is able to restore the HSPC differentiation capability impaired by cohesin depletion, indicating that these

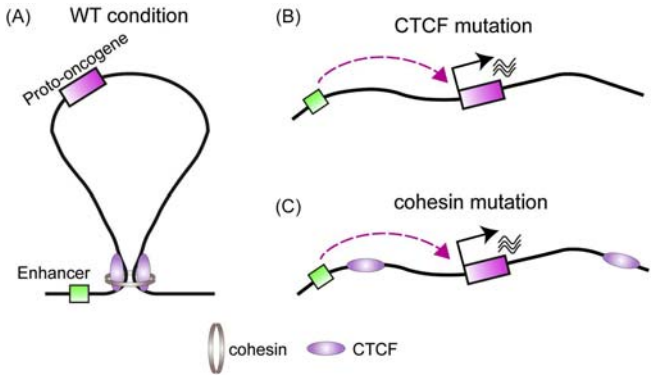

Fig. 4 Proto-oncogene activation through CTCF and cohesin loss-of-function. (A) A model showing that chromatin looping mediated by CTCF and cohesin blocks the communication between an enhancer and the promoter of a proto-oncogene in wildtype (WT) cells. (B and C) In cancer cells carrying loss-of-function mutations in CTCF (B) or cohesin (C), ectopic enhancer-promoter communication is established, which activates the proto-oncogene.

important AML oncogenes may be downstream of cohesin's regulation. Collectively, these findings demonstrate a tumor suppressor role for cohesin in solid and hematological malignancy.

Conclusions and Perspectives

Transcription deregulation is a common theme of cancer pathogenesis. Enhancer malfunction plays an essential role in gene misregulation of cancer cells. In this review, we discussed the malfunction of enhancers both in *cis* and in *trans*. Both mutations in enhancers and enhancer regulating proteins are frequently found in human cancer, suggesting that enhancer malfunction is one of the major drivers of oncogenesis and tumor progression. However, the functional relationship between the cancer-related mutations and oncogenesis is not clear and studies that focus on the roles of mutations are still lacking. Future studies using the CRISPR/Cas9 technique in cell lines and animals to create specific cancer-associated mutations will be very helpful to understand the functions of the mutated DNA sequences or mutant proteins in cancer.

Whether the oncogenic or tumor-suppressing role of enhancer-regulating epigenetic enzymes depends on the enzymatic activities remain largely unknown. For example, catalytic-independent regulation of enhancer activity by the H3K4 methyltransferase Mll3/Mll4/COMPASS has been shown in noncancer biological systems. The further dissection of catalytic-dependent and independent functions of chromatin modifiers on enhancer activation will be essential to understand the mechanisms of oncogenesis and to develop novel cancer therapies. Furthermore, the direct link between promoter-enhancer looping and regulators of chromatin architecture in cancer is not well established. CTCF and cohesin's tumor suppressor roles in cancer have been linked with DNA damage repair. Although deletions in CTCF/cohesin binding sites have an impact on chromatin architecture, the effects of CTCF and cohesin mutations on looping during carcinogenesis are not known. Hi-C and 4C-seq experiments in the mutant cell lines as well as the rapid depletion of these proteins using the auxin inducible degradation (AID) system will elucidate the causal relationship between chromatin looping and regulation of cancer associated genes and allow disambiguating loss of enhancer function due to cohesin mutation from DNA instability due to loss of sister chromatid cohesion.

It is noteworthy that enhancers may impact their target genes through basic transcription machineries during pathogenesis, as recent findings indicate that the pausing of RNA pol II at gene promoters may be modulated by their enhancers. Such a mechanism could be utilized by transcription factor binding at enhancers to regulate oncogenes or tumor-suppressor genes during cancer pathogenesis. Our understanding of enhancer malfunction in cancer prompts the development of novel therapies for cancer treatment. The BET inhibitor JQ1 has already been shown to suppress the growth of different malignancies including lung cancer, leukemia, neuroblastoma, melanoma, prostate cancer, breast cancer, and diffuse intrinsic pontine gliomas in mouse models. Similarly, a recently developed specific inhibitor of P300/CBP has been found to be effective in mouse models of hematological malignancies and prostate cancer. We believe that the generation of compounds that target other epigenetic modifiers such as Mll3/Mll4/COMPASS, UTX, and the histone acetylation binding protein ENL, will significantly advance the treatment of cancer.

Environmental and Occupational Exposures

Harvey Checkoway, University of California San Diego, La Jolla, CA, United States

Introduction

Many environmental exposures have been established as causes of human cancer. Some established examples are listed in Table 1. Early indications for potential carcinogenic effects are often case reports of unexpected, typically rare cancers among people with well-defined exposures, often among occupational groups. It should be noted that the term "environmental" in the chapter encompasses both the workplace and ambient general environment. The initial indications of cancer risks potentially related to environmental exposures have often been prompted by case reports, or clusters, of relatively rare cancers occurring among workers with characteristic exposures. Cancer clusters have also been reported from the general population whose environmental carcinogen exposures result from contaminated air, water, or food supplies. Classic examples of exposure/disease associations prompted by case reports are asbestos and mesothelioma, benzene and acute myeloid leukemia, and vinyl chloride and liver angiosarcoma among exposed workers. Case reports can then lead to epidemiologic studies that are designed to estimate the strength and specificity of associations in the population, dose-response gradients, and possible synergistic effects with other causes of the cancer under investigation. Epidemiologic studies of well-defined occupational groups are especially informative regarding cancer risks related to environmental exposures because the workplace typically represents the "high dose" setting. When there is consistent epidemiologic evidence derived from multiple studies examining an etiologic relation, public health agencies can undertake surveillance programs that identify new cases and measure exposure levels in workplaces and the general environment. Ultimately, regulatory agencies rely on epidemiologic evidence to set permissible exposure limits in the workplace and ambient environment.

The components involved in identify environmental carcinogens, starting with initial case reports, and culminating in setting exposure standards to prevent cancer are summarized in Fig. 1. It should be noted that the process includes contributions by clinicians, epidemiologists, environmental exposure scientists, toxicologists, biostatisticians, risk assessors, and policy makers.

Illustrative Examples

The following examples of environmental chemicals were chosen to illustrate the approaches for and concepts underlying recognition of carcinogenic potential from the epidemiologic perspective. Each of the chemicals has been classified by the International Agency of Research on Cancer [IARC] as a confirmed human carcinogen (category 1), although the strength of etiologic evidence varies by cancer site. Considerations of differences in sources of exposure, bio-persistence, and presumed carcinogenesis mechanisms also contribute to challenges in carcinogen characterization.

Formaldehyde

Formaldehyde is a simple one'carbon molecule that is produced commercially for use as a biocide, preservative, and basic chemical in the manufacture of common materials such as plastics, building materials, glues and fabrics, and many household and consumer products, including medicines, health and beauty aids. Formaldehyde is also a product of organic matter combustion. Formaldehyde is a widespread environmental exposure worldwide. Major exposure sources include some laboratories, indoor air (e.g., carpets), vehicle emissions, cigarette smoke, and workplaces manufacturing or using resins, various wood products (e.g. particle board), adhesives, textiles, and numerous other products. Inhalation is the predominant route of exposure to exogenous formaldehyde.

Table 1 Some established[a] environmental and occupational carcinogens

Agent	*Sources*	*Major cancer site(s)*
Arsenic	Smelters, mines, drinking water	Bladder, lung, skin
Asbestos	Mining, insulation	Lung, pleura, peritoneum
Benzene	Solvents, petroleum products	Leukemias, lymphomas
Dioxin	Herbicides	Multiple (promoter)
Formaldehyde	Foam insulation, embalming, tobacco smoke	Nasophayrnx, sinonasal, leukemias
Polychlorinated biphenyls	Insulation materials, flame retardants	Melanoma, non-Hodgkin lymphoma
Radon	Underground mines, tunnels	Lung
Silica	Mining, ceramics, construction	Lung
Vinyl chloride	Polyvinyl chloride manufacturing	Liver
Wood dust	Furniture making, lumber, construction	Sinonasal

[a]Classified by IARC as confirmed carcinogens (Category 1).

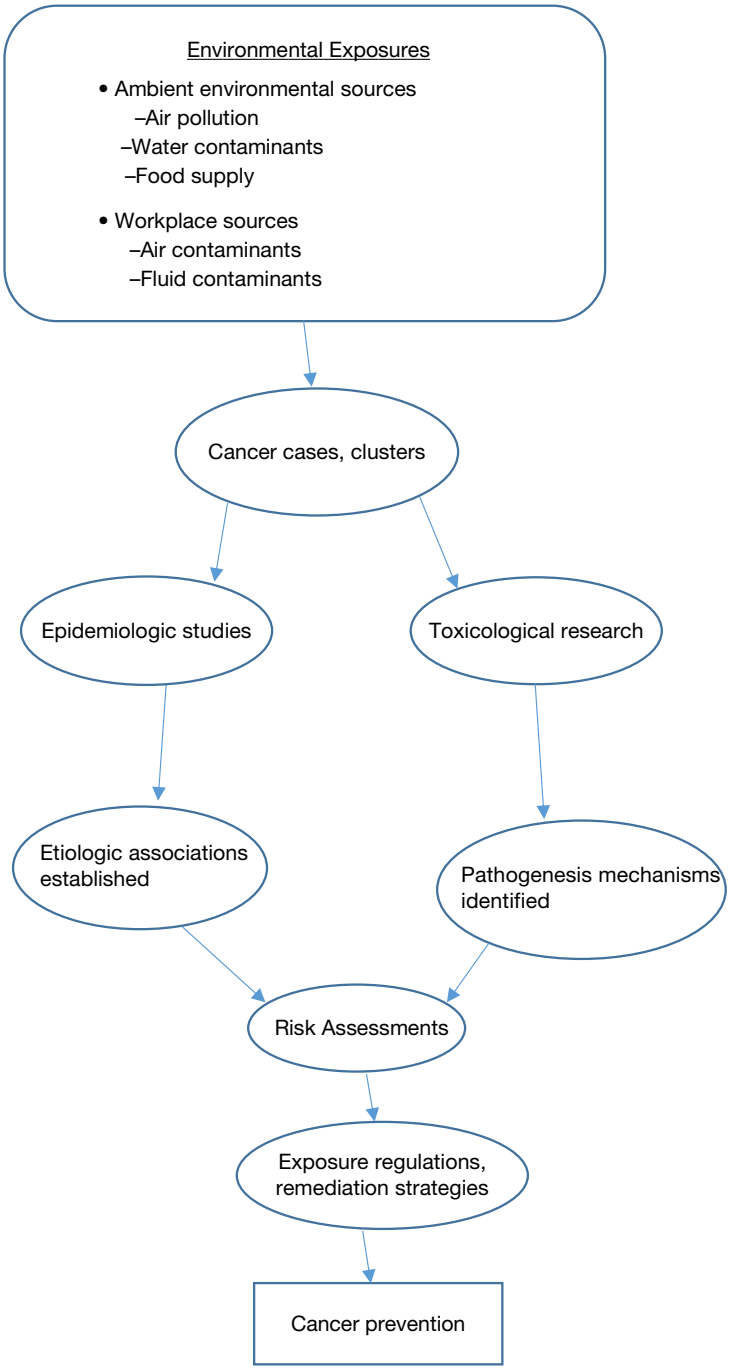

Fig. 1 Identification of environmental carcinogens and methods for prevention.

Concerns about the carcinogenicity of formaldehyde were prompted in the early 1980s by the induction of nasal tumors in rats exposed at high concentrations. As a consequence, the focus of early epidemiologic studies was on nasal and upper airway tract cancers, based on the understanding that formaldehyde is rapidly metabolized at the site of contact. There have also been numerous epidemiologic studies of associations with other malignancies, including the leukemias and lymphomas. IARC has classified formaldehyde as a confirmed (category 1) human carcinogen, based largely on evidence for etiologic associations with nasopharyngeal cancer and myeloid leukemia, malignancies that have very different sets of putative causes and pathogenesis mechanisms. The nasal upper airway passage is a primary initial target for inhaled formaldehyde, which strengthens arguments for biological plausibility for an etiologic relation with nasopharyngeal cancer. In contrast, findings from experimental toxicokinetic studies indicate that exogenous formaldehyde from environmental sources does not reach the bone marrow, which is the prime target site for the lymphohematopoietic malignancies.

Findings from an occupational cohort study of cancer mortality among over 25,000 workers in U.S. formaldehyde-exposed industries (e.g., urea formaldehyde foam insulation) conducted by the U.S. National Cancer Institute have been especially influential in establishing an association with myeloid leukemia and other lymphohematopoietic malignancies. The investigators conducted an occupational cohort mortality in which workers' historical exposures were reconstructed by linking occupational history data with a job-specific formaldehyde exposure matrix based on historical measurements taken in the workplaces. As shown in **Table 2**, a much stronger association with myeloid leukemia was detected for peak exposure than for cumulative exposure, which is the standard dose metric in epidemiologic research. Interpretation of the findings is therefore complicated because of the absence of an established carcinogenesis mechanism for peak formaldehyde exposure.

Wood Dust

Since the 1960s, there have been numerous case reports of nasal cancers among furniture workers and other occupational groups exposed to wood dust. Sinonasal adenocarcinoma has been identified as mostly strongly related nasal cancer to wood dust.

Reliable data on dose-response trends are limited in the epidemiologic literature, as few studies have generated quantitative wood dust exposure data based on industrial hygiene measurements for dose estimation. Moreover, the rarity of sinonasal cancer in most occupational cohorts has hindered dose-response estimation. A case-control study of adenocarcinoma nested in the German wood industry involved quantitative wood dust exposure estimation and a distinction between hard and soft wood exposure. The cases were identified from worker illness and injury claims among employees in wood-working industries, such as lumber preparation and furniture making. Controls were also wood working employees who had experienced work-related accidents. The dose-response findings are summarized in **Table 3**.

There are some suggestions associations with SNC risk varies by exposure to different types of wood dust, usually classified as "hard" or "soft" wood (IARC 2012). Comparing high vs. low level hard wood dust exposures in the aforementioned German case-control study yielded a strong association (Relative Risk = 3.98 [95% Confidence Interval 1.92–8.25]), whereas a seemingly "protective" effect was observed for high vs. low level soft wood dust exposure (Relative Risk = 0.34 [95% Confidence Interval: 0.17–0.65]).

In summary, exposure to wood dust has been convincingly linked epidemiologically to excess risk for SNC, especially of adenocarcinoma histology. It is reasonable to presume that there is an underlying dose-response etiologic relation that perhaps may differ

Table 2 Associations between cumulative and peak exposures to formaldehyde and myeloid leukemia mortality among U.S. formaldehyde products industry workers[a]

	No. deaths	*Relative risk (95% CI)*
Cumulative exposure (ppm[b]-years)

[c]Milligrams per cubic meter air.

by type of wood (e.g., soft vs. hard), and by source (e.g., furniture making, construction). However, sparse data on dose-response trends by type of wood and source can complicate causal attribution and standard setting.

Polycyclic Aromatic Hydrocarbons (PCBs)

Polycyclic aromatic hydrocarbons are bio-persistent compounds whose main commercial applications have been as coolants and insulating fluids in electrical transformers, waterproofing flame retardants, and plasticizers in paints and cements. Two hundred nine (209) PCB congeners have been identified, based on the extent and location of chlorination. From a carcinogenesis standpoint, PCB congener groupings have been developed to represent chemical structural and toxicological features: estrogenic, dioxin-like, immunotoxic, and induction of phenobarbital and cytochrome P450s.

PCB exposures occur in occupational settings, (e.g., electrical capacitor manufacturing), from contaminated air, soil or water, and from dietary sources (e.g., seafood). Exposures typically occur as mixtures of congeners. For logistical reasons, many epidemiologic studies have based exposure assessments on plasma concentrations, rather than concentrations measured in environmental media. Tissue concentrations in target organs (e.g., breast) have also been evaluated in relation to cancer risk in some studies. Physiological PCB concentrations change over time due to exposure variability and metabolism; consequently, repeated measures of PCBs would be most desirable epidemiologically. This has seldom been achievable, however. Instead, physiological concentrations are generally divided into pre- and post-diagnostic time intervals. It is logical to assume that pre-diagnostic concentrations are most relevant etiologically, as they should best reflect exposures prior to cancer occurrence and would not be influenced by the disease process.

It should be evident from the foregoing description of PCBs that assessing epidemiologic evidence for carcinogenicity is complicated by variability in chemical features, routes of exposure, and presumed toxicological mechanisms.

IARC (2016) concluded that PCBs can cause malignant melanoma and non-Hodgkin lymphoma, and that there is suggestive evidence for causation of breast and prostate cancers. The following two examples of epidemiologic studies of malignant melanoma are illustrative of epidemiologic studies whose findings provided mixed evidence for an etiologic association.

Gallagher et al. (2011) conducted a population-based case-control study in British Columbia, Canada that included 80 cases and 310 controls matched on age and gender. PCB exposures were based on lipid-adjusted plasma measurements of 14 congeners. As shown in Table 4, there was a strong dose-response trend for total PCB levels, adjusted for potential confounders, including total recreational sun exposure. This study had the advantage of assessing exposures from multiple sources, as indicated by plasma concentrations. However, the plasma samples were post-diagnostic and specific sources of PCB exposure and their relative contributions could not be determined.

A cohort mortality study conducted by the U.S. National Institute for Occupational Safety and Health addressed risks for multiple cancer outcomes in relation to PCB exposures (Ruder et al. 2014). The cohort included nearly 25,00 workers from three electrical capacitor plants. PCB exposures were assessed by a job-exposure matrix that classified jobs according to semi-quantitative estimates of inhalation exposure. The results, summarized in Table 4, do not indicate a dose-response relation, and in fact, might be construed as evidence for a "protective" effect of PCB exposures. Data interpretation is limited, however, by the absence of direct quantitative exposure measurements, and reliance on mortality, rather than incidence of malignant melanoma (Table 5).

Prospective Vision

Identifying etiologic relations between environmental exposures and malignant diseases is a critical first step in cancer prevention in the population. The strongest evidence is obtained when the cancer of concern has few or no other established causal factors, such as the case of asbestos and mesothelioma, or when cancer rates increase dramatically after introduction of an environmental exposure. A well-known example of the latter is arsenic contamination of drinking water in Bangladesh resulting from greatly increased installation of residential tube wells for drinking water that led to sharply elevated rates of cancers of the skin, bladder, kidney, and lung. More typical are situations where cancer hazards related to environmental exposures become evident over time, as epidemiologic and toxicological research develops.

[c]Standardized rate ratio (95% Confidence Interval).

Ideally, decisions regarding control or elimination of exposures to an environmental agent should be based on consistently strong evidence derived from high-quality research. Challenges that epidemiologists often confront are limitations of exposure assessment for the agent of concern and co-occurring carcinogens that may be confounders. By way of illustration, characterizing PCB exposures is complicated for several reasons. There are 209 PCB congeners with various toxicity features, and there are multiple sources of exposure that include the workplace, ambient environment, and the food chain. Blood or target tissue PCB concentrations can vary greatly over time, and seldom indicate contributing exposure sources. Reliance on exposure surrogates, such as occupational, residential, or dietary history, due to the absence of personal exposure measurement data is a major limitation in many epidemiologic studies of environmental carcinogens.

Case reports and cancer clusters will likely remain the primary triggers for in-depth epidemiologic investigations and disease surveillance. Updating existing epidemiologic databases will also be extremely valuable to determine whether cancer risks have been affected by temporal changes in exposure, or by replacement of an established carcinogen with a presumed safer agent. Future research will clearly benefit by incorporation of improved methods for measuring environmental exposures at the individual level, advances in techniques to link exposure data with population-based cancer incidence data, such as Geographical Information System modeling, and increased collaboration with toxicologists and other experimental scientists engaged in research to predict carcinogenesis pathways. Moreover, further development of biomarkers of genetic variability, including DNA polymorphisms and blood proteins indicative of pre-clinical carcinogenesis, will be valuable for identifying subgroups of the population who are especially susceptible to cancers resulting from environmental exposures.

Environmental Exposures and Epigenetic Perturbations

Igor P Pogribny, National Center for Toxicological Research, Jefferson, AR, United States

Glossary

Carcinogenesis A complex multistep process of the turning a normal cell into the cancer cell.

Epigenetics The study of phenomena and mechanisms that cause chromosome-bound changes in gene expression that do not involve changes in DNA sequence.

Nucleosome The fundamental unit of chromatin that consists of 146 base pairs of DNA coiled in two superhelical turns around an octamer of core histones.

DNA methylation The addition of methyl groups from the universal methyl group donor *S*-adenosyl-L-methionine to carbon five on cytosine residues and results in the formation of 5-methylcytosine in DNA.

Histone modification A posttranslational covalent modification, for example, methylation, acetylation, phosphorylation, ubiquitination, sumoylation, and ADP-ribosylation, of the amino-terminal tails of histones.

Genotoxic carcinogens Agents that interact with DNA, either directly or after metabolic activation, causing the formation of covalent DNA adducts as part of their mechanism of carcinogenicity

Nongenotoxic carcinogens A diverse group of carcinogens that cause cancer by mechanisms other than directly damaging DNA.

TOPOIIα DNA topoisomerase II

Cancer is a disease characterized by the acquisition of multiple heritable abnormal cellular phenotypes, including persistent uncontrolled cell proliferation, resistance to cell death, deregulated metabolism, compromised immune response, and genomic instability, driven by mutations from exogenous and endogenous damage to genomic DNA. Because of that, traditionally, the research on cancer has been focused on investigating the role of DNA damage and genetic aberrations in cancer causation and progression. However, after many years of extensive research it is clear that DNA damage is "necessary but not sufficient" for tumor induction and additional factors contribute to carcinogenesis. One of these factors associated with the carcinogenic process is epigenetic alterations, research on which has greatly evolved over the recent years, despite the fact that the importance of epigenetic component in the carcinogenesis was suggested almost a half of a century ago. Currently, it is well-established that cancer is a genetic and epigenetic disease, and both genetic and epigenetic alterations cooperate and complement each other at every stage of cancer development.

Brief Overview of Epigenetics

The term "epigenetics" defines the phenomena and mechanisms that cause chromosome-bound changes in gene expression without changes in the primary DNA sequence. The epigenetic phenomena include cytosine DNA methylation, posttranslational modifications of histone proteins, and nucleosome positioning along DNA.

In the mammalian genome, negatively charged linear DNA is compacted into chromatin, a complex of DNA and proteins, and assembled into chromosomes (Fig. 1). The fundamental repeating units of chromatin are nucleosomes. Approximately 80% of the genomic DNA is packaged into nucleosomes and 20% is associated with the short-linker regions connecting neighboring nucleosomes. Nucleosome consists of 146 base pairs of DNA coiled in two superhelical turns around an octamer of core histones formed by two copies of each histone monomers H2A, H2B, H3, and H4·Histones are evolutionary conserved proteins that consist of a globular carboxy-terminal domain critical to nucleosome formation and a positively charged amino-terminal tail that can bind tightly to DNA.

The chromatin structure is dynamic and subject to chemical modifications that can occur anywhere in the genome. Cytosine DNA methylation, which is the addition of methyl groups from the universal methyl group donor *S*-adenosyl-L-methionine (SAM) to carbon five on cytosine residues and results in the formation of 5-methylcytosine (5-meC) in DNA, is a major and much-studied epigenetic modification. This reaction is mediated by a family of DNA methyltransferases (DNMTs), which includes the maintenance DNA methyltransferase DNMT1 and two de novo DNA methyltransferases, DNMT3A and DNMT3B.

In the genome of somatic mammalian cells, methylation of DNA occurs almost exclusively at CpG dinucleotides, and approximately 70%–90% of them are methylated; however, the distribution of the methylated CpG sequences across the genome is uneven (Fig. 1). In normal cells, most of the methylated CpG dinucleotides are located in repetitive sequences and in exonic, intronic, and intergenic unique sequences, while the unmethylated high-density CpG sites are primarily found in gene promoters. Methylation of DNA is a dynamic and well-balanced process between DNA methylation and DNA demethylation reactions. DNA methylation is initiated and established by de novo DNA methyltransferases DNMT3A and DNMT3B and maintained during DNA replication by the maintenance DNA methyltransferase DNMT1. DNA demethylation is achieved through two different mechanisms: (i) a "passive" replication-dependent mechanism during cell division and (ii) an "active" replication-independent mechanism. During active DNA demethylation, a family of ten-eleven-translocation (TET) proteins sequentially oxidizes 5-meC to

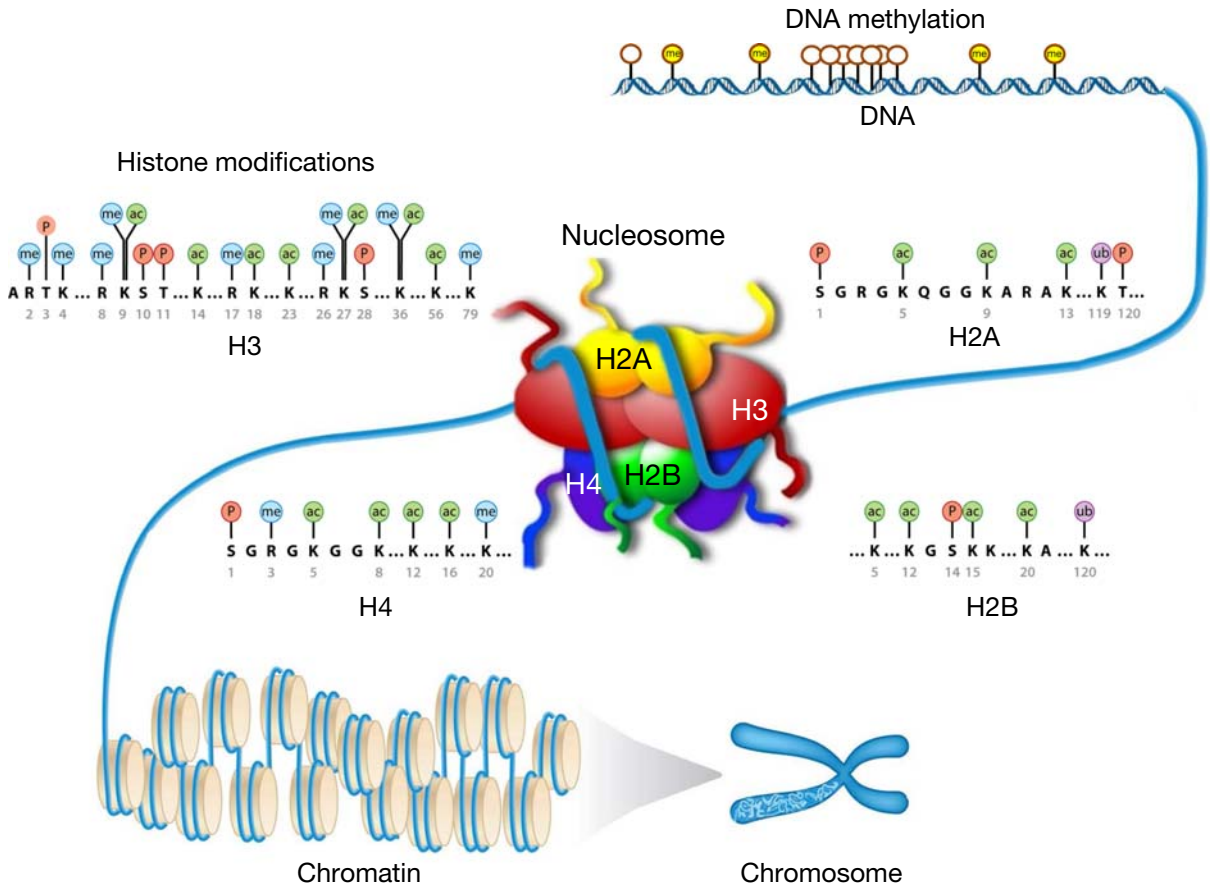

Fig. 1 The structure of the mammalian epigenome. Epigenome, a complex regulatory network that modulates the chromatin structure and the function of the genome, consists of chemical modifications to the DNA and histone proteins. The changes in the epigenome result in alterations in the structure of chromatin and altered expression of genetic information.

5-hydroxymethylcytosine (5-hmeC) and 5-carboxycytosine, which are later removed and replaced by cytosine via base excision DNA repair mechanism.

A second major epigenetic mechanism, which is tightly and interdependently connected to cytosine DNA methylation, is post-translational covalent modifications of the amino-terminal tails of histones. This includes methylation, acetylation, phosphorylation, ubiquitination, sumoylation, and ADP-ribosylation. Multiple interdependent histone modifications may occur on a given histone tail (Fig. 1). These histone modifications are established by "writers" (e.g., histone acetylases, methylases, and phosphorylases) that introduce a chemical modification, interpreted by "readers", proteins that bind specifically to a modified histone (e.g., bromodomains and chromodomains), and removed by "erasers" (e.g., histone deacetylases, demethylases, and phosphatases), which remove a chemical modification from histone proteins.

The primary function of cytosine DNA methylation and histone modifications is to establish the defense of the genome by controlling the accurate chromatin structure and transcription. DNA methylation occurs, mainly, but not exclusively, at regulatory regions functions as a transcriptional "OFF-ON" switch. The occurrence of DNA methylation at unmethylated CpG sites inhibits transcription, whereas demethylation of methylated CpG sequences activates transcription. In contrast, various types of modifications either on the same (e.g., trimethylation and acetylation at lysine residue 27 of histone 3) or different histone amino-terminal tails (e.g., trimethylation at lysine residue 4 of histone 3 and trimethylation at lysine residue 20 of histone 4), or the same type of modification at different amino acid residues on the same histone amino-terminal tail (e.g., trimethylation at lysine residues 4 and 27 of histone 3), have different effects on gene expression. For example, while trimethylation of lysine residues 4 on histone 3 is associated with active gene transcription, trimethylation of lysine 27 at the same histone amino-terminal tail is associated transcriptional silencing.

Well-balanced and tightly regulated epigenetic mechanisms are essential for the maintenance of normal cell homeostasis, normal cell functioning, and, especially, for proper control of the expression of genetic information. The disruption of this fine balance is one of the key events associated with carcinogenesis.

Epigenetic Alterations Induced by Carcinogen Exposure

All carcinogenic agents can be classified based on the mechanism of cancer causation as genotoxic or nongenotoxic carcinogens. Genotoxic carcinogens are agents that interact with DNA to cause damage to DNA or form covalent DNA adducts that result in mutations and genetic aberrations. In contrast, nongenotoxic carcinogens are agents that cause tumor formation by mechanisms other than direct damage to DNA. Despite the different mechanisms of action, evidence suggests that exposure to genotoxic and nongenotoxic carcinogens can alter the cellular epigenome. A link between epigenome alterations induced by environmental carcinogens and tumor development may be related to (i) major exposure-related cancer-specific epigenetic abnormalities, the consequences of which can be observed in the resulting tumors, and (ii) the fact that carcinogen-induced epigenetic perturbations may create an environment susceptible to cancer-prone mutations in the cells.

Table 1 lists the examples of major epigenetic alterations induced by well-known chemical and physical environmental agents classified as Group 1, "a known human carcinogen" or Group 2B, "a possible human carcinogen", by the International Agency for Research on Cancer (IARC). Direct evidence for the carcinogenicity of these agents was obtained in epidemiological and experimental studies.

Epigenetic Effects of Environmental and Occupational Carcinogens

Benzene

Benzene is a natural constituent of crude oil and a "high production volume" industrial chemical. Wide usage of benzene in a variety of industries, including the production of petrochemicals, and its presence as a common component of vehicle exhaust are public health concerns worldwide. Exposure to benzene has been associated with the development of acute myeloid and chronic lymphocytic leukemia driven by genotoxic and epigenotoxic abnormalities, including noticeable changes in DNA methylation. Specifically, exposure to benzene at low concentrations was linked to reduced 5-meC levels at repetitive DNA elements and demethylation of the melanoma antigen family A, 1 (*MAGEA1*) gene in humans. On the other hand, benzene-induced genome instability may be the result of compromised DNA repair caused by epigenetically mediated inhibition of DNA repair genes, including the poly (ADP-ribose) polymerase 1 (*PARP-1*), the excision repair cross-complementation group 3 (*ERCC3*) genes, and DNA topoisomerase II (*TOPOIIα*).

Benzo[α]pyrene

Benzo[*a*]pyrene, a representative polycyclic aromatic hydrocarbon, is one of the human genotoxic carcinogens (IARC Group 1) showing tumorigenic potential in virtually all in vivo experimental animal model systems. The carcinogenic activity of benzo[*a*]pyrene is associated with an induction of tightly interconnected genotoxic and nongenotoxic epigenetic alterations. In particular, exposure to benzo[*a*]pyrene results in extensive and selective formation of anti-7β, 8α-dihydroxy-9α,10α-epoxy-7,8,9,10-tetrahydrobenzo[*a*]pyrene (BPDE) adducts at the major hot-spot mutation codons 157, 248, and 273 in the human tumor suppressor *P53* gene, and at codon 14 in human *KRAS* oncogene. CpG methylation at these codons greatly increases the formation of the aforementioned genotoxic benzo[*a*]pyrene-DNA adducts.

Furthermore, the presence of BPDE-DNA adducts affects global and gene-specific DNA methylation by impairing the functioning of DNA methyltransferases. As a consequence, hypermethylation of critical cancer-related cyclin-dependent kinase inhibitor 2A (*CDKN2A*; $p16^{INK4A}$), retinoic acid receptor β_2 ($RAR\beta_2$), hypermethylated in cancer 1 (*HIC1*), and glutathione-*S*-transferase genes are frequently detected upon benzo[*a*]pyrene exposure.

1,3-Butadiene

1,3-Butadiene, one of the most common representatives of conjugated genotoxic dienes, is a "high-production-volume" chemical and ubiquitous environmental pollutant. 1,3-Butadiene is human genotoxic carcinogen (IARC Group 1). The major mechanism of 1,3-butadiene carcinogenicity is associated with the formation of DNA adducts, mainly N7-(2,3,4-trihydroxybut-1-yl)guanine and 1,4-bis-(guan-7-yl)-2,3-butanediol crosslinks, and protein adducts. Similar to other classic genotoxic carcinogenesis models, the formation of DNA adducts is necessary, but not sufficient to cause the development of cancer. Several experimental studies have established the importance of an epigenotoxic component, in addition to a genotoxic component, in 1,3-butadiene carcinogenicity. Specifically, exposure to 1,3-butadiene caused loss of global cytosine DNA methylation in the lung and liver, the two main target organs for tumor development induced by exposure to 1,3-butadiene. Additionally, exposure to 1,3-butadiene resulted in a reduction in trimethylation of histone H3 at lysine 9 and lysine 27 and histone H4 at lysine 20 in the liver and deacetylation of histone H3 at lysine 56 and histone H4 at lysine 16 in the lung. The presence of these epigenetic abnormalities has been reported in several types of human cancer.

Table 1 Environmental carcinogens and epigenetic alterations.

		Epigenetic alterations	
Carcinogen	*IARC carcinogen classification*	*DNA methylation*	*Histone modifications*
Genotoxic carcinogens			
Aflatoxin B1 	Group 1	*Hypomethylation*: genomic *Hypermethylation*: *MGMT, CDKN2A, RASSF1A*	*Increased:* H3S10ph *Reduced*: H3K9ac
Benzo[*a*]pyrene 	Group 1	*Hypermethylation*: *CDKN2A, RAR* β_2*, HIC1*	
1,3-Butadiene 	Group 1	*Hypomethylation*: genomic	*Reduced*: H3K9me3, H3K27me3, H4K20me3, H3K56ac, H4K16ac
Nicotine-derived nitrosamine ketone 	Group 1	*Hypermethylation*: *DAPK, CDKN2A, RAR* β*, GATA2, RUNX3, LOX*	
Tamoxifen 	Group 1	*Hypomethylation*: genomic, LINE-1, *PAX2* *Hypermethylation*: *MGMT*	*Reduced*: H4K20me3
Ultraviolet radiation	Group 1	*Hypomethylation*: genomic *Hypermethylation*: *CDKN2A, RASSF1A, CDH1*	
Nongenotoxic carcinogens			
Inorganic arsenic	Group 1	*Hypomethylation*: genomic *Hypermethylation*: *P53, CDKN2A, RASSF1A, DAPK*	*Increased:* H3K9me2, H3S10ph *Reduced*: H4K16ac
Furan 	Group 2B	*Hypomethylation*: genomic *Hypermethylation*: *CDKN2A, RASSF1A, FOXE1*	*Increased:* H3K9me3, H3K27me3 *Reduced*: H3K9ac, H3K27ac, H3K56ac
Methapyrilene 		*Hypomethylation*: genomic	*Reduced*: H3K9ac
Phenobarbital 	Group 2B	*Hypermethylation*: region-specific *Hypomethylation*: genomic	

Nicotine-Derived Nitrosamine Ketone

Nicotine-derived nitrosamine ketone (4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone; NNK) is a potent tobacco human genotoxic lung carcinogen (IARC Group 1). The molecular mechanisms of NNK-induced lung tumorigenesis are associated with genotoxic and epigenotoxic events. The major epigenetic alteration induced by NNK exposure is hypermethylation of the promoter region of a number of tumor suppressor and cancer-related genes, including the death-associated protein (DAP)-kinase (*DAPK*), *CDKNA2*, *RARβ*, GATA binding protein 2 (*GATA2*), runt-related transcription factor-3 (*RUNX3*), and lysyl oxidase (*LOX*) genes. Importantly, NNK induces unique promoter hypermethylation signatures in the *RAR-beta* and *RUNX3* genes that can differentiate lung tumors associated with NNK exposure from spontaneous tumors or tumors induced by other carcinogens. The underlying molecular mechanisms behind NNK-induced tumor suppressor gene promoter hypermethylation are associated with (i) NNK-induced accumulation of the DNMT1 in the nucleus, and (ii) enhanced binding of DNMT1 to promoter regions of the tumor suppressor genes.

Arsenic

Inorganic arsenic is one of the most common elements in the Earth's crust and an abundant environmental contaminant. The primary sources of human exposure to arsenic include contaminated food and drinking water. Inorganic arsenic was one of the earliest identified human carcinogens (IARC Group 1). Chronic exposure to arsenic may cause the development of skin, lung, bladder, and liver cancer. The molecular mechanisms of arsenic carcinogenicity include, but are not limited to, the induction of oxidative stress, chromosomal aberrations, disruption of signaling pathways, and epigenetic alterations. Arsenic-induced epigenetic dysregulation contributing to its carcinogenicity consists of pronounced alterations in cytosine DNA methylation and histone modifications, among which cytosine demethylation of DNA is the most prominent and consistent finding. This is evidenced by paralleling the extent of genome-wide DNA demethylation and malignant cell transformation documented in a number of independent in vitro and in vivo studies. Additionally, an extensive amount of data has demonstrated region-specific DNA demethylation (e.g., demethylation of repetitive elements, oncogenes, and cancer-related genes) during arsenic-induced malignant cell transformation in vitro and arsenic-induced tumorigenesis in vivo.

The main mechanisms of DNA demethylation in response to arsenic exposure may be attributed to (i) a reduced cellular availability of SAM because of its absolute requirement for the biomethylation of inorganic arsenic; (ii) induction of oxidative stress and oxidative damage to DNA that severely compromises the ability of DNA methyltransferases to methylate target cytosines; (iii) activation of DNA repair pathways that promote active demethylation of DNA; and (iv) downregulation of DNA methyltransferases.

In addition to global and gene-specific DNA hypomethylation, inorganic arsenic exposure causes methylation-induced transcriptional silencing in a number of tumor suppressor genes and cancer-related genes, including *P53*, *CDKN2A*, Ras association domain family member 1(*RASSF1A*), and *DAPK*.

Aberrations in posttranslational global and gene-specific histone modifications are additional epigenetic events associated with arsenic carcinogenicity. A number of independent studies have documented that arsenic induces higher levels of dimethylation of histone H3 at lysines 9, phosphorylation of histone H3 serine 10, and deacetylation of histone H4 lysine 16.

Ultraviolet Radiation

Exposure to ultraviolet (UV) radiation, a human Group 1 carcinogen and one of the main constituents of natural sunlight, is the main environmental etiological risk factor for the development of basal cell carcinoma, cutaneous squamous cell carcinoma, and melanoma in humans. Ultraviolet irradiation directly damages DNA, causing the formation of cyclobutane pyrimidine dimers and pyrimidine (6–4) pyrimidone photoproducts. Cyclobutane pyrimidine dimers specifically are responsible for the vast majority of C → T mutations induced by UV exposure. The underlying mechanism of ultraviolet radiation carcinogenicity consists of tightly and interdependently connected genotoxic and epigenotoxic components. First, similar to benzo[*a*]pyrene, the cyclobutane pyrimidine dimers are preferentially formed in DNA at dipyrimidine with methylated cytosines. Second, damage to DNA induced by ultraviolet radiation exposure causes a broad range of epigenotoxic alterations, including abnormalities in DNA methylation and histone modifications. One of the major epigenetic alterations caused by ultraviolet radiation exposure is demethylation of DNA that may be attributed to (i) formation of cyclobutane pyrimidine dimers, presence of which compromises the methylating ability of DNA methyltransferases and (ii) loss of methylated cytosines during DNA repair. Additionally, ultraviolet radiation induces hypermethylation of *CDKN2A*, *RASSF1A*, and cadherin 1 (*CDH1*) tumor-suppressor genes indirectly, mainly due to the compensatory elevated expression and activity of DNA methyltransferases and induction of inflammatory-mediated 5-halogenated cytosine intermediates that can mimic 5-meC and direct maintenance DNA methyltransferase DNMT1 to methylate previously unmethylated CpG sites.

Ultraviolet radiation, similarly to ionizing radiation, causes major chromatin conformational and functional alterations. These chromatin changes are tightly associated with alterations in global histone modifications, mainly those involved in DNA damage response and repair.

Ionizing Radiation

Ionizing radiation is an abundant environmental human genotoxic carcinogen (IARC Group 1). Additionally, there are a progressively rising number of people exposed to ionizing radiation either due to their occupation or due to medical diagnostic imaging and radiation treatments. It is well established that DNA damage is the main mechanism associated with ionizing radiation tumorigenicity; however, ionizing radiation also causes major aberrations in the cellular epigenome, including alterations in DNA methylation, histone modifications, and chromatin accessibility. Among these epigenetic abnormalities, a loss of global DNA methylation, driven by either demethylating mechanisms similar to those caused by ultraviolet radiation orionizing radiation-induced damage of 5-meC, and aberrant DNA damage-related histone modifications are the major epigenetic alterations.

Epigenetic Effects of Food Contaminants

Aflatoxin B_1

Aflatoxin B_1 is an abundant food contaminant and human genotoxic carcinogen (IARC Group 1). Aflatoxin B_1 is one of the main risk factors for the development of hepatocellular carcinoma, one of the most aggressive human cancers. The carcinogenicity of aflatoxin B_1 is mainly attributed to its genotoxicity, especially to the ability of aflatoxin B_1-DNA adducts to induce G:C → T:A transversion mutations in the human tumor suppressor *P53* gene. In addition to a genotoxic component of aflatoxin B_1 carcinogenicity, epigenetic alterations, including transcriptional silencing of O^6-methylguanine-DNA methyltransferase (*MGMT*), *CDKN2A*, and *RASSF1A* tumor-suppressor genes mediated by promoter hypermethylation, are typical epigenetic events usually observed in liver carcinogenesis induced by aflatoxin B_1 exposure. Additional cancer-related epigenetic events of aflatoxin B_1-carcinogenicity include global and gene-specific DNA demethylation, increased phosphorylation of histone H3 at serine 10, and deacetylation of a transcription activating mark histone H3 at lysine 9.

Furan

Furan is a volatile heterocyclic organic industrial chemical and food contaminant found in a wide spectrum of common human foods. Furan is a liver toxicant and carcinogen in mice and rats. The carcinogenic effects of furan have been attributed to genotoxic and nongenotoxic mechanisms; however, the lack of evidence for furan genotoxicity in vivo suggests that nongenotoxic mechanisms may be involved in furan liver carcinogenicity. Indeed, accumulated data showed the occurrence of sustained cytosine DNA hypomethylation, promoter region hypermethylation in the tumor suppressor genes *CDKN2A*, *RASSF1A*, and forkhead box E1 (*FOXE1*), and deacetylation of histone H3 at lysines 9 and 56 in the liver upon exposure to furan. Importantly, these epigenetic alterations are tightly interconnected (e.g., gene-specific hypermethylation was accompanied by increased trimethylation at lysine 9 and lysine 27 of histone H3, transcription silencing marks, whereas gene-specific hypomethylation was paralleled with deacetylation of histone H3 lysine 9 and lysine 27). This indicates that epigenetic alterations are not a random event and play a fundamental role in furan-related hepatobiliary carcinogenesis.

Epigenetic Effects of Pharmaceuticals

Tamoxifen

Tamoxifen is a nonsteroidal selective estrogen receptor modulator widely used to treat and prevent occurrence and re-occurrence of breast cancer in women; however, despite this indisputable benefit, the use of tamoxifen has been shown to increase the risk of endometrial cancer in women and to induce liver cancer in rats.

The existing experimental data revealed that a critical mechanistic component of tamoxifen rat liver carcinogenesis is its binding to DNA and the formation of (*E*)-α-(deoxyguanosin-N^2-yl)-tamoxifen and (*E*)-α-(deoxyguanosin-N^2-yl)-*N*-desmethyltamoxifen DNA adducts. Similarly, emerging evidence suggests that the occurrence of tamoxifen-associated endometrial tumors in humans may be partially due to DNA adduct formation. Among other factors contributing to the tumorigenic activity of tamoxifen, epigenetic alterations may play a major role. This was evidenced by a presence of global loss of DNA methylation, decreased methylation of repetitive DNA elements such as LINE-1, and reduced level of histone H4 lysine 20 trimethylation in the livers of tamoxifen-exposed rats. Additionally, substantial demethylation of the paired box 2 (*PAX2*) gene and hypermethylation in the promoter region of the *MGMT* gene have been reported in tamoxifen-induced endometrial tumors in humans.

Phenobarbital

Phenobarbital, a commonly used antiseizure and sedative drug, was one of the first therapeutic drugs to be investigated for its liver cancer-inducing potential with a nongenotoxic mode-of-action. Exposure to phenobarbital results in rapid and progressive accumulation of both types of DNA demethylation and DNA hypermethylation abnormalities in the livers of experimental animals, especially in tumor-prone B6C3F1 mice.

Methapyrilene

Methapyrilene, a histamine antagonist that belongs to the class of pyridine chemicals, was widely used in many nonprescription drugs until 1979, when it was demonstrated to cause the development of liver tumors in rats. Because of the absence of DNA adducts in the livers of rats treated with methapyrilene, the hepatocarcinogenicity of methapyrilene has been attributed to nongenotoxic mechanisms, mainly to induction of mitochondrial dysfunction and disruption of the cellular epigenome. Exposure to methapyrilene caused target organ-specific epigenetic alterations that consisted of a reduction in the levels of cytosine DNA methylation, and global and gene-specific deacetylation of histone H3 lysine 9. These epigenetic alterations were induced by methapyrilene at the concentration that exhibited no cytotoxicity and were associated with reduced expression of critical cancer-related genes, including prospero homeobox 1 (*PROX1*), HNF1 homebox A (*HNF1A*), and peroxisome proliferator activated receptor alpha (*PPARA*), providing a mechanistic link between methapyrilene-induced epigenetic aberrations and liver carcinogenesis.

Mechanisms of Carcinogen-Induced DNA Methylation Alterations

The molecular events that lead to carcinogen-induced epigenetic abnormalities are elusive, and it is likely that multiple processes and pathways are involved (Fig. 2).

DNA Integrity and Epigenetic Alterations

Genotoxic DNA Adducts and Epigenetic Alterations

DNA damage and epigenetic alterations are two of the key tightly linked characteristic events of the carcinogenic process caused by carcinogen exposure. With respect to genotoxic carcinogens, the formation of DNA adducts, especially with guanine or cytosine

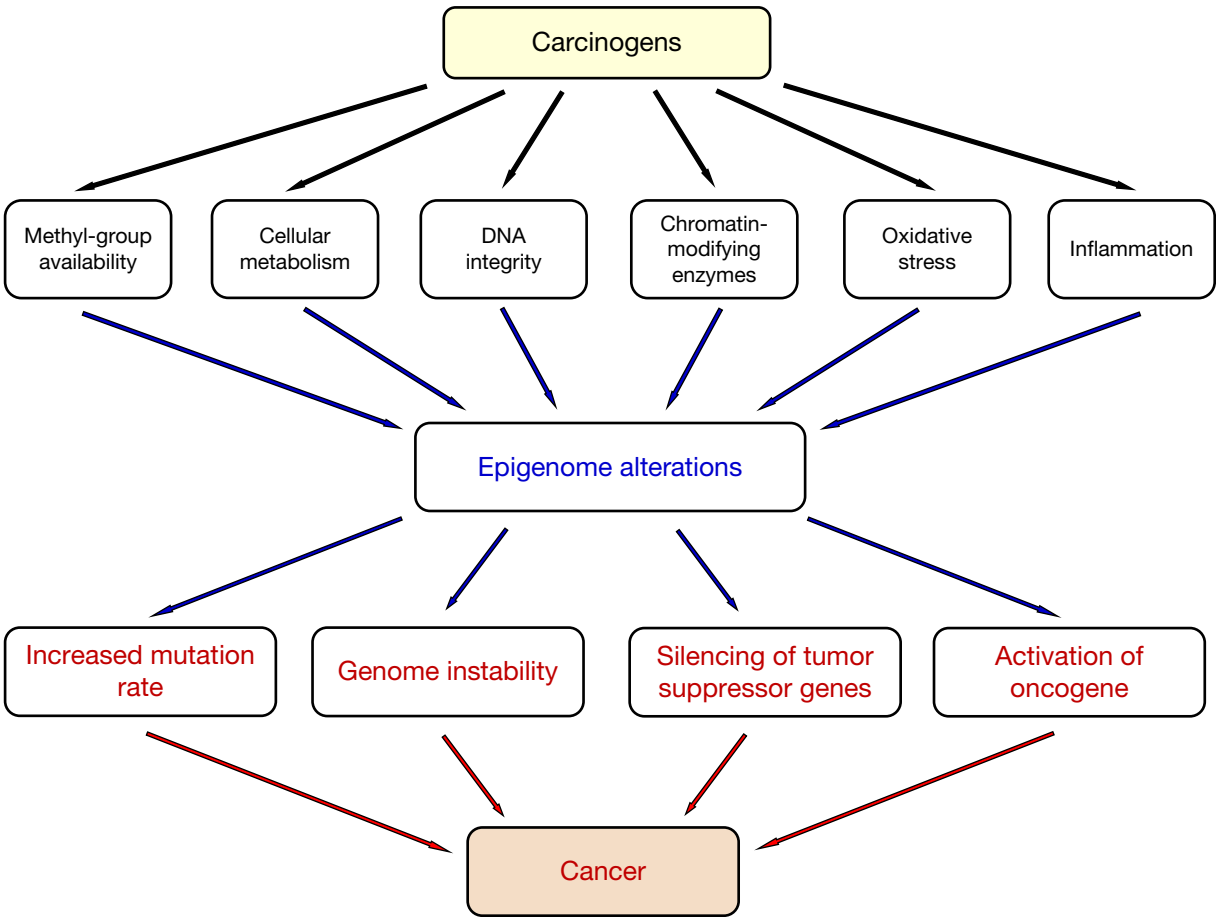

Fig. 2 Epigenetic alterations induced by environmental carcinogens and cancer development. Exposure to carcinogens induced a number of molecular alterations that affect the cellular epigenome. These alterations compromise the stability of the genome and expression of genetic information, any or all of these events may trigger neoplastic cell transformation and promote cancer development.

nucleobases at CpG dinucleotides, may diminish the ability of DNA methyltransferases to methylate a target cytosine resulting in the demethylation of DNA. For instance, the presence of benzo[*a*]pyrene-2′-deoxyguanosine or cyclobutane pyrimidine dimers in DNA inhibit methylation of DNA. Also, miscoding properties of many DNA adducts, for example, (*E*)-α-(deoxyguanosin-N^2-yl)-tamoxifen, or deamination of cyclobutane pyrimidine dimers may cause sequence variations at CpG dinucleotides, which could lead to the loss of 5-meC from CpG sites in DNA.

In addition to carcinogen-DNA damage-mediated changes in DNA cytosine methylation, carcinogen exposure affects histone proteins, evidenced by the formation of anti-BPDE-histone adducts with lysine residues and crosslinks between the glutathione conjugate of *cis*-2-butene-1,4-dial and lysine 107 of histone H2B. Moreover, a number of histone modifications, including the phosphorylation of the histone H2AX and changes in methylation of histone H3 lysine 9, histone H3 lysine 27, and histone H4 lysine 20, and acetylation of histone H3 lysine 9, histone H3 lysine 56, and histone H4 lysine 16, are mediated by the DNA damage response and DNA repair.

Oxidative DNA Damage and Epigenetic Alterations

A common carcinogenesis-related event, which is specific for both genotoxic and nongenotoxic carcinogens, is the induction of oxidative stress. Oxidative stress is a multistressor condition that arises when the generation of reactive oxygen species exceeds the capacity of the cellular antioxidant defense system to control their detoxification. As a result dynamic cellular "redox equilibrium" is compromised. Reactive oxygen intermediates directly damage DNA, resulting in a variety of lesions, among which 8-oxo-7-hydroxydeoxyguanosine (8-oxo-dG) is the most prevalent and universal oxidative DNA lesion. The replacement of guanine with 8-oxo-dG in CpG dinucleotides substantially impairs DNA methylation of adjacent cytosines by (i) inhibiting the binding of the methyl-CpG binding protein 2 (MECP2) to DNA and (ii) diminishing the ability of DNA methyltransferases to methylate a target cytosine in a mechanism similar to genotoxic carcinogen-induced DNA adducts. A similar mechanism of DNA demethylation is specific also for 5-hydroxymethylcytosine, another major oxidative DNA lesion.

DNA Repair and Epigenetic Alterations

Finally, an activation of DNA repair processes and removal of carcinogen-induced DNA lesions could also lead to the demethylation of DNA via replacing 5meC with regular cytosine.

Chromatin Modifying Enzymes and Epigenetic Alterations

One intriguing carcinogenesis-related epigenetic phenomena is global demethylation of DNA accompanied by an increased expression and activity of DNA methyltransferases. This upregulation of DNA methyltransferases may be viewed as a compensatory cellular reaction aiming to restore the normal pattern of DNA methylation and to preserve the integrity of the epigenome and the genome. Despite this upregulation, DNA methyltransferases are unable to restore the original DNA methylation pattern. This may be attributed to the greater binding affinity of DNA methyltransferases to carcinogen-induced DNA lesions resulting in the sequestration of the enzyme. On the other hand, the inability of the DNA methyltrasferases to maintain a proper cytosine methylation status could trigger compensatory upregulation of DNA methyltransferases and lead to random hypermethylation of normally unmethylated promoter CpG islands.

Intracellular Metabolism and Epigenetic Alterations

One of the hallmark alterations during the carcinogenic process is a profound deregulation of the intracellular metabolism. Exposure to carcinogenic agents greatly contributes to this deregulation. The proper functioning of many chromatin-modifying enzymes and epigenetic processes depends greatly on cofactors or cosubstrates generated by cellular metabolism. This tightly links a number of intracellular metabolic pathways and epigenome and, therefore, altered intracellular metabolism, especially tricarboxylic acid cycle (TCA cycle; Krebs cycle), one carbon, lipid, and iron metabolic pathways, induced by carcinogen exposure can cause a variety of epigenetic abnormalities and contribute to cancer development.

One Carbon Metabolism and Epigenetic Alterations

SAM is the major methyl donor for all cellular methylation reactions. The biosynthesis of SAM from L-methionine and adenosine is catalyzed by methionine adenosyltransferase in the cytosol of all mammalian cells and depends on the status of methionine, choline, folic acid, and vitamin B_{12}. SAM is the link to three key metabolic pathways: *trans*-methylation, trans'sulfuration, and polyamine synthesis.

In the *trans*-methylation pathway, SAM donates its methyl group to a large variety of acceptor biomolecules, including proteins and nucleic acids, in reactions catalyzed by methyl-transferases. In this *trans*-methylation pathway, after donation of a methyl group, SAM is converted to *S*-adenosyl-L-homocysteine(SAH) which is subsequently hydrolyzed in a reversible reaction to homocysteine

and adenosine by *S*-adenosylhomocysteine hydrolase. SAH is a potent competitive inhibitor of methylation reactions, and prompt removal of adenosine and homocysteine is required to prevent accumulation of SAH. Homocysteine undergoes remethylation to methionine in the *trans*-methylation pathway or conversion to cysteine in the trans'sulfuration pathway. Remethylation of homocysteine to form methionine is mediated by two enzymes: methionine synthase, which requires normal levels of folate and vitamin B_{12}, and betaine-homocysteine methyltransferase, which is dependent on betaine, a metabolite of choline. Methionine synthase-catalyzed homocysteine remethylation requires 5-methyltetrahydrofolate (5-MTHF), which is derived from 5,10-methylenetetrahydrofolate (5,10-MTHF) in a reaction catalyzed by the enzyme methylenetetrahydrofolate reductase (MTHFR). 5-MTHF is then converted to tetrahydrofolate (THF) as it donates its methyl group and then is converted to 5,10-MTHF to complete the folate cycle.

Another route of homocysteine removal is the irreversible trans'sulfuration pathway, which involves two pyridoxal phosphate-dependent enzymes, cystathionine β-synthase and cystathionine y-lyase. Serine can condense enzymatically with homocysteine to generate cystathione by cystathionine β-synthase. Cystathione is then cleaved by cystathionine y-lyase to generate α-ketobutyrate and cysteine, which can be shunted into glutathione (GSH) production.

Glutathione, the most abundant cellular physiological antioxidant, is greatly depleted during tumorigenesis, mainly by enhanced metabolism of exogenous and endogenous chemicals and their metabolites and by induction of oxidative stress. Consequently, this results in the increased need for glutathione synthesis, activation of the trans'sulfuration pathway causing a reduction in the synthesis of methionine and SAM, and, consequently, perturbing DNA and histone methylation reactions.

Inflammation and Epigenetic Alterations

Inflammation is another main hallmark of carcinogenesis and the main pathophysiological event of carcinogen exposure. In addition to a broad range of cancer-inducing and cancer-promoting molecular alterations, carcinogen-induced inflammation causes several epigenetic alterations, among which gene-specific hypermethylation is of special interest since it provides another important mechanism of cancer-related genes. In particular, the formation of inflammation-induced 5-halogenated cytosine intermediates in DNA, including 5-chlorocytosine and 5-bromocytosine, mimics 5-meC and direct DNA methyltransferases to target unmethylated cytosine causing abnormal cytosine hypermethylation at unmethylated CpG sites.

Prospective Vision

Increasing human exposure to the growing number of carcinogens in the form of environmental, agricultural, industrial contaminants, pharmaceutical products, and food additives is a high-priority concern to all public health agencies worldwide. The major challenge in carcinogenicity testing is associated with the fact that the production of chemicals greatly exceeds our testing capacity.

The current primary "gold standard" approach for determining the carcinogenic potential of chemicals in humans is the 2-year, 2-species rodent carcinogenicity bioassay. This is the most reliable assay in the assessment of carcinogenicity. The value of this assay may be illustrated by the fact that all human carcinogens have produced positive results in at least one animal model. However, because of substantial limitations of rodent bioassays, including the time and resources required, there is a crucial need for alternative testing strategies to increase testing efficiency. The process of carcinogenicity assessment and proper cancer risk management consist of several fundamental steps, including hazard identification and characterization, exposure assessment, and health risk evaluation. A key point in this process is an identification of hazard, which relies on the ability to detect adverse effects of exposure early, in other words on biomarkers of exposure.

The measurement of DNA damage, gene mutations, and chromosome damage is frequently assessed as the primary approach for identification of genotoxic human carcinogens; however, some shortcomings in the use of this approach still exist. Additionally, predicting the carcinogenic potential of nongenotoxic compounds is extremely challenging due to the diversity in modes of action that may lead to tumorigenesis. Recognition of the fundamental role of epigenetic abnormalities in cancer development and the results of human epidemiological and exploratory in vivo studies showing the induction of a spectrum of epigenetic alterations by both genotoxic and nongenotoxic carcinogens suggest that they may be used as biomarkers in the evaluation of carcinogenicity. Incorporation of epigenetic biomarkers in the carcinogenicity testing guidelines holds a number of advantages over traditionally used methods. Specifically, the following features of epigenetic alterations favor their use as biomarkers in the studies for the investigation of carcinogenic potential of environmental exposures: (a) early appearance; (b) stability; (c) target organ specificity; (d) applicability to physical and chemical genotoxic and nongenotoxic carcinogens; and (e) a greater number of detectable epigenetic abnormalities than the genetic aberrations. Furthermore, evaluation of epigenetic alterations in carcinogenicity assessment promises to substantially enhance testing efficiency, increase identification of carcinogenic hazard, and improve risk management strategies aimed to reduce or prevent human exposure to carcinogenic agents.

EDITORS IN CHIEF

Paolo Boffetta, MD, MPH, graduated in Medicine from the University of Turin and obtained a Master in Public Health from Columbia University. He worked at the American Cancer Society, the International Agency for Research on Cancer, a specialized agency of the World Health Organization located in Lyon, France, and at the German Cancer Research Center in Heidelberg, Germany. In 2010 he moved to Icahn School of Medicine at Mount Sinai, New York, where he is Professor of Medicine, Global Health, Oncological Sciences, and Preventive Medicine, and Associate Director for Global Oncology of the Tisch Cancer Institute, a NCI-designated Cancer Center.

Dr. Boffetta also holds a full professorship at the University of Bologna and adjunct appointments at Harvard School of Public Health, Vanderbilt University, Catholic University of Rome, and University of South Carolina. Since 2017 he is Senior Advisor for Research at Vinmec Health System. His main fields of research are cancer epidemiology and cancer prevention, with emphasis on modifiable risk factors (environmental exposure and personal behaviors), gene–environment interactions, molecular epidemiology, and evidence integration. He is the initiator and coordinator of several large-scale international consortia of molecular cancer epidemiology studies, including ILCCO (lung cancer), INHANCE (head and neck cancer), PANC4 (pancreatic cancer), StoP (stomach cancer), and ILCEC (liver cancer).

Dr. Boffetta is the editor or associate editor of 5 scientific journals and member of the editorial board of 10 additional journals; he is a member of review panels of NIH and several medical research agencies in Europe. He has edited 13 books and is Editor in Chief of the new edition of Elsevier's *Encyclopedia of Cancer*. He has published over 1250 peer-reviewed publications; his publications have been quoted more than 90000 times; his h-index is 148.

Pierre Hainaut is Professor of Exceptional Class in Cancer Biology at University Grenoble-Alpes, France and Director of the Institute of Advanced Biosciences (IAB), a joint research center of Institut National de la Santé et de la Recherche Médicale (Inserm), Centre National de la Recherche Scientifique (CNRS), and University Grenoble-Alpes. He also heads the IAB research team on Molecular Biology and Biomarkers.

Pierre Hainaut holds a PhD in Biology (Zoology) from University of Liège, Belgium (1987). After postdocs in Nice (France, 1988–90), Cambridge, and York (United Kingdom, 1990–94), he joined the International Agency for Research on Cancer (IARC, World Health Organization) in 1995, where he held the post of Head of Molecular Carcinogenesis from 1999 to 2011. In 2012, he joined the International Prevention Research Institute (Lyon, France) and became Professor at the Strathclyde Institute of Pharmacy and Biomedical Science (Glasgow, United Kingdom). In 2014, he was awarded a Chair of Excellence in Translational Research from University Grenoble-Alpes (Grenoble, France).

His research focuses on *TP53* mutations and p53 protein regulation in cancer and chronic diseases. From 1994 to 2011, he has led the development of the international IARC TP53 database, a source of information on the causes and consequences of mutations affecting the *TP53* suppressor gene in cancer. His work addresses the mechanisms of *TP53* mutagenesis as well as the prognostic and predictive significance of *TP53* mutations in lung, liver, and oesophageal cancers. His studies on p53 regulation have focused on the role of environmental mutagens in *TP53* mutagenesis, on the biochemical mechanisms of p53 control by oxidation-reduction and by metabolism, and on the identification of p53 isoforms as factors acting as dominant inhibitors of p53 functions in cancers without *TP53* mutations. His current activities focus on germline *TP53* mutation and on the diversity of genetic and nongenetic factors that modulate the penetrance of the Li–Fraumeni Syndrome, as well as on the mechanisms that maintain optimal p53 protein balance in cells and tissues over lifetime. He is the author of over 450 publications and 50 book chapters. He is Editor of the Cancer Biology section of *Current Opinion in Oncology*. He has co-edited books on p53 (*25 Years of p53 Research*, 2005, 2007, *p53 in the Clinics*, Springer), a textbook on molecular epidemiology (*Molecular Epidemiology: Principle and Practice*, IARC Press, 2011) and two-volume textbook on human biobanking (*Human Biobanking, Principle and Practice*, 2017, 2018).

EDITORIAL BOARD

This page intentionally left blank

SECTION EDITORS

Fred T. Bosman MD PhD, studied Medicine at the University of Leiden (MD 1971), where he also earned his PhD degree (in cytogenetics, 1976), and trained as a pathologist. He was staff pathologist at the University of Leiden, Professor and Chair of Pathology at the Faculty of Medicine of the University of Maastricht, Faculty of Medicine of the Erasmus University in Rotterdam, Director of the University Institute of Pathology, and Professor of Pathology at the University Medical Center (CHUV) of Lausanne in Switzerland, now emeritus. He is Honorary Fellow of the Royal College of Pathologists (United Kingdom) and foreign correspondent of the Royal Netherlands Academy of Sciences.

Fred Bosman's research activities (combining diagnostic and experimental pathology) focused on the biology of digestive tract cancer, notably Barrett's esophagus and colorectal cancer, with a strong emphasis on the development of molecular diagnostics. He has written over 350 original publications and over 50 book chapters. Fred Bosman was Series co-editor of the 4th edition of the WHO Series *Classification of Human Tumours*, the international standard for tumor classification, and co-editor of the Volume on *Tumours of the Digestive Tract*.

Graham A. Colditz, MD, DrPH, FAFPHM, is an internationally recognized leader in cancer prevention. As an epidemiologist and public health expert, he has a longstanding interest in the preventable causes of chronic disease, particularly among women. He focuses his research on early life and adolescent lifestyle, growth, and breast cancer risk. He is also interested in approaches to speed translation of research findings into prevention strategies that work. Dr. Colditz developed the award-winning Your Disease Risk website (www.yourdiseaserisk.wustl.edu) which communicates tailored prevention messages to the public. He has published over 1100 peer-reviewed publications, six books and six reports for the Institute of Medicine, National Academy of Sciences. His h-index is over 220.

In October 2006, on the basis of professional achievement and commitment to public health, Dr. Colditz was elected to membership of the National Academy of Medicine, an independent body that advises the US government on issues affecting public health. In 2011, he was awarded the American Cancer Society Medal of Honor for cancer control research. In 2012 he received the AACR-American Cancer Society Award for Research Excellence in Cancer Epidemiology and Prevention. He also received awards in 2014 for cancer prevention research from ASCO and from AACR. During 2016 he served on the Implementation Science Work Group of the Blue-Ribbon Panel to advise the National Cancer Moonshot. He received the 2018 Daniel P. Schuster Award for Distinguished Work in Clinical and Translational Science, Washington University School of Medicine. He was also elected as a Fellow, American Association for the Advancement of Science

Carlo La Vecchia received his MD from the University of Milan and a Master of Science degree in Medicine (epidemiology) from Oxford University. Presently, he is Professor of Medical Statistics and Epidemiology at the Faculty of Medicine at the University of Milan. Dr. La Vecchia serves as an editor for numerous clinical and epidemiologic journals. He is among the most renowned and productive epidemiologists in the field with over 2040 peer-reviewed papers in the literature and is among the most highly cited medical researchers in the world, according to ISI HighlyCited.com, the developer and publisher of the Science Citation Index (2003, 2017, H index 153, H10 index 1543, second Italian in Clinical Medicine). Dr. La Vecchia is Adjunct Professor of Medicine at Vanderbilt Medical Center and the Vanderbilt-Ingram Cancer Center (2002-18).

Gerd. P. Pfeifer received a PhD degree in biochemistry from Goethe University in Frankfurt, Germany. After postdoctoral training, he became a faculty member at the Beckman Research Institute of the City of Hope in Duarte, California, where he spent much of his career working on cancer research. In 2014, Dr. Pfeifer joined the new Center for Epigenetics at the Van Andel Research Institute in Grand Rapids, MI, United States, as a Professor of Epigenetics. Dr. Pfeifer has authored more than 300 publications, has held an NIH MERIT award, and was elected Fellow of the American Association for the Advancement of Science in 2015. Research in Dr. Pfeifer's laboratory has been concerned with genetic and epigenetic mechanisms of human carcinogenesis, with emphasis on DNA methylation and genetic toxicology.

Marco Alessandro Pierotti graduated in 1973 in Biological Sciences at the University of Milan, Italy, and started working at the Fondazione IRCCS Istituto Nazionale dei Tumori (INT) in Milan. From 1978 to 1980 he was Visiting Investigator at the Laboratory of Chemical Cancerogenesis of the NCI-NIH Bethesda (MD, United States) and Postdoctoral Research Fellow at the Laboratory of Viral Oncology of the Memorial Sloan-Kettering Institute in New York. In 2006, Dr. Pierotti was appointed Scientific Director of the Fondazione IRCCS Istituto Nazionale dei Tumori in Milan, where, since 1970, he had already held various positions, including Director of the Department of Experimental Oncology.

Since 1988, he has been Professor of Molecular Genetics of Cancer at the Postgraduate School of Oncology, University of Milan Medical School and co-director of the Laboratory of Molecular Diagnosis at the INT. In September 2014 he resigned from his position at INT to take the position of President and CEO of Nerviano Medical Sciences (NMS) srl, one of the biggest oncological pharma companies in Europe. In April 2015 he left the company and took the position of Scientific Coordinator of the Institute of Pediatric Researches (IRP) in Padua, Italy, devoted to study molecular aspects of the main pediatric diseases with particular focus on pediatric onco-hematology. The Institute was created by a private Charity, The City of Hope Foundation of Monte Malo (Vi).

Since 2000 he is Senior Group leader of the Molecular Genetics of Cancer group at the Institute FIRC of Molecular Oncology (IFOM, Milan). Past President (2006–08) of the Italian Cancer Society, Dr. Pierotti is a member of the American Association for Cancer Research and of its Advisory Board and the Laboratory Research Awards Selection Committee. He has also been President (2006–08) of the European Association for Cancer Research (EACR) and in this role was among the founders of the European CanCer Organisation (ECCO) where he was appointed as member of the Policy Committee.

In recent years, he was the Italian Representative at the Scientific Committee of the International Agency for Research on Cancer (IARC), Lyon. From 2006 to 2014 he was Scientific Secretary of Alleanza Contro il Cancro (ACC), promoted by the Italian Ministry of Health. In 2008 he was Member of the Evaluation of the Research Program Functional and Structural Genomics for DKFZ. He was an expert for the Oncology Research Projects of the European Community and was a consultant in oncology research for the Ministries of Research of different Countries. From 2006 to 2014 he was Chair of the regional Project, The Region Lombardy Oncological Network (ROL), selected in 2014 by the EC as one of the best examples of oncological network. His appointments in the Organisation of European Cancer Institutes (OECI) started in 2007 when he took the position of Vice-President. From 2008 he was the President-elect and then the President of the Organization. Finally, in 2014 he was appointed OECI Executive Secretary.

Over the years, Dr. Pierotti has been Principal Investigator or Head of several national and international research grants, funded by both private and public bodies. His authorship includes over 470 publications that deal with various aspect of experimental oncology including studies on immunology, biochemistry, and molecular biology using both experimental and human tumors.
In addition, since its fifth edition he is the first author of the chapter on "Oncogenes" in the most reputed textbook *Cancer Medicine* (Holland-Frei). The metrics of his scientific activity is summarized by an H index of 96 and total citations of 37.256 (Google scholar June 2018).

Professor **Thomas Tursz**, born in Kraków, Poland, in 1946, died in Paris, France, on April 27 2018. He was Professor of Oncology at the Faculty of Medicine Paris-Sud since 1986 and General Director of the Institut Gustave Roussy (1994–2010). He was the leader of the French Doctoral School of Oncology which he founded in 1999, and President of the French Federation of Comprehensive Anticancer Centres (FNCLCC) from 2004 to 2010. He was highly involved in the European Organization for the Research and Treatment of Cancer (EORTC) as both Chairman of the Scientific Advisory Committee (2003–06) and Vice President of the Board (2006–09). His experience as President of the FNCLCC was crucial for the Organization of European Cancer Institutes (OECI) when he acted as President from 2002 to 2005.

His scientific interests included the biology of virus-induced tumors, as well as immunological responses including the role of thioredoxin in lymphocytes infected by Epstein–Barr virus. In the clinical research area, he conducted a number of important clinical trials in breast cancer, lung cancer, and soft-tissue sarcoma. He had a particular interest in cytokines and gene therapy, and his clinical research activities were further disseminated to the European level when he was the Chairman of the Sarcoma Group of the EORTC (1993–96).

Prof. Tursz received several prestigious awards, such as the Prix de Cancérologie from the French National League Against Cancer (1979), the Bernard Halpern Immunology Award (1983), the Rosen Oncology Award (1989), the Grand Prix in Oncology from the Academy of Medicine (1992), the Hamilton Fairley Award for clinical research (1998), and the Prix de Rayonnement Français (2001). He was the author of 350 international scientific publications. He was also an esteemed member of the Editorial Board of *Molecular Oncology* ever since its creation in 2007.

Modified from Ulrik Ringborg and Julio E. Celis. Thomas Tursz (1946–2018) in: *Molecular Oncology* (2018). Published by FEBS Press and John Wiley & Sons Ltd. https://doi.org/10.1002/1878-0261.12361

HOW TO USE THE ENCYCLOPEDIA

Structure of the Encyclopedia

All articles in the encyclopedia are arranged alphabetically as a series of entries.

There are four features to help you easily find the topic you are interested in: an alphabetical contents list, cross references, a full subject index, and contributors.

1. Alphabetical contents list: The alphabetical contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia. So that they can be easily located, entry titles generally begin with the key word or phrase indicating the topic, with any generic terms following. For example, "Multiple Myeloma: Pathology and Genetics" is the entry title rather than "Pathology and Genetics of Multiple Myeloma".
2. Cross references: Virtually all the entries in the encyclopedia have been extensively cross-referenced. The cross references which appear at the end of an entry, serve three different functions:
   i. To draw the reader's attention to related material on other entries
   ii. To indicate material that broadens and extends the scope of the article
   iii. To indicate material that covers a topic in more depth

Example
The following list of cross-references appears at the end of the entry "Carcinogen—DNA Adducts".

> ***See also:*** Cancer Risk Reduction Through Lifestyle Changes. Cell Responses to DNA Damage. Genetic Instability. Hereditary Risk of Breast and Ovarian Cancer: BRCA1 and BRCA2. Molecular Epidemiology and Cancer Risk. Role of DNA Repair in Carcinogenesis and Cancer Therapeutics.

3. Index: The index appears at the end of volume 3 and includes page numbers for quick reference to the information you are looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.
4. Contributors: At the start of each volume there is a list of the authors who contributed to all volumes.

This page intentionally left blank

SUBJECT CLASSIFICATION

Causes of Cancer

Aflatoxins
Aging and Cancer
Cancers as Ecosystems: From Cells to Population
Diabetes and Cancer
Dietary Factors and Cancer
Helicobacter Pylori-Mediated Carcinogenesis
HIV (Human Immunodeficiency Virus)
Obesity and Cancer: Epidemiological Evidence
Opisthorchis Viverrini, *Clonorchis Sinensis*, and Cholangiocarcinoma
Papillomaviruses
Physical Inactivity and Cancer
Radiation Therapy-Induced Metastasis and Secondary Malignancy
Sleep Disturbances and Misalignment in Cancer

Diagnosis and Therapy

Acute Lymphocytic Leukemia: Diagnosis and Treatment
Acute Myelogeneous Leukemia: Diagnosis and Treatment
Bladder Cancer: Pathology, Genetics, Diagnosis, and Treatment
Bone and Soft Tissue Sarcoma: From Molecular Features to Clinical Applications
Cancer Vaccines: Dendritic Cell-Based Vaccines and Related Approaches
Cholangiocarcinoma: Diagnosis and Treatment
Chromatin Dynamics and Cancer: Epigenetic Parameters and Cellular Fate
Chronic Myelogenous Leukemia: Pathology, Genetics, Diagnosis, and Treatment
Colorectal Cancer: Diagnosis and Treatment
End of Life Support
Esophageal Cancer: Diagnosis and Treatment
Glioblastoma: Biology, Diagnosis, and Treatment
Interferons: Cellular and Molecular Biology of Their Actions
Kidney Cancer: Diagnosis and Treatment
Laryngeal Cancer: Diagnosis and Treatment
Malignant Tumors of the Eye, Conjunctiva, and Orbit: Diagnosis and Therapy
Myelodysplastic Syndromes: Mechanisms, Diagnosis, and Treatment
Nasopharyngeal Carcinoma: Diagnosis and Treatment
Neuroblastoma: Diagnosis and Treatment
New Rationales and Designs for Clinical Trials in the Era of Precision Medicine
Non-Hodgkin Lymphoma: Diagnosis and Treatment
Oncology Imaging
Oral Cavity Cancer: Diagnosis and Treatment
Ovarian Cancer: Diagnosis and Treatment
Pancreatic Cancer: Diagnosis and Treatment
P-Glycoprotein-Mediated Multidrug Resistance
Pituitary Tumors: Diagnosis and Treatment

Prostate Cancer: Diagnosis and Treatment
Radiation Oncology
Squamous Cell and Basal Cell Carcinoma of the Skin: Diagnosis and Treatment
Symptom Control
Thyroid Cancer: Pathology, Genetics, Diagnosis, and Treatment
Uterine Cervix Cancer: Diagnosis and Treatment

Hallmarks of Cancer

Anoikis
Autophagy and Cancer
Cancer-Related Inflammation in Tumor Progression
Cell Adhesion During Tumorigenesis and Metastasis
Cell Responses to DNA Damage
DNA Mismatch Repair: Mechanisms and Cancer Genetics
Epithelium to Mesenchyme Transition
Genetic Instability
Glutamine Metabolism and Cancer
Induced Pluripotent Stem Cells and Yamanaka factors
Inhibitors of Lactate Transport: A Promising Approach in Cancer Drug Discovery
Lipid Metabolism
Metastatic Signatures—The Tell-Tale Signs of Metastasis
Mevalonate Pathway
Mitogen-Activated Protein Kinases (MAPK) in Cancer
Pyruvate Kinase
Role of DNA Repair in Carcinogenesis and Cancer Therapeutics
Senescence and Cellular Immortality
Telomeres, Telomerase, and Cancer
TGF-β in Cancer Progression: From Tumor Suppressor to Tumor Promotor
TP53
Tumor-Associated Macrophages
Tumors and Blood Vessel Interactions: A Changing Hallmark of Cancer
Tunneling Nanotubes (TNTs): Intratumoral Cell-to-Cell Communication

Mechanisms

Animal Models of Cancer: What We Can Learn From Mice
Ataxia Telangiectasia Syndrome
Carcinogen—DNA Adducts
Carcinogenesis: Role of Reactive Oxygen and Nitrogen Species
Chromosome Rearrangements and Translocations
Copy Number Variations in Tumors
Defective 5-Methylcytosine Oxidation in Tumorigenesis
DNA Methylation Changes in Cancer: Cataloguing
DNA Methylation Changes in Cancer: Mechanisms
Enhancers in Cancer: Genetic and Epigenetic Deregulation
Environmental Exposures and Epigenetic Perturbations
Epigenetic Therapy
Genome Wide Association Studies (GWAS)
Hereditary Risk of Breast and Ovarian Cancer: BRCA1 and BRCA2
Hormones and Cancer
Li–Fraumeni Syndrome
Lynch Syndrome
Microbiota and Colon Cancer: Orchestrating Neoplasia Through DNA Damage and Immune Dysregulation
Mod Squad: Altered Histone Modifications in Cancer
Mutational Signatures and the Etiology of Human Cancers
Mutations in Chromatin Remodeling Factors

Mutations in DNA Methyltransferases and Demethylases
Mutations in Histone Lysine Methyltransferases and Demethylases
Mutations: Driver Versus Passenger
Polyomaviruses in Human Cancer
Systems Biology Approach to Study Cancer Metabolism
TCA Cycle Aberrations and Cancer
Unprogrammed Gene Activation: A Critical Evaluation of Cancer Testis Genes
Wnt Signaling in Intestinal Stem Cells and Cancer
Xeroderma Pigmentosum: When the Sun Is the Enemy

Pathology and Genetics of Specific Cancers

Adrenal Glands Tumors: Pathology and Genetics
Anal Cancer: Pathology and Genetics
Bladder Cancer: Pathology, Genetics, Diagnosis, and Treatment
Bones and Joints Cancer: Pathology and Genetics
Breast Cancer: Pathology and Genetics
Chronic Lymphocytic Leukemia: Pathology and Genetics
Chronic Myelogenous Leukemia: Pathology, Genetics, Diagnosis, and Treatment
Colorectal Cancer: Pathology and Genetics
Endometrial Cancer: Pathology and Genetics
Esophageal Cancer: Pathology and Genetics
Eye and Orbit Cancer: Pathology and Genetics
Gastric Cancer: Pathology and Genetics
Germ Cell Tumors: Pathology and Genetics
Glioblastoma: Pathology and Genetics
Hepatocellular Carcinoma: Pathology and Genetics
Hodgkin Lymphoma: Pathology and Genetics
Integrative Molecular Tumor Classification: A Pathologist's View
Jaws Cancer: Pathology and Genetics
Larynx Cancer: Pathology and Genetics
Malignant Skin Adnexal Tumors: Pathology and Genetics
Melanoma: Pathology and Genetics
Multiple Myeloma: Pathology and Genetics
Neuroblastoma: Pathology and Genetics
Non-Hodgkin Lymphoma: Pathology and Genetics
Nonsmall-Cell Cancers of the Lung: Pathology and Genetics
Oral and Oropharyngeal Cancer: Pathology and Genetics
Ovarian Cancer: Pathology and Genetics
Pancreatic Cancer: Pathology and Genetics
Parathyroid Cancer: Pathology and Genetics
Pituitary Tumors: Pathology and Genetics
Prostate Cancer: Pathology and Genetics
Renal Cell Cancer: Pathology and Genetics
Small-Cell Cancer of the Lung: Pathology and Genetics
Thyroid Cancer: Pathology, Genetics, Diagnosis, and Treatment
Uterine Cervix Cancer: Pathology and Genetics
Wilms Tumor: Pathology and Genetics

Prevention and Control

Aspirin and Cancer
Cancer Disparities
Cancer in Populations in Transition
Cancer in Sub-Saharan Africa
Cancer in the Middle East
Cancer Risk Reduction Through Lifestyle Changes

Cancer Survival and Survivorship
Cervical Cancer: Screening, Vaccination, and Preventive Strategies
Chemoprevention of Cancer: An Overview of Promising Agents and Current Research
Chemoprevention Trials
Diet and Cancer
Environmental and Occupational Exposures
Financial Burden of Cancer Care
Hereditary Cancer Syndromes: Identification and Management
Metformin
Molecular Epidemiology and Cancer Risk
Prevention and Control: Nutrition, Obesity, and Metabolism

PREFACE

Cancer holds a special status in biology, medicine, and society. It offers formidable challenges to basic, clinical, and population science; it ranks at the top of medical research priorities and healthcare costs in most countries. The general public is continuously exposed to news of discoveries promising to defeat the disease in the near future. Indeed, ground-breaking advances are being made, from preventive vaccines to genome-guided personalized medicine, sophisticated imaging and surgical technologies, and systemic therapies aimed at awakening natural immune responses against cancer. These novel therapeutic approaches make cure a real possibility for a growing number of patients. They also launch cancer care into a new era of maintaining the disease under control for an indefinite period of time, turning it into a form of chronic disease. At the same time, evidence-based prevention and early detection strategies have opened a new window on the natural history of the disease, enabling effective intervention well ahead of diagnosis. As a result, the first two decades of this millennium have witnessed a marked decrease in the mortality and, in some instances, the incidence of cancers that have dominated the death toll in more developed countries during the second half of the 20th century.

A turning point in our understanding of cancer is the deciphering of the human genome and its spin-off endeavors aimed at exploring the genomic landscape and architecture of human cancers. These discoveries are causing a major overhaul of our vision of cancer as a dynamic, rapidly evolving, and heterogeneous disease at the individual level. Harnessing this complexity requires mastering increasingly complex sources of data at molecular, cellular, systemic, personal, environmental, and societal level, heralding the emergence of big-data science in cancer diagnosis and treatment. However, this exceptional acceleration in knowledge and solutions cannot hide the fact that cancer remains a global scourge that exerts a massive burden on humankind and societies worldwide, in particular in societies in transition and in low-resource contexts.

Today, cancer crystallizes many of the major societal challenges pertaining to lifestyles, sustainable development and environmental policies, demography and population aging, access to education and healthcare, sharing of resources and knowledge, and protection of persons and personal information. The information on cancer available at a fingertip is overwhelming in volume, complexity, veracity, and velocity. We worked on the Third Edition of Elsevier's *Encyclopedia of Cancer* with this rapidly changing background. Rather than aiming at developing a comprehensive framework encompassing all aspects, we attempted to address the literal meaning of the greek terms ἐγκύκλιος παιδεία, which means "general education". While we retained some articles from the previous edition, which, at the time of the publication, represented an exceptional achievement of Dr. J. Bertino, we largely modified the structure and the list of chapters, and the possibility of continuous update of the articles has been a great incentive for us and for the authors of the chapters. This new edition of the Encyclopedia consists of six major parts: (i) mechanisms of cancer, (ii) hallmarks of cancer, (iii) causes of cancer, (iv) cancer prevention and control, (v) diagnosis and treatment of specific cancers, and (vi) pathology and genetics of specific cancers. This repartition is necessarily artificial and is complemented by the extensive cross-references between articles. The repartition, however, reflects our effort to identify discrete topics that would best address the needs of a wide community of readers.

The primary target readership of the Encyclopedia comprises medical and other health science students, as well as non-specialized physicians and other health practitioners. Cancer researchers, oncologists, and other cancer professionals may find the articles pertaining to their specific field to be too short, over-simplistic, and perhaps obsolete; they too, however, may benefit from articles on topics other than their own. The Encyclopedia also offers an easy way to navigate across concepts and topics that should be appealing to readers from other communities, including social sciences or stakeholders in public decision-making.

We were fortunate to work with a formidable team of section editors, including Fred Bosman, Graham Colditz, Carlo La Vecchia, Gerd Pfeifer, and Marco Pierotti. An additional section editor was Professor Thomas Tursz, who passed away prematurely during the preparation of the Encyclopedia. Thomas was a great colleague and mentor, and a major figure in oncology in France and internationally. We had the privilege to involve him in the last project of his long career, and we want to dedicate this work to him. We wish to thank the many article authors, who agreed to contribute to the success of this international endeavor, and in particular Dr. Katarzyna Szymańska, who drafted several cancer-specific articles. Finally, we want to thank the staff at Elsevier, whose patience and perseverance helped us bringing the project to the final stage. All these individuals are responsible for the many strengths of the new edition of the *Encyclopedia of Cancer*, while weaknesses are mainly ours.

Paolo Boffetta
Pierre Hainaut

CONTENTS OF ALL VOLUMES

VOLUME 1

Acute Lymphocytic Leukemia: Diagnosis and Treatment 1
Katarzyna Szymańska and Sophie Park

Acute Myelogeneous Leukemia: Diagnosis and Treatment 9
Katarzyna Szymańska and Sophie Park

Adrenal Glands Tumors: Pathology and Genetics 18
Thomas G Papathomas, Thomas J Giordano, Eamonn R Maher, and Arthur S Tischler

Aflatoxins 30
Joshua W Smith and John D Groopman

Aging and Cancer 44
Mingyang Song

Anal Cancer: Pathology and Genetics 53
Fred T Bosman

Animal Models of Cancer: What We Can Learn From Mice 60
Giustina Ferone, Paul Krimpenfort, and Anton Berns

Anoikis 75
Sharan Malagobadan and Noor Hasima Nagoor

Aspirin and Cancer 85
Mangesh A Thorat

Ataxia Telangiectasia Syndrome 101
Palak R Parekh and France Carrier

Autophagy and Cancer 112
Christina G Towers and Andrew Thorburn

Bladder Cancer: Pathology, Genetics, Diagnosis, and Treatment 122
Katarzyna Szymańska, Fred T Bosman, and Pierre Hainaut

Bone and Soft Tissue Sarcoma: From Molecular Features to Clinical Applications 134
Sarah Watson and Olivier Delattre

Bones and Joints Cancer: Pathology and Genetics 153
Pancras C W Hogendoorn and Carlos E de Andrea

Breast Cancer: Pathology and Genetics 170
Amy E McCart Reed, Emarene Kalaw, Andrew Reid, and Sunil R Lakhani

Cancer Disparities 184
Ivana Kulhánová and Salvatore Vaccarella

Cancer in Populations in Transition 191
Aleyamma Mathew and Preethi S George

Cancer in Sub-Saharan Africa 212
Mariana Brandão, Ivo Julião, Carla Carrilho, Filipa Fontes, and Nuno Lunet

Cancer in the Middle East 225
Iman El Sayed

Cancer Risk Reduction Through Lifestyle Changes 243
Christina Bamia

Cancer Survival and Survivorship 250
Dana Hashim and Elisabete Weiderpass

Cancer Vaccines: Dendritic Cell-Based Vaccines and Related Approaches 260
Laurence Chaperot, Olivier Manches, and Caroline Aspord

Cancer-Related Inflammation in Tumor Progression 275
Alberto Mantovani

Cancers as Ecosystems: From Cells to Population 278
Graham A Colditz

Carcinogen—DNA Adducts 282
Annette M Krais, Rajinder Singh, and Volker M Arlt

Carcinogenesis: Role of Reactive Oxygen and Nitrogen Species 296
Jean Cadet and J Richard Wagner

Cell Adhesion During Tumorigenesis and Metastasis 307
Lubor Borsig and Heinz Läubli

Cell Responses to DNA Damage 315
Jean Y J Wang

Cervical Cancer: Screening, Vaccination, and Preventive Strategies 326
Paolo Giorgi Rossi and Francesca Carozzi

Chemoprevention of Cancer: An Overview of Promising Agents and Current Research 345
Elizabeth G Ratcliffe, Andrew D Higham, and Janusz A Jankowski

Chemoprevention Trials 352
Kunal C Kadakia, Ashley G Matusz-Fisher, and Edward S Kim

Cholangiocarcinoma: Diagnosis and Treatment 367
Katarzyna Szymańska

Chromatin Dynamics in Cancer: Epigenetic Parameters and Cellular Fate 372
Daniel Jeffery, Katrina Podsypanina, Tejas Yadav, and Geneviève Almouzni

Chromosome Rearrangements and Translocations 389
Stefan K Bohlander, Purvi M Kakadiya, and Alix Coysh

Chronic Lymphocytic Leukemia: Pathology and Genetics 405
Julio Delgado, Neus Villamor, Ferran Nadeu, and Elías Campo

Chronic Myelogenous Leukemia: Pathology, Genetics, Diagnosis, and Treatment 418
Katarzyna Szymańska and Sophie Park

Colorectal Cancer: Diagnosis and Treatment 425
Katarzyna Szymańska

Colorectal Cancer: Pathology and Genetics 428
Fred T Bosman

Copy Number Variations in Tumors 444
Tao Huang

Defective 5-Methylcytosine Oxidation in Tumorigenesis 452
Gerd P Pfeifer and Seung-Gi Jin

Diabetes and Cancer 459
Rachel Dankner

Diet and Cancer 471
Livia S A Augustin, Concetta Montagnese, Ilaria Calabrese, Giuseppe Porciello, Elvira Palumbo, Sara Vitale, and Stephanie Nishi

Dietary Factors and Cancer 501
Isabelle Romieu

DNA Methylation Changes in Cancer: Cataloguing 512
Tibor A Rauch and Gerd P Pfeifer

DNA Methylation Changes in Cancer: Mechanisms 520
Hideyuki Takeshima and Toshikazu Ushijima

DNA Mismatch Repair: Mechanisms and Cancer Genetics 530
William J Graham V, Christopher D Putnam, and Richard D Kolodner

End of Life Support 539
Kavitha J Ramchandran and Jamie Von Roenn

Endometrial Cancer: Pathology and Genetics 549
Ben Davidson

Enhancers in Cancer: Genetic and Epigenetic Deregulation 559
Kaixiang Cao and Ali Shilatifard

Environmental and Occupational Exposures 569
Harvey Checkoway

Environmental Exposures and Epigenetic Perturbations 574
Igor P Pogribny

VOLUME 2

Epigenetic Therapy 1
Richard L Bennett, Aditya Bele, Sayantan Maji, and Jonathan D Licht

Epithelium to Mesenchyme Transition 14
Laia Caja and E-Jean Tan

Esophageal Cancer: Diagnosis and Treatment 24
Katarzyna Szymańska

Esophageal Cancer: Pathology and Genetics 32
Jean-François Fléjou

Eye and Orbit Cancer: Pathology and Genetics 47
Sarah E Coupland, Santosh U Kafle, and Jakub Khzouz

Financial Burden of Cancer Care 61
Bernardo H L Goulart and Veena Shankaran

Gastric Cancer: Pathology and Genetics 77
Irene Gullo and Fátima Carneiro

Genetic Instability 99
Meiyun Guo, Lin Mei, and Christopher A Maxwell

Genome Wide Association Studies (GWAS) 110
Giuliana Restante, Elena Arrigoni, Marzia Del Re, Antonello Di Paolo, and Romano Danesi

Germ Cell Tumors: Pathology and Genetics 121
J W Oosterhuis and Leendert H J Looijenga

Glioblastoma: Biology, Diagnosis, and Treatment 154
Akanksha Sharma, Maciej M Mrugala, and Jan Buckner

Glioblastoma: Pathology and Genetics 165
Christian Hartmann and Pieter Wesseling

Glutamine Metabolism and Cancer 179
Nianli Sang, Dan He, and Shuo Qie

Helicobacter Pylori-Mediated Carcinogenesis 187
Matthew G Varga and Meira Epplein

Hepatocellular Carcinoma: Pathology and Genetics 198
Luigi M Terracciano, Salvatore Piscuoglio, and Charlotte K Y Ng

Epigenetic Therapy

Richard L Bennett, Aditya Bele, Sayantan Maji, and Jonathan D Licht, University of Florida, Gainesville, FL, United States

Glossary

Bromodomain A protein domain that recognizes acetylated lysines.
Chromatin Histone protein DNA complex.
Epigenetics Heritable changes in gene expression not attributed to genomic sequence.
Euchromatin Loosely structured or less tightly packed chromatin regions that are enriched for actively transcribed genes.
Heterochromatin Tightly packed chromatin that is less accessible to protein factors and repressed gene transcription.
Methyltransferase Enzymes that transfer a methyl group from *S*-adenosylmethionine to DNA or protein substrates.
Xenograft A tissue or cell graft from a different species than the recipient. For instance human cancer cells xenografted into a mouse.

Nomenclature

ac Acetylation
bp Base pair
K Lysine
me1, me2, me3 Mono-, di- and tri-methylation
nt Nucleotide

Epigenetic Dysregulation in Cancer

Heritable changes in gene expression not due to the underlying DNA sequence are maintained and regulated by epigenetic mechanisms. These mechanisms allow for cellular identity and context differences in gene expression when there is no DNA sequence variation. The epigenome is dynamically regulated by the three dimensional organization of the genome. In eukaryotic cells, DNA is complexed with histone proteins to form the nucleosome, consisting of ~145 bp of DNA wrapped around an octamer of the four core histone proteins: H2A, H2B, H3, and H4. Nucleosomes are the basic repeating units that allows folding of chromosomal DNA into the higher order structure of chromatin, maintenance of genome structure during condensation of chromatin into chromosomes and segregation of chromatids during cell division. Nucleosomes have a general inhibitory effect on RNA transcription and are important for maintaining the structural integrity of DNA, protecting it from damage during interphase. Nucleosome positioning allows for the occlusion of critical DNA binding sites from transcription factors that inhibits the formation of the pre-initiation complex. In regions of the genome that are transcriptionally inert, heterochromatin consists of nucleosomes tightly packed together to form a higher order solenoid structure. In contrast, euchromatin may be bound by nucleosomes with significant nucleosome free regions that can be accessed by sequence specific transcription factors, co-factors and the transcriptional machinery.

The existence of overexpressed and chimeric transcription factors in human cancer has been known for several decades but only recently, with the advent of next generation genome sequencing, have we discovered that mutations affecting the transcriptional apparatus are some of the most common in human tumors. For example, pan-cancer sequencing efforts found that along with frequently occurring mutations in well-known oncogenes such as Ras, p53, and PTEN, a number of chromatin regulators are frequently deregulated across the cancer spectrum. Mutations have been detected in DNA methyltransferases that participate in gene silencing and heterochromatin promotion, transcription factors that bind DNA, cofactors that recruit the polymerase machinery, chromatin remodeling co-factors such as subunits of the SWI/SNF complex and enzymes that govern posttranslational modification of histones such as acetyl- and methyltransferases. Furthermore, molecules that recognize covalent histone modifications (marks) may be affected in cancer, causing aberrant interpretation of such modifications and the histone residues modified during gene regulation may even become mutated. Chromatin integrity can also be altered in cancer by inactivation of either cohesin complex subunits that link distal enhancers with proximal promoters or replication independent histone chaperones that place specific forms of histone at sites of transcription.

Epigenetic marks are dynamic information carriers. Chromatin can store and transmit heritable information in the patterns of DNA methylation or histone posttranslational modifications. Protein complexes that carry out these epigenetic processes can be classified as writers, readers, and erasers. Epigenetic writers catalyze the addition of epigenetic marks onto either DNA or histones,

such as methylation of N-terminal histone "tails" extending from the nucleosome structure. The recognition of a mark by reader protein complexes facilitates tethering of enzymatic activities that may alter the chromatin architecture further or regulate enzymatic processes such as transcription factor binding and RNA polymerase processivity. Erasers such as histone deacetylases remove epigenetic marks. Unlike genetic events, epigenetic regulation is a dynamic and reversible process. Anti-cancer therapies that target these classes of epigenetic mechanisms are currently showing promise in clinical trials both as single agents and in combination with other therapies.

Anti-Cancer Strategies That Target DNA Methylation

DNA Methylation in Cancer

In mammals, DNA methylation almost exclusively occurs on cytosines that precede a guanine (CpG) and often plays a key role in regulation of gene expression. Endogenous palindromic methylation patterns are maintained in the genome and transmitted through the germline. CpG dinucleotides are often concentrated within "islands" of CpG-rich DNA regions located near transcription start sites (TSSs). Hypermethylation of CpG islands may repress expression of the corresponding gene by preventing binding of transcription factors and recruiting methyl-CpG binding proteins that interact with repressive histone modifying enzymes. This initial model for the function of cytosine methylation has been augmented by more recent genome-wide studies which demonstrated that methylation of enhancers can modulate the function of these elements, methylation of insulator sequences can affect the ability of different regions of chromatin to interact with each other and methylation of gene bodies enhances high-fidelity gene transcription. Changes in both global and individual gene methylation patterns are often found in cancer and aberrant methylation patterns have been used to differentiate tumor subtypes. In general, global DNA hypomethylation is observed in tumors due to loss of repeat region methylation and hypomethylation of specific loci. However, hypermethylation of specific CpG rich regions has been frequently reported in malignant transformation leading to silencing of tumor suppressors such as Rb and p16. Furthermore, aberrant methylation patterns and hypomethylation outside CpG islands has been reported to contribute to increased expression of proto-oncogenes such as Hox11, ERBB2, Bcl-2, and Ras in a variety of malignancies. The enzymes responsible for establishing and maintaining these patterns of DNA methylation are DNA methyltransferases (DNMTs). DNMT3A and DNMT3B establish de novo DNA methylation patterns that are maintained by DNMT1, which can recognize methylation in DNA and assures methylation of daughter strands after replication. Demethylation of DNA is facilitated by the TET enzymes which convert methyl cytosine into hydroxymethylcytosine which is not recognized by DNMT1. DNA methylation patterns may be upset in cancer due to loss of function mutations of DNMT3A or TET enzymes as well as chronic inflammation and exposure to heavy metals. One current thread of epigenetic therapeutics attacks methylation in cancer.

Therapeutic Strategies Targeting DNA Methyltransferase

The cytosine analogues 5′-azacytidine (Azacitidine, Aza) and 5-aza-2′-deoxycytidine (decitabine) were originally developed as high-dose anti-leukemia cytotoxic agents. These compounds are azanucleosides with nitrogen at the C-5 position of their pyrimidine ring that when incorporated into DNA cause irreversible binding with DNMT1, leading to DNMT1 degradation and genome-wide DNA hypomethylation. Decitabine is mostly incorporated into DNA, but about 80%–90% of Aza is incorporated into RNA and some of its effects may be due to altered composition of RNA which is now known to also be covalently modified. Classical studies from the 1980s and 1990s revealed that DNMT inhibitors (DNMTi) may reactivate silenced genes such as fetal globin in adult red cell precursors. The ability of DNMTi to reactivate silenced tumor suppressor genes in cancer cells was a prime motivation for testing these agents in hematological and other malignancies. As a result, Aza and decitabine were approved for the treatment of myelodysplastic syndrome (MDS) (**Table 1**). These agents typically cause a slow improvement in blood counts in these pre-leukemia patients due to suppression of the malignant dysplastic cell population and emergence of increased normal hematopoiesis. In addition, a second-generation analogue, SGI-110 whose active metabolite is decitabine, is currently being tested in clinical trials for acute myeloid leukemia (AML), MDS, ovarian cancer and hepatocellular carcinoma (**Table 1**). While hypomethylating agents can reverse promoter methylation and reactivate silenced tumor suppressor gene expression in some instances, many reports attribute their anticancer activity to other mechanisms. For instance, treatment with decitabine causes the formation of DNA-DNMT adducts, subsequent double-stranded DNA breaks and G2 arrest. In addition, reports suggest that DNMTs may associate with histone modifying enzymes and a global increase of histone H3 and H4 acetylation has been observed after treatment with Aza. Furthermore, decitabine has been reported to stimulate expression of normally silent endogenous retroviral sequences in colon cancer cell lines to cause a host antiviral response including activation of interferon response genes independent of promoter demethylation. Taken together these results indicate that DNA methyltransferase inhibitors can have cooperative functions that contribute to their cytotoxic effect.

Cooperation of DNA Hypomethylating Agents With Immunotherapy

Recently one of the most promising therapeutic anticancer strategies has been to combine single agent epigenetic therapies with other epigenetic or chemotherapies. The benefit of this approach is that often lower drugs doses can be used that may limit side

Table 1 Select epigenetic therapies targeting DNA methylation or histone deacetylation

Drug	*Target*	*Cancer type*	*Clinical status*
Single agent therapy			
5-Azacytidine (AZA)	DNMT1	MDS	Approved
5-Aza-2′-deoxycytidine (Decitabine)	DNMT1	MDS	Approved
SGI-110 (Guadecitabine)	DNMT1	Clinical trials: MDS, AML, ovarian, HCC	NCT01261312 NCT01752933
Belinostat	Pan HDAC	PTCL	Approved
Panobinostat	Pan HDAC	MM	Approved
Romidepsin	HDAC1, 2	CTLC, PTCL	Approved
Vorinostat (SAHA)	Pan HDAC	CTLC	Approved
Entinostat	HDAC1,2,3	NSCLC, HL, solid tumors	NCT001349959 NCT00866333
Ricolinostat (ACY-1215)	HDAC6	MM, lymphoma	NCT02091063
Combination therapy			
AZA/Romidepsin/PD-1 Ab		CRC	NCT02512172
SGI-110/GVAX/CY		CRC	NCT01966289
AZA/entinostat/nivolumab		NSCLC	NCT01928576
Entinostat/interleukin-2		Kidney	NCT01038778
Decitabine/dendritic cell vaccine		High grade glioma	NCT02332889
ACY-1215/paclitaxel		Breast	NCT02632071

Abbreviations: *ALL*, Acute lymphocytic leukemia; *AML*, acute myelogenous leukemia; *CLL*, chronic lymphocytic leukemia; *CRC*, colorectal cancer; *CTLC*, cutaneous T-cell lymphoma; *HCC*, hepatocellular carcinoma; *HL*, Hodgkin's lymphoma; *MDS*, myelodysplastic syndrome; *MM*, multiple myeloma; *NSCLC*, non-small cell lung cancer; *PTCL*, peripheral T-cell lymphoma.

effects and reduce the potential for development of drug resistance. A more recent emphasis of clinical cancer therapy research has been directed towards testing DNMT inhibition in combination with immunotherapy.

DNA demethylating agents may induce an antiviral, antiproliferative state that reactivates tumor antigen presentation and alters apoptotic cell signaling cascades. In some circumstances evidence suggests that 5-azacytidine induces expression of typically silent endogenous retroviral sequences by demethylation of normally heavily methylated and inactivated long terminal repeat regions to promote the production of dsRNA and activation of the host anti-viral defense mechanism including interferon production. Significantly, inhibition of DNA methylation has been reported to sensitize a mouse melanoma model to anti-CTLA4 therapy and Aza induced an immune response expression signature in non-small cell lung cancer cells (NSCLC) that included increased expression of PD-L1 (CD274). These findings have led to subsequent clinical trials testing Aza in combination with anti-PD1 immune checkpoint inhibitors such as nivolumab and pembrolizumab. Epigenetic agents have also been reported to benefit cell-based immunotherapies. For example, decitabine has been reported to induce expression of NY-ESO-1 (CTAG1B) in glioblastoma cells which could be targeted with antigen specific lymphocytes in vivo. Thus, combination therapies that include demethylating agents to increase antigen production in cancer cells have emerged as a promising anti-cancer strategy to boost the effectiveness of either antibodies directed against immune checkpoint regulators or cell based immunotherapy (**Table 1**).

Targeting Defective DNA Demethylation

Defects in CpG demethylation cause DNA hypermethylation that may alter gene expression and promote tumorigenesis. Mutations and translocations of *TET2* were observed in MDS, myeloproliferative syndrome and in AML are associated with poor prognosis. Loss of function of *TET2* might rationally be approached by use of demethylating agents and some clinical data suggests that *TET2* mutant MDS may be more amenable to Aza. Aberrant loss of DNA demethylation is also associated with recurrent site specific heterozygous mutations of the enzymes isocitrate dehydrogenase 1 and 2 (IDH1 and IDH2) which are found in gliomas, AML, chondrosarcomas and cholangiocarcinoma. The mutant IDH1/2 protein reduces α-ketoglutarate (αKG) to 2-hydroxygluterate (2-HG), a competitive inhibitor of TET proteins. The TET enzymes contain the Jumonji C domain representing an α-ketoglutarate dependent dioxygenase that converts 5′-methylcytosine to 5′-hydroxymethylcytosine, an important intermediate in cytosine demethylation. IDH1/2 mutations are associated with a pattern of aberrant hypermethylation and gene expression in AML, a block of white cell differentiation and enhanced self-renewal. Pharmacological agents (Ivosidenib and enasidenib) that target mutant IDH1 and IDH2 respectively were recently approved for the treatment of AML. These agents block the production of 2-HG by the mutant enzymes, thus restoring TET2 function and reverting DNA methylation and gene expression patterns towards the normal state. This represents a form of differentiation therapy, analogous to the use of retinoic acid in acute promyelocytic leukemia, in that the mature granulocytes that appear in the circulation of patients treated with these agents are derived from the malignant clone. Complete remissions occur without the bone marrow aplasia typical of cytotoxic chemotherapy, making this therapy more tolerable for elderly leukemia patients.

Anticancer Strategies That Target Histone Acetylation

Histone Acetylation in Cancer

Lysine acetylation of histones is important for regulation of chromatin structure, transcription and DNA repair. Two competing enzyme families regulate this highly dynamic modification, histone lysine acetyltransferases (HATs) and histone deacetylases (HDACs). Approximately 30 HATs have been identified and classified into two groups based on their subcellular location. The mainly nuclear type-A HATs acetylate chromatin bound histones and nuclear proteins while the cytoplasmic type-B HATs acetylate newly translated histones. Type-A HATs are further categorized into families based on structural and functional homology. HATs transfer the acetyl group from acetyl-CoA to the amino group of a histone lysine thereby neutralizing the positive charge of lysine and diminishing the interaction of histone with DNA. In general this causes a more relaxed and accessible chromatin structure that favors binding of proteins such as transcription factors, and thus acetylation of chromatin is associated with transcriptional activation while deacetylation is associated with gene repression. In many cancers chromosomal translocations (e.g., MLL-CBP and MOZ-CBP) or mutations (e.g., p300/CBP) of HATs have been reported. Deletions or mutations that inactivate CBP have been reported in about 40% of diffuse large B-cell and follicular lymphomas and this is associated with defective acetylation of Bcl6 and p53, potentially contributing to lymphomagenesis. Cells defective in CBP appear to require the related p300 acetyltransferase protein for survival and hence inhibitors of HATs may be useful in specific settings. HAT inhibitors are currently at the preclinical stage of development. One promising p300-HAT inhibitor, C646, was reported to specifically inhibit growth of lung and hematopoietic cancer cells and more recently A-485, an even more potent and drug like inhibitor that competes with acetyl-coA, was effective in models of castration-resistant prostate cancer.

Histone Deacetylase Inhibitors as Cancer Therapy

HDACs play a key role in gene expression by removal of the activating histone acetylation and may also have other roles in the cell by controlling acetylation of non-histone and non-nuclear proteins (Fig. 1). HDACs may be aberrantly recruited to target genes through overexpressed transcription factors or chimeric transcription factors such as those created by chromosomal fusions in AML. These latter findings motivated the targeting of these proteins for cancer therapy. HDACs are classified into four groups based

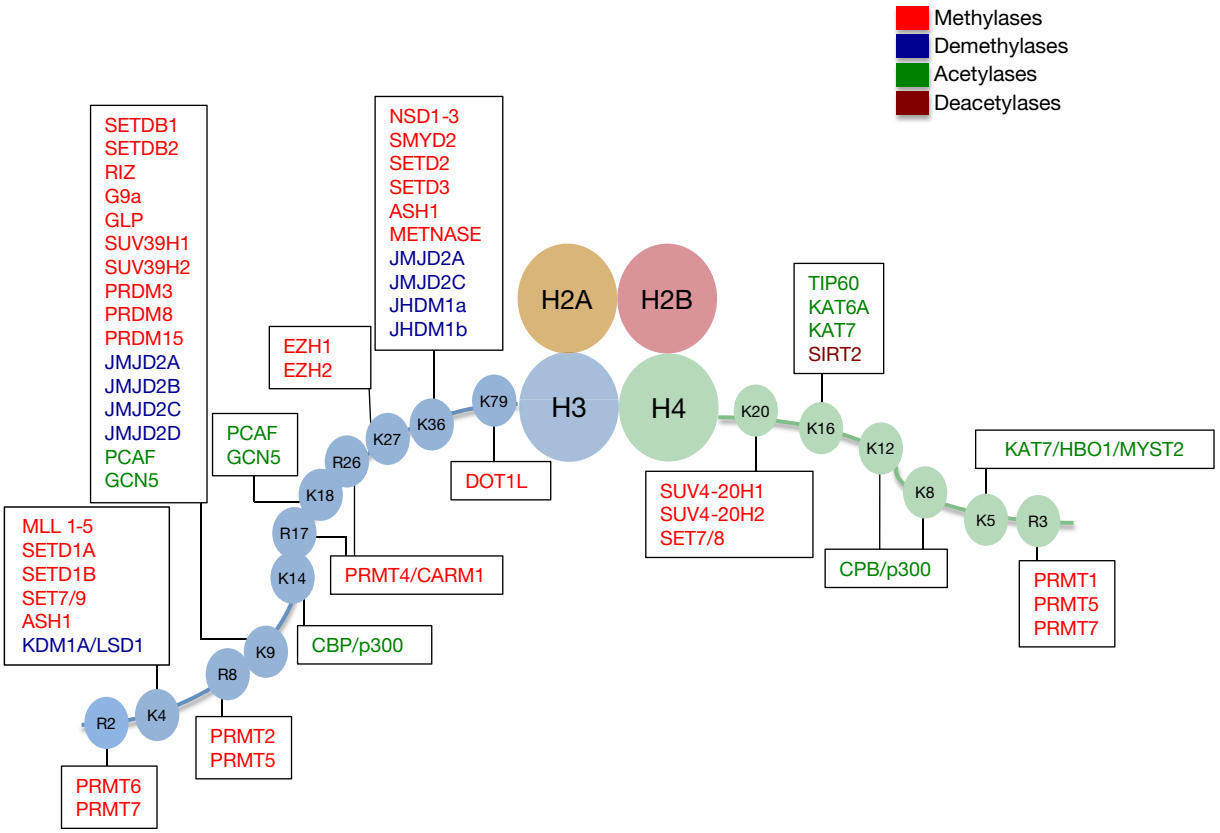

Fig. 1 Histone modifying enzymes and their targets. The lysine (K) and arginine (R) residues on histone H3 and H4 tails are targets for modification by epigenetic mark writers (methyltransferases and acetyltransferases) and erasers (demethylases and deacetylases). Some amino acid residues can serve as targets for several different types of epigenetic modifications as depicted.

on homology and structure. HDACs in classes I, II, and IV are Zn^{++}-dependent while class III HDACs are nicotine adenine dinucleotide (NAD)-dependent sirtuins. Class I (HDACs 1–3, and 8) and class II (HDACs 4–7, 9, and 10) HDACs have been reported to play roles in tumorigenesis. Many synthetic or natural product HDAC inhibitors (HDACi) have been developed as cancers therapies. These HDACi can be organized into four groups based on their chemical structure: hydroxamates, benzamides, cyclic peptides or short-chain fatty acids (**Table 1**). Several nonselective and broad spectrum HDACi target the Zn^{2+} ion in the active site of Zn^{2+} dependent HDACs to inhibit their enzymatic activity. These include the hydroxamate class agents vorinostat, belinostat, and panobinostat. Vorinostat has been approved to treat patients with cutaneous T-cell lymphoma (CTCL) and induces cell cycle arrest, apoptosis and sensitivity to chemotherapy. Belinostat and panobinostat have been approved for treatment of peripheral T-cell lymphomas (PTCL) and multiple myeloma (MM) respectively and are in clinical trials to treat solid tumors. These nonselective HDACi can reverse aberrant epigenetic chromatin changes to reactivate tumor suppressor genes such as p21. In addition, HDACi may block acetylation of non-histone proteins such as transcription factors that contribute to cell cycle regulation, differentiation and apoptosis in cancer cells. These initially approved HDACi have pleotropic actions and the exact mechanism for their antitumor effect remains uncertain. Additional non-transcriptional mechanisms may include generation of excess reactive oxygen species, hyperacetylation of chaperone proteins causing oncoprotein instability, DNA damage due to highly accessible, hyperactylated chromatin and mitotic anomalies due to hyperacetylation of critical regulatory proteins. Selective HDACi include romidepsin that targets HDAC1 and 2 and ricolinostat, an HDAC6 specific inhibitor. Romidepsin has been approved for use in patients with CTCL or PTCL while ricolinostate is in clinical trials for patients with MM or lymphoma. Interestingly, HDAC6 is a cytoplasmic deacetylase that regulates the acetylation of histone chaperones and also binds ubiquitinated proteins. HDAC6 inhibition leads to the accumulation of unfolded ubiquitinated proteins and cell death. Thus, ricolinostat has been especially promising for MM since these cells are dependent on clearance of misfolded/aggregated proteins due to high immunoglobulin production. Many clinical trials are ongoing to test the efficacy of HDACi against various cancers (**Table 1**), and understanding how HDACi affect mechanisms of cancer cell survival is an active area of basic and translational research.

Combination Therapies That Include Histone Deacetylase Inhibition

In addition to being used as a single agent therapy, many reports indicate that low dose application of HDACi improves the ability of Aza to reactivate expression of genes in vitro, specifically in cancer cells with hypermethylated promoter CpG islands. Because of these data, several ongoing studies are testing combinations of DNMTi and HDACi in the treatment of hematologic malignancies and solid tumors. One of the most promising applications of combination HDACi and hypomethylating agents has been with NSCLC patients where Phase I/II trials indicate that low doses of 5-azacytidine and entinostat were associated with improved progression free and overall survival in a small cohort of patients with a complete and a partial response observed in one patient. The evidence that the effect of HDACi/demethylation combination is due to reactivation of gene expression is mixed. Alternative explanations could be due to the ability of HDAC inhibitors to hyperacetylate chromatin and sensitize cells to DNA damaging effects of Aza or decitabine. Another possibility is that the combination can briskly reactivate endogenous retroviruses and induce an antiproliferative, antiviral response in the cancer cell.

Anticancer Strategies That Target Histone Methylation

Histone Methylation in Cancer

Post-translational modification of histone N-terminal and C-terminal tails that extend beyond the nucleosome core influence downstream biological processes such as transcription, replication, and chromosomal stability. Reversible methylation of histone tails is orchestrated by lysine methyltransferases (KMTs) and arginine methyltransferases (PRMTs) while lysine and arginine demethylases (KDMs and PRDMs) remove these marks (**Fig. 1**). Histone methyltransferases (HMTs) catalyze transfer of a methyl group to the basic amino acids lysine, arginine and histidine present in histone tails. Histone lysine residues can be modified to mono-, di- or tri-methylated forms (me1, me2 or me3) and histidine can be mono-methylated but this modification is rare. Arginine may be mono or di-methylated and dimethylation may be either symmetrical, meaning that methyl groups are added to both nitrogen atoms in the side chain or asymmetrical in which two methyl groups are added to only one of the side chain nitrogen atoms.

Except for DOT1L1, which has an unique enzymatic domain, the enzymatic activity of all KMTs resides in the Su(var)3-9, Enhancer-of-zeste and Trithorax (SET) catalytic domain (SET) domain while type I and type II PRMTs share a well conserved *S*-adenosyl methionine (SAM)-binding catalytic core of about 350 amino acids. These enzymatic domains have pockets that bind SAM to be used as a donor co-factor for the transfer of methyl groups to substrates. Quantitative analysis of methylated histone residues by mass spectrometry demonstrates that all histone proteins (H1, H2A, H2B, H3, and H4) may be methylated, and the most frequently methylated histones are H3 and H4. Commonly observed lysine methylation sites include K4, K9, K27, K36, and K79 on histone H3, K20 on histone H4, and K26 on histone H1. Major arginine methylation sites are R2, R8, R17, R26 on histone H3, R3 on histone H4 and R11 and R29 on histone H2A. Lysine methylation causes an increase in hydrophobicity with no net change in charge, in contrast to acetylation that neutralizes the positive charge of lysine. These methylated histones can be recognized by chromatin "reader" molecules and further recruit other molecules to alter chromatin and/or transcription states. Chromatin regulators may contain one or many different types of chromatin reader modules and often chromatin "writers" recognize the very modification they make, attracting more molecules of the enzyme to chromatin and allowing chromatin modifications

to spread along the length of chromatin. Bromodomain and PHD domains recognizes acetylated histone. Methyl-lysine may be recognized several different classes of domains including chromo, PWWP, WD40, and MBT, while methyl-arginine is recognized by the Tudor domains. As discussed below some of these domains represent therapeutic targets.

Demethylation of histones is accomplished by two main classes of histone demethylases: the flavin adenine dinucleotide (FAD) dependent amine oxidases and the Fe(II)/2-oxoglutarate (2-OG) dependent Jumonji C domain family. In addition, arginine residues within proteins can be converted to citrulline by peptidyl arginine deiminases (PADs) to block arginine monomethylation. A major group of deiminated proteins are the core histones: H2A, H3, and H4. Analogous to histone lysine acetylation, histone citrullination neutralizes the positive charge of arginine and is associated with an open chromatin structure.

Dynamic changes in histone methylation state can occur based on cell type, tissue type or cell cycle phase and are important for the response to factors such as DNA damage, mitogen signaling and environmental stress. The balance between the methylated and demethylated states of histones at specific lysine residues can regulate transcriptional activity (Fig. 2). For instance, lysine methylation of histone H3 at amino acid residue 4 (H3K4), 36 (H3K36), and 79 (H3K79) are associated with activation of gene expression while methylation at lysine 9 (H3K9), 20 (H3K20), and 27 (H3K27) are associated with repression of gene expression. Dysfunctional histone methylation and the resultant aberrant gene expression has been linked to a range of malignancies. Loss or gain of KMT or KDM activity can result from missense mutation, deletion, amplification or chromosomal rearrangement affecting the genes encoding these enzymes. KMT or KDM dysfunction has often been reported to be linked with tumor grade, chromosomal instability, mutation burden and clinical outcome. Given the importance of these enzymes in regulating gene expression, and the fact that methylation is reversible, there has been considerable effort towards developing pharmacological inhibitors for methyltransferases and demethylases in hopes of restoring histone methylation balance in cancer cells leading either to either cell death or enhanced response to chemotherapy or other therapies.

Anti-Cancer Therapeutic Strategies Targeting Histone Methyltransferases

Inhibitors of DOT1L methyltransferase

DOT1L is a mammalian ortholog of yeast disruptor of telomeric silencing-1 (Dot1) gene, and plays an important role in regulating various biological functions including cell cycle, development and DNA repair. DOT1L is the only known methyltransferase that methylates H3K79 and has an important role in leukemia associated with rearrangement of the MLL (Mixed lineage leukemia) gene. Translocations of MLL/KMT2, which encodes a HMT specific for H3K4me3, yields an in frame fusion of the N terminus of MLL that is devoid of HMT activity with other nuclear proteins such as AF4, AF9, AF10 or ENL. These fusion proteins recruit DOT1L and other MLL related factors to increase DOT1L mediated methylation of H3K79 which promotes transcription elongation. This methylation mark serves as a signal for active transcription and is thought to be responsible for oncogenic expression of HOXA9 and MEIS1 in leukemias. Since the H3K79 methylation signature of MLL-rearranged leukemia is distinct from other forms of AML, targeting DOT1L may be a useful therapeutic strategy for MLL-rearranged leukemias.

Most methyltransferase inhibitors identified to date compete with the methyl donor *S*-adenosyl methionine (SAM) for binding to the enzyme and developing drugs specific for any one HMT has proven a challenge. Several small molecule inhibitors developed

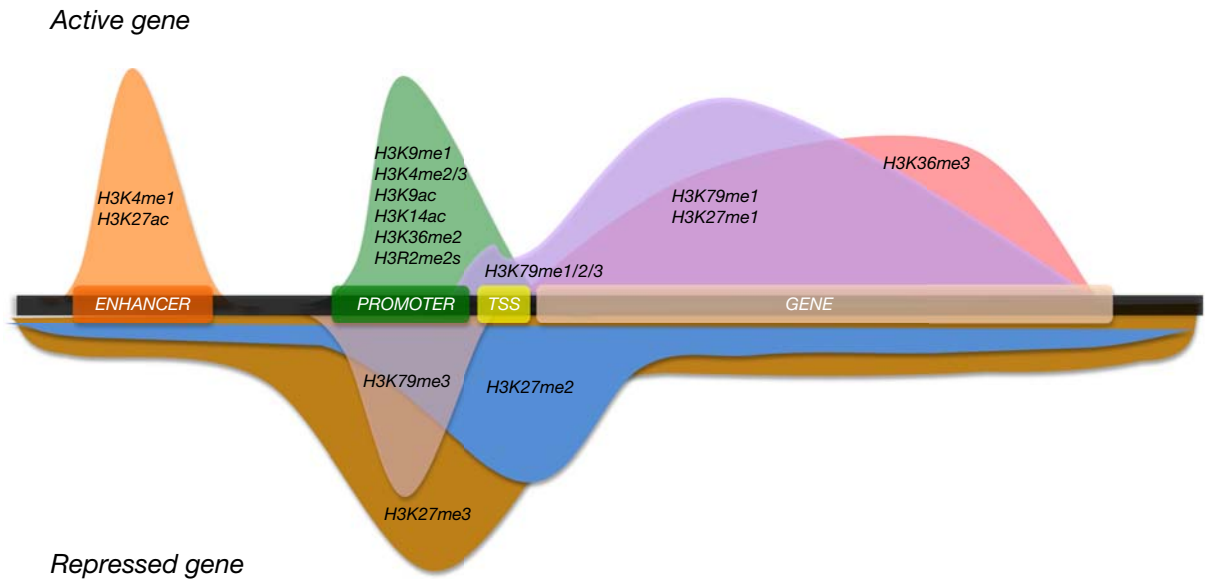

Fig. 2 Distribution of histone marks across a gene. Enrichment of widely studied histone modification marks associated with gene activation (upward peaks) and gene repression (downward peaks) at the enhancer, promoter and the gene body regions is represented. TSS = Transcription start site.

Table 2 Select epigenetic therapies targeting histone tail methylation

Drug	*Target*	*Cancer type*	*Clinical status*
HMT inhibitors			
GSK3326595	PRMT5	Solid tumors, non-HL	NCT02783300
Pinometostat (EPZ-5676)	DOT1L	Clinical trials: hematologic malignancies	NCT01684150
Tazemetostat (EPZ-6438)	EZH2	Clinical trials: solid tumors, DLBCL, HL, non-HL	NCT02889523
HDM inhibitors			
ORY-1001	LSD1	Clinical trials: AML	
GSK2879552	LSD1	Clinical trials: AML, relapsed/refractory small cell lung carcinoma	NCT02034123 NCT02034123
Tranylcypromine	LSD1	Clinical trials: AML, MDS	NCT02273102

Abbreviations: *AML*, Acute myelogenous leukemia; *DLBCL*, diffuse large B-cell lymphoma; *HL*, Hodgkin's lymphoma; *MDS*, myelodysplastic syndrome.

to inhibit DOT1L function by targeting the interaction between DOT1L and SAM. Two potent inhibitors developed by Epizyme are in clinical trials (**Table 2**). EPZ004777 selectively binds DOT1L and other methyltransferases that utilize SAM as a methyl-group donor and was shown to selectively eliminate rearranged-MLL tumor cells in vitro as well as increase survival of mice. A derivative of EPZ004777 known as Pinometostat (EZ-5676) effectively inhibits the proliferation of MLL-rearranged cells and decreases expression of HOX genes associated with H3K79 methylation and DOT1L function. Mouse xenograft models showed significant reduction and regression of tumors upon EZ-5676 treatment. Due to poor pharmacokinetic properties and toxicity of EPZ004777 it was eliminated in earlier phases of clinical development. However, the derivative EZ-5676 exhibits less toxicity, has completed Phase I trial (ClinicalTrials.gov identifier: NCT01684150 and NCT02141828) and is currently in further development (**Table 2**). Both the drugs specifically target the MLL-rearranged leukemia cells with little to no effect on other leukemia cells. EZ-5676 has also been tested in combination with other therapies including DNMT3 inhibitors like 5-azacytidine, daunorubicin or cytarabine and with inhibitors of menin, a critical cofactor for MLL-fusion associated leukemia. In general, these preclinical studies demonstrate a synergistic effect between EZ-5676 and other therapies in killing of tumor cell lines.

Inhibitors of EZH2 methyltransferase

Enhancer of zeste2 (EZH2) is the catalytic component of the polycomb repressive complex 2 (PRC2) that is responsible for trimethylation of H3K27 associated with chromatin compaction and transcriptional repression. EZH2 contains a SET catalytic domain, is an important regulator in several cellular pathways including cell cycle regulation, X-chromosome inactivation and metastasis. EZH2 is generally overexpressed in metastatic tumors relative to normal tissues or primary tumor specimens and promotes cancer cell growth and an epithelial-mesenchymal transition (EMT). Gain of function mutations of EZH2 are found in diffuse large B cell lymphoma of the germinal center type and more rarely in thyroid cancer and malignant melanoma. These heterozygous mutations represent a change of function that enhances the ability of the enzyme to cause trimethylation of H3K27 and in lymphoma this leads to aberrant repression of tumor suppressor genes and late B cell genes, thus locking the B cell in a state of continuous proliferation at the germinal center stage of differentiation. Loss of function and deletion of EZH2 is found in MDS and AML and is associated with global decreases in the repressive H3K27me3 mark that activates oncogene expression (**Fig. 2**). Thus, depending on the cellular context or function of dysregulated gene expression, EZH2 can have either an oncogenic or tumor suppressor function.

Several pharmacological inhibitors of EZH2 have been developed and studied both in vitro and in clinical trials. The first widely studied inhibitor of EZH2 was 3-deazaneplanocin A (DZNep), an adenosine analogue that interferes with the methionine cycle causing the level of *S*-adenosyl-L-homocysteine (SAH) to increase and inhibit SAM-dependent methylases. In addition, DZNep induced degradation of PRC2 complex members including EZH2 to reactivate epigenetically silenced gene expression in cancer cells and induce apoptosis. Recently, significant efforts have been made to develop inhibitors that are more selective and effective EZH2 inhibitors than DZNep. Perhaps the most promising agent currently undergoing clinical trials is Tazemetostat (EPZ-6438), an orally bioavailable EZH2 inhibitor developed by Epizyme (**Table 2**). Tazemetostat effectively inhibited tumor growth in xenograft models and is currently being tested in Phase 1 and 2 clinical trials (ClinicalTrials.gov: NCT01897571 and NCT 02601950) for B-cell lymphomas and synovial sarcomas. Tazemetostat is also under study for the treatment of sarcomas associated with rearrangements or mutations of genes encoding the SWI/SNF chromatin remodeling complex. Preclinical studies showed that the lack of SWI/SNF activity leads to a failure of expression of specific genes which can be overcome by inhibition of the repressive action of EZH2 and the PRC2 complex. Another EZH2 inhibitor under investigation in Phase I clinical trial is CPI-1205 developed by Constellation Pharmaceuticals (ClinicalTrials.gov: NCT02395601). A SAM-competitive inhibit with high specificity for EZH2, CP-1205 effectively reduced H3K27me3 in vitro and inhibited tumor growth in animal studies. GlaxoSmithKline also developed small molecule compounds that demonstrate inhibition of EZH2 in preclinical studies. GSK343 exhibited high specificity for enzymatic inhibition of both EZH1 and EZH2 while GSK126 specifically inhibited proliferation of diffuse large B-cell lymphoma (DLBCL) cells that have a gain of function EZH2 mutant. Unfortunately, while GSK126 worked well in cell line and animal models to decrease H3K27 methylation levels, it failed in early phase clinical trials due to unsatisfactory efficacy (Clinicaltrials.gov: NCT02082977). Other

SAM competitive inhibitors of EZH2 have been identified by high throughput screens and been the subject of preclinical studies. For instance the compound EI1 developed by Novartis is reported to specifically inhibit EZH2 compared to other HMTs including EZH1, and EPZ005687, developed by Epizyme, inhibited H3K27 methylation in lymphomas bearing activating EZH2 mutations. In addition, UNC1999 was the first orally bioavailable SAM competitive inhibitor of EZH1 and EZH2 identified, and preclinical studies have demonstrated its effectiveness at decreasing H3K27 methylation and promoting cell death of DLBCL cell lines.

Because combination therapies are preferable to prevent cancer cell escape from any single agent and secondary EZH2 mutations have been observed in cell lines that acquired resistance to EL1, several preclinical studies have investigated the efficacy of combination therapies that include EZH2 inhibition. In a non-Hodgkin lymphoma (NHL) model combining Tazemetostat with a standard therapy cocktail containing cyclophosphamide, hydroxyldaunorubicin, oncovin and predinosone (CHOP) promoted synergistic cell killing of EZH2 mutant germinal center NHL cell lines. In this study, significant synergy was observed between Tazemetostat and Predinosone, a glucocorticoid receptor agonist, suggesting a cooperation between glucocorticoid mediated gene regulation and EZH2-mediated chromatin remodeling. The combination of Tazemetostat and Predinosone is in Phase 1/2 clinical trials for patients with DLBCL (Clinicaltrials.gov: NCT01897571). In addition, GSK126 was observed to cooperate with etoposide to promote cell death in prostate cancer cell lines. Furthermore, EZH2 inhibitors increased cell sensitivity to topoisomerase inhibition specifically in BRG1 or EGFR mutant NSCLC cell lines. Together, these preclinical data demonstrate the potential of combining EZH2 inhibition therapy with traditional chemotherapies.

Inhibitors of arginine methyltransferases

Nine PRMTs have been identified in mammalian cells. PRMTs 1–4, 6, and 8 are type I PRMTs that catalyze the monomethylation and asymmetric dimethylation of arginine residues. PRMT5 and 9 are type II PRMTs that catalyze mono and symmetric dimethylation of arginine. PRMT7 is a type III PRMT that only catalyzes monomethylation of arginine. Arginine methylation regulates protein-protein interactions with Tudor domain-containing proteins and asymmetric or symmetric dimethylated arginine motifs bind to distinct subsets of Tudor domain containing proteins. In general, asymmetric dimethylation of histones has been associated with transcriptional activation while symmetric dimethylation is linked to transcriptional repression. Arginine methylation can be further regulated by the composition of PRMT containing protein complexes. For instance PRMT1 substrate specificity can be regulated by binding to BTG family proteins, PRMT3 methyltransferase activity is inhibited by association with tumor suppressor DAL-1, PRMT4/CARM1 has the ability to methylate nucleosomal histone H3 when part of the nucleosomal methylation activator complex and PRMT5 can be activated by MEP50 binding to associate with the SWI/SNF chromatin remodeling complex.

Several studies have associated PRMT activity with tumorigenesis. For instance, increased PRMT1 expression promotes survival and invasion, while loss of PRMT1 leads to cell cycle arrest in cancer cell lines. PRMT1 was reported to methylate and promote the activity of the AML1-ETO fusion found in about 15% of AML. Furthermore, PRMT1 has been reported to be required for the transformation activity of MLL fusion proteins such as MLL-EEN or MLL-GAS7 in MLL rearranged leukemias. PRMT1 is the primary cellular arginine methylase since it is broadly expressed in both the cytoplasm and nucleus and is responsible for almost all global asymmetric arginine dimethylation. PRMT1 substrates include histone H4 (H4R4), transcription factors, transcription initiation factors and RNA splicing factors. PRMT1 was also reported to have roles in DNA damage repair, RNA splicing, signal transduction as well as gene expression. In addition, PRMT4/CARM1 and PRMT6 expression as well as asymmetric dimethylation of arginine was found to be elevated in many cancers. Significantly, PRMT4 was required for initiation and maintenance of AML-ETO or MLL-AF9 driven leukemia in mouse models. Overexpression or increased activity of type II PRMT5 has also been observed particularly in hematopoietic malignancies, and deletion or inhibition of PRMT5 relieves the differentiation block characteristic of MLL-rearranged leukemia in vitro and in vivo.

Extensive efforts have been made to develop PRMT inhibitors as anti-cancer agents. Early studies utilized SAM analogues such as sinefungin as pan-methylase competitive inhibitors to study PRMT function. More recently several pharmacological compounds have been identified that more potently and selectively inhibit PRMTs. These compounds include AMI-1 that selectively inhibits type I PRMTs as well as inhibitor 6e and C7280948 that specifically inhibit PRMT1. In addition, AMI-408 has can inhibit PRMT1 and decrease transformation of AML cells expressing an MLL-GAS7 or MOZ-TIF2 fusion. Furthermore, EPZ015666 (GSK3235025) is a selective inhibitor of PRMT5 that decreases symmetric dimethylation of arginine and exhibits anti-tumor activity in mantle cell lymphoma xenograft models. In addition, EPZ015666 delayed disease progression and improved survival of MLL-fusion AML xenografts by inducing myeloid cell differentiation without affecting expression of MLL-fusion oncogene targets. This compound primarily inhibited arginine dimethylation of non-histone targets. Many preclinical studies have identified and characterized PRMT inhibitors as anticancer agents in cell lines and animals and GSK3326595, a PRMT5 inhibitor, is currently in Phase I trials for patients with solid tumors and non-Hodgkin's lymphoma (**Table 2**). Studies with PRMT inhibitors have been important to dissect the mechanism and function of arginine methylation in cancer but also demonstrate the challenges to develop HMT inhibitors that are specific and efficacious enough to have a clinical impact.

Anticancer Therapeutic Strategies Targeting Histone Demethylases

Since the discovery of the first lysine specific demethylase in 2004, the number of histone demethylases identified has expanded to include more than 30 enzymes that can be classified into two families based on their mechanisms: the flavin-dependent KDM1 family (also called LSDs) and the Fe(II) and 2-oxogluterate (2OG)-dependent Jumonji (JmjC) family consisting of the KDM2 to KDM8 subfamilies. In addition, a subset of JmjC lysine demethylases have been reported to demethylate arginine in vitro but

the biological activity of these enzymes in cells is presently unclear. The substrate specificity of KDMs is often dictated by their binding partners which can change in different cellular contexts. Mutations or aberrant expression of demethylases may be observed in cancer and function to deregulate chromatin structure and gene expression. Thus, inhibition of demethylases that are overexpressed or activated by mutations in cancer may rebalance the methylation load and trigger cell death mechanisms in tumor cells.

Inhibitors of KDM1 demethylases

The KDM1 family is comprised of KDM1A (LSD1) and closely related KDM1B (LSD2) that for mechanistic reason are only able to demethylate mono- and di-methylated residues. KDM1A (LSD1) has been reported to demethylate H3K4me1/me2, H3K9me1/me2, DNMT1, E2F1 and p53 while KDM1B (LSD2) demethylates H3K4me1/me2. KDM1A may be overexpressed in both solid tumors and hematologic malignancies. Because the catalytic domain of the KDM1 family is related to monoamine oxidases (MOAs) that catalyze the oxidation of neurotransmitters, the first generation of inhibitors tested for inhibition of KDM1 were relatively nonspecific MOA inhibitors first approved for depression and other psychiatric disorders. Many of these MOA inhibitors function by irreversibly binding the KDM1 cofactor flavin adenine dinucleotide (FAD) within the active site of the demethylase. MOA inhibitors that have been characterized to inhibit KDM1 and are being evaluated in clinical trials include phenelzine, tranylcypromine (TCP or PCPA), and pargyline (**Table 2**). In addition several TCP derivatives have been developed with improved potency and selectivity for KDM1A that are being tested in preclinical studies, Phase 1 and 2 trials. These TCP derivatives include the compounds ORY-1001 and GSK2879552 which have been reported to be effective in cell lines and mouse models of human tumors and are in Phase 1 clinical trials for AML and small cell lung cancer (**Table 2**). Significantly, reports suggest that KDM1A inhibition sensitizes cells to all-trans-retinoic acid (ATRA), and KDM1A inhibitors TCP, GSK2879552, INCB059872 or IMG-7289 are currently being evaluated in combination with ATRA in clinical trials for patients with AML, MDS or myelofibrosis (NCT02273102, NCT02842827, NCT03136185, and NCT02177812). Several other agents have been developed to specifically inhibit KDM1A in cell lines and human tumor xenograft models. These include hydrazine-derivatized peptides that function as substrate mimetics, polyamines and the small molecule inhibitors Namolin and GSK354. However, more detailed in vitro and in vivo studies are required before these compounds are ready to be tested clinically.

Inhibitors of JmjC family demethylases

Jumonji domain containing αKG-dependent dioxygenases can demethylate mono-, di- or tri-methylated lysines by a hydroxylation pathway involving a reactive Fe(IV) intermediate. These demethylases contain Tudor and plant homology domains (PHD) that are responsible for recognition and specificity of particular histone lysine residues. KDM2A and 2B demethylate H3K36me2, and KDM2B also demethylates H3K4me3. KDM2B is reported to be significantly overexpressed in pancreatic ductal adenocarcinoma to repress development genes and senescence mechanisms as well as regulate the TRAIL response in glioblastoma cells. The KDM3 family consists of KDM3A, KDM3B, and JMJD1C. KDM3A and 3B remove repressive H3K9me1/me2 marks. In addition, KDM3A has been reported to promote chemo-resistance by demethylating p53 leading to increased chromatin binding by p53, and depletion of KDM3A reactivates p53 to increase expression of proapoptotic genes in breast and ovarian cancer cell lines. The KDM4 family consists of four members that recognize H3K9me2/3, H3K36me2/3, and H1.4K26me3 as substrates. Multiple reports indicate that KDM4A, 4B and/or 4C are overexpressed by translocations or gene amplifications in various solid tumors and hematologic malignancies where they may alter the function of steroid receptor transcription factors. The KDM5 family members demethylate H3K4me2 and H3K4me3 and are often found amplified in cancers to activate oncogene expression and cause therapy resistance. KDM6A and KDM6B act on the H3K27me3 repressive mark, and inactivating mutations or deletions of KDM6A are among the commonest lesions in epigenetic regulators across all cancer, being most commonly inactivated in bladder cancer. KDM6A has been reported to regulate the cell cycle in an RB-dependent mechanism. Loss of KDM6B has been reported in the progression of pancreatic cancer and is associated with a more aggressive phenotype. KDM7A, 7B, and 7C act on the H3K9me2/1, H3K27me2/1, and H4K20 me1 repressive marks. Genetic alterations that elevate expression of KDM7B were reported in several cancers including NSCLC and esophageal carcinoma and KDM7C is an epigenetic activator of p53 located in a colorectal predisposition locus. KDM8 has been reported to demethylate H3K36me2 and be required for regulation of cyclin A1 expression and cell cycle progression.

Because of the large number of JmjC-domain containing demethylases involved in cancer and the availability of structural and mechanistic information, the development and testing of JmjC KDMs is a promising field of cancer therapy development. However, despite the large number of KDM inhibitors developed to date, in general these compounds demonstrate a lack of specificity and have not progressed beyond preclinical studies. One of the first types of JmjC KDM inhibitors discovered were the *N*-oxalyl amino acid-based JmjC KDM inhibitors such as *N*-oxalylglycine (NOG) a closely related analogue of αKG. However, NOG is a broad spectrum inhibitor that inhibits almost all tested JmjC KDMs. In addition, analogs of NOG such as pyridine-2,4-dicarboxylic acid (2,4-PDCA) were also reported to inhibit most JmjC KDMs. Several other efficient KDM inhibitors have been identified recently using high-throughput screening strategies such as GSK-J1 and its prodrug GSK-J4 which inhibit KDM6A and 6B, but these also display lesser activity against KDM5A and 5B. In preclinical studies GSK-J4 was reported to increase H3K27 methylation and demonstrated potent antitumor effects both in cell lines and animal models of glioma. In addition, a potent and selective inhibitor of KDM5B, EPT1013182, discovered by high throughput screening also has antiproliferative effects on cell lines and multiple myeloma xenograft models. Interestingly, several groups have coupled chemical features of KDM1 family inhibitors with JmjC domain family inhibitors to yield compounds that effectively inhibit KDMs with little or no activity against other αKG enzymes lacking KDM

activity. Taken together these reports suggest that although inhibition of KDM activity is a promising therapeutic strategy, significant technical hurdles remain before development of specific inhibitors that will be clinically useful is achieved.

Anti-Cancer Strategies That Target Epigenetic Reader Molecules

The Role of Epigenetic Mark Readers in Cancer

Many proteins that regulate transcription or chromatin structure bind to distinct nucleosome modifications and act as epigenetic mark readers. A variety of specific domains of reader proteins allows recognition of distinct covalent modifications on lysine residues and even distinguish between specific mark complexities such as mono- versus di-methylation. Examples of protein domains commonly found in reader proteins include the plant homology domain (PHD) and the proline–tryptophan–tryptophan–proline (PWWP) domain that bind to methylated histones, bromodomains that bind to acetylated lysines and the YEATS domain that preferentially binds crotonylated histone lysine residues. Reader complexes play an instructive role in transcription by directing the activity of chromatin remodeling complexes and regulating the rate of transcription to maintain homeostasis. For example, bromodomain containing proteins have been found to act as transcription factors (BRD1–4), transcriptional repressors (BRD7), transcriptional co-activators (TAF1), SWI/SNF ATPases (SMARCA2A/B and SMARCA4), methyltransferases (ASH1L), and chromatin remodelers (CECR2, FALZ).

Mutations and translocations that alter reader proteins frequently may occur in cancer and can significantly deregulate gene expression. One of the best characterized family of epigenetic readers in cancer is the bromodomain and extra-terminal (BET) family that includes BRD2, BRD3, and BRD4. These proteins share a conserved structural element consisting of two bromodomains that recognize acetylated lysine on the N-terminal tails of histones H3 and H4. Importantly, BRD4 associates with the positive transcription elongation factor (P-TEFb) protein that activates RNA polymerase II to promote transcription elongation at paused sites. BRD4 is enriched at transcription start sites, enhancer and super enhancer regions, and BRD4 promotes expression of many transcription factors that are known to have roles in cancer development and progression such as Myc. BRD4 was also reported to recruit the histone methyltransferase NSD2 to the estrogen receptor alpha (ERα) gene to increase ER expression in breast cancer cells. Increased BRD4 expression was reported in melanoma tissues and hepatocellular carcinoma where it is associated with poor prognosis. In addition, the majority of patients that develop the rare lethal midline carcinoma have chromosomal rearrangements that create a fusion protein between BRD3 or BRD4 and the NUT protein. The BRD4-Nut fusion is localized in distinct subnuclear speckles in cancer cells, recruits HATs and sequesters cofactors normally associated with activated, acetylated chromatin away from normal gene targets, blocking expression of differentiation associated genes and maintaining cancer cells in an undifferentiated state of self-renewal. Treatment of BRD-NUT expressing cell lines with a small molecular inhibitor of BET domain acetyl lysine binding led to a reactivation of gene expression and induction of differentiation in these cells. This finding helped stimulated the development of pharmacological approaches to inhibit BRD4 and other BET domain proteins.

BET Family Inhibitors as Anticancer Therapy

Pharmacological inhibitors of BET family proteins that block bromodomain binding to acetylated lysine have been studied extensively and some of these agents are currently in clinical trials as anticancer agents (**Table 3**). These BET inhibitors displace BRD4 from gene regulatory regions to inhibit gene expression. Thus, the antitumor efficacy of BET family inhibitors is particularly promising for those cancers with increased expression of oncogenic transcription factors such as c-Myc. The prototypical BET inhibitor is JQ1 that was designed to target BRD4 and displace it from chromatin. JQ1 has been used extensively in preclinical studies where it has been demonstrated to block proliferation and induce apoptosis of many cancer cell lines. JQ1 can downregulate the expression of Myc and its entire transcription program in multiple myeloma cells and displace BRD4 from the promoter of the IL7 receptor gene to promote cell death in B-ALL cell lines. In ER+ tamoxifen-resistant breast cancer cell lines JQ1 suppressed ERα and cMyc expression and restored sensitivity to the mTOR inhibitor everolimus. Furthermore, JQ1 induced apoptosis specifically in KRAS mutant NSCLC cell lines and androgen receptor positive prostate cancer cell lines. JQ1 treatment downregulated NF-κB gene expression in diffuse large B cell lymphoma (DLBCL) cells and also blocked the binding of BRD4 to Ac-Lys310 of NF-kB causing ubiquitin-mediated protein degradation. In addition, JQ1 has been reported to sensitize AML cell lines to p53 mediated cell death. While JQ1 never succeeded in clinical trials due to its short half-life, preclinical results using it demonstrated the promise of BET inhibition as anticancer therapy and provided a template for further drug development.

Another compound used in preclinical studies to demonstrate the promise of BET family inhibitors as anticancer agents is I-BET151 (GSK1210151A) which inhibits BRD3 and BRD4. I-BET151 has been reported to induce apoptosis and cell cycle arrest in mixed-lineage leukemia (MLL) cell lines via decreased BCL-2, MYC, and CDK6 gene expression. In addition, it has been reported to have potent anti-myeloma activity not only through transcriptional repression of MYC but also by upregulation of HEXIM1 expression, an inhibitor of P-TEFb. Furthermore, I-BET151 has been reported to be effective inducing cell death of NPM1-mutated AML cell lines and demonstrated BIM-dependent apoptosis and cell cycle arrest in melanoma cells. Significantly, I-BET151 was reported to arrest cell cycle progression and inhibit proliferation even in myeloproliferative neoplasms and glioblastomas driven by constitutively active JAK2 kinase.

Recently, more effective bioavailable BET inhibitors have been developed and about 20 early phase clinical trials are currently open to evaluate various 2nd generation BET inhibitors on patients with cancer (**Table 3**). Among those being tested clinically,

Table 3 Select therapies targeting BET family epigenetic mark readers

Drug	*Target*	*Cancer type*	*Clinical status*
Single agent therapy			
OTX015 (MK-8628)	BRD2, 3, 4	Breast, NMC, B cell lymphoid, MDS, NSCLC, GBM, AML, DLBCL: advanced solid tumors	NCT01713582 NCT02259114 NCT02296476 NCT02698189 NCT01713582
TEN-010	BET domain	AML, MDS, solid tumors, NMC	NCT02308761 NCT01987362
I-BET762 (GSK525762)	BET domain	Prostate, MM, refractory hematological malignancies, NMC	NCT01587703 NCT01943851
GS-5829	BET domain	DLBCL, T cell lymphoma, solid tumors, ER+ breast cancer	NCT02392611 NCT02983604
PLX51107	BET domain	Solid tumors, lymphoma, AML, MDS	NCT02683395
ZEN003694	BET domain	Metastatic CRPC	NCT02705469 NCT02711956
CPI-0610	BET domain	Lymphoma, MM, acute leukemia, MDS, myelofibrosis	NCT01949883 NCT02157636 NCT02158858
Combination therapy			
GSK525762/trametinib	BET + MEK1/2 inhibitor	Solid tumors	NCT03266159
GSK525762/fulvestrant	BET + ER inhibitor	Estrogen receptor positive (ER+) breast cancer	NCT02964507
ZEN003694/enzalutamide	BET + nonsteroidal antiandrogen	CRPC	NCT02711956
OTX015/azacitidine	BET + DNMT inhibitor	AML and B cell lymphoma	NCT02303782
RO6870810/daratumumab	BET + CD38 inhibitor	MM	NCT03068351

Abbreviations: *AML*, Acute myelogenous leukemia; *CRPC*, Castration resistant prostate cancer; *DLBCL*, Diffuse large B-cell lymphoma; *ER*, Estrogen receptor; *MDS*, myelodysplastic syndrome; *MM*, Multiple myeloma; *NMC*, Nut midline carcinoma.

OTX015 (also named MK-8628) is a broad spectrum BRD (BRD2/3/4) inhibitor that has been investigated for treatment of AML and solid tumors such as glioblastoma multiforme (GBM). In addition, OTX015 targets genes associated with NF-κB and JAK-STAT signaling pathways that are significant participants in the initiation and progression of cancer. In preclinical studies, OTX015 promoted cell cycle arrest and apoptosis in acute leukemia cell lines and had a stronger anti-proliferative effect than JQ1 to inhibit tumor growth in GBM mouse models. A Phase 1 clinical trial examining OTX015 in solid tumor patients was recently completed (NCT02259114) but results have not yet been reported, and another Phase 1 trial for patients with hematologic malignancies is currently underway (NCT02698189). In addition, GSK525762 (also named I-BET762), is in a Phase 1 trial for patients with relapsed refractory hematologic malignancies (NCT01943851), a Phase 1 trial for patients with solid tumors (NCT01587703) and a Phase 2 trial that tests BET inhibition in combination with the MAPK inhibitor Trametinib in patients with solid tumors (NCT03266159). In vitro, GSK525762 disrupted the expression of inflammatory genes in activated macrophages. Another BET inhibitor currently being tested is CPI-0610 that is in Phase 1 or 2 clinical trials for patients with lymphoma (NCT01949883), multiple myeloma (NCT02157636), acute leukemias and MDS (NCT02158858), as well as nerve sheath tumors (NCT02986919). CPI-0610 is a BET family inhibitor that decreases MYC gene expression and inhibits growth of MV-4-11 cells in mice. Other BET inhibitors currently being evaluated in clinical trials include FT1101 for hematologic malignancies (NCT02543879), RO6870810 (also named TEN-010) for multiple myeloma (NCT03068351) and ZEN003694 in combination with the hormone therapy enzalutamide in patients with metastatic castration-resistant prostate cancer (NCT02711956).

While the mechanism for many of the BET inhibitors being evaluated clinically has not been fully characterized, these agents are expected to decrease oncogene expression that may restore cell sensitivity to anticancer therapies. For instance, if resistance is mediated by the upregulation of specific transcription factors, BET inhibitors may reduce their expression. In support of this, ER positive breast cancer resistance to the mTOR inhibitor everolimus is usually mediated by c-Myc and treatment with the BET inhibitor OTX015 leads to downregulation of MYC expression and restoration of cell sensitivity to everolimus in breast cancer cell lines. Similarly, other studies have reported that treatment with BET inhibitors can reverse tamoxifen resistance in ER-positive tumors or increase the potency of an ER antagonist (fulvestrant) when cells are also treated with BET inhibitor. Furthermore, BET inhibitors can restore sensitivity to lapatinib, a tyrosine kinase inhibitor of EGFR and HER2, via reprograming of the kinome and activation of ERBB2/ERBB3 receptors in breast cancer cell lines. These results suggest that BET inhibitors are not only promising anti-tumor agents on their own but combination therapies may be useful to overcome therapy resistance caused by activation of alternative gene expression or signaling pathways. Recent findings by many laboratories have demonstrated that BET inhibitors can synergize with other anti-cancer agents such kinase inhibitors, DNMT inhibitors, BCL2 inhibitors and HDAC inhibitors to promote cell death of various hematologic and solid tumor cell lines. These multiple reports highlight the potential of using a BET inhibition strategy for frontline cancer therapy.

Additional Reader Domain Inhibitors in Preclinical Studies

Along with the widely studied BET inhibitors, a handful of inhibitors targeting methyl lysine reader domains such as PHD or Royal family domains (Chromodomains, Tudor, Agenet, PWWP, and MBT) have been identified and tested in preclinical studies. These compounds typically target the amino acid pocket that forms the "aromatic cage" of the reader domain which is responsible for binding to methylated lysine. For instance, MS37452 and UNC3866 are small molecule chromodomain inhibitors that block methyl lysine interaction with CBX7, a chromodomain protein associated with growth advantage and aggressive cancers. In prostate cancer cell lines, MS37452 reduced binding of CBX7 to the INK4A/ARF locus and de-repressed gene expression while UNC3866 inhibited prostate cancer cell line proliferation. Similarly, UNC2170 is a compound identified to bind at the interface of two Tudor domains of the p53BP1 dimer to block chromatin binding, and in cultured splenocytes UNC2170 significantly reduced class switch recombination. While results such as these are promising, relatively few inhibitors directed towards blocking methyl lysine reader domains have been identified and none have progressed to clinical trials of cancer patients. A significant technical hurdle remains to identify compounds that selectively target a single member among a family of structurally similar reader proteins.

Prospective Vision

It is now widely accepted that dysregulation of the epigenetic state plays a significant role in cancer development but our ability to target the epigenome therapeutically is still in its early stages. While many epigenetic therapies have reached clinical trials only a few have been approved for patient use. Novel drugs directed against many epigenetic regulatory mechanisms such as histone methylation/demethylation have been difficult to develop. Perhaps the most promising emergent cancer therapies that target epigenetic mechanisms are those being used in combination with immunotherapy. However, a caveat against combining epigenetic and immunotherapy may be that epigenetic therapies can be immunosuppressive or even promote a malignant phenotype in some contexts. For instance Aza has been reported to increase development of T-reg cells while treatment with EZH2 inhibitors can decrease CD4+ helper T-cells. These changes in T-cell populations may prevent effective immunotherapies based on T-cell mediated tumor destruction. Furthermore, epigenetic therapies may inadvertently promote T cell exhaustion which has been associated with nonresponse or relapse after treatment with checkpoint inhibitors.

It is likely that a survey of DNA methylation state and histone modifications in a specific patient tumor may be helpful to determine the context specific responses to therapy. For instance only specific epigenetically defined subgroups of patients may benefit from a particular epigenetic therapy. In support of this, recent studies suggest that methylation of certain CpG islands predict response to chemotherapy in AML and methylation of the *MGMT* promoter is prognostic for temozolomide response in glioblastoma. In addition, altering the balance of epigenetic regulator activity in the cell may have unexpected or detrimental consequences. For instance, epigenetic regulators such as EZH2 and DNMT3A have been reported to have both oncogenic and tumor suppressor functions depending on the context. Thus, only specific epigenetically defined subgroups of patients may benefit from particular combinations of epigenetic treatment strategies. However, work to define specific epigenetic signatures that are predictive of therapy response is still in its early stages.

Epithelium to Mesenchyme Transition

Laia Caja and E-Jean Tan, Uppsala University, Uppsala, Sweden

Glossary

Cancer stem cell (CSC) Rare subset of cells within a tumor that could self-renew and give rise to many cell types that constitute a tumor.

Circulating tumor cell (CTC) A cancer cell shed by primary tumor mass into the blood circulatory system.

Disseminated tumor cell (DTC) CTC that have left the circulatory system and survived after infiltrating a distant site.

Epigenetics DNA or histone modification of chromatin structure that modulate accessibility of transcription machinery to gene loci to regulate gene expression levels without a change of DNA sequence.

miRNA Non-coding RNA of 21–25 nucleotides in length which repress the expression of its target(s).

Transforming growth factor β (TGFβ) A multifunctional cytokine that regulate cell growth, differentiation and apoptosis in any cell types. It is also a potent inducer of EMT.

Tumor microenvironment The tumor milieu, including tumor cells, stromal cells, immune cells, and ECM.

Introduction

There are two main cell types, epithelial and mesenchymal, that are described based on the cell shape and cellular organization. Epithelial cells form sheets of contiguous cells connected by specialized cell-to-cell and cell-to-substratum adhesion contacts. These cell-to-cell adhesive structures include adherens junctions, tight junctions, gap junctions, and desmosomes. They ensure close lateral connections between adjacent epithelial cells. They are polarized along the apical-basal axis and attached firmly to the basal lamina, which is part of the extracellular matrix (ECM). Mesenchymal cells present disorganized adhesive structures and exhibit spindle-like morphology. They form weak contacts with neighboring cells and do not have the same apical-basal polarity as epithelial cells. Instead, they have front-rear polarity that allows cell migration. Furthermore, they secrete ECM-degrading enzymes, and these properties allow their invasion through the basement membrane and surrounding tissues.

Epithelial–mesenchymal transition (EMT) occurs during embryogenesis and development, as well as in several pathologic conditions, such as tissue fibrosis and cancer. EMT was first described in the 1960s by development biologist Elizabeth Hay in the formation of primitive streak in chick embryo model. EMT is a differentiation switch, where epithelial cells dedifferentiate into motile mesenchymal cells. It is a vital program during embryogenesis for the formation of mesoderm. Newly formed mesenchymal cells are able to travel long distances to differentiate into various cell types. After migration and homing in to new sites, mesenchymal cells revert back to epithelial cells for tissue and organ development in the reverse process, mesenchymal–epithelial transition (MET). The ability of a cell to change phenotype, between EMT and MET processes, reflects a high degree of cellular plasticity.

There are several molecular mechanisms involved in the initiation and progression of EMT. These mechanisms include the induction and activation of transcription factors, suppression of expression of specific intercellular adhesion complexes, reorganization of cytoskeletal proteins, production of ECM-degrading enzymes, and changes in the expression of specific microRNAs (miRNA). Upon undergoing EMT, cells acquire migratory and invasive properties that allow them to migrate through the ECM. Finally, it is worth to mention that cancer cells may pass through EMT to differing extents; some cells will retain some epithelial traits as they acquire some mesenchymal ones (i.e., partial EMT), and other cells will lose all their epithelial characteristics and become fully mesenchymal (Fig. 1). Furthermore, EMT attributes tumor cells with properties associated with cell survival, resistance to anoikis and senescence, evasion of immunosurveillance, gain of cancer stem cell (CSC)-like features and therapeutic resistance.

Several studies now provide direct evidence that an EMT process occurs in carcinomas. In cancer, the epithelial tumor cells become more invasive after undergoing EMT and access the circulatory system through intravasation, resulting in dissemination of cancer cells to distal loci away from the primary tumor. Consequent metastatic colonization of secondary sites by cancer cells is thought to involve the MET process, based on the observation that metastases re-express the E-cadherin protein and are epithelial-like, resembling the primary tumor. This reversibility in gene expression suggests that transcriptional regulation rather than irreversible genetic loss may confer a selective advantage for cancer cell progression. However, there is also evidence that tumor invasion can occur in the absence of EMT. Some studies show that expression of podoplanin promotes an alternative pathway of tumor cell invasion in the absence of EMT. There are several lines of evidence suggesting that some invasive carcinomas have not undergone a complete transition to a mesenchymal phenotype or even lack signs of EMT, and that invasive carcinomas do not invade adjacent connective tissue as individual mesenchymal-like cells. Instead, these carcinoma cells invade as multicellular aggregates or clusters. In fact, it has been described that hepatocytes can migrate as cohorts in response to transforming growth factor β (TGFβ) stimuli.

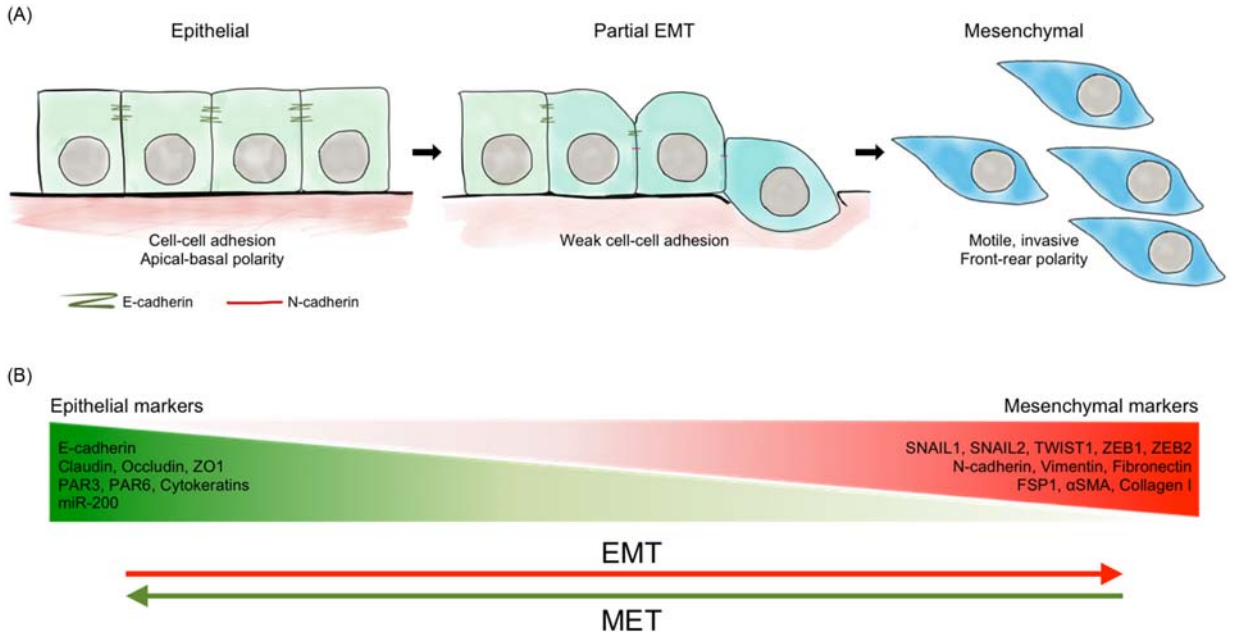

Fig. 1 Morphological changes during EMT. (A) EMT involves the disassembly of cell–cell junctions, loss of apical-basal polarity, upregulation of mesenchymal proteins, cytoskeletal reorganization, degradation and remodeling of the ECM, and thereby allowing migration and invasion. (B) Expression gradients of epithelial (*green*) and mesenchymal (*red*) markers during EMT and MET.

EMT Characteristics

Change in expression of cadherins, or cadherin switch, is a classical EMT mark. E-cadherin, a cell adhesion molecule that is important for the maintenance of epithelial integrity, is expressed in epithelial cells. Its expression is decreased during EMT in embryonic development, tissue fibrosis, and cancer. Its downregulation represents a determining step in destabilizing the epithelial architecture and is often associated with tumor aggressiveness and poor clinical outcome. Other epithelial markers include occludin, claudin, desmoplakin, and cytokeratin. The cadherin switch from E-cadherin to N-cadherin, which is expressed in mesenchymal cells, fibroblasts, cancer cells, and neural tissue, has often been used to monitor the progress of EMT during embryonic development and cancer progression. Typical mesenchymal markers expressed in cells that have undergone EMT are: (1) fibroblast-specific protein 1 (FSP1; also known as S100A4 and MTS-1) is a member of the family of Ca^{2+}-binding S100 proteins, which is detected in cells that have suffered EMT in cancer and fibrogenesis; in the same line of evidence FSP1 itself facilitates EMT in adult epithelial cells and cancer cells. (2) Vimentin is commonly used to identify cells undergoing EMT in cancers. (3) Alpha-smooth muscle actin (αSMA) is also expressed in mesenchymal cells after an EMT process. Other mesenchymal markers that are upregulated during an EMT process include fibronectin and matrix metalloproteinase (MMP).

EMT Classification

The EMT program also operates in other pathological settings, which involves inflammatory responses. Based on the biological context, EMT can be classified into three subtypes. Developmental EMTs are type 1 (not associated with inflammation); type 2 EMT is associated with tissue regeneration, such as wound healing, tissue repair and organ fibrosis; and type 3 EMT contributes towards cancer progression and metastasis. EMT confers tumor cells with motility, survival, stemness properties and therapeutic resistance.

Type 1 EMT is associated with implantation, embryo formation, and organ development to generate diverse cell types that share mesenchymal phenotypes and biomarkers; it generates cells with mesenchymal phenotype to create new tissue(s) with diverse functions. During development, EMT plays a critical role in generating the first set of mesenchymal cells, which are known as the primary mesenchyme. Subsequently, as tissue expands and specifications emerge, primary mesenchyme gives rise to secondary epithelia via MET. The EMT associated with gastrulation is dependent on and orchestrated by canonical Wnt signaling, TGFβ superfamily proteins, notably Nodal and Vg1. Their deficiencies can lead to mesodermal defects due to a dysfunctional EMT process; Wnts also cooperate with FGF receptors to help regulate EMT associated with gastrulation. In the absence of the EMT process, gastrulation cannot occur, and therefore, the development of the embryo does not progress past the blastula stage.

Type 2 EMT is associated with wound healing, tissue regeneration, and organ fibrosis; EMT in this context begins as part of a repair-associated event to generate fibroblasts to reconstruct and repair tissue following trauma and/or inflammatory injury. This process ceases once repair is achieved and inflammation is attenuated. However, in the case of organ fibrosis, type 2 EMT can continue to respond to ongoing inflammation, leading eventually to organ destruction. Organ fibrosis, which occurs in

a number of epithelial tissues, is mediated by inflammatory cells and fibroblasts that release a variety of inflammatory signals as well as components of a complex ECM that includes collagens, laminins, elastin, and tenacin; such EMTs are found to be associated with fibrosis occurring in kidney, intestine, liver, and lung. Cells that have undergone a type 2 EMT process express the mesenchymal marker FSP1 and αSMA, but concomitantly continue to have epithelial-specific morphology and molecular markers, such as cytokeratins and E-cadherin. Such cells are likely to represent intermediate stages of EMT, the behavior of these cells provided one of the first indications that epithelial cells under inflammatory stresses can advance to various extents through an EMT, creating the notion of "partial EMTs." TGFβ has proved to be an inducer of EMT, promoting type 2 EMT; interestingly, BMP7 functions as an endogenous inhibitor of TGFβ-induced EMT; systemic administration of recombinant BMP7 to mice with severe fibrosis resulted in reversal of EMT and repair of damaged epithelial structures, with repopulation of healthy epithelial cells and restoration of organ function. Different cell types in the liver have been shown to undergo an EMT process: cholangiocytes from rats with biliary fibrosis co-expressed epithelial and mesenchymal markers; and hepatocytes undergo EMT both in in vitro and in vivo-induced fibrosis. Moreover, three different fate-mapping studies have provided data showing that hepatocytes, hepatic stellate cells or oval cells might be contributing to the fibrotic process in certain types of adult liver injury through an EMT/MET mechanism.

Type 3 EMT occurs in carcinoma cells that have already suffered genetic and epigenetic alterations, which make them more sensitive to EMT-inducing signals originated from the tumor-associated stroma. The EMT process does not mean a lineage change for these cells, but a mechanism of transition and to provide epithelial tumor cells the ability of movement, invasion, and metastasis; these cells invade and metastasize via the circulation, and once they find themselves in distant tissue, they form secondary tumors exhibiting an epithelial phenotype, through a MET process.

EMT Induction

Signaling Networks Regulating EMT

EMT can be triggered in a tissue-specific manner by several extracellular stimuli. There are many growth factors and cytokines implicated in activating the EMT program, such as TGFβ, Wnt, Notch, Hedgehog, epidermal growth factor (EGF), fibroblast growth factor (FGF), insulin-like growth factor (IGF), and hepatocyte growth factor (HGF). These diverse signal transduction pathways, influenced by microenvironmental factors such as hypoxia and inflammation, cross-talk to activate downstream effectors such as ERK, MAPK, PI3K, β-catenin, NFκB, SRC, integrin, and RhoGTPases pathways. These signaling networks converge to orchestrate EMT transcription factors (EMT-TFs) which establish the EMT program by regulating epithelial and mesenchymal genes (**Fig. 2**).

TGFβ is a major inducer of EMT in embryogenesis and cancer progression by regulating a plethora of genes controlling cell motility, invasion, actin cytoskeleton, and ECM. TGFβ ligand binding leads to formation of TGFβ type I/II receptors (TβRI/TβRII) heterotetrameric receptor complex. TβRI is activated and phosphorylates SMAD2/3, which in turn translocate with SMAD4 to the nucleus. In the nucleus, the SMAD complexes associate with other cofactors to regulate expression of target genes (**Fig. 2**). Heart valve morphogenesis in chicken involves TGFβ signaling. While the TGFβ2 member is required to initiate EMT, it is TGFβ3 that is accredited with driving EMT-invasion of endocardial cells into the cardiac cushion to establish the septa and valves. Moreover, TGFβ3 is required for cleft palate formation in mice. Transgenic mice with aberrant TGFβ1 expression in keratinocytes subjected to a chemical carcinogenesis treatment, secreted endogenous TGFβ3 to accelerate EMT and development of highly invasive spindle cell carcinomas, indicating that TGFβ drives EMT during cancer progression in vivo. TGFβ plays a role in dissolution of tight junctions and disruption of cell polarity, through protein interactions with occludin and PAR6, respectively. Moreover, TGFβ mediates EMT via chromatin protein high mobility group A2 (HMGA2) to induce SNAIL1, SNAIL2, TWIST1 and repression of inhibitor of differentiation 2 (ID2). In other words, TGFβ directly regulate majority of the EMT-TFs, underpinning the potency of this cytokine in EMT.

A key component of epithelial junction complex is β-catenin, which is part of the protein complex that connects E-cadherin to the actin cytoskeleton at the adherens junctions. In response to Wnt ligands, glycogen synthase kinase 3β (GSK3β) is inhibited, allowing β-catenin translocation from the cell membrane to the nucleus, where it can activate TCF/LEF transcription factors to induce EMT. Interestingly, SNAIL1 interacts with β-catenin and stimulates its transcriptional activity. TGFβ plays a role to disrupt cell polarity during EMT. TβRI is found in complex with PAR6 and occludin at epithelial tight junctions. The activation of TGFβ signaling pathway leads to phosphorylation of PAR6 by TβRII, and subsequently, leads to RhoA degradation and dissolution of tight junctions. Furthermore, Notch signaling has also been shown to contribute to EMT in both tumor progression and cardiac development. In addition, integrin signaling facilitates EMT, and various integrins are expressed on both epithelial and mesenchymal cells. As a result, integrins in general have limited utility as generalized biomarkers for EMT. Kidney fibrosis is associated with increased α5 integrin expression. Moreover, high α5 integrin expression also correlates with EMT and metastatic potential in melanoma cells, suggesting that α5 integrin plays a role in EMT.

EMT-Transcription Factors

The well-studied and classic EMT-TFs include the zinc finger SNAIL superfamily (SNAIL1 and SNAIL2/Slug), ZEB family members (ZEB1 and ZEB2/SIP1), and basic helix-loop-helix transcription factors (TWIST and E47). These factors have the common characteristic of repressing the expression of E-cadherin, a suppressor of invasion during carcinoma progression. EMT-TFs can be divided into two groups depending on their effects on the *CDH1* (gene encoding E-cadherin) promoter. SNAIL1/2, ZEB1/2, E47, and KLF8

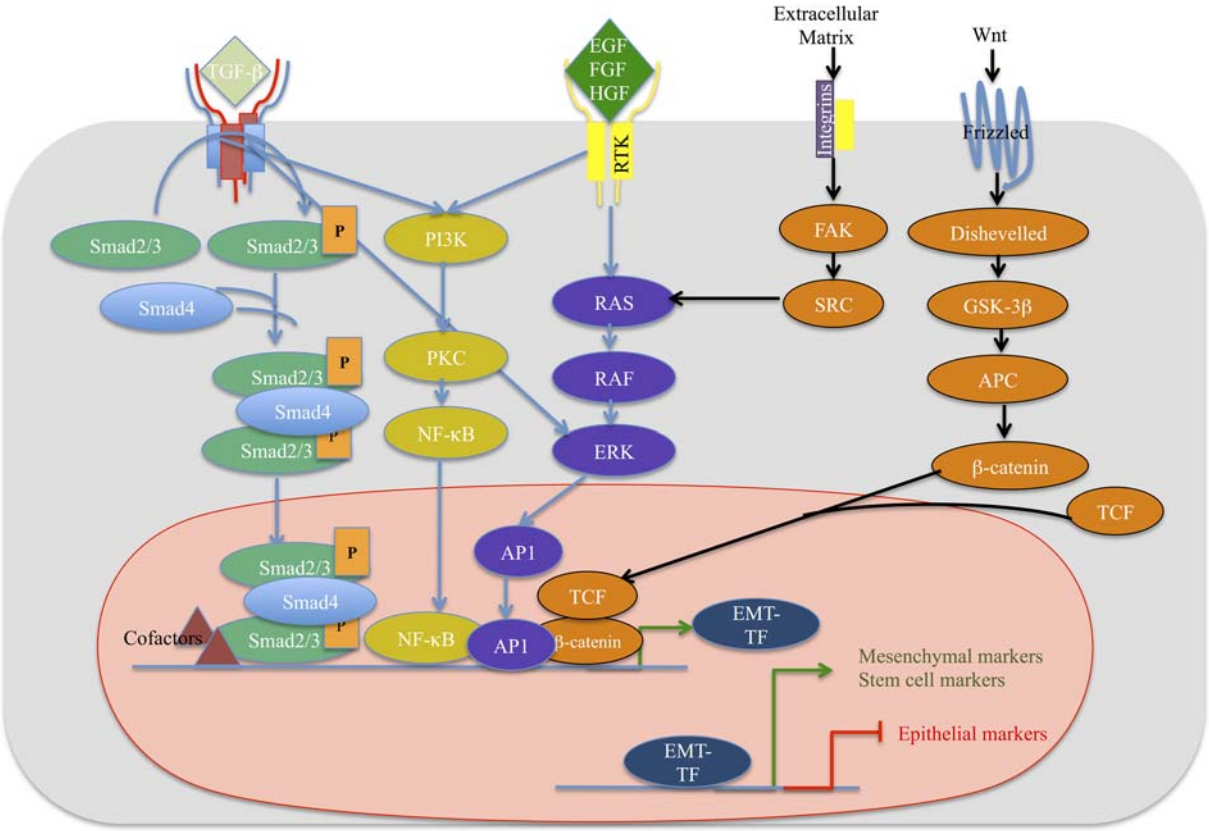

Fig. 2 Signaling pathways promoting epithelial–mesenchymal transition. Hepatocyte growth factor (HGF), fibroblast growth factor (FGF), and epidermal growth factor (EGF) signal via receptor tyrosine kinases (RTKs) to activate the signaling cascade RAS-RAF-MAPK or the PI3K pathway. The extracellular matrix, via integrins, transduces the SRC-STAT pathway. TGFβ signals via its serine/threonine kinase receptors to activate the canonical SMAD pathway or the non-canonical pathways via PI3K and MAPK. The Wnt ligands signal via Frizzled receptors to activate β-catenin and the transcription factors TCF/LEF. All these pathways modulate gene expressions that are involve in the activation of the EMT program.

factors bind to and repress the activity of the *CDH1* promoter, whereas factors such as TWIST1, Goosecoid, E2.2, and FoxC2 repress E-cadherin transcription indirectly and induce a mesenchymal gene program. In certain contexts, other transcription factors also have critical roles, such as HMGA2, PRRX1, and SOX4. Interestingly, these transcription factors regulate each other enabling positive feedback loops acting as master regulators of the EMT program and empowering the induction of EMT. The classic EMT program involves the repression of genes related to the epithelial phenotype such as E-cadherin, tight junctions proteins and cytokeratins, while inducing the expression of genes related to the mesenchymal phenotype such as N-cadherin, fibronectin, and vimentin (Fig. 1B).

The role of SNAIL1 in EMT is evident as SNAIL1 deletions in mice are embryonic lethal because they fail to complete gastrulation. SNAIL1 directly represses the expression of *CDH1* gene by binding to the *E*-box element with the consensus 5′-CANNTG-3′ on the promoter and recruits transcriptional corepressors SIN3A and HDAC complexes. SNAIL2, ZEB1, and ZEB2 use similar mechanisms to repress *CDH1* gene. Additionally, SNAIL proteins repress a variety of genes involved in maintaining epithelial structure and function, including tight junction genes encoding claudin and occludin, as well as genes important for apicobasal polarity, such as CRUMBS3. SNAIL1 upregulation also results in decreased expression of a subset of cytokeratins, that is, cytokeratin 17, 18, 19, and 20, thus affecting the epithelial cytoskeletal organization. While repressing epithelial gene expression, SNAIL1 proteins activate the expression of the fibronectin, vitronectin and N-cadherin, the extracellular matrix proteins collagen type III and V, and proteins involved in migration and invasion, such as RhoB, plasminogen activator inhibitor-1 and MMP family which help to degrade the basal membrane.

ZEB1- or ZEB2-knockouts in mice are not viable, which indicate that the two ZEBs are not able to compensate for each other's function despite being structurally similar. In addition to repressing E-cadherin, ZEB2 directly represses the expression of the tight junction proteins claudin 4 and ZO3, ZEB2 also suppresses the expression of the desmosome protein plakophilin 2; while it induces the expression of vimentin, N-cadherin, and MMP2; consequently, ZEB proteins promote cell migration and induce invasion.

TWIST1 proteins are essential for proper gastrulation, mesoderm formation and neural crest migration during development. *Twist1*-null mice die shortly after gastrulation due to defects in neural tube closure and malformation of the cranium and limbs. Ectopic expression of TWIST1 induces EMT of Madin-Darby canine kidney cells (MDCK) cells by repressing expression of

E-cadherin, α-catenin, and promoting expression of vimentin and N-cadherin. TWIST1 upregulates the expression of N-cadherin and AKT2, promoting migration and invasion. TWIST1 is essential for invasion and lung metastasis as silencing of TWIST1 suppressed lung metastases in a mouse mammary tumor model. TWIST1 also upregulates PDGF receptor α (PDGFRα), which participates in invadopodia formation that facilitates metastasis. High expression of TWIST1 and PDGFRα correlated with poor survival outcome in breast cancer patients.

Epigenetic and miRNA Regulation in EMT

How do these EMT-TFs repress gene expression? In order to make some of the changes in expression more stable and to provide long-term regulation, EMT-TFs cooperate with many other proteins that can control several layers of epigenetic regulation: (a) DNA methylation, (b) histone modifications, and (c) RNA interference. Each of these processes requires a tightly regulated machinery.

Epigenetics is the heredity of a phenotype that is the result of alterations on the chromatin and not due to genetic changes in the DNA nucleotide sequence. There are two main epigenetic mechanisms—histone modification and DNA methylation. DNA methylation is a stable mark which is usually linked to gene repression. A methyl group is covalently attached to cytosine in a CpG dinucleotide sequence by DNA methyltransferases (DNMTs). This process can be reversed by the ten–eleven translocation oxidases (TET). CpG islands are clusters of CpG sites that are sometimes found near active gene promoters. Methylation of such CpG islands lead to stable gene silencing. For example, both SNAIL1 and ZEB1 associate with DNMT1 to methylate the *CDH1* promoter, and thereby inactivate the E-cadherin gene, which is a common event in multiple carcinomas including breast, bladder, lung, liver, and prostate.

Histone posttranslational modifications by methylation, acetylation, ubiquitinylation, phosphorylation and sumoylation can alter histone–DNA interactions, and thereby, affecting chromatin structure and DNA processes like transcription, replication or repair. Through these modifications the chromatin can shift from active state, in which lysine 4 on histone H3 (H3K4) is methylated or lysine 9 on histone H3 (H3K9) is acetylated; to intermediate poised states, which are bivalently marked by trimethylation of H3K4 or lysine 27 on histone H3 (H3K27); and to a stably repressed chromatin with H3K9 or H3K27 trimethylation marks; and vice versa. The bivalent state of certain promoters in embryonic stem cells, for example, bears both trimethylation marks on lysine 4 and 27 of histone H3 (i.e., H3K4me3 and H3K27me3) to allow prompt response to specific signaling cues in transcribing their genes. The *ZEB1* promoter in some epithelial cancer cells is maintained with a bivalent H3K4me3 and H3K27me3 configuration, poised to become activated rapidly upon TGFβ signaling. The induction of ZEB1 expression commits cancer cells to the EMT program, with a gain of migratory mesenchymal phenotype and stem cell-like properties. Thus, the bivalent epigenetic modification of EMT-related genes could be a possible mechanism for epithelial plasticity observed in cancer cells.

SNAIL1 represses *E*-cadherin expression by specific binding to the latter's E-box at the proximal promoter region of *CDH1* gene. SNAIL1 recruits and interacts with various epigenetic regulators like histone methyltransferases, G9a and suppressor of variegation 3–9 homolog 1 (SUV39H1); polycomb repressive complex 2 (PRC2) which consists of the enhancer of zeste homolog 2 (EZH2) and suppressor of zeste 12 homolog (SUZ12) subunits; co-repressor SIN3A; histone deacetylases (HDACs); and lysine-specific demethylase 1 (LSD1). These proteins, together, coordinate histone modifications, that is, methylation, demethylation, and/or deacetylation, of H3K4, H3K9, and H3K27. TWIST1 induces the expression of B lymphoma Mo-MLV insertion region 1 homolog (BMI1), a component of polycomb repressive complex 1 (PRC1). TWIST and BMI bind to *E*-box sequences and cooperate to repress the expression of E-cadherin and the cell cycle inhibitor p16 (*CDKN2A*). This cooperation involves recruitment of PRC2, which then trimethylates H3K27 at the *CDH1* and *CDKN2A* gene promoters. ZEB1 also interacts with the SWI/SNF chromatin remodeling protein BRG1 to inhibit E-cadherin expression.

MicroRNAs (miRNAs) are a subclass of non-coding regulatory RNAs spanning 21–25 nucleotides in length. MiRNA are involved in post-transcriptional control of gene expression, they repress the translation of their target mRNA or promote the degradation of such mRNAs by binding to the 3′ untranslated region. MiRNAs have been shown to regulate many biological processes such as embryonic development, stem cell function, angiogenesis and cancer progression, and their biogenesis is regulated by different signaling pathways. Intriguingly, each miRNA can regulate more than one target gene and pathway. They can be classified as oncogenic miRNA (*oncomir)* or tumor suppressor miRNA. Tumor suppressor miRNA expressions are usually downregulated in cancer. In contrast, the expressions of oncomirs are overexpressed in EMT.

The EMT program is regulated by miRNA networks that target EMT-TFs, and as well as, the epithelial and mesenchymal genes. One of the best-characterized tumor suppressor miRNAs in EMT is the miR-200 family which downregulates the expression of ZEB1 and ZEB2 proteins. Forced expression of miR-200 family members in mesenchymal cells led to MET and high E-cadherin expression. On the other hand, the ZEB proteins repress the expression of miR-200 during TGFβ-induced EMT, establishing a double negative feedback loop. Interestingly, miR-200 can also act as tumor promoter because it targets *Sec23a* which is involved in the anterograde transport of metastasis suppressor proteins from the endoplasmic reticulum to the Golgi apparatus, such as insulin-like growth factor binding protein 4 (IGFBP4) and tubulointerstitial nephritis antigen-like 1 (TINAGL1). Therefore, miR-200 has a dichotomous function in metastasis as it blocks EMT and invasion (by repressing ZEB1/2), but promotes colonization of tumor cells via MET at distal sites by targeting the cancer cell secretome, avoiding the secretion of tumor suppressor proteins. SNAIL1 and miR-34 are another example of a double feedback loop. The miR-34 family attenuates the expression of SNAIL1, which in turn represses the expression of miR-34. Other tumor suppressor miRNA that inhibit EMT are: miR-124 which directly target of SNAIL2

in gastric cancer cells; miR-720 and miR-300 target TWIST1 expression in breast cancer cells and head and neck squamous cell carcinoma, respectively.

TGFβ upregulates miR-155 during EMT to disrupt tight junctions by targeting RhoA. In addition, miR-155 targets differentiation transcription factor C/EBPβ which activates epithelial genes like *CDH1* and *CAR*. High miR-155 expression correlates with C/EBPβ loss in triple-negative breast cancer, which are often negative for E-cadherin expression. MiR-373 drives EMT and metastasis by suppressing thioredoxin-interacting protein (TXNIP) pathway, which in turn promotes the upregulation of HIF1α and TWIST proteins. The miR-221/222 cluster was first identified as a basal-like breast cancer-specific miRNA and promotes EMT by affecting several targets like ERα, Dicer and trichorhinophalangeal syndrome type 1 protein (TRPS1). Downregulating TRPS1 relieves ZEB2 repression, and thereby, allowing ZEB2 to repress *CDH1*. Furthermore, miR-9 directly suppresses E-cadherin mRNA, leading to increased cell motility and micrometastasis; whereas miR-9 inhibition resulted in reduced metastasis formation by highly malignant breast cancer cells.

Long noncoding RNAs (lncRNA) consist of RNA transcripts longer than 200 bp, and have been implicated in epigenetic regulation of genes in relation to cancer progression and metastasis. TGFβ induces a few lncRNAs during EMT, one of which is Hotair. Hotair binds and guides PRC2 to repress its gene targets during the EMT process and maintenance of cancer stem cells. Similarly, Malat1 lncRNA associates with PRC2 subunit, SUZ12, to regulate EMT genes, and knockdown of Malat1 inhibits tumor metastasis. The H19 lncRNA is upregulated in a feed-forward mechanism by SNAIL2, that is induced by TGFβ during EMT. H19 and SNAIL2, together with miR-675, repress E-cadherin expression and promote metastasis in vivo. Recently, ZEB1 antisense RNA1 (ZEB1-AS1) and ZEB2 antisense RNA1 (ZEB2-AS1) were identified as non-coding transcripts in the promoters of ZEB1 and ZEB2, respectively. ZEB1-AS1 and ZEB2-AS1 positively regulate ZEB1 and ZEB2 expression, respectively, and promote tumor progression.

Collectively, EMT-TFs guide chromatin-modifying proteins and non-coding RNAs, with specificity, in order to amplify their effects on gene expression facilitating the transcription and epigenetic regulation of epithelial and mesenchymal genes.

EMT Generates Stem Cell-Like Properties

The concept of cancer stem cells (CSCs) defines the existence of a subpopulation of cells in a tumor capable of seeding new tumors, which are more resistant to conventional chemo- and radiotherapies. CSCs resemble normal stem cells in that they are able to self-renew, and generate new CSCs and progenies that differentiate into more differentiated and less tumorigenic cells, the non-CSCs, which are also described as the bulk tumor.

CSCs were initially isolated from acute myeloid leukemia based on cell-surface marker ($CD34^{+}/CD38^{-}$) expression. Based on similar principle, CSCs have been identified and isolated from several solid malignancies such as breast, brain, colon, and pancreatic cancer. They are defined for having the ability to form spheres in vitro from very few cells, and more importantly, the ability to seed new tumors in host mice when very few cells are injected (100–1000 cells per mouse).

Interestingly, in the last decade a link between the EMT program and the acquisition of CSC properties has been elucidated. The induction of EMT by overexpression of TWIST1, SNAIL1, ZEB1, or TGFβ treatment, in human mammary epithelial (HMLE) cells or in immortalized breast epithelial cell line MCF10A, results in the enrichment of $CD44^{+}/CD24^{-/low}$ population, which is associated with both human breast CSCs and normal mammary epithelial stem cells. Moreover, cells generated by an EMT process acquired the ability to form mammospheres and enhanced the ability to seed tumors in mice, an attribute of mammary stem cells. Another example, is that the metastatic breast cancer cell line to the lung, SUM1315, requires Wnt signaling for maintenance of the dedifferentiated epithelial phenotype consistent with EMT and cancer cell self-renewal. Wnt signaling maintains the expression of $CD44^{high}/CD24^{low}$, and the ability of these cells to metastasize through the expression of SNAIL2 and TWIST1. Furthermore, the sine oculis homeobox homolog (SIX1), expressed during early embryogenesis for the development of numerous organs, is silent in most adult tissues. SIX1 induces EMT and promotes stem/progenitor cell phenotype in the mouse mammary gland and in SIX1-driven mammary tumors. TGF-β has also been described to induce EMT, concomitant with acquisition of CSC traits in hepatocellular carcinoma.

The ability of EMT to confer CSC properties indicates that the activation of EMT in non-CSCs allows them to convert to CSCs through a dedifferentiation process. Therefore, in theory, CSCs can differentiate via MET into non-CSCs. Based on these assumptions, together with the reversibility of EMT and MET observed in carcinoma cells, suggest that cancer cells have a lot of plasticity.

However, under certain conditions, the link between EMT and stemness becomes uncoupled. PRRX1, an EMT inducer, needs to be downregulated in order for MET to occur at the metastatic site. Breast cancer cells decrease PRRX1 levels, with concomitant increased proliferation and gain of stemness properties. Similarly, it has been shown that EMT can suppress stem cell-like properties in prostate and bladder cancer models.

Tumor Microenvironment

The tumor microenvironment (TME) has a fundamental role in the contribution towards the malignancy of cancer progression. Tumor cells recruit nearby non-cancerous cells and modify ECM to support their growth and survival. The TME harbors a myriad of immune and inflammatory cells, fibroblasts, endothelial cells, ECM components and soluble factors, such as cytokines and

chemokines, growth factors and proteinases. The interactions between the TME and tumor cells add another layer of complexity, as not only is EMT subjected to dynamic regulation by the TME, the EMT program could influence changes in the TME to promote metastasis.

Inflammation in the Tumor Microenvironment

Chronic inflammation is associated with tumorigenesis, due to the infiltration of immune cells that are recruited by tumor cells into the TME to elicit proinflammatory responses to support tumor growth, progression, and metastasis. Tumor-infiltrating inflammatory cells, which include tumor-associated macrophages (TAMs), mast cells, neutrophils, T- and B-cells, produce an ample source of growth factors, chemokines and cytokines. Regulatory loops occur between EMT induction and inflammation. TAMs are one of the most potent EMT inducers as they secrete cytokines like TGFβ, tumor necrosis factor α (TNFα), interleukin 6 (IL6), and interleukin 8 (IL8). TAMs are often found in abundance in the TME and are associated with poor prognosis. TAMs produce TGFβ to sustain the EMT program in tumor cells to maintain the latter mesenchymal phenotype. TNFα activates the NFkB signaling pathway to stabilize SNAIL1. IL6 is one of the most abundant cytokine in cancer and has been shown to drive EMT in MCF7 breast adenocarcinoma cells with upregulation of SNAIL1 and TWIST1 and concomitant downregulation of E-cadherin. In a xenograft model where injected cancer cells with ectopic expression of IL6 generated tumors with EMT phenotype, that is, loss of E-cadherin and gain of vimentin expression, and increased lung metastasis. In a paracrine or autocrine manner, IL8 can trigger EMT in carcinoma cells. EMT-TFs regulate the expression of proinflammatory factors, which are capable of triggering EMT. Chemokine IL8 expression is regulated by EMT-TFs, SNAIL1 and TWIST, in cancer cells and secreted to recruit other immune cells. Recently, ZEB1 has also been reported to promote an inflammatory phenotype in several breast cancer cells, by binding to IL1β, IL6, and IL8 gene promoters and inducing their expressions, which results with increased recruitment of myeloid-derived suppressor cells (MDSCs) to the tumors formed by the breast cancer cell line 4T1 overexpressing ZEB1. Little is known about how tumor cells break out of latency to reinitiate metastatic outgrowth. A recent study suggests that a synergistic role by the ZEB1 and inflammation (possibly mediated by neutrophils) for tumor cells to escape dormancy to permit metastasis in a mouse model.

Cancer-Associated Fibroblasts

One key component of the TME are the cancer-associated fibroblasts (CAFs), they are a major player in tumorigenesis, regulating cell proliferation, angiogenesis, EMT, and metastatic processes. The origin of CAFs remains unclear, and presumably from: (1) resident fibroblast and host mesenchymal cells; or (2) myofibroblasts, which are activated fibroblasts that are identifiable by expression of αSMA and often found at inflammatory sites, as well as in the stroma surrounding high-grade carcinomas. Tumor cells produce TGFβ to stimulate CAFs to secrete an enormous supply of cytokines and growth factors (most notably TGFβ), MMPs, and ECM components, thus, underlying the importance of CAFs.

Interestingly, CAFs exhibit different biological properties compared to fibroblasts from adjacent non-neoplastic tissues. CAFs, not normal fibroblasts, could activate EMT, tumor-initiation and invasive processes in cancer cells. Furthermore, a subtype of CAFs that express FSP1 were found to have higher tumor-promoting potential than other subtypes. CAFs are often observed at invasive tumor fronts in carcinomas, an indicator of active paracrine signaling between CAFs and invasive tumor cells in sustaining EMT and ECM remodeling. In addition to TGFβ, CAFs produce FGF, PDGF and HGF to promote cancer cell proliferation. CAFs are known to deposit ECM and modulate its matrix composition. Lysyl oxidase (LOX), an enzyme which crosslinks collagen, is secreted by CAFs to drive matrix stiffening to regulate EMT and facilitate tumor dissemination and metastasis. An increasing number of studies have described the induction of EMT-TFs expression in CAFs which is required for CAFs activity to support paracrine signaling of cancer cells in a loop of feed-forwards. CAFs upregulate SNAIL1 and TWIST1 expressions to promote matrix rigidity. Furthermore, CAFs activity is dependent on SNAIL1 to promote tumor progression in vivo.

Hypoxia

Tumor hypoxia contributes to tumor aggressiveness and is associated with poor clinical outcome in cancer patients. Under hypoxic conditions, transcription factors hypoxia-inducible factors 1 and 2 (HIF1; HIF2) become stabilized and drive the transcription of many hypoxia-response genes which are involved in cell proliferation, survival, angiogenesis, EMT, and metastasis. Furthermore HIF is essential for CSC maintenance. HIF activates the EMT program by regulating the transcription of EMT-TFs, such as SNAIL1, SNAIL2, ZEB1, ZEB2, and TWIST1. For example, HIF has been shown to bind directly to *TWIST1* promoter to induce its expression and promote metastasis. Hypoxia-induced TWIST1 induces BMI1, a PRC1 component that maintains self-renewal, and together they promote EMT and tumor initiation. Blocking EMT by silencing TWIST1 attenuates self-renewal capacity in hypoxia-induced CSCs.

The Intermediate EMT State

EMT is not a "all-or-none" unidirectional process and not necessary entails a full mesenchymal phenotype. Observations from development, wound healing, fibrosis and cancer progression studies, have described the existence of an intermediate hybrid state (or partial EMT), where cells have both epithelial and mesenchymal features (Fig. 1A). Complete EMT with mesenchymal markers

have been observed in carcinosarcomas, whereas most other tumors often display a mix of epithelial and mesenchymal phenotypes. Co-expression of epithelial markers, cytokeratin 8 and cytokeratin 18, together with mesenchymal marker vimentin, in invasive breast carcinoma correlates with aggressiveness, metastatic potential and poor prognosis.

Cells do not need to acquire the expression of a mesenchymal marker to achieve an intermediate state. Epithelial cells remodel their cell adhesion complexes to gradually destabilize cell polarity and weaken cell–cell contact. A transcription factor OVOL has been identified from a mathematical model, and shown to maintain partial EMT status by modulating ZEB1/miR-200 and SNAIL1/miR-34 axes. Knocking down OVOL induces EMT. Conversely, OVOL overexpression leads to MET.

Interestingly, cells in the intermediate state, also gained stemness properties. CSCs from various breast cancer subtypes coexpressing both epithelial and mesenchymal signatures had increased plasticity, compared to the mesenchymal-like CSCs; and higher self-renewal capacity, compared to the epithelial-like CSCs. In line with this, hybrid EMT tumor cells isolated from a prostate cancer mouse model had higher sphere formation and tumor-initiating capacity than those with mesenchymal phenotype.

Cells undergoing incomplete EMT retain some epithelial properties with the concomitant acquisition of migratory traits. This allows them to coordinate their movements collectively while maintaining cell–cell adhesions. Collective migration have been observed at tumor fronts of invasive carcinomas, where invasive "leader" cells activate the EMT program for motility, and the "follower" cells express E-cadherin to sustain the cohesion among the latter in the tumor bulk.

Circulating tumor cells (CTCs) isolated from breast cancer patients typically express both epithelial and mesenchymal markers and tend to migrate in clusters. Clustered CTCs are 50-fold more metastatic than individually migrating CTCs. Furthermore, the heterogeneity within the clusters that have disseminated could account for the polyclonal nature of metastatic outgrowth. CTC clusters can be cloaked by platelets, which provides an ample source of TGFβ. These CTC clusters are well-protected from anoikis during circulation and easily extravasate through blood vessels at distant sites. Given their high plasticity, CTCs could switch between EMT and MET without being dependent on external signaling cues.

EMT–MET Dynamics in Progression of Metastasis

Metastasis is the leading cause for majority of cancer-associated deaths. It is a complex, multistep progression of malignant cancer cells spreading from the primary tumor to form a new tumor at a distal secondary site. The metastatic cascade begins with local invasion of tumor cells into surrounding tissue and intravasation into the circulatory system. These CTCs have to survive the sheer forces and immune cells encountered in transit through the blood stream. Surviving CTCs extravasate out of the vasculature and infiltrate distant tissues to seed micrometastases and initiate outgrowth into overt macrometastases.

The acquisition of invasive phenotype in carcinoma cells and metastatic dissemination have been linked to EMT. Disseminated tumor cells (DTCs) are CTCs that survived the blood circulatory passage have to undergo MET to establish secondary metastases, drawing parallels with embryogenesis when migrating embryonic cells shed their mesenchymal characteristics via MET to generate new tissues. This has been met with skepticism by pathologists, as EMT could not observed histopathologically in patient samples. Neighboring stromal cells display similar mesenchymal markers, makes them indistinguishable from cancer cells undergoing EMT by histological or molecular methods. Metastatic lesions at distal sites showed epithelial characteristics that resemble the primary tumor, and not mesenchymal if ascribed to activation of EMT program. However, the cells at tumor invasive fronts often exhibit signs of EMT activation. Reduced or loss of E-cadherin expression in cancers correlates with metastasis and poor prognosis, although E-cadherin loss is not sufficient to induce complete EMT. The EMT and MET processes are highly plastic and transient, thus, are hard to follow in time and space in human cancers. In the past decade, advances in imaging techniques, animal models and CTC analyses have amass strong data for the relevance of EMT in cancer progression.

Expression of EMT-TFs are often found upregulated in many tumors, including breast, colon, gastric, lung, pancreatic, and prostate cancers. SNAIL1 directly represses the *CDH1* gene and drives EMT in cancer cell lines and in vivo models. Detection of SNAIL1 was also found in tumor samples from breast cancer patients and correlates with metastasis and recurrence. The expression of SNAIL1 is transient as deletion of SNAIL1 in primary breast tumor resulted in decreased DTCs and metastases; on the other hand, a continuous overexpression of SNAIL1 has also been shown to reduce metastases despite an increase in DTCs. TWIST1 is required for invasion and metastasis, though not necessary for tumor initiation, in mouse mammary tumor model. However, the inactivation of TWIST1 expression is needed for the MET process to occur for the formation of macrometastasis in mouse skin cancer model. Similarly in a breast cancer cells, another EMT-TF, PRRX1, is required to be silent at distant site for overt metastasis. Furthermore, the miR-200 family, which negatively regulate ZEB1 and ZEB2, induces MET to promote metastatic colonization and associates with poor prognosis in breast cancer. SNAIL1 and TWIST1 have been shown to reduce cell proliferation, therefore, the downregulation of EMT-TFs during MET allows tumor cells to revert back to the epithelial phenotype and grow the secondary tumors. To put it simply, a constant activation of the EMT program would inhibit metastasis, and its reversibility, that is MET, would be essential for colonization. The above, not only attest that EMT and stemness need to be uncoupled, but also suggest an important role for EMT–MET dynamics in primary tumor invasion, dissemination and metastatic colonization.

Is EMT a Prerequisite for Metastasis?

Two mouse lineage-tracing models of breast cancer and pancreatic ductal adenocarcinoma (PDAC) have challenged the notion of the role of EMT program in metastasis progression. In a PyMT breast-to-lung metastasis model, FSP1 was used as a marker to

monitor cells that have undergone EMT and found that FSP1-negative (non-EMT) tumor cells formed metastasis in the lung. In a PDAC model which used αSMA as an EMT readout, deletion of SNAIL1 or TWIST1 in the primary tumor did not block tumor dissemination or formation of metastasis. Interestingly, the cancer cells in the above two studies were found to have increased chemoresistance after EMT, contributing to the aggressiveness of the disease. This raises the question whether if EMT is indeed a requirement for metastatic capability in carcinomas.

However, the use of FSP1 and αSMA as mesenchymal markers reflects the terminal mesenchymal status in tumor cells, and preclude those aggressive cells that are in the EMT/MET intermediary state (partial EMT) in the lineage-tracing systems used in these studies. EMT-TFs, not only cooperatively target common genes, but they regulate each other's expression. A recent study performed in the same PDAC model showed that ZEB1 depletion suppressed stemness, colonization, invasion, and metastasis. The deletion of one EMT-TF could allow compensatory effects by the upregulation of other EMT-TFs to drive metastasis. In a separate study based also on the PyMT breast cancer model supports the role of EMT and plasticity in vivo. Intravital microscopy was utilized to identify a rare pool of tumor cells spontaneously undergoing EMT, without any modifications of EMT-TFs expression levels, became motile, disseminate, and finally reverting to an epithelial state upon arrival at metastatic site. This indicates that the EMT program does not operate in a stereotypical mode and more studies are needed to determine whether EMT is critical for metastatic progression in other tumors and under various conditions.

Therapeutic Resistance

The contribution of EMT program to metastasis remains debatable, as mentioned above, but solid evidence from many research groups concur that the EMT program confers therapeutic resistance. This has been observed in many cancer cell lines and in vivo mouse models. However, the exact mechanisms in gaining therapeutic resistance remains unclear.

EMT contributes to immunosuppression in tumors. SNAIL1-induced EMT in melanoma cells confers resistance to immunotherapy by inducing immunosuppression. SNAIL1^{+} melanoma cells secrete TGFβ and thrombospondin into the tumor milieu, leading to an increase of regulatory T cells population in the TME. In line with this, mesenchymal breast cancer cells of a mouse breast cancer model elevate their expression of programmed cell death 1 ligand 1 (PD-L1) to evade recognition by cytotoxic T cells, and increased their production of thrombospondin. Due to the increased presence of regulatory T cells, this protects the other epithelial cancer cells with low PD-L1 protein levels from the cytotoxic T cells.

CSCs are known to have drug resistance properties due to their ability to mediate drug efflux. Breast cancer cells overexpressing SNAIL1, TWIST1 or FOXC2, have an increased expression of ATP-binding cassette (ABC) transporters, which play a role in the development of multidrug resistance. In addition, several binding sites for EMT-TFs were identified on the promoters of ABC transporters. Hence, these EMT-cells showed a higher doxorubicin resistance compared with to the control cells.

Chronic exposure to TGFβ, not only induced EMT, but also allows mammary epithelial cells to escape apoptosis. Moreover, TGFβ treatment allow cells to resist ultraviolet-light-induced apoptosis. EMT induced by EGFR signaling has been linked to tamoxifen resistance and increased invasiveness of MCF7 breast cancer cells. In addition to regulating genes involved with migration and invasion, SNAIL1 regulates genes required for cell survival, which are frequently intertwined with EMT during embryonic development or in pathological conditions. SNAIL1 inhibits cell proliferation through suppression of cyclin D proteins, and protects against apoptotic signals induced by serum-withdrawal, pro-apoptotic proteins or DNA damage, by regulating the expression of caspases and BCL-XL. Additionally, overexpression of SNAIL1 and SNAIL2 generates cells with stem cell-like phenotype and promotes chemoresistance against doxorubicin, paclitaxel and radiotherapy in several cancer cells, including breast and ovarian cancer. Similarly, TWIST1 inhibit apoptosis and have pro-survival functions in many cancer cells. TWIST1 directly upregulate AKT2 expression, promoting survival and chemoresistance to paclitaxel in breast cancer cells. TWIST1 and ZEB1 protect cells from oncogene-induced senescence by downregulating cyclin-dependent kinase inhibitors, $p16^{Ink4a}$ and $p21^{Cip1}$.

There is an association of elevated resistance towards chemotherapy in cells that have undergone a partial EMT, compared to their epithelial counterparts. In the clinic, the cell populations that survived and found in patients receiving chemotherapy had the mesenchymal phenotype. Chemotherapy had enriched for cells with CD44^{+}/CD24^{-} in these patients, with increased mesenchymal markers and claudin-low signatures, insinuating that the EMT program had been activated.

Conclusion

EMT is an important and complex process in embryonic development that is recapitulated during cancer progression. In the past several decades, there has been an enormous progress in understanding the signaling pathways and molecular mechanisms that contribute towards EMT. The EMT program could bestow many capabilities, such as migratory and invasiveness, pro-survival, stemness and immunosuppression—all of which are favorable functions for any cancer cell to usurp and initiate metastasis.

There has been much interest in the link between EMT and CSC, and the debate of EMT contribution to the metastasis. EMT is not a dichotomous switch between epithelial or mesenchymal entities, but shifts through a spectrum of intermediate states, that is, partial EMT. This helps to reconcile the notion that cancer cells utilize the EMT program for invasion and dissemination, whereas MET helps establish the metastatic outgrowth. Therefore, it would seem that targeting EMT would be an ideal strategy to block

invasion and dissemination. This could have dire consequences as it could promote colonization of DTCs, via MET, and reinstate rapid proliferative activity of the metastatic cells. Cells in the partial EMT state acquire stemness properties, as it has been demonstrated that they have higher self-renewal and tumor-initiating capacity than their mesenchymal counterparts. The partial EMT state is also associated with both de novo and adaptive drug resistance and higher malignancy than cells in complete mesenchymal state. Therefore, they could be regarded as CSCs with high plasticity with the flexibility to shift through the spectrum between EMT and MET. Hence, it would be vital to find a set of markers to identify and target these partial EMT cells as a strategy for therapeutics development.

Definition and Classification

Malignant neoplasms of the esophagus comprise mainly two entities: squamous cell carcinoma and adenocarcinoma.

Squamous cell carcinoma of the esophagus (ESCC; ICD-O code: 8070/3; also called epidermoid carcinoma, squamous carcinoma, and squamous cell epithelioma) is a malignant epithelial tumor with squamous-cell differentiation, microscopically characterized by keratinocyte-like cells with intercellular bridges and/or keratinization.

Adenocarcinoma of the esophagus (EAC; ICD-O code: 8140/3) is a malignant epithelial tumor with glandular differentiation. These tumors arise predominantly from columnar ("Barrett") mucosa in the lower third of the esophagus. In rare cases, EAC originates from heterotopic gastric mucosa in the upper esophagus, or from mucosal and submucosal glands.

SCCs are more common in the upper and middle third of the esophagus, whereas EACs usually originate in the lower third of the esophagus (distal esophagus), often involving the esophagogastric (gastroesophageal) junction. The appropriate demarcation between gastric and esophageal adenocarcinoma as well as the classification of adenocarcinomas spanning over the esophagogastric junction and the utility of treating them as distinct entities are a subject of debate.

Presentation and Diagnosis

Despite important epidemiological and biological differences between the two major histological types of esophageal cancer, their symptoms and diagnostic workup are similar.

The most common presenting symptom is solid food dysphagia, followed by liquid food dysphagia. The latter usually occurs when esophageal lumen diameter is under 13 mm and indicates locally advanced disease. Dysphagia and tumor-related anorexia lead to weight loss which is observed in about half of the cases. Patients may also experience bleeding from the tumor leading to iron deficiency anemia. Other symptoms include regurgitation, epigastric or retrosternal pain, hoarseness due to invasion of the

 https://doi.org/10.1016/B978-0-12-801238-3.65301-1

recurrent laryngeal nerve, and respiratory symptoms (persistent cough and recurrent pneumonia). Pain in the bones indicates metastatic disease.

As early-stage disease does not give any apparent symptoms, most patients present with advanced disease. Superficial ESCC may sometimes be associated with a tingling sensation and is therefore occasionally detected at endoscopy of the upper gastrointestinal tract. Barret's esophagus, the precursor lesion for EAC, gives symptoms in about 10% of patients (the same as those of the gastro-esophageal reflux disease (GERD)). Physical findings other than cachexia and palpable supraclavicular lymph nodes are rare.

Endoscopic examination is the standard technique used to determine the presence and exact localization of esophageal neoplasia. High-resolution and narrow-band endoscopic imaging may be used to enhance visualization (i.e. resolution of the surface mucosa) and improve cancer detection. Endoscopy can also be improved by using Lugol's iodine dye (chromoendoscopy) to identify early cancers. Multiple biopsies are taken during endoscopy for histological evaluation. In early stage disease, endoscopic resection (ER) of focal nodules should be performed for pathological evaluation of the tumor differentiation and the depth of invasion. This is particularly important in case of Barret's-associated high-grade dysplasia and squamous cell dysplasia. Cytological brushings and washings are usually not adequate for initial diagnosis.

Any complaint of dysphagia in an adult should always prompt an endoscopy to help rule out the presence of esophageal cancer. Endoscopy may be followed by a barium swallow study which is very sensitive in detecting strictures and intraluminal masses. However, as it does not allow for staging or biopsy, it is no longer often used, unless to study distal anatomy in obstructive tumors which are inaccessible to endoscopy. Endoscopy is also used for surveillance of high-risk individuals, for example those with Barrett's esophagus or a familial history of esophageal cancer.

Computed tomography (CT) of the chest and abdomen is usually the first diagnostic workup procedure conducted for staging. It allows to exclude metastases to the liver and the lungs and may be helpful in determining invasion to adjacent structures. Positron emission tomography (PET) scanning is also useful, in particular to detect occult distant lymph node metastases and bone spread, and it becomes standard in esophageal cancer staging. Endoscopic ultrasound (EUS) has been shown to be the most accurate in assessing tumor depth and it allows for lymph node sampling. EUS is recommended to improve the accuracy of staging in patients with no evidence of unresectable metastatic disease. However, PET using the radiolabeled glucose analog fluorine F 18-fludeoxyglucose (18F-FDG) is more sensitive than CT or EUS in detection of distant metastases. EUS-guided fine-needle aspiration (FNA) biopsy provides a greater accuracy than EUS alone for the evaluation of lymph node metastasis.

Laparoscopy and thoracoscopy are also used in some centers for esophageal cancer staging. Laparoscopy allows to assess subdiaphragmatic, peritoneal, liver, and lymph node metastases with a high accuracy, whereas thoracoscopy can spare radical resections in patients with intrathoracic dissemination. Bronchoscopy is indicated for cancers of the middle and upper third of the thoracic esophagus (tumor at or above carina) in nonmetastatic patients to help exclude invasion of the trachea or bronchi.

The macroscopic appearance of ESCC varies according to the depth of invasion and it may be polypoid, flat, or ulcerated. ESCC spreads both horizontally and vertically. Tumors in which invasion is restricted to the mucosa and submucosa are often referred to as "superficial," independently of the presence of regional lymph node metastasis.

Early AECs are often contiguous with the squamous epithelium. Typical salmon-pink mucosa of Barret's esophagus may be evident adjacent to the tumor. At the time of diagnosis, most tumors are advanced, with deep infiltration of the esophageal wall. A majority of advanced adenocarcinomas are flat and ulcerated, while about one third have a polypoid or fungating appearance. AEC may occasionally arise independently of Barret's mucosa from ectopic gastric glands (mostly ulcerated tumors) and esophageal glands (usually polypoid). These tumors are also found in the upper and middle third part of the esophagus where ESCC is more common.

Epidemiology and Risk Factors

Burden

Esophageal cancer is the eighth most common cancer worldwide, with estimated 456,000 new cases in 2012, and the sixth most common cause of cancer-related death (400,000 deaths in 2012). There are striking geographical variations in the prevalence of the two histological subtypes. Still, taking the two subtypes together, about 80% of cases occur in less developed regions. Esophageal cancer incidence rates worldwide in men are more than double those in women (male:female ratio 2.4:1). Geographical variations in the incidence (up to 20-fold) are observed for both sexes, with the highest rates in Asia, south-east Africa, and Northern France (Fig. 1). The incidence increases with age in all countries. Esophageal cancer patients have a very poor survival, with an overall mortality to incidence ratio of 0.88 and 5-year survivals for all patients below 20% even in developed countries with high standards of medical care.

The most common type worldwide is ESCC (almost 90% of all esophageal cancer cases). However, EAC prevails in the United States and Western European countries. The incidence of ESCC is particularly high in the so-called esophageal cancer belt which stretches from northern China through central Asia to northern Iran. The overall worldwide incidence of esophageal cancer is rising. 725,582 new cases are predicted to occur in the year 2030 (643,095 of them in less developed regions). EAC is predominant in white males in whom its incidence has been steeply rising. However, it is gradually rising also in men of other ethnicities and in females in Western countries, while ESCC becomes less frequent. This "histological shift" merely reflects lifestyle changes.

(2013). *GLOBOCAN 2012 v1.0, cancer incidence and mortality worldwide: IARC Cancer Base No. 11 [Internet]*. Lyon, France: International Agency for Research on Cancer. Available from: http://globocan.iarc.fr, accessed on February 20, 2018.

Etiology and Risk Factors

The etiological factors differ between the two histological types of esophageal cancer. The major risk factor for developing ESCC is tobacco smoking, followed by consumption of alcohol and hot beverages. A clear dose-response relationship has been shown between tobacco smoking (duration and quantity) and ESCC risk, while smoking cessation reduces the risk of developing the

disease. Also tobacco chewing is associated with an increased ESCC risk, which may explain a high incidence of this cancer type in India and Southern Africa. Many tobacco carcinogens have been incriminated as mutagens, including PAH and nitrosamines. The deleterious effect of alcohol on the esophageal mucosa is mostly mediated by acetaldehyde, secondary to oxidation by the oral microbiota and salivary products. Alcohol and tobacco have a synergistic effect on the risk of developing ESCC and, taken together, they account for over 90% of ESCC cases in Europe and North America. In the same line, some variants of genes involved in detoxification processes, such as alcohol dehydrogenase, may increase the susceptibility of squamous epithelium to environmental carcinogens, thus contributing to an increased ESCC risk. Drinking very hot beverages, like mate in Brazil and Argentina or hot tea in Iran, contributes to ESCC carcinogenesis by inducing chronic thermal injury.

A low intake of fruit and vegetables as well as specific regional marginal micronutrient deficiencies (e.g., vitamin A and E) are also associated with an increased risk of ESCC. In the same line, Plummer–Vinson syndrome, a sideropenic dysphagia caused by deficiency in iron, riboflavin, and other vitamins, is associated with a higher risk of developing ESCC. Low fruit and vegetable consumption as well as high red meat consumption are also associated with an increased risk of EAC.

Tobacco smoking is also a risk factor for EAC but the association is moderately strong. High body mass index (BMI) and obesity, especially central/visceral obesity increase the risk of EAC but not that of ESCC. The major condition predisposing to EAC, however, is the gastro-esophageal reflux disease (GERD) with associated Barrett's esophagus. In GERD patients, the squamous epithelium of the esophagus is damaged and replaced by metaplastic, columnar, or glandular epithelium predisposed to malignancy. Patients with Barret's esophagus have a 30–60-fold higher risk to develop EAC than the general population.

Some studies have suggested that infection with high-risk Human Papillomaviruses may be associated with the development of ESCC. However, the data had been inconsistent and the results of a recent study by The Cancer Genome Atlas (TCGA) Research Network have rejected this hypothesis.

ESCC may also develop in relation with some hereditary conditions. In particular, Howel–Evans syndrome (tylosis), a very rare autosomal dominant disorder caused by a germline mutation in the *RHBDF2* gene, resulting in palmar and plantar hyperkeratosis, is associated with a 90% cumulative risk of developing ESCC by 70 years of age. Overall, nearly 40% of individuals with tylosis develop ESCC during their lifetime.

In contrast to ESCC, genetics contributes to about one-third of the risk to develop EAC, and approximately 7% of Barret's esophagus and EAC cases may be familial. A number of susceptibility loci have been identified, in particular in genes whose products are involved in the embryonic development of the esophagus and in regulating inflammatory response. The established risk factors for developing esophageal cancer are listed in Table 1.

Pathology and Genetics

Consistent with different etiologies, ESCC and EAC develop through different pathways and have distinct molecular profiles. A recent TCGA study has shown that ESCCs share more genetic features with squamous cell carcinomas of the head and neck than with EACs which, in turn, strongly resemble the chromosomally unstable variant of gastric carcinoma.

ESCC develops from basal cell hyperplasia and dysplasia (from low to high grade) which progresses to carcinoma in situ (Tis) and invasive carcinoma. Dysregulation of *TP53* and other genes encoding cell cycle regulators, such as cyclin-dependent

Table 1 Risk factors for esophageal cancer

Carcinogenic agents classified by "IARC monographs on the evaluation of carcinogenic risks to humans (volumes 1–120)"
Agents of sufficient evidence for esophageal carcinogenicity in humans
Acetaldehyde associated with consumption of alcoholic beverages (ESCC)
Alcoholic beverages (ESCC)
Betel quid with and without tobacco (ESCC)
Smokeless tobacco and tobacco smoking (strong association with ESCC, moderate with EAC)
X-radiation, gamma-radiation
Agents of limited evidence for esophageal carcinogenicity in humans
Dry cleaning
Traditional Asian pickled vegetables (ESCC)
Rubber production industry
Very hot beverages (ESCC)
Other carcinogenic agents and lifestyle risk factors
High BMI and obesity (EAC)
Low fruit and vegetable, and high red meat consumption (EAC)
Medical conditions and hereditary factors
Gastro-esophageal reflux disease (GERD; EAC)
Barret's esophagus (EAC)
Howel–Evans syndrome (tylosis; ESCC)
Plummer–Vinson syndrome (ESCC)

BMI, body mass index; *EAC*, esophageal adenocarcinoma; *ESCC*, esophageal squamous cell carcinoma.

kinase inhibitor 2A (CDKN2A) and retinoblastoma-associated protein (RB; encoded by the *RB1* gene), are early events in ESCC development and can already be detected in precursor lesions. Abnormal p53 expression has been shown in normal esophageal tissue adjacent to dysplasia or ESCC, and increased levels of CDKN2A and RB have been associated with a stepwise progression from inflammation to cancer in esophageal lesions. In a recent TCGA study, ESCC showed a higher prevalence of C>A substitutions (associated with tobacco smoking and chewing) and of the APOBEC mutational signature than EAC.

EAC usually develops from Barret's mucosa, which is an adaptive response to recurrent injury of the squamous mucosa by acid and bile which damage esophageal mucosa by inducing the formation of reactive oxygen species and nitric oxide. These species lead to DNA damage with a characteristic mutational signature of A>C transversions. These transversions are commonly found both in Barrett's esophagus and EAC, meaning that DNA damage contributes to the disease pathogenesis at early precancer stages. Two most probable mechanisms of Barret's mucosa progression to EAC have emerged, with loss of p53 function being an early event in both cases. The first mechanism involves a stepwise loss of tumor suppressor genes, such as *CDKN2A* and *TP53*, as well as mutations in *SMAD4* and the disruption of chromatin modeling pathway, but without major amplifications in the genome. The second one involves acquisition of large-scale chromosomal instability that is associated with aneuploidy following loss of p53 function. Indeed, loss of heterozygosity (LOH) of 17p (which contains *TP53*) in Barrett's esophagus has been associated with the development of aneuploidy and with an increased potential for malignant progression.

Overall, *TP53* and *CDKN2A* are the two genes that are most frequently altered in both ESCC and EAC. Inactivation of these two tumor suppressors is an early event in tumor progression for both tumor types and can be detected in a large proportion of precancerous lesions. Alterations in numerous other genes have also been identified, with different proportions between ESCC and EAC (**Table 2**). Accumulation of all these alterations results in a substantial deregulation of multiple cellular pathways. It also opens the door to screening and early detection strategies based on molecular analyses as well as to molecular therapies targeting specifically the altered genes and pathways (**Fig. 2**). Interestingly, a recent TCGA study has identified three molecular subtypes of ESCC correlated with some clinical parameters.

Table 2 Gene loci that are most frequently altered in esophageal carcinoma

Pathway	*Gene (locus)*	*Alteration type*	*Prevalence*
Cell-cycle control	*TP53* (17p13.1)	Point mutations, small insertion or deletions, and LOH of 17p	Inactivation occurs early in both EAC and ESCC development (alterations frequently detectable in precursor lesions)
	CDKN2A (9p21.3)	Deletions, epigenetic silencing (hypermethylation), and infrequent point mutations	76% of both ESCC and EAC cases; mostly deletions in ESCC, hypermethylation most common in EAC (detectable in Barrett's mucosa)
	CCND1 (11q13.3)	Amplifications	57% of ESCC and 15% of EAC cases
	CDK6 (7q21.2)	Amplifications	16% of ESCC and 14% of EAC cases
	CCNE1 (19q12)	Amplifications	4% of ESCC and 14% of EAC cases
	RB1 (13q14.2)	Deletions	9% of ESCCs, not found in EAC
	MYC (8q24.21)	Amplifications	23% of ESCC and 32% of EAC cases
Cell differentiation	*GATA4* (8p23.1)	Amplifications	1% of ESCC and 19% of EAC cases
	GATA6 (18q11.2)	Amplifications	3% of ESCC and 21% of EAC cases
	NOTCH1 (9q34.3)	Mutations	4% of EAC and 17% of ESCC cases
	TP63 (3q28)	Amplifications	48% of ESCC and 11% of EAC cases
	SOX2 (3q26.33)	Amplifications	
Hippo–YAP pathway (organ size control)	*VGLL4* (3p25.3-p25.2)	Chromosomal deletions encompassing the locus	ESCC
Autophagy regulation	*ATG7* (3p25.3)	Chromosomal deletions encompassing the locus	ESCC
Chromatin remodeling	*ARID1A* (1p36.11)	Deletions and truncating mutations	1% of ESCC and 8% of EAC cases
	KDM6A (Xp11.3)	Deletions and rare truncating mutations	19% of ESCC and 4% of EAC cases
ERBB/P13K signaling (cell metabolism)	*ERBB2* (HER-2; 17q12)	Amplifications and point mutations	3% of ESCC (amplifications only) and 32% of EAC cases
	VEGFA (6p21.1)	Amplifications	3% of ESCC and 28% of EAC cases
	EGFR (7p11.2)	Amplifications and rare point mutations	19% of ESCC and 15% of EAC cases
	KRAS (12p12.1)	Mostly amplifications	7% of ESCC and 14% of EAC cases
	PIK3CA (3q26.32)	Point mutations	13% of ESCC and 3% of EAC cases
	FGFR1 (8p11.23)	Amplifications	12% of ESCC and 4% of EAC cases
Embryonic development	*SMAD4* (18q21.2)	Deletions	8% of ESCC and 24% of EAC cases

EAC, esophageal adenocarcinoma; *ESCC*, esophageal squamous cell carcinoma; *LOH*, loss of heterozygosity.

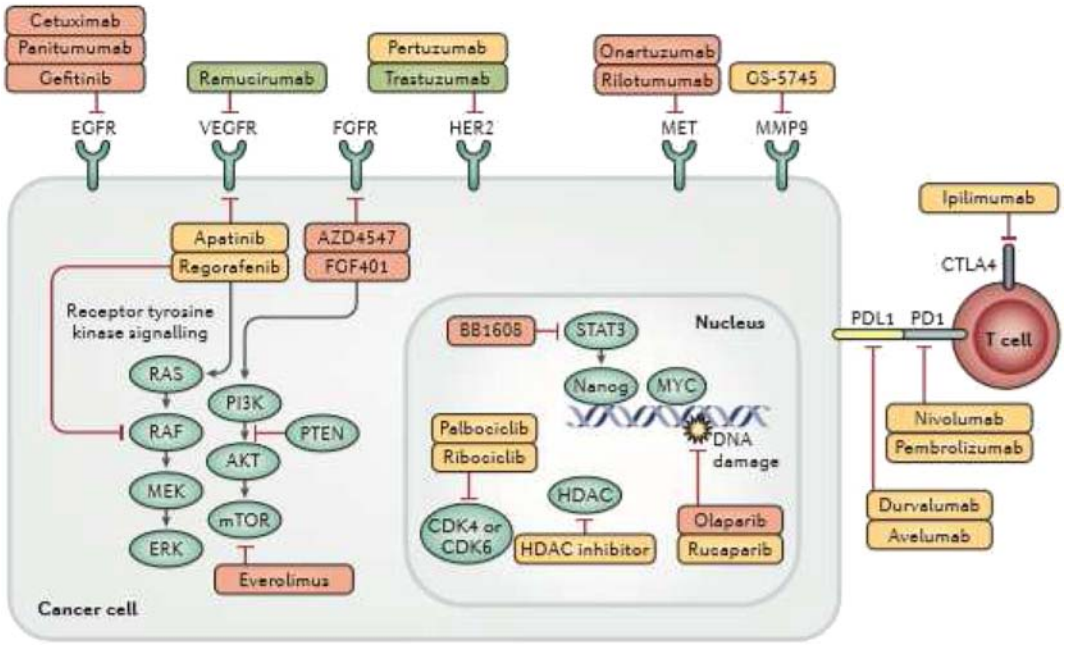

Fig. 2 Potential drug targets in esophageal cancer. Drugs shown in red have been tested in patients with esophageal cancer, without success. Drugs highlighted in yellow are currently being evaluated or could be evaluated on the basis of emerging data on active pathways in esophageal cancer. Regorafenib, apatinib, and nivolumab have improved the overall survival of patients with gastric cancer in randomized trials. At the time of publication, the only drugs that have achieved a survival advantage in patients with esophageal cancer in randomized trials with a control group are trastuzumab and ramucirumab (*in green*). CDK, cyclin-dependent kinase; CTLA4, cytotoxic T lymphocyte protein 4; EGFR, epidermal growth factor receptor; ERK, extracellular signal-regulated kinase; FGFR, fibroblast growth factor receptor; HDAC, histone deacetylase; HER2, human epidermal growth factor receptor 2; MEK, MAPK/ERK kinase; MMP9, matrix metalloproteinase 9; mTOR, mechanistic target of rapamycin; PD1, programmed cell death protein 1; PDL1, PD1 ligand 1; PI3K, phosphoinositide 3-kinase; PTEN, phosphatase and tensin homologue; STAT3, signal transducer and activator of transcription 3; VEGFR, vascular endothelial growth factor receptor. Reprinted with permission from: Smyth, E.C. et al. (2017). Oesophageal cancer. *Nature Reviews Disease Primers* **3**, 17048. https://doi.org/10.1038/nrdp.2017.48.

Biomarkers

Precursor lesions which predispose to esophageal cancer are well known and quite well described in molecular terms. However, screening for esophageal cancer is based on invasive endoscopy and identifying reliable noninvasive biomarkers which would allow to identify premalignant lesions that are likely to progress to malignant tumors remains an unmet need. Similarly, no diagnostic biomarkers exist other than standard techniques used to evaluate histological samples.

Generally, esophageal cancer is associated with poor survival rates. Complete cure is only possible in early-stage disease, with tumor stage, the presence and depth of invasion, lymph node involvement and the presence of metastases being adverse prognostic factors for both ESCC and EAC. In patients undergoing preoperative therapy, assessing pathological complete response (pCR) and histopathological tumor regression grade (TRG) following this treatment provides the most reliable prognostic information for both tumor types.

Recent molecular profiling studies have identified a number of potential molecular therapeutic targets for treatment of esophageal cancers (Fig. 2). Determining the molecular subtype of the tumor to predict its responsiveness to particular treatments is certainly the future of esophageal cancer management. However, as of now, few molecular analyses have been introduced into clinical practice. Among those, testing for the expression of human epidermal growth factor 2 (HER2) in EAC patients has long been standard practice. The prognostic significance of HER2 overexpression in esophageal cancer is not very clear, even though it has been shown to be correlated with tumor invasion and lymph node metastasis, and thus associated with poorer survival. However, HER2-positive tumors may be responsive to treatment with trastuzumab (an anti-HER2 antibody). Therefore, evaluating HER2 expression is recommended for advanced and metastatic tumors which cannot be cured by surgical resection. This is usually done by immunohistochemistry (IHC) and fluorescence in situ hybridization (FISH). An IHC score of 3+ or 2+ with additional evidence of HER2 amplification by FISH is indicative of a possible trastuzumab treatment benefit.

Management and Therapy

Management of esophageal cancer depends on the tumor stage and localization as well as on the patient's performance status.

Early-stage tumors confined to the mucosa in patients with no evidence of metastasis may be treated by endoscopic mucosal resection (EMR) or endoscopic submucosal dissection (ESD), frequently combined with radiofrequency ablation, especially in patients with Barrett's mucosa. Both these procedures are associated with substantially lower complication rates than surgical resection while giving similar survival rates. For advanced and node-positive disease, a multimodality approach employing chemotherapy with radiation in the preoperative setting (trimodality therapy) is favored.

Surgical resection of the esophagus (esophagectomy) remains an important component of the treatment. However, it is associated with considerable morbidity and changes in postoperative life quality. Therefore, a careful selection of patients who meet the criteria for resection is essential to minimize the risk of futile surgery in patients with incurable disease. This includes assessing whether patients are medically fit (able to tolerate general anesthesia and a major thoracic or abdominal surgery) and staging the tumor. Laboratory studies include complete blood count (CBC) and comprehensive metabolic panel (CMP). Liver function studies should be performed in patients who abuse alcohol. Evaluating nutritional status is particularly important, and pretreatment nutritional support should be considered for all patients with significant dysphagia and weight loss. Enteral nutrition is usually the best option. According to the guidelines of the US National Comprehensive Cancer Network (NCCN), surgery should be considered for all physiologically fit patients with localized, resectable thoracic esophageal tumors more than 5 cm from cricopharyngeus as well as intra-abdominal esophageal or esophagogastric junction tumors, whereas cervical and cervicothoracic tumors less than 5 cm from cricopharyngeus should be treated with definitive chemoradiation. Lymph node dissection (lymphadenectomy) should also be performed. However, the optimal number of lymph nodes that should be removed depending on the treatment regimen is not clear.

The optimal surgical approach for radical resection of esophageal cancer is not defined and depends pretty much on the preference of the patient as well as on the experience and preferences of the surgeon. The two most common techniques are transhiatal esophagectomy and transthoracic esophagectomy. Recently, minimally invasive approaches have emerged as alternatives to open esophagectomy. These may be entirely minimally invasive procedures, or hybrid operations combining laparoscopy with open thoracotomy, or thoracoscopy with open laparotomy. Minimally invasive esophagectomy (MIE) offers potential advantages of smaller incisions, decreased intraoperative blood loss, fewer postoperative complications, and shorter hospital stays. However, the ability to obtain negative surgical margins, the adequacy of lymph node dissection, and long-term outcomes following MIE have not been fully assessed. Moreover, the optimal location of anastomosis is a subject of debate but a recent randomized trial has shown cervical and thoracic anastomoses to be equally safe when performed in a standardized way. Gastric conduit is preferred by a majority of surgeons for esophageal reconstruction.

Surgery alone is associated with poor survival rates even in patients in whom complete tumor resection is possible (5-year survival rates of 15%–20%). Therefore, combined regimens are usually applied. Most commonly, patients with resectable tumors are treated with preoperative chemoradiation, even though this approach remains investigational. So far, carboplatin and paclitaxel seem to be the best combination to this effect, in particular in EAC patients. Induction chemotherapy prior to preoperative chemoradiation may also provide important benefit to some patients. However, it has not yet been evaluated in phase III randomized trials.

Postoperative treatment depends on histology, surgical margins and nodal status. NCCN recommend no further treatment for ESCC patients with no residual disease at surgical margins (R0 resection). For EAC patients, perioperative chemotherapy is recommended in all cases of R0 resection, while postoperative fluoropyrimidine-based chemoradiation is recommended for most R0 patients who have not received a preoperative therapy.

Definitive chemoradiation is the preferred first-line treatment for patients who are either medically unfit for surgery or have advanced unresectable tumors, with fluoropyrimidine- or taxane-based regimens being the recommended options. For patients who are unable to tolerate chemotherapy or chemoradiation, palliative radiotherapy and best supportive care are the remaining options.

Palliating the obstructed esophagus and relieving the symptoms of dysphagia are particularly important for the quality of life of the patients. A log-term palliation of partially obstructed esophagus and associated dysphagia may be obtained by placing an expandable metallic stent or by radiation therapy (if the patient has disseminated disease or is not a candidate for surgery). Alternative methods of relieving dysphagia have been reported, including laser therapy and electrocoagulation to destroy intraluminal tumor. In case of complete esophageal obstruction in patients with no clinical evidence of systemic metastasis, palliative surgery (surgical excision of the tumor with mobilization of the stomach to replace the esophagus) is the most popular solution.

Much hope for treatment of esophageal cancer is placed in targeted molecular therapies (**Fig. 2**). Metastatic AECs which overexpress HER2-neu may be responsive to trastuzumab, an anti-HER2 monoclonal antibody. Combining trastuzumab treatment with cisplatin-fluoropirymidine chemotherapy has been shown to improve overall survival in gastric and esophagogastric junction cancer patients. As AEC has recently been shown to be molecularly similar to these cancers, the current consensus is to follow the same HER2-positivity criteria to select AEC patients for trastuzumab treatment which—in combination with cisplatin and fluoropyrimidine—is now considered to be the preferred first-line treatment for patients with HER2-overexpressing advanced or metastatic AEC. Similarly, ramucirumab, an antibody against vascular endothelial growth factor receptor (VEGF), may provide some benefit to AEC patients. Ramucimurab has been shown to improve overall survival in patients with gastric and esophagogastric junction cancer. It has been approved by the US Food and Drug Administration (FDA) for treatment of adenocarcinomas originating at these sites and refractory to or progressing after first-line treatment with platinum- or fluoropyrimidine-based chemotherapy, either as a single agent or in combination with paclitaxel. However, its utility for treating EAC patients awaits clinical trial evaluation. A novel epidermal growth factor receptor (EGFR) inhibitor, nimotuzumab, has shown promising results for treatment of locally

advanced EAC in combination with standard chemoradiotherapy in a phase II trial. Studies on immune checkpoint inhibitors, like pembrolizumab or nivolumab (PD1 inhibitors), have also given encouraging results. Finally, some new approaches, such as peptide vaccines and T-cell immunotherapies, may potentially offer some benefits in the treatment of this so-far extremely fatal cancer.

Esophageal Cancer: Pathology and Genetics

Jean-François Fléjou, Saint-Antoine Hospital, AP-HP, Faculty of Medicine, Sorbonne University, Paris, France

Glossary

Adenocarcinoma A malignant epithelial tumor with glandular differentiation.

Barrett's esophagus An acquired condition, in which a segment of normal squamous esophageal epithelium is replaced by a metaplastic columnar epithelium.

Dysplasia An unequivocal neoplastic lesion strictly limited to the epithelium (synonymous: intraepithelial neoplasia).

Squamous cell carcinoma A malignant epithelial tumor with squamous cell differentiation, microscopically characterized by keratinocyte-like cells with intercellular bridges and/or keratinization.

Definition and General Features

This group of neoplasms comprises all malignant tumors of the esophagus. There are two major histological types with entirely different risk factors, squamous cell carcinoma (SCC) and adenocarcinoma. All other tumor types are uncommon, including neuroendocrine neoplasms, mesenchymal tumors, lymphomas and secondary tumors; due to their rarity, they will not be presented in this chapter, which is only devoted to esophageal SCC and adenocarcinoma. The current World Health Organization (WHO) classification of esophageal tumors (fourth edition, 2010) is shown in Table 1, and the current TNM system of esophageal tumors (eighth edition, 2017) is shown in Table 2.

Esophageal cancer is the eighth most common cancer overall. In 2012, including SCC and adenocarcinoma, worldwide there are estimated to have been 456,000 new cases (3.2% of all incident cancer cases). About 80% of cases occur in less developed regions. The incidence in men is more than double that in women (male to female ratio 2.4:1). In both sexes, a striking feature is a major variability across the regions of the world, with 2012 incidence rates (per 100,000 population) ranging from 0.8 case in Western Africa to 17.0 cases in Eastern Asia in men, and from 0.2 case in Micronesia/Polynesia to 7.8 cases in Eastern Africa in women. The incidence of esophageal cancer is increasing. However, some features differ between the two major histological types, with a declining incidence for SCC and a major increase for adenocarcinoma.

Esophageal cancer is the sixth most common cause of cancer death, with an estimated 400,000 deaths in 2012 (4.9% of all cancer deaths).

In both histological types, recent advances have been made in endoscopy, allowing detection of early cancers and precancerous lesions. Although still a disease with dismal prognosis in most patients, advances in therapeutics including endoscopic resection, surgery, radiotherapy, chemotherapy, and targeted therapies have led to substantial improvements in clinical management and outcome. Recent basic research studies have improved knowledge in cellular and molecular mechanisms leading to esophageal malignant transformation.

Squamous Cell Carcinoma

Definition

The WHO defines esophageal SCC as a malignant primary epithelial tumor of the esophagus with squamous cell differentiation, microscopically characterized by keratinocyte-like cells with intercellular bridges and/or keratinization.

Burden, Epidemiology

Globally, the incidence of esophageal SCC is threefold higher in men than women, and approximately 80% of cases occur in developing countries. The incidence increases with age and peaks in the seventh decade. There is a hugely different frequency in various locations of the world and certain ethnic groups, with gradients of incidence between regions located in the same geographic area. The incidence is high in East Asia, Eastern and Southern Africa, and some parts of Europe. On the contrary, the incidence is low in North America and other parts of Europe. Although still the predominant type of esophageal cancer, the incidence of SCC is on the decline, both in Western countries and in Asia. In the United States, the incidence is higher in African Americans than in European Americans, and the rate for both groups declined during the past decades.

Risk Factors

The known risk factors for esophageal SCC are summarized in Table 3. Although the etiology of this tumor type is unknown, it is well established that tobacco smoking and alcohol drinking play a major role, but still several other factors have been recognized as

Table 2 TNM classification of carcinoma of the esophagus (eighth Edition, 2017)

T—Primary tumor
T1: Tumor invades lamina propria, muscularis mucosa, or submucosa
T1a: Tumor invades lamina propria or muscularis mucosa
T1b: Tumor invades submucosa
T2: Tumor invades muscularis propria
T3: Tumor invades adventitia
T4: Tumor invades adjacent structures
T4a: Tumor invades pleura, pericardium, azygos vein, diaphragm, or peritoneum
T4b: Tumor invades other adjacent structures such as aorta, vertebral body, or trachea
N—Regional lymph nodes
NX: Regional lymph nodes cannot be assessed
N0: No regional lymph node metastasis
N1: Metastasis in 1 to 2 regional lymph nodes
N2: Metastasis in 3 to 6 regional lymph nodes
N3: Metastasis in 7 or more regional lymph nodes
M—Distant metastasis
M0: No distant metastasis
M1:Distant metastasis

Table 3 Risk factors for esophageal squamous cell carcinoma

Tobacco smoking
Alcohol consumption
Tobacco and alcohol: independent effects, but synergistic interaction
Thermal irritation by hot beverages and food
Physical irritation due to loss of teeth
Dietary factors
Low intake of fruits and vegetables
Carcinogens. e.g., nitrosamines, polyaromatic hydrocarbures
Betel quid chewing
Extremely high salt intake
High-risk HPV (16 and 18) *suspect, still not proven*
Ionizing radiation
Plummer Vinson syndrome
Achalasia
Celiac disease

potentially responsible, that may differ between geographical areas and may act synergistically. These factors include nutritional/dietary factors, and probably genetic factors. In low incidence regions the use of alcohol and tobacco plays a major role, with a strong male predominance, while in high incidence areas, nutritional factors are on the lead, with a male to female ratio close to 1.

Alcohol

Alcohol consumption is a major risk factor for esophageal SCC. Ingested alcohol is absorbed from the upper GI tract and transported to the liver where it is metabolized to acetaldehyde by alcohol dehydrogenase 1B (ADH1B). Acetaldehyde is then detoxified to acetic acid by ALDH2. The high amount of acetaldehyde in certain types of alcoholic beverages may explain why these beverages incur a higher risk of SCC. Numerous studies support the mutagenic and carcinogenic effects of acetaldehyde. Among the mechanisms that have emerged from experimental and epidemiological studies, the formation of DNA adducts and ALDH2 polymorphisms could account for the higher incidence of this tumor type in Asian versus Western countries.

Tobacco

Tobacco smoking is another major risk factor for esophageal SCC. The relative risk in heavy smokers is four to eight times that observed in nonsmokers. A dose-risk relationship exists for smoking duration and average consumption. Stopping smoking reduces the risk, with a relative risk approaching that of never smokers 10–20 years after cessation. Chewing tobacco-containing products is an important risk factor in some parts of the world. Tobacco smoke contains carcinogenic substances such as nitrosamines, which are directly in contact with the esophageal epithelium. Tobacco smoke also contains the carcinogen acetaldehyde, which could explain the synergistic effect of both carcinogens (alcohol and tobacco) in people with some specific polymorphisms in ADH1B and ALDH2.

Taken together, tobacco smoking and alcohol consumption account for more than 90% of cases of esophageal SCC in Western Europe and North America. However, this proportion is lower in developing countries, especially in regions of Asia and South America with a very high risk, suggesting other risk factors in these areas.

Dietary/nutritional factors

The risk of esophageal SCC is reduced by a diet rich in fruit and vegetables, and increased by a high intake in meat. Deficiencies of various micronutrients are common in regions with a high incidence of SCC, including selenium, zinc, calcium, vitamin A, and vitamin C among others. However, large chemoprevention trials and meta-analyses have failed to firmly demonstrate their responsibility. In high-risk areas of China, eating of pickled vegetables increases the risk of esophageal SCC. There is also an association between SCC and consumption of hot foods and drinks. Contamination of food by fungi is frequent in high-incidence regions of China, and may play a role.

Other risk factors

Numerous studies have focused on the role of human papilloma viruses (HPV) in esophageal squamous carcinogenesis. However, due to the marked differences in the association between esophageal SCC and HPV infection, a role of this infection is still considered as unproven.

Other associated conditions include ionizing radiation, caustic esophagitis, achalasia, esophageal diverticula, and Plummer-Vinson syndrome. This latter syndrome can be secondary to celiac disease induced anemia, which may explain the increased risk observed in celiac patients.

Precancerous Lesions

As in many epithelial cancers, the development of esophageal SCC is a multistep process, going from normal epithelium to invasive carcinoma through dysplasia (or intraepithelial neoplasia, a synonymous term, favored in the Far East).

Before the development of morphologically recognizable dysplasia, a stage of chronic esophagitis with basal cell hyperplasia has been described, especially in populations with a high incidence of esophageal SCC. This lesion manifests as white patches on endoscopy, which do not stain with lugol iodine. However, the precise role of this lesion in the development of esophageal SCC is still debated in the literature.

Dysplasia is defined as an unequivocal neoplastic lesion strictly limited to the epithelium (intraepithelial). This definition applies both in squamous and glandular epithelium.

Squamous dysplasia is asymptomatic, and on endoscopy it has a wide variety of aspects, from normal mucosa to erythematous or plaque-like lesions. The endoscopic diagnosis is sensitized by the application of lugol iodine solution. Endoscopic screening is not applicable in the general population. In high-risk areas, balloon cytology has been proposed as a screening test. In low-risk areas, endoscopic screening can be proposed to selected high-risk populations, such as patients with head and neck SCC.

Histologically, as in other epithelium, squamous dysplasia shows both architectural and cytological abnormalities. Architectural abnormalities include cellular disorganization with a disorderly proliferation of abnormal cells. Cytological abnormalities include hyperchromasia, increased mitoses, and an increased nucleus-cytoplasm ratio. A two grades classification is recommended, in which low-grade dysplasia shows abnormalities confined to the lower half of the epithelium and high-grade dysplasia has abnormal cells involving the upper half of the epithelium (**Fig. 1**). Carcinoma in situ constitutes the upper end of the spectrum of dysplastic lesions, and is difficult to distinguish from high grade dysplasia. Dysplastic cells may extend laterally in a Pagetoid fashion or deeply into the ducts of the submucosal esophageal glands.

The most frequent and crucial differential diagnosis is a regenerative process secondary to inflammation, due to reflux in most cases. The only immunohistochemical marker that can help distinguishing dysplasia from regeneration is p53 protein, as p53 abnormal expression is observed in approximately 80% of high-grade dysplasia and cancer. In case of severe inflammation, the diagnosis of dysplasia has to be made with caution. In such cases, a diagnosis of epithelium "indefinite for dysplasia" may be appropriate.

Macroscopy

Esophageal SCC is localized most often in the middle third, then in the lower and upper third, respectively. The gross appearance differs between superficial (early) cancers limited to the mucosa and submucosa, and advanced cancers. The Japanese classification of superficial cancers (type 0) comprises three types: a protruding type (0-I), a flat type (0-II) subclassified in 0-IIa (slightly elevated), 0-IIB (completely flat), 0-IIc (slightly depressed), and an ulcerated type (0-III). Advanced SCC may be exophytic, ulcerating or infiltrating, with often a mixture of these different aspects. In patients treated preoperatively with radio- and/or chemotherapy, the tumor may show a wide spectrum of changes. In case of complete response, this results to an esophageal scar with frequent partially re-epithelialized ulcer.

Microscopy

By definition esophageal SCC is a squamous neoplasm that penetrates the epithelial basement membrane and invades at least the lamina propria, and often deeper layers of the esophageal wall. In most cases the tumor shows the classical features of squamous carcinoma, with varying grades of differentiation, from well-differentiated mature keratinizing neoplasms to undifferentiated tumors. The WHO classification grades esophageal SCC in four groups of differentiation: well differentiated carcinoma with prominent keratinization showing squamous pearl formation (**Fig. 2**)—moderately differentiated, the most common histological type

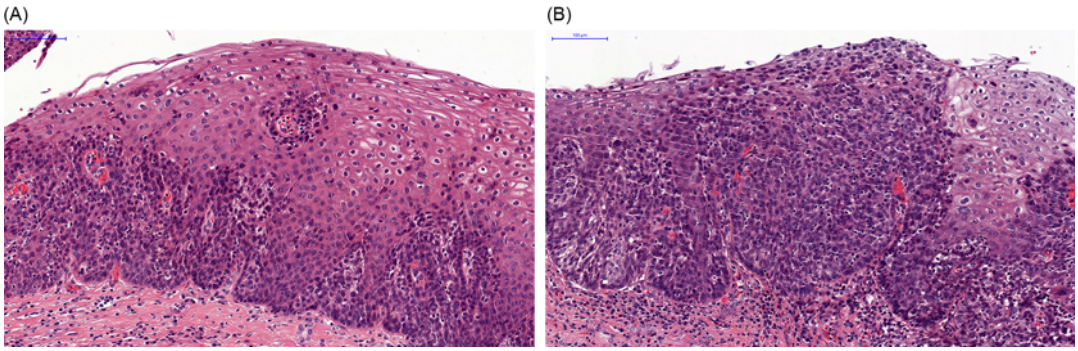

Fig. 1 Esophageal squamous dysplasia. In low-grade dysplasia, abnormal cells remain in the lower half of the epithelium (A). In high-grade dysplasia, the entire thickness of the epithelium is composed of neoplastic cells (B).

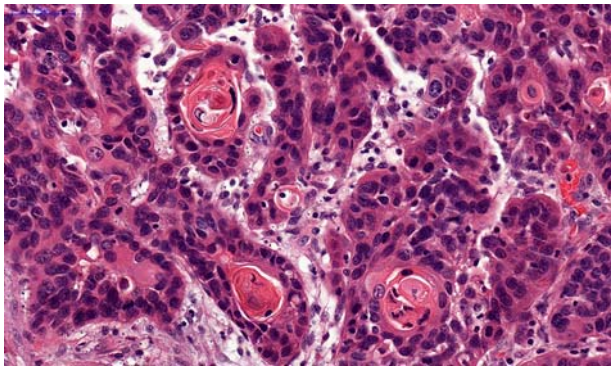

Fig. 2 Well-differentiated squamous cell carcinoma of the esophagus, with a trabecular proliferation of squamous cells showing prominent keratin pearl formation.

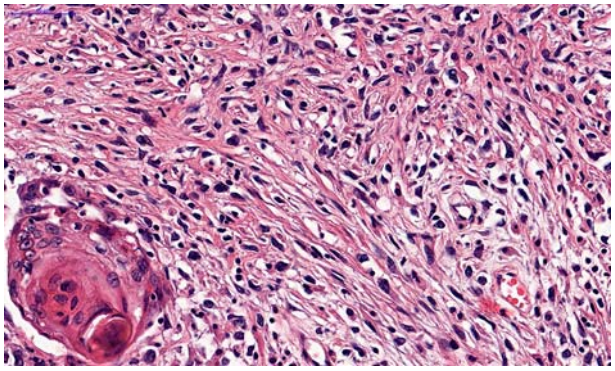

Fig. 3 Sarcomatoid variant of squamous cell carcinoma of the esophagus, with prominent "sarcomatous" cells and a focal epithelial squamous component on the lower left.

with variable signs of squamous differentiation but usually lacking pearl formation—poorly differentiated with sheets of basal-like cells and occasional parakeratotic cells—undifferentiated with no features of squamous lineage, confirmed by immunohistochemistry that also shows negative neuroendocrine markers. Variation of differentiation in different parts of the tumor is a common feature, and even focal adenocarcinomatous differentiation can be seen in a proportion of cases of the lower third of the esophagus. However, such cases are considered as SCC in terms of grading, treatment, and prognosis.

Three histological variants are recognized in the WHO classification:

- Verrucous carcinoma is extremely rare, and usually presents as a large papillary or warty tumor, often localized in the upper third of the esophagus. On histological examination, it is a highly differentiated tumor, which may be difficult to diagnose as a malignant neoplasm on a biopsy. This tumor has a slow local growth with locoregional invasion but rare metastases.
- Spindle cell carcinoma, also called sarcomatoid carcinoma, is an uncommon type of esophageal SCC. Macroscopically it is a large polypoid mass, often located in the middle and lower esophagus. On histological examination, it is a biphasic tumor, with prominent pleomorphic spindle and stellate cells and an epithelial squamous component that may be focal, localized in tiny zones at the base of the polypoid mass (Fig. 3). Hematogenous spread is common in this tumor type, but the overall prognosis is similar to that of classical SCC.
- Basaloid SCC is a relatively uncommon variant of squamous cancer, similar to tumors that occur more commonly in the upper aerodigestive tract. It is more common in elderly men, and presents in most cases as an advanced lesions of the middle or lower third of the esophagus. On histology, it is composed of basaloid cells arranged in solid or in cribriform lobules (Fig. 4). Areas of conventional SCC are often present. Basaloid carcinoma has to be distinguished from adenoid cystic carcinoma, which is less aggressive.

Molecular Pathology and Genetics

Molecular pathology

Several recent studies have used high-throughput next generation sequencing (NGS) to characterize molecular features of esophageal cancer. They confirm that, similarly to epidemiological and histopathological features, molecular alterations clearly

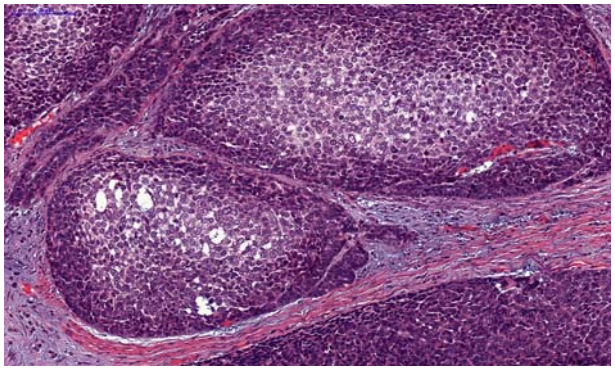

Fig. 4 Basaloid variant of squamous cell carcinoma of the esophagus composed of basaloid cells arranged in large lobules.

differentiate esophageal SCC from esophageal adenocarcinoma. The former resembles SCC from other organs (lung, head and neck…) more than it does esophageal adenocarcinoma.

Whole exome sequencing and whole genome sequencing analyses of esophageal SCC have confirmed the frequency of mutations in several genes: *TP53*, *CCND1*, *CDKN2A*, *FHIT*, *NOTHCH1*, *PIK3A*, *KMT2D*, *NFE2L2* among others. Mutation in the *TP53* gene is the most frequent event, present in 70%–80% of the cases, followed by amplification of *CCND1* in 20%–40%, and inactivation of *CDKN2A*. *TP53* pattern of mutation differs from that observed in lung SCC and other tobacco-associated cancers.

Precancerous lesions (dysplasia—intraepithelial neoplasia) show the same repertoire and frequency of mutations and copy number alterations that invasive SCC, suggesting that these events occur early during the transformation of esophageal squamous epithelium. However, basal cell hyperplasia, frequently observed in high-risk areas, harbors few somatic alterations compared to intraepithelial neoplasia and SCC, which suggests that it is an adaptive nonneoplastic response.

The major signaling pathways dysregulated in esophageal SCC include the Notch pathway, cell adhesion, PIK3CA pathway, *TP53*, Hedgehog pathway, chromatin remodeling, and the MAPK pathway. An APOBEC signature is predominant in ESCC individuals in China. However, differences in pathways involved are observed between geographical populations, suggesting a role for environmental factors, such as tobacco smoking or chewing. Limited molecular data are available regarding HPV, but they do not support an important etiological role for HPV in esophageal SCC.

Genetics

Tylosis esophageal cancer (TOC) is the only hereditary disease with a strong susceptibility to esophageal SCC. This autosomal dominant syndrome is characterized by palmoplantar keratoderma, oral and esophageal leukoplakia, and esophageal SCC. The causative gene is *RHBDF2*, coding for a rhomboid protease involved in EGFR signaling.

Polymorphisms in enzymes involved in alcohol and tobacco metabolism are responsible for increased susceptibility to these carcinogens. Among these enzymes, *ALDH2*2* variant allele increases the risk of esophageal SCC in alcoholics, and some CYP450s and GSTM1 variants increase the risk in heavy smokers.

Staging and Grading

As in many tumor types, grading of esophageal SCC is based on mitotic activity, nuclear atypia, and more importantly degree of squamous differentiation. Those differentiation criteria have been described on resection specimens, but they can also be used on endoscopic biopsies. In heterogeneous tumors, the overall grade is assigned based on the foci with the highest grade within the specimen. The grading can be more difficult in patients operated after neoadjuvant chemotherapy or chemoradiotherapy, in which the residual tumor cells may be dispersed as single, atypical cells within the esophageal wall. In such cases, the cancer may be upstaged inaccurately to poorly differentiated carcinoma.

The natural history of esophageal SCC goes from a "superficial" cancer, limited to the mucosa or submucosa, with or without lymph node metastases, to deep esophageal cancer. After invading the esophageal wall, locally advanced lesions may involve adjacent structures such as the trachea, aorta and pericardium. The risk of lymph node metastasis increases with the depth of invasion, but is already as high as 30%–40% in tumors that invade the submucosa.

The TNM (tumor–node–metastasis) staging system proposed by the UICC–AJCC (American Joint Committee on Cancer) has been revised recently, resulting in the eighth edition, with only minimal changes in the esophagus compared to the previous version. The staging criteria are presented in **Table 2**. Although the prognosis differs between SCC and adenocarcinoma, the TNM categories are identical in both tumor types. Those TNM categories allow determining the anatomic pathologic stage groups (from stage IA to stage IVB), identical in SCC and adenocarcinomas. The TNM system also provides pathological prognostic groups that take into account tumor grade and location in the esophagus in supplement to TNM categories, and differ between SCC and adenocarcinoma (**Fig. 5**).

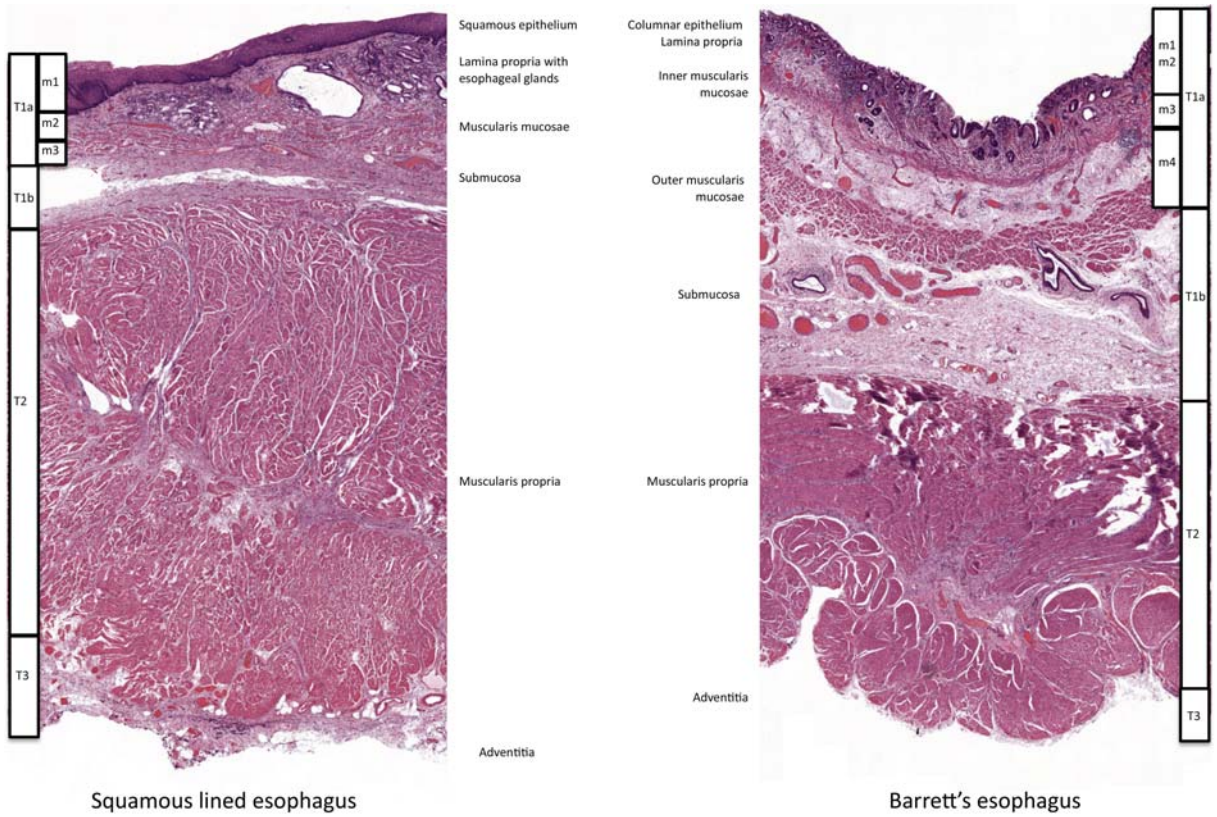

Fig. 5 T stages of esophageal carcinoma in the TNM classification (eighth edition), comparing squamous cell carcinomas and adenocarcinomas developed in Barrett's esophagus.

In superficial SCC, the intraepithelial (Tis) and mucosal (T1a) cancers can be divided into m1 (epithelium—Tis), m2 (lamina propria T1a), or m3 (muscularis mucosae T1a), and the submucosal cancers (T1b) into cases invading the inner (sm1), middle (sm2), and outer (sm3) thirds of the submucosa. In early tumors treated with endoscopic resection, it is recommended to estimate the submucosal invasion by the depth of vertical infiltration, ideally limited to 200 μm or less from the muscularis mucosae.

Neoadjuvant therapy induces major changes that can render the ypTNM staging more difficult. The residual cancer is admixed with fibrosis and elastosis. These changes have to be estimated semiquantitatively. The TRG (tumor regression grade) described by Mandard et al. is still the most widely used system, classifying cancers from TRG5 (absence of regressive changes) to TRG1 (absence of residual cancer).

Prognostic and Predictive Biomarkers

The overall prognosis for esophageal SCC is poor, with a global 5-year survival rate at about 10%. Besides pathological and molecular factors, the prognosis is influenced by age and gender, nutritional status; together with the stage of the tumor disease, these criteria are decisive to decide the therapeutic scheme in individual patients. The squamous phenotype of the tumor is by itself a negative prognostic factor, as the prognosis of SCC is less favorable than that of adenocarcinoma, with higher postoperative mortality, and more frequent lymph node metastasis even in early-stage tumors.

Morphological factors

The most important prognostic factor is tumor stage. The depth of invasion and the presence of nodal or distant metastasis are independent predictors of survival. Any lymph node involvement indicates poor prognosis, even in tumors limited to the esophageal wall (T1b or T2). The prognostic influence of TNM stage is demonstrated both in patients operated without (pTNM stage) or with (ypTNM stage) neoadjuvant treatment.

Additional prognostic factors recommended by the AJCC include:

- Differentiation (four grades), although there is no consensus on its prognostic influence.
- Tumor site.
- Lymphatic and/or vascular invasion.

- Assessment of the surgical margin (R category in the TNM system), a positive microscopic margin (R1) being correlated with the risk of locoregional recurrence.

Molecular factors

A number of studies have indicated a prognostic influence of various molecular alterations in esophageal SCC, including *TP53*, cyclin D1, cyclin B1, EGFR, HER2, TGFa, VEGF, E-cadherin. Until now, none of these factors is used in clinical practice, neither for therapeutic decision making nor for prognostic evaluation. However, it might be that results of large-scale genomic studies of esophageal SCC will provide indications of the efficacy of new-targeted anticancerous drugs that are currently tested in many tumor types, including esophageal cancer.

There is no biomarker that is either available for early detection of cancer or for prediction of the efficacy of neoadjuvant or adjuvant therapy.

Esophageal Adenocarcinoma

Definition

Esophageal adenocarcinoma is a malignant epithelial tumor of the esophagus with glandular differentiation. In the vast majority of cases it develops from acquired columnar metaplasia of the esophagus, the so-called Barrett's esophagus (BE). Much more rarely, adenocarcinoma originates from heterotopic gastric mucosa in the upper esophagus, or from mucosal and submucosal esophageal glands.

Burden, Epidemiology

The most striking feature of esophageal adenocarcinoma is its rapid increase in frequency in many Western countries, including Europe, North America, and Australia. Esophageal adenocarcinoma is now the main histological type of esophageal cancer in the West, with more than 18,000 cases in 2014 in the United States. However, in 2012, there were approximately 52,000 incident cases of esophageal adenocarcinoma worldwide, to be compared to 400,000 cases of SCC. Therefore, the major type of esophageal cancer remains SCC, due to its very high frequency in Asia and some parts of Africa. In the United States and several European countries, it is estimated that the incidence of esophageal adenocarcinoma doubled between the early 1970s and late 1980s, and continued to increase at a rate of about 5% per year, although the increase seemed to have slowed down to 2.6% per year from year 2000 onwards. Esophageal adenocarcinoma is most common in industrialized countries with populations of predominantly European ancestry. The countries with the highest incidence are the United Kingdom, Australia, the Netherlands, and the United States. Cases of esophageal adenocarcinoma are rare in Asia and Africa. In the United States, the incidence is higher in non-Hispanic whites, followed by Hispanic whites, American Indian natives, Blacks, and lowest in Asian.

This increase in esophageal adenocarcinoma is paralleled by rising rates of adenocarcinoma of the esophago-gastric junction and of the proximal stomach. Interestingly, esophageal adenocarcinoma and adenocarcinoma of the esophago-gastric junction share most epidemiological characteristics, including a high male: female ratio (between 4:1 and 7:1), and a high incidence among Whites and groups with higher socioeconomic status. As for most epithelial cancers, esophageal adenocarcinoma incidence increases with age.

Risk Factors

Gastro-esophageal reflux disease and Barrett's esophagus

Gastro-esophageal reflux disease (GERD) is the most important risk factor for esophageal adenocarcinoma. The relative risk of adenocarcinoma in persons with heartburn for at least 30 years is 6.2-fold higher than in persons without heartburn (Table 4).

Table 4 Risk factors for esophageal adenocarcinoma

Gastro-esophageal reflux disease (GERD)
Barrett's esophagus
Tobacco smoking
H. pylori (protective role)
Overweight and obesity
Dietary factors
High intake of vegetables (protective role)
Medications use
Anticholinergic drugs
Aspirin and NSAIDS (protective)

In predisposed people, GERD induces erosive esophagitis, followed by an abnormal healing process resulting in Barrett's epithelium, a metaplastic, so-called "specialized" epithelium. The relative risk of esophageal adenocarcinoma in patients with BE is in the order of 30–60. However, BE progresses to adenocarcinoma in only a small percentage of patients, at a rate of approximately 0.12% to 0.60% per year, resulting in a lifetime risk of adenocarcinoma in patients with BE between 2.7% and 10%. Factors predisposing for the development of BE and esophageal adenocarcinoma include increased duration of esophageal exposure to refluxed gastric and duodenal content (a "mixed" reflux).

Tobacco smoking

Tobacco smoking is a well-established moderately strong risk factor for esophageal adenocarcinoma, with ever smoking conferring a doubled risk of adenocarcinoma compared with never smoking. There is dose–response association between pack-years of smoking and adenocarcinoma risk. Although smoking cessation appears to reduce the risk of adenocarcinoma, this risk in former smokers does not return to the level observed in never-smokers.

Alcohol consumption

Although alcohol is a risk factor for the development of many cancers, including esophageal SCC, the association does not apply to esophageal adenocarcinoma. It is conceivable that individuals with GERD reduce alcohol consumption.

Overweight and obesity

Increasing body mass index has been consistently associated with increased risk of esophageal adenocarcinoma in a linear exposure-response pattern. In meta-analyses, the risk of adenocarcinoma was increased 2.4–2.8-fold among obese individuals, compared with individuals of normal weight. The increasing prevalence of obesity in Western populations may partially account for the increasing incidence of esophageal adenocarcinoma. The mechanism behind this association is not fully elucidated. This may be mechanical through intra-abdominal obesity, which might increase intra-abdominal pressure, promoting GERD and BE. Obesity, as a systemic condition, may also increase esophageal adenocarcinoma risk through inflammatory and metabolic alterations.

Dietary habits

Although many observational studies have associated dietary habits with the risk of esophageal adenocarcinoma, these findings have not been supported by subsequent randomized trials of dietary supplementation. Therefore, at present, for none of the dietary aspects evidence of an association with an increased risk of adenocarcinoma is judged strong, whereas only for vegetable intake limited evidence suggests a relation to a reduced risk of esophageal adenocarcinoma.

Helicobacter pylori

Infection with *H. pylori* appears to protect against esophageal adenocarcinoma. Observational studies have reported a 40%–60% reduced risk associated with *H. pylori* infection, especially with CagA positive strains. The mechanism of this reduction might include reduced volume and acidity of gastric juice, because of *H. pylori* induced atrophic gastritis. It has been proposed that the decreasing prevalence of *H. pylori* infection in Western populations may have contributed to the increasing incidence of esophageal adenocarcinoma.

Medications

The use of certain medications has been associated with an increased or decreased risk of esophageal adenocarcinoma. Medications that relax the lower esophageal sphincter—particularly anticholinergics, have been associated with an increased risk of esophageal adenocarcinoma. On the contrary, use of aspirin and nonsteroidal antiinflammatory drugs is associated with a decreased risk of adenocarcinoma, particularly when used daily and for a long duration. However, it is considered that there is insufficient evidence to use these drugs in esophageal adenocarcinoma prevention.

Precancerous Lesions

Barrett's esophagus

BE is an acquired condition, in which a segment of normal squamous esophageal epithelium is replaced by metaplastic columnar epithelium. It occurs secondary to GERD, and affects approximately 1%–5% of the general population. However, it is clinically silent in the majority of patients. Currently, the definition of BE requires both endoscopic and histological criteria. On endoscopy, there must be visible columnar mucosa proximally to the gastro-esophageal junction, extending more (long segment BE) or less (short segment BE) than 3 cm. The Prague C and M criteria are used to designate the circumferential extent (C) and the maximum extent (M) of Barrett metaplasia.

Histologically, biopsies taken from the endoscopically visualized columnar mucosa must show metaplastic glandular epithelium (Fig. 6). In the United States, the presence of intestinal metaplasia with goblet cells is mandatory, while in the United Kingdom the definition is broader, needing only a columnar epithelium on histology, which can be either cardia- or intestinal-type, or both. The Barrett epithelium usually contains a mixture of gastric foveolar and intestinal cells. Intestinal cells include goblet cells, "intermediate" columnar cells, endocrine cells, and less frequently Paneth cells. Intermediate cells have features of both absorptive and mucus secreting cells. A villiform architecture is common at the surface. In the deeper part of the mucosa, glands may be intestinal,

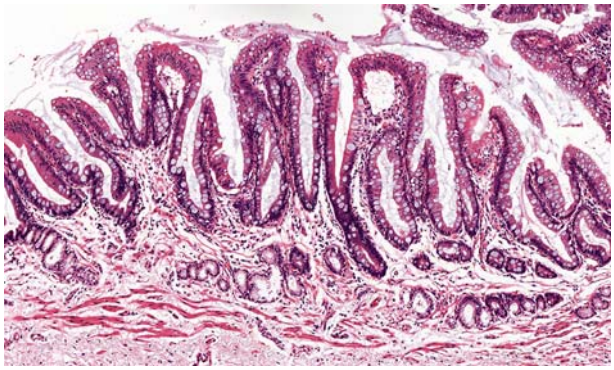

Fig. 6 Metaplastic intestinal Barrett's mucosa, with intermediate columnar cells and numerous goblet cells. Note the villiform pattern, and the clear pyloric type glands in the deeper part of the mucosa.

cardiac, oxyntic or a mixture of these types. The lamina propria shows variable numbers of inflammatory cells. The muscularis mucosa is almost always duplicated in Barrett's mucosa, an important feature to be aware of for correct staging of early adenocarcinoma developed in BE.

As intestinal differentiation is the pivotal criterion to diagnose Barrett epithelium, there has been much debate on the techniques that have to be used on mucosal biopsies. Indeed, goblet cells are usually easily identified on standard HE stained sections. Goblet cells contain acidic mucin, strongly stained with Alcian blue, making their recognition easier. However, there may be dilated pseudogoblet intermediate cells that also stain positively with Alcian blue. Another difficult diagnostic issue is to distinguish "ultrashort" segment BE from intestinal metaplasia of the gastric cardia. Some histological features may help to confirm the esophageal origin of the mucosa, including the presence of submucosal esophageal glands, squamous islands surrounded by columnar epithelium, hybrid glands showing both intestinal (in their upper part) and gastric (in their lower part) differentiation, multilayered epithelium, and duplicated muscularis mucosa. However, these features are inconstant, especially in superficial biopsy samples. In addition, numerous immunohistochemical markers have been proposed to ascertain a diagnosis of Barrett epithelium, including cytokeratins (CK7/CK20 pattern), Das-1, MUC2, CDX2. However, at present there is no recognized biomarker able to distinguish Barrett epithelium from intestinal metaplasia of the cardia.

Dysplasia—Intraepithelial neoplasia

As the major risk of patients with BE is to develop an esophageal adenocarcinoma, there has been considerable interest in defining a subgroup of high-risk patients in whom effective surveillance can be undertaken. Adenocarcinoma develops in BE through a classical multistep process with progression via dysplasia/intra-epithelial neoplasia toward invasive neoplasia. The risk of adenocarcinoma increases parallel to the severity of the dysplastic changes. At present, the morphologic identification of dysplasia in endoscopic mucosal biopsies is the standard method of detecting patients at increased risk for cancer and is used to delineate this population. The most widely used system to classify dysplastic changes in BE is the Vienna classification (**Table 5**), adapted from the Riddell's classification of dysplasia in inflammatory bowel disease; this classification can be used in every location of early type of columnar neoplasm of the tubal gut, including BE. On endoscopy, dysplasia is either undetectable, or visible as elevated, flat or depressed lesions. Endoscopic screening consists of systematic quadrant biopsies every other centimeter plus biopsies on every suspicious lesion, the so-called "Seattle protocol."

As for other epithelia, the diagnosis of dysplasia in BE relies on both cytological and architectural changes (**Fig. 7**). Architectural changes include glandular distortion and crowding. Papillary extensions into gland lumina may be present, and villiform configuration of the mucosal surface can be observed. Cytological changes include nuclear alterations such as variation in size and shape,

Table 5 Vienna classification of neoplasms of the gastrointestinal tract, including Barrett's neoplasia, with clinical implications

	Terminology in Vienna classification	*Clinical consequences in patients with Barrett's esophagus*
Category 1	Negative for dysplasia	Follow-up or no surveillance
Category 2	Indefinite for dysplasia	Follow-up. Reinforce medical treatment
Category 3	Low-grade dysplasia	Endoscopic treatment or reinforced follow-up
Category 4	4.1 High-grade dysplasia	Endoscopic or surgical treatment
	4.2 Noninvasive carcinoma (carcinoma in situ)	
	4.3 Suspicion of invasive carcinoma	
	4.4 Intramucosal carcinoma	
Category 5	Invasive neoplasia	*Surgical resection*
	Submucosal carcinoma or beyond	

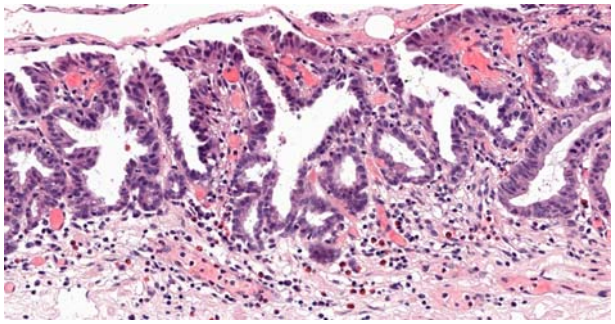

Fig. 7 High-grade dysplasia in Barrett's mucosa, with both cytologic and architectural abnormalities.

nuclear and/or nucleolar enlargement, increased nuclear-to-cytoplasmic ratio, hyperchromasia, and increased number of abnormal mitoses. In Barrett mucosa negative for dysplasia, although there may be reactive changes with crowded nuclei and numerous mitoses, the changes remain confined to the deeper parts of the glands. Dysplasia typically involves the surface of the mucosa. However, there are cases showing features of dysplasia that are confined to the deeper part of the mucosa, with a surface still appearing mature. Those changes are designed as crypt dysplasia with surface maturation, and are associated with an increased frequency of dysplasia or adenocarcinoma elsewhere in BE. In typical cases of dysplasia, the cytological changes involve the surface epithelium. Compared to low-grade dysplasia, in high-grade dysplasia cytologic atypia is more pronounced, and architectural changes are present, with branching of crypts and intraglandular epithelial budding, forming in the most severe cases a cribriform pattern. In such cases, it may be difficult to distinguish high-grade dysplasia (Vienna category 4.1) from intramucosal carcinoma (Vienna category 4.4), and one can make a diagnosis of high-grade dysplasia with suspicion of invasive carcinoma (Vienna category 4.3). The distinction between high-grade dysplasia and carcinoma in situ (Vienna category 4.2) is more theoretical than usable in practice. The category indefinite for dysplasia (Vienna category 2) can be used when histological features do not allow to make a distinction between reactive and neoplastic changes, especially when ulceration and inflammation are present. It does not correspond to a specific intercalated lesion between nondysplastic and dysplastic mucosa, but motivates the clinician to close endoscopic surveillance, with re-biopsy after proton pump inhibitor therapy.

Histological subtypes of dysplasia in BE have been described, that do not result in variation in surveillance protocols, but that can induce diagnostic difficulties. Adenomatous or intestinal dysplasia is the most common type. Dysplastic cylindrical cells have basophilic cytoplasm, and atypical, hyperchromatic and enlarged nuclei, with irregular nuclear membranes, prominent nucleoli, increased nuclear to cytoplasmic ratio, increased mitotic figures, marked nuclear pseudostratification and loss of nuclear polarity. Goblet cells and Paneth cells are scarce or completely absent. Foveolar (nonadenomatous) dysplasia is characterized by glands lined by cuboidal to columnar cells with pale clear to light eosinophilic cytoplasm, and round to oval nuclei. Mitoses are scarce and nuclear pseudostratification mild. Foveolar type dysplasia commonly expresses MUC5AC but is negative for markers of intestinal differentiation (MUC2, CDX2 and villin). An even less frequent serrated type of dysplasia has been described.

The diagnosis of dysplasia in BE remains a difficult issue, with major consequences for the patient. There is important interobserver variability, especially at the lower end of the spectrum (indefinite for dysplasia and low-grade dysplasia). For this reason, considerable attempts have been made to find markers able either to confirm a diagnosis of dysplasia, or to indicate independently an increased risk of malignant progression. In BE the situation is similar to that in squamous esophagus, with p53 protein as the only marker usable in daily practice. Abnormal expression of p53 occurs in a minority of low-grade dysplasia cases, and in the vast majority of cases of high-grade dysplasia and adenocarcinoma. Cases of low-grade dysplasia with p53 overexpression have a high risk of rapid progression to a high-grade or malignant lesion. Interestingly, in addition to this classical pattern of p53 overexpression, a p53 "absent" pattern can be observed, with a very high risk of rapid evolution to adenocarcinoma. These different patterns result from different *TP53* gene mutations, the most frequent molecular alteration in Barrett neoplastic mucosa.

Macroscopy

A large majority of adenocarcinomas arise in BE. Therefore, most cases are located in the distal part of the esophagus. However, in case of very long segment BE, the tumor can be situated more proximal, in rare cases even in the upper third of the esophagus. As for any carcinoma developing in the tubal gut, the tumor can present as a polypoid or fungating mass, a flat or depressed lesion, or an ulcerative and infiltrating lesion. Contrarily to what is observed in *linitis plastica* of the stomach, a diffusely infiltrative pattern is very uncommon. In typical cases, adjacent to the tumor, the salmon-pink Barrett mucosa may be evident, especially in early carcinomas. However, in large tumors, the metaplastic mucosa may be replaced entirely by the tumor. The tumor is usually limited to the esophagus, but large tumors of the distal part of BE can cross the gastroesophageal junction, becoming indistinguishable from gastric cardia adenocarcinoma (Siewert types I and II). Adenocarcinomas at an early stage can be difficult to recognize, almost invisible in some cases, or appearing as sessile flat or depressed lesions. Multifocal adenocarcinomas may be seen. When patients have surgical resection of their cancer after strong tumor response to neoadjuvant radio-chemotherapy, the lesion may appear as an

ulcerated and/or indurated scar, or can even entirely disappear. In such cases, the whole tumor bed has to be sampled for histological confirmation of the tumor response.

Rare adenocarcinomas do not develop from BE, but from heterotopic gastric patches and native esophageal glands. They display predominantly ulcerated and fungating gross features in the upper and middle esophagus.

Microscopy

Microscopic features of esophageal adenocarcinoma are similar to those of gastric adenocarcinoma. The majority of cases show a tubular or papillary pattern, corresponding to the intestinal type in Lauren's classification of gastric adenocarcinoma. Well or moderately differentiated tumors with glandular structures in more than 50% of the tumor are predominant (Fig. 8). Extremely well differentiated tumors can be very difficult to distinguish from high-grade dysplasia, especially on endoscopic samples of early neoplastic lesions. Mucinous adenocarcinomas with tumor cells floating in mucinous pools in more than 50% of the tumor can be seen (Fig. 9). Poorly differentiated infiltrative "signet ring cell" adenocarcinomas (Lauren's diffuse type of gastric cancer) are less common than in the stomach. Mixed cases showing both intestinal and diffuse histology can be seen occasionally. Pagetoid spread of malignant glandular cells into the surrounding squamous epithelium can be seen in poorly differentiated adenocarcinomas.

Tumors examined after neoadjuvant radio-chemotherapy often show major changes, with clusters of residual pleomorphic tumor cells embedded in dense fibrosis, and acellular pools of mucin. The amount of residual tumor tissue must be evaluated semi-quantitatively, as it has been shown to be a prognostic factor. However, there is no universal consensus for a particular grading system to evaluate this response.

Some histological variants of esophageal adenocarcinoma have been described:

- Adenosquamous carcinomas have discrete elements of adenocarcinoma and SCC, and mucoepidermoid carcinomas have an intimate mixture of these two components. Both types have a poor prognosis.
- Adenoid cystic carcinoma is also infrequent, and is believed to arise from esophageal glands. Its morphology is identical to the classical salivary gland tumor (Fig. 10). They can be confused with basaloid SCC, a much more aggressive tumor.
- Very rare cases of medullary carcinoma can be seen, with microsatellite instability involved in their development.
- Choriocarcinoma of the esophagus is a very uncommon tumor. It presents as a large fungating lesion with necrosis and hemorrhage. Syncitiotrophoblastic tissue and cytotrophoblastic tissue are present in the tumor. The prognosis is very poor.

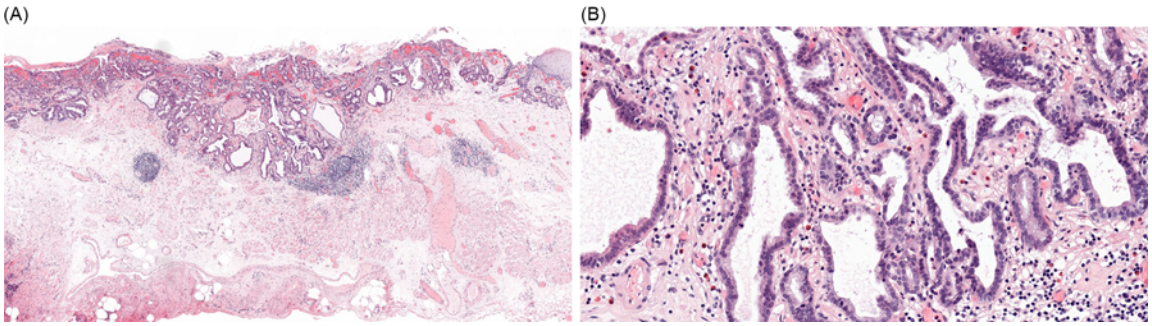

Fig. 8 Well-differentiated adenocarcinoma developed in a short segment Barrett's esophagus. The lesion has been removed by mucosectomy, and invades the mucosa between the two layers of muscularis mucosae (A). On high power, the tubulopapillary pattern can be seen (B).

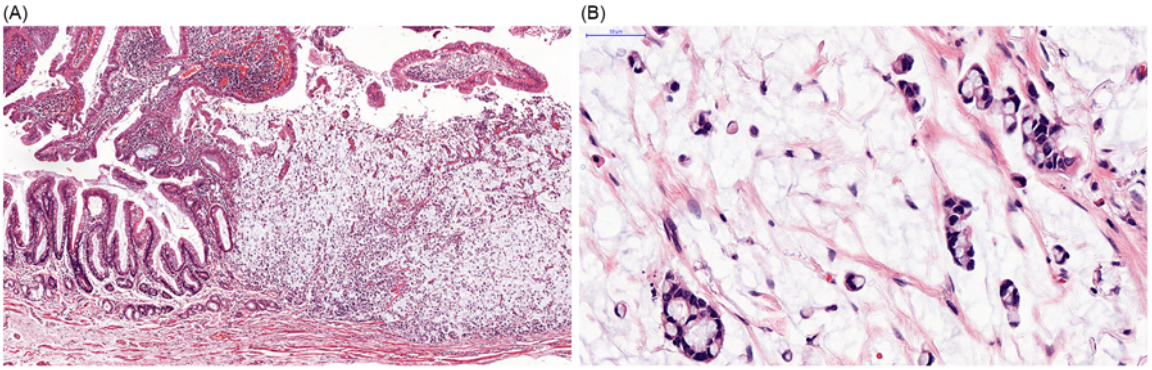

Fig. 9 Mucinous adenocarcinoma developed in Barrett's esophagus (A). On higher power, mucinous pools containing mucin-secreting cells are visible (B).

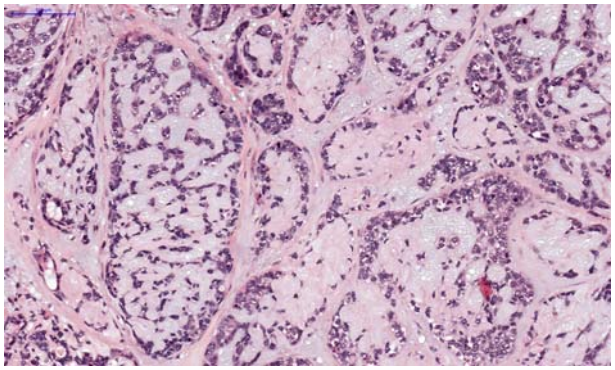

Fig. 10 Adenoid cystic adenocarcinoma of the esophagus, with a characteristic architectural pattern, similar to that observed in salivary glands.

- Poorly differentiated and undifferentiated carcinomas must be distinguished from small cell neuroendocrine carcinoma. In this latter type, there may be focal squamous or glandular differentiation. The diagnosis depends on the expression of neuroendocrine markers (chromogranin A, synaptophysin, CD56).

Molecular Pathology and Genetics

Molecular pathology

It has been known for a long time that BE shows increasing chromosomal instability as it progresses toward adenocarcinoma. Early founding studies, using DNA cytometry, fluorescent in situ hybridization, array comparative genomic hybridization, and *TP53* analyses, have been confirmed by more recent large scale genomic investigations, including those performed by international consortia such as TCGA (The Cancer Genome Atlas) and ICGC (International Cancer Genome Consortium). These studies have demonstrated that most esophageal adenocarcinomas have massive genomic alterations, including high frequency of mutations and chromosomal alterations. Different molecular signatures have been described in esophageal adenocarcinoma, with potential therapeutic relevance. In large whole-genome sequencing analyses, three distinct molecular subtypes have been identified: a BRCA signature with defects in homologous recombination pathway, T > G mutational pattern with a high mutational load and neoantigen burden, C > A/T mutational pattern with evidence of an aging imprint.

TP53 has been known for a long time as the only gene with a very high (70%–80%) rate of mutation in esophageal adenocarcinoma (70%–80%), and this has been confirmed by more recent analyses. Other less commonly altered genes include *CDKN2A* (encoding p16), *SMAD4*, *ARID1A*. High-level amplification of genes encoding receptors to tyrosine kinases are observed in subgroups of cancers, including amplifications of *ERBB2* (*HER2*), *EGFR*, *MET*, *FGFR*.

Among these various molecular alterations, only *TP53* gene mutation and the ensuing p53 protein modified expression (overexpression or more rarely complete loss of expression) can be used to strengthen a diagnosis of dysplasia, as this event occurs in few cases of low-grade dysplasia, and in high-grade dysplasia at the same frequency as in adenocarcinomas.

Genetics

Approximately 7% of cases of BE or esophageal adenocarcinoma occur within families. These familial cases develop at an earlier age than sporadic cases. It is considered that BE and esophageal adenocarcinoma have sizable heritable components, estimated around 35% and 25%, respectively. This heritability is conferred by a combination of many genetic factors that each increase risk by a small amount. Candidate gene studies and more recently genome wide association studies (GWAS) have associated loci with BE and EAC risk (*CRTC1*, *BARX1*, *FOXF1*, *FOXP1*, *GDF7*, *TBX5*). Almost all discovered genetic variants have been associated with both BE and esophageal adenocarcinoma, confirming the neoplastic sequence from Barrett's metaplasia to adenocarcinoma. Even if the massive increase in esophageal adenocarcinoma in Western countries cannot be explained by rapid changes in the population's genetic make-up, genetic predisposition might play a role in the variation of incidence of esophageal adenocarcinoma in different geographic areas.

Staging and Grading

Contrarily to esophageal SCC and to other digestive adenocarcinomas (gastric, colorectal), there is no precisely defined WHO grading system of differentiation for esophageal adenocarcinoma. However, the same rules can probably be applied as those used for gastric cancer. Most esophageal adenocarcinomas are well or moderately differentiated. Glandular structures predominate in well-differentiated cancers, are only slightly formed in poorly differentiated cancers, and are absent in undifferentiated cancers. On endoscopic biopsies, well-differentiated adenocarcinomas may be difficult to recognize as invasive and to distinguish from high-grade dysplasia. Similarly to many other carcinomas, the grading is more difficult when patients have surgical resection after neoadjuvant therapy.

The natural history goes from superficial cancer limited to the mucosa or submucosa to deeply infiltrative cancers. After invasion of the esophageal wall, adenocarcinomas behave in the same manner than SCC, extending into the adventitial tissue, and then into adjacent organs. Metastases appear in para-esophageal and paracardial lymph nodes, and then into lymph nodes of the lesser curvature of the stomach and celiac nodes.

The TNM classification used for esophageal SCC is applicable to adenocarcinoma, with identical categories of staging. However, the TNM prognostic groups slightly differ between SCC and adenocarcinoma, taking into account not only the tumor stage but also the tumor grade and location in the esophagus.

Importantly, among superficial cancers, tumors infiltrating between the inner and outer muscularis mucosae of BE remain intramucosal (T1a) although they have already a slightly increased frequency of angio-invasion and lymph node metastasis, compared to those limited to the inner muscularis mucosae. This peculiarity renders the subclassification of superficial cancers a little bit more complex in adenocarcinoma than in SCC. In particular, among intramucosal adenocarcinomas (T1a), a fourth m4 category has been added by some authors to designate adenocarcinomas invading between the two muscularis mucosae layers (Fig. 5).

Prognostic and Predictive Biomarkers

Although the prognosis of esophageal adenocarcinoma is slightly better than that of SCC, it is still a disease with a poor prognosis, with overall survival of 20% at 5 years.

Morphological factors

Tumor stage remains the major prognostic factor, with 5 years survival rates decreasing from more than 80%–90% in superficial cancers to 10%–20% for those that invade the muscularis propria. Metastasis to regional lymph nodes is the other powerful indicator. Histological type and grade are not considered as independent prognostic factors, although mucinous and signet ring cell carcinomas are associated with lower survival rates.

As for esophageal SCC, there is no consensus regarding the system that has to be applied for the evaluation of tumor regression after neoadjuvant therapy of esophageal adenocarcinoma. However, it is admitted that complete pathological response and absence of lymph node metastasis after neoadjuvant therapy are associated with good prognosis.

Molecular factors

The only molecular marker with recognized prognostic influence in esophageal adenocarcinoma is HER2 protein overexpression, due to HER2 gene amplification. HER2 expression is associated with lower tumor grade, fewer lymph node metastases, and improved survival. Moreover, HER2 overexpression renders the patient eligible to receive anti-HER2 therapy, a targeted therapy shown to improve survival in patients with HER2 positive tumors, both gastric adenocarcinomas and esophageal adenocarcinomas. Although the expression profile and mutational status of several other proteins and genes has been shown in some studies to affect prognosis in esophageal adenocarcinoma, including EGFR, VEGF, COX-2, none of these markers is recommended in routine practice for prognostic evaluation.

Introduction

Although ophthalmic pathology specimens are rarely encountered by general pathologists, when it happens there tends to be a general sense of anxiety surrounding them. Hence, we have included a range of neoplasms that occur in and around the eye and which are regularly encountered by the ophthalmic pathologist, in an attempt to allay these fears. Biopsies from various ocular adnexal and intraocular sites, including incisional and excisional, ranging from tiny biopsies to local tumor resections, enucleation or orbital exenteration are received frequently for histopathological and molecular analysis. Like all specialist pathologists, ophthalmic pathologists are being sent samples of diminishing size with the challenge of obtaining as much (if not more!) information with respect to morphology, immunohistochemistry and molecular genetics from them. In this article, the basic aspects of each neoplasm—epidemiology, microscopical features, immunophenotype, genotype and typical clinical behaviour—are discussed. All ophthalmic malignancies described are staged according to the 8th edition of the AJCC TNM Staging system. Ophthalmic lymphomas are also staged using the Ann Arbor system. Carcinomas (except Merkel cell carcinoma) and retinoblastoma are graded into four categories based on its morphology and differentiation. Sarcomas are graded into three grades according to French Federation of Cancer Centers Sarcoma Group (FNCLCC). Similar to skin melanomas, no grading system is applied for to the conjunctival or intraocular (uveal) melanomas.

Tumors of the Eyelid

Basal Cell Carcinoma

Definition: Basal cell carcinoma (BCC) of the eyelid is a primary malignant epithelial tumor that originates by neoplastic transformation of the basal cells of the epidermis, which proliferate and invade into the underlying dermis.

Burden: BCC is the most common cancer in the world, with 80% occurring in the head and neck region, of which 20% involve the eyelids. BCCs represent 90% of malignant eyelid tumors. Of the eyelid BCCs, 50% arise on the lower lid, 30% in the medial canthus, 15% on the upper lid, and 5% in the lateral canthus. The typical age of onset is 60–80 years. There is a slight male preponderance. The incidence of BCC is higher in more equatorial latitudes. High incidence of BCC and a larger BCC size are two features that are associated with patients living in areas of socioeconomic deprivation.

Risk factors: The most important known risk factor of BCC is the intermittent intense exposure to ultraviolet (UV) radiation. Short-wavelength UVB radiation (290–320 nm, sunburn rays) plays a more important role in BCC formation than long-wavelength UVA radiation (320–400 nm, tanning rays). Other risk factors include sunbed use, family history of skin cancers, immunosuppression, previous radiotherapy, and chronic exposure to toxic substances.

Pathology: The histological types of BCC are solid (**Fig. 1**), nodular, nodular-ulcerative, morpheaform, infiltrative, cystic, nodular-cystic, basosquamous, and plexiform (adenoid pattern). The nodular and superficial types of BCC are the most common in the eyelid. The morpheaform, infiltrating and basosquamous subtypes of BCC are rare (only 5%–7% of all cutaneous BCCs). BCC usually presents as a single lesion with ulceration, or central scarring and peripheral keratosis, with even deep infiltration. BCCs with orbital invasion or aggressive histology occur more frequently in the medial canthus (53%–56%) compared to the lower eyelid (20%–35%), upper eyelid (4%–7%) or lateral canthus (3%–18%).

Molecular pathology and genetics: Mutations in the *TP53* tumor-suppressor gene induced by UV radiation have been found in about 50% of BCC cases. *Ptch-1* mutations promote the development of eyelid BCC. Long-term exposure to UV radiation may induce *Ptch-1* mutations and thus promote the development of BCC. The morpheaform type of BCC shows a high expression of Bcl-2 and moderate levels of proliferation markers (e.g., Ki-67) in a histological and immunohistochemical study of eyelid BCCs. The telomere length is shortened in BCC samples compared with normal tissues.

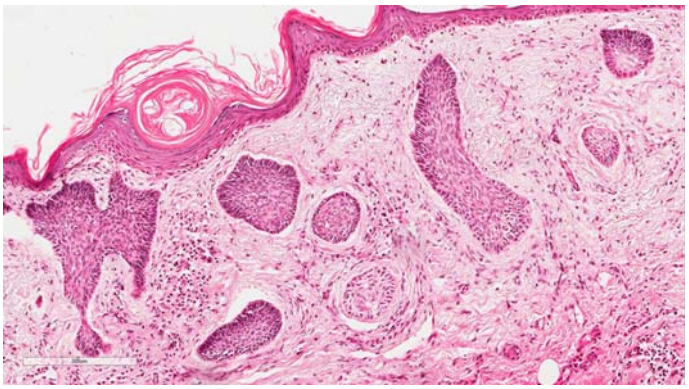

Fig. 1 BCC. Small nodules of basaloid cells infiltrate the dermis. Peripheral palisading and clefts are seen between tumor cells and the dermis. (H&E 10×).

Microenvironment including immune response: BCCs are typically characterized by a desmoplastic reaction with little inflammation, with the exception of those cases with central or extensive areas of ulceration, which can induce an acute inflammation.

Staging and grading: The Staging system used is the 8th edition of the AJCC TNM Staging system.

Grading of Eyelid BCCs: In four grades from well- to undifferentiated.

Prognostic parameters: The prognosis of a completely excised nodular BCC is excellent. Incomplete primary resection of an eyelid BCC is the main risk factor for recurrence. Incomplete resection is significantly associated with medial canthus location and morpheaform type of BCC.

Sebaceous Carcinoma

Definition: Sebaceous carcinoma of the eyelid is generally considered the second most common neoplasm of this anatomical region after BCC. Sebaceous carcinoma usually originates from the tarsus of the upper eyelid and less commonly from the lower lid, the Zeiss gland, or the sebaceous glands of the caruncle with secondary involvement of the conjunctival epithelium by pagetoid invasion.

Burden: Its incidence is about 5% of all malignant eyelid tumors. Mean age at diagnosis ranges from 57 to 72 years.

Risk factors: Advanced age, Asian race, and female gender. Muir–Torre syndrome, a form of the rare Lynch syndrome, is associated with sebaceous carcinomas.

Pathology: The pre-invasive form of sebaceous carcinoma is "in situ" disease. Three histopathologic patterns are seen in sebaceous carcinoma in situ: bowenoid, pagetoid, and papillary (**Fig. 2**). The bowenoid type is characterized by replacement of the epithelium by large, pleomorphic cells with hyperchromatic nuclei and prominent mitotic activity. The pagetoid type is characterized by scattered individual or aggregates of large pleomorphic tumor cells with a vacuolated foamy cytoplasm and nuclei with dense chromatin within the epidermis or conjunctival epithelium. The papillary pattern is less common and exhibits papillary projections with areas of confluent tumor cells.

Invasive sebaceous carcinoma is characterized by infiltrating lobules of tumor cells with vacuolated foamy cytoplasm extending into the underlying dermis or conjunctiva stroma. Tumor cell nuclei are hyperchromatic, pleomorphic with prominent nucleoli and atypical mitoses. Some tumors also grow in a comedocarcinoma-like pattern with large lobules having central necrosis. The tumor lacks peripheral palisading unlike BCC. Other sebaceous carcinomas can have a squamous-like appearance with areas of keratinization, and therefore can be mistaken for squamous carcinoma.

Molecular pathology and genetics: Dysregulation of several pathways have been identified in sebaceous carcinoma: *MAPK* and *JAK/STAT*, *NF-κB*, *PTEN* as well as *TGF-β*. UV radiation independent *p53* mutations have been found in a high proportion of sebaceous carcinomas. Sebaceous carcinoma associated with Muir–Torre syndrome shows microsatellite instability and loss of expression of DNA mismatch repair genes MLH1, MSH2, and MSH6, which are usually not detected in sporadic sebaceous carcinoma.

Microenvironment including immune response: Sebaceous carcinomas are typically characterized by a distinct lack of an inflammatory response.

Staging and grading: The Staging system used is the 8th edition of the AJCC TNM Staging system, and is the same as used for BCC as described above. Similarly, the same grading system as for BCC is used for sebaceous carcinoma.

Prognostic and predictive biomarkers: Sebaceous carcinomas with increasing AJCC tumor stage, pagetoid invasion of the overlying epithelia, poor differentiation, and multifocal origin, including orbital infiltration as well as vascular involvement, are associated with worse prognoses.

Merkel Cell Carcinoma

Definition: A rare aggressive neuroendocrine tumor of the skin. It also occurs rarely in the eyelid.

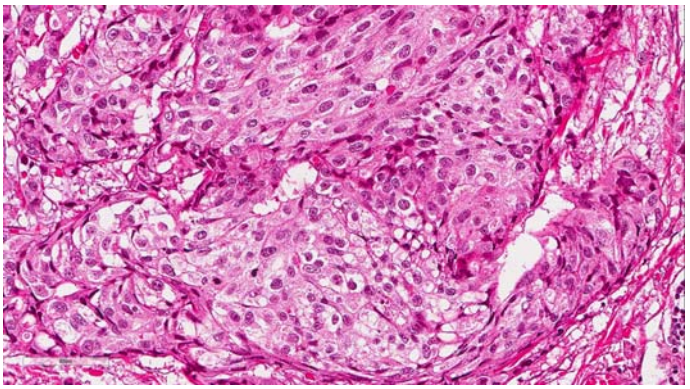

Fig. 2 Sebaceous carcinoma. Well -differentiated sebaceous carcinoma. Tumor cells show large nuclei with prominent nucleoli. The cytoplasm is vacuolated. (H&E 20×).

Burden: Merkel cell carcinoma (MCC) mostly affect the head and neck region, followed by the trunk and the limbs. Its incidence varies; it is higher in Australia (1.6 per 100.000) than in the United States (0.44 per 100.000). Immunocompromised patients with T-cell dysfunction are more likely to be affected by MCC. Eyelid MCC mostly occurs in the upper lid. The median age at presentation is 77 years (range, 58–91 years), and 52% are women.

Risk factors: Fair skin, chronic sun exposure, chronic immune suppression, and advanced age.

Pathology: Infiltration of the dermis by monotonous tumor cells with large nuclei and scant cytoplasm (**Fig. 3**). Frequent apoptotic bodies and mitotic figures are also present. Immunohistochemical stains can be needed to differentiate this tumor from other skin tumors and small cell carcinoma. MCC is positive for CK20 (perinuclear dot staining pattern) and EMA. Neuroendocrine stains are positive including synaptophysin, chromogranin, and CD56. TTF-1 is negative in this tumor unlike small cell carcinoma.

Molecular pathology and genetics: MCC development has been linked to Merkel cell polyomavirus (MCPyV) and UV radiation. Integration of the viral genome into the host-genome and mutation of the large T (LT) antigen eventually leads to uncontrolled proliferation. Exposure to UV radiation leads to mutation involving *p53* and *Rb* genes. In both cases (MCPyV-positive and -negative) MCC exhibit nuclear accumulation of oncogenic transcription factors such as *NFAT*, phosphorylated *CREB*, and phosphorylated *STAT3*.

Microenvironment including immune response: A subset of MCCs express PD-1 on tumor-infiltrating lymphocytes and express PD-L1 on tumor cells, which suggests an endogenous tumor-reactive immune response.

Staging: The Staging system used is the 8th edition of the AJCC TNM Staging system (Merkel cell carcinoma staging system).

Grading: There is no recommended histologic grading system at this time.

Prognostic and predictive biomarkers: MCC has a mortality rate of 30%. Compared with MCCs occurring in other locations, MCCs of the eyelid appear to be associated with a better prognosis, which may be related to earlier detection. They are still associated with significant rate of metastasis and recurrences.

Tumors of the Conjunctiva

Squamous Cell Carcinoma

Definition: Squamous cell carcinoma (SCC) of the conjunctiva and caruncle is a malignant epithelial tumor with squamous differentiation and can be keratinising or non-keratinising.

Burden: There is significant geographical variation in the incidence of conjunctival SCC. Worldwide, the mean age-standardized incidence is 0.18 per year per 100,000 for males and 0.08 per year per 100,000 for females. Worldwide, a high incidence has been demonstrated in HIV-positive and in other immunosuppressed populations. A higher incidence is also seen in xeroderma pigmentosum.

Risk factors: UV radiation remains the strongest risk factor. It is the only risk factor where a dose–response relationship has been established. Impaired immune surveillance clearly plays a role in the development of conjunctival SCC, and it unites risk factors such as UV (which suppresses cell-mediated immunity) and immunosuppression (HIV, post-transplant). Reduced immunity potentiates the effect of oncogenic viruses such as HPV. In Africa, the combination of low latitude, HIV and/or HPV infection explains the relatively high incidence of conjunctival SCC.

Pathology: Both pre-invasive and invasive forms of conjunctival SCC are recognized. In SCC in situ, dysplasia involves the full thickness of conjunctival epithelium; however, the basement membrane is not breached. It can be seen in flat or papillary lesions. Invasive SCC breaches the epithelial basement membrane of the conjunctiva and extends into the subepithelial stroma (**Fig. 4**). Both SCC in situ and invasive SCC can occasionally involve pterygia.

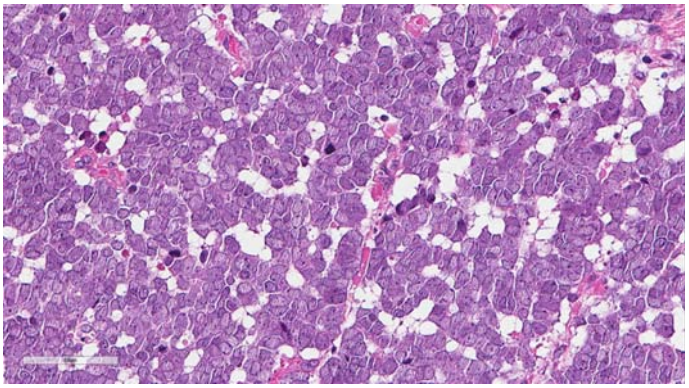

Fig. 3 Merkel cell carcinoma. Sheets of monotonous tumor cells with large nuclei and little cytoplasm. Numerous mitotic figures and apoptotic bodies are present. (H&E 40 ×).

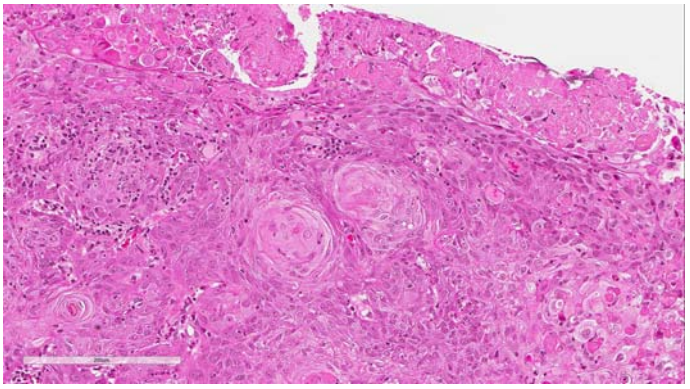

Fig. 4 SCC. The epithelium is eroded. The conjunctival stroma is infiltrated by nests of keratin-forming malignant squamous cells showing abundant eosinophilic cytoplasm and intracellular bridges. (H&E 20 ×).

Molecular pathology and genetics: UV-induced mutations in the p53 gene is the only consistent genetic abnormality identified to date. Xeroderma pigmentosum. No other genetic susceptibilities have been demonstrated to date.

Microenvironment including immune response: SCC typically induces a desmoplastic reaction with varied scattering of T-cells at the edge of the invasion front.

Staging: The Staging system used is the 8th edition of the AJCC TNM Staging system.

Grading: Grading of conjunctival SCC is based on degree of differentiation. Well-differentiated SCC produce keratin, have abundant eosinophilic cytoplasm, readily identifiable intercellular bridges, low mitotic counts and minimal nuclear pleomorphism. Moderately differentiated SCCs show variable keratinisation. Compared to well-differentiated SCCs, they are mitotically more active and show increased nuclear pleomorphism. Poorly differentiated invasive SCC can have basaloid or spindled morphology, with scanty cytoplasm, and necrosis is often present.

Prognostic and predictive biomarkers: SCC of the conjunctiva and caruncle is considered a disease of low virulence but high rate of recurrence (12%–40%). Prognosis for invasive SCC is favorable if treated at an early stage by local surgical excision with adjuvant cryotherapy or topical chemotherapy. Recurrence is most likely in those SCC of stage T3 or T4 with positive surgical margins or with untreated in situ disease. Orbital exenteration may be required for advanced stage disease. Recurrences can occur >5 years after primary excision, particularly in cases where there is poor differentiation. The risk of metastasis and death is considered very low; however, the data are sparse.

Conjunctival Melanoma

Definition: A malignant tumor arising from conjunctival melanocytes.

Burden: Conjunctival melanoma represents 5% of all ocular melanomas. The annual incidence ranges from 0.1 to 0.7 per million population. Geographic variation follows racial composition of populations. Increasing incidence has been shown in several populations over the last 50 years. Roughly 10% of conjunctival melanomas arise in or involve the caruncle. The average age at diagnosis is 50–60 years. They are rare in children, and there is no gender predilection.

Risk factors: Evidence linking chronic UV light exposure to conjunctival melanoma is accumulating, but is less robust than for cutaneous melanoma. No other environmental cause is established.

Pathology: Conjunctiva melanomas may arise from melanocytic intraepithelial neoplasia (about 65%), pre-existing nevus, or de novo (Fig. 5A). These may be present adjacent to the main invasive lesion. Invasive conjunctival melanomas consist of varying combinations of atypical spindle cells, polyhedral cells, and epithelioid cells. These are usually contained within ill-defined nests within the conjunctival stroma (Fig. 5B). Large epithelioid cells are characterized by nuclei with conspicuous nucleoli, and quite often stain with cell cycle markers, such as cyclinD1 and Ki-67. Spindle-shaped melanoma cells tend to be less pigmented. Clusters of so-called "balloon" cells with clear or vacuolated cytoplasm are occasionally encountered. Invasion of capillaries and lymphatics within the stroma can be seen. It is often difficult to judge the surgical margins, particularly in tangential sections of small biopsies. MelanA immunohistochemical staining may aid this.

Molecular pathology and genetics: There is no known genetic susceptibility. Between 30% and 50% of conjunctival melanomas have *BRAF* mutations, and nearly 20% have *NRAS* mutations, similar to the proportions found with cutaneous melanoma. Other less common mutations involve *TERT* and *KIT*.

Microenvironment including immune response: Conjunctival melanomas are typically surrounded by a dense chronic inflammatory infiltrate, composed predominantly of T-cells. Melanophages are typically interspersed within the tumor cells.

Staging and grading: Melanomas are not graded. The Staging system used is the 8th edition of the AJCC TNM Staging system.

Prognostic and predictive biomarkers: Depending on the case series, the 10-year melanoma-related mortality is 25%–30%. Tumor-related death has been associated with de novo origin, nonlimbal location, large T size, orbital invasion, as well as nodular growth and multi-centric origin. Nonlimbal location or thickness over 2 mm have been proposed as indication for considering a sentinel

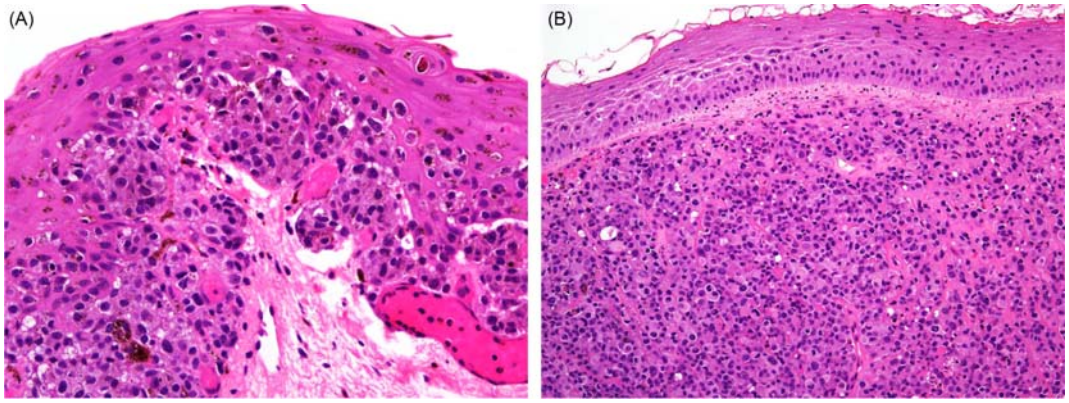

Fig. 5 Conjunctival melanoma. (A) Conjunctival biopsy demonstrating melanoma in situ. (B) Invasive conjunctival melanoma of epithelioid cell type with extensive subepithelial infiltration. (H&E 20 ×).

lymph node biopsy. Determination of the presence of *BRAF*-mutations at first diagnosis may aid the patient management should they develop metastases. Incisional biopsy and excision without adjuvant therapy (e.g., plaque or topical chemotherapy) have also been correlated with poor outcome.

Conjunctival Lymphoma

Definition: Primary conjunctival lymphomas are extranodal monoclonal proliferations of atypical lymphocytes arising in the bulbar, palpebral, forniceal or caruncular conjunctiva. Secondary conjunctival lymphomas are manifestations of systemic non-Hodgkin lymphoma (NHL) in the conjunctiva.

Burden: Primary conjunctival lymphomas represent 25%–30% of ocular adnexal lymphomas (OAL) which constitute 2% of all extranodal lymphomas. They occur more commonly in middle-aged and elderly individuals, although they may occasionally occur in young adults. Low-grade primary conjunctival lymphomas tend to occur in the sixth decade, whereas high-grade tumors affect those >70 years of age. Females are slightly more commonly affected than males. The incidence of conjunctival NHL has increased at up to 3% per annum from 1980 to 2005. This may be biased due to their increased recognition rather than subsuming them under the diagnosis of "pseudotumour." Secondary conjunctival lymphomas occur more commonly in males, with the most common subtype being mantle cell lymphomas (MCL).

Risk factors: Proposed risk factors for conjunctival lymphoma development include: autoimmune disease, infection by *Chlamydia psittaci*, *Helicobacter pylori* or HIV-infection.

Pathology: Most primary conjunctival lymphomas are non-Hodgkin lymphoma (NHL) of B-cell type (98%) whereas T-cell NHL are exceptionally rare (2%). The three most common primary conjunctival NHL types are extranodal marginal zone lymphoma (EMZL) (60%) (Fig. 6), follicular lymphoma (FL) (10%), and diffuse large B-cell lymphoma (DLBCL) (9%).

The most common "secondary" conjunctival NHLs include MCL, plasmacytomas and T-cell lymphomas. Hodgkin lymphoma are exceptionally rare. See reviews for the morphological, immunophenotypical and genomic features of each of these tumors.

Molecular pathology and genetics: Conjunctival EMZL are characterized by the following translocations: t(11;18)(q21;q21), t(1;14)(p22;q32), t(14;18)(q32;q21), and t(3;14)(p13;q32), resulting in uncontrolled activation of the NF-κB signaling pathway.

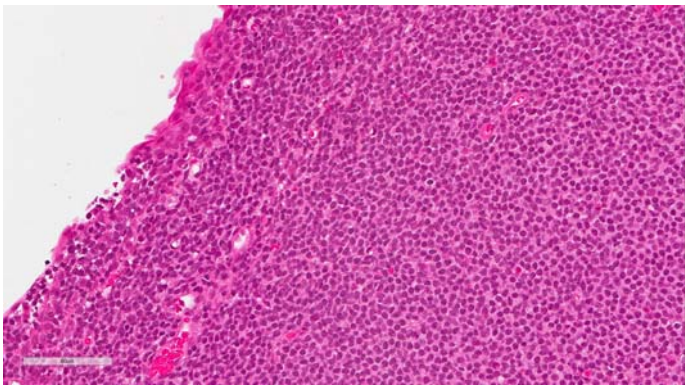

Fig. 6 Extranodal marginal zone lymphoma. The conjuctival stroma shows monotonous proliferation of small B lymphocytes. Lymphoepithelial lesions are seen in the epithelium. (H&E 20 ×).

Conjunctival FL show the pathognomic translocation t(14;18)(q32;q21), involving the *BCL2* gene rearrangement, resulting in apoptosis arrest in the neoplastic B-cells.

Most conjunctival DLBCL demonstrate immunophenotypic and molecular features of the activated B cell (ABC)-like subtype. Multiple oncogenic alterations and dysregulating signal transduction pathways have been documented in DLBCL, including mutations of *MYD88*, with recurrent targets of genetic lesions being *NF-κB*, particularly in the less curable ABC-like subtype.

Microenvironment including immune response: The microenvironment of conjunctival lymphomas is dependent on the lymphoma subtype. Conjunctival FL can be surrounded by regions of sclerosis but this tends not to be as extensive as that seen in nodal FL.

Staging and grading: Staging according to the Ann Arbor staging system as well as the 8th edition of the TNM/AJCC system.

Grading: Is assigned only to follicular lymphoma and DLBCL.

Prognostic and predictive biomarkers: Prognosis of conjunctival and caruncular lymphomas is dependent on lymphoma subtype (EMZL vs. non-EMZL) and clinical stage of disease (Stage IE vs. >Stage IIE; <T2 vs. ≥T3). Lymphoma-related survival (5-year) depends on subtype: conjunctival EMZL and FL patients with Stage IE have a favorable prognosis (82% and 72%, respectively), whereas DLBCL and MCL carry a poor prognosis (33% and 8%, respectively).

Age and gender are reliable predictors of disease-specific survival for EMZL and FL, respectively, as are Ann Arbor and TNM stages of disease for EMZL, FL and DLBCL, respectively. The tumor cell growth fraction (using Ki-67) is also proposed to be predictive. Conjunctival T-cell NHL is associated with a poor prognosis, with 50% of patients having progression or recurrence within the first year of diagnosis.

Tumors of the Uveal Tract

Melanoma

Definition: Uveal melanoma (UM) is a malignant tumor occurring predominantly in the choroid (90%) with remainder being confined to the ciliary body and the iris.

Burden: The overall incidence of UM is 6–7 per million per year. It increases with age from about 2.5 per million between the ages of 15 and 44 years to 25 per million after the age of 65 years. The tumor is extremely rare in children. There is no significant sex difference.

Risk factors: UM is much more common in Caucasians than in Africans or Asians. Epidemiological studies suggest that UM is 2–3 times more common in blue/gray than in brown eyes. The etiology of UM is unknown; however, there are known associations with UM. These include: ocular melanocytosis (increased population of melanocytes within the uvea and episclera), oculodermal melanocytosis (naevus of Ota, which also involves the periocular skin and meninges), simple and dysplastic cutaneous naevi and cutaneous melanomas, and neurofibromatosis type 1.

Rare reports of families with an excess of UM cases have been published. UM is part of the autosomal dominantly inherited "*BAP1* (BRCA1-associated protein-1) familial cancer syndrome." Affected patients, who have germline mutations in *BAP1* develop mesotheliomas and unusual benign atypical melanocytic skin tumors as well as UM.

Pathology: UM can be either dome- or mushroom shaped lesions, the latter due to perforation of Bruch's membrane (Fig. 7A). They consist predominantly of tumor cells with some admixed reactive cells usually representing a smaller proportion of the tumor's cellular content. According to the modified Callender classification, UM consist of spindle B cells and/or of epithelioid cells (Fig. 7B and C). The former are long and fusiform with a small oval nucleus and a prominent nucleolus. Epithelioid, which means "epithelial-like," cells are large and round with abundant eosinophilic cytoplasm, usually distinct cell margins, and prominent nucleoli. Variants of epithelioid cells include wildly anaplastic tumor giant cells and relatively uniform small epithelioid cells. Spindle A cells are now regarded as benign and most commonly seen in uveal naevi.

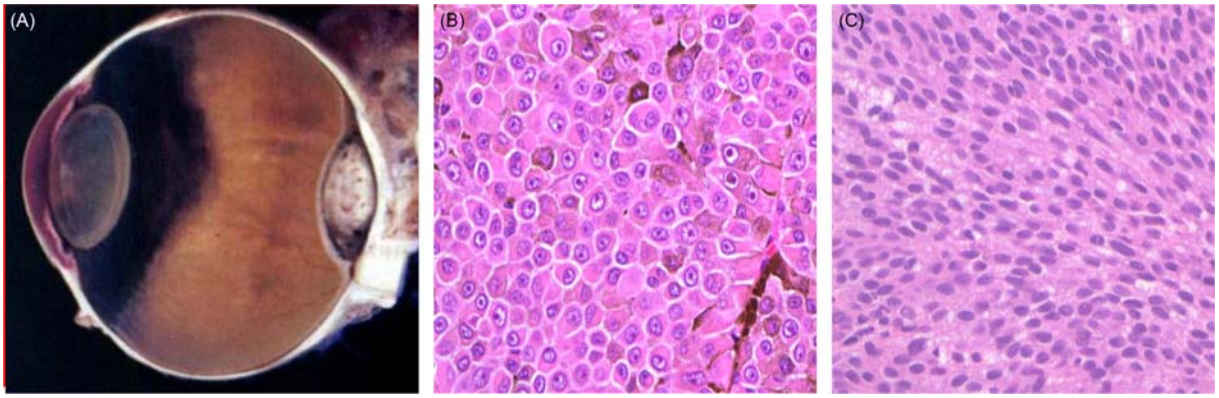

Fig. 7 Uveal melanoma. (A) A dome-shaped posterior choroidal melanoma. (B) Epithelioid cells vary in their proportions within the tumor, are usually nuclear BAP1 negative, and as such are strongly predictive of the metastatic potential of the UM (H&E 20×). (C) Spindle cell UM tend to be associated with disomy 3 and nuclear BAP1 positive tumors, but not always.

Notable histological features include:

(a) Pigmentation of the melanoma cells—this can vary considerably between tumors and within tumors.
(b) Lymphocytic and macrophage infiltration, which can be prominent and has been associated with a poorer prognosis.
(c) Connective tissue or extracellular matrix patterns: nine different types have been identified, of which the "closed (or back-to-back) loops" are associated with a poor prognosis.
(d) Necrosis—varying degrees of necrosis may be found in UM. It tends to be more prominent in rapidly growing choroidal melanomas at the equator of the globe, or in tumors that have undergone brachytherapy. Aggregates of melanophages are typically in the necrotic areas. Total infarction of the tumor may result in destruction of adjacent tissues, including the sclera, possibly resulting in extraocular spread. The necrosis may lead to a "cystic"-like appearance to the tumor on ultrasound biomicroscopy.
(e) Extraocular melanoma extension. The size of this should be noted, as this implications for the risk of recurrence and metastasis.

Positive immunohistochemistry with S-100P, Melan A or HMB45 can aid confirmation of the diagnosis in most cases, but are not really necessary for routine diagnostics. Cell proliferation status can be gauged by markers such as Ki-67, PC-10, and PHH3 (Ser10). Nuclear BAP1 protein expression using immunohistochemistry corresponds closely with BAP1 mutational status, and indirectly with chromosome 3 status.

Molecular pathology and genetics: As above, the familial *BAP1 syndrome* is associated with UM. *GNAQ* and *GNA11* mutations are also found in uveal naevi and in most UM regardless of their tumor stage, chromosomal constellation or other outcome predictors (see below). These mutations appear to be necessary but not sufficient for complete malignant transformation to UM. These data suggest that *GNAQ* and *GNA11* mutations are early events in the molecular pathogenesis of UM.

It has been known for almost 20 years that UM show specific chromosomal alterations, which are quite distinct from melanomas at other sites, particularly those of the skin. The most striking abnormality in UM is the complete or partial loss of chromosome 3. Other common genetic abnormalities of UM include loss on 1p, 6q, 8, and 9p as well as gain on 1q, 6p, and 8q. These alterations were initially identified by standard karyotypic analyses. They have subsequently been confirmed by several groups using differing technologies, including: fluorescence in situ hybridization (FISH); comparative genomic hybridisation (CGH); spectral karyotyping; microsatellite analysis (MSA); multiplex ligation-dependent probe amplification (MLPA), and single nucleotide polymorphisms (SNPs).

Recent advances in the molecular characterization of UM using multiple and complex molecular techniques have identified additional molecular changes that contribute to the development and progression of this disease. These include alterations in the following genes with decreasing frequency: *BAP1*, *SF3B1*, *EIFAX1*, *PLCB4*, *CYSLTR2*, *TP53BP1*, *CSMD1*, *TTC28*, *DLK2*, and *KTN1*. The biological significance of all of these findings is not yet clear. Other genetic changes of relevance to metastatic progression include the amplification of *c-MYC* on chromosome 8q.

Microenvironment including immune response: UM are typically characterized by varying infiltrates of T-cells and macrophages: increased densities of both are associated with poor prognoses. Following proton beam therapy, there is often an increased infiltration of macrophages and interestingly plasma cells.

Staging and grading: Melanomas are not graded. The Staging system used is the 8th edition of the AJCC TNM Staging system.

Prognostic and predictive biomarkers: The above-mentioned chromosomal alterations in primary UM are clinically relevant because of their correlation with the risk of metastatic death. Chromosome 3 loss is associated with a reduction of the 5-year survival probability from approximately 100% to 50%. Similarly, chromosome 8 gains and loss of chromosome 1 significantly correlate with reduced survival. Both chromosome 3 loss and polysomy 8q are also associated with other poor prognostic factors, including increasing tumor basal diameter, ciliary body involvement, presence of epithelioid cells, high mitotic count, and closed connective tissue loops. Conversely, gains in chromosome 6p correlate with a good prognosis, suggesting this aberration may have a functionally protective effect. A PCR-based 12-gene assay based on gene expression profiling (GEP), divides UM into two "classes" on the basis of an mRNA expression signature: class 1 and class 2. Class 1 UM often show 6p and 8q gain. Class 2 UM tend to show more aneuploidy with 1p loss, 3 loss, 8p loss, and 8q gain. Increasingly prognostic testing is being performed on small intraocular biopsies. Essential for precise prognostication is: (a) morphological examination of the biopsy; and (b) the integration of relevant clinical, histological and genetic factors, resulting in an individualized curve allowing for improved downstream personalized care (e.g. https://mpcetoolsforhealth.liverpool.ac.uk/matsoap/lumpo3cr_v5.htm).

Tumors of the Retina

Retinoblastoma

Definition: A malignant neoplasm of the neurosensory retina, affecting young children. Hereditary cases are typically bilateral with multiple tumor foci in one or two eyes and, more rarely, intracranially at midline.

Burden: Retinoblastoma (RB) is the most common primary intraocular malignant tumor in infants and young children, and is thought to be the most common primary malignant intraocular neoplasm overall. It accounts for approximately 3% of all cancers occurring in young children. The incidence of RB is reported as 1 in 16,000–18,000 live births with approximately 7000–8000 new cases worldwide yearly. The incidence of retinoblastoma appears to be higher in Africa, India, and among children of Native American descent.

Risk factors: Germline and somatic mutations in the *RB1* gene or rarely somatic amplification of *MYCN*.

Pathology: Histopathologically, retinoblastoma is a "small round blue cell tumour," composed of primitive neuroblastic cells with basophilic nuclei and scant cytoplasm (Fig. 8). Numerous mitotic figures and apoptotic cells are present. Retinoblastoma cells tend to outgrow their blood supply and undergo necrosis. This typically occurs when the cells have grown 90–110 μm away from a nutrient vessel. A characteristic pattern of basophilic "sleeves" and "cuffs" of viable basophilic tumor cells separated by sheets of necrotic tumor results. Foci of dystrophic calcification typically develop within the necrotic foci.

Varying degrees of retinal differentiation are evident in retinoblastoma as "Homer Wright" and "Flexner–Wintersteiner" rosettes and fleurettes, which represent photoreceptor differentiation. "Homer Wright" rosettes represent neuroblastic differentiation, and appear as tangle of neurofilaments ringed by nuclei. They also occur in other tumors such as neuroblastoma. "Flexner–Wintersteiner" rosettes are a characteristic feature of retinoblastoma, but do occur in some other neoplasms, such as medulloepithelioma. Flexner–Wintersteiner rosettes represent early retinal differentiation and have a central lumen that corresponds to the subretinal space. Rosettes are more common in retinoblastomas that are enucleated from younger children. Tumors typically become less well-differentiated as the age of the patient increases.

Foci of photoreceptor differentiation called "fleurettes" are found histopathologically in at least 15%–20% of retinoblastomas. Photoreceptor differentiation occurs in areas of viable tumor that appear more eosinophilic than typical retinoblastoma. A retinal neoplasm composed entirely of photoreceptor differentiation is termed a retinoma (clinically) or retinocytoma (histopathologically), and is considered to be a benign, often transient, precursor of retinoblastoma. Foci of photoreceptor differentiation are found in the basal portions of endophytic retinoblastomas, supporting the notion they may be precursor lesions. Photoreceptor differentiation appears as bouquet-like aggregates of eosinophilic structures (fleurettes, from fleur-de-lis) that correspond to the inner segments of photoreceptors, and often are aligned along segments of neoplastic external limiting membrane.

Varying degrees of anaplasia have been described in retinoblastoma, and it has been suggested that severe anaplasia is a risk factor for metastasis, although this requires validation. Severely anaplastic tumors are poorly differentiated and have cells with large, very pleomorphic nuclei that are angular, rhomboid or fusiform in shape. Cell wrapping and numerous mitotic figures also are present.

Retinoblastoma arises from the retina and initially invades the vitreous cavity and subretinal space. Ultimately, the tumor may infiltrate Bruch's membrane and invade the choroid, gaining access to vessels that serve as a route for distant haematogenous metastasis. Retinoblastoma also readily invades the optic nerve. The tumor may travel along the nerve to the brain or be dispersed in the cerebrospinal fluid. Massive posterior uveal invasion and retrolaminar optic nerve invasion are high-risk features and indicate to the clinicians that adjuvant chemotherapy is required. Invasion of anterior segment structures also is thought to increase the risk of metastasis.

On immunohistochemistry, retinoblastoma stains for neuron specific enolase and synaptophysin, with these stains being of help to confirm the presence of optic nerve invasion when routine histopathology is equivocal.

Molecular pathology and genetics: Mutations in the *RB1* gene are responsible for almost all cases of retinoblastoma. The tumor suppressor gene *RB1* located on chromosome 13, and follows the Knudson's two hit hypothesis for development of tumors. Approximately 40% of Rb cases are caused by heterozygous de novo or inherited germline mutations in the *RB1* gene. Offspring of affected individuals have a 50% chance of inheriting the pathogenic variant. The inheritance pattern is autosomal dominant. In 60% of cases retinoblastoma is sporadic and unilateral, and the pathogenic variant of *RB1* occurs only within retinal cells. To develop retinoma or retinoblastoma both alleles must have the pathogenic variant. Two percent of unilateral patients have the *MYCN* oncogene amplified (RB1+/+ MYCNA) in the tumors.

Microenvironment including immune response: Very little inflammatory infiltrate is associated with intraocular retinoblastoma.

Staging: The Staging according to the AJCC 8th edition.

Grading:

GX: Grade cannot be assessed.

G1: Tumor with areas of retinoma (fleurettes or neuronal differentiation).

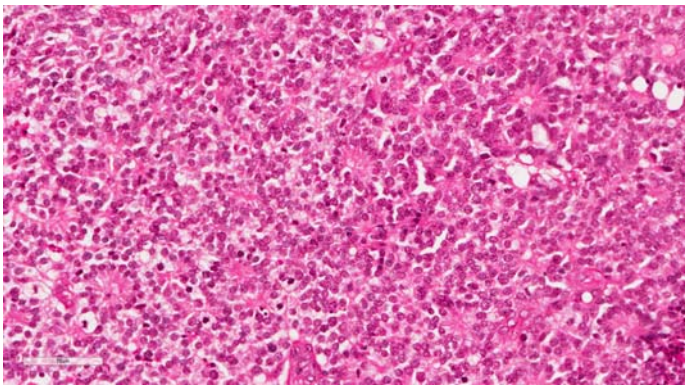

Fig. 8 Retinoblastoma. Primitive neuroblastic cells with small basophilic nuclei and scant cytoplasm, forming Homer-Wright and Flexner–Wintersteiner rosettes (H&E 20×).

G2: Tumor with many rosettes (Flexner–Wintersteiner or Homer Wright).

G3: Tumor with occasional rosettes (Flexner–Wintersteiner or Homer Wright).

G4: Tumor with poorly differentiated cells without rosettes and/or with extensive areas (more than half of tumor) of anaplasia.

Prognostic and predictive biomarkers: The most powerful feature predictive of successful treatment of retinblastoma is early diagnosis when the tumor is small and entirely contained within the eye and has not invaded any of the ocular coats, especially in sporadic tumors. The cure rate is >95% in such cases.

Retinal Haemangioblastoma

Definition: Retinal hemangioblastoma is a tumor derived from developmentally arrested angioblasts, generally due to a mutation in the *VHL* gene.

Burden: Von Hippel–Lindau (VHL) disease occurs in 1/36,000 live births per year. VHL has a remarkable penetrance of over 90% by 65 years of age. Of all VHL patients, 49%–85% develop retinal hemangioblastomas, making this ocular sign the most common presentation of the disease. VHL-associated retinal hemangioblastomas usually develop at a mean age of 25 years.

Risk factors: VHL which is an autosomal dominant inherited syndrome. It is caused by a germline alteration of the *VHL* gene, a tumor suppressor gene located on chromosome 3p25.5. Retinal hemangioblastomas are often the most common and earliest presentation of VHL disease.

Pathology: Hemangioblastomas are composed of capillary sized vascular channels surrounding stromal cells. The stromal cells characteristically have a prominently vacuolated cytoplasm. In addition, small clusters of angiomesenchymal cells, tumourlet cells, have been described in ocular and cerebellar hemangioblastomas. The stromal cells and the "tumourlet" cells may express CD133, a marker present on hematopoietic, endothelial, and neural progenitor cells. Stromal cells are the cells that harbor the genetic alterations in the *VHL* gene. These alterations are not present in the vascular or glial components.

Molecular pathology and genetics: In VHL disease there is a germline defect in one copy of the gene and with random loss of the normal allele (loss of heterozygosity, LOH) patients are predisposed to develop hemangioblastomas. Presumably, in sporadic cases there is somatic loss of both normal copies of the *VHL* gene, resulting in a similar but solitary tumor.

Microenvironment including immune response: Surrounding the vascular channels are stromal cells with vacuolation. There are limited inflammatory infiltrates within this stroma.

Staging and grading: Not applicable.

Prognostic and predictive biomarkers: The type of germline mutation present in the *VHL* gene has an effect on the disease phenotype. Deletions and truncating mutations are associated with a Type I phenotype, characterized by renal cell carcinoma and haemangioblastoma but not pheochromocytomas. Type II phenotype with renal cell carcinoma and pheochromocytoma is associated with missense mutations. Patients with complete deletions of the *VHL* gene are also much less likely to develop retinal hemangioblastomas (9%), than patients with partial deletions, simple missense, and nonsense mutations (45%).

The prognosis for vision is good in patients with VHL. Overall, 88% of patients will retain 20/20 or better vision in at least one eye. Laser or cryotherapy is effective treatment for small to medium sized intraocular hemangioblastomas that do not involve the optic nerve. Increasingly, surgical resection of unresponsive and large retinal hemangioblastomas is being employed with good visual outcomes. Treatment of hemangioblastomas involving the optic nerve remains challenging. The prognosis related to systemic morbidity and overall survival in VHL is dependent on the treatment of the associated cerebellar haemangioblastoma and renal cell carcinoma.

Vitreoretinal Lymphoma

Definition: A high-grade malignant lymphoproliferative disease in which atypical lymphocytes infiltrate the retina and vitreous in the absence of lymph node or visceral involvement. It is frequently accompanied by involvement of the central nervous system.

Burden: The incidence of primary vitreoretinal lymphoma (PVRL) is difficult to estimate because of its rarity and the effect of improvement in diagnostic techniques employed. The incidence is reported to have steadily increased from 0.23–0.48 per million population from 1990 to 2010. A slight predominance of female patients is reported.

Risk factors: Based on overlap with primary central nervous system lymphoma (PCNSL), HIV and Epstein-Barr virus (EBV) infections are predisposing factors for the development of PVRL. No other environmental risk factors are known.

Pathology: Most PVRL are diffuse large B cell lymphomas (DLBCL) of ABC type, according to the WHO lymphoma classification. The atypical lymphoid cells are generally medium-to-large cells with a condensed chromatin pattern and prominent nucleoli (**Fig. 9**). The nucleus often is irregular in shape. The neoplastic lymphocytes are usually admixed with reactive inflammatory cells, such as T-cells and macrophages. In some cases, the presence of small, mature T-lymphocytes overwhelms and can mask the neoplastic B-cells. PVRL cells are typically friable with numerous apoptotic bodies, thus vitreous samples often contain abundant lytic cell remnants or ghosts, often within macrophages. Such cell ghosts are uncommon in other diseases associated with vitreous infiltrates, so their presence is highly suggestive of PVRL. The neoplastic B-cells of PVRL have the following profile: CD79a+, CD20+, PAX5+, BCL-2+, BCL-6+, MUM1+, IgM+, and a high cell proliferation.

Molecular pathology and genetics: Monoclonal expansion of B lymphocytes can be assessed using immunoglobulin heavy chain (IgH) polymerase chain reaction (PCR). IgH-PCR can be performed on fluid and tissue samples (fresh-frozen or fixed), and is

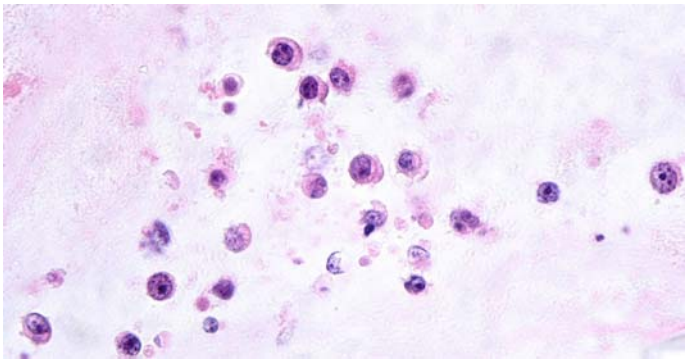

Fig. 9 Vitreoretinal lymphoma. Scattered lymphoid blasts in a cytoblock of a vitrectomy sample (H&E 20×).

very useful in PVRL diagnosis as an adjunctive test to cytomorphology and immunophenotyping. Recently, evaluation for the *MYD88* mutation has confirmed its presence in 70% of cases of PVRL.

Microenvironment including immune response: Typically PVRL contain admixed macrophages and T-cells, which can make the diagnosis difficult, particularly as the neoplastic B-cells are quite fragile.

Staging: PVRL can be staged using the Lugano Classification (Modified Ann Arbor Classification) for Hodgkin and Non- Hodgkin Lymphoma.

Prognostic and predictive biomarkers: The prognosis of PVRL patients is generally poor: it is dependent on the presence and/or subsequent development of CNSL. In patients diagnosed with PVRL, CNS involvement is present in 15% of patients at first diagnosis. Secondary CNSL has been reported to develop in a high percentage of PVRL patients during follow-up. To date, there are no predictive factors for the development of CNS involvement. Steady improvement in the survival of PNCSL patients has been observed with varying chemotherapeutic regimens. At present, the median overall survival is close to 5 years.

Tumors of the Lacrimal Gland and Orbit

Adenoid Cystic Carcinoma (ACC)

Definition: A rare aggressive epithelial malignant neoplasm of the lacrimal gland and other glandular tissues, most commonly the salivary glands, characterized by malignancy of modified myoepithelial and ductal (luminal) cells.

Burden: ACC represents around 20% of epithelial lacrimal gland tumors and is the commonest malignant tumor accounting for approximately half or even more of malignant epithelial lacrimal gland lesions. ACC is generally known to have a wide age range (12–75 years) and a bimodal age distribution with a peak in adulthood around the age of 40 and a smaller peak in teenage years.

Risk factors: Not known.

Pathology: ACC is a non-encapsulated tumor, which infiltrates the surrounding orbital soft tissue and includes proliferating modified myoepithelial cells as well as luminal ductal differentiated cells. Depending on the cellular composition and cytomorphological features, the tumor shows three growth patterns seen individually or together in variable combinations (Fig. 10).

The cribriform pattern is the commonest, described as "Swiss cheese" because of the formation of cystic structures where the connective tissue stroma is filled with basophilic amorphous glycosaminoglycans and/or eosinophilic hyalinized basal lamina.

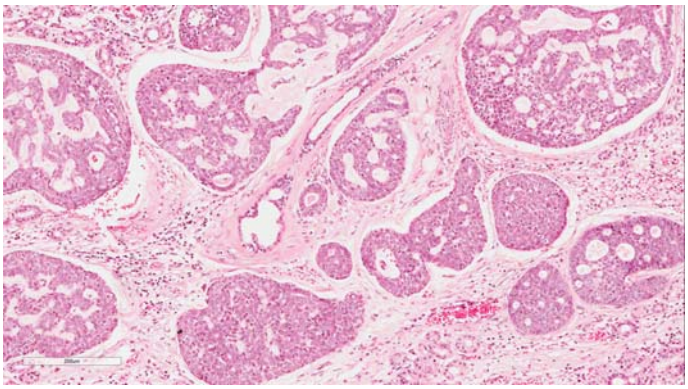

Fig. 10 Adenoid cystic carcinoma. Cribriform ("Swiss cheese") growth pattern of myoepithelial cells as well as luminal ductal cells. The stroma is filled with basophilic amorphous material. (H&E 20×).

The tubular pattern shows small glandular structures while the solid pattern shows predominantly proliferating basaloid myoepithelial cells with little glycosaminoglycan deposits or cyst-like basal lamina glandular spaces. In most series, the solid pattern is the least common. This pattern can be associated with higher numbers of mitotic figures which may explain its worse prognosis. Histopathological confirmation of perineural and bone invasion is essential. Tumor extent and margins are also important to document histopathologically. On immunohistochemistry, most ACC are MYB (myeloblastosis gene marker) positive and all are PLAG1 (pleomorphic adenoma gene marker 1) negative, in contrast to pleomorphic adenoma. High-grade transformation, previously known as dedifferentiation, may occur.

Molecular pathology and genetics: Loss of chromosome 6q is a frequent finding in ACC. This may be associated with t(6;9)(q22–23; p23–24) resulting in a *MYB-NFIB* fusion gene. This may be associated with t(6;9)(q22–23; p23–24) resulting in a MYB-NFIB fusion gene. *KRAS*, *NRAS* and *MET* mutations were reported in lacrimal gland epithelial neoplasms with highest frequency (44%) in ACC.

Microenvironment including immune response: ACC are typically surrounded by a variable desmoplastic reaction, but have very limited inflammatory infiltrates around them.

Staging: Staging according to AJCC TNM 8th edition.

Grading: In four grades from well differentiated to undifferentiated.

Prognostic and predictive biomarkers: Age at diagnosis, completeness of surgical resection and tumor stage are important determinants of disease specific survival in epithelial lacrimal gland tumors in general.

Prognostic factors in ACC include: Tumor histologic features (solid pattern being associated with a worse prognosis, perineural invasion being associated with local recurrence and skull invasion, bone invasion being associated with a fatal outcome in large tumors), tumor size (with the cut-off size of 2.0 cm in greatest dimension for T1 according to the 8th edition of AJCC), and tumor stage (recurrence, metastasis are significantly more common while survival is significantly worse in patients with T3 = 2.5–5.0 cm according to the 6th edition of the AJCC, which is approximately equivalent to T2 = > 2.0–4.0 cm in the 8th edition).

Lacrimal Gland Lymphomas

Definition: Primary lacrimal gland lymphoma is a malignant proliferation of lymphocytes arising in the tissue without evidence of concurrent systemic lymphoma. Secondary lacrimal gland lymphoma occurs in patients as part of disseminated NHL.

Burden: Lacrimal gland lymphomas are rare, representing ~9% of all ocular adnexal lymphomas, which in turn constitute 2% of all extranodal lymphomas.

Risk factors: They occur more commonly in elderly females, particularly those with Sjögren's syndrome. No racial predilection.

Pathology: Most lacrimal gland NHL are of B-cell type and are usually low-grade, although high grade transformation can occur. The most common subtype is the extranodal marginal zone B-cell lymphomas (EMZL), followed by FL and DLBCL. Histologically, EMZL show a nodular to diffuse heterogeneous B-cell infiltrate surrounding scattered reactive germinal centres and cause effacement of the normal glandular architecture.

They are variably comprised of atypical small lymphocytes, centrocyte-like cells, monocytoid B-cells, immunoblasts, lymphoplasmacytic cells and plasma cells. Plasmacellular differentiation, including Dutcher bodies, may be striking. Lymphoepithelial lesions, representing infiltration of the ductal and epithelial structures by neoplastic B cells, can be seen. EMZL cells show reactivity for B-cell markers (CD20, CD79a, PAX5), BCL-2, and surface immunoglobulin. They are negative for CD5, CD10, CD23 and Cyclin D1. Cytokeratin highlights epithelial remnants in the lymphoepithelial lesions. Ki-67 growth fraction is low, ~5%.

Molecular pathology and genetics: Molecular testing using IgH-PCR demonstrates clonal rearrangement of the immunoglobulin chains. The genetic profile is dependent on lymphoma subtype.

Microenvironment including immune response: Variable according to lymphoma subtype.

Staging and grading: According to the 8th edition of the AJCC TNM Staging 2018, and also to the Ann Arbor staging system.

Prognostic and predictive biomarkers: Most patients with stage I or II lymphoma are treated with low-dose radiotherapy ± chemotherapy. Patients presenting with stage > III lymphoma were treated with chemotherapy alone. The prognosis of lacrimal gland lymphomas depends on the histologic type and clinical stage; however, the 5-year overall survival is 70%.

Rhabdomyosarcoma

Definition: A malignant neoplasia that arises from pluripotential mesenchymal cells with a predilection to differentiate into skeletal muscle cells. Ocular rhabdomyosarcoma (RMS) may originate from the orbit, conjunctiva, eyelid or, rarely, the uveal tract.

Burden: RMS is the most common primary orbital tumor in childhood accounting for 5% of all childhood malignancies. Based on histopathologic features, RMS is subdivided into embryonal, alveolar and pleomorphic type (see below). The embryonal type is most frequently seen in the first decade of life, accounting for > 90% of published cases of ocular origin. Alveolar RMS is observed in adolescents and young adults. Pleomorphic RMS occurs almost exclusively in adults.

Risk factors: None known.

Pathology: Tumor cells appear in the substantia propia beneath the epithelium as loosely spindle-shaped cells, with hyperchromatic nuclei with indistinct tapered cytoplasmic processes, some with long ribbons of eosinophilic cytoplasm ("tadpole"-like cells), with variable degrees of pleomorphism and proliferative rate (Fig. 11). The botryoid type contains linear condensations of tumor cells underneath the epithelial layer ("cambium layer") and polypoid nodules with abundant, loose, myxoid stroma. Striking

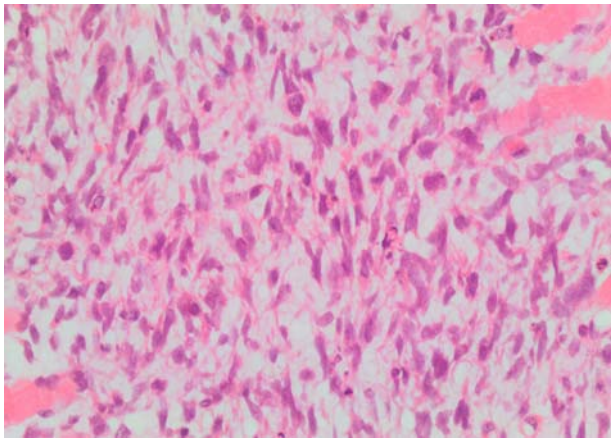

Fig. 11 Rhabdomyosarcoma. Typical "tad-pole" like cells in a botyroid type rhabdomyosarcoma of the orbit (H&E, 40 ×).

anaplasia may be present. Alveolar RMS is a small blue round cell neoplasm, with a worse prognosis. The term "alveolar" refers to a growth pattern in nests with central discohesion, separated by fibrovascular septa.

The presence of specific immunohistochemical markers for muscle correlates with the degree of tumor cell differentiation. Desmin and actin are acquired by developing rhabdomyoblasts. Myoglobin, myosin and creatine kinase correspond to terminal differentiation. Antibodies against MyoD1 and myogenin/Myf4 are sensitive and specific to RMS.

Molecular pathology and genetics: Embryonal RMS is characterized by loss of heterozygosity on the short arm of chromosome 11 (11p15.5), suggesting inactivation of a tumor-suppressor gene. By contrast, the majority of the alveolar RMS have the reciprocal chromosomal translocations t(2;13)(q35;q14) or t(1;13)(p36;q14), the former in approximately 70% of patients. The molecular counterpart of this translocation consists of the generation of a chimeric fusion gene involving the *PAX3* gene, located on chromosome 2, and a member of the fork-head family *FOXO1*, located on chromosome 13.

Staging and grading: Staging according to AJCC 8th edition.

Grading: Currently, the preferred system for grading of sarcomas is the one proposed by the French Federation of Cancer Centers Sarcoma Group (FNCLCC). It uses three independent prognostic factors to determine the grade: mitotic activity, necrosis, and degree of differentiation of the primary tumor. Each feature is scored separately and the three scores are added to obtain the grade. Grade 1 is defined as a total score of 2 or 3, grade 2 as a total score of 4 or 5, and grade 3 as a total score of 6–8.

Prognostic and predictive biomarkers: Poor prognostic factors in adults include age, pleomorphic histological subtype and more advanced disease at presentation. The embryonal type has a better prognosis.

Orbital Liposarcoma

Definition: Malignant mesenchymal tumor with lipomatous differentiation.

Burden: Generally, liposarcoma is the most common soft tissue sarcoma in adults. Liposarcoma of the orbit is rare; it can be primary or metastatic in origin. The mean age of presentation is 42.9 years (range 15–77) with slight female preponderance.

Risk factors: Patients with genetic evidence of Li-Fraumeni syndrome harbor a risk to developed liposarcoma including two reported cases of orbital myxoid liposarcoma.

Pathology: Liposarcoma is characterized by the presence of lipoblasts (**Fig. 12**). There are four major liposarcoma subtypes: atypical lipomatous tumor/well-differentiated liposarcoma (which includes the adipocytic, sclerosing, inflammatory and spindle cell variants), de-differentiated liposarcoma; myxoid liposarcoma; and pleomorphic liposarcoma. Myxoid liposarcoma is a low-grade tumor characterized by myxoid stroma containing chicken-wire vascular channels and lipoblasts in variable stages of differentiation. It is reported to be the most common subtype occurring in orbital region. High-grade myxoid liposarcoma (formerly round cell liposarcoma) is defined by the presence of hypercellular areas, exceeding 5% of the lesion. ALT/WDL type is the second most common type occurring in this anatomical region; it is composed of variably sized adipocytes and bands of fibrosis containing spindle cells and hyperchromatic nuclei. The dedifferentiated type has been reported in the orbit, and is composed of high-grade spindle cell component resembling fibrosarcoma in addition to the well-differentiated component. Pleomorphic liposarcoma is a high-grade tumor and is composed of large polymorphic cells with bizarre nuclei. Abundant mitotic figures and areas of necrosis are also present.

Molecular pathology and genetics: Both well differentiated liposarcoma and dedifferentiated liposarcoma harbors cytogenetic aberration in the form of Ring chromosomes and giant markers (12q13–15), and show amplification of *MDM2*, *CDK4*, and *HMGA2*. Myxoid liposarcoma is characterized by two main karyotypic aberrations: >95% of cases carry a specific t(12;16)(q13;p11), which fuses the *DDIT3* (CHOP) gene on 12q13 with the *FUS* (TLS) gene on 16p11. Approx. 5% of myxoid liposarcoma harbor t(12;22)(q13;q22), which fuses *DDIT3* with *EWSR1* on 22q12. Pleomorphic liposarcoma in contrast has complex karyotypic aberrations. p53 mutation occur in 60% of cases and NF1 mutation occur in 5% of cases.

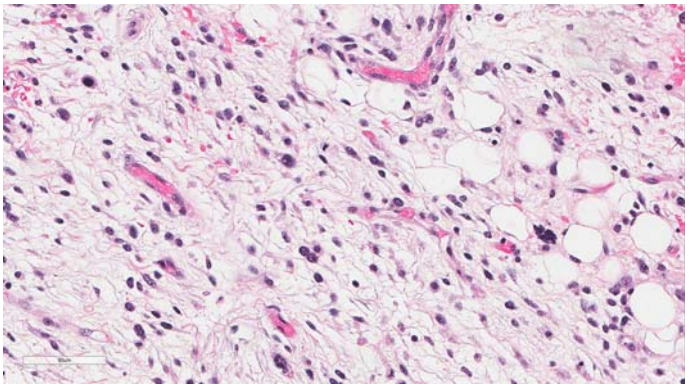

Fig. 12 Liposarcoma. Hyperchromatic spindle cells in a myxoid background. Lipoblasts are seen characterized by variably sized clear cells with scalloped hyperchromatic nuclei (H&E 20×).

Staging and grading: Staging according to AJCC 8th edition.

Grading: See rhabdomyosarcoma.

Prognostic and predictive biomarkers: Prognosis depends on histological type and the size of tumor. Orbital liposarcoma appears to be relatively favorable, likely due to small tumor size and predominantly well-differentiated histology. Plemorphic liposarcoma has a poorer prognosis with evidence of multiple recurrences. Distant metastasis from liposarcoma happens with the lung being the most common site.

Financial Burden of Cancer Care

Bernardo HL Goulart and Veena Shankaran, Hutchinson Institute of Cancer Outcomes Research (HICOR), Seattle, WA, United States; Fred Hutchinson Cancer Research Center, Seattle, WA, United States; and University of Washington, Seattle, WA, United States

Glossary

Economic perspective Individual, group, institution, or entity that bear the costs for goods or services, for example, health insurance payers, hospitals, society in general.

Direct medical costs Expenses directly related to the use of medical services and goods, for example, physician fees, acute inpatient care, laboratory and imaging tests, surgery, radiotherapy, chemotherapy.

Direct nonmedical costs Expenses related to the logistics of pursuing healthcare or costs that are not medically-related but result from the use of healthcare services. Examples include transportation costs to medical facilities, childcare cost for parents undergoing cancer treatment, unpaid caregiver time.

Indirect costs Productivity losses that result from cancer or cancer treatment. Examples include morbidity costs from missed work days due to cancer complications or treatment; mortality costs from loss of productivity due to death.

Targeted therapies Oral or intravenous antineoplastic drugs that bind and modify the activity of specific trans-membrane or intracellular proteins or enzymes, leading to downstream intracellular events that cause cell death or cell cycle arrest.

Medicare The publically-funded federal insurance program in the United States Medicare is the largest insurance program in the country and reimburses medical services for all individuals age 65 year or older, or those with permanent disabilities or chronic renal insufficiency. Commercial insurance plans tend to follow the reimbursement policies and fees set by Medicare.

Introduction

The economics of cancer care has become a central topic in the broader debate of healthcare delivery. A simple, undeniable fact justifies the shifting perception of cancer costs as a relatively unimportant matter to a key factor in health policy: cancer costs are globally soaring and threatening the sustainability of healthcare systems.

From a simplistic point of view, the skyrocketing cancer costs represent an unavoidable consequence of the rapid pace of innovation in cancer diagnostics and therapeutics. Those in support of this view argue that the high costs represent society's willingness to pay for innovation in cancer care. From a granular point of view, cancer costs result from complex interactions between multiple factors, including (in)efficiencies of care delivery, obsolete reimbursement models (e.g., fee-for-service), and conflicting interests among stakeholders, including patients, providers, hospital administrators, insurance payers, pharmaceutical industry, and government.

Irrespective of the different opinions, a growing body of evidence supports the following concerns: (1) cancer care costs are increasing faster than the gross domestic product, at least in the United States, threatening the sustainability of healthcare programs; (2) cancer patients are directly experiencing negative consequences of high cancer care costs in the form of financial distress from unaffordable medical bills, a phenomenon known as "financial toxicity"; (3) uncontrolled costs can magnify cancer disparities by creating further barriers in access to care to those who cannot afford expensive treatments. Collectively, these areas of concern indicate the urgent need for multilevel changes in cancer care delivery that emphasize quality, lower costs, and value (i.e., better health outcomes for the unit of money spent).

This article initially provides an overview of the temporal trends in cancer care costs, followed by a dissection of the healthcare components that significantly contribute to cost. Next, a discussion ensues about the market forces that drive up cancer costs, particularly for hospitalizations and oncology drugs. The final section describes several strategies that have the potential to bend the cost curve and increase the value of cancer care.

Although cancer costs are context-specific and vary broadly across healthcare systems, the article focuses mostly on United States cost data for simplicity of scope and greater availability of published literature. The economic perspective will be the United States public or private healthcare payer (e.g., Medicare and commercial insurance plans), unless mentioned differently. Most data refer to direct medical costs as defined in the glossary, unless noted otherwise.

Temporal Trends in Cancer Costs

Total United States spending in cancer has been continuously increasing over the past several decades, from an estimated $27 billion in 1990 to $125 billion in 2010. Although cancer costs have consistently accounted for approximately 5% of total US

healthcare expenditures, most health economists consider cancer as an increasingly concerning area of spending, given the increasing number of cancer survivors and the rising costs of cancer treatments.

In recent years, total cancer costs have been increasing at a slightly faster pace than the U.S. gross domestic product (GDP). Between 1998 and 2012, total cancer expenditures increased from $104.5 to $143.6 billion, corresponding to an average annual growth of 2.5% (Table 1). In the same period, the United States GDP grew annually at an average of 2.2%. Conservative projections indicate that US cancer costs will continue to rise at a similar pace, from $125 billion in 2010 to $154 billion in 2020, based solely on current demographic trends in cancer incidence and survival (Fig. 1). Assuming a 2% annual increase in cancer treatment costs, United States cancer expenditures will increase to $187 billion in 2020, or a 49% cost hike from 2010.

Cancer costs also represent a significant portion of healthcare expenditures in other developed nations, accounting for 6.3% and 9.3% of total healthcare costs in the European Union (E.U.) and Japan, respectively. In 2009, the European Union spent an estimated €126 billion in cancer, though the figures varied broadly by country, from €184 per capita in Luxembourg, to €16 per capita in Bulgaria. The United States leads in cancer spending across all developed nations, as indicated by a study that estimated the total direct medical costs attributable to cancer to be €212 per person in the United States for the year of 2004, followed by Switzerland, which spent €199 per capita.

Most studies report on direct medical costs to describe national estimates of cancer spending, as the data sources are more readily available for costs related directly to medical care. Recent studies suggest that direct nonmedical costs (e.g., unpaid caregiver time) and indirect costs (i.e., productivity losses) contribute substantially to total cancer costs, justifying the need for more robust methods to estimate expenses other than those directly related to cancer treatment. In 2009, of the estimated €126 billion spent in cancer by the European Union, €51 billion (41%) related to direct medical costs, €23 billion (18%) corresponded to unpaid caregiver time, and €52 billion (41%) accounted for productivity losses, respectively. In the United States, very few studies have reported on unpaid caregiver time or other cancer direct nonmedical costs, and no readily available data informs on costs of productivity losses from cancer morbidity. One study estimated the United States costs attributable to productivity losses from cancer mortality to be $116 billion in 2000.

Collectively, the available evidence overwhelmingly confirms that cancer is a major source of healthcare spending in most countries. Healthcare policy makers are all too aware of the need to closely monitor trends in cancer expenditures at national and regional levels, as well as engage all stakeholders in a debate about strategies to implement affordable and high-quality cancer care. In order to inform discussions about strategies to implement cost-effective cancer care, the following sections will describe the components of cancer care costs in greater detail, as well as the factors driving these costs.

Components of Direct Medical Costs in Cancer Care

Studies have consistently shown that acute inpatient care (hospitalizations) accounts for the largest fraction (nearly 50%) of cancer care spending, followed by antineoplastic drug therapies (15%–30%). Other services (e.g., imaging diagnostics, radiation therapy, hospice) correspond to smaller fractions of cancer expenditures (Table 2).

Brooks et al. estimated Medicare spending in the first 6 months after the diagnosis of advanced breast, prostate, nonsmall cell lung, colorectal, and pancreatic cancers in a sample of over 60,000 beneficiaries (Table 2). Of the total mean cost of $35,122 per patient, acute hospital care accounted for $16,953 (48%), followed by oral and intravenous chemotherapy ($5705; 16%), and outpatient procedures ($2281; 6%). Utilizing data from the Medical Expenditure Panel Survey (MEPS), one study showed that hospitalizations represented 48%–55% of all cancer care expenditures in the United States between 1998 and 2012, followed by professional and clinical services (including chemotherapy and outpatient visits), which accounted for 33%–40%. Cost distributions are similar in the European Union: in 2009, of the €51 billion spent in cancer, hospitalizations accounted for €28.4 billion

(56%), followed by €13.5 billion (27%) spent in antineoplastic drugs, while outpatient and emergency visits accounted for less than 20%.

Although hospitalizations and antineoplastic drugs are responsible for the majority of cancer care costs, spending in other services have been proportionally increasing over time and may become significant contributors in the near future. One example is the use of expensive imaging diagnostic modalities. Between 1999 and 2006, Medicare beneficiaries with lung cancer had a mean annual increase of 36% and 7% in the use of positron emission tomography (PET) and magnetic resonance imaging (MRI), respectively. The increase in utilization of advanced imaging modalities corresponded to a difference in imaging costs per beneficiary of $1482 in 1999, to $3260 in 2006, or an average 9.5% annual escalation, compared with an average 2.6% annual escalation in total costs. No readily available data describe recent trends in radiation therapy costs, but those are likely to increase, given the dissemination of newer and expensive radiotherapy modalities, including stereotactic techniques, proton beam radiation, and tomotherapy.

The following sections focus on costs of hospitalizations and antineoplastic drugs, as those are the two service categories in which the greatest opportunities exist for implementation of strategies that improve the value of cancer care.

Factors Driving Hospitalization Costs

Two groups of factors independently influence hospitalization costs: those associated with higher utilization of acute inpatient care, and those related to variations in the unit price that hospitals charge for inpatient services.

Predictors of Utilization of Acute Inpatient Care

Limited access to outpatient care seems to substantially contribute to higher utilization of inpatient care services, and, by extension, to hospitalization costs. Population-based data from the California Cancer Registry has shown that 71% of 25,032 patients with advanced breast, prostate, colorectal, nonsmall cell lung, and pancreatic cancer underwent at least one hospitalization in the first year after the diagnosis, and 16% had three or more hospitalizations in the same period. Most of the hospital admissions (64%) originated from the emergency department (ED). Several patient and health-system characteristics predicted higher likelihood of re-hospitalizations, including Non-Hispanic Black and Latino race/ethnicity, lower socio–economic status, higher number of comorbidities, for-profit hospital ownership, and lack of outpatient palliative care. In a smaller study, investigators evaluated the medical reasons for hospitalizations in a retrospective cohort of 154 patients treated for gastrointestinal cancers at Dana–Farber Cancer Institute. Of a total of 201 hospitalizations, 53% were due to cancer-related symptoms, followed by 28% attributable to complications from cancer treatment. These studies jointly provide indirect evidence that limited access to outpatient care, which disproportionally affects patients of lower socioeconomic status or from racial/ethnic minority groups, lead to higher utilization of ED and inpatient acute care services.

Aggressive end-of-life (EOL) care leads to higher hospitalization rates and costs, presumably due to cumulative toxicities from consecutive lines of treatment or from poorly controlled cancer symptoms. Although definitions of aggressive EOL care differ across studies, a growing body of evidence consistently demonstrates that patients are more likely to undergo hospitalizations if they receive chemotherapy in the last months of life, do not receive timely hospice services, or do not have access to outpatient palliative care programs. In the study of 154 patients with gastrointestinal cancers treated at Dana–Farber Cancer Institute, investigators classified 39 of the 201 (19%) hospital admissions as avoidable. Patients who received third or subsequent lines of noncurative chemotherapy were significantly more likely to have an avoidable hospitalization compared with patients who received only one line of chemotherapy (36% vs. 23%). In a secondary analysis of a landmark randomized trial comparing early palliative versus standard care in advanced nonsmall cell lung cancer, patients randomized to the early palliative care group had lower hospitalization costs in the last 30 days of life (mean cost difference = $2896 per patient) compared with the control group. In a retrospective matched cohort study of Medicare decedents diagnosed with cancer or other diseases, patients who received hospice care at any time had lower number of hospitalizations, shorter hospital length of stay, and lower likelihood of admissions to the Intensive Care Unit.

Comorbidities and inpatient complications also contribute to higher hospitalization costs for adults with advanced cancer. In a prospective, multicentric cohort study involving 1020 hospitalized patients diagnosed with multiple solid and hematologic malignancies, the mean admission cost was US$10,364 per patient. Mean costs increased by $852, $5289, and $8267 for patients with higher number of comorbidities, or who had minor or major inpatient complications, respectively (**Table 3**). In the same study, consultation with inpatient palliative care was associated with a decrease in mean admission costs of $1506 when no complications occurred, and of $5617 in the setting of a minor or major complication, respectively.

This body of evidence strongly suggests that health systems may reduce the rate and costs of hospitalizations by improving access and coordination of care, symptom management, and by incorporating palliative care services to the inpatient and outpatient settings.

Predictors of Higher Hospital Service Prices

Very few studies have systematically evaluated the degree of variation in prices charged by hospitals for specific inpatient services, but emerging data indicates substantial differences in the dollar amount billed for the same services across healthcare systems. In

a retrospective study of claims data from privately insured individuals in the United States between 2007 and 2011, variation in hospital transaction prices was the primary driver of total spending variation across hospital referral regions, after accounting for differences in patient characteristics. The same study revealed that service prices are 15.3% higher for hospitals that hold market monopoly power in their geographic regions, that is, have few or no competitors in the area. This type of data supports the concern that the ongoing merging of large for-profit healthcare systems contribute considerably to total healthcare spending, and, by extension, to cancer costs.

The Growing Costs of Antineoplastic Drugs

The cost of antineoplastic drugs (hereafter, cancer drugs) is the fastest growing of all cancer cost categories. Bach et al. have analyzed temporal trends of monthly acquisition costs for new cancer drugs at the time of their market approval. These costs have exponentially increased from a median of approximately US$100 in the 1970s to more than $10,000 after 2010 (Fig. 2). Medicare spending in cancer drugs has increased from $3 billion in 1997 to $11 billion in 2004, a 267% difference, partly due to increase in drug prices, partly due to higher drug utilization over time. Cancer drugs account for 7 of the 10 most expensive drugs reimbursed by Medicare part B, which is the federal public insurance program responsible for payments of injectable medicines in the United States. Recent studies show that the prices of novel target drugs have been growing at a much faster pace than the overall cancer costs in the United

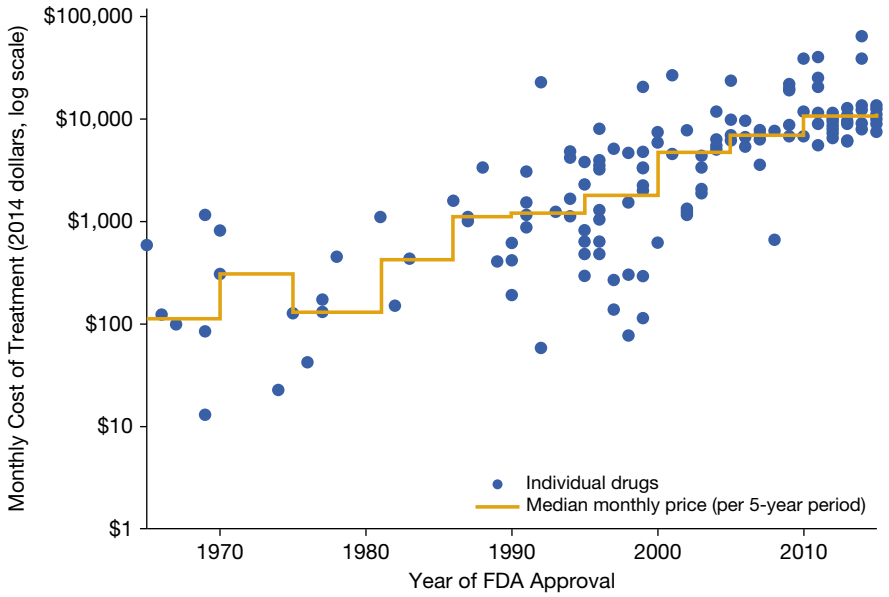

Fig. 2 Temporal trends in monthly drug acquisition costs at the time of drug regulatory approval (1965–2015). Adapted from the American Society of Clinical Oncology, (2016). States, with annual increase rates of 12%–14%. Finally, the prices of cancer drugs have also been rapidly increasing even after their market approval. One study estimated an average annual increase of 11% in the monthly payments for oral target drugs years after approval (Table 4; Fig. 3).

Although one could be tempted to attribute the rapid increase in cancer drug prices to the development of new drugs with innovative mechanisms of action, evidence suggests that this is not necessarily the case. In a metaanalysis of 74 clinical trials that supported the United States regulatory approval of drugs for solid tumors between 2000 and 2015, the median monthly drug acquisition costs (2016 US$) were $10,583, $11,980, $13,320, and $15,240, for chemotherapy, oral target drugs, immunotherapy, and antiangiogenic drugs, respectively ($P = .22$). Of note, this study revealed an annual increase in monthly drug prices of 13%, a finding consistent with other literature reports. In addition, the authors reported a lack of correlation between monthly drug prices with efficacy endpoints reported in the trials, including progression-free and overall survival. This and other studies indicate that high drug prices have little correlation with innovation.

Why Cancer Drugs Are Expensive

The general consensus is that pharmaceutical companies set drug prices based on what "the markets can bear." This practice would be reasonable if it were not for the several distortions that characterize the oncology drug market. These market imperfections are the driving forces of the rapidly escalating costs of cancer drugs, and the misalignment between drug prices and efficacy, as outlined below. For didactic purposes, we classify the drivers of drug costs as those that lead to high acquisition prices, followed by those associated with increased drug utilization.

Factors Associated With High Drug Prices

Pharmaceutical Industry's Monopoly Power

Simply put, patent protection laws allow pharmaceutical companies to behave like monopolies and set very high prices for their drugs. The rationale for patent protection is to give companies the opportunity to obtain a favorable return on the risky investment of developing a drug. In general, patent laws prohibit other companies from manufacturing generic formulations of the same compound, which prevents competition from forcing drug prices down. Pharmaceutical company representatives argue that this monopoly power is necessary and justified given the high risks and costs involved in research and development (R&D), estimated at US$2.6 billion per approved drug if one accounts for the money spent in preclinical and clinical research of agents that fail to receive market approval.

The counterpoints to the Pharma views are several: (1) some health economists challenge the accuracy of reported R&D costs; (2) pharmaceutical companies do not really incur risks if the sales of approved drugs are supposed to compensate for the money spent in the development of failed compounds; and (3) drug prices can be elastic to demand, that is, pharmaceutical companies may decrease prices if clinics are not willing to adopt their high-cost drugs when cheaper alternatives exist. The case of aflibercept (Zaltrap, Sanofi) illustrates the latter point. This drug received US regulatory approval for the treatment of metastatic colorectal cancer in August of 2012. Sanofi set the monthly price of aflibercept at roughly $11,000. In October 2012, clinicians at Memorial Sloan-Kettering Cancer Center publically announced that they would not include aflibercept in their drug formulary after noticing that bevacizumab, a drug of similar class, offered nearly identical efficacy at a monthly cost of roughly $5000. After Memorial's public announcement, Sanofi decreased the price of aflibercept by 50% to allow its inclusion in drug formularies. The aflibercept case indicates that pharmaceutical companies can retain profitability despite large cuts in drug prices, which confirms the notion that monopoly practices contribute to costs that have little correlation with drug efficacy.

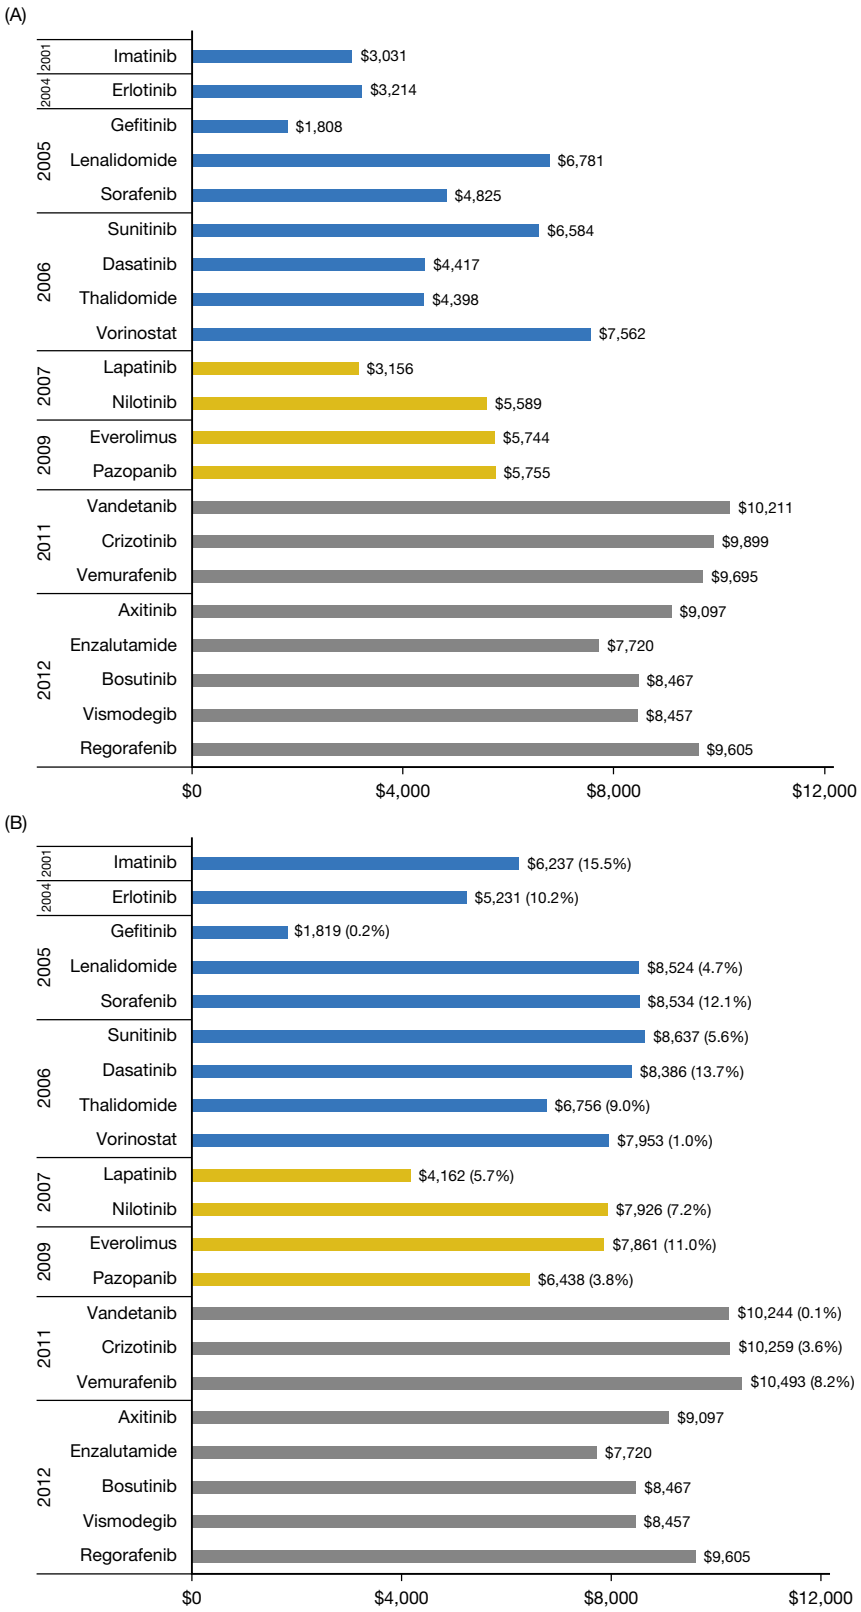

Fig. 3 Per patient per month (PPPM) Medicare costs of oral target therapies at year of launch and in 2012. PPPM costs represent a proxy of actual monthly drug prices paid by Medicare. Panel A shows PPPM costs for oral target drugs at launch year or in 2007 (whichever was later). Panel B shows PPPM costs for the same drugs in 2012, including drugs approved before 2012 and in 2012. Percentages in parentheses indicate the annual rate of increase in PPPM costs. The figure shows that 5 out of the 16 oral drugs approved before 2012 had annual rates of increase above 10%. *Source*: SEER-Medicare, 2007 to 2012. Adapted from Shih, Y. T., Xu, Y., Liu, L., et al. (2017). Rising prices of targeted oral anticancer medications and associated financial burden on Medicare beneficiaries. *Journal of Clinical Oncology*, **35**(22), 2482–2489.

Federal Legislation on Drug Pricing in the United States and Abroad

US federal laws preclude any considerations of costs for regulatory and market approval of drugs. Specifically, the Food and Drug Administration (FDA) appraises the evidence supporting drug efficacy and safety for regulatory approval, but not costs. Federal law also mandates that Medicare covers all drug products approved by the FDA. The Medicare Prescription Drug, Improvement, and Modernization Act of 2003 determined that Medicare reimburses drug costs based on the price set by the manufacturer, without engaging in price negotiations.

In the current format, the United States federal policies on drug pricing give unfair market advantages to the pharmaceutical industry at the expense of patients, payers, and society. Since Medicare has no bargaining power to negotiate the reimbursement for drugs, companies have yet an additional incentive to set high prices to maximize profits regardless of drug efficacy. The influence of legislation on drug prices affects not only Medicare beneficiaries, but also the commercially insured population, since commercial plans tend to adopt similar drug reimbursement schedules paid by Medicare. The ultimate consequence is that the United States legislation significantly contributes to high cancer drug costs.

To quantify the impact of the United States federal legislation on cancer drug costs, investigators have compared drug prices in the United States versus other national health systems that explicitly consider costs for drug regulatory approval. One study showed that the launch prices were 42% higher in the United States compared with the United Kingdom (UK) for 10 top-selling cancer drugs. The British National Institute for Health and Care Excellence (NICE) has developed and implemented a highly transparent and standardized process of appraisal of evidence to recommend the acceptance or rejection of new drug applications for market approval in the United Kingdom. The evidence appraisal requires the conduct of formal cost-effectiveness analysis (CEAs). In order to meet criteria for market approval in the United Kingdom, a given drug cannot exceed preestablished cost thresholds per unit of clinical benefit, usually measured in quality-adjusted life-years (QALYs). The explicit consideration of cost-effectiveness has enabled the U.K. National Health System to cover cancer drugs at lower costs. Additional studies also showed higher cancer drug prices in the United States versus other developed countries, including Norway, Australia, and Canada.

In response to country-specific requirements for drug market approvals, pharmaceutical companies have commonly adopted a strategy of setting lower drug prices where cost regulations exist, and higher prices in countries that do not impose price caps. This global pricing strategy essentially forces the United States healthcare system to subsidize the costs of cancer drugs abroad and contributes to the escalation of cancer costs.

Drug Development Costs

Representatives from the pharmaceutical industry claim that expenditures in drug research and development (R&D) at least in part explain the high prices of approved cancer drugs. A recent study suggests that R&D costs, though considerable, explain only a minor fraction of marketed drug prices. The investigators analyzed the R&D spending and the revenue sales for 10 companies and their respective 10 drugs that received market approval in the United States. The median time and costs (2017 US$) to develop a drug was 7.3 years and $648 million, respectively. With a median time of 4.0 years since approval, the median revenue sales was $1.6 billion, resulting in a $1 billion return on investment per approved drug. For all 10 drugs, the total R&D spending was $7.2 billion, compared with a total of $67.0 billion in revenue sales. The study intentionally did not consider the R&D costs of failed drugs, and concluded that the costs of drug development do not seem to justify the postmarket costs of approved cancer drugs.

Factors Associated With Higher Drug Utilization

Fee-For-Service Reimbursement Models

In the United States, the most common reimbursement policy for injectable drugs follows the fee-for-service (FFS) model, also known as "buy and bill." In FFS, insurers pay a reimbursement fee to clinics whenever physicians prescribe injectable antineoplastic drugs. Clinics derive variable profit margins from administering injectable drugs, which depend on the negotiated drug price with drug manufacturers and the actual amount covered by insurance plans. Since clinics' total revenues increase with higher number of prescribed drugs, this reimbursement model incentivizes physicians to overutilize cancer drugs in general, and to prioritize use of more costly drugs, which contributes to higher spending. The FFS model rewards clinics for higher quantity of drugs delivered, as opposed to better value offered by these drugs.

This perverse incentive became more evident after the implementation of the medicare modernization act (MMA) of 2003, which determined that the reimbursement for injectable drugs would consist of the average sales price (ASP, or the average of sales transactions between drug manufacturers and clinics purchasing the drugs) plus 6%. The goal of the MMA was to reduce drug spending by cutting reimbursement fees. One study reviewed the patterns of chemotherapy prescribing for advanced lung cancer before and after the implementation of the MMA in January 2005, and showed that chemotherapy spending actually increased with the new legislation. The authors explain the findings by a change in prescription patterns from less to more costly agents (e.g., docetaxel as a substitute to paclitaxel), as a way to maximize profit margins from the 6% fee. Clearly, new reimbursement models are necessary to reduce drug spending while preserving treatment efficacy. Such models need to link payments to clinical benefits, as opposed to the quantity or price of drugs prescribed.

Imperfect Information

A perfect competitive market assumes that consumers have adequate knowledge about the features of the goods and services that they purchase. Consumer information influences the demand for goods, which ultimately affects prices. In markets characterized by high degree of consumer information (e.g., food and clothing), prices tend to closely reflect how consumers value goods and services. In markets characterized by inadequate consumer information, prices often exceed what consumers would be willing to pay had they possess appropriate knowledge about the goods. The latter is the case of the oncology drug market. If we consider the patient as the consumer of cancer drugs, a legitimate concern arises about the amount and quality of the information that patients use to make decisions to pursue or forego drug treatments, including data regarding clinical benefits, toxicities, and out-of-pocket costs.

Not only patients may have limited understanding about the benefits and harms of cancer drugs, but their emotions and fears can impact their ability to make rational decisions about their care. Patients frequently make treatment decisions under substantial emotional distress, and often have overly optimistic expectations about the likelihood of benefit. When options are limited and prognosis is poor, fear and despair prompt many cancer patients to pressure their physicians to initiate subsequent lines of chemotherapy despite the minimal likelihood of favorable outcomes and often high risks of harm, which increases utilization of low-value drugs, drug spending, and hospitalization costs. In fact, current evidence shows that second- or third-line chemotherapy lines are not associated with longer overall survival in "real-world" settings (i.e., practice outside clinical trials), but do contribute to cancer spending.

Concerns About High Cancer Drug Costs

The previous sessions characterized cancer drugs as the fastest growing category of cancer-related costs, and provided market-based explanations for this phenomenon. Yet, drug costs account for 15%–30% of cancer spending, which raises the question of whether concerns about drug costs are justifiable or constitute a distraction. The following sessions discuss the reasons why cancer drug costs clearly represent a public health concern.

Low-Value: Marginal Benefits, Sobering Costs, Budget Constraints

A wealth of data demonstrates a lack of correlation between drug efficacy and costs. Despite their soaring prices, most cancer drugs offer modest clinical benefits. In a review of the clinical trials that supported the FDA approval of 71 drugs for a variety of solid tumors between 2002 and 2014, the aggregate median increase in progression-free survival was 2.5 months, and the aggregate median increase in overall survival was 2.1 months (Fig. 4). Of the 71 drug approvals, only 30 (42%) qualify as providing a "clinically meaningful" improvement, as defined by a consensus statement published by the American Society of Clinical Oncology (ASCO). In a review of 20 cancer drugs approved by the FDA between 2009 and 2013, 1-year drug costs ranged from US$59,000 to $157,000. The authors found weak correlations between annual drug costs and improvements in patient outcomes ($R^2 = 0.132$ for progression-free survival; $R^2 = 0.165$ for overall survival). Although some drugs represent true therapeutic breakthroughs (e.g., imatinib in chronic myeloid leukemia), most recently approved agents offer low value for their cost. The adoption of expensive, marginally effective drugs results in waste of scarce healthcare resources that could be spent in other interventions that offer greater benefits to cancer patients or society in general.

If the escalation of cancer drug costs continues, healthcare budgets will eventually approach their limits, and the sustainability of health programs will be at risk. This trend may result in implicit rationing of care. When faced with budget constraints, insurance plans react by imposing coverage restrictions on expensive drugs, increasing copays and deductibles, or increasing premiums. Patients who cannot afford higher co-pays or premiums will have limited access to treatments, a situation that characterizes implicit rationing. Those who oppose the notion of regulation of drug prices avoid the topic of implicit rationing, but at the same time accuse regulatory agencies such as NICE of rationing. If we characterize NICE's processes of drug appraisals as rationing, we should define it as explicit rationing, as the appraisals are at least transparent to the public. Regardless of whether society members choose to ignore or to consider costs in the approval process of new cancer drugs, at some point, decisions will have to be made about who receives treatment and who does not, either implicitly or explicitly.

Is Immunotherapy an Exception?

The emergence of immunotherapy drugs represents the newest paradigm in the treatment of several advanced solid and hematologic cancers. The most popular class of immunotherapy drugs consist of the programmed death 1 (PD1) or programmed death-ligand 1 (PD-L1) checkpoint inhibitors. These are monoclonal antibodies that induce an antitumoral immune response by prompting T-cells to recognize and kill tumor cells. Immune checkpoint inhibitors have gained much attention from the oncology community for their ability to induce durable tumor responses in several advanced solid and hematologic cancers. Although media outlets often portray immune checkpoint inhibitors as miraculous drugs, trial data show that their efficacy is not as impressive. Response rates range from 15% to 40% across diseases, the overall survival gain is usually measured in a few months, and most patients do not derive a survival benefit from these drugs.

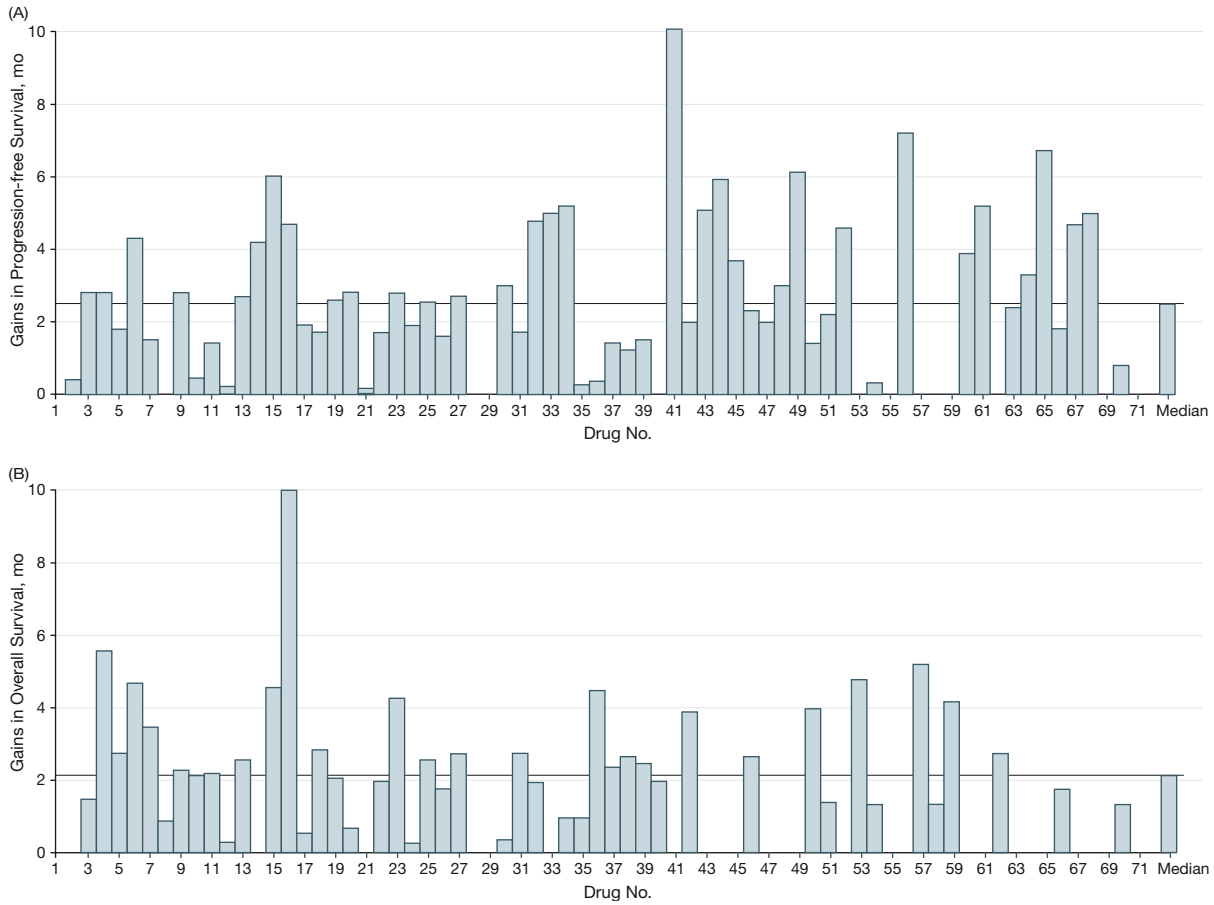

Fig. 4 Progression-free and Overall Survival of 71 Oncology Drugs Approved by the U.S. Food and Drug Administration from 2002 to 2014. The horizontal bars represent median increases in progression-free survival (PFS, panel A) and overall survival (OS, panel B) based on results of clinical trials that led to drug approval by the Food and Drug Administration (FDA). Across the 71 approved drugs, the aggregated gain in PFS and OS were 2.5 and 2.1 months, respectively. Adapted from Fojo, T., Mailankody, S., Lo, A. (2014). Unintended consequences of expensive cancer therapeutics-the pursuit of marginal indications and a me-too mentality that stifles innovation and creativity: The John Conley Lecture. *JAMA Otolaryngology—Head & Neck Surgery* **140**, 1225–1236.

Despite much advertising, PD1 and PD-L1 checkpoint inhibitors bring the same concerns of excessive costs relative to benefits. In the United States, two PD1 (nivolumab, pembrolizumab) and three PD-L1 (atezolizumab, durvalumab, avelumab) checkpoint inhibitors have received FDA approval for the treatment of several cancers. In 2017, the monthly costs for these drugs ranged from US$13.8,000 to $14.9,000, based on average wholesale prices (**Table 5**). Multiple ongoing cost-effectiveness analyses are estimating the value of these drugs, but published studies suggested that checkpoint inhibitors are not cost-effective for the treatment on nonsmall cell lung cancer and head and neck cancers.

Some peculiarities of PD1 and PD-L1 drugs deserve attention when considering the value of checkpoint inhibitors. These drugs are clearly less toxic than conventional chemotherapy. In randomized trials of second-line therapy for metastatic nonsmall cell lung cancer, grade 3 or 4 toxicities occurred in 7%–16% versus 35%–55% of patients treated with checkpoint inhibitors versus docetaxel,

Table 5 Monthly average wholesale price (AWP) for immune checkpoint inhibitors approved in the United States

Drug	*AWP*	*Indication*	*Dose*	*Monthly cost (2017 US$)*
Nivolumab	$3054.18/100 mg	Melanoma	240 mg Q14 days	$14,660.1
Pembrolizumab	$2628.44/50 mg	NSCLC	200 mg Q21 days	$14,018.3
Atezolizumab	$10,344/1200 mg	Urothelial	1200 mg Q21 days	$13,792.0
Durvalumab	$4174.57/500 mg	Urothelial	10 mg/Kg Q14 days	$13,809.5
Avelumab	$1804.8/200 mg	Merkel cell	10 mg/Kg Q14 days	$14,925.7

NSCLC, Nonsmall cell lung cancer; *Q14* days, every fourteen days; *Q21* days, every twenty-one days.

respectively. In order to estimate the value of checkpoint inhibitors, further studies need to fully account for the effect of their low toxicity profile on cost-effectiveness.

Financial Toxicity

In response to rapidly rising healthcare costs in the United States, many insurers have shifted excess costs to patients in the form of higher premiums, deductibles, and copayments. The Kaiser Family Foundation estimates that annual out-of-pocket costs for employer-based health plan premiums and deductibles increased by over 50% between 2008 and 2015 (from $2943 to $5138). Further, an increase in multitiered prescription drug formularies in this same period from 7% to 32% disproportionately affects cancer patients who often require specialty drugs in the highest prescription tier associated with the highest level of cost sharing. In older Medicare beneficiaries, total Medicare spending on noncancer drugs is four times higher than spending on cancer drugs, as might be expected given that other medical conditions (e.g., heart disease, diabetes) are more common in the elderly. However, average annual beneficiary cost share is substantially higher in cancer patients versus others ($7226 vs. $1286). This trend in increased cost sharing coincides with one of the largest economic crises in recent times and a harsh reality that the average family with an income at 250%–400% of the federal poverty level has less than $3000 in liquid financial assets and a recent finding by the pew charitable trust that less than 40% of Americans can come up with $500–$1000 in cash in the case of an emergency.

High cost sharing for cancer drugs and other services in combination with chronicity and intensity of cancer care leading to loss of work and income contributes to a set of circumstances that puts cancer patients and their families at particularly high risk for financial hardship. A growing body of literature had led to the recognition of an emerging side effect of cancer treatment known as "financial toxicity," a term that encompasses a range of financial hardships including difficulty meeting household expenses, debt, bankruptcy, and permanent loss of career and income. A 2011 study by Bernard et al. utilizing data from the Medical Expenditures Panel Survey (MEPS) showed that patients with cancer who were either uninsured or enrolled in private and public health plans consistently reported higher financial burden (defined as $>20\%$ of income spent on healthcare) than individuals with other chronic medical conditions. Another analysis of bankruptcy rates in cancer cases versus matched controls in Washington State showed that individuals with cancer were 2.65 times more likely to file for bankruptcy after diagnosis than matched controls. Several other studies have shown that, across various cancer types, approximately 20%–50% of patients experience significant financial hardship or "toxicity" postdiagnosis including missed work days, disability, inability to cover medical care costs or household expenses, accumulation of debt, and bankruptcy filings. Further, a recent analysis of 2011 MEPS data in approximately 1200 cancer patients showed that approximately 23% experienced "psychological financial hardship" defined as significant anxiety or worry about the costs and affordability of cancer care.

Emerging evidence suggests that financial hardship before and after cancer diagnosis can potentially lead to worse health outcomes including poorer treatment adherence, lower clinical trial enrollment, poorer quality of life, and even worse survival. A recent study reported quality of life scores using multiple measures in patients with lung and colorectal cancer; patients who reported having fewer financial reserves (money in the bank to cover household expenses for 2 months or less) scored significantly lower on all quality of life measures than cancer patients with greater financial reserves. In the previously mentioned bankruptcy study, cancer patients who filed for bankruptcy had a significantly higher risk of death than propensity score matched cancer patients who did not file for bankruptcy (HR 1.79, 95% CI 1.64–1.96). While the exact pathway that leads from poorer financial status or financial hardship to poorer survival is not well elucidated, it is clear that financial toxicity contributes to undesirable outcomes and therefore must be addressed by the oncology community.

Across studies, risk factors for financial toxicity include lower income, younger age, poorer preexisting financial status, advanced stage cancer, cancers requiring more aggressive treatment, and lack of health insurance. Other potential risk factors include role as the primary household income earner and being unmarried, though to potentially a lesser degree. Professional organizations such as the American Society of Clinical Oncology (ASCO) have emphasized the importance of screening patients and families for financial distress and intervening to mitigate financial toxicity in patients who might be at high risk. Unfortunately, few cancer clinics routinely screen for financial distress and, more importantly, even fewer have the capability to prevent financial hardship in those at high risk. Efforts to improve out-of-pocket cost transparency and increase communication between patients and oncologists about cost of care issues are needed. Certainly, addressing the larger problem of value in cancer care and the high price of cancer drugs may help to address financial toxicity. However, novel solutions such as changes in insurance benefit design and provision of financial counseling and navigation services as a routine part of cancer care are also needed.

Disparities in Treatment Access

High drug costs can widen ongoing disparities in access to cancer treatments. Multiple studies have consistently shown that patients of lower social economic status or who lack insurance coverage tend to present with more advanced cancer stages and are less likely to receive standard therapies. Those findings indicate that poverty represents a major access barrier to cancer treatments. New to these investigations is the recent evidence that high drug out-of-pocket costs represent a barrier to treatment initiation in and of itself. The impact of copays on treatment access is particularly relevant for oral cancer drugs. One such example regards to access to imatinib or other similar oral tyrosine kinase inhibitors for the treatment of chronic myeloid leukemia (CML). Imatinib substantially increases overall survival in CML patients, and has become a standard of care for this disease. In a study of Medicare beneficiaries diagnosed with CML, patients initiated imatinib or a similar kinase inhibitor earlier if they had drug cost-sharing subsidies

versus those who did not, suggesting that higher drug copay prevented timely initiation of therapy. Likewise, a cross-sectional survey of 174 cancer patients showed that 28% and 22% of the participants did not fill prescriptions or took fewer doses of oral cancer drugs due to costs, respectively. In this study, lower income was associated with lower adherence to oral medications. Other studies in breast cancer demonstrated an association of higher drug co-pays for tamoxifen and aromatase inhibitors with lower adherence to these medications.

The rising cost of cancer drugs increases the gaps between innovation and access, and accentuates the differences in the treatment patterns of high versus low income patients. Patients who can afford expensive therapies have an increasing number of treatment options, including the latest approved high-cost drugs, while those with limited financial resources can only receive a relatively fixed number of treatments. With the rapid pace of innovation, disparities in treatment access will also intensify on a global scale, as high-income countries will continue to implement cutting edge expensive technologies, while low- and middle-income countries struggle to develop infrastructure for basic cancer treatment, such as centers that offer surgery and radiation. Despite these obvious concerns, more rigorous research and policy changes are in order to address the impact of cancer costs on access to life-prolonging therapies.

Potential Solutions: Focusing on Value

Value is a construct that links the benefits of healthcare interventions to their additional costs. Value-based approaches offer appealing solutions to financially strained healthcare systems, by prioritizing the adoption of interventions that offer higher benefits when costs are similar among alternatives, or interventions that cost less but offer similar benefits compared with the alternatives. The following sessions briefly describe strategies that can improve value in cancer care, including those that focus on better quality care, innovative reimbursement models, and legislation reform.

Better Quality Care

Cancer care pathways

Cancer care pathways consist of software physician-oriented decision tools that provide evidence-based recommendations at the point of treatment decisions through the disease course, from first- to subsequent lines of chemotherapy. Currently available pathways mostly focus on systemic therapies for common advanced solid tumors, although their role is expanding to include early stage cancers. The goal of pathway adoption is to reduce the substantial variation in chemotherapy prescribing practices, thereby reducing costs while maintaining or improving patient outcomes. Several third-party vendors have developed and licensed pathways to clinics, but academic groups and insurance companies have occasionally created their own pathways as well. A recent study from Dana–Farber Cancer Institute showed that adoption of an internally developed pathway decreased the 1-year costs while maintaining overall survival of patients with advanced nonsmall cell lung cancer (**Table 6**). Studies of commercial pathways have shown similar results in early and advanced stage lung and colorectal cancer, respectively. Despite the promising data, concerns have arisen regarding the processes of pathway development and implementation, including issues of transparency about the selection of regimens included in pathways, physicians' restrictions of regimen choices, and the extra administrative burden of reporting pathway adherence. Formal guidelines for pathway implementation, such as the one proposed by the American Society of Clinical Oncology (ASCO), are necessary to ensure that patients have access to high-quality, evidence-based treatments.

Early palliative care

Early integration of palliative care holds great potential to decrease costs, prolong survival, and improve quality of life, as demonstrated in a pivotal randomized trial that assigned patients with advanced nonsmall cell lung cancer to a palliative care team at the time of first-line chemotherapy versus standard of care. Subsequent randomized studies confirmed that early palliative care improved patient outcomes in other advanced solid tumors. These studies suggest that early palliative care can decrease costs particularly by reducing the rates of hospital admissions and emergency room visits, and by facilitating timely transitions to hospice. Inpatient palliative care also decreases hospital costs by avoiding unnecessary escalation of care (e.g., ICU admissions), and by

Table 6 One-Year direct medial costs of before and after implementation of the Dana–Farber Cancer Care Pathways for stage IV Nonsmall cell lung cancer (Hospital perspective; $N = 370$)

Pathways cohort	*Mean cost (2014 US$)*	*95% Confidence interval*
Unadjusted cost		
Prepathway	64,508	53,140–75,876
Postpathway	48,515	41,421–55,608
Adjusted cost		
Prepathway	69,122	33,242–105,001
Postpathway	52,037	25,200–48,849

Adapted from Jackman, D. M., Zhang, Y., Dalby, C., et al. (2017). Cost and survival analysis before and after implementation of Dana–Farber Clinical Pathways for Patients with stage IV non-small-cell lung cancer. *Journal of Oncology Practice* **13**, e346–e352.

shortening the length of admissions. Despite the clear benefits, several challenges prevent widespread adoption of palliative care services, including a shortage of specialists, lack of proper reimbursement, and heterogeneous acceptance of palliative care by oncologists and patients. Future efforts should focus on training a workforce of palliative care providers, and educating patients and physicians about the benefits of early integration of palliative care.

Electronic symptom monitoring

Electronic symptom monitoring is a novel method of following and addressing patients' symptoms through web-based questionnaires. Patients are asked to report their symptoms frequently in between office visits. Symptoms that are intense or worsening prompt electronic messages to the physician's office, allowing providers to timely intervene. A recent randomized study showed that electronic symptom monitoring reduces ED visits and hospitalizations, allows earlier detection of tumor progression and changes in chemotherapy regimens, improves quality of life, and prolongs survival in patients with advanced solid tumors. Economic analyses of electronic symptom monitoring are underway, but this type of intervention will very likely help decrease cancer costs and improve patient outcomes. In Fact, many clinics in the United States and Europe are embracing different versions of electronic symptom reporting tools.

Precision oncology

At least in theory, precision oncology can improve the value of cancer drugs. This concept involves the use of predictive molecular biomarkers that allow the selection of patients who are more likely to benefit from target therapies, while avoiding the unnecessary costs of treating patients that will not benefit. The current data is conflicting to support or refute the hypothesis that precision oncology is cost-effective. Some published cost-effectiveness analyses have shown prohibitive costs per QALY gained for testing lung cancer patients for epidermal growth factor receptor (EGFR) or anaplastic lymphoma kinase (ALK) mutations, and treat those whose tumors harbor these genetic abnormalities with the appropriate target drug. Other studies showed favorable cost-effectiveness ratios ranging from US$30,000 to $40,000 per QALY gained for treating patients with EGFR mutated lung adenocarcinomas with tyrosine kinase inhibitors compared with chemotherapy, but these studies did not account for the money spent in testing several patients to identify one mutation. The value of precision oncology will ultimately depend on several factors, including the performance and prices of multigene testing platforms such as next generation sequencing, the price, and survival benefits of target drugs, and the prevalence of clinically validated biomarkers.

Hospice

Timely referral to hospice decreases cancer costs without impacting on survival. A randomized trial from 1980s showed no differences in overall survival and decreased number of hospitalizations for cancer patients assigned to hospice versus those who did not receive hospice care. In a more recent retrospective study of Medicare beneficiaries with advanced lung cancer, hospice use was associated with a nonstatistically significant survival benefit compared with no hospice use. In a subsequent retrospective matched cohort study of Medicare patients, assignment to hospice decreased total and hospital costs compared with patients who did not receive hospice care. In this study, the decrease in costs was more pronounced with earlier hospice referrals (**Table 7**). Physicians should be aware that a transition to hospice adds value in cancer care, particularly when patients have exhausted treatment options or are experience a decline in performance status. Several barriers may prevent patients from receiving hospice, including the psychological discomfort involved in the discussions of transitions from active therapy to comfort care, and cultural influences on patients' perception of hospice. Oncology providers need appropriate training, psychological support, and reimbursement to appropriately conduct conversations involving hospice care and end-of-life planning.

Decision frameworks

Many organizations have developed decision frameworks to facilitate formal assessments of the value offered by cancer drug regimens, with the hope that summarized information about costs and benefits will encourage stakeholders to make value-based treatment choices. Examples of such efforts include ASCO's Value Framework, the European Society for Medical Oncology (ESMO) Magnitude of Clinical Benefit Scale, and the Institute for Clinical and Economic Review (ICER) Evidence Rating Matrix, among

Table 7 Medicare expenditures at the end of life in hospice and matched nonhospice controls ($N = 3069$)

Hospice use before death	*Mean expenditures per patient, hospice group (2008 US$)*	*Mean expenditures per patient, nonhospice group* [a] *(2008 US$)*	*Adjusted mean difference (2008 US$)*

others. Frameworks provide various methods and processes that quantify clinical benefits in a transparent manner, while some of these tools also explicitly consider drug costs. Although conceptually sound, prospective studies will be necessary to confirm the impact of value frameworks on treatment patterns, quality of care, and costs. One important limitation of frameworks is that they differ in regards to target audiences and scope, which prevents accurate comparisons of their impact. For example, the ASCO Value Framework targets physicians and patients, whereas ESMO's and ICER's frameworks were designed to inform policy makers and payers.

New Reimbursement Models

Under the pressure to contain costs, healthcare payers are developing and implementing novel treatment reimbursement models that emphasize value. Common to these models is the financial or performance accountability shared by payers, clinics, and drug manufacturers.

Oncology care model

In June 2016, the Centers for Medicare and Medicaid Services launched the Oncology Care Model (OCM) initiative, which consists of payment agreements between physician practices and multiple payers, including Medicare and commercial insurance plans. In OCM, physician practices are accountable for the expenses and performance surrounding predefined episodes of care that involve chemotherapy administration. Clinics that spend less than target expenditures per episode can retain a percentage of the savings if they meet prespecified quality benchmarks for that episode. OCM is an example of performance-based reimbursement models that incentivize physician practices to provide high-quality care at lower costs. Performance-based reimbursement has stirred some controversy, as clinics may have to accept financial losses when expenses exceed the targets or their performance does not meet quality benchmarks, depending on the contents of the payment agreements. Additional time and follow up assessments will be important to determine whether the OCM model actually increases value in cancer care.

Performance-linked reimbursement

Performance-linked reimbursement represents yet another model that links the payments for cancer drugs to the achievement of prespecified clinical outcomes. Different than OCM models, performance-linked reimbursement involves risk-sharing agreements between drug manufacturers and clinics or payers. If a given drug provides the expected benefits in real-world settings, clinics or payers will pay the manufacturer the full drug price. If the drug proves to be less effective than expected, manufacturers offer drug price discounts, rebates, or refunds to the purchaser. One example of this model regards to the use of bortezomib (Velcade, Johnson & Johnson) in patients with multiple myeloma. In 2006, the U.K. National Health System entered a performance-linked agreement with Johnson and Johnson, in which patients would undergo four cycles of bortezomib, followed by an assessment of serum M proteins to determine tumor response. Patients were considered to have had treatment failure if the serum M protein levels declined by less than 50%. For those patients, Johnson & Johnson agreed to refund the expenses for bortezomib, or provide the same amount of drug to other patients at no charge. Although appealing, performance-linked reimbursement requires robust infrastructure for real-world data collection, and considerable negotiations among parties to determine what constitutes the desired outcome measures. Despite these caveats, this model will likely gain traction among drug manufacturers and payers in the near future.

Episode-based payments

Episode-based payment models consist of lump-sum payments made to physicians at the beginning of an episode of care for each patient. Episodes of care are discrete cancer treatment events that span a predictable time period, usually of 6 months (e.g., adjuvant chemotherapy for breast or colorectal cancer). In this model, physicians take financial risk by absorbing the losses when the expenses exceed the amount paid at the beginning of the episode. The rationale is that physicians will prioritize regimens of similar efficacy and lower costs when alternatives exist, and will optimize the management of treatment- and disease-related complications to avoid patients from undergoing costly hospitalizations. A retrospective study evaluated the impact of an Episode-based payment model among volunteer clinics that contracted with United-Healthcare, a large private insurance company in the United States. In a sample of 810 patients with breast, lung, and colorectal cancers, episode-based payments resulted in estimated total savings of US$33.4 million with no effects on overall survival compared with historical controls (**Table 8**). In the Episode-payment patient cohort, chemotherapy utilization and costs were curiously higher than predicted, and most savings seem to have derived from lower

Table 8 Impact of an episode-based payment model on direct medical costs in five medical oncology groups ($N = 810$)

Cost category	*Predicted (2012 US$)*	*Actual (2012 US$)*	*Savings (US$)*
Total	98.1 million	64.8 million	33.4 million
Chemotherapy	7.5 million	20.9 million	−13.4 million

Adapted from Newcomer, L. N., Gould, B., Page, R. D. et al. (2014). Changing physician incentives for affordable, quality cancer care: Results of an episode payment model. *Journal of Oncology Practice* **10**, 322–326.

hospitalization costs. Other insurance groups are implementing episode-payment agreements, but additional data is necessary to inform the applicability of this model to other diseases and episodes of care, as well as the impact on patient survival, quality of life, and satisfaction with care.

Legislation Reform

No matter how impactful are the practice changes and reimbursement models implemented by physician and payers, cancer costs will continue to threaten budgets if drug acquisition prices follow the current escalating trend. Only comprehensive legislation reform can address the current lack of control on drug prices in countries like the United States. New federal policies need to give Medicare and other public insurance programs the autonomy to reject coverage for low-value drugs, and to use bargain power to negotiate prices that reflect value.

The first pillar of legislation reform should be a provision that allows Medicare to decline coverage for drugs based on price. Like in any negotiations, the "walk away" option is crucial to allow buyers and sellers to agree upon prices that are perceived as fair. Without the option to say no, Medicare does not really enter any negotiations, but acts as a price taker. On the same note, provisions need to allow the use of explicit methodologies to evaluate drug value and affordability, including cost-effectiveness analysis and budget impact models. This approach would allow the implementation of value-based drug pricing policies in a publically transparent manner. New policies should also give Medicare the flexibility to consider factors other than cost-effectiveness for drug coverage decisions, including disease severity, the specific characteristics of the patient population, equity issues, and budget constraints.

Legislative changes should promote more competition among manufacturers, instead of less. Competition allows market forces to decrease oncology drug prices. Generic medications and biosimilars need to enter the market sooner, and new laws need to restrict the ability of drug companies to buy extra patent protection time. Likewise, public insurance programs need to be able to import less costly cancer drugs, a strategy that would also create competition among domestic manufacturers and force prices down.

Despite the clear rationale, legislation reform would require strong political motivation from society. The pharmaceutical industry has a vetted interest to maintain current federal laws regarding drug pricing, and industry lobbyists exert powerful political influence that prevent the enactment of any meaningful reform. The prospects of legislative transformation ultimately depend on the leading role of other stakeholders, including healthcare providers, payers, and patient advocates. These groups need to jointly demand major legislative changes from politicians and counterbalance the industry lobby.

Conclusions

The rising costs of cancer care pose a risk to the sustainability of healthcare programs, and this trend will likely continue for the foreseeable future. Hospitalization and oncology drugs account for the majority of cancer expenditures, and result from multiple inefficiencies and misaligned incentives that affect the healthcare system. Stakeholders are developing several strategies to transform cancer care from a high-cost to a high-value enterprise.

Gastric Cancer: Pathology and Genetics

Irene Gullo and Fátima Carneiro, São João Hospital, Porto, Portugal; and University of Porto (FMUP), Porto, Portugal

Glossary

Advanced gastric cancer An invasive carcinoma infiltrating into the muscular propria and beyond.

***CDH1* gene** The human *CDH1* gene [MIM#192090] is localized in the long arm of chromosome 16, comprises 16 exons and encodes E-cadherin.

***CTNNA1* gene** The human *CTNNA1* gene [MIM#116805] is localized in the long arm of chromosome 5, comprises 16 exons and encodes α-E-catenin.

Diffuse carcinoma Subtype of gastric carcinoma composed of poorly cohesive neoplastic cells.

Early gastric carcinoma An invasive carcinoma limited to the mucosa or submucosa, regardless of nodal status.

Early onset gastric cancer Early onset gastric cancer (EOGC) is a gastric cancer presenting at the age of 45 or earlier, representing approximately 10% of all patients with stomach cancer.

E-cadherin E-cadherin is a transmembrane calcium-dependent protein that is predominantly expressed at the basolateral membrane of epithelial cells, where its functions are primarily cell–cell adhesion and suppression of invasion.

Epstein–Barr virus Double-strand DNA virus belonging to the herpes virus family (HHV4).

Gastric adenocarcinoma Malignant epithelial neoplasms with glandular differentiation.

Gastric adenocarcinoma and proximal polyposis of the stomach (GAPPS) GAPPS is a variant of familial adenomatous polyposis (FAP) and is caused by point germline mutations in the promoter 1B of the *APC* gene. It is characterized by fundic gland polyposis, with areas of dysplasia and carries an increased risk of gastric adenocarcinoma.

Gastric carcinoma with lymphoid stroma (GCLS) GCLS is a morphological subtype of GC composed of irregular sheets, trabeculae, poorly developed tubular structures and isolated cells, embedded within a prominent lymphocytic infiltrate, with occasional lymphoid follicles.

Gastric microbiota The whole microbial community within the stomach.

Helicobacter pylori *Helicobacter pylori* are Gram-negative bacteria that colonize gastric mucosa, considered by WHO as a group I carcinogen for gastric cancer.

Hereditary diffuse gastric cancer (HDGC) HDGC is an autosomal dominant cancer susceptibility syndrome characterized by signet ring cell (diffuse) gastric cancer and lobular breast cancer, caused by germline mutations of *CDH1* and *CTNNA1* genes.

Immune inhibitory checkpoint Molecules of the immune system that inhibit the T cell signal by antagonizing costimulatory molecules necessary to the activation of the T cells.

Intestinal carcinoma Subtype of gastric carcinoma with glandular structure.

Tumor immune microenvironment Noncancerous cells and extracellular components constituting the tumor stroma.

Definitions: Types and Subtypes

The vast majority of stomach cancer cases are gastric carcinomas (malignant epithelial neoplasms). Nonepithelial tumors predominantly include lymphomas and mesenchymal tumors. In this article, we will focus on gastric carcinoma (GC).

Most cases of GC are sporadic. Familial clustering is observed in about 10% of the cases. Hereditary GC accounts for a very low percentage of cases (1%–3%), encompassing hereditary diffuse gastric cancer (HDGC) and familial intestinal GC (FIGC). Gastric adenocarcinoma and proximal polyposis of the stomach (GAPPS) has been recently recognized as a rare variant of familial adenomatous polyposis (FAP) with a distinct gastric phenotype. Furthermore, GC can develop in the setting of other hereditary cancer syndromes (see "**Molecular Pathology and Genetics**" section).

According to the depth of invasion, GC is classified as early and advanced. Early GC refers to an invasive carcinoma that is limited to the mucosa (pT1a) or the mucosa and submucosa (pT1b), with or without lymph-node metastases and regardless of tumor size. This classification is prognostically relevant (see "**Prognostic and Predictive Biomarkers**" section): early GCs have a better prognosis compared to advanced GCs, with a 5-year survival rate of 80%–95%, after surgical resection. By contrast, GCs infiltrating into the *muscularis propria* and beyond are defined as "advanced." *P*atients with advanced GC, if the tumor is unresectable, have a dismal prognosis with an expected survival of few months, even with chemotherapy and best supportive care.

Regarding the anatomic location, tumors arising in the esophagogastric junction (EGJ) are staged as esophageal or GCs, depending on the location of the tumor epicenter with respect to the EGJ. According to the 8th edition of the American Joint Committee on Cancer (AJCC) staging system, EGJ tumors with the epicenter located >2 cm distal to the EGJ should be classified using the stomach cancer system, while EGJ tumors with the epicenter at ≤ 2 cm below the EGJ that straddle the junction should be staged as esophageal tumors.

GCs represent a biologically heterogeneous group of tumors with multifactorial etiologies, encompassing environmental, genetic and molecular factors. They are characterized by broad morphological heterogeneity with respect to the architecture, pattern of growth, cell differentiation, histogenesis and molecular pathogenesis (**Fig. 1**). Several histopathological classifications have been proposed along the years, reflecting the heterogeneity of GC morphology (see "**Pathology**" section). Moreover, the advent of high-throughput molecular technologies has recently led to a better understanding of GC molecular complexity (see "**Molecular Pathology and Genetics**" section).

Burden

GC accounts for about 7% of cancers worldwide (being the fifth most common malignancy in the world, behind cancers of the lung, breast, colo-rectum and prostate) and is the third leading cause of cancer death in both sexes. However, the distribution is uneven, from areas with high incidence (>60 per 100,000 males) such as East Asia, central and eastern Europe and Latin America, to low incidence areas (<15 per 100,000 population) such as North America, Northern Europe and most countries in Africa and South-Eastern Asia. More than 70% of the cases occur in developing countries. Countries with a high incidence of GC, in which there are screening programs of asymptomatic individuals, have a high incidence of EGCs, ranging from 30% to 50% in East Asia (e.g., Japan), with lower figures for the West (16%–24%).

In regions with high incidence of GC, most cases are localized in the antrum and pylorus. GCs of the proximal stomach and the EGJ are more common in low incidence countries (e.g., North America and Europe) and are associated with gastro-esophageal reflux disease (GERD).

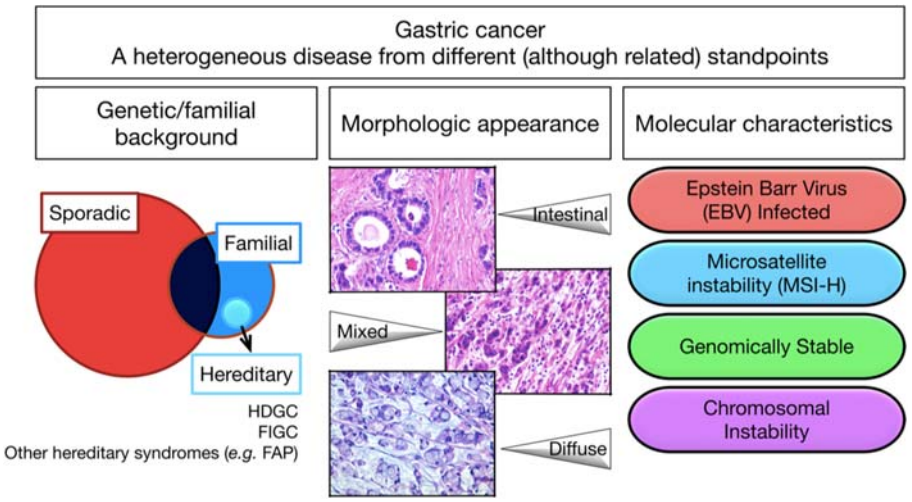

Fig. 1 Gastric cancer is a heterogeneous disease from different standpoints: etiology and pathogenesis, morphology and molecular characteristics. HDGC, hereditary diffuse gastric cancer; FIGC, familial intestinal gastric cancer; FAP, familial adenomatous polyposis.

Notably, EGJ adenocarcinoma shares many epidemiological characteristics with cancers developing in the distal esophagus and proximal stomach, and the incidence is higher in Caucasians, namely in male old patients. The incidence of EGJ adenocarcinoma increased markedly in the second half of the 20th century both in the United States and Europe, in parallel with rising incidence of adenocarcinomas of the lower esophagus.

Time Trends

Worldwide, there has been a steady decline in the incidence and mortality of GC over the last 15 years. However, the absolute incidence rate continues to rise, due to the advancing age of the global population. More specifically, there has been a shift in the proportion of some subtypes: the incidence of "intestinal" carcinoma has decreased mainly in young patients, and the incidence of "diffuse" carcinoma localized to the proximal stomach is increasing.

The decline of incidence has been attributed to the decrease in the prevalence of *Helicobacter pylori* (*H. pylori*) infection, better food refrigeration, reduced intake of preserved foods and salt, and a richer and more varied diet, including a higher intake of fruit and vegetables (see diet in "Risk Factors" section).

Age and Sex Distribution

Age-standardized incidence rates are about twice as high in men compared to women. In general, incidence increases progressively with age in males and females.

Early onset GC (EOGC) is defined as any GC presenting at the age of 45 or earlier and represents approximately 10% of all patients with stomach cancer. In some populations, susceptibility genetic factors and the infection by virulent strains of *H. pylori* may be important for early-onset disease. GC occurrence before the age of 30 years is very rare (1.1%–1.6%) and patients diagnosed before 20 years are exceptional. Many cases display diffuse histology and occur in HDGC families. Several studies point to a pathogenesis of EOGC different from that of sporadic cancers occurring at a later age.

Risk Factors

Gastric carcinogenesis is a multistep and multifactorial process which, in many cases, appears to involve a progression from normal mucosa through chronic gastritis (chronic inflammation of the gastric mucosa), atrophic gastritis (with loss of gastric glands) and intestinal metaplasia (substitution of gastric epithelium by intestinal epithelium) to dysplasia (intraepithelial neoplasia) and carcinoma, a sequence of events that may last several years. This sequence has been designated as the Correa's cascade of multistep gastric carcinogenesis. However, the Correa's model does not explain the carcinogenetic pathway of all types of GC. Actually, a proportion of GCs arises in nonintestinalized mucosa and retains gastric phenotype (and gastric differentiation is also observed in gastric

dysplasia, the ultimate precursor lesion of GC). Another pattern of metaplasia, which is believed to represent an alternative pathway to gastric neoplasia, is spasmolytic polypeptide-expressing metaplasia (SPEM), which expresses trefoil factor family 2 (TFF2) spasmolytic polypeptide and represents the metaplastic replacement of oxyntic glands by mucin secreting antral-like glands. SPEM develops in the gastric body and fundus and is strongly associated with chronic *H. pylori* infection and development of GC. Moreover, as occurs in GAPPS syndrome, gastric dysplasia and GC may arise in fundic gastric polyps. Together, this evidence shows that GC may also arise from the gastric epithelium.

Helicobacter Pylori Infection

Among environmental factors, *H. pylori* infection plays a major role. Almost all noncardiac GCs develop from a background of *H. pylori* infected mucosa. *H. pylori* are Gram-negative, spiral-shaped, microaerophilic bacteria that colonize the gastric mucosa within the mucus layer and also in contact with epithelial cells. In 1994, the WHO categorized *H. pylori* as a group 1 carcinogen for GC, based on results of epidemiological studies that were available at that time, and later confirmed. The bacteria can be identified in gastric mucosa by routine stains, such as hematoxylin–eosin, modified Giemsa and other ancillary methods, such as Warthin–Starry staining and immunohistochemistry (Fig. 2). The infection is commonly acquired during early childhood and persists throughout adult life unless eradicated.

H. pylori virulence factors that appear to influence the pathogenicity of the bacteria, as well the risk of GC development, include the cag pathogenicity island-encoded CagA, and the vacuolating cytotoxin, VacA.

CagA is present in about 60%–70% of strains and is a marker for the presence of the cag pathogenicity island. This pathogenicity island encodes a type IV secretion system that allows the translocation of CagA into the host cells. CagA can activate multiple host signaling pathways leading to cell proliferation, cytoskeletal rearrangements, and disruption of cell–cell junctions. Transgenic expression of CagA was shown to lead to GC in mice. Strains producing the cagA protein that induce a greater degree of inflammation are associated with gastric precancerous lesions and a greater risk of developing cancer of the distal stomach.

The gene encoding VacA is present in all *H. pylori* strains, but is polymorphic and varies significantly in the signal (s)-, the intermediate (i)-, and the mid (m)-regions, each with two major types. Infections with the more virulent vacA s1, i1, and m1 strains increase the risk for peptic ulcer disease and for GC, when compared with the less virulent vacA s2, i2, and m2 strains. The more virulent strains are frequently found associated with higher levels of inflammation, epithelial damage, gastric atrophy and intestinal metaplasia. Although the risk of GC in some countries of Europe and North America has been related to vacA genotype, such relationships have not been observed in eastern Asian countries, suggesting that consequences of the variation in vacuolating activity are dependent on geographical region. In East Asia, most *H. pylori* strains are vacA s1, i1, and m1, and are not associated with any particular clinical outcome.

Corpus-predominant gastritis with multifocal gastric atrophy, and hypo- or achlorhydria is seen in approximately 1% of subjects infected with *H. pylori*.

The acidic pH of the stomach, ranging from 1–3, works as a primary innate defense mechanism and provides an effective barrier to microbial overgrowth. Development of atrophic gastritis, which induces elevation in gastric pH, due to parietal cell loss, may lead

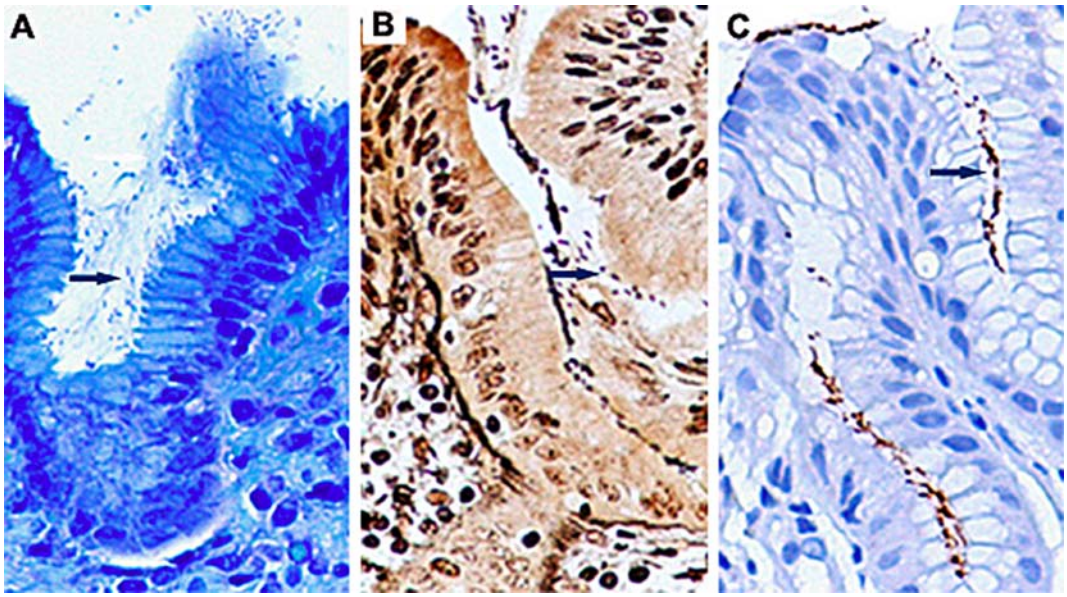

Fig. 2 *Helicobacter pylori* detected in the lumen of gastric glands and adherent to the apical pole of epithelial cells: (A) modified Giemsa, (B) Warthin Starry, (C) immunohistochemistry.

to a shift in the composition of the gastric microbiota (the microbial community within the stomach). This event may contribute to malignant transformation, through maintenance of inflammation, and conversion of nitrates into mutagenic *N*-nitroso compounds. It has been demonstrated that patients with decreased acid secretion caused by *H. pylori*-associated atrophic gastritis, partial gastrectomy, or long-term acid suppression, especially with proton pump-inhibitors, have significant intragastric bacterial overgrowth, increased counts of nitrate-reducing bacteria, and increased nitrite and N-nitrosamine levels. This would in part explain the lack of success of *H. pylori* eradication in preventing GC in patients that have atrophy and intestinal metaplasia at baseline. Recent advancements in molecular techniques and computational analysis have provided evidence that the complex microbiota colonizing the gastric epithelium may influence gastric homeostasis and disease in combination with *H. pylori*. In support of this hypothesis, it was recently demonstrated that the microbial community of GC patients has increased nitrosating functions and genotoxic potential, compared with patients with chronic gastritis.

However, the large majority (>90%) of the individuals do not develop GC, indicating a role for other causative agents and the genetic background (Fig. 3). Host genetic susceptibility to GC involves several genes, each one however, with small effects. In this regard, several genes have been studied, namely those involved in the protection of gastric mucosa against damaging agents, in inflammatory response, in detoxification of carcinogens, in the synthesis and repair of DNA, in folate metabolism, in the regulation of gene expression and in the cell adhesion. Having all these issues in mind, it can be stated that GC (as many other, if not all diseases) is the end product of gene (genetic susceptibility)/environment interaction (Fig. 4).

Epstein–Barr Virus Infection

Epstein–Barr virus (EBV) is a double-strand DNA virus that belongs to the herpes virus family (HHV4) and has been recognized as a distinct pathogenic cause of GC. EBV associated GC (EBVaGC) is considered a distinct subtype with peculiar molecular characteristics (see "Molecular Pathology and Genetics" section) and is defined by monoclonal proliferation of carcinoma cells infected by EBV, as demonstrated by EBV-encoded small RNA (EBER) in situ hybridization (Fig. 5). Distinct latency-associated patterns have been associated with specific malignancies and, in the case of GC, a latency type I or II has been found, in which EBERs, EBNA-1, BARTs, LMP-2A, and BART miRNAs are expressed.

The frequency of EBVaGC varies from 2% to 20%, with a worldwide average of nearly 10%. EBVaGC occurs more frequently in male, younger patients and in the proximal stomach, or in the gastric stump of patients submitted previously to subtotal gastrectomy.

EBVaGC is generally not associated with *H. pylori* infection. In the rare instances of coinfection (*H. pylori* and EBV) EBV appears to potentiate the oncogenic effects of *H. pylori* infection.

EBVaGC may present three histological variants: (1) gastric cancer with lymphoid stroma (see "Pathology" section) (Fig. 5), in up to 50% of cases; (2) GC with Crohn's disease-like lymphoid reaction, characterized by the presence of numerous lymphoid follicles with active germinal centers at the advancing edge of the tumor; and (3) conventional-type GC, with scant lymphocytic infiltrate, in a minority of cases.

EBVaGC has frequently a favorable prognosis, which could be explained, at least in part, by the intense immune response elicited by EBV infection.

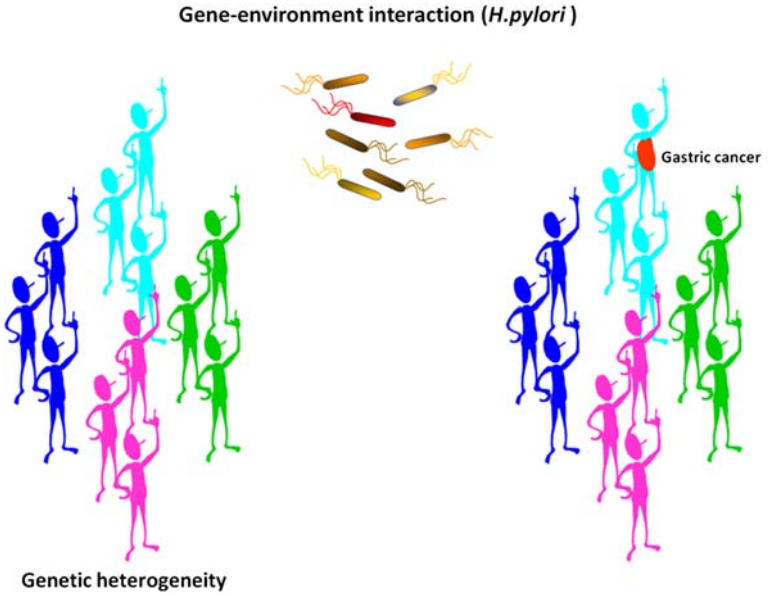

Fig. 3 Among the individuals infected with *Helicobacter pylori*, the large majority (>90%) of the individuals do not develop gastric cancer, indicating a role for other causative agents and the genetic background of the host.

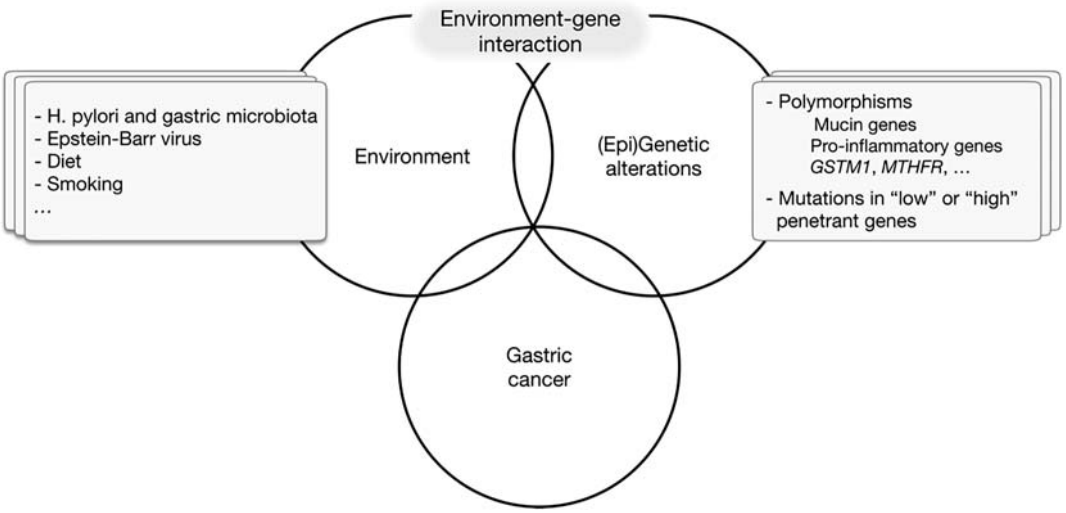

Fig. 4 Gastric cancer (as many other, if not all diseases) is the end product of genetic susceptibility/environment interaction.

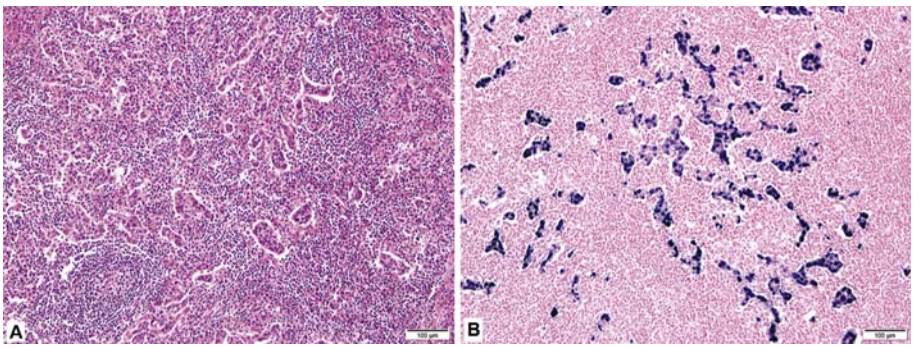

Fig. 5 Gastric cancer with lymphoid stroma (medullary carcinoma, lymphoepithelioma-like carcinoma) is characterized by abundant lymphocytic infiltrate, with scattered lymphoid follicles (A). This morphology is frequently associated to EBV infection, as in this case, demonstrated by EBER-ISH (B).

Diet

Certain dietary habits are associated with an increased risk of GC. These include high intakes of salt-preserved and/or smoked foods and low intakes of fresh fruit and vegetables, particularly in combination with *H. pylori* infection. Intake of all meat, red meat and processed meat is also associated with an increased risk of GC in the distal stomach. The so-called "Mediterranean diet" was shown to be associated with a significant reduction in the risk of incident GC; it is defined as the high consumption of fruit, vegetables, cereals, legumes, nuts and seeds, and seafood, with olive oil as the main fat source, moderate alcohol consumption (particularly red wine), a low-to-moderate consumption of dairy products and a relatively low consumption of red and processed meat.

Smoking

An association has been shown between smoking and stomach cancer that could not be explained by bias or confounding factors. Smoking also potentiates the carcinogenic effect of infection with cagA—positive *H. pylori*.

Genetic Polymorphisms

Polymorphisms of the interleukin 1 β (*IL1B*) gene (initiation and amplification of inflammatory response) and the interleukin 1 receptor antagonist gene (*IL1RN*) (modulation of inflammation) are associated with individual (or familial) susceptibility to carcinogenesis associated with *H. pylori*. It has been shown that in individuals with alleles that predispose to inflammation, infection with *H. pylori* may cause increased production of gastric interleukin 1 β, leading to severe and sustained inflammation that increases the risk of developing GC.

Other clinic-pathologic conditions that are associated with an increased risk of GC encompass autoimmune gastritis, peptic ulcer disease, hypertrophic gastropathies, gastric stump (operated stomach), and gastric polyps.

Precursor Lesions

Gastric dysplasia represents the penultimate stage of the gastric carcinogenesis sequence. It is characterized by cellular atypia, reflective of abnormal differentiation, and disorganized glandular architecture. Determination of the correct diagnosis and grade of dysplasia is critical, because it predicts both the risk of malignant transformation and the risk of metachronous GC.

According to World Health Organization, dysplasia is graded in a two-tier system: low-grade and high-grade dysplasia, on the basis of architectural and cell features. The term "indefinite for dysplasia" (IFD) was coined for epithelia that were neither unequivocally dysplastic nor unequivocally nondysplastic. An alternative designation for dysplasia is intraepithelial neoplasia (IEN).

Low-grade intraepithelial neoplasia/dysplasia shows minimal architectural disarray and only mild to moderate cytological atypia. The nuclei are elongated, polarized and basally located, and mitotic activity is mild to moderate (Fig. 6A). For polypoid lesions, the term "low-grade adenoma" can be used.

High-grade intraepithelial neoplasia/dysplasia displays neoplastic cells that are usually cuboidal instead of columnar, with a high nucleus to cytoplasm ratio, prominent amphophilic nucleoli, more pronounced architectural disarray and numerous mitoses, which can be atypical (Fig. 6B). Increased mitotic activity per se is not pathognomonic of intraepithelial neoplasia/dysplasia, since it is seen in regenerating epithelium as well. Importantly, the nuclei frequently extend toward the luminal half of the cell and nuclear polarity is usually lost. For polypoid lesions, the term "high-grade adenoma" can be used. In general, the diagnosis of high-grade intraepithelial neoplasia/dysplasia is more reproducible than the diagnosis of low-grade lesions. The distinction between high-grade intraepithelial neoplasia/dysplasia and well-differentiated, tubular EGC, can be very challenging, especially in biopsy material, and diagnostic criteria are slightly different for Western and Japanese pathologists. The distinction between high-grade intraepithelial neoplasia/dysplasia and well-differentiated EGC has become of limited clinical interest, since these two conditions could be managed endoscopically.

Further, gastric dysplasia may present an intestinal or gastric phenotype, according to the histomorphological profile. These two phenotypes may be distinguished also on the basis of immunohistochemical expression of lineage-differentiation markers. MUC5AC and TTF1 are markers of surface gastric epithelium (foveolar cells); MUC6 and TTF2 represent markers of mucous neck cells, pyloric glands and Brunner's glands; MUC2, CD10, and CDX2 are intestinal goblet cells differentiation biomarkers. According to their expression, four immunophenotypes may be attributed to dysplastic lesions, both low- and high-grade: intestinal (expressing MUC2, CD10, CDX2), gastric (expressing MUC5AC/TTF1 and/or MUC6/TTF2), hybrid (expressing intestinal and gastric markers) and null phenotype.

Intestinal-type intraepithelial neoplasia/dysplasia generally develops in the setting of chronic atrophic gastritis with intestinal metaplasia and is considered the precursor lesion of intestinal type of GC.

Dysplastic lesions harboring gastric immunophenotype may represent a divergent carcinogenesis model, compared to the conventional Correa's cascade.

Precursor lesions of the diffuse type of GC are not well characterized, except for hereditary diffuse gastric carcinoma (see "Molecular Pathology and Genetics" section).

Pathology

Macroscopy

Endoscopists divide EGCs into three types, on the basis of the endoscopic appearance. These are: protruded (type I), subcategorized into pedunculated (Ip) and sessile (Is); superficial (type II), and excavated (type III). Type II accounts for 80% of EGCs and is further subdivided into elevated type (IIa), flat type (IIb), and depressed type (IIc), the last being the most common.

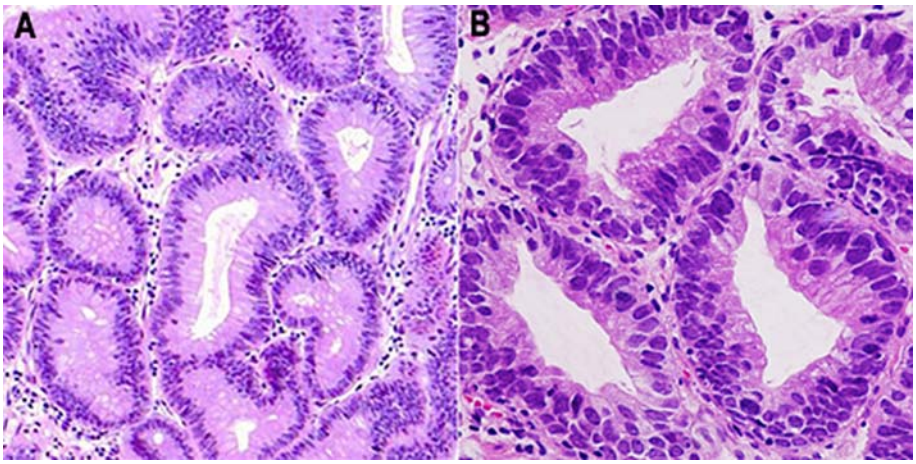

Fig. 6 Gastric dysplasia: (A) low-grade, (B) high-grade.

Advanced gastric cancer

Advanced GC can display various gross appearances. Borrmann's classification remains the most widely used and divides GC into four distinct types: polypoid carcinoma (type I), fungating carcinoma (type II), ulcerated carcinoma (type III), and diffusely infiltrative carcinoma (type IV) (Fig. 7).

Polypoid and fungating tumors typically consist of friable, ulcerated masses that bleed easily and project from a broad base in the gastric lumen. They tend to develop in the body of the stomach, in the region of the greater curvature, posterior wall or fundus.

Ulcerated tumors can differ from benign ulcers by an irregular margin with raised borders and thickened, uneven and indurated surrounding mucosa. The ulcer base is necrotic, shaggy and often nodular. Mucosal folds radiating from the crater are irregular and frequently show club-like thickening and fusion. Malignant ulcers tend to be larger than their benign counterparts. However, many malignant ulcers lack these typical features and, therefore, endoscopic appearance is not a sufficiently reliable guide to diagnosis and should be complemented by systemic biopsies.

Infiltrative tumors may spread superficially in the mucosa and submucosa, giving rise to plaque-like lesions with flattening of the rugal folds. In some cases, superficial ulceration supervenes. Frequently, though, the infiltration involves the entire thickness of the wall, usually over a limited area but sometimes extensively, to produce the so-called linitis plastica or "leather bottle" stomach. In these cases, the wall assumes a stiff consistency due to an extensive desmoplastic response to tumor cells. In such cases, there is usually no visible localized growth. A characteristic feature, at endoscopy, of this tumor type is that, because of the diffuse involvement of the stomach, it fails to inflate, in marked contrast to the normal stomach.

Some GCs may secrete considerable amounts of mucin, which gives the tumor a gelatinous appearance to the naked eye. These are sometimes referred to as mucinous or colloid carcinomas.

Microscopy

GC is very heterogeneous from the morphological standpoint. Several histopathological classifications have been proposed, underlying such heterogeneity. As many carcinomas show morphological heterogeneity, that is, a great variety of different patterns within the same tumor, defining the predominant component could be difficult and some concerns have been raised about accuracy and reproducibility of the current classifications. The most widely accepted and used are the World Health Organization and the Laurén classifications.

Two major types of GC have been described by Laurén—intestinal and diffuse types—which display different clinicopathologic profiles, molecular pathogenesis and biological behavior, often occurring in distinct epidemiologic settings. Intestinal GC occurs predominantly in elderly, male patients; diffuse GC is more common in young, female patients. Both subtypes share environmental risk factors; however, diffuse GC pathogenesis is less well understood and presents a hereditary component.

According to the World Health Organization (WHO), five major types of GC are recognized: tubular, papillary (Fig. 8A), poorly cohesive (with or without signet-ring cells) (Fig. 8B and C), mixed (Fig. 8D), and mucinous (Fig. 8E). Tubular and papillary carcinomas roughly correspond to the Laurén intestinal type and the poorly cohesive carcinomas (encompassing cases constituted, partially or totally, by signet-ring cells) correspond to the diffuse type in Lauren's classification.

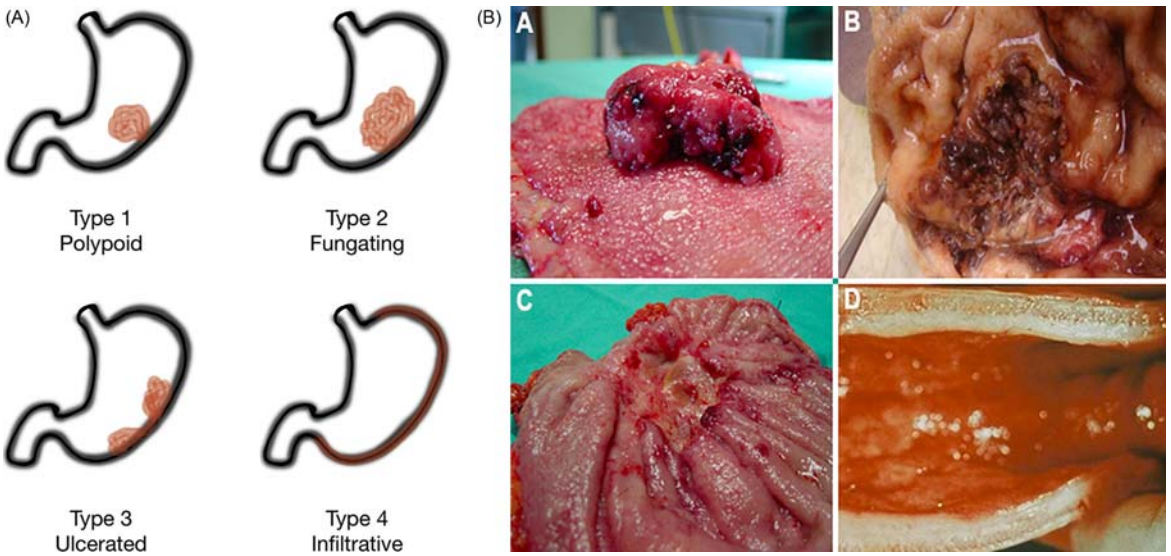

Fig. 7 (A) Growth patterns of advanced gastric cancer according to the Borrmann classification: type 1—polypoid, type 2—fungating, type 3—ulcerated, type 4—infiltrative. (B) Macroscopic appearance of advanced gastric cancer according to the Borrmann classification (surgical specimens): (A) type 1—polypoid, (B) type 2—fungating, (C) type 3—ulcerated, (D) type 4—infiltrative.

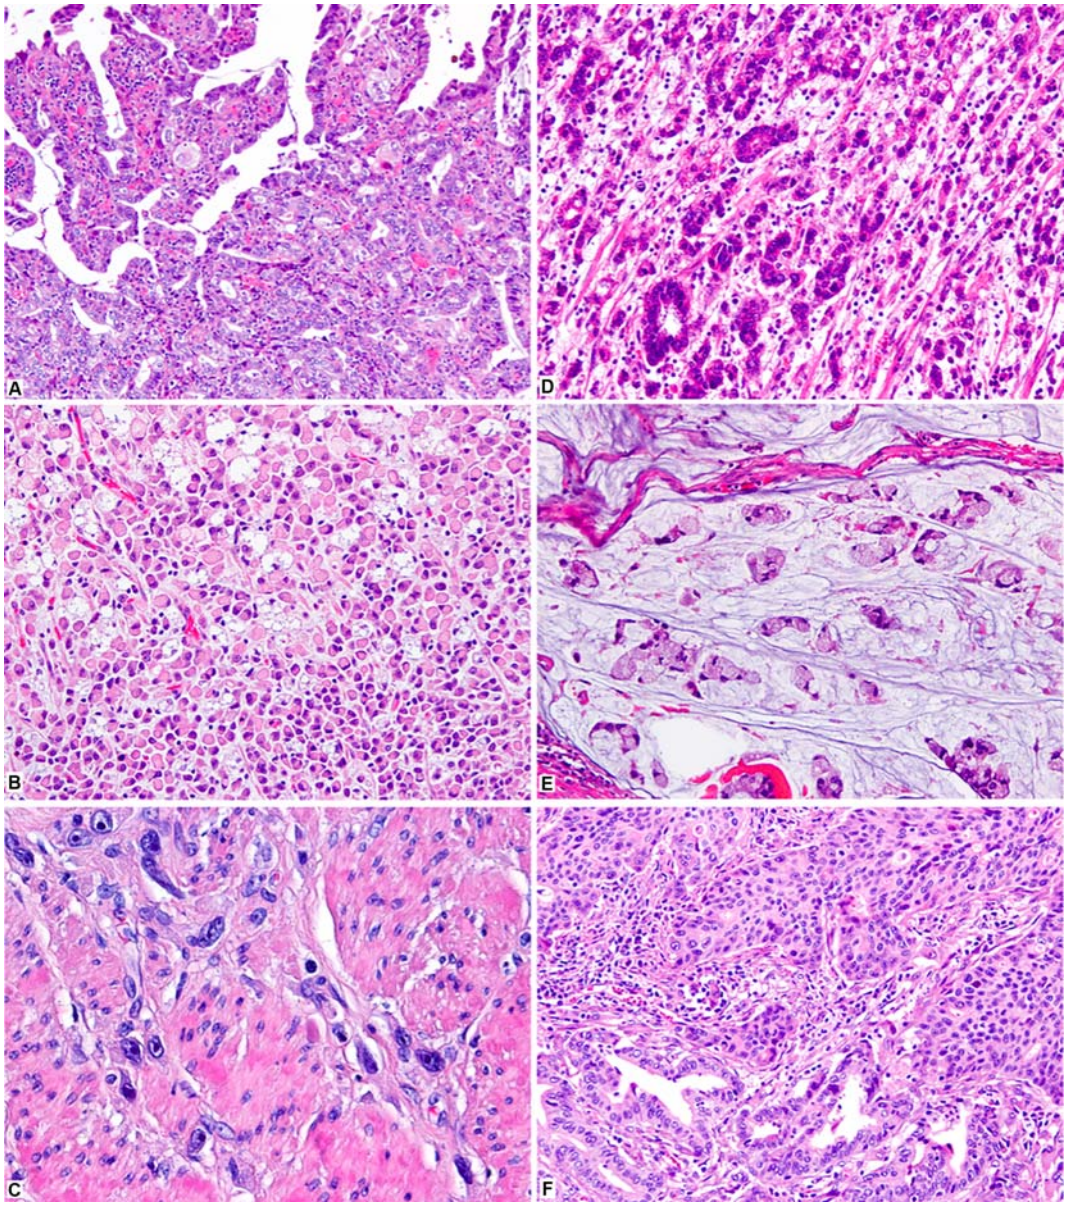

Fig. 8 Gastric carcinoma: (A) Tubulo-papillary (intestinal type), (B) poorly cohesive, with signet-ring cells (diffuse type), (C) poorly cohesive, without signet-ring cells (diffuse type) composed of pleomorphic cells infiltrating the muscularis propria, (D) mixed, (E) mucinous, (F) adenosquamous.

Uncommon histological variants account for about 5% of GCs, encompassing: gastric carcinoma with lymphoid stroma (GCLS, see below) (Fig. 5), adenosquamous (Fig. 8F), squamous cell carcinoma, hepatoid adenocarcinoma, choriocarcinoma, small cell carcinoma, gastric carcinosarcoma, gastroblastoma, micropapillary carcinoma, gastric carcinoma of fundic gland type, parietal cell carcinoma, Paneth cell carcinoma, mucoepidermoid carcinoma, malignant rhabdoid tumor and undifferentiated carcinoma.

GCLS, also described as medullary carcinoma or lymphoepithelioma-like carcinoma (Fig. 5), is composed of irregular sheets, trabeculae, poorly developed tubular structures and isolated cells, embedded within a prominent lymphocytic infiltrate, with occasional lymphoid follicles. The lymphoid infiltrate can be so prominent that immunohistochemical study may be necessary to confirm the epithelial nature of the tumor. GCLS is frequently associated to EBV infection (in over 80% of cases) and a similar morphology can be observed in GC with microsatellite instability. As demonstrated by immunohistochemical studies, cytotoxic (CD8+) T lymphocytes constitute the predominant component of the infiltrate, which also contains B lymphocytes, plasma cells, neutrophils and eosinophils.

Molecular Pathology and Genetics

GC is the result of accumulated genomic damage affecting cellular functions essential for cancer development, the so-called hallmarks of cancer: self-sufficiency in growth signals, escape from antigrowth signals, apoptosis resistance, sustained replicative potential, angiogenesis induction and invasive or metastatic potential. Emerging hallmarks have been recently added to the list: deregulation of cellular energetics, escape from immune destruction, tumor-promoting inflammation and genomic instability/mutations.

Numerous gene mutations, somatic copy number alterations, epigenetic changes, transcriptional changes, etc. have been detected in GC, highlighting the remarkable molecular heterogeneity of this cancer. With the recent advent of next-generation sequencing, several groups have analyzed GC molecular alterations at high resolution, using various high-throughput platforms. These studies have tried to decipher such complex molecular alterations, proposing integrated molecular classification schemes, which attempt to cluster the comprehensive molecular data obtained into clinical and biological homogenous subgroups.

The Gene Expression Profiles From the Singapore-Duke Group

The Singapore-Duke group used high-throughput transcriptomic technologies to identify gene expression signatures with clinical relevance. This study led to the recognition of three subtypes: (1) the mesenchymal subtype, enriched with diffuse GCs and characterized by cancer stem cell and epithelial-to mesenchymal transition (EMT) properties; (2) the proliferative subtype, with high levels of *TP53* mutations, genomic instability, and activation of oncogenic pathways; and (3) the metabolic subtype, overexpressing genes that are normally expressed in gastric mucosa. Proliferative and metabolic subtypes frequently correspond to the Laurén intestinal type. New molecular profiling technologies (e.g., NanoString nCounter technology) have demonstrated the possibility of generating similar accurate molecular information from formalin-fixed and paraffin-embedded GC tissues.

The Four-Tiered Molecular Classification From the Cancer Genome Atlas

The landmark study of GC molecular-based stratification was carried out by The Cancer Genome Atlas (TCGA) research network, which proposed a four-tiered molecular classification (**Fig. 9**) that identifies: (1) Epstein–Barr virus-positive (EBV+) GC, characterized by recurrent PIK3CA mutations, frequent JAK2 and PD-L1 amplification, and a high level of DNA hypermethylation; (2) GC with microsatellite instability (MSI-high) characterized by DNA hypermethylation and *MLH1* silencing; (3) genomically stable GC, associated with a diffuse morphology and recurrent *CDH1* and *RHOA* events; and (4) GC with chromosomal instability (CIN), exhibiting intestinal morphology, a high number of *TP53* mutations, and amplifications of tyrosine kinase receptors (TKR).

The Four-Tiered Molecular Classification From the Asian Cancer Research Group

The Asian Cancer Research Group (ACRG) described four molecular subtypes with distinct prognostic impact: (1) MSI-high tumors, with an intestinal morphology and the best prognosis; (2) MSS/EMT GC, with a diffuse morphology and the worst prognosis; and (3 and 4) MSS adenocarcinomas, with no EMT signature, either *TP53*-active (MSS/*TP53*+) or inactive (MSS/*TP53*−), and with an intermediate prognosis. The MSS/*TP53*− subtype (which roughly corresponds to the proliferative and CIN subtypes) is frequent (36%–50% of GCs) and harbors genomic amplifications of TKR and/or *RAS*, some of which are potential therapeutic targets. The ACRG found that TKR and *RAS* amplifications tended to be mutually exclusive, emphasizing GC intertumor heterogeneity and the importance of investigating molecular alterations for targeted therapy.

As shown in **Table 1**, the three molecular classifications, described above, overlap only partially, highlighting the need for a consensual classification.

In-depth studies combining molecular features with histopathological and immunohistochemical profiles may reveal interesting associations. On this note, several groups have proposed practical algorithms, based on in situ hybridization techniques, that is, EBER-ISH, and immunohistochemistry (IHC), that is, mismatch repair proteins, E-cadherin, and p53 expression, currently available in routine diagnostic practice. In these studies, the authors accomplished to translate different molecular subgroups into specific immunophenotypes with prognostic and predictive significance.

Genetic Predisposition and Hereditary Syndromes

First-degree relatives of patients with GC are almost three times as likely as the general population to develop GC. This may be partly attributable to *H. pylori* infection being common in families and to the potential role of *IL-1* gene polymorphisms. Susceptibility to carcinogens may play a role as well. For example, polymorphisms of genes encoding for glutathione S-transferase enzymes, known to metabolize tobacco-related carcinogens and *N*-acetyltransferase 1, increase the risk of GC development. Evidence of familial clustering is found in about 10% of GCs; among such cases, about 1%–3% GCs are truly hereditary, encompassing hereditary diffuse gastric cancer (HDGC) and familial intestinal gastric cancer (FIGC) syndromes. Despite the growing number of FIGC families, the genetic cause underlying the disease remains to be elucidated. Clinical criteria for the definition of this syndrome vary, based on the incidence of GC in the population to which the family belongs (**Table 2**).

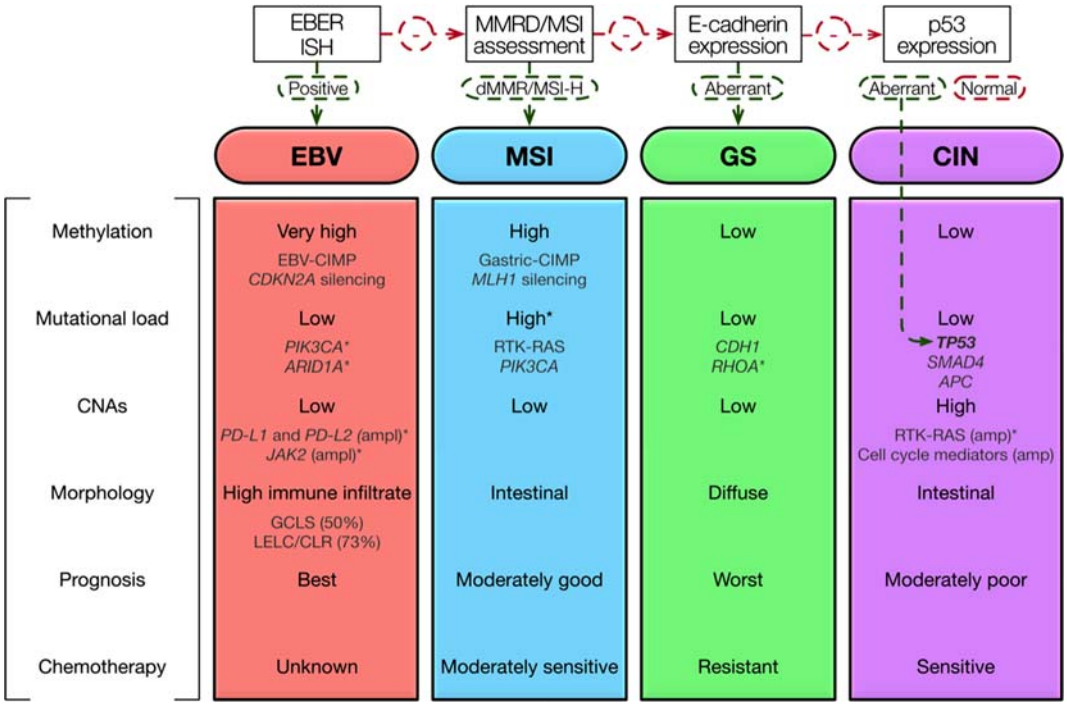

Fig. 9 The molecular classification of gastric cancer proposed by The Cancer Genome Atlas (TCGA) recognizes four molecular subtypes with distinct characteristics. EBER-ISH, EBV-encoded small RNA in situ hybridization; EBV, Epstein–Barr virus; MMRD, mismatch repair deficiency; MSI, microsatellite instability; GS, genomically stable; CIN, chromosomal instability; CIMP, CpG island methylator phenotype; GCLS, gastric cancer with lymphoid stroma; LELC, lymphoepithelioma-like carcinoma; CLR, Crohn-like reaction.

The stomach is also affected by GAPPS syndrome (gastric adenocarcinoma and proximal polyposis of the stomach) that was recently recognized as a rare variant of familial adenomatous polyposis (FAP).

Hereditary diffuse gastric cancer (HDGC)

HDGC (OMIM #137215) is an autosomal dominant cancer syndrome characterized by signet-ring cell (diffuse) GC and lobular breast cancer. The genetic basis of this syndrome was discovered in 1998 by Guilford et al., who studied three Maori kindreds in New Zealand with multigenerational, diffuse GC, in which germline mutations of the *CDH1* gene were identified by linkage analysis and mutation screening. *CDH1* is a tumor suppressor gene, located on chromosome 16q22.1, and encodes epithelial cadherin (E-cadherin), a transmembrane glycoprotein governing the formation of *adherens* junctions and cell–cell adhesion.

In 1999, the International Gastric Cancer Linkage Consortium (IGCLC) defined families with HDGC syndrome, on the basis of clinical criteria. Guidelines for genetic counseling and *CDH1* mutational testing were updated in 2010 and 2015. The current guidelines to select patients for *CDH1* testing are described in **Table 2**.

An alternative genetically based nomenclature has been proposed, in which the term "HDGC" is restricted to families with germline mutations in the *CDH1* gene.

In clinically defined HDGC, *CDH1* mutations are detected in 30%–40% of cases. Most (80%) are pathogenic, truncating mutations. The remainder is missense mutations, which require in silico and in vitro functional studies to elucidate the pathogenicity. In addition to point mutations, *CDH1* germline deletions and promoter methylation have been found, respectively, in about 5% and 1% of HDGC families who tested negatively for point mutations. Another mechanism that has been implicated is germline monoallelic *CDH1* RNA downregulation (allelic imbalance), which is found in about 37% of HDGC families. *CTNNA1* gene, encoding α-E-catenin, which is also involved in intercellular cell adhesion, has been identified as the second gene whose germline alterations cause HDGC. In several familial/hereditary gastric cancer cases, germline mutations were identified in genes associated with other hereditary cancer predisposition syndromes, namely *BRCA2*, *TP53*, *STK11*, *SDHB*, *PRSS1*, *ATM*, *MSR1*, *PALB2*, *INSR*, *FBXO24* and *DOT1L*. *MAP3K6* and *MYD88* genes have been studied in depth, but there is no evidence to consider *MAP3K6* as a GC predisposing genes and the relevance of biallelic MYD88 germline mutations remain to be established. Taking all these data into account, only 16% of HDGC families are negative for germline alterations (**Fig. 10**).

Unlike the somatic *CDH1* mutations, which occur in sporadic GCs and cluster around exons 7 and 8, *CDH1* germline mutations in HDGC families span the whole length of the gene and no hot spots have been identified.

In HDGC, the *CDH1* wild allele can be inactivated by a number of mechanisms. Most frequently, this occurs via promoter hypermethylation (epigenetic modification) and less frequently by loss of heterozygosity (LOH) and *CDH1* mutations. Intragenic deletions in the wild-type allele were also reported.

Table 1 Molecular classifications of GC

Table 2 Clinical criteria, recommended screening and histopathological features of major hereditary syndromes affecting the stomach

Hereditary GC syndrome	*Clinical criteria*	*Recommended genetic testing*	*Histopathological findings*	*Surveillance/risk-reduction surgery*
Hereditary diffuse gastric cancer (HDGC)[a]	- Two or more patients with GC at any age, one confirmed diffuse GC; - Individuals with diffuse GC before the age of 40; - Families with diagnoses of both diffuse GC and lobular breast cancer (one diagnosis before the age of 50) - Gastric polyps restricted to the body and fundus with no evidence of colorectal or duodenal polyposis; - More than 100 polyps carpeting the proximal stomach in the index case or >30 polyps in a first-degree relative;	- *CDH1* mutational analysis; - Search for large *CDH1* rearrangements; - Search for *CDH1* allelic imbalance; - *CTNNA1* mutational analysis	- Diffuse GC and precursor lesions (in situ signet ring cell carcinoma, pagetoid spread of signet ring cells); - Lobular breast cancer	- Prophylactic (risk-reducing) total gastrectomy or annual endoscopic surveillance - Breast magnetic resonance imaging
Gastric adenocarcinoma and proximal polyposis of the stomach (GAPPS)[b]	- Predominantly FDPs, some having regions of dysplasia (or a family member with either dysplastic FDPs or GC); - Autosomal dominant pattern of inheritance; - Exclusion of another gastric polyposis syndrome and use of proton-pump inhibitors	*APC* promoter 1B mutational analysis	- Fundic gland polyposis of the stomach with areas of dysplasia; - Hyperplastic polyps of the stomach; - Adenomatous polyps of the stomach; - Mixed polyps with FGP-like, adenomatous and hyperplastic features; - Intestinal-type GC	- Endoscopic surveillance with biopsies, polipectomies or prophylactic (risk-reduction) gastrectomy
Familial intestinal gastric cancer (FIGC)	High incidence countries: - At least three relatives with intestinal GC, one of them a first-degree relative of the other two; - At least two successive generations affected; - In one of the relatives, intestinal GC diagnosed before the age of 50 Low incidence countries: - At least two first/second-degree relatives affected by intestinal GC, one diagnosed before the age of 50; - Three or more relatives with intestinal GC at any age	NA	Intestinal-type GC	NA

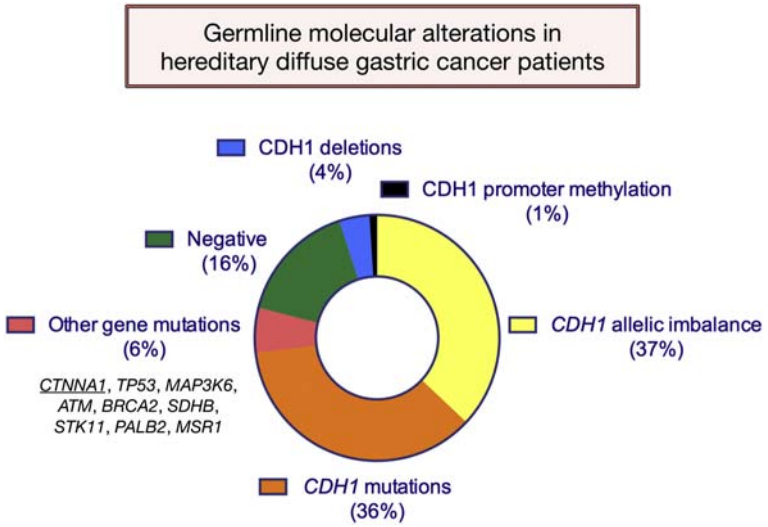

Fig. 10 Germline molecular alterations in hereditary diffuse gastric cancer.

Clinical features of HDGC

The age of onset of clinically significant diffuse GC may be extremely variable (with a range of 14–85 years), even within families. Prophylactic/risk-reduction total gastrectomy (PTG) in early adulthood is the only current curative approach. Indeed, age of onset is unpredictable and, at the time of clinical presentation, affected individuals present with advanced and frequently incurable disease, in >90% of cases. DGC frequently spreads beneath intact gastric mucosa and white light high definition endoscopy, chromoendoscopy, or endoscopic ultrasonography, have low sensitivity for detecting early HDGC.

Because of the great variability in the age of onset, the optimal timing of genetic testing/PTG is still controversial. The age at which to offer genetic testing to at-risk relatives should take into consideration the earliest age of cancer onset in that family. Testing from the late teens or early 20s is favored in families with early onset GC.

Current guidelines recommend that asymptomatic carriers of *CDH1* mutations be offered prophylactic gastrectomy or, for selected groups, annual endoscopic surveillance, as risk-reduction strategies. Surveillance is recommended for individuals aged less than 20 years; for those aged more than 20 years who elect to delay surgery; for those for whom prophylactic gastrectomy (biopsy-negative) is unacceptable but gastrectomy with curative intent (biopsy-positive) is acceptable; and for those with mutations of undetermined significance (e.g., missense). Total gastrectomy is recommended in at-risk family members greater than 20 years of age who have a *CDH1* mutation. In biopsy-positive individuals, a curative total gastrectomy is advised, regardless of age. In women, breast magnetic resonance imaging is advised, starting at 30 years of age.

Histopathology of HDGC

Early-stage HDGC in *CDH1* mutation carriers is characterized by multiple *foci* of invasive (T1a) signet-ring cell (diffuse) carcinoma in the superficial gastric mucosa (Fig. 11), with no nodal metastases. Mapping of the entire gastric mucosa performed in many

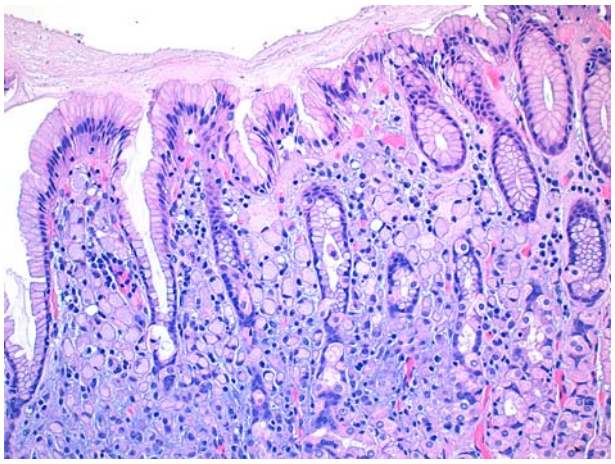

Fig. 11 Intramucosal signet ring cell carcinoma.

stomachs from kindred with different *CDH1* mutations showed that there is wide variation in the number of T1a *foci* observed in these stomachs, both within and between kindreds, ranging from one *focus* to hundreds of tiny *foci*. The cause of this variation in number of *foci* is currently unknown. Discordant results have been published regarding the anatomical localization of the cancer *foci*. Several authors reported a proximal clustering, which is in contrast with previous reports from New Zealand Maori kindred, where most *foci* were found within the body-antral transitional zone and distal stomach. The cause of this variation remains to be clarified, but genetic susceptibility and environmental factors have been suggested as possible contributing factors.

The signet ring cell (diffuse) carcinomas observed in asymptomatic *CDH1* mutation carriers show almost always abnormal staining for E-cadherin, in keeping with a clonal origin of the cancer *foci*, indicating that the second *CDH1* allele has been down-regulated or lost. Aberrant E-cadherin staining patterns include absence of immunoreactivity, reduced membranous expression, "dotted," and cytoplasmic staining, in contrast to the normal membranous, complete pattern of adjacent nonneoplastic gastric mucosa.

Two precursors (Tis) to T1a signet ring cell carcinoma are recognized in HDGC: (i) Pagetoid spread of signet ring cells, below the preserved epithelium of glands and foveolae but within the basal membrane (**Fig. 12**); (ii) in situ signet ring cell carcinoma, corresponding to the presence of signet ring cells within the basal membrane, substituting for normal epithelial cells, generally with hyperchromatic and depolarized nuclei (**Fig. 13**). In cases in which in situ carcinoma is identified adjacent to diffuse-type GC, genetic testing should be considered since this is rarely, if ever, seen in sporadic cases. In these lesions, E-cadherin immunoexpression is reduced or absent. Confirmation of in situ carcinoma by an independent histopathologist with experience in this area is strongly recommended.

The gross and microscopic appearances of advanced ($pT > 1$) HDGCs and sporadic DGC are indistinguishable. Because the neoplastic cells diffusely invade the gastric wall, "*linitis plastica*" is the most common gross phenotype. In contrast to the early,

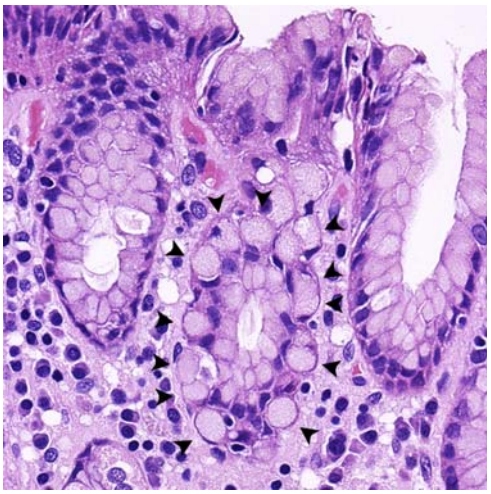

Fig. 12 Pagetoid spread of signet ring cells (arrowheads), below the nonneoplastic foveolar epithelium.

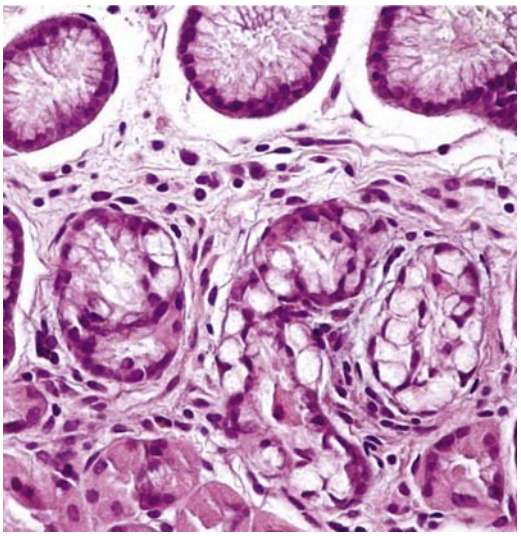

Fig. 13 In situ signet ring cell carcinoma.

"indolent" HDGC phenotype, advanced cases show frequently an aggressive phenotype and are composed of poorly cohesive, pleomorphic cells, sometimes admixed with classic signet ring cells. Glandular/tubular structures, rosettes and mucinous areas can be observed, particularly in foci of lymphovascular invasion and lymph-node metastasis.

The biological events leading to disease progression from early to advanced disease are poorly understood. Humar B et al. suggested that epithelial–mesenchymal transition (EMT) could mediate such progression and demonstrated the activation of c-Src kinase and downstream targets (p-Fak, fibronectin, and Stat-3) in poorly differentiated cells of intramucosal HDGC and more advanced lesions. Still, subsequent studies failed to reproduce such findings. More recently, we found a significant association between "aggressive" morphological features and aberrant (overexpressed) p53 immunoreactivity. These findings are consistent with those observed in murine models, which require inactivation of both *CDH1* and *TP53* genes for DGC development, and indicate that *TP53* may be involved in HDGC progression. Therefore, we suggest that p53 and Ki-67 may serve as biomarkers of prognosis and progression from indolent to widely invasive lesions, and that the finding of an "aggressive" phenotype in screening biopsies of *CDH1* mutation carriers should be taken as a predictive sign of widely invasive carcinoma and require prompt clinical intervention.

GAPPS (gastric adenocarcinoma and proximal polyposis of the stomach)

In 2012, a new hereditary syndrome was identified: "Gastric adenocarcinoma and proximal polyposis of the stomach" (GAPPS). GAPPS is a unique gastric polyposis syndrome with a significant risk of GC, characterized by the autosomal dominant transmission of fundic gland polyposis (FGP), with areas of dysplasia or intestinal-type GC, restricted to the proximal stomach, with no evidence of colorectal or duodenal polyposis or other heritable gastrointestinal cancer syndromes. Nine families have been reported in the literature, so far. Diagnostic criteria for GAPPS syndrome are described in **Table 2**. The syndrome is characterized by incomplete penetrance, with a few elderly obligate carriers having normal endoscopies.

GAPPS syndrome is characterized by florid gastric polyposis. The polyps (>100) are usually <10 mm in diameter and carpet the gastric body and fundus, with relative sparing along the lesser curve of the stomach (**Fig. 14**). The esophagus, gastric antrum, pylorus and duodenum are usually normal. The age of onset of widely invasive GC is variable, ranging from 23 to 75 years (median age of 50 years).

Histopathology is characterized by FGPs, including areas of dysplasia (**Fig. 15**). Hyperplastic, pure adenomatous and mixed polyps with FGP-like, adenomatous and hyperplastic features have also been described. GCs, detected in GAPPS patients, display the features of intestinal-type and mixed GC.

The genetic alteration underlined GAPPS syndrome has been recently identified: point germline mutations in promoter 1B of the *APC (Adenomatous Polyposis Coli)* gene (YY1 binding motif). Therefore, GAPPS syndrome has been interpreted as a variant along the broad phenotypic spectrum of familial adenomatous polyposis (FAP). Genetic testing for point mutations in *APC* promoter 1B is currently advised for patients fulfilling GAPPS diagnostic criteria.

Upper gastrointestinal endoscopy and colonoscopy is advised in all first-degree relatives of the probands.

Endoscopic surveillance with biopsies/polypectomies or prophylactic (risk-reduction) gastrectomy may be considered.

Gastric cancer in other hereditary syndromes

Several inherited cancer predisposition syndromes have been associated with increased risk of GC. These include FAP (*APC* germline mutations), *MUTYH*-associated polyposis, Lynch syndrome (germline mutations in DNA mismatch repair genes), Li–Fraumeni syndrome (*TP53* germline mutations), Peutz–Jeghers syndrome (*STK11* germline mutations), Juvenile Polyposis syndrome (*SMAD4/BMPR1A* germline mutations), hereditary breast and ovarian cancer syndrome (*BRCA1/BRCA2* germline mutations) and Cowden syndrome (*PTEN* germline mutations).

Microenvironment Including Immune Response

The tumor stroma, also referred to as tumor microenvironment (TME) is a complex, dynamic, and heterogeneous tissue, composed of extracellular matrix, vessels, nerves and numerous cell types, including fibroblasts, immune cells and endothelial cells. The inflammatory cells of the TME contribute to its complexity, by supplying also soluble molecules, including growth factors, survival and proangiogenic factors, chemokines, cytokines, metabolites, proteases and other enzymes that may facilitate progression, invasion and metastasis.

Increasing evidence demonstrated the essential role of the interplay between tumor cells and the TME in sustaining tumor cell survival and behavior, tumor growth and progression, contributing to the acquisition of hallmarks traits. In addition, the TME has been associated with response to chemotherapy, affecting drug delivery and efficacy.

Cancer Associated Fibroblasts and Extracellular Matrix

Cancer associated fibroblasts (CAFs) are frequently the most common cell type in TME and play a critical role in regulating the tumor–stroma interactions. Compared to normal fibroblast, CAFs present a cancer-promoting phenotype, with proprieties that resemble the fibroblasts involved in wound healing, and are regulated by protumoral growth and inflammation factors, including, among many others, platelet-derived growth factor (PDGF), TGF-β, and fibroblast growth factor-2 (FGF-2).

Available evidence suggests that an increase in CAF quantity and secretion of matrix components (collagen, fibronectin, etc.) and soluble components (hypoxia inducible factor, VEGF, fibroblast activating protein, metalloproteinases, TGF-β, osteopontin, etc.) is associated to bad prognosis and resistance to chemotherapy, and explain, at least in part, the poor prognosis of diffuse GC patients, whose tumors are frequently characterized by a prominent desmoplastic reaction.

To assess the prognostic and predictive significance of CAFs/extracellular matrix, recent studies have quantified, by morphometric evaluation, the proportion of intra-tumor stroma within GC specimens. A high tumor stroma percentage, defining a "desmoplastic microenvironment," was found to be associated with worse prognosis and rapid tumor progression. By contrast, tumors characterized by high immune infiltrate and low desmoplastic response, were related to early clinical stages and favorable prognosis.

A recent molecular study, based on large transcriptomic data, identify a gene expression program of stromal-related genes ("stromal super-module"), characterized by TGF-β signaling, poor patient survival and high percentages of intratumoral stroma. Such findings suggest that the morphological, morphometric evaluation of tumor stroma may be useful in the daily pathologist's practice, as may serve as a surrogate marker for stromal gene expression and may be predictive of therapies targeting TGF-β signaling.

Tumor Immune Microenvironment

The inflammatory response against tumor has been shown to play an important role in cancer development and progression. Immunosuppression has been considered a new hallmark of cancer. As such, the tumor immune microenvironment, that is, the immune cells that populate the tumor stroma and the soluble factors produced by them, is emerging as prognostic and predictive biomarkers, and, in recent years, many efforts have been made aiming to understand the complex interplay between cancer cells and the host immune system.

The immune context is a double-edge sword in cancer: immunity has not only a host-protective function, by recognizing and protecting tissues from nascent tumor cells ("cancer immune-surveillance"), but also a tumor- promoting action, resulting in tumor

"escape" from immune-surveillance. The tumor cells and the immune cells within the TME can shape the immune response and facilitate tumor cell growth, survival and metastatic potential.

Both tumor-antagonizing and tumor-promoting immune cells can be found in most neoplastic lesions in different proportions, which influence the delicate equilibrium between the phase of tumor elimination or escape. Anti-tumor immune cells include both cells of the innate immune system, for example, dendritic cells, natural killer cells, and cells of the adaptive immune system, for example, tumor-specific CD8+ effector T cells (cytotoxic T lymphocytes), CD4+ helper T cells, and T memory cells.

Tumor associated macrophages (TAM) may present different pattern of differentiation, displaying tumor-suppressing (M1) or tumor-promoting (M2) phenotypes. The M2 macrophages increase immunosuppression and angiogenesis and are associated with unfavorable outcomes. Besides M2 macrophages, a protumorigenic immune infiltrate may be constituted of myeloid derived suppressor cells (MDSCs), neutrophils, regulatory T cells (Tregs) and T helper interleukin (Th17) cells.

The impairment of antigen presentation, for example, alterations of MHC complex, the decrease of costimulating signal pathways of T cells, for example, CD28 interaction with B7-1 (CD80) and B7-2 (CD86), and the aberrant increase of coinhibitory molecules of T cells, for example, CTLA-4, PD-1, PD-L1, LAG-3, TIM-3, are other important factors that may contribute to immune evasion and that may be enhanced by a TME enriched by Tregs.

The systemic inflammatory response is also emerging as having a key role in cancer progression, and may influence the TME composition. Several systemic inflammatory indicators differ between GC patients and healthy controls and have been pointed as independent prognostic factors. Such parameters include preoperative values of neutrophil/lymphocyte ratio (NLR), platelet/lymphocyte ratio (PLR), plasma fibrinogen, plasma albumin and C-reactive protein, among others.

The deeper knowledge of the tumor immunobiology enabled a direct translation into immunotherapy. Antibodies blocking the interaction between PD-1 and PD-L1 have been used with promising results in several cancer types, including GC. In September 2017 the Food and Drug Administration (FDA) approved the use of pembrolizumab, an anti-PD-1 antibody, for the treatment of patients with recurrent, locally advanced or metastatic, GC/EGJC with PD-L1 expression.

Although the relation between PD-L1 expression and response to PD-1/PD-L1 immune checkpoint inhibitors is not straightforward, PD-L1 expression, evaluated by immunohistochemistry, is the current available biomarker to predict response to immune checkpoint blockade.

A recent study demonstrated that MSI-high solid tumors, regardless of the cancers' tissue of origin, respond better to immune checkpoint blockade, compared to MSS tumors, and the FDA approved pembrolizumab as a treatment also for patients with unresectable or metastatic, MSI-H or mismatch repair deficient solid tumors.

Staging and Grading

Staging

The American Joint Committee on Cancer (AJCC) staging system defines the staging of GC. The most recent edition (Eight Edition) was published in 2017 and is described in the next paragraphs.

The staging of GC encompasses the evaluation of the tumor in the gastric wall (T stage), lymph nodes (N stage) and distant organs (M stage) (**Fig. 16** and **Table 3**). In the gastric wall, GC is staged as T1 (invasion of the mucosa or muscularis mucosae—T1a; or infiltration of the submucosa—T1b), T2 (invasion of the muscularis propria), T3 (invasion of the subserosa) and T4 (penetration of the serosa—T4a; or invasion of adjacent structures—T4b).

Nodal staging is based on the number of metastatic lymph nodes: N0 (no regional lymph-node metastasis), N1 (metastasis in 1–2 regional lymph nodes), N2 (metastasis in 3–6 regional lymph nodes), N3 (metastasis in 7–15 regional lymph nodes—N3a; or in 16 or more regional lymph nodes—N3b). Adequate N staging requires that at least 16 lymph nodes to be examined and, thus, careful examination of surgical resection specimens by pathologists. The ideal number of lymph node to be evaluated is ≥ 30. If the minimum number of lymph nodes is not reached, a pN category should be attributed nevertheless.

For M staging, M0 corresponds to the absence of distant metastasis and M1 to the presence of distant metastasis. It is worthy of note that the designation of pM0 must not be used: if a suspected metastatic site is biopsied and the biopsy is negative, the disease should be classified as cM0. To assign a pM1 category, histopathological diagnosis is required.

Prognostic and Predictive Biomarkers

EGCs have a low incidence of vessel invasion and lymph-node metastasis and a good prognosis (about 90% of patients survive 10 years). If untreated, 63% of EGCs progress to advanced tumors within 5 years. Lymph-node metastasis occurs in 10%–20% of all EGCs: various multivariate analyses have identified (1) submucosal invasion, (2) tumor diameter >3.0–3.5 cm, (3) the presence of vascular invasion, (4) the presence of lymphatic permeation, (5) depressed or ulcerated subtypes and (6) undifferentiated histology as independent risk factors for nodal metastasis. For patients meeting these criteria, endoscopic resection is likely to be an ineffective therapeutic modality and surgery should be considered. However, some authors claim that small intramucosal GCs of undifferentiated histology, measuring <20 mm in size and without lymphovascular invasion have a negligible risk of lymph-node metastasis and could also be considered for endoscopic resection.

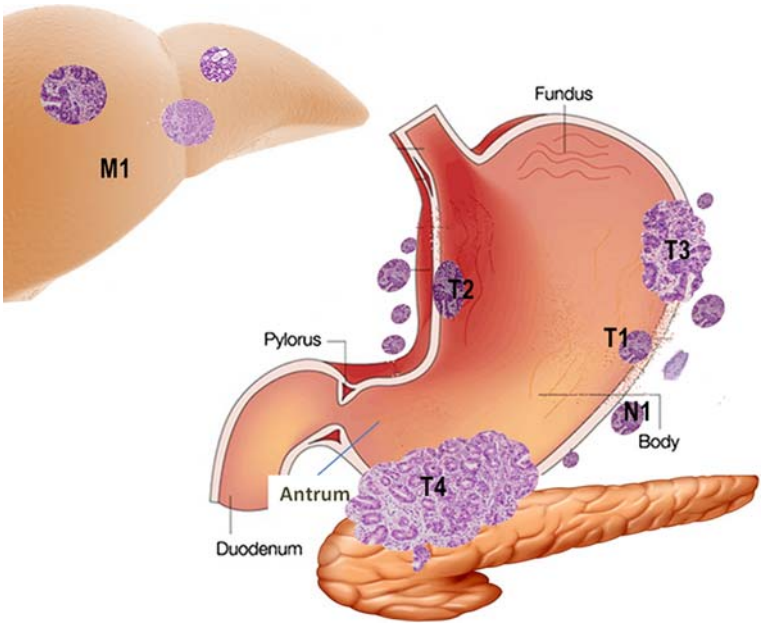

Fig. 16 Staging of gastric carcinoma.

Table 3 TNM classification of gastric carcinoma[a]

T	*Primary tumor*
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ: intraepithelial tumor without invasion of the lamina propria, high-grade dysplasia
T1	Tumor invades lamina propria, muscularis mucosae, or submucosa
T1a	Tumor invades lamina propria or muscularis mucosae
T1b	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor penetrates the subserosal connective tissue without invasion of the visceral peritoneum or adjacent structures
T4	Tumor invades the serosa (visceral peritoneum) or adjacent structures
T4a	Tumor invades the serosa (visceral peritoneum)
T4b	Tumor invades adjacent structures/organs
N	*Regional lymph nodes*
Nx	Regional lymph node(s) cannot be assessed
N0	No regional lymph-node metastasis
N1	Metastasis in one or two regional lymph nodes
N2	Metastasis in three to six regional lymph nodes
N3	Metastasis in seven or more regional lymph nodes
N3a	Metastasis in seven to 15 regional lymph nodes
N3b	Metastasis in 16 or more regional lymph nodes
M	*Distant metastasis*
M0	No distant metastasis
M1	Distant metastasis

[a]Ajani, J.A., In, H., Sano, T., et al. (2017). Stomach. In Amin, M.B., Edge, S.B., Greene, F.L., et al. (eds.). *AJCC cancer staging manual*. 8th edn., pp. 203–220. New York: Springer.

In Japan, the 5-year survival for T2 adenocarcinoma is 60%–80% and decreases to 50% for T3 tumors. Lower survival rates have been observed in the West. Female sex and Japanese ethnicity have been associated with a survival advantage. Higher frequency of early-stage carcinomas, accurate staging and surgical expertise has also been associated with improved survival in Japan compared to Western nations.

The stage of GC with special reference to extension to the serosa and lymph nodes (summarized in the TNM staging system) remains the strongest prognostic indicator. Five-year survival is 60%–80% for patients with tumors that invade the *muscularis propria*, but 50% for those with tumors invading the subserosa. At the time of diagnosis most patients with advanced carcinoma already have nodal metastases. Lymphatic and vascular invasion, often seen in advanced cases, carry a poor prognosis. In patients with involvement of 1–6 lymph nodes, the 5-year survival rate is 46%, compared with 30% in patients with more than seven lymph

nodes involved. The extent of the regional lymphadenectomy performed and the quality of lymph-node evaluation are relevant. Patients undergoing a "curative" gastrectomy but limited lymph-node dissection (D1/D0) have an overall 5-year survival of only 23%, versus more than 50% for those undergoing a more aggressive lymphadenectomy (D2).

In resectable cases, complete tumor removal with negative margins (R0) is important. The depth of invasion, the number of positive lymph nodes and postoperative complications are important prognostic factors. After curative resection, recurrence is loco-regional (resection margins, surgical bed and/or regional lymph nodes) in 40% of cases and systemic (liver and peritoneum) in 60% of cases. Whether distal adenocarcinomas have a better prognosis compared with proximal carcinomas is debated. Saito and colleagues reported a 5-year survival rate of 62% in patients with carcinoma of the "cardia" versus 83% for those with carcinoma of the lower third of the stomach. In another series, however, the prognoses were equally grim, with 28% and 29% survival rates, respectively.

Histological Features and Prognosis

The value of histological typing in predicting prognosis is controversial. Whether the prognosis for diffuse carcinoma (Lauren classification) is or is not worse than that for intestinal carcinoma is debated. Recently, it has been suggested that diffuse carcinomas encompass lesions with different prognoses, such as a low-grade desmoplastic subtype (with no or scarce angio-lympho-neuroinvasion) and a high-grade subtype (with anaplastic cells). The prognosis is particularly bad for children and young adults with poorly cohesive carcinoma, for whom diagnosis is often delayed.

Mixed GC displays more aggressive features than "pure" intestinal and diffuse GC, including larger tumor size, deeper invasion, lymphatic invasion, and lymph-node metastases. Interestingly, mixed GC shows a dual metastatic pattern, including hematogenous metastases and peritoneal dissemination with lymph-node metastases, suggesting a cumulative effect of the adverse behaviors of intestinal and diffuse-type GC.

The prognostic significance of histological typing is limited, also because of the intra-tumor heterogeneity of GC, that is, the presence of distinct morphologic patterns in the tumor. Solid, trabecular, tubular and poorly cohesive components frequently coexist in the same tumor. This limitation applies particularly to biopsy specimens.

HER2 Expression/Amplification

HER2 overexpression and/or amplification are found in 7%–38% of EGJC/GC, being slightly more frequent in EGJ tumors. HER2 is a transmembrane TKR of the epidermal growth factor receptor (EGFR) superfamily, which regulates cell proliferation, survival, differentiation, migration, and other cancer-relevant cellular responses.

The prognostic significance of this biomarker is debated, but *HER2* expression/amplification is a predictive biomarker of response to HER2-targeted therapy. In 2010, the phase III ToGA (trastuzumab for GC) trial (ClinicalTrials. gov identifier: NCT01041404) demonstrated a significant improvement in response rate, progression-free survival, and overall survival with the addition of trastuzumab to chemotherapy compared with chemotherapy alone, in prestratified patients with HER2-positive GEJC/GC. Since then, the use of trastuzumab with conventional chemotherapy has been approved by the FDA and the European Medicines Agency (EMEA) as first line therapy in advanced (defined as unresectable loco-regional, recurrent, or metastatic disease) HER2- positive GEJC/GC patients. An HER2-positive status, evaluated by IHC (3+) and/or fluorescent or chromogenic ISH (HER2+/ISH+) (Fig. 17), is predictive of the patient response to Trastuzumab-based treatment.

Compared to breast carcinoma, HER2 expression in GEJC/GC is highly heterogeneous and membrane immunoreactivity is often incomplete. Consequently, a HER2 scoring system specific for EJGC/GCs has been proposed, that is quite different from that of

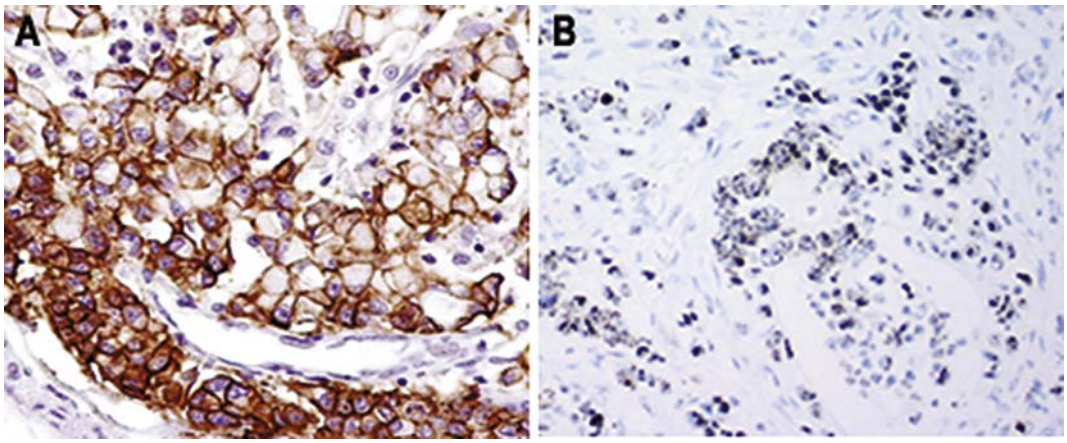

Fig. 17 Expression of HER2: (A) immunohistochemistry, displaying strong immunoreactivity at the cell membrane (IHC 3+), (B) *HER2* gene amplification confirmed by chromogenic in situ hybridization.

Table 4 HER2 testing in gastric cancer[a]

Score	*Criteria for resection specimens*	*Criteria for biopsy specimens*	*Interpretation*
0	No reactivity or membranous reactivity in $<10\%$ of tumor cells	No reactivity in any tumor cells	Negative
1+	Faint (generally visible only at 400× magnification) complete, basolateral, or lateral membrane staining in $\geq 10\%$ of tumor cells	Cluster(s) of at least five tumor cells with faint (generally visible only at 400× magnification) complete, basolateral or lateral membrane staining, irrespective of percentage of tumor cells stained	Negative
2+	Weak to moderate (generally visible only at 100–200× magnification) complete, basolateral, or lateral membrane staining in $\geq 10\%$ of tumor cells	Cluster(s) of at least five tumor cells with weak to moderate (generally visible only at 100–200× magnification) complete, basolateral or lateral membrane staining, irrespective of percentage of tumor cells stained	Equivocal: perform ISH testing
3+	Strong (generally visible at 25–50× magnification) complete, basolateral, or lateral membrane staining in $\geq 10\%$ of tumor cells	Cluster(s) of at least five tumor cells with strong (generally visible at 25–50× magnification) complete, basolateral or lateral membrane staining, irrespective of percentage of tumor cells stained	Positive

ISH, in situ hybridization.

[a]Bartley, A.N., Washington, M.K., Colasacco, C., et al. (2017). HER2 testing and clinical decision making in gastro-esophageal adenocarcinoma: Guideline from the College of American Pathologists, American Society for Clinical Pathology, and the American Society of Clinical Oncology. *Archives of Pathology & Laboratory Medicine* **140**(12), 1345–1363.

breast cancer (Table 4). The College of American Pathologists, American Society for Clinical Pathology, and American Society of Clinical Oncology published in 2016 new guidelines for HER2 testing in EGJC/GC. Among others (see Further Reading), the authors suggest to follow these recommendations: (1) in EJGC/GC patients who are potential candidates for HER2-targeted therapy, the treating clinician should request HER2 testing on tumor tissue, preferably before the initiation of trastuzumab therapy; (2) laboratories/pathologists must specify the antibodies and probes used for the test and ensure that assays are appropriately validated; (3) pathologists should use the Ruschoff/Hofmann method in scoring HER2 IHC and ISH results; (4) pathologists should identify areas of invasive adenocarcinoma and also mark areas with strongest intensity of HER2 expression by IHC in specimens for subsequent ISH scoring when required; (5) HER2 testing on fine-needle aspiration (FNA) specimens (cell blocks) is an acceptable alternative.

Given the issue of intra-tumor heterogeneity of HER2 immunoreactivity, (1) pathologists should select the tissue block with the areas of lowest grade tumor morphology in biopsy and resection specimens. More than one tissue block may be selected if different morphologic patterns are present; (2) testing of multiple biopsy fragments (from a primary or metastatic site), or from the resected primary tumor, is preferred. For biopsy specimens, current recommendations state that, when possible, a minimum of five biopsy specimens and optimally, six to eight, should be obtained.

Other Prognostic/Predictive Biomarkers

Advances in genomic and molecular research have provided large data on molecular biomarkers and genetic tests with promising prognostic and predictive significance. However, despite this rapidly increasing body of evidence, the only predictive markers currently in use for EJGC/GC are HER2 and PD-L1 and no other prognostic factors, besides T, N, M categories, have been recognized for use in the clinical practice. Nevertheless, some recent findings, on molecular biomarkers, are worth of mention.

MSI-H GC is diagnosed more frequently at early stages (Stage I or II) and, among the molecular subtypes defined by TGCA/ARGC, has the best prognosis. A study demonstrated that GC patients with MSI-H or mismatch repair protein deficiency (MMRD) have better survival compared to MSS tumors, when treated with surgery alone. Conversely, MSI-H GC patients have poor survival, when treated with perioperative chemotherapy plus surgery, compared to MSS GC patients. These findings suggest that patients with MSI-H or MMRD may not benefit from perioperative chemotherapy. The study of additional cohorts will be necessary to confirm such data for the application in clinical practice.

MSI-high status and PD-L1 immunoreactivity are predictors of response to monoclonal antibodies directed to immune checkpoint inhibitors (see "**Microenvironment Including Immune Response**" section).

FDA approved Ramucirumab, a recombinant monoclonal antibody that targets the vascular endothelial growth factor receptor 2 (VEGFR2) for use as a single agent for the treatment of patients with advanced or metastatic EJGC/GC. However, no immunohistochemical/molecular biomarker is available to predict response to this targeted therapy.

Genetic Instability

Meiyun Guo, Lin Mei, and Christopher A Maxwell, University of British Columbia, Vancouver, BC, Canada

Glossary

Chromosomal instability Is defined as an increased rate of change in the structure or number of chromosomal segments or whole chromosomes, including amplification, deletion, loss of heterozygosity, translocation, insertion, inversion, and homozygous deletion.

Chromothripsis Is a chromosomal instability phenomenon where hundreds of chromosomal rearrangements occur during one event in a localized region of one or a few chromosomes.

DNA double-strand break Essentially separates the DNA double-helix molecule into two pieces.

Genetic instability Refers to alterations in the DNA of tumor cells, ranging from single nucleotide mutations to changes in chromosomal structures and numbers.

Microsatellite instability Is characterized by the expansion, shortening, deletion or insertion of microsatellites and is often attributed to the impairment of the mismatch repair pathway.

Nucleotide instability Is an increased occurrence of mutations, including base substitutions, deletions and insertions of one or several nucleotides.

Cancer is thought to arise as a result of continuous changes to the genome resulting from random mutation and followed by natural selection applied on the cancerous cell and its progeny by the environment, including by neighboring cancerous cells, infiltrating immune cells, energy and oxygen requirements, exposure to drugs, etc. Early observations of cancer cell division by von Hansemann (1847) and Boveri (1914) indicated that cancer cells were characterized by abnormal hereditary material. Indeed, many cancers contain cells with abnormal chromosome numbers (aneuploidy) or translocations, such as the Philadelphia translocation between chromosomes 9 and 22 in chronic myeloid leukemia. Some propose that cancer is a chromosome rather than a genetic disease due to the frequency that aneuploidy is observed in cancer. Concurrently, the cancer cell genome accumulates several different genetic alterations ranging from single nucleotide variation to insertions or deletions to focal or large scale copy number alterations. It is apparent that some of this variation contributes to a greater degree to the growth and survival advantage observed in cancers; other alterations, termed passenger, may have little function on tumor development. The term genetic instability encapsulates this impressive degree of heterogeneity and the changes to this heterogeneity over time, which is observed in the cancer cell component of the tumor and also in the neighboring cells. This article will review the classification and detection of genetic instability; the cellular and tissue mechanisms for its suppression; environmental factors that induce genetic instability; the relationship between instability, the immune system and cancer progression; and, the emerging approaches to treat a heterogeneous and unstable tumor.

Classification and Detection of Genetic Instability

Genetic instability refers to alterations in the DNA of tumor cells, ranging from single nucleotide mutations to changes in chromosomal structures and numbers. It is important to note that genetic instability refers to changes over time rather than the simple appearance of a mutation or an aneuploid genome. These genetic changes can be divided into the following three categories: nucleotide instability, microsatellite instability, and chromosomal instability (Fig. 1).

Nucleotide Instability

Nucleotide instability is an increased occurrence of mutations, including base substitutions, deletions, and insertions of one or several nucleotides. Replication errors and malfunction in repair pathways, such as base excision repair and nucleotide excision repair, can lead to nucleotide instability. Although nucleotide instability induces small-scale changes in DNA sequence, nucleotide instability can lead to dramatic phenotypic changes, including the development of malignancy, through altered gene expression and changes to the structure or function of the affected gene products. Importantly, nucleotide instability refers to the mutation rate rather than the presence or abundance of mutations in a particular cancer. For example, by analyzing the number of mutations per cell division in human breast cancer cell lines, spontaneous point mutation rates were found to be increased (2.9X to 12X) relative to a nonmalignant mammary epithelial cell line or a colorectal cancer cell line. More recently, single nucleus gene sequencing,

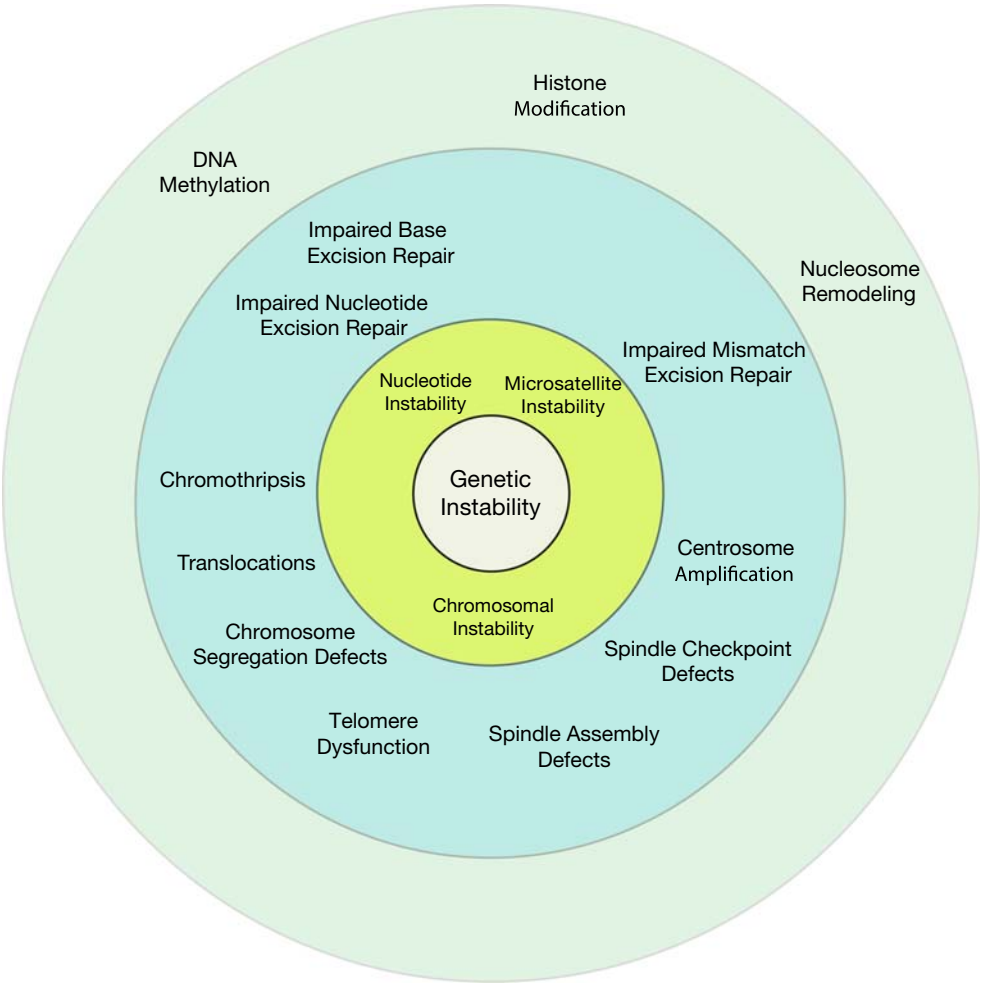

Fig. 1 An overview of the types of genetic instability and the pathways that generate genetic instability. The *yellow inner circle* displays the three main types of genetic instability. The *middle blue circle* displays some processes that result in the three types of genetic instability. The *outermost green circle* represents the epigenetic modifications that affect DNA repair pathways.

in combination with mathematical modeling, found cells comprising a triple negative breast cancer demonstrated an increased mutation rate (13.3X) relative to normal cells and this breast cancer exhibited extraordinary genetic diversity in isolated tumor nuclei.

Microsatellite Instability

Microsatellites, or short tandem repeats, are DNA repeats consisting of one to six base pairs that occur throughout the genome. The distribution of microsatellites in eukaryotic genomes is not random and they display different properties in different genomic regions. Microsatellite instability is characterized by the expansion, shortening, deletion, or insertion of microsatellites and is often attributed to the impairment of the mismatch repair pathway. Changes to microsatellite sequences are thought to occur during DNA replication due to polymerase slippage that is inefficiently mended due to a deficient mismatch repair response. About 15% of colorectal cancers exhibit deficient mismatch repair and microsatellite instability and the inheritance of mutations in mismatch repair genes, such as *MLH1* and *MSH2*, can predispose a hereditary cancer predisposition syndrome (Lynch Syndrome) that associates with an elevated risk to develop nonpolyposis colon cancer.

Chromosomal Instability and Chromothripsis

Chromosomal instability is highly prevalent in human cancers with about 90% of tumors displaying chromosomal abnormalities. Chromosomal instability is defined as an increased rate of change in the structure or number of chromosomal segments or whole chromosomes, including amplification, deletion, loss of heterozygosity, translocation, insertion, inversion, and homozygous deletion. The consequence of chromosomal instability can be severe owning to the large-scale alterations that can affect the expression

of thousands of gene products and, as a result, can dramatically alter cancer cell phenotypes that enable progression or endow intrinsic multidrug resistance. Therefore, many cellular mechanisms are dedicated to the preservation of chromosome stability, including DNA repair pathways, telomere regulation, and checkpoints to ensure mitotic spindle assembly and chromosome segregation.

Chromothripsis is a chromosomal instability phenomenon where hundreds of chromosomal rearrangements occur during one event in a localized region of one or a few chromosomes (Fig. 2). An analysis of 746 cancer cell lines revealed that more than 2%–3% of cancers display massive genomic rearrangements on one chromosome. It is proposed that the massive rearrangements occur from one single chromosome fragmentation event followed by faulty DNA repair that joins the fragments together. DNA sequencing analysis of a patient with chronic lymphocytic leukemia revealed some characteristics of chromothripsis. First, chromothripsis occurs at specific locations of the genome while rearrangement events that characterize conventional genetic instability are assumed to occur randomly across the genome. Second, the copy number at many regions in an individual chromosome changes between one or two copies, and regions with only one copy are not generated simply by deletion but through rearrangements. Third, the breakpoints at the chromosome arm are clustered so that multiple rearrangements take place within a narrow region, and the fragments of the chromosome connected at breakpoints are originally located distal from each other. Since the locations of breakpoints are clustered, it is plausible that chromothripsis occurs during chromosome condensation related to mitosis. The occurrence of chromothripsis is especially high in bone cancers, but the process is not restricted to a specific tumor subtype.

Detection of Genetic Instability

As illustrated above, genetic instability occurs across multiple genetic levels. Thus, methods that measure changes in chromosomes, microsatellites, or nucleotides are adequate to measure a component of genetic instability. Such methods include, but are not limited to, karyotyping, flow cytometry, single nucleotide polymorphism arrays, whole-genome sequencing, and polymerase chain reaction. However, the measurement of the mutation rate or the change of the mutation rate over time can be challenging. Changes to the mutation rate or karyotype can be determined for immortalized cell lines and tumor evolution can be inferred by the examination of multiple sites of the same tumor or the progression of a tumor over time; that is, from diagnosis through minimal residual disease to metastasis or first relapse or second relapse. In addition, a variety of methods are often used to calculate the frequency and extent of genetic changes for static tumor cell populations, which are frequently used as a surrogate to describe genetic instability.

Intratumor heterogeneity is one surrogate marker of genetic instability. Recent developments in the field of single-cell sequencing now resolve cell-to-cell genetic heterogeneity at a base-pair level within a tumor and through tumor evolution. That is, comparative analysis of temporally and spatially distinct regions in a single tumor has revealed clonal dynamics and intratumor heterogeneity. Single-nucleus-sequencing is a method that combines flow-sorting, whole genome amplification and next-generation sequencing to produce genome-wide datasets from single cancer cells. Based on data obtained from this new approach, a punctuated model of chromosome evolution is now postulated, which challenges the model of gradual chromosome evolution. Data from single-nucleus-sequencing imply that chromosome alterations occur at initial stages of carcinogenesis. This method has also uncovered

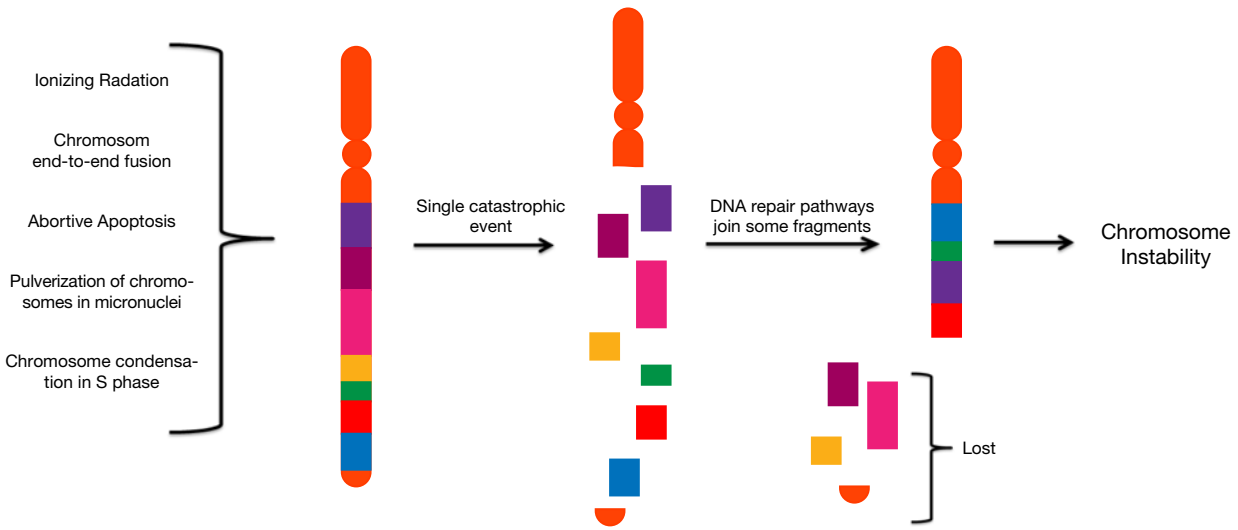

Fig. 2 Chromothripsis leads to chromosomal instability and is often found in aggressive tumor cells. There are several proposed insults that can induce chromothripsis, including ionizing radiation acting on condensed chromosomes, chromosome end-to-end fusion caused by telomere shortening that leads to a double strand break, abortive apoptosis, pulverization of chromosomes in micronuclei, and chromosome condensation that occurs in S phase. These insults may cause a single catastrophic event which fragments specific regions of a chromosome. During the subsequent DNA repair, some of the chromosomal fragments are lost and some are rearranged.

large numbers of subclonal and de novo mutations that were identified to occur at low frequency (< 10%). This illustrates perhaps that no single tumor cell is genetically identical to another in the analyzed primary tumors. Such radical diversity in an evolving tumor context illustrates the remarkable plasticity with which a tumor can respond to a variety of challenges, including those presented by neighboring cancerous cells, infiltrating immune cells, energy and oxygen requirements, and exposure to therapy.

Mechanisms That Suppress Genetic Instability

Genetic instability can occur across many genetic levels, ranging from base-pair changes, to focal or large scale amplifications or deletions, to whole chromosome gains and losses. The cell possesses multiple mechanisms to dampen the development of an unstable genome including: processes that ensure the replication of the genome occurs with high-fidelity; processes that recognize and repair mutations when they arise; and, processes that ensure cell division results in genetically identical daughter cells.

High-Fidelity DNA Replication

The replication of DNA must occur with high fidelity and, therefore, is guarded by many factors. A detailed review of DNA replication is beyond the scope of this article. Briefly, the fidelity of DNA replication depends upon the quality of the template, the selectivity and proofreading of the polymerase, the supply of nucleotides during the process and, finally, the repair of errors by the mismatch repair process. DNA lesions in the template can present challenges to the replicative DNA polymerase and affect the selection of the incoming nucleotide or activate a checkpoint. The MTH1 protein can remove some oxidized dNTPs that may present difficulties to the polymerases. Three DNA polymerases are responsible for eukaryotic DNA replication: DNA polymerase α (Pol α), DNA polymerase δ (Pol δ), and DNA polymerase ε (Pol ε). Theses enzymes individually form a complex with the DNA template and bind a nucleotide and two metal ions in the active site of the enzyme, which induces a conformational change in the polymerase (an induced fit mechanism) that imparts high selectivity to these enzymes (about 1 error per 10^4 to 10^5 nucleotides). Proofreading by DNA Pol δ and Pol ε, which contain an exonuclease activity, and mismatch repair further improves replication fidelity. It is proposed that due to the combination of these processes the error rate for DNA replication is 1 error per 10^9–10^{10} nucleotides.

DNA Repair Pathways

DNA repair pathways are important safeguards to maintain genetic stability and distinct pathways are responsible for the recognition and repair of different types of DNA damage.

Nucleotide excision repair. Nucleotide excision repair can act on a wide range of DNA lesions with different structures, such as lesions caused by ultraviolet radiation, intrastrand crosslinks, chemical adducts, and reactive oxygen species-generated cyclopurines. Nucleotide excision repair occurs during two lesion detection mechanisms: global genome nucleotide excision repair and transcription-coupled nucleotide excision repair. Global genome nucleotide excision repair searches for disturbed base pairing and distortions of nucleotide structures whereas transcription-coupled nucleotide excision repair is triggered by the stalling of RNA polymerase II due to a lesion on the DNA template strand. Deficiency in the process of global genome nucleotide excision repair, such as in Xeroderma pigmentosum (XP), can lead to the accumulation of lesions in the whole genome and result in cancer predisposition. For example, as a consequence of deficient global genome nucleotide excision repair, XP cells are very sensitive to ultraviolet radiation and XP patients have a higher risk of developing skin cancer than normal individuals.

Base excision repair. Reactive oxygen species produced from cellular metabolism are believed to underlie the majority of endogenous DNA damage and inappropriate repair of these oxidative lesions can induce oncogenic mutations. The base excision repair pathway detects and repairs DNA damage caused by oxidation, deamination, and alkylation. Base excision repair is initiated by a DNA glycosylase, which detects and cleaves the targeted base, generating a baseless site (AP site) that is edited by short-patch repair or long-patch repair. Importantly, AP sites are highly prone to mutagenesis and, as a consequence, genetic stability depends upon efficient and appropriate base excision repair.

DNA mismatch repair. A DNA mismatch refers to a non-Watson–Crick nucleotide base pair in double strand DNA. DNA mismatch repair is believed to reduce the amount of DNA errors 100 to 1000-fold. Mismatch repair begins with the detection of mismatched DNA by MutS, an essential protein in mismatch repair that activates downstream repair proteins. With the recruitment of MutL α, strand excision is initiated in a PCNA-, RFC- and ATP-dependent manner. Finally, DNA Pol δ or Pol ε and DNA ligase 1 complete the synthesis of the strand. Deficient mismatch repair is common in colorectal cancers (15%), endometrial cancer (30%), and hereditary ovarian cancer (10% to15%).

Double-strand break repair. A DNA double-strand break essentially separates the DNA double-helix molecule into two pieces. This is frankly more severe than a single strand break wherein the genetic information is still preserved on one intact strand; thus, double-strand breaks can lead to more severe consequences, such as fragmentation and alterations of chromosomes. Double-strand break repair mechanisms can be divided into nonhomologous end-joining and homology-directed repair. Nonhomologous end-joining can occur in all cell cycle phases whereas homology-directed repair requires a homologue and thus only occurs during S- and G2-phases of the cell cycle. Double-strand break repair is a critical tumor suppressive mechanism and deficiencies in these pathways, as the result of mutation to key components such as *BRCA1*, can causes genetic instability and cancer development. For example, female carriers of causal *BRCA1* mutations are more highly prone to develop breast and ovarian cancers and those tumors tend

to display a higher degree of aneuploidy and chromosomal rearrangements, which are potentially indicative of an elevated rate of genetic instability.

Epigenetics and Genetic Instability

While genetic instability refers to the rate of change of alterations encoded in the genome, epigenetic alterations impact not only the expression of molecular regulators of stability but also change the compaction and access to DNA, which directly influences the stability of the genome.

DNA methylation. DNA methylation refers to the attachment of a methyl group to the 5′ carbon of a cytosine ring, usually at CpG dinucleotides, which will alter (often turn off) the transcription of the affected genes. In cancer, the regulation of DNA methylation is impaired and can lead to hypomethylation at repeated sequences throughout the genome and hypermethylation at CpG islands. CpG islands contain 60% of the gene promoters and the hypermethylation of some CpG islands can lead to the reduced expression of tumor-suppressor genes. For example, a hypermethylated promoter region of the mismatch-repair gene *MLH1* causes microsatellite instability. On the other hand, a loss of overall DNA methylation is an epigenetic characteristic of cancer. Hypomethylation of tandem repeats at the centromere can decondense heterochromatin and enable genomic rearrangements. Whereas retrotransposons Alu and LINE-1 elements are silenced by DNA methylation in normal tissues, the overall hypomethylation that characterizes cancer can lead to their elevated activation, which, in the case of LINE-1 elements, can lead to their insertion into the genome and the induction of deletions or inversions.

Histone modification. Histone modifications, such as acetylation and methylation, can either activate or repress gene transcription. Histone acetylation occurs on lysine residues with an N-terminal tail extending from the nucleosome and can induce a chromatin conformation that is more accessible for protein binding. DNA double-strand break repair, for example, is very reliant upon protein access to DNA: histone deacetylase (HDAC) 1 and HDAC2 are recruited and regulate acetylation of histone H3 at sites with DNA damage. Consequently, a deficiency in HDAC1 and HDAC2 will impair double-strand break repair and can induce genetic instability. While histone methylation can either upregulate or suppress transcription depending on specific sites of methylation, SETD2-dependent H3K36 trimethylation regulates DNA mismatch repair while the lysine-specific histone demethylase 5B (KDM5B) enables DNA double-strand break repair. Consequently, cancers with impaired SETD2/HYPB methyltransferase activity may display chromosomal aberrations.

Nucleosome remodeling. The structure of chromatin is dynamic and can have either an "opened" or "closed" conformation, which regulates the accessibility of DNA segments and relies upon the arrangement of nucleosomes. The nucleosome remodeling process is vital to DNA double-strand break repair. Briefly, double-strand break repair requires: (1) the detection of DNA damages in chromatin structure; (2) access to the DNA damage site; (3) a proper organization of nucleosome and DNA for repair process; and, (4) restoration of the chromatin structure after repair. Nucleosome remodeling is needed for each of these processes and it is suggested that, as a consequence, DNA repair is less efficient in heterochromatin, which may lead to the accumulation of mutations in certain heterochromatin regions.

Cell Cycle Checkpoints

DNA damage is induced by many different factors, such as ultraviolet light and oxidizing agents, and these damages can trigger a pause, or checkpoint, in cell cycle progression to allow DNA repair pathways to recognize and repair the damage and prevent the damage from being inherited by progeny cells. The detection and repair of a double-strand break in G1 phase relies upon Ataxia Telangiectasia Mutated (ATM) kinase to phosphorylate and activate Chk2 kinase, which induces a G1-phase checkpoint by stabilizing p53 and, through cyclin-dependent kinase (Cdk) inhibitor p21, blocking cell cycle progression. During S-phase, DNA replication forks stall at genetically fragile sites leading to the binding of replication protein A and the recruitment of Ataxia Telangiectasia and Rad3-related (ATR) kinase, which activates Chk1 to degrade Cdc25A and induce a S-phase checkpoint. ATM and ATR oversee double-strand break repair pathways and can also arrest cells at G2-phase or during the transition from G2-phase into mitosis. Mutations in *ATM* predispose a tumor susceptibility syndrome with heightened risks to develop lymphomas and certain types of solid tumors, including breast cancer.

Chromosomal instability is suppressed by a critical checkpoint during cell division, termed the mitotic spindle assembly checkpoint. Mitosis is a process that ensures the equivalent segregation of the cell's genetic material to two daughter cells. Briefly, this process relies upon the construction of a microtubule-based structure, termed the mitotic spindle, and the coordinated actions of microtubule-associated molecular motor proteins and their adaptors. Microtubules are largely nucleated from two poles, termed centrosomes or spindle poles, as well as near to the chromosomes themselves, termed kinetochore (K)-fibers. These microtubules are aligned and organized into a bipolar structure that contacts each chromosome and forms a bipolar attachment at the kinetochore on each chromosome. A complex of proteins located at the kinetochores monitors microtubule attachment and the establishment of interkinetochore tension, which is a cue that helps fulfill the spindle assembly checkpoint and promotes the transition to anaphase. For example, Aurora kinase B is localized to the inner centromere and will phosphorylate components of kinetochore KNL/Mis12 complex/Ndc80 complex network to destabilize kinetochore-microtubule attachments in the absence of proper interkinetochore tension. Upon bipolar attachment, tension will stretch the kinetochores and separate the outer kinetochore components from Aurora kinase B. Deficiency in the spindle assembly checkpoint pathway, as induced for example through mutation of *BUB1B*, induce a tumor susceptibility disorder termed mosaic variegated aneuploidy.

Centrosome Amplification and Clustering

During cell division, it is vital that each chromosome attains bipolar attachment. However, almost all types of solid tumors display centrosome amplification, which is characterized by an abnormal number or size of centrosomes with, or without, an increased number of centrioles. Centrosome amplification can cause multipolar spindles, which can result in mitotic failure, mitotic death or aneuploidy. For instance, transgenic mice designed to express widespread centrosome amplification, through induced PLK4 overexpression, exhibit an increased tendency to generate lymphomas, squamous cell carcinomas, and sarcomas by 35 weeks of age.

Cancer cells seem to have developed a mechanism to cluster supernumerary centrosomes in order to avoid catastrophic multipolar cell division. Cells with supernumerary centrosomes undergo a MAD2-dependent delay before anaphase and tension on spindle microtubules is proposed to cluster centrosomes to form pseudo-bipolar spindles. Human cancer cells often overexpress proteins involved in the centrosome clustering process, which may permit these cells to bypass potential mitotic catastrophe that may result from recurrent multipolar cell divisions.

Telomere Length

Telomeres are G-rich repetitive sequences (TTAGGG) located at the end of chromosomes that maintain the integrity of replication and genetic stability by protecting the ends of chromosomes from degradation and chromosomal end fusion events. Telomeres are shortened gradually by chromosome end-processing during each cell division and telomere maintenance is required for ongoing cell division. Although telomere shortening prevents transformed cells from proliferating, it can also lead to chromosome breakage and instability. In some cancer types, mutations in *TERT* (encoding the catalytic subunit of telomerase) promoter regions were found to activate transcription suggesting that telomerase activation occurs during tumorigenesis. Moreover, longer telomere lengths may be associated with an increased risk to develop non-Hodgkin lymphoma or chronic lymphocytic leukemia. Telomere crisis can induce fusion of telomeres and lead to dicentric chromosomes, chromosome translocation, regional amplification, and eventually genetic instability.

Environmental Causes of Genetic Instability

In addition to reactive oxygen species produced by cellular metabolism, exogenous agents, such as X-rays, ultraviolet light, and various chemicals, can cause genetic changes that can promote cancer. DNA adducts, resulting from chemical carcinogens or ultraviolet radiation, are sensed by Xeroderma pigmentosum group C (XPC), which initiates the global genome nucleotide excision repair pathway to eliminate damage and maintain genome stability. However, additional precautions that reduce exposure will also dampen the initiation of genetic instability (Fig. 3).

Radiation

Ultraviolet radiation can penetrate tissue and cause biological damage. Ultraviolet radiation induces crosslinks between neighboring pyrimidines creating cyclobutane pyrimidine dimers and (6-4) photoproducts (6-4PPs). However, most organisms possess a very rapid, highly efficient, and safe enzymatic tool for the repair of photolesions in the form of DNA photolyases that, by

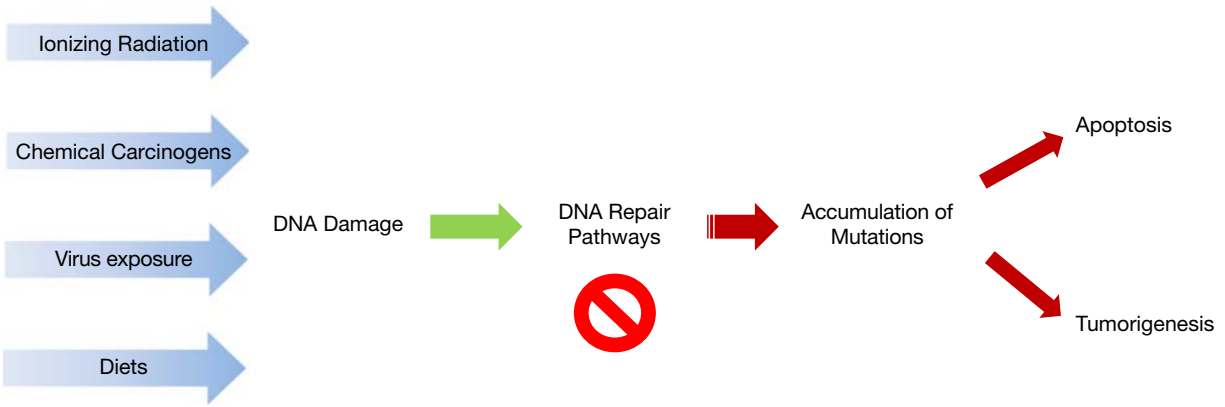

Fig. 3 External causes of genetic instability. Ionizing radiation, chemical carcinogens, exposure to virus and diets are the major mechanisms that cause DNA damage. In the presence of impaired DNA repair pathways, mutations in the DNA can accumulate and lead to programmed cell death or tumorigenesis.

light-driven catalysis, revert cyclobutane pyrimidine dimers or 6-4PPs to pyrimidine monomers without excision of bases or any deoxyribose-phosphate residues. It is believed that skin cancer, the most common cancer, is at least in part the consequence of ultraviolet damage. In melanoma, the majority of mutations are cytosine to thymine (C>T) at adjacent pyrimidine residues, which reflects the generation of thymine dimers after exposure to ultraviolet light. Protective barriers, including shade, ultraviolet-attenuating sunglasses or topical sunscreens, are an effective way to reduce exposure and damage.

Ionizing radiation is suggested to cause 1% to 3% of cancers and exposure to ionizing radiation can arise from cosmic and terrestrial radiation, radon, or medical applications. Like X-rays and gamma rays, ionizing radiation carries enough energy to move electrons from an atom. Ionizing radiation can cause direct DNA damage in tissues, including in the germline, which can induce birth defects and tumorigenesis.

Chemical Carcinogens

Genotoxic chemicals react directly with DNA while nongenotoxic carcinogens interfere with pathways that are critical for DNA repair or chromosome separation. Exposure to either of these classes of chemicals can induce DNA lesions and chromosome rearrangements. Examples of genotoxic chemicals, many of which are present in cigarettes, include polycyclic aromatic hydrocarbons (PAHs), *N*-nitrosamines, aromatic amines, aldehydes, benzene, and 1,3-butadiene. Exposure to PAHs, for example, can give rise to high levels of both 8-OHdG in urine and DNA damage detected by the alkaline comet assay. In addition, high levels of PAH–DNA adducts are seen in tobacco smokers that developed lung cancer. Exposure to benzene, a solvent historically used in printing inks and gasoline, may result in leukemogenesis, including acute myeloid leukemia, acute lymphocytic leukemia, chronic lymphocytic leukemia, and myelodysplastic syndrome. Exposure to nongenotoxic carcinogens, such as heavy metals, acrylamide, bisphenol A, or benomyl, disrupt DNA repair pathways, DNA damage signaling and chromosome segregation pathways and therefore impair genetic integrity. While it is not possible to absolutely avoid exposure to many of these chemicals, it is critical to limit one's exposure as completely as possible.

Virus

Human papillomaviruses (HPVs) are small DNA tumor viruses that can transform squamous epithelia. HPVs replicate their own genomes by reprogramming the host cell's DNA replication machinery. The high-risk HPV E6 and E7 oncoproteins target negative growth regulatory signaling in the host cell to enable viral genome replication in these postmitotic cells. HPV E6 and E7 oncoproteins disturb the normal regulation of cell division and centrosome duplication, which disrupts chromosomal integrity of the host cell and promotes the proliferation of HPV infected cells. Vaccines against HPV, including HPV-16 and HPV-18, may significantly reduce the prevalence of HPV-induced cancers. In addition, HPV-associated cancers may be combated through the enhancement of host immune responses and more effective antitumor immunity, as these cancers are believed to result in part from immunosuppressive factors. Combinatory therapy, partnering HPV vaccination with immune enhancement, may alter the pro-tumor inflammatory environment and suppress HPV-associated tumorigenesis.

Hepatitis C virus (HCV) infection is highly associated with hepatocellular carcinoma, one of the most common malignancy. HCV replicons can endow host cells with a variety of cancer stem cell-like traits. HCV proteins can also increase the production of reactive oxygen species by enhancing mitogenesis, blocking cell death, or inducing chronic inflammation. The oxidative stress caused by high levels of reactive oxygen species, and the accumulated DNA damage caused by increased cell proliferation and inflammation, may induce genetic instability that acts as the basis for HCV-mediated carcinogenesis.

Diet

Diet is an important environmental factor that influences cancer risk and may modulate genetic stability. There are several mechanisms by which diet can influence genome stability. First, folate plays a key role in several processes related to DNA integrity, such as DNA synthesis and methylation. In vitro studies have shown that folic acid deficiency causes increased uracil incorporation in human lymphocyte DNA. Folate administration reduces DNA uracil incorporation and the presence of chromosome breaks in human cells. A low folate concentration has also been implicated as a potential promoter of tumorigenesis in, for example, colorectal cancer, lung, breast, pancreatic, gastric, esophageal, and prostate malignancies. Second, niacin, or nicotinic acid, is one of the few vitamins that has an important role in DNA synthesis, DNA repair, and cell death. Niacin is required as a substrate for poly(ADP-ribose) polymerase 1 (PARP1), which is involved in DNA repair and telomere length maintenance. The consequence of niacin deficiency is an increase in the number of DNA breaks and in the rate of chromosome damage. Epidemiologic evidence indicates that intake of foods that are naturally rich in vitamin C is associated with reduced risk of various cancers, but the extent to which vitamin C contributes to this effect remains unclear. In general, low dietary intake of folate, nicotinic acid, calcium, vitamin E, retinol, and β-carotene and high intake of pantothenic acid, biotin, and riboflavin are associated with increased genetic instability indicating the importance of a balanced diet to the maintenance of genetic integrity. Finally, a greater understanding of the interconnection between diet, gut microbiota, the immune system, and cancer (including responses to immune-based treatments and immune surveillance) is an emerging and exciting field for future research.

Genetic Instability and Cancer Progression

Many human cancers arise in epithelial tissues and these cancers would be easily treated through surgery were they to remain in their tissues of origin; unfortunately, carcinomas and other human cancers progress and move to other sites in the body, termed metastasis. It is speculated that metastasis accounts for up to 90% of the deaths associated with human cancer. It is also speculated that the process of metastasis involves numerous selective pressures on tumor cells, including: (1) growth at primary site, which involves the escape from antitumor immune responses and intrinsic antiproliferative pathways in their premetastatic niche; (2) invasion of the surrounding parenchyma, lymphatics or blood vasculature; and, (3) survival and proliferation at the metastatic site.

Studies of anatomically distinct metastatic lesions in 29 prostate cancer patients have found close clonal relationships between different metastatic lesions within the same patient, which implies the metastases share a monoclonal origin with the primary tumor. However, a high degree of genetic divergence, based upon radically different patterns of allelic loss, was found between primary prostate tumors and lymph node metastases as well as primary breast tumors and asynchronous metastases. Distinct clonal evolution, as assessed by comparative-genomic hybridization, was also evident in a subset of primary breast or renal cell tumors versus metastases. Moreover, the comparison of mutations present in primary and secondary lobular breast cancers revealed multiple mutations present only in metastases and several other mutations with increased frequency in metastatic sites. Thus, while metastases retain some genetic linkage to primary tumors there is ample evidence for genetic divergence, which may be the result of a heterogeneous primary tumor cell population, generated through genetic instability, overcoming the multiple selective pressures applied through the metastatic process.

The immune system plays a significant role in pruning the growth of primary tumors and maintaining dormancy of metastasized tumor cells. However, tumor variants with reduced immunogenicity will overcome the immune system, which may promote mutated characteristics that escape immunological detection and elimination. This process, termed immunoediting, has three phases: elimination, equilibrium, and escape.

Elimination is the initial phase during which the immune system reacts to and initiates the destruction of transformed cells. When the tumor remodels the local stroma and disrupts the tissue's structure, pro-inflammatory molecules and chemokines produced during this process will recruit innate immune cells to the tumor site. Innate immune cells produce IFN-γ and generate a positive feedback loop that then recruits more immune cells. This inflammation and recruitment of immune cells will lead to apoptosis, angiostasis, and cell cycle inhibition that partially eradicates the tumor. Moreover, dead tumor cells displaying tumor antigens will further activate antitumor responses from the adaptive immune system. Thus, these molecules, IFN-γ, perforin, or NKG2D, and an intact lymphocyte compartment apply a major selection pressure on the tumor cells. During this period of Darwinian selection, many of the original tumor cells will be eliminated, but cells that are genetically unstable and are able to mutate rapidly may withstand immune attack, survive and establish an equilibrium with the immune system.

Tumor cells that survive the elimination phase may equilibrate with the host immune system and undergo the equilibrium phase, wherein the remaining tumor population may be sculpted by the immune system. In particular, lymphocytes and IFN-γ will apply pressures that can amplify genetic instability in the tumor population and enable further adaption, including the promotion of tumor cells with reduced immunogenicity. Such beneficial mutations may occur in tumor cells during the equilibrium phase, which can last for a long time with no obvious sign of tumor development. Eventually, surviving tumor cells that have acquired genetic changes will resume expansion and escape from immunologic detection and elimination. The surviving tumor cells need to escape from both innate and adaptive immune responses. So, tumor cells often escape antitumor immune responses through the production of immunosuppressive cytokines or through immunosuppressive activities of T cells. Interestingly, there is another aspect of the escape phase, termed "reverse immunoediting." Here, the tumor cells may affect immunological response through tumor antigens. That is, the immune system may select for the reduction of strong tumor antigen presented in the context of major histocompatibility complex (MHC) 1 or MHC2, which will favor the development of tumors that are more resistant to future immune responses. In addition, tumor cells actively build an immunosuppressive microenvironment by the generation of cytokines that summon a different population of cells. Taken together, genetic instability in the tumor population enables plasticity in response to the negative selection pressure applied through the immune response, and this plasticity may enable immune suppression and tumor progression.

Cancer Therapies That Target Genetic Instability

Intratumoral heterogeneity enabled by genetic instability presents a great therapeutic challenge given the plasticity with which numerous clones can respond, or evolve, depending upon therapeutic pressures. Alternatively, genetic instability is a phenotype that is likely exclusive to tumor cells and, thus, represents a unique therapeutic target.

Targeting DNA Repair Pathways

Tumors can display a variety of defects in the pathways needed to recognize and repair DNA. These defective repair responses can augment the heterogeneity of the tumor clones but can also increase the tumor cell's susceptibility to inhibition of compensating pathways. That is, a tumor cell with a defective homology-directed repair capacity may be more heavily reliant upon the

nonhomologous end-joining pathway; this is the basis for synthetic lethality approaches to target tumor susceptibilities due to dampened or dysfunctional repair pathways.

BRCA1 and BRCA2 are essential for high-fidelity repair of DNA double-strand breaks through a homology-directed pathway. Cells with deficiencies in BRCA1 or BRCA2 have a decreased rate of homologous recombination and increased sensitivity to ionizing radiation. These observations suggest that tumor cells deficient in BRCA1 or BRCA2 may be more heavily reliant upon PARP1-directed repair and, therefore, susceptible to PARP1 inhibition.

Recent phase 3 trials have been extremely encouraging for the use of PARP inhibitors against *BRCA*-mutated, platinum-sensitive, relapsed ovarian cancer with two companies reporting median progression free survival of approximately 20 months compared to 5.5 months for the control arm. It is proposed that patients with breast cancer may also benefit from PARP inhibition. Although only about 5% of patients carry mutations in *BRCA1* or *BRCA2*, nearly a quarter of breast cancer patients may carry tumor mutational signatures that support the use of these drugs. These encouraging results represent a leap forward following a series of disappointing clinical trial results published in 2011 and 2012. However, acquired resistance to PARP inhibition has been observed in most patients with advanced tumors, which is a common attribute of targeted therapies. Indeed, the PARP inhibitor olaparib may also increase genetic instability in mouse embryonic stem cells leading to translocations and chromosome aberrations by increasing DNA double-strand breaks. With three PARP inhibitors approved for use against ovarian cancer, however, it is an exciting time for the evaluation of combining PARP inhibition with conventional treatments, immunotherapy, or antiangiogenesis treatments for the treatment of genetically unstable and difficult-to-treat, aggressive cancers.

A similar synthetic lethality approach is proposed for the directed inhibition of MutT homologue 1 (MTH1), which regulates the incorporation of oxidized nucleoside triphosphates into DNA or RNA during replication and transcription. The level of reactive oxygen species is generally increased in cancer cells and results in not only more direct damage to DNA but also the incorporation of more damaged deoxynucleoside triphosphates. Consequently, cancer cells may be more heavily reliant upon the action of MTH1 and inhibitors of MTH1 may more effectively damage tumor cells than neighboring normal cells.

Targeting Microsatellite Instability

Hereditary nonpolyposis colorectal cancer is often characterized by high-level microsatellite instability (MSI-H) and an associated increased antigenicity (markers on cell membrane that can bind to antibody). The high antigenicity of MSI-H tumors makes them recognizable by the immune system. In order to overcome host immune defense mechanisms, MSI-H carcinomas express some immune checkpoint molecules to either turn up or down a signal in the immune system and create a localized immunosuppressive environment. For example, tumor cells make proteins to bind to the programmed cell death protein 1 (PD-1) receptor on lymphocytes, which dials down the immune system's response to self and impairs the immune response to the tumor. In this context, checkpoint inhibitors, like pembrolizumab, that inhibit PD-1 on the lymphocytes may release the immune system's ability to target and kill cancer cells. Pembrolizumab has shown an objective response rate of 40% to 50% in patients with progressive mismatch repair-deficient metastatic colorectal cancer compared to 0% in patients with mismatch repair-proficient cancer. This remarkable specificity comes with a cost as these checkpoint inhibitors will have the potential for off-target side effects on the immune system. Moreover, while the blockade of the PD-L1/PD-1 axis is a proven immunologic approach, not all patients will respond to monotherapy. The combination of a checkpoint inhibitor and chemotherapeutic regimens may provide an improved therapeutic index; this combination has been shown to be well tolerated without unexpected toxicities and more clinical trials are ongoing.

Targeting Gene Expression of Cell Cycle Components

As outlined in "**Cell Cycle Checkpoints**" section, cell cycle checkpoints are intended to suppress genetic instability and are often compromised in cancer cells. Moreover, in spite of an unstable genome, tumor cells continue to proliferate without control; thus, a variety of cell cycle regulators are considered potential targets in cancer therapy. There are two types of cell cycle control mechanisms: (1) a cascade of protein phosphorylation that transfers a cell from one stage to the next and, (2) a set of checkpoints that monitor completion of critical events and delay progression to the next stage, when necessary.

Cyclin-dependent kinase (CDK) activity controls many critical events during cell cycle progression. Activation of these kinases generally requires a complex with a second subunit that is only expressed at the appropriate period of the cell cycle; the periodic cyclin subunit associates with its partner kinase to generate an active complex with unique substrate specificity. Regulatory phosphorylation and dephosphorylation control CDK–cyclin complexes and ensure clear transitions between cell cycle stages. Silencing individual cyclins or CDKs, or inhibition of cyclin–CDK kinase activity, in tumor-bearing mice selectively blocks tumor initiation and progression of specific cancer types without having major effects on normal tissues. Various CDK inhibitors (dinaciclib, palbociclib with PD-0325901) have shown encouraging activity against tumors that are known to be characterized by unstable genomes, such as relapsed myeloma or KRAS mutant nonsmall cell lung cancer.

The second type of cell cycle regulation, checkpoint control, is more supervisory. Checkpoint kinase 1 (CHK1) and WEE1 regulate the activation of p53, which inhibits CDKs and arrests the cell cycle. Cancer cells, particularly those with loss of p53 function, often inhibit CHK1 or WEE1 to enable cell cycle progression in the presence of DNA damage; these cancer cells mainly depend on the G2 checkpoint, especially in the presence of DNA damage-inducing drugs. For this reason, inactivation of p53 selectively renders cancer cells sensitive to inhibition of CHK1 or WEE1. For example, a CHK1 inhibitor in combination with radiation is able to kill

p53-defective tumor cells by inhibiting double-strand break repair. An alternate CHK1 inhibitor, alone or in combination with a WEE1 inhibitor, shows activity against solid tumors. Overall, these results support possible clinical trials in the future.

Centrosome Amplification

Centrosome amplification is a recurrent characteristic in tumor cells. Real-time imaging of different cell types in vitro and in vivo indicates that supernumerary centrosomes tend to cluster at the poles of mitotic spindles to induce a pseudo-bipolar spindle and prevent multipolar division. Extra centrosomes assemble in small clusters during prometaphase resulting in two ring-shaped groups at the poles. However, should supernumerary centrosomes fail to cluster, the resulting multipolar spindles often trigger mitotic failure, death or apoptosis. Because supernumerary centrosomes are rare in normal cells, the inhibition of pathways used by tumor cells to cluster centrosomes would specifically target tumor cells with potentially minimal off-target effects. Crenolanib, an inhibitor for platelet-derived growth factor receptor β, inhibits centrosome clustering and induces multipolar divisions with increased cytotoxicity by cofilin-mediated disruption of the cortical actin cytoskeleton for cells with centrosome amplification. A small-molecule screen for inhibitors of centrosome clustering identified a Stat3 inhibitor; Stat3 is a regulator of gene transcription that removes a Stathmin-dependent brake on polo-like kinase 1 activity to promote centrosome amplification. Stat3 depletion and inhibition caused significant inhibition of centrosome clustering and reduced the viability of cancer cell lines and tumors grown in animal models.

Personalized Medicine and Genetic Instability

The US National Cancer Institute defined personalized medicine as "a form of medicine that uses information about a person's genes, proteins, and environment to prevent, diagnose, and treat disease". Such personalized clinical applications include screening, diagnosis, prognosis, prevention and disease-risk reduction, prediction of treatment response, pharmacogenomics and dose adjustments, and the early detection of recurrence and stratification of patients into specific cancer subtypes for more targeted treatment. Many cancer treatments, such as radiotherapy and chemotherapy, are mostly nonselective with strong side effects. In comparison, targeted therapies are hoped to be more specific and the survival rate for some cancers has increased from 0% to 70% due to more developed targeted treatments. In the era of personalized medicine, existing drugs and drugs used for other diseases can be reintroduced for targeted treatments on subgroups or subtypes of tumors.

Individualized treatments are heavily reliant upon accurate measurements of protein, DNA, RNA, and microRNA levels that, in turn, determine the tumor subclasses, prognosis, and treatment responses. Treatment dose and safety in different subtypes of cancer patients can be determined or predicted by genetic variation in the tumor. For example, high-grade serous carcinoma of the ovary displays chromosomal instability that is caused by an impaired homologous recombination repair pathway. Analysis of loss of heterozygosity in these tumors divides patients into different subgroups, which corresponds with different levels of chemotherapy resistance and progression-free survival. Similarly, the level of microsatellite instability in tumors of patients with colon cancer correlates to the efficacy of fluorouracil-based adjuvant chemotherapy.

Genetic instability presents a great challenge to the introduction of targeted therapies and personalized medicine. One of the difficulties is the identification of valid biomarkers for different types of cancers and their subtypes, which is especially difficult for low frequency events. Biomarkers are critical for the development of targeted therapy since they may reveal information of individual response to treatments. An accurate quantification of targeted treatment for one patient not only requires broad sample collection but also needs enormous resources for the analysis, ranging from academic specialists to effective data processing systems. Tumor heterogeneity and selective tumor sampling may provide a biased biomarker analysis and detrimentally affect the application of treatment or the treatment response. Moreover, the need for and generation of high-content data (e.g., whole genome sequencing) and its associated analysis and application in clinical use is still not cost effective. Standardization of testing is also very difficult when many factors need to be considered, including methods of specimen collection and storage, types of specimen, biomarker selection, the platform for experiments and the interpretation of data.

Although intratumor heterogeneity is a challenge to treatment prediction by biomarkers, it is still possible to take advantage of this feature of tumors by giving sequential therapies. Drug resistance is one of the most difficult challenges in cancer therapy development. Often, a population of cancer cells will develop different adaptation mechanisms against the prescribed drug depending on the targeting mechanism and the inherent genetic instability of the tumor. However, there is a cost to tumors cells that develop an adaptation mechanism. That is, tumor cells will need more resources to sustain the development of resistant clones. Thus, there may be a limitation to the number of adaptation mechanisms the tumor population can carry out. It is possible to use this limitation in the design of more effective combinatory targeted treatments.

The evolution of resistance against a specific drug in a tumor population can be modeled for three different types of therapies, including: (1) monotherapy; (2) multidrug therapy where only one adaptation is required to establish resistance; and (3) multidrug therapy that targets different mechanisms. In general, resistance to a drug will increase when the tumor cells are on treatment and will decrease when the tumor cells are off treatment. The tumor cells can become completely resistant to the drugs within on–off cycles. This observation led to the proposal by Cunningham and colleagues of an "evolutionary double blind therapy" that theoretically will use the first line of therapy to drive the tumors to a specific adaptation form which will be targeted by the second line of therapy. Since the tumor cells theoretically invest more resources to adapt to the first drug, the ability of the tumor population to resist the second drug may be reduced and the efficacy of the second line of therapy may be increased. This adaption response may

be informative in another avenue; that is, there is likely an optimal level of instability that affords resistance to cytotoxic therapy. As an example, breast tumors with severe chromosomal instability have a better prognosis than those with moderate chromosomal instability. Thus, drugs that can augment chromosome instability, such as those that decluster centrosomes, may push the tumors into a suboptimal level of instability and make these tumors more vulnerable to cytotoxic therapy.

Perspective Vision

Genetic instability is often associated with cancer and can be indicative of a poor prognosis for some tumor subtypes. But, is genetic instability a consequence of tumor progression or a driving force for tumor evolution? Is genetic instability an early and essential development in tumorigenesis and, if so, what tumor cell-intrinsic or environmental pathways restrict its consequences prior to the observation of an overt tumor? The answers to these questions have still not been completely resolved. Intriguingly, the most common form of genetic instability observed in cancer, aneuploidy, remains in many respects to be the most mysterious. A central goal of ongoing research is to systematically identify the many genetic changes that occur in the cancer cell genome and to understand how these functionally interact to cause cancer cell phenotypes. This effort will provide new insight into the genetic landscape of cancer cells, and the novel driver mutations that are discovered may have a significant impact on future cancer therapy development. In summary, as genetic instability is an enabling attribute of cancer and a modifier of sensitivity and resistance to therapy, our improved understanding of the mechanisms that generate an unstable genome and the pathways that can alter the resulting phenotypes will provide new insights into the origins of cancer subtypes and new directions for their treatment.

Glossary

Allele One of several forms of a gene arised through mutation that control a specific characteristic or phenotype. Humans, being diploid organisms, have two alleles at each genetic locus, with one allele inherited from each parent.

Cancer susceptibility variants Pathogenic variants responsible of the predisposition to cancer. Based on their role in biochemical and physiological pathways of tumor cells, cancer susceptibility variants may be common or rare, with high or low penetrance. Usually, variants of genes with a potent effect on apoptosis, proliferation or DNA repair processes have a moderate penetrance and are rare. On the contrary, variants of genes that play a role in molecular and cellular processes controlling the interaction between genetic and environmental components have a low penetrance and are common. Cancer phenotypes associated with high-penetrance susceptibility variants tend to be influenced by the hereditary background, while low-penetrance susceptibility variants could also modify the behavior of hereditary cancer.

Effect size The strength of association between a SNP and risk to develop a specific disease.

Genetic locus A specific position or spot on a chromosome, where the allele is located.

Genetic variant or mutation A change in the DNA sequence of a particular gene with harmful, beneficial, neutral, or uncertain effect on health. It may be inherited as autosomal dominant or recessive trait, or X-linked trait, if the phenotypic effect of the variant is caused when a copy of the altered gene is located on X chromosome.

Genotyping The analysis of the exact sequence of nucleotides, to identify changes in the target sequence compared to the reference sequence that is the most common among genomes in the general population.

Odds ratio (OR) The ratio of the odds of disease for individuals having a specific allele and the odds of disease for individuals who do not have the same allele.

Pathogenic variant or predisposing mutation, or susceptibility variant The genetic alteration that increases the risk to develop deleterious symptoms associated with a certain disease or disorder. Pathogenic variants inherited as autosomal dominant trait that limit life expectancy and reproduction are usually rare in the population (prevalence $<1\%$). Instead, the pathogenic variant inherited as autosomal recessive trait, may be relatively common in the general population (prevalence $>1\%$), because subjects carrying one copy of the altered gene are healthy people without serious disability early in life.

Penetrance The likelihood that in an organism with a particular genotype the corresponding phenotype may or may not be expressed. In particular, the expression of traits with an autosomal dominant pattern of inheritance may be altered if modifier or suppressor genes exist in the rest of the genome or because of a modifying effect of the environment. Thus, penetrance is defined as the percentage of individuals with a given genotype who exhibit the phenotype associated with that genotype. High penetrance would refer to a Mendelian disease.

Polygenic A trait controlled by the interaction of many genes. In contrast to Mendelian disease in which mutations in a single gene cause a specific phenotype and for which the pattern of inheritance is very clear, a polygenic disease is controlled by two or more different genes located at different loci on different chromosomes, each one usually having a relatively small effect.

Risk assessment The quantitative or qualitative assessment of an individual's risk of carrying a certain gene mutation, or developing a particular disorder done by using mathematical or statistical models incorporating selected factors such as personal health history, family medical history and ethnic background.

SNP Single nucleotide polymorphism, a kind of genetic variant characterized by a change of one nucleotide in the sequence of DNA.

Introduction

In the last years several progresses in mapping complex traits in humans have revealed that, for prevalent and common diseases, the predominant pattern of hereditability is controlled by the interaction of many loci, with small effect on phenotype if taken individually, in addition to the interactions between inherited genetic and environmental factors.

Advances in both genetic tools, including the mapping of single nucleotide polymorphisms (SNPs), comparative genomic hybridization (CGH) and gene expression microarrays, together with the cross-species approaches, allowed the characterization of loci and genes critical for risk prediction, diagnosis, prevention, and therapy of human diseases.

Moreover, genome-wide association studies (GWAS) have detected—with a strong statistical significance—hundreds of genetic variants associated with a large number of diseases, through the comparison of SNPs in large numbers of affected cases compared to healthy controls.

In particular, GWAS, also known as whole genome association study (WGAS), is an observational study of a genome-wide set of multiple genetic variants in different individuals, able to understand if any variant is associated with a specific trait. As reported above, these studies are focused on the association existing between one or more SNPs and characteristic features of major human diseases (Fig. 1).

In contrast to methods that specifically test a small number of preselected genetic loci, GWAS studies have the capability to investigate the entire genome, using a noncandidate-driven approach, and to identify SNPs and other DNA variants associated with a specific disease. Before the advent of GWAS, linkage and candidate gene studies had limited power to detect common genetic risk factors of diseases. In order to overcome the major limitation of linkage studies, and to improve the resolution owing to the limited number of meiosis within families, the candidate gene studies ignore many causal genomic region or genes because they focus on variants in specific genes that have a priori biological involvement in disease.

Instead, in GWAS, allele frequencies at thousands of polymorphic sites (i.e., SNPs) are compared in a large number of cases versus a similar number of controls. These studies have successfully identified some of the common susceptibility variants for different common diseases and traits, including cancer.

The first GWAS was published in 2005, on patients affected by age-related macular degeneration. Nowadays, it is possible to count over 3000 human GWAS that have examined over 1800 diseases, including several tumors, and thousands SNP association have been discovered.

During last years, many novel associations between genetic variants or chromosomal aberrations and diseases were detected by GWAS, but most of these are not strongly predictive of disease occurrence, due to the low penetrance and limited public health impact, as well as the lack of validated genetic testing. The reason why, for complex traits studied in humans, the identified genetic effect comprises less than half of the estimated trait heritability, is related both to the role of the untested rare variants and the understanding of gene–gene and gene–environment interactions requiring extremely large sample sizes and well-characterized environmental exposures. Interestingly, one might consider genetic tests based on combinations of associated SNPs and evaluate if the inheritance of a panel of SNPs can reveal a higher risk to develop the disease, as often occur for cancer. As sample sizes increase, GWAS will also be able to detect additional SNP associations that have even smaller effect sizes than those observed to date.

Steps of GWAS: From Study Design to Genetic Analysis and Result Interpretation

Around 10 million of the human genome's 3 billion nucleotides are polymorphic SNPs, meaning that they occur in two or more common forms in different subjects. GWAS reveals genetic variations that are correlated with disease, but this does not mean that the variants identified by the studies cause the disease. The idea is that if a genetic variant increases the risk to develop a disease, it should be more frequent among cases than among healthy controls (Fig. 2).

Thus, the genotyping of both cases and control subgroups, could uncover regions of the genome that harbor DNA changes leading to the disease, but the functional role of the identified genetic variants in disease needs to be tested. Common questions in the area of translational medicine are: how do the mutations that underlie GWAS alter the way that genes, protein, cells, or tissue function? How do this knowledge can inform the search for new medicine targeting the molecular basis of the disease? (Fig. 3).

Sequencing of the human genome together with the identification of millions of SNPs, provided the initial foundation for GWAS. In the scientific literature it has been reported that many of these identified SNPs were in linkage disequilibrium (LD) with the common genetic variations.

It is known that, in order to detect with statistical power the expected modest associations (e.g., odds ratio [OR] < 1.5) between a genetic variation and a specific disease, it is needed to involve thousands of subjects and to evaluate hundreds of thousands of SNPs.

Nevertheless, the large sample sizes and initial high cost of SNP arrays motivated the development and use of multistage GWAS designs.

Using a multistage GWAS design, it is possible to discover the strongly associated SNPs in a subset of samples, using the genome-wide SNP array and subsequently validating these SNPs with a less-expensive genotyping platform in the remaining samples (Fig. 1).

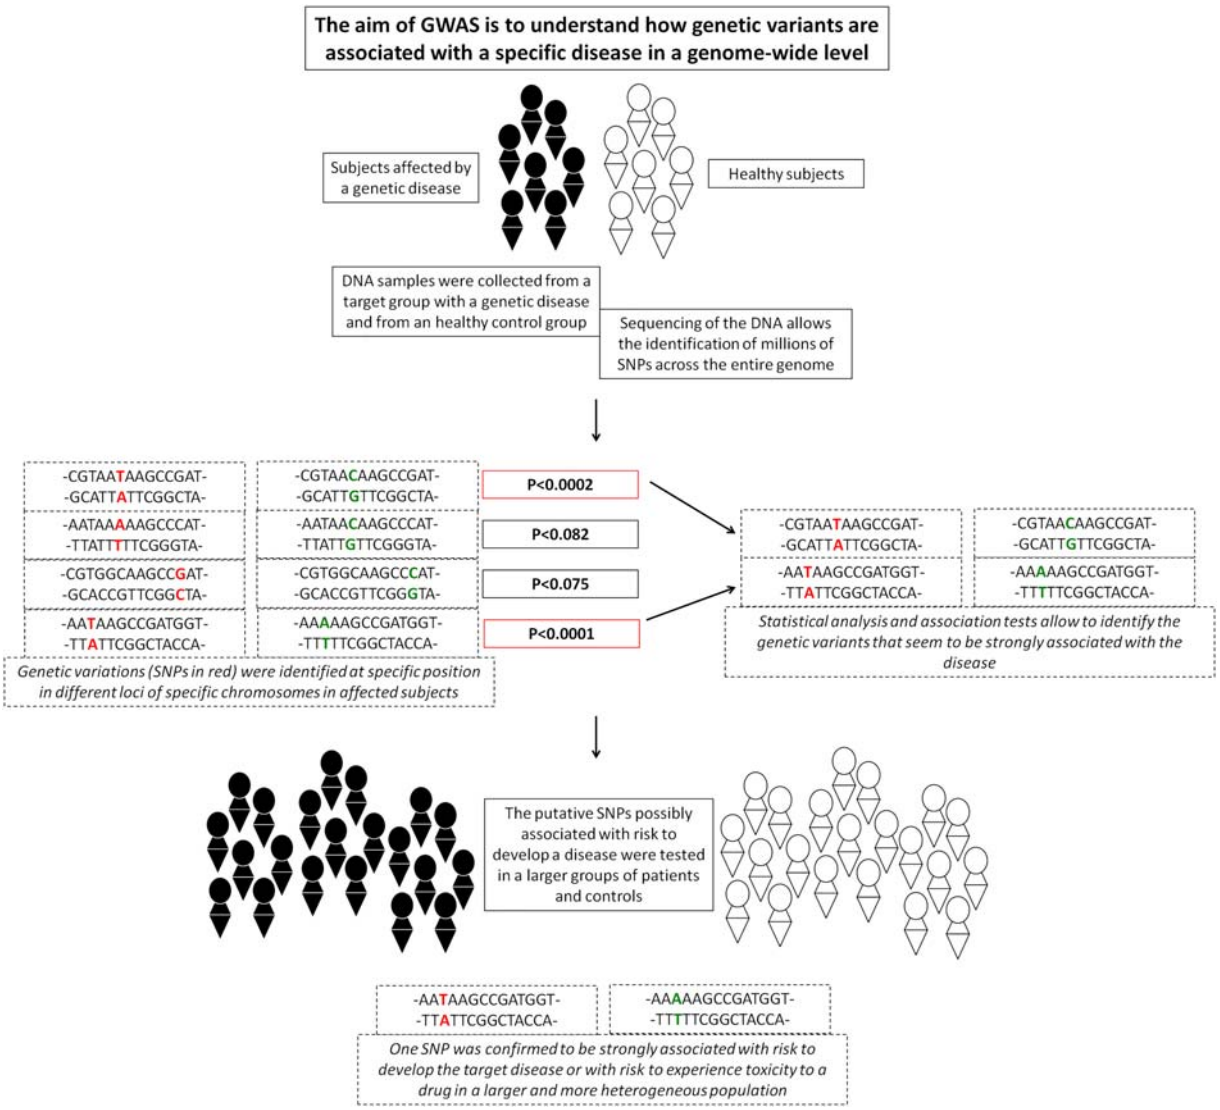

Fig. 1 Steps of genome-wide association study (GWAS). In a multistage GWAS, a large number of individuals affected by a specific type of genetic disease, such as cancer, and a suitable healthy group as a comparison, are selected. In phase I, the entire genome of each subject of a small group of cases and controls are sequenced in order to identify common genetic variants in the form of single nucleotide polymorphisms (SNPs). Stringent statistical methods are used to assess the associations between SNPs and disease. In phase II, the SNPs found to be significantly associated with risk to develop the disease, are tested in a larger group of patients and controls using arrays containing the putative SNPs of interest. The association found with this approach could have clinical utility being possible the use of the biomarker to perform a genetic test to facilitate clinical decision making and improve health outcomes.

Concomitantly with the increasing understanding of the human genome, an enormous number of SNP arrays able to capture an ever-increasing number of variants were developed, permitting to cover a high number of common genetic variations across the human genome.

In the last years, the use of multistage GWAS has permitted to significantly reduce the cost of these analyses. Indeed, while the array prices were initially high, at present, they have steadily decreased, because fewer SNPs are typed in a second stage. Since the data from the first and second stages are combined, analyzed, and penalized for multiple comparisons, the single-stage GWAS has been undertaken.

Today, the decreasing SNP array costs have made multistage GWAS designs less essential. Indeed, genotyping 10,000–20,000 SNPs in a follow-up stage can cost just about as much as a genome-wide SNP array. The newly developed GWAS have permitted to genotype all samples in an initial SNP array, allowing to analyze simultaneously both SNPs and other forms of genetic variation in one study sample (e.g., copy number variants, CNV), but increasing the cost of analysis and encouraging, when possible, the use of multistage design.

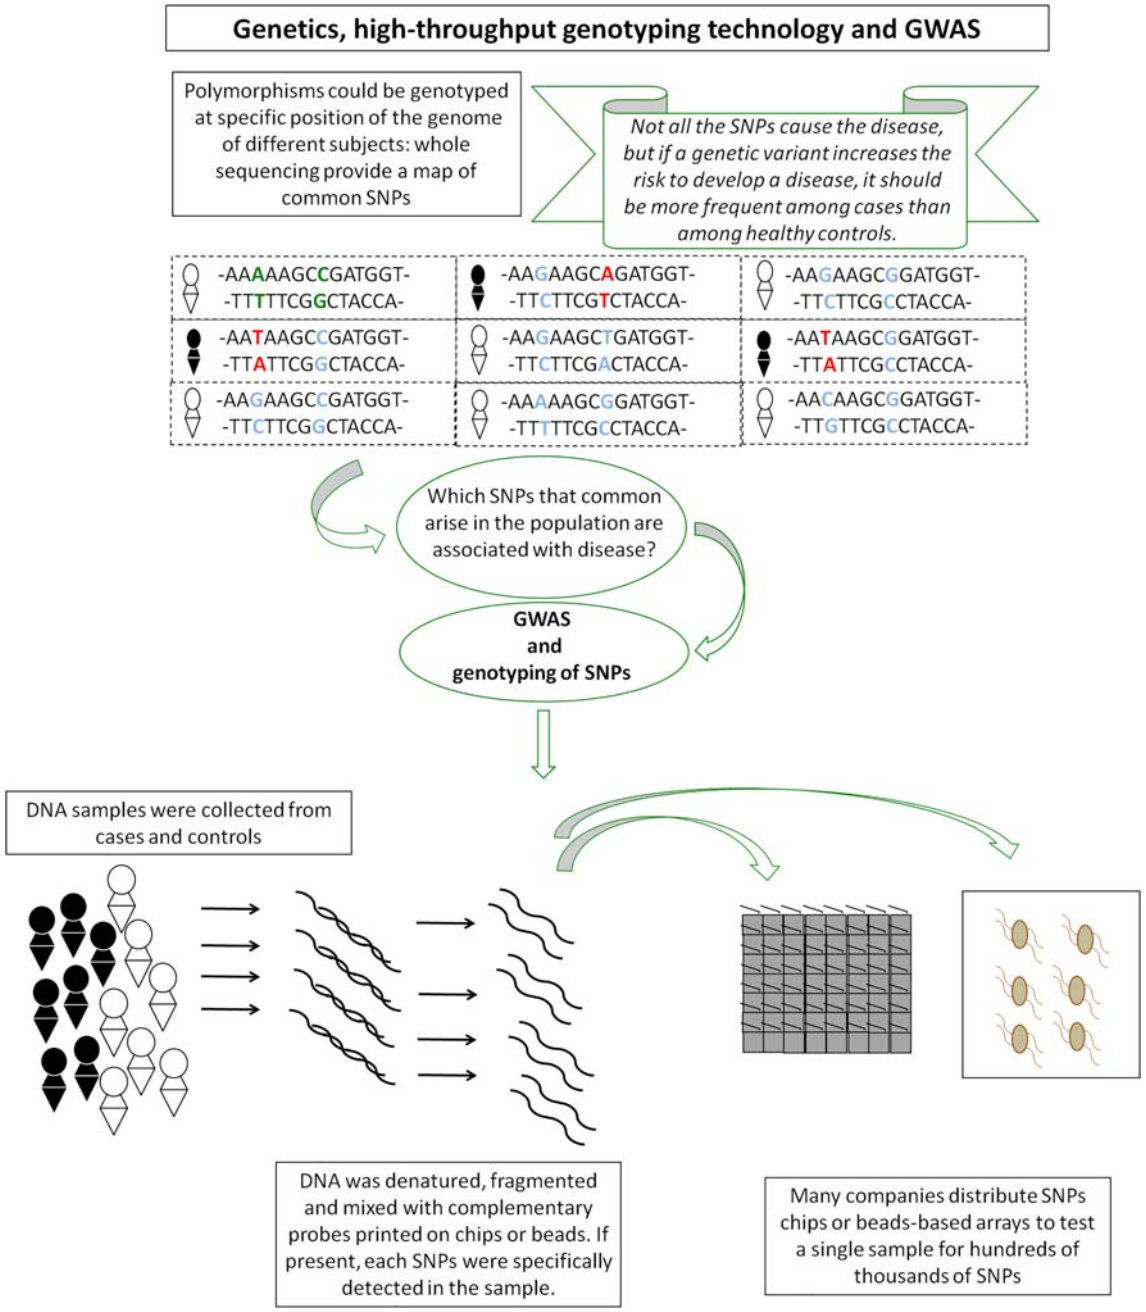

Fig. 2 Genetics, high-throughput genotyping technology and GWAS. GWAS is an "hypothesis-generating" tool. The researchers, through an agnostic genome-based approach and high-throughput genotyping technologies, interrogate the entire human genome to reveal whether SNPs that arise in the population are associated with a specific disease. In this figure, the green colored are the most common nucleotides in the general population, while the others are polymorphic; only those in red represent the genetic variants that increase the risk to develop a disease, and are more frequent among cases colored in black than in controls colored in white. In 2005, as an evolution of the HapMap project, the cost and the resources required to test a DNA sample for the bulk of its common variations became less expensive. The International Hap Map Consortium provides a map of SNPs across the entire human genome that are often inherited together in DNA blocks, called haplotypes. The so called "SNP chips" are cost-effective genotyping arrays produced by several companies that allow the researchers to test a single sample for hundreds of thousands of SNPs.

The primary platforms that have been used for most GWAS are the Affymetrix technology (Santa Clara, CA) that use a chip with short DNA sequence able to detect—by means of hybridization—the specific allele contained in the sample (Fig. 2) and the Illumina system (San Diego, CA) that prints a slightly longer DNA sequence on the surface of beads in order to detect the specific allele with somewhat better specificity.

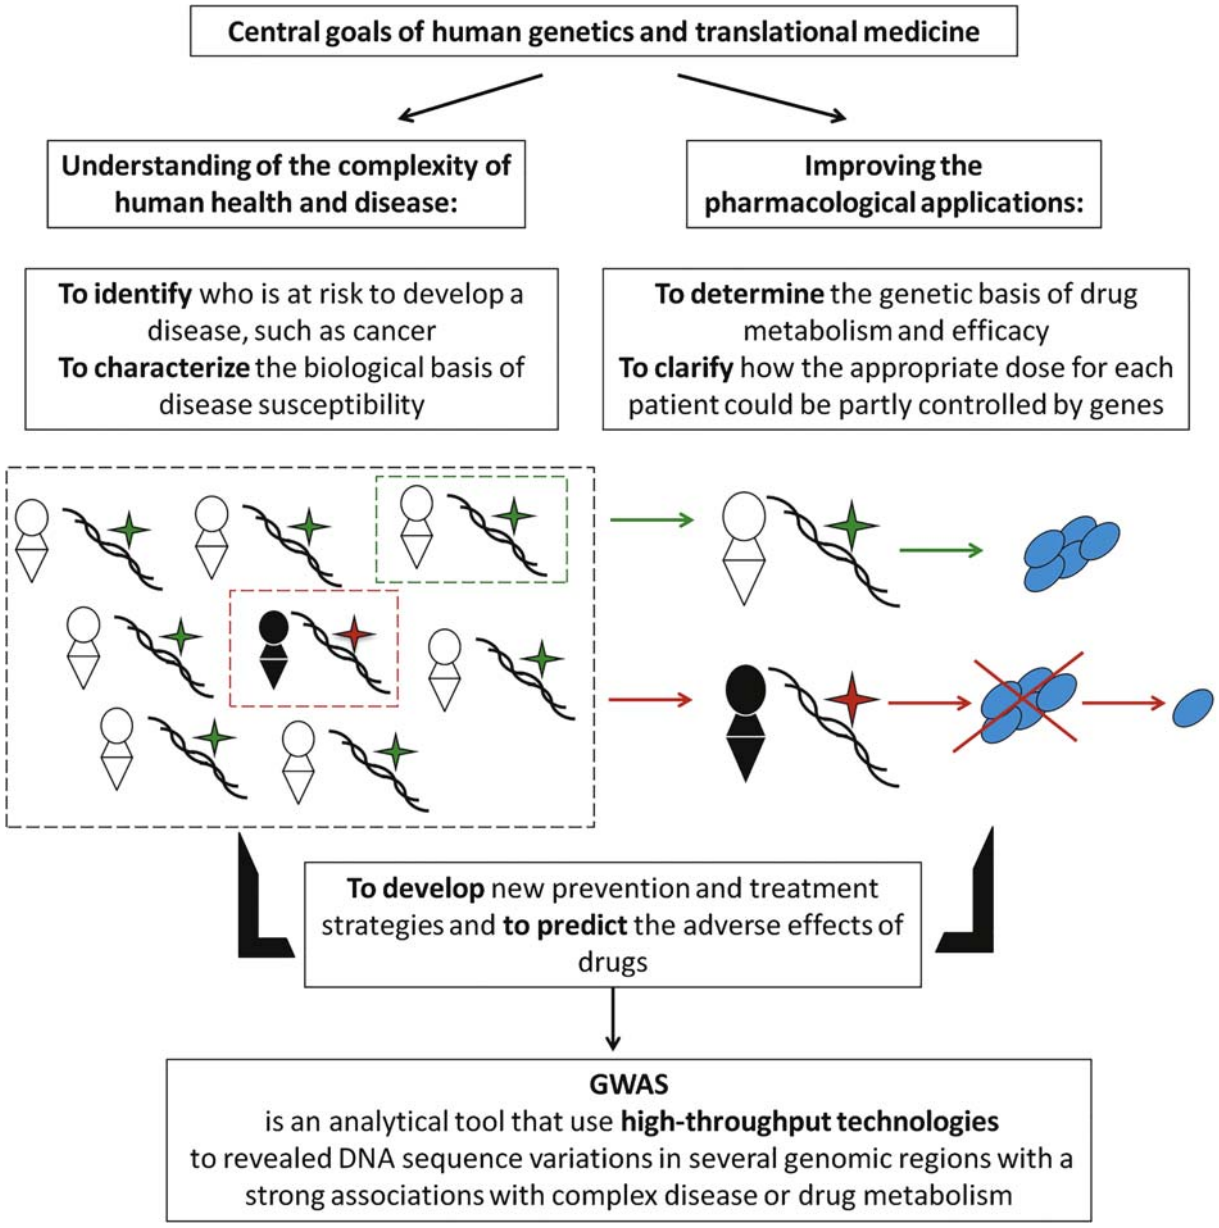

Fig. 3 Central goals of human genetic, translational medicine and the role of GWAS. GWAS plays a central role in human genetic revolution thanks to the identification of robust associations between thousands of genetic variants and hundreds of different traits and diseases. This revolution provides not only an improvement in the understanding of common complex diseases in translational field, but also in clinical and pharmacologic areas where the use of genomic informations contributes to the optimization of patient treatment. In the figure, subjects with genetic variants associated with neither drug toxicity nor pathogenic effects, are represented in white, near a double stranded DNA associated with a green star representing a neutral variant of the DNA sequence. Instead, subjects with a genetic variant associated with an alteration of drug metabolism and toxicity are represented in black, near a double stranded DNA associated with a red star representing the susceptibility variant. The identification of patients carrier of a genetic variant strongly associated with toxicity to a drug (represented as blue circles) allows the clinicians to reduce the dose to minimize the adverse effects to drugs.

The prerequisite to provide a GWAS is to compare two large groups of individuals, comprising selected cases affected by a particular disease and healthy subjects as controls. Generally, all individuals in each group are genotyped for the majority of common known SNPs (Figs. 1 and 2). In order to increase the power to detect associations, it is possible to select those with the extreme traits or symptoms instead to study the entire group of subjects.

Despite study subjects should be representative of their source population and rigorous control selection should be made, in order to reduce the costs of subject recruitment and genotyping, it is possible to use existing genotype informations among controls derived from previous studies and made available to researchers.

Once genotyping is complete, SNPs are subject to a number of quality-control checks and statistical analysis. The relationship between SNPs and disease is generally evaluated trough combinations and interaction tests and haplotypes. For each of analyzed SNPs it is then investigated if the allele frequency is significantly altered between the case and the control group, evaluated by using the OR. Additionally, a *P*-value for the significance of the OR is typically calculated using a simple chi-squared test (the conventional threshold is 5×10^{-8} to be significant in the face of hundreds of thousands to millions of tested SNPs).

The effect size is in inverse relationship with sample size: studies with larger sample size have higher power than those with smaller sample size, being able to detect smaller associations.

Thus, thanks to GWAS, SNPs in genes or genome regions that were not been previously identified as implicated in the initiation and development of the disease, as well as the genetic variants involved in cell adhesion, signal transduction, transport activity, and protein phosphorylation, could be identified.

The GWAS findings are published in the National Human Genome Research Institute's (see the web site of "Catalog of Published Genome-Wide Association Studies").

In the last years, many of the GWAS results have been highly replicated; nevertheless, few of these variants have been described to be associated with disease, although their causative role is not firmly established. A fine mapping and mechanistic studies could determine the pathogenetic implication of GWAS results, even if this could be complicated by the fact that ~30% of the associations detected to date are not even in gene regions, posing a challenge to the understanding of the biological basis of GWAS results, and to the implementation of preventive or therapeutic measures.

Implications and Limitations of GWAS Findings

The findings emerged from GWAS widely increase the interest into a mechanistic work that is aimed at validation of the GWAS data and clarification of the biological basis of disease processes. For example, in order to understand the association between a specific SNP in a given locus with risk to develop a different type of cancer, the in vitro approaches could reveal important molecular and biochemical information.

If of clinical interest, one or more SNPs or a panel of variants, could became part of a genetic test prescribed by a physician or marketed directly to the consumer that pay to have information about variations in the entire genome and genetic counseling about the risk to develop a disease or to benefit from a treatment. Interestingly, in the last years, the pharmacogenetic studies evaluating the genetic basis of drug response, have widely used the GWAS approaches (**Fig. 3**). Indeed, starting from these tests, it is possible to obtain pharmacogenetic information related to the drug and dosage that an individual with a specific pattern of genes involved in drug metabolism should receive.

However, it is important to note that the justification for genetic testing also depends on the existence of effective intervention. Most of these screening tests based on GWAS SNPs may not distinguish between individuals with low and high risk of disease, and, even if some individuals are carriers of a large number of SNPs, their screening in the global population would not be cost-effective.

The use of GWAS have several issues and limitations that should be taken into account for proper quality control and study set-up. Lack of well defined case and control groups, insufficient sample size, control for multiple testing and for population stratification are common problems. In addition, the high number of statistical tests performed have been reported and present a potential for false-positive results.

The Role of GWAS in the Identification of Cancer Susceptibility Genes

Cancer is a highly heterogeneous disease, in terms of time of development and biological properties of each tumor. Among individuals exposed and susceptible to the same carcinogen, tumors do not appear at the same time. The origin and evolution of cancer have been proposed to be the consequence of the combined effects of a number of different alleles and variants, which may control intrinsic (i.e., apoptosis, proliferation, or DNA repair) and/or extrinsic (i.e., stroma, angiogenesis, or endocrine and immune systems) functions of cancer cells.

GWAS have demonstrated that much of heritable risk of most common cancers is polygenic. Thus, every susceptibility variant contributes to a small amount of risk and cancer susceptibility originates from the additive effects of combinations of common low-penetrance variants.

Studies focused on the analysis of linkage in family pedigrees comprising of several members affected by certain cancers allowed the detection of several high-penetrance susceptibility genes: BRCA1 and BRCA2 for breast and ovarian cancers; APC, MLH1, and MSH2 for colorectal cancer; CDKN2a for melanoma. Despite the linkage studies have described candidate loci containing cancer susceptibility genes, often these loci were not statistically significant due to the low number of families affected by each locus and to the regions of interest; it is therefore advisable to replicate and confirm findings in larger populations.

While family studies involve few patients, GWAS involve thousand of patients, thereby significantly increasing density markers. Anyway, these two approaches can be complementary, because the pedigree evaluation, relying on genetic transmission of disease-causing alleles between affected family members, can offer direct and persuasive sign of genetic effects.

As described above, in the last years, multiple GWAS have been reported for each of the major cancers, including breast, prostate, lung, colorectal, pancreatic, gastric, renal, and bladder cancers. In addition, GWAS have been performed for malignant melanoma,

ovarian cancer, glioma, and several hematological malignancies including acute lymphocytic leukemia (ALL), chronic myeloid leukemia (CML) and Hodgkin's lymphoma. Additionally, common risk alleles have been identified through GWAS associated with several pediatric solid cancers.

Breast Cancer

Regarding the studies focusing on family members affected by breast cancer, the inherited variations in the two main susceptibility genes, BRCA1 and BRCA2, account together for only around 20% of hereditary breast cancer, elucidating $<5\%$ of the total breast cancer susceptibility. This encouraged extensive efforts to discover additional high penetrance susceptibility genes. With the advent of GWAS, two classes of variants that have an influence on cancer susceptibility have been detected: rare moderate-penetrance variants and common low-penetrance variants. For example, through the direct interrogation of candidate genes encoding proteins involved in the DNA-damage response pathway, in addition to BRCA1 and BRCA2, also ATM, CHECK2 and PALB2 have been associated with an increased breast cancer risk.

The first breast cancer GWAS was published in 2007 by Easton and colleagues. The Authors, using a two-stage GWAS analyzing 227,876 SNPs in 4398 breast cancer cases and 4316 controls, and followed by a third stage in which 30 SNPs were tested for confirmation in 21,860 cases and 22,578 controls, they identified five novel risk loci in *FGFR2* [rs2981582, rs1219648, and rs1078806], *TNRC9* [rs3803662], *MAP3KI* [rs889312], and *LSP1* [rs3817198] genes, with a strong and consistent evidence of association with breast cancer ($P < 10^{-7}$; OR ranging from 1.05 to 1.41). In particular, *FGFR2* and *MAP3K1* are members of the RAS/RAF/MEK/ERK-signaling pathway and could be important tumor markers of breast cancer risk. In particular, it has been showed that FGFR2 rs1219648 and rs2981582 genotypes were significantly associated with breast cancer in estrogen receptor-positive (ER+), progesterone receptor-positive (PR+) and HER2/Neu-negative (HER2−) tumors.

Some of the other susceptibility loci identified in gene-containing regions have not been implicated in cancer previously (e.g., *TOX3*, *STXBP4*, *SLC4A7*, *MRPS30*, *RAD51L1*, *LOC643714*, and *STXBP4*) and are being evaluated for their potential role in carcinogenesis. Nevertheless, the risk associated with each identified SNPs is modest, with ORs ranging from 1.1 to 1.4, and with a contribution to the familial risk of breast cancer of about 8%.

Prostate Cancer

With the increasing incidence of prostate cancer, the identification of common genetic variants that confer risk of developing the disease has become important. In a recent meta-analysis of 87,040 individuals, it have been identified 23 new susceptibility loci for prostate cancer ($P < 5 \times 10^{-8}$), with ORs mostly ranging from 1.2 to 2.0. It has been also demonstrated that this loci in genes like *GOLPH3L* (rs17599629, 1q21), *NEDD9* (rs4713266, 6p25), *HLA-DRB6* (rs115306967, 6p21), *CDKN2B-AS1* (rs17694493, 9p21), *TTC9* (rs8014671, 14q24), *SLC41A1* (rs1775148, 1q32), *TMPRSS2* (s1041449, 21q22), *PEX14* (rs636291, 1p35), *MYO6* (rs9443189, 6q14), among others, combined with the known prostate cancer risk variants, explain 33% of the familial risk for this disease. In particular, variant rs4713266 is located in intron 1 of *NEDD9*, a gene involved in cell adhesion, motility, cell cycle and apoptosis, and is implicated in the progression and metastasis of several cancers. Otherwise, rs9443189 on *MYO6* gene, is described to be a modulator of androgen-dependent gene expression, and it has been found to be overexpressed in prostate cancer driving tumor growth and metastasis.

Moreover, several studies have identified independent risk variants in the 8q24 region (HapC 14 SNPs, rs16901979, DG8S737, rs1447295, rs1016343, rs6983267, rs4242382, rs1006908, rs620861, and rs16902094). Risk SNPs at or near genes (i.e., *MSMB* [rs10993994], *KLK3* and *KLK2* [rs2735839], *NKX3-1* [rs2928679], and *CTBP2* [rs4962416]) with possible roles in prostate carcinogenesis have also been found. Zheng and colleagues also evaluated the impact of carrying multiple risk SNPs on prostate cancer risk, demonstrating that men carrying four out of five possible risk SNPs (rs4430796 [17q12], rs1859962 [17q24.3], rs16901979 [8q24], rs6983267 [8q24], and rs1447295 [8q24]) had a 4.5-fold increased risk of disease. No evidences highlighted that the risk SNPs were associated with disease aggressiveness, earlier age at diagnosis or presence or absence of family history.

Nowadays, the validity and the clinical utility of the use of individual or multiple SNP panels as screening test for prostate cancer have not been demonstrated. Nevertheless, the identification of genetic variants able to predict early-onset or more aggressive disease are in progress.

Lung Cancer

In the field of research investigating the association between SNPs and lung cancer risk, a growing number of studies have been published. In a recent work published by Liu and co-workers, evidences from meta-analyses and GWAS revealed the association between 108 variants and lung cancer. Among these, about 63 were reported to be significantly associated with lung disease, and, in particular, 15 SNPs on or near 12 genes and one miRNA showed strong evidence of association with lung cancer risk, including *TERT* [rs2736098], *CHRNA3* [rs1051730], *AGPHD1* [rs8034191], *CLPTM1L* [rs401681 and rs402710], *BAT3* [rs3117582], *TRNAA* [rs4324798], *ERCC2* [Lys751Gln], miR-146a2 [rs2910164], *CYP1B1* [Arg48Gly], *GSTM1* [null/present], *SOD2* [C47T], *IL-10* [−592C/A and −819C/T], and *TP53* [intron 6]. Among these variants, SNP rs2736098 is localized to telomerase gene *TERT*, a reverse transcriptase component of telomerase, playing an essential role in telomerase enzyme production and maintenance of telomeres. In the literature, it has been reported that TERT gene amplification is commonly described in lung

adenocarcinoma. Among other genes, *CHRNA3* encodes for a member of nicotinic acetylcholine receptor family which may be a key player in nicotine-mediated suppression of apoptosis in lung cancer cells. *CLPTM1L* contributes to the accumulation of DNA damage, which confers susceptibility to tumorigenesis, whereas *BAT3*, a member of the Bcl-2-associated athanogene (BAG) family of proteins, participates in a variety of primary cellular processes, playing also an important role in apoptosis regulation.

In another GWAS for squamous lung cancer, rare variants of BRCA2 (p.Lys3326X [rs11571833]) and CHECK1 (p.Ile157Thr [rs17879961]), in association with the common variation 3q28 (TP6, rs13314271) were also implicated in lung adenocarcinoma.

More recently, a large-scale association analysis has identified new lung cancer susceptibility loci. In this study, 14,803 cases and 12,262 controls of European descent were genotyped and combined with existing data for an aggregated GWAS analysis of lung cancer in 29,266 cases and 56,450 controls. Eighteen new susceptibility loci in several genes (*FUBP1* [rs71658797], *RNASET2* [rs6920364], *CHRNA2* [rs11780471], *BRCA2* [rs11571833], *SEMA6D* [rs66759488], *CHRNA5* [rs55781567], *CYP2A6* [rs56113850], *TP63* [rs13080835], *TERT* [rs7705526], *NRG1* [rs4236709], *CDNK2A* [rs885518], *OBFC1* [rs11591710], *AMICA1* [rs1056562], *SECISBP2L* [rs77468143], *RTEL1* [rs41309931], *MHC* [rs116822326], *RAD52* [rs7953330], *CHEK2* [rs17879961]) were identified, showing the striking heterogeneity in genetic susceptibility across the histological subtypes of lung cancer, with four loci associated with lung cancer overall and six loci associated with lung adenocarcinoma.

The locus 15q21 is predicted to target *SECISBP2L*. The genetic risk allele appears to correlate with decreased expression levels of *SECISBP2L*, already known to be downregulated in lung cancer. rs77468143 was nominally associated with lung function, potentially implicating inflammation of lung as a part of the mechanism at this locus.

Three of the identified variants associated with lung adenocarcinoma are located near gene related to telomerase regulation: rs7902587 and rs41309931 near *OBFC1* and *RTEL1*, respectively, and rs2853677 near *TERT* as previously noted.

The genetic susceptibility alleles described in GWASs explain approximately 12.3% of the familial relative risk. Nevertheless, ongoing studies on target genes will provide new insights into the etiology of lung cancer.

Colorectal Cancer

Among the most common malignancies, colorectal cancer (CRC) has one of the largest proportions of familial cases. It is reported in the literature that approximately 30% of all CRC cases are an inherited form of the disease, and of these, only about 5% of cases are associated with highly penetrant inherited mutations (i.e., common polymorphisms in genes that regulate metabolism or genes that are regulated by environmental or other genetic factors). Inherited CRCs are also likely to be caused by alterations in multiple susceptibility loci that have additive effects. In particular, it has been described that common variants influence CRC risk. In detail, performing different meta-analysis of several GWAS, several CRC risk loci were identified, including 1q41 (rs6691170 and rs6687758), 3q26.2 (rs10936599), 6p21 (rs1321311, *CDKN1A*), 8q23 (rs16892766, *EIF3H*), 8q24 (rs6983267, *LOC727677*, *POU5F1P1*), 11q13.4 (rs3824999, *POLD3*), 12q13.13 (rs11169552 and rs7136702), 18q21.1 (rs4939827, *SMAD7*), 20q13.33 (rs4925386), and Xp22.2 (rs5934683, *SHROOM2*), associated approximately with 0.92 to 1.27-fold increased risk of disease.

These data derived from GWAS on CRC provide important insight into the biological basis of inherited genetic susceptibility to CRC, identifying risk factors able to influence the development of CRC.

Pancreatic Cancer

As CRC, pancreatic cancer is one of the most common cancers, considered as the fourth leading cause of death in the developed world. Both inherited high-penetrance mutations in *BRCA2*, *ATM*, *PALB2*, *BRCA1*, *STK11*, *CDKN2A* and mismatch-repair genes and low-penetrance loci are associated with increased risk.

Conducting GWAS, several loci risk associated with pancreatic cancer have been described: 9q34 (rs505922, *ABO blood group* gene – OR = 1.20), 13q22.1 (rs9543325 and rs9564966, *KLF5* – OR = 1.26 and 1.26, respectively), 1q32.1 (rs3790844, *NR5A2* – OR = 0.77) and 5p15.33 (rs401681, *CLPTM1L-TERT* – OR = 1.19). Recently, to identify new risk loci, Childs and colleagues performed a GWAS on 9925 cases and 11,569 controls, identifying three newly associated regions, including 17q25.1 (*LINC00673*, rs11655237, OR = 1.26), 7p13 (*SUGCT*, rs17688601, OR = 0.88) and 3q29 (*TP63*, rs9854771, OR = 0.89), with high pancreatic cancer risk penetrance.

Two highly correlated variants (rs11655237 and rs7214041) were associated with pancreatic cancer risk. Variant rs7214041 is to *LINC00673* (long intergenic nonprotein coding RNA 673); rs11655237, a noncoding transcript variant, shows significant DNase hypersensitivity in multiple cancer cell lines and binds transcription factors including *P300*, *FOXA1*, *FOXA2*, and the DNA repair protein *RAD21*. A significant association for two variants in high LD (rs9854771 and rs1515496) and located in an intron of TP63, is also described. p63 is a p53 homologue implicated in tumorigenesis and metastasis, playing a role in cell-cycle arrest and apoptosis.

Renal Cell Carcinoma

Similarly, clear cell renal carcinoma (RCC), the most common type of kidney cancer in adults, is responsible for approximately 90%–95% of cases. GWAS approaches in RCC patients have identified several variants conferring risk of the disease. One variant, rs35252396 located at 8q24, has been described to be significantly associated with RCC (OR = 1.27). The conduction of two-stage GWAS of RCC in 3772 affected individuals and 8505 controls, identified two additional risk loci, 2p21 (rs11894252 and rs7579899 mapping to EPAS1) and 11q13.3 (rs7105934, SCARB1), associated with RCC susceptibility, in addition to the more recent seven

new loci at 1p32.3 (rs4381241), 3p22.1 (rs67311347), 3q26.2 (rs10936602), 8p21.3 (rs2241261), 10q24.33-q25.1 (rs11813268), 11q22.3 (rs74911261), and 14q24.2 (rs4903064).

Bladder Cancer

Bladder cancer is also one of the most common cancer in men and its frequent recurrence requires regular screening and intervention. GWAS in bladder cancer identified common variants in four genomic regions on chromosome 3q289 (*TP63*), 4p16.3 (*TMEM129*, *TACC3-FGFR3*), 8q24.219, and 8q24.311 (*PSCA*) all associated with increased risk. Interestingly, the variants on 8q24.21 map to a region centromeric to MYC that has been identified in GWAS of breast, colorectal and prostate cancers, as well as chronic lymphocytic leukemia. Association with bladder cancer risk has been suggested also for variants near the TERT-CLPTM1L locus on chromosome 5p15.33, which has been described to be associated with increased risk of basal cell carcinoma, cutaneous melanoma, lung, brain, and pancreatic cancers, together with three new regions on chromosomes 22q13.1 (rs1014971), 19q12 (rs8102137, *CCNE1*), and 2q37.1 (rs11892031, *UGT1A*).

These findings on common variants associated with bladder cancer risk should provide, together with further discovery, new insights into the mechanisms of carcinogenesis.

Other Malignancies

Other malignancies have been subject of GWAS with the aim to identify genetic variants associated with an increased risk of cancer.

Cutaneous melanoma is a disease of fair-skinned individuals, with an increased risk associated with a family history of the disease. As reported in the literature, the most common high-penetrance melanoma susceptibility gene (*CDKN2A*) maps to 9p21. Germline *CDKN2A* mutations are carried by about 2% of all melanoma cases across populations.

One of the first genome-wide association study of melanoma, conducted of 317K tagging SNPs for 1650 selected cases and 4336 controls, identified three risk loci: 16q24 (*MC1R*, rs258322), 11q14-q21 (*TYR*, rs1393350) and 9p21 adjacent to *MTAP* and flanking *CDKN2A* (rs7023329). In particular, *MC1R* and *TYR* genes are associated with pigmentation and cutaneous sun sensitivity, well-recognized melanoma risk factors.

An international two-stage meta-analysis of 11 cutaneous melanoma GWAS (totaling 15,990 cases and 26,409 controls), has identified some loci not previously associated with melanoma risk ($P < 5 \times 10^{-8}$), including 2p22.2 (*RMDN2/CYP1B1*, rs6750047), 6p22.3 (*CDKAL1*, rs6914598), 7p21.1 (*AGR3*, rs1636744), 9q31.2 (*TMEM38B/RAD23B/TAL2*, rs10739221), 10q24.33 (*OBFC1*, rs2995264), 11q13.3 (*CCND1*, rs498136), and 15q13.1 (*OCA2*, rs4778138).

In addition to this, Barret and colleagues, identified additional new regions with at least one SNPs with $P < 1 \times 10^{-5}$ in *ATM* (rs1801516), in *MX2* (rs45430), a SNP adjacent to *CASP8* (rs13016963), and a fourth locus near *CCND1* (rs1485993).

Ovarian cancer accounts for the most common cause of deaths than all other gynecological cancers combined, with a heritable component explaining less than half of the excess familial risk. Performing GWAS, during the years, identified several common ovarian cancer susceptibility alleles. The prevalent SNPs associated with disease risk ($P < 10^{-8}$) included SNPs at 9p22 (rs3814113, OR = 0.82), variants at 1p36 (nearest gene, *WNT4* [rs56318008]), 4q26 (*SYNPO2* [rs17329882]), 9q34.2 (*ABO* [rs635634]) and 17q11.2 (*ATAD5*) associated with epithelial ovarian cancer (EOC) risk, and at 1p34.3 (*RSPO1* [rs58722170]) and 6p22.1 (*GPX6* [rs116133110]) variants, specifically associated with the serous EOC subtype. In addition, the analysis of *HOXD1* (rs2072590), *MYC* (rs10088218), *TIPARP* (rs2665390), *SKAP1* (rs9303542) and of *BNC2* at 9p22 supports a functional role for these genes in ovarian cancer development.

Gliomas represent about 40% of all primary brain tumors and cause around 13,000 death in the USA each year. These cancers are heterogeneous and typically associated with a poor prognosis irrespective of clinical care, having a median overall survival of only 10–15 months. As described in literature, GWASs identified SNPs in at least eight loci influencing glioma risk: 3q26.2 (near *TERC*), 5p15.33 (near *TERT*), 7p11.2 (near *EGFR*), 8q24.21 (near *CCDC26*), 9p21.3 (near *CDKN2A/CDKN2B*), 11q23.3 (near *PHLDB1*), 17p13.1 (*TP53*), and 20q13.33 (near *RTEL1*).

Moreover, a metaanalysis of four GWASs totaling 4147 cases and 7435 controls identified new glioma susceptibility loci for glioblastoma (GBM) at 12q23.3 (*POLR3B*, rs3851634) and non-GBM at 10q25.2 (*VTI1A*, rs111696067), 11q23.2 (*ZBTB16*, rs648044), 12q21.2 (intergenic, rs12230172), and 15q24.2 (*ETFA*, rs1801591).

In addition, several hematological malignancies including acute lymphocytic leukemia (ALL), chronic lymphocytic leukemia (CLL) and Hodgkin's lymphoma, have been addressed within several GWAS to determine the presence of risk loci associated with the disease. Examples included the risk loci 7q12.2 (*IKZF1*, rs4132601), 10q21.2 (*ARID5B*, rs10994982), and 14q11.2 (*CEBPE*, rs2239633) for ALL, the variants 2q13 (*ACOXL/BCL2L11*, rs17483466), 2q37.1 (*SP140*, rs13397985), 2q37.3 (*FARP2*, rs757978), 6p25-p23 (*IRF4*, rs872071), and 19q13.2-q13.3 (*PRKD2/STRN4*, rs11083846) for CLL.

It is well known that the risk of Hodgkin's lymphoma (HL), a common B-cell-derived cancer involving germinal center of lymph nodes, is influenced by HLA genotype variation within the major histocompatibility complex (MHC). Nevertheless, GWASs on this cancer have identified susceptibility loci for HL at 2p16.1 (*REL*, rs1432295), 8q24.21 (*PVT1*, rs2019960), and 10p14 (*GATA3*, rs501764), together with loci mapping to 3p24.1 (*EOMES*, rs3806624), and 6q23.3 (*HBS1L* and *MYB*, rs7745098).

Recently, a metaanalysis performed on three GWASs (1816 cases and 7877 controls) identified a novel variant at 19p13.3 associated with HL (rs1860661; OR = 0.81), located in intron 2 of *TCF3* (also known as *E2A*), a regulator of B- and T-cell lineage commitment known to be involved in HL pathogenesis, suggesting a link between the 19p13.3 locus and HL risk.

In conclusion, despite GWAS provided a direct evidence of polygenic susceptibility, almost all variants identified in several cancers and other diseases have no proven biological or mechanistic relevance to the disease, or medical utility for diagnosis or therapy. Almost all low-penetrance variations discovered to date have weak effects; a meta-analysis approach showed that few loci were replicated in different studies. In this regard, the genetic heterogeneity could be the reason for the limited number of genes that could play an important role in cancer susceptibility exclusively within a limited number of families, and this effect could be lost as soon as they are diluted in the general population. Moreover, the synergistic interactions of low-penetrance genes together with the environmental exposure could characterize an important portion of the heritability of cancer.

For this reason, in order to improve the knowledge regarding the causative relationship between variants and diseases, large-scale association or case-control studies are warranted.

Genome-Wide Association Studies in Pharmacogenetics

Pharmacogenetics is the study of inherited genetic differences in drug metabolic pathways, which can affect the individual response to drug in term of both therapeutic and adverse effects (**Fig. 3**).

Pharmacogenetics is often related to the oncology field, and involves the study of germline mutations, included SNPs, affecting genes coding for liver enzymes and drug carriers responsible for drug metabolism and transport across membranes. Pharmacokinetics and pharmacodynamics are thus involved. Among the most important genes, a relevant role is played by the cytochrome P450 oxidase and genes coding for drug targets like receptor, transporters or enzymes.

Since 2007, GWAS have increasingly been applied in this field. For example, the immunosuppressant thiopurine drugs, used in several cancer treatments, can cause bone marrow suppression associated with inactivating polymorphisms of thiopurine *S*-methyltransferase (TPMT).

In particular, the TPMT c.719A>G SNP has been known to cause a decrease in TPMT activity, increased intracellular thiopurines, and drug toxicities. The majority of low activity phenotypes can be explained by two common variant alleles, TPMT*3A and *3C, both of which are characterized by the nonsynonymous SNP c.719A>G (rs1142345). Similarly, an association has been also described between the uridine diphosphate glucuronosyltransferase 1A1 allele *28 (UGT1A1*28) and neutropenia induced by irinotecan.

One of the first GWA study referred to the analysis of genetic and nongenetic response to the anticoagulant warfarin, was performed on 1053 patients, resulting in an association with two genes: CYP2C9, encoding the main metabolizing enzyme for both drugs, and vitamin K epoxide reductase complex 1 (VKORC1), showing genome wide significance with low *P* values (1×10^{-78}). The role of GWAS in this process is evident in the evaluation of the genetic component of warfarin dosing.

Another example is referred to methotrexate, a chemotherapeutic agent and immune system suppressant used to treat cancer (i.e., breast, leukemia, lung cancer, and lymphoma), and autoimmune diseases (i.e., psoriasis, rheumatoid arthritis, and Crohn's disease). The GWA study, performed on a cohort of 434 children with leukemia, has identified the SLCO1B1 gene affecting methotrexate pharmacokinetics, thus influencing both toxicity of this drug, and possible drug interactions with widely used OATP1B1 substrates, such as statins. In conclusions, ongoing GWAS are demonstrating their potential not only for the identification of genes related to the development and/or progression of a disease, but also in pharmacogenetics and pharmacogenomics. In particular, the complex physiology of drug response highlights the need for analytical methods that address this complexity, using the wealth of information available about drug mechanisms and pathways.

Conclusions

Cancer is an extremely complex phenomenon and, together with the incomplete penetrance of the inherited tumor susceptibility alleles, the interaction with environmental risk factors could substantially alter hereditary susceptibility. The results of currently published GWAS have demonstrated that much of the heritable risk of most common cancers is polygenic, and that the increased risk of cancer associated with the known genetic variants are not medically addressed. With the exception of breast and prostate cancers, the currently identified loci explain only a small proportion of the familial risk of many cancers. Nevertheless, the loci identified through GWAS have greatly expanded the existing knowledge of genes that influence cancer risk. However, determining the functional consequences of data from GWAS could be important in order to gain a deeper understanding of cancer biology and to suggest potential targets for therapeutic and preventive strategies.

Therefore, despite the GWAS limitations, these analysis provide a more complete understanding of the genetic basis of disease, and a wide view of the genetic architecture of complex phenotypes.

Prospective Vision

In contrast to the original hypothesis according to which a common disease may be caused in part by genetic variants (e.g., SNPs) with minor allele frequency (MAF) > 5%, selected diseases are also due to rare variants. GWAS mainly contributed to the identification of common low-penetrance risk variants associated with a low relative-risk to develop a disease. Thus, efforts are currently

being directed towards testing rare variants for association with complex traits. The development of new analytic approaches and the test of rare variants for association with complex traits using imputed variants from the publicly available 1000 Genomes Project resequencing data and from direct resequencing of clinical samples, are now ongoing. In particular, novel analytic approaches are based on the integration of in vitro and in vivo experimental approaches with genomic data.

Therefore, GWAS approaches are powerful tools that have enhanced and will continue to expand our understanding of cancer genetics and will inevitably lead to the identification of novel pathways of carcinogenesis.

Until now, most GWAS evaluated genetic variation depend only on SNPs. At present, the research regarding other forms of genetic variation in the human genome, including genomic structural changes and sequence variation (i.e., CNV), is just beginning to emerge and will provide further insight into the genetic basis of complex diseases. Due to rapid expansion of genomic knowledge, it will be important to build and adequate collaboration between "bench" scientists and "bedside" stakeholders.

Germ Cell Tumors: Pathology and Genetics

JW Oosterhuis and Leendert HJ Looijenga, Erasmus University Medical Center, Rotterdam, The Netherlands

Glossary

Choriocarcinoma Malignant germ cell tumor composed of trophoblastic tissue.

Dermoid cyst Cystic benign tumor of the ovary composed of mature somatic tissues, predominantly from the cranial part of the body.

Developmental state (synonym: pluripotency state) Determines the developmental potential of embryonic stem cells: 2C-state, omnipotent, capable of producing a complete organism; naïve-state (synonym: ground-state), totipotent, capable of producing all lineages of the embryo proper, extraembryonic tissues (yolk sac and trophoblast), and the germ line; primed-state, pluripotent, capable of producing all somatic tissues, but not extraembryonic tissues and the germ line. (Table 1) Plasticity of developmental states allows gradual transitions between the defined states.

Embryonal carcinoma Malignant germ cell tumor composed of transformed embryonic stem cells, so-called embryonal carcinoma cells, the stem cells of nonseminomas.

Genomic imprinting The mechanism whereby the expression of genes may differ depending on parental origin.

Germ cell neoplasia in situ (GCNIS) In situ malignant germ cell tumor confined to seminiferous tubules, composed of transformed gonocytes, located in the spermatogonial niche.

Gonadoblastoma In situ malignant germ cell tumor of dysplastic gonads, composed of transformed gonocytes enveloped by supporting stromal cells, usually granulosa cells.

Hydatidiform mole Benign germ cell tumor composed of trophoblastic tissue.

Nonseminoma Malignant germ cell tumor, resulting from reprogramming of neoplastic primordial germ cell/gonocyte, consisting of embryonal carcinoma, embryoid bodies, teratoma, yolk sac tumor and choriocarcinoma, either pure or in various combinations, and thus representing caricatures of embryonic development. Identical tumors are referred to as nonseminoma in the testis and mediastinum, nondysgerminoma in the ovary, and nongerminoma in the brain.

Parasitic twin Poorly developed, usually monozygotic twin attached to outside of the body, or included within the body.

Pre-GCNIS Lesion of the seminiferous tubule at risk of progressing toward GCNIS.

Seminoma Malignant germ cell tumor composed of transformed primordial germ cells (extragonadal) or gonocytes (testis, ovary, and dysgenetic gonad). Identical tumors are referred to as seminoma in the testis and mediastinum, dysgerminoma in the ovary, and germinoma in the brain.

Spermatocytic tumor Benign germ cell tumor composed of postpubertal spermatogenetic cells before meiosis. Previously referred to as spermatocytic seminoma.

Teratoma Germ cell tumor composed of mature somatic tissues; depending on originating germ cell tumor type (Table 1) teratomas can be benign (type I and IV), malignant (type II), or both (type VI).

Undifferentiated gonadal tissue Combination of granulosa cells and gonocytes in an ambiguous gonad at risk of progressing toward gonadoblastoma.

Yolk sac tumor (synonym primitive endodermal tumor) Malignant germ cell tumor composed of extraembryonic structures (allantois and yolk sac), and intraembryonic endodermal derivatives (primitive gut and liver).

Introduction

Germ cell tumors (GCT) are a heterogeneous family of gonadal and extragonadal tumors derived from germ cells, and their precursors: primordial germ cells (PGC)/gonocytes (Fig. 1). The wide range of clinical manifestations of GCT is due to the different developmental potential and anatomical sites of the originating cells. Characteristics of seven defined types of GCT are summarized in Table 1.

Migration of PGC and Localization of Extragonadal GCT Types I and II

In human embryos PGC can be recognized in the wall of the yolk sac from week 3 to 4 postconception (wpc). They express cKIT, the receptor for KIT ligand (KITLG), which is essential for survival, proliferation, and migration of PGC. In wpc 4–5 PGC leave the gut

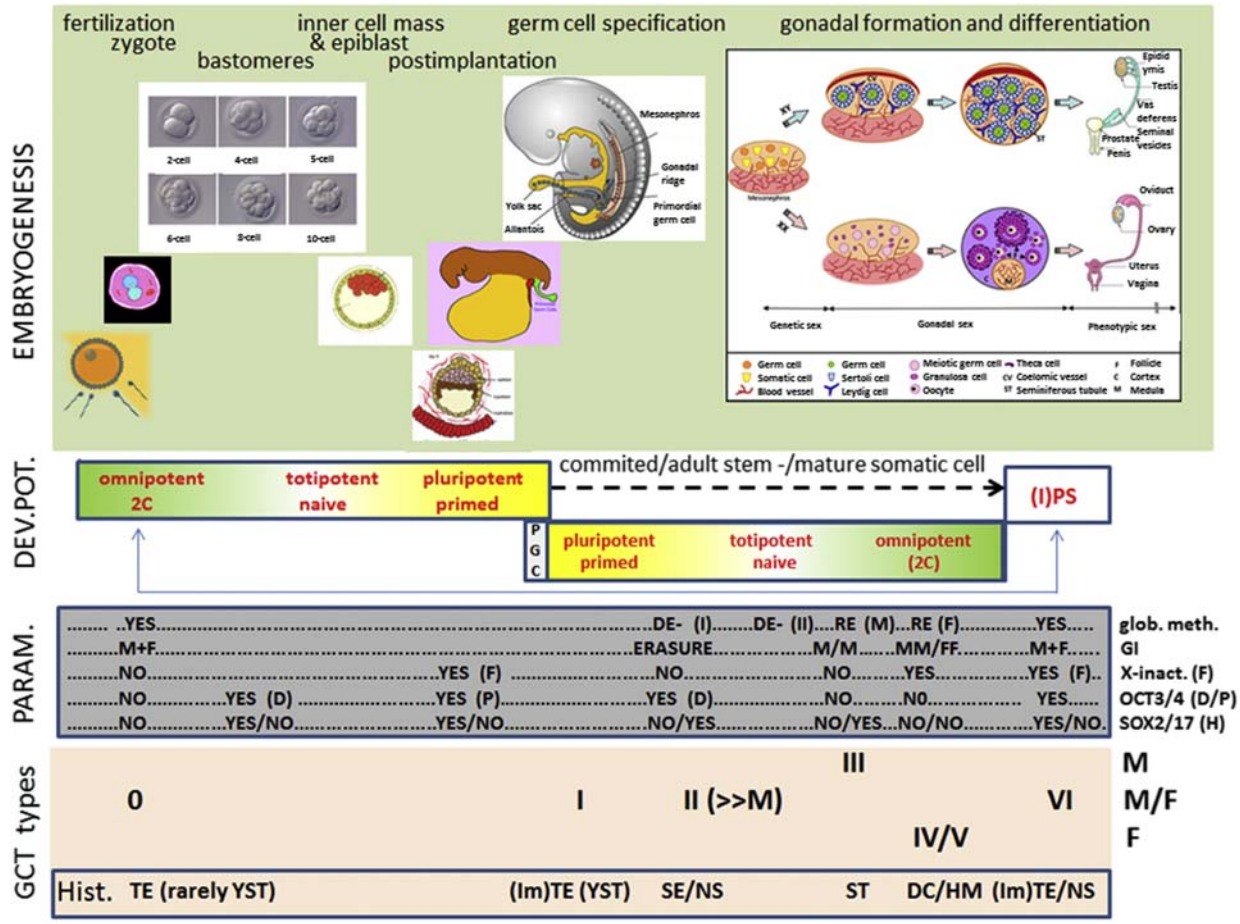

Fig. 1 Unifying model of the pathogenesis of GCT based on the hypothesis that the developmental potential of GCT is determined by the developmental state (2C, naïve, or primed) of the originating cell. Shown in the figure are stages of embryogenesis (upper panel), developmental potential of stem cells in subsequent stages of embryonic development and the germline (second panel), critical features of the involved stem cells (third panel), and corresponding GCT types with gender distribution and their histology, reflecting developmental potential of originating cell (bottom panel, linking **Figure 1** to **Table 1**). Abbreviations in order of appearance: *DEV.·POT.*, developmental potential; *PGC*, primordial germ cell; *iPSC*, induced pluripotent stem cell; *PARAM*, parameters; *M*, male; *F*, female; *DE-(I)*, first wave of demethylation; *DE-(II)*, second wave of demethylation; *RE*, remethylation; *glob. meth.*, Global methylation; *GI*, genomic imprinting; *X-inact*, X-inactivation; *D*, distal enhancer; *P*, proximal enhancer; *H*, human; *GCT*, germ cell tumor; *TE*, teratoma; *YST*, yolk sac tumor; *Im*, immature; *SE*, seminoma; *NS*, nonseminoma; *ST*, spermatocytic tumor; *DC*, dermoid cyst; *HM*, hydatidiform mole. Oosterhuis, J. W. and Looijenga, L. H. J. (2017). Germ cell tumors from a developmental perspective: Cells of origin, pathogenesis and molecular biology; emerging patterns. In F. F. Nogales and R. E. Jimenez (eds.), *Pathology and biology of human germ cell tumors*, Berlin: Springer Nature, pp. 23–129.

epithelium by epithelial mesenchymal transition (EMT) (Fig. 2). In the period wpc 4–6 they are present in the hindgut epithelium, the mesenchyme of the dorsal mesentery, and the developing genital ridge. KITLG activates KIT signaling and facilitates the migration of PGC. After establishment of connections between the enteric and sympathetic nervous systems, PGC follow sympathetic nerve fibers towards the gonads. Numerous PGC are still present in the nervous system by wpc14. PGC failing to exit the nerve branches at the gonadal site may continue along the sympathetic trunk along the midline of the body and may end up in other distant localizations including the retroperitoneum (suprarenal region, adrenal glands), abdomen (stomach), anterior mediastinum, heart, lungs, head and neck, and central nervous system (CNS). These so-called mis-migrated PGC may, unless eliminated by apoptosis (Fig. 3), give rise to GCT in these various extragonadal sites.

Upon arrival in the genital ridges human PGC, from then on called gonocytes, enter a premeiotic stage and upregulate meiotic genes. In the male genital ridge the germ cells enter mitotic arrest as G0/G1 prespermatogonia, due to the low exposure to retinoic acid (RA) within the seminiferous tubules. In the female genital ridge, and extragonadal localizations both in male and female embryos, the germ cells enter meiotic prophase due to exposure to RA.

Migrating PGC undergo progressive germline-specific global demethylation, so-called reprogramming 1. In the gonads reprogramming 2 takes place, including completion of erasure of parental genomic imprinting.

Extragonadal type I GCT occur at all sites where mis-migrated PGC have been demonstrated. In the developing embryo methylated early stage PGC are more robust than late stage PGC, but nonetheless will perish through apoptosis, unless they escape this

Table 1 Characteristics of seven defined types of germ cell tumors (GCT)

Type GCT	*Age (years)*	*Sex*	*Anatomical site*	*Phenotype/ developmental potential*	*Developmental state*	*Precursor cell*	*Genomic imprinting; methylation*	*Karyotype*	*Animal model*
0	Neonates	F/M	Retroperitoneum/ sacrum/skull/hard palate	Included and parasitic twins	2C-state (omnipotent)	Blastomere	Biparentental	Normal diploid	Not available
I	Neonates and children$n < 6$; rarely beyond childhood	F/M	Testis/ovary/sacral region/ retroperitoneum/ anterior mediastinum/neck/ midline brain/other rare sites	(Immature) teratoma (TE)/yolk sac tumor (YST)	Primed-state (pluripotent)	PGC/gonocyte before start of global demethylation	Biparental partially erased	Diploid (TE)/ aneuploid (YST): gain: 1q,12(p13),20q loss: 1p,4,6q	Mouse teratoma
II	After start of puberty. In disorders of sexual developm., Klinefelter's- and Down's syndrome rarely before puberty	>>M	Dysgenetic gonad/ testis/ovary/anterior mediastinum (thymus)/midline brain (pineal gland)	Seminoma/ dysgerminoma/ germinoma reprogrammed to nonseminoma/ nondysgerminoma/ nongerminoma	Naïve-state (totipotent)	PGC/gonocyte undergoing global demethylation	Erased	Aneuploid (+/- triploid) gain: X,7,8,12p,21 loss: Y,1p,11,13,18 In mediastinum and midline brain also (near)diploid and (near)tetraploid with gain of 12p	Not available
III	Older men, usually > 55	M	Testis	Spermatocytic tumor	Spermatogonium to premeiotic spermatocyte	Spermatogonium/ spermatocyte	Partially-completely paternal	Gain: 9	Canine seminoma
IV	After puberty	F	Ovary	Dermoid cyst	Maternally imprinted 2C-state	Oogonia/oocyte (gynogenote)	Partially-completely maternal	(Near) diploid diploid/tetraploid peritriploid gain: X,7,12,15	Mouse gynogenote
V	After puberty	F	Placenata/uterus	Molar pregnancy	Paternally imprinted 2C-state	Empty ovum/ spermatozoa (androgenote)	Completely paternal	Diploid (XX and XY)	Mouse androgenote
VI	Older age, usually >60	F/M	Atypical sites for GCT	Resembling type I or nonseminoma components of type II	Primed state or nonseminoma lineages of naïve-state	Somatic cell induced to pluripotency	Imprinting pattern of originating cell	Depending on precursor cell	Xenografts derived from iPSC

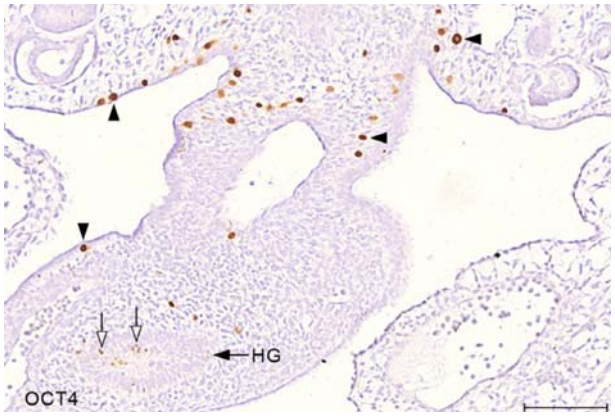

Fig. 2 Transverse section through the hindgut and dorsal mesentery of a human embryo, 4.5 weeks postconception. Remnants of OCT4 reactivity (*open arrows*) are shown in the hindgut epithelium (HG), as well as many migrating, OCT4-positive PGCs (*arrowheads*). Mamsen, L. S., Brochner, C. B., Byskov, A. G., Mollgard, K. (2012). The migration and loss of human primordial germ stem cells from the hind gut epithelium towards the gonadal ridge. *The International Journal of Developmental Biology* **56**, 771–778.

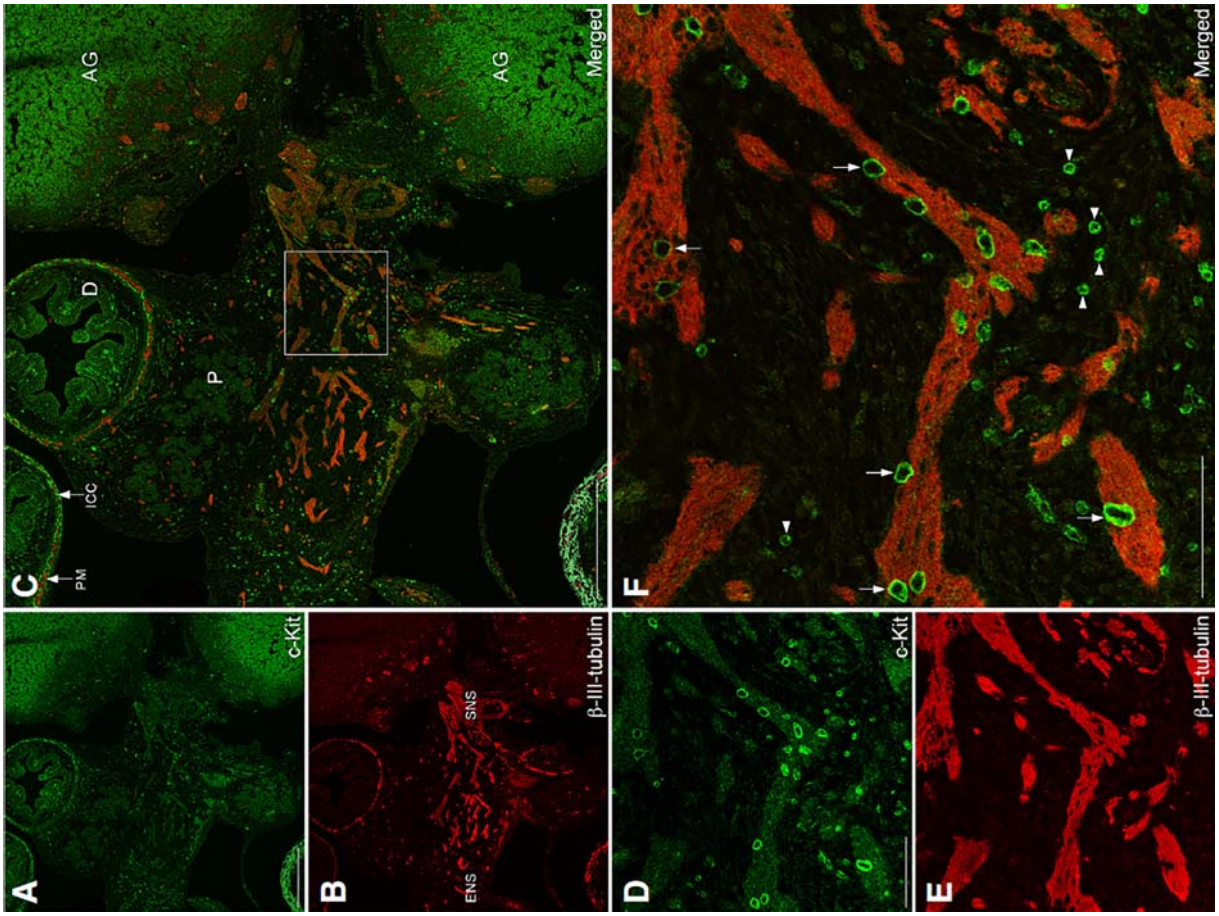

Fig. 3 Horizontal section through abdomen of human embryo, CRL = 30 mm, 7 weeks and 6 days pc, immunofluorescent labeled against c-Kit and b-III-tubulin antibody. Survey depicted (A–C), with commencing connectivity of the enteric (ENS) and sympathetic (SNS) nervous system (B). (C) Some sympathetic nerve fibers are found in the adrenal glands (AG), the pancreas (P), and especially in the dorsal mesentery located in the middle of the section. Positive b-III-tubulin reactivity is seen in nerve fibers of ENS, in general in the plexus myentericus (PM) and similar reactivity is observed in the duodenum (D). Furthermore, c-Kit is also observed in the interstitial cells of Cajal (ICC) of PM. (D) The PGCs in the nerve fibers demonstrate c-Kit reactivity. (E) Higher magnification of (B) demonstrating b-III-tubulin reactivity of SNS. (F) Higher magnification of boxed area in (C). The larger PGCs, with strong membranous c-Kit reactivity are located in close correspondence to the periphery of the individual nerve fibers of the SNS (F, *arrows*). The small, densely labeled c-Kit-positive cells outside of the nerve fibers are mast cells (F, *arrowheads*). Scale bars: (A,B) 500 mm, (C) 200 mm, (D,E) 100 mm, (F) 50 mm. Mamsen, L. S., Brochner, C. B., Byskov, A. G., Mollgard, K. (2012). The migration and loss of human primordial germ stem cells from the hind gut epithelium towards the gonadal ridge. *The International Journal of Developmental Biology* **56**, 771–778.

fate through reprogramming into an embryonic stem cell (ESC) in the primed state, the precursor of type I GCT. Extragonadal type II GCT only occur in the thymus and midline of the brain. This more limited distribution of extragonadal type II GCT compared to type I GCT is probably due to the demethylated, partially erased genome of late stage PGC, which renders them fragile and highly apoptosis-prone. These cells can normally only survive as gonocytes in specific niches in the developing gonads. Presumably, in the thymus and the midline of the brain the conditions of the developing gonads are mimicked to the extent that late stage PGC can occasionally survive there, and give rise to type II GCT.

Pathology and Genetics of GCT Types

Type 0 GCT (Included and Parasitic Twins)

Included and parasitic twins have an estimated incidence of 1/500,000 births. A family history of twinning is a risk factor. Included twins are in 80% localized in the retroperitoneum. External parasitic twins are localized at the same sites where conjoined twins are attached (Fig. 4).

Both are composed of highly organized, mature somatic tissues often with a vertebral axis, limbs and internal organs. Most of the cranial part of the embryo, including the brain, is usually missing. Immature components are rare; progression to yolk sac tumor (YST) is exceptional.

Parasitic twins have the same genetic constitution as the host, consistent with their origin as monozygotic diamniotic twins. Epidemiological data suggest a continuum between twins, conjoined twins, external parasitic twins, acardiacs (external parasitic twins attached via the placenta) internal parasitic twins, and type I teratomas.

The common pathogenesis of these conditions seems proneness of the 2C state, omnipotent blastomeres (Table 1, Fig. 1), to escape control of their developmental potential by the developing embryo. If the resulting twin fails to develop a functional heart it will die. If it succeeds in getting its circulation from the host, it will develop as a parasitic twin or, exceptionally, as a type I teratoma.

Type I GCT (Pediatric GCT; Prepubertal-type GCT)

Epidemiology and risk factors

The incidence of type I GCT is estimated at 1–1.5 per 100,000; more than half are benign teratomas. A family history of twinning is a risk factor, and possibly Down's syndrome.

The age distribution of GCT shows a small neonatal peak (Fig. 5), before the age of six. This represents type I GCT of the sacrococcygeal area/pelvis, retroperitoneum, anterior mediastinum, head and neck (not shown), brain, and testis. Type I GCT of the ovary occur from birth through adulthood, partially overlapping with the age range of type II and IV GCT. Rarely type I GCT occur in older individuals at other sites than the ovary. Type I GCT occur more often in girls than in boys. Multiplicity of type I GCT is rare (Table 1).

Anatomical localization

Type I GCT occur in the testis, ovary, and, outside the gonads, along the midline of the body at sites where mis-migrated PGC have been demonstrated. They occur also in the thymus where PGC have not yet been identified.

Pathology

Extragonadal type I GCT result from accidental reprogramming of mis-migrated, early stage, still methylated PGC that have escaped immediate apoptosis. Reprogramming, due to failure of cell intrinsic factors that check developmental potential (SOX 17, BLIMP1,

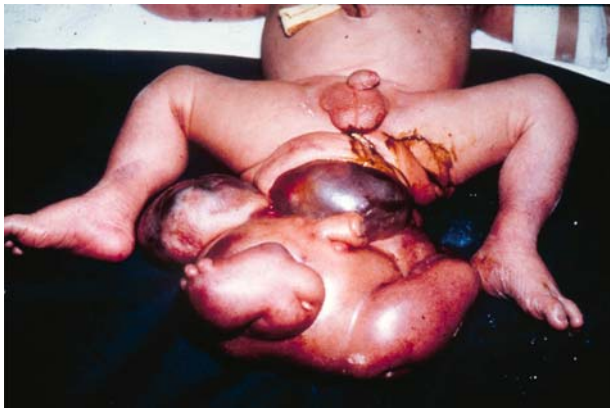

Fig. 4 Neonate with parasitic twin (Type 0 GCT) attached to sacrum; clearly recognizable foot. Oosterhuis, J. W., Stoop, H., Honecker, F., Looijenga, L. H. (2007). Why human extragonadal germ cell tumours occur in the midline of the body: Old concepts, new perspectives. *International Journal of Andrology* **30**, 256–263.

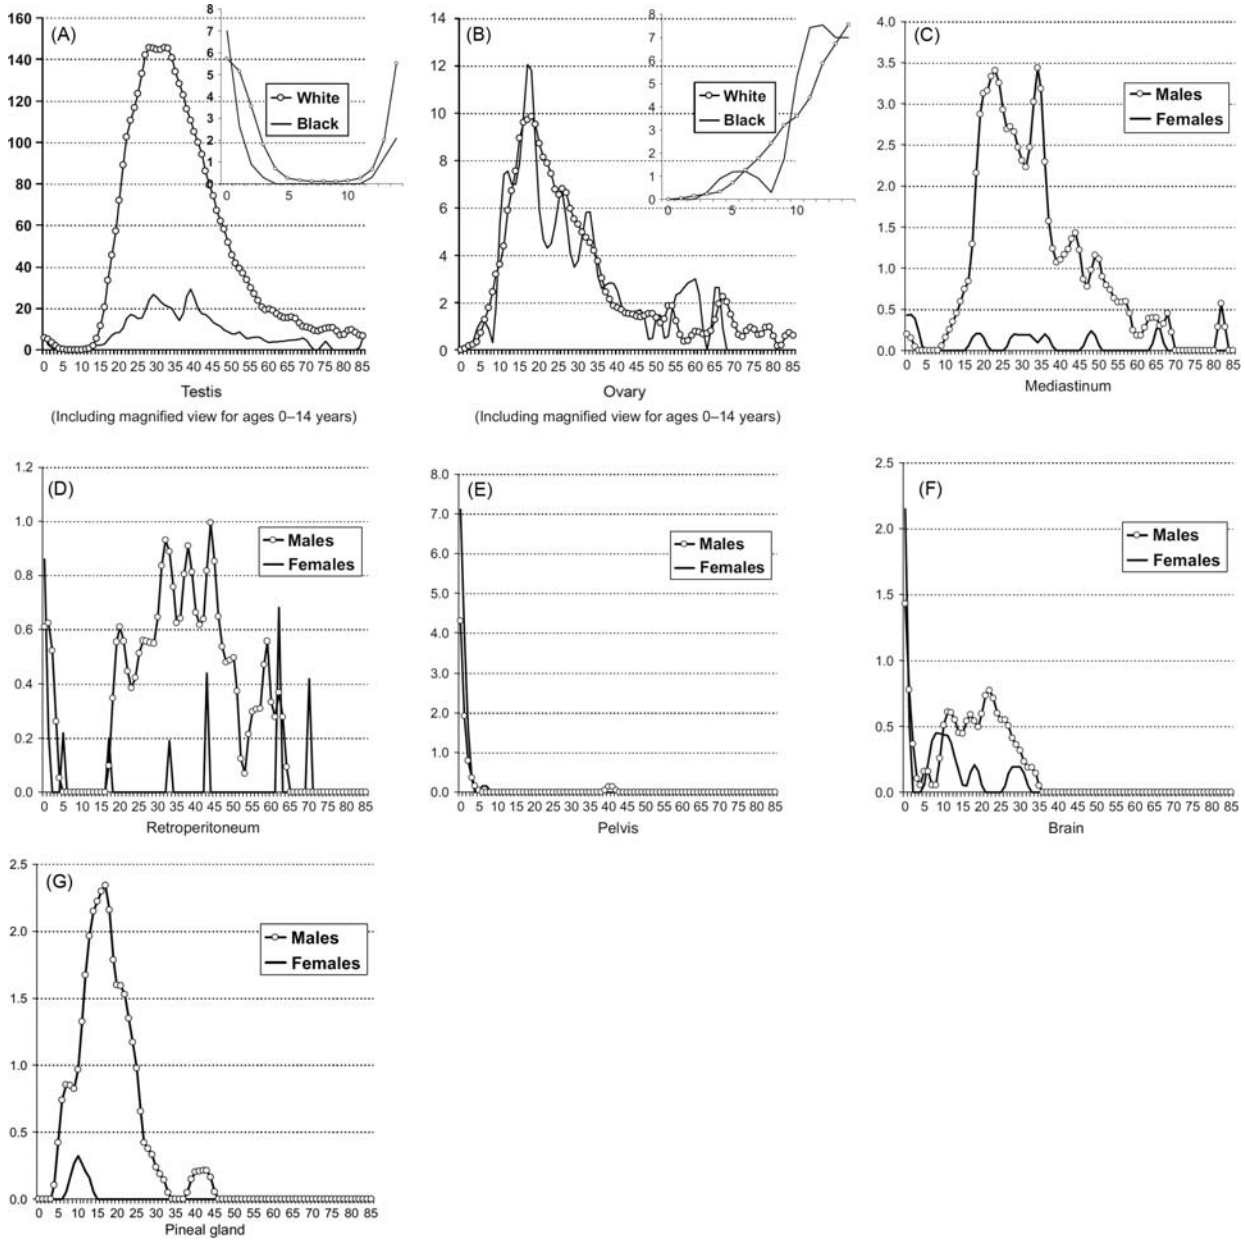

Fig. 5 Age-specific incidence rates of gonadal germ cell tumors in the United States by race, US SEER-9, 1973–2007 (Cases per 1 million) for testis (A); ovary (B); mediastinum (C); retroperitoneum (D); pelvis (E); brain (F); pineal gland (G). Note the early peak before age 6 in testis, mediastinum, retroperitoneum, pelvis, and brain representing type I GCT. This peak is missing in the ovary due the broad age range of ovarian type I GCT. In the pineal gland type I GCT do not occur, only type II GCT. The large majority of extragonadal type II GCT occur in males. Stang, A., Trabert, B., Wentzensen, N., Cook, M. B., Rusner, C., Oosterhuis, J. W., McGlynn, K. A. (2012). Gonadal and extragonadal germ cell tumours in the United States, 1973–2007. *International Journal of Andrology* **35**, 616–625.

and OCT4), results in apoptosis resistant ESC in the primed state. In the testis and ovary preerased gonocytes are reprogrammed to ESC in the primed state due to failure of control of developmental potential by germ cell-intrinsic-and niche factors, such as GDNF. This developmental origin of type I GCT explains the rarity of driver mutations in these tumors.

Most type I GCT consist of immature and/or mature teratoma, in accordance with the developmental potential of ESC in the primed state. OCT4-positive stem cells, which are negative for other pluripotency markers and CD30, are occasionally found in the immature teratoma component. Small foci of YST, often only detectable with the use of immunohistochemical markers such as AFP and glypican 3, may also be present, associated with immature teratoma. The YST component will eventually outgrow and obscure the teratoma component, resulting in pure YST. Histologically, YST can be composed of intraembryonic (primitive gut and liver) and extraembryonic structures (allantois and yolk sac). Trophoblastic extraembryonic differentiation rarely occurs (Fig. 6).

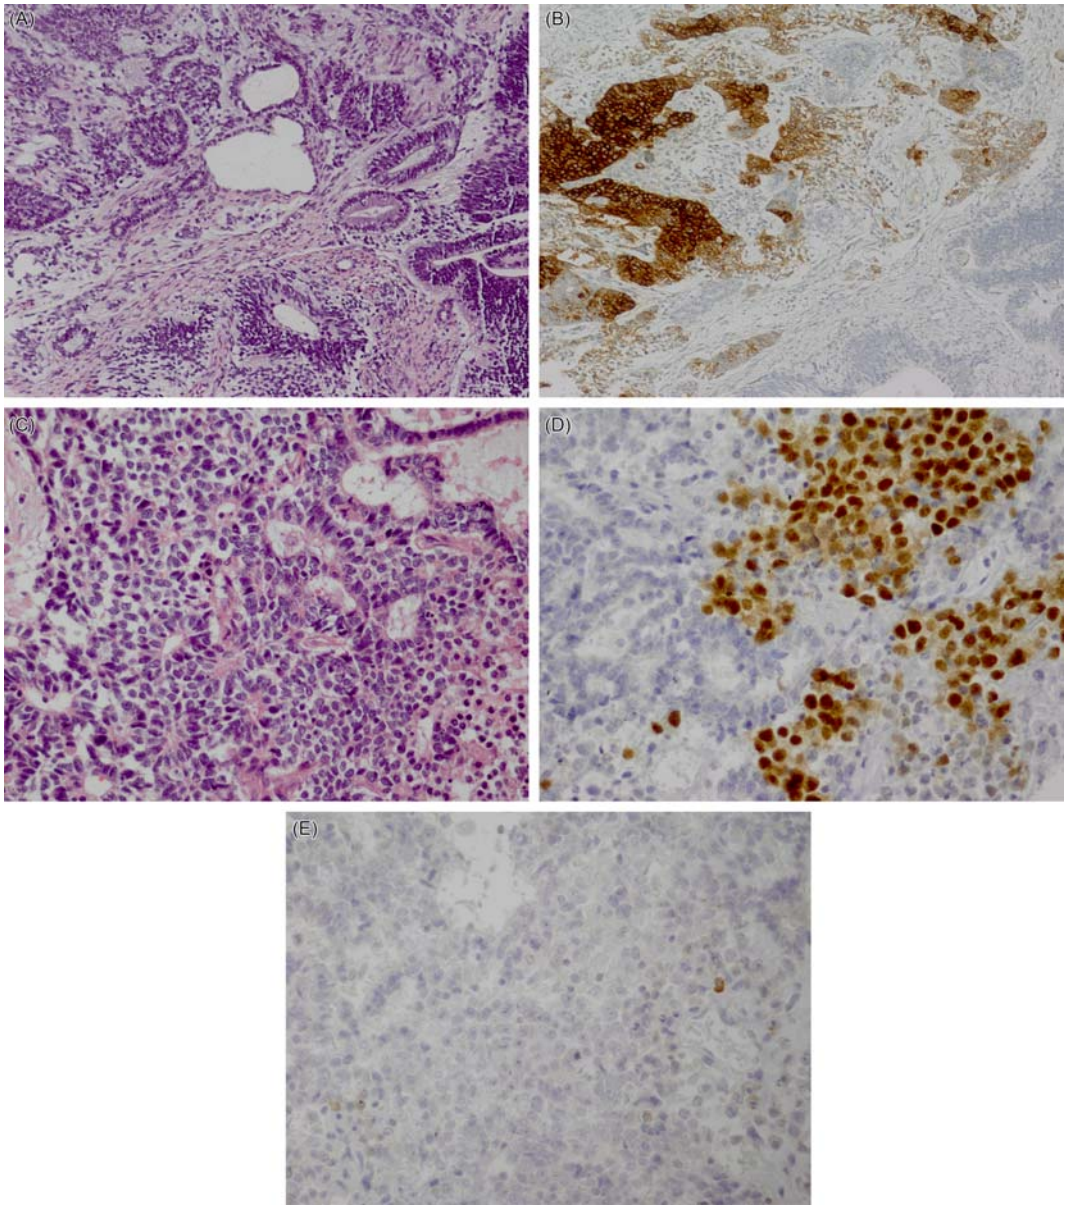

Fig. 6 Histology of testicular type I GCT: immature teratoma (A, H and E, ×200); appears to contain foci of YST on staining for glypican 3 (B, glypican 3 *brown*, ×200); area of pluripotent stem cells (C, H, and E, ×200); with nuclei staining positive for OCT4 (D, OCT4 *brown*, ×200); but, apart from one lymphocyte, negative for CD30 (E, no membranous brown staining, CD30 *brown*, ×200).

Apart from high-grade immature teratoma of the ovary, type I immature and mature teratoma is benign. A YST-component, overall recognized in 5%–10% of the cases at birth, and clinically detectable by increased levels of serum AFP, is the only predictor of malignant behavior at any site. When not, or incompletely removed, type I teratoma has a high risk of progressing to YST.

(Cyto)genetics and epigenetics

A genome wide association study (GWAS) suggests that a single nucleotide polymorphism (SNP) variant in *BAK1*, a gene involved in suppression of apoptosis, might be associated with type I GCT.

Type I immature and mature teratoma is diploid, lacking chromosomal rearrangements. YST of type I, pure or combined with teratoma, is usually near-diploid and may have gains of 1q, 3, 3p, 8q24, 12p13, 20q, 22, and X, and losses of 1p (1p36), 4, 4q, 6q (6q24-qter), 16q, and 20p (Fig. 7). Overrepresentation of the whole of 12p or the region 12p11.2–p12.1, characteristic for type II GCT, is not a feature of type I GCT. Possibly involved genes in the affected chromosomes are *MYC* (8q24) and the pluripotency genes *STELLAR*, *NANOG*, and *GDF3* (12p13). Some of the changes, such as gain of 1q and loss of 1p and 6q, are shared by type II YST and may be related to the phenomenon of progression toward YST rather than being specific for type I GCT.

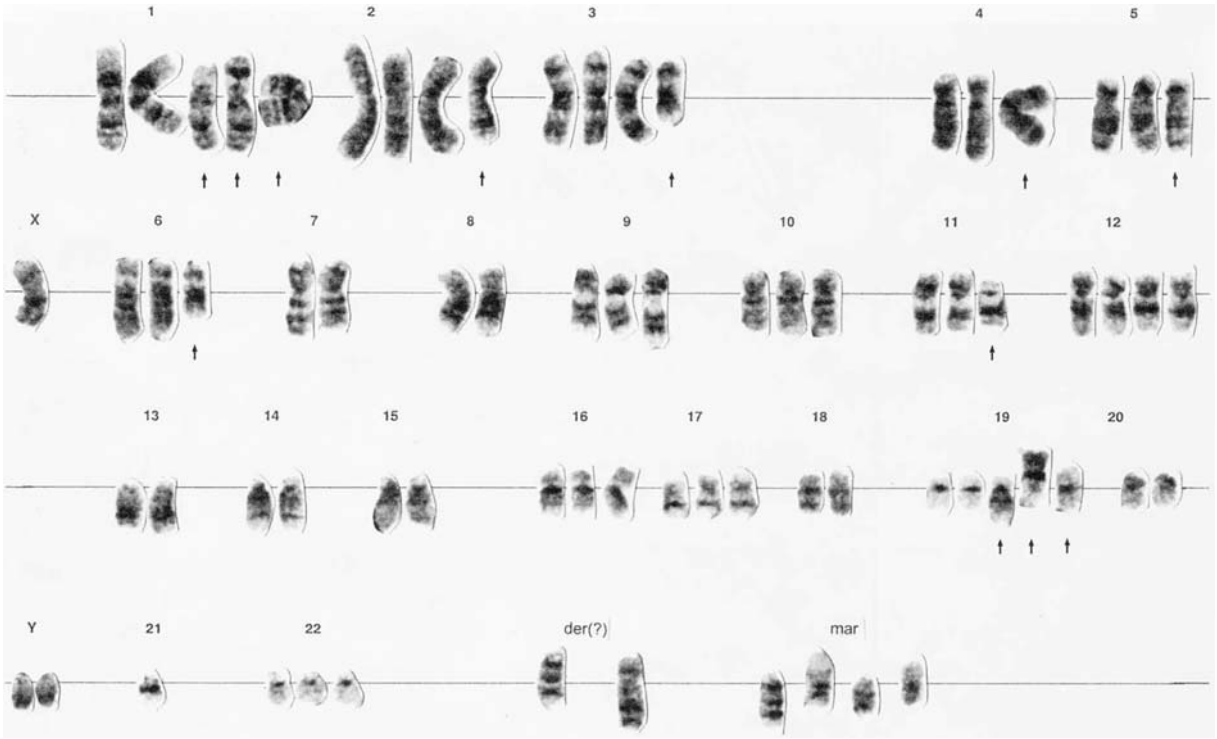

Fig. 7 Karyotype of testicular type I YST, note aneuploidy with characteristic gain of 1q and loss of 6q, and absence of overrepresentation of 12p.

The Wnt/beta-catenin and TGFbeta/BMP signaling pathways are strongly expressed in type I and II YST. Methylation of APC and LOH at 5q21-22 suggests that APC might be involved in the activation of the Wnt pathway.

Type I GCT by anatomical site

- Sacral region
  The sacrococcygeal region is the most common site of type I GCT. The male-to-female ratio is 1:3.5. With a frequency of 1/35,000 live births they constitute about a third of all type I GCT. It is the most frequent neonatal tumor, rarely diagnosed beyond the age of 2 years; exceptionally they remain undetected until adult age, and are diagnosed as a type I GCT beyond infancy. The continuum between type 0 and type I GCT makes the distinction sometimes difficult and arbitrary.
- Other extragonadal sites
  Other localizations of type I GCT are: retroperitoneum (10%); stomach (2%–3%); mediastinum/thymus (2%–3%); heart (5%); head and neck (15%); brain (10%). Females are more often affected than males.
- Testis and ovary
  Ten percent of type I GCT occur in the testis (Fig. 8). Type I GCT of the testis are not associated with germ cell neoplasia in situ (GCNIS) and testicular dysgenesis syndrome (TDS), and do not share the risk factors of testicular type II GCT nor their increasing incidence.
  About 20% of all type I GCT are localized in the ovary, the second most frequent site, with a broad age range from neonates to adults.

Type I GCT beyond infancy

At sites other than the ovary, type I GCT are exceedingly rare beyond the age of 6. However, recently so-called prepubertal type-teratomas have been described in the testis after puberty. It is clinically important to distinguish these type I teratomas from type II teratoma, which is malignant, notwithstanding its deceptively bland histology.

Remarkably, these prepubertal type teratomas of the postpubertal testis may grossly be partly solid, partly cystic, and even present as dermoid cysts, sometimes containing hair, like type IV GCT, the dermoid cysts of the postpubertal ovary. Similar partly cystic teratomas may also occur beyond infancy at extragonadal sites, like the mediastinum and brain. Particularly in the mediastinum, mature teratomas may have the gross and microscopic appearance of a dermoid cyst, containing hair and even tooth structures (Fig. 9).

Thus, type I teratomas beyond infancy may show phenotypes intermediate between typical type I and type IV GCT. In the ovary, typical type I teratomas may occur side by side with type IV teratomas, both uni- and bilaterally. The explanation may be that PGC at

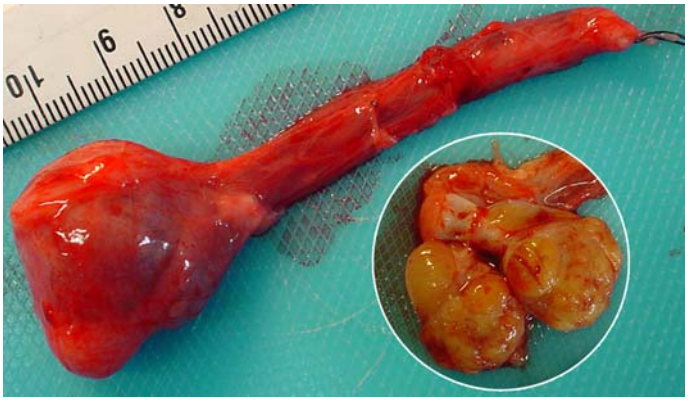

Fig. 8 Gross image of surgically removed testis of infant. On cross section friable yellowish tissue of type I YST; left most nodule is remnant of testis.

Fig. 9 Surgical specimen of mediastinal type I GCT beyond infancy in a 48 year old women showing a cystic tumor containing sebaceous material and hairs, resembling a type IV GCT (dermoid cyst) of the ovary. Probably an intermediate phenotype between a type I and a type IV GCT. Oosterhuis, J. W. and Looijenga, L. H. J. (2017). Germ cell tumors from a developmental perspective: Cells of origin, pathogenesis and molecular biology; Emerging patterns. In: Nogales, F. F. and Jimenez, R. E. (eds.), *Pathology and Biology of Human Germ Cell Tumors*, Berlin: Springer Nature, pp. 23–129.

all sites, except in the seminiferous tubules, both in females and males enter meiotic prophase like in the ovary. These cells resemble primary oocytes (the precursors of type IV GCT), perhaps with a genotype in between that of gonocyte/oogonium and primary oocyte, with partial erasure of GI and some degree of maternal imprinting. Such cells may give rise to teratomas beyond infancy with a phenotype intermediate between type I and type IV GCT.

Type II GCT (Seminoma and Nonseminoma)

Epidemiology

Worldwide the average incidence is 1.5/100,000 with a 20-fold difference between areas with the lowest and highest incidence. Over 90% of type II GCT occur in the testis, the most frequent cancer of males aged 25–45 in Western white Caucasian populations. The remainder develop in dysgenetic gonads/ovary (about 4%) and in the extragonadal sites: anterior mediastinum/thymus and brain midline/pineal gland (about 3%).

Type II GCT occur in patients in whom puberty has started or is completed, except for rare cases associated with disorders of sex development (DSD), Down's syndrome, and Klinefelter's syndrome. The peak age of type II GCT is about 30 for of the testis, 25 for ovary and mediastinum, and 15 for the brain.

At each of the extragonadal sites, males greatly outnumber females. Apparently, type II GCT is very much a disease of adolescent and adult males, probably related to the presence of the TSPY gene on the Y chromosome (Table 1).

Testicular and ovarian type II GCT are bilateral, respectively, in 3%–5% and over 6%. Rarely, gonadal tumors may be combined with extragonadal type II GCT in the same individual.

Type II GCT of the testis have a strong familial component: over 5% of patients with a testicular type II GCT have a relative with a similar tumor; an estimated 25% of testicular cases is due to familial susceptibility. Although much rarer, familial clustering is also documented for ovarian tumors, and testicular- may cluster with ovarian type II GCT. The only difference between sporadic and

familial cases is a younger age of clinical manifestation: 2–3 years for testicular tumors and about 7 years for ovarian cases. Gonadal type II GCT may cluster in families with I GCT, and very rarely with type III GCT (spermatocytic tumor).

Anatomical localization

Type II GCT occur at sites that provide niches for late stage, demethylated PGC/gonocytes: dysgenetic gonads, testis and ovary. Outside the gonads they occur only in the thymus and the midline of the brain, which offer surrogate niches for late stage PGC. So-called retroperitoneal extragonadal type II GCT are not primary tumors, but metastases from unrecognized primary testicular type II GCT.

Pathology

Type II GCT are derived from late stage, demethylated PGC/gonocytes. They can be transformed into seminoma cells in two different ways. Firstly, and most frequently, the "developmental pathway" involving TSPY in the GBY region on Y in concert with OCT4. Secondly, the much rarer "somatic mutation pathway," usually in the absence of TSPY.

Identical tumors are traditionally named seminoma and nonseminoma in the testis and thymus; dysgerminoma and nondysgerminoma in the ovary and dysgenetic gonad; germinoma and nongerminoma in the midline of the brain (Table 1). From here on we will only use the terms seminoma and nonseminoma.

At all anatomical sites, over half of all primary type II GCT are pure seminomas. The younger the patient population, the higher the proportion of seminoma (in dysgenetic gonads and the brain about 80%, in the ovary 60%, in the mediastinum 55%, and in the testis about 50%), suggesting that reprogramming to nonseminoma is a chance event accumulating over time. Reprogramming occurs when due to chromosomal imbalances NODAL- prevails over BMP-signaling (with downregulation of BLIMP1, SOX17, OCT4), whereby niche factors (such as GDNF in the testis) fail to check the potential omnipotency seminoma cells. In invasive seminoma stromal NOGGIN may start reprogamming by inhibiting BMP in the tumor cells.

Seminomas are by definition pure tumors of neoplastic late stage PGC/gonocytes. The only other cells are scattered trophoblastic cells occurring in less than 10% of cases. Reactive host lymphocytes are a consistent histological feature (Fig. 10).

Nonseminomas contain combinations of embryonal carcinoma (EC), YST, choriocarcinoma, immature, and mature teratoma with or without a seminoma component. Early germ cell differentiation is occasionally encountered. The proportions vary by primary site (Fig. 11).

The more aggressive biology of nonseminoma explains its earlier clinical manifestation than seminoma, at all sites. Somatic tissues in nonseminomas may progress to form somatic-type malignancies that closely resemble their somatic counterparts (Fig. 12).

Seminomas and nonseminomas may metastasize to regional lymph nodes and from then on to lungs, liver, brain, and bone, so-called visceral metastasis. Choriocarcinoma has a propensity for blood–borne metastases, sometimes the first clinical manifestation of the tumor. In up to 44% of cases, seminoma cells at metastatic sites are reprogrammed to nonseminoma. In nonseminoma, EC cells are the main metastatic cell type. This is microscopically apparent as tumor emboli are virtually always composed of EC cells only (Fig. 13). At the site where these tumor stem cells eventually lodge, they may resume differentiation, mimicking the histology of the primary tumor. The level of differentiation at the metastatic site is in general less than in the primary tumor.

(Cyto)genetics and epigenetics

Testicular type II GCT are virtually always peritriploid (GCNIS and seminoma hypertriploid, and nonseminoma hypotriploid), whereas in the ovary, mediastinum, and brain, type II GCT may be (near)diploid or (near)tetraploid.

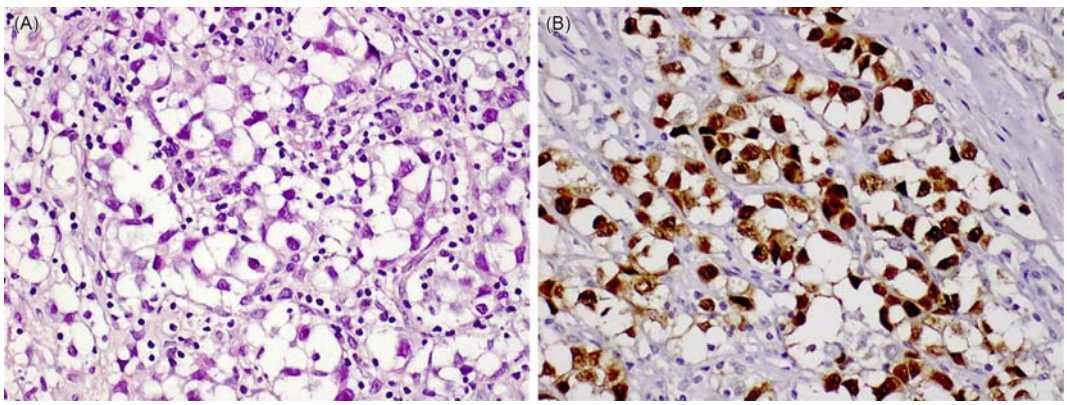

Fig. 10 Histology of seminoma, a tumor composed of transformed gonocytes, large pale cells with angulated nuclei, eliciting a host response, apparent from the many lymphocytes (dark small nuclei) in between the tumor cells (A: H and E, ×200). The seminoma cells show a strictly nuclear staining for OCT4 (B, OCT4 *brown*, ×200).

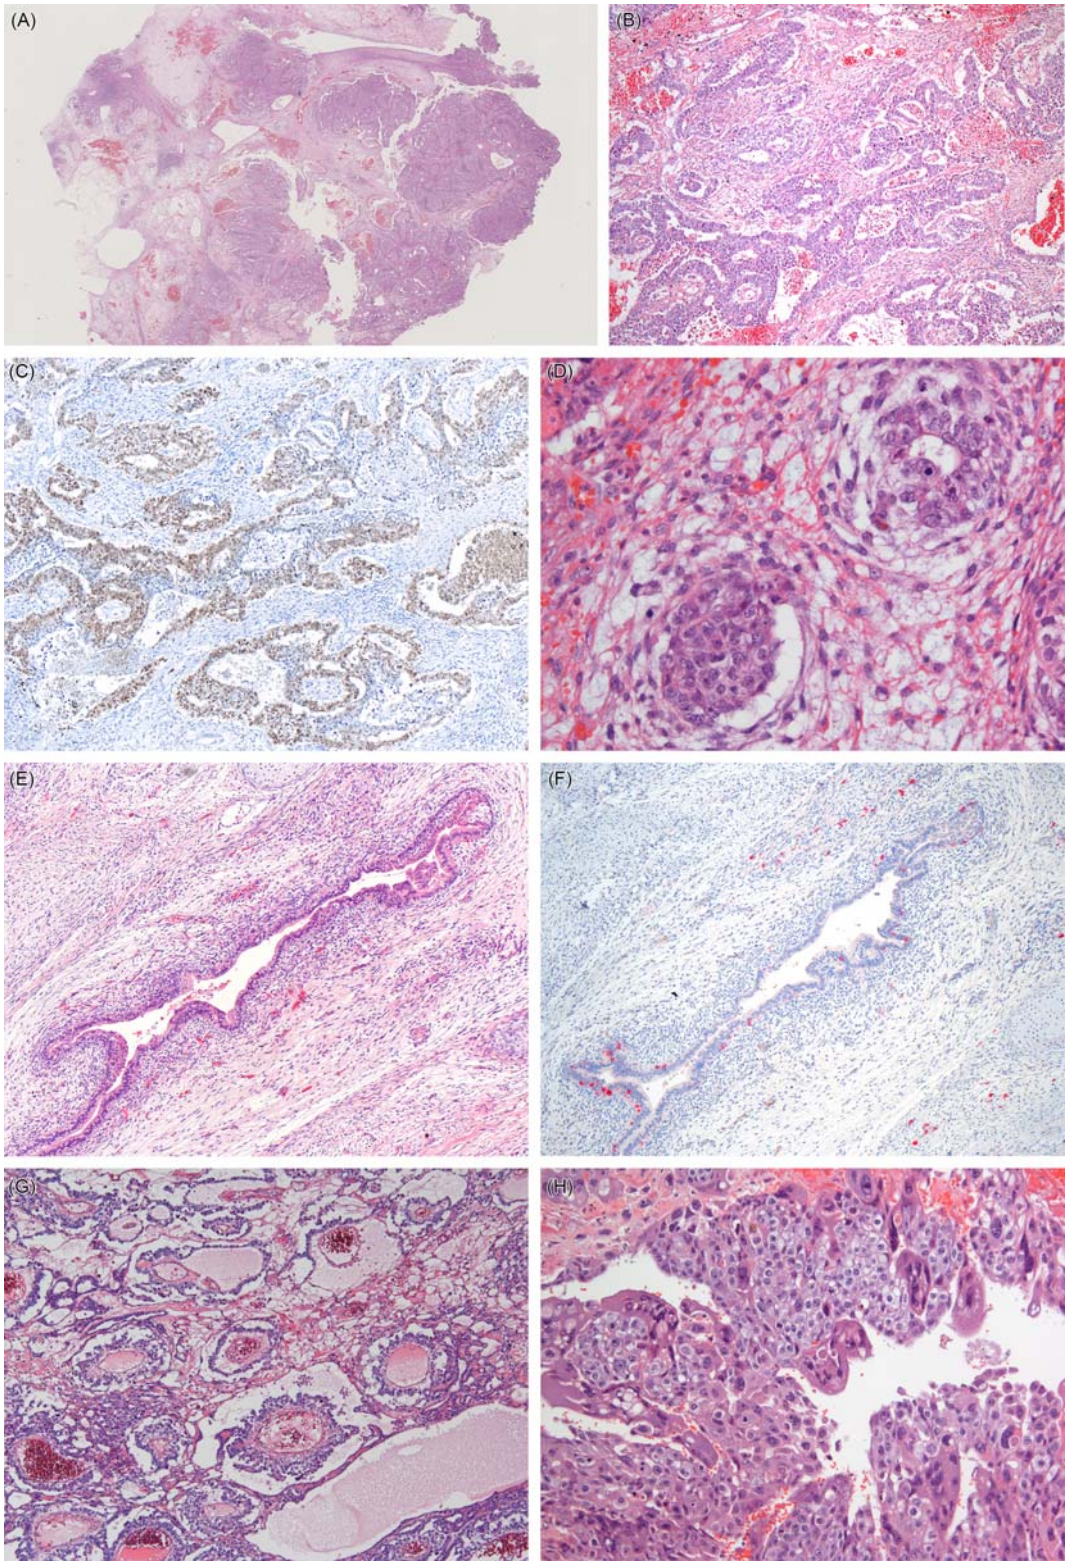

Fig. 11 Histology of nonseminoma with a variegated appearance on low power; the dark areas represent EC, the lighter areas mainly consist of YST, the *red* areas are bleedings caused by trophoblastic giant cells (A: H and E, ×12.5); EC cells arranged in strands and tubular structures (B: H and E, ×50); these totipotent stem cells express OCT4 in the nucleus and the cytoplasm (C: OCT4 *brown*, ×50); EC cells may form embryoid bodies, representing early embryos (D: H and E, ×200); gut-like structure in mature teratoma (E: H and E, ×50); upon staining for TSPY, an early marker of germ cell differentiation, it appears that there are germ cell present in the gut epithelium and the surrounding stromal tissue (F: TSPY *red*, ×50); YST with characteristic Schiller–Duval bodies, concentric structures centered around blood vessels, representing yolk sac elements (G: H and E, ×40); choriocarcinoma, in fact, malignant placenta-like tissue with large multinucleated syncytiotrophoblastic giant cells alternating with mononuclear cytotrophobastic cells (H: H and E, ×100).

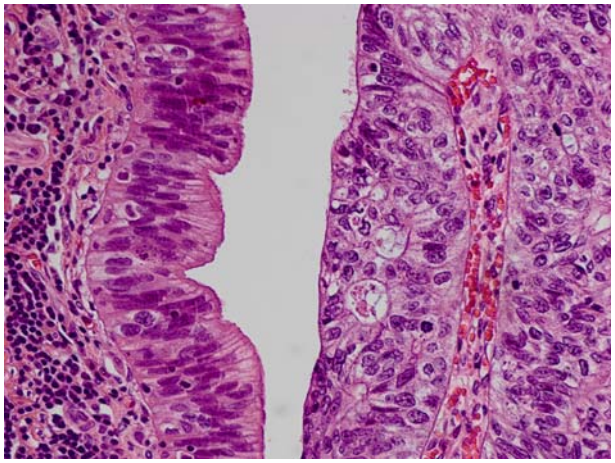

Fig. 12 Teratoma showing progression to somatic-type malignancy; to the left glandular tissue lacking features of malignancy, and to the right glandular tissue with malignant features, to be classified as adenocarcinoma (H and E, ×200). Oosterhuis, J. W., Peeters, S. H., Smit, V. T., Stoop, H., Looijenga, L. H., Elzevier, H. W., Osanto, S. (2013). Patient with two secondary somatic-type malignancies in a late recurrence of a testicular non-seminoma: Illustration of potential and flaw of the cancer stem cell therapy concept. *The International Journal of Developmental Biology* **57**, 153–157.

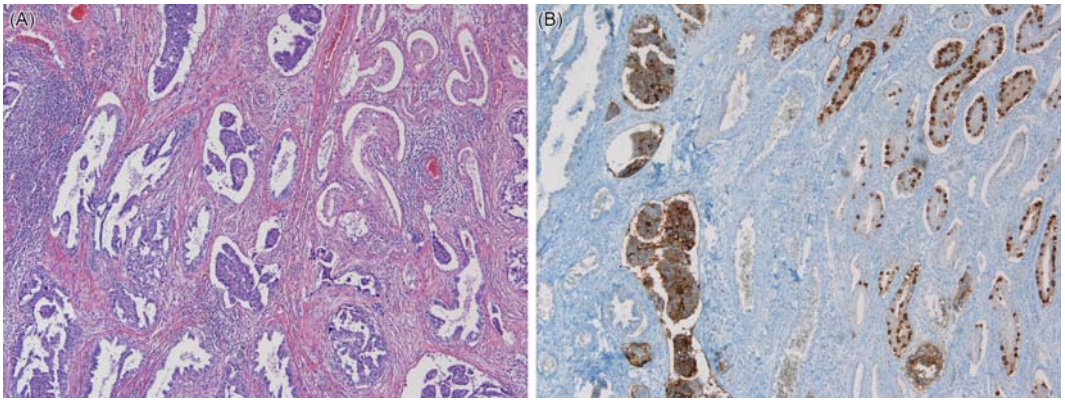

Fig. 13 EC cells, the stem cells of nonseminoma, are the cells invading lymphatics and blood vessels; shown here are numerous tumor emboli in vessels (A: H and E, ×40); similar area stained for D2–40 which demonstrates that the vessels are lymphatics, and the tumor cells within the vessels are EC cells; the right half of the panel shows GCNIS cells with membranous staining for D2–40 within seminiferous tubules (B: D2–40 *brown*, ×40).

At all anatomical sites type II GCT are characterized by gain of (parts of) the short arm of chromosome 12, most often in the form of an isochromosome of 12p (i(12p)) (Fig. 14). In the testis, it occurs in almost 100% of cases, in the ovary/dysgenetic gonad in about 75%, in the mediastinum in close to 90%, and in the midline of the brain in 60%. Especially in invasive components the more proximal parts of 12p, in particular 12p11.2-p12.1, may be amplified. The proportion of tumors with 12p gain increases with the age of clinical presentation. The very high rate of 12p gain and the peritriploidy in testicular tumors is probably due to the long period of intratubular karyotype evolution.

Isochromosome 12p is of uniparental origin, arising from an erroneous centromeric division during mitotic anaphase preceded by tetraploidization. Among the genes involved in the 12p aberrations are *NANOG*, *STELLAR*, *GDF3*, and *EDR1* for maintaining pluripotency; *cyclin D2* and *KRAS* providing proliferative advantage; genes involved in glucose or glycolytic metabolism, including *GLUT3*, *GAPDH*, and *TPI1* for energy metabolism in a low-oxygen environment; and genes involved in suppression of apoptosis such as *EKI1*, *SOX5*, and *DAD-R*. Expression of these genes maintains the PGC/gonocyte-phenotype of the tumor cells and allows them to survive and proliferate in the proper niches.

In addition to 12p gain the tumors have numeric changes involving other chromosomes: gain of chromosomes X, 7, 8, 12, and 21 and loss of chromosomes Y, 1p, 11, 13, and 18. The pattern is explained by early tetraploidization of the tumor cells, followed by nonrandom losses and gains of (parts of) chromosomes. The large stretches involved, often entire chromosome arms, suggest that aberrant meiotic division plays a role in the evolution of these chromosomal aberrations. The resulting polyploid genome, combined with hypomethylation, renders Type II GCT chromosomally instable. Chromosomal instability likely drives tumor progression of type II GCT.

Mutations and amplifications of oncogenes are rare in type II GCT, which is at 0.5 mutations per Mb lower than in any other solid cancer of adults. *KIT* is most frequently mutated and mainly involved in seminoma: of the testis in about 30%; of the ovary in

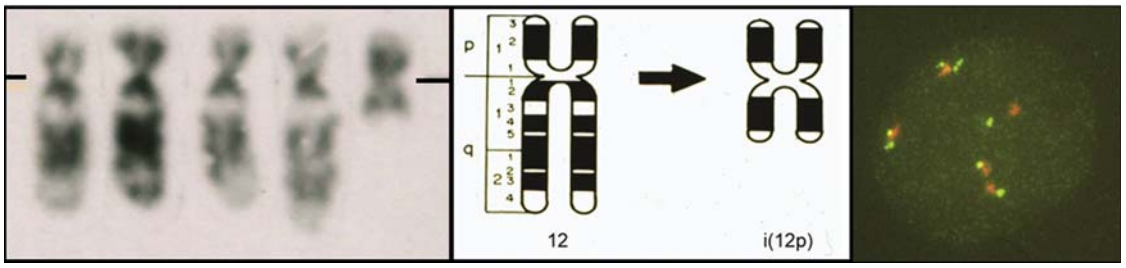

Fig. 14 Left panel, partial karyotype showing four copies of chromosome 12 and one isochromosome 12p; middle panel, cartoon of chromosome 12 and isochromosome 12p; right panel, in situ hybridization of type II GCT cell with three copies of chromosome 12, and two isochromosomes 12p (*red dots*, centromeres of chromosome 12; *green dots*, marker on 12p). Ulbright, T. M., Amin, M. B., Balzer, B., Berney, D. M., Epstein, J. I., Guo, C., et al. (2016). Germ cell tumours. In: Moch, H., Humphrey, P. A., Ulbright, T. M., Reuter, V. E. (eds), *WHO classification of tumors of the urinary system and male genital organs*, 4th edn. Lyon: IARC Press, p. 189–226.

up to 50%; of the mediastinum in 40%; and of the brain in over 50%. In nonseminomas, KIT mutations are rare, less than 1.5%; a similar low figure has been reported in gonadoblastoma and derived seminomas. *KIT* mutations are activating and occur predominantly in the activation loop (exon 17, usually in codons 816, 820, 822, 823, and 825) of the second TK domain.

In seminomas mutations of *KIT* appear to be only one of the mechanisms of activation of KIT signaling and its downstream pathways: KRAS/RAF/MEK/ERK and AKT/mTOR. In these tumors, KIT signaling is always activated either by upregulation of expression or genetically by mutation or amplification (**Figs. 15–17**).

The fact that *KIT* mutations are predominantly found in seminomas and only rarely in nonseminomas suggests that they are in general involved in the progression of seminomas, rather than in initiation of type II GCT. Activating *KRAS* mutations occur in some type II GCT, more or less at the same rate in seminomas and nonseminomas. *KIT* and *KRAS* mutations are mutually exclusive in type II GCT.

Due to early tetraploidization, loss of heterozygosity is an unlikely event in type II GCT. In addition, inactivation of tumor suppressor genes by promoter hyper-methylation is rare. Therefore, tumor suppressor genes probably play a minor role in initiation and progression of type II GCT. In somatic-type malignancies the same mutations may be found as in their somatic counterparts, such as 2q37 rearrangements in rhabdomyosarcoma, p53 mutations in sarcomas, and t(11;22) translocations in PNET.

Type II GCT including GCNIS and gonadoblastoma are globally demethylated, with permissive histone modifications and an open chromatin structure; parental genomic imprinting is erased. In nonseminomas only Alu repeats and some CpG islands are methylated. Mature teratoma components are methylated. The developmentally important miRNAs, miR-371-373 as well as miR-302 and miR-367, which have a crucial role in development of embryonic stem cells, are highly expressed in type II GCT.

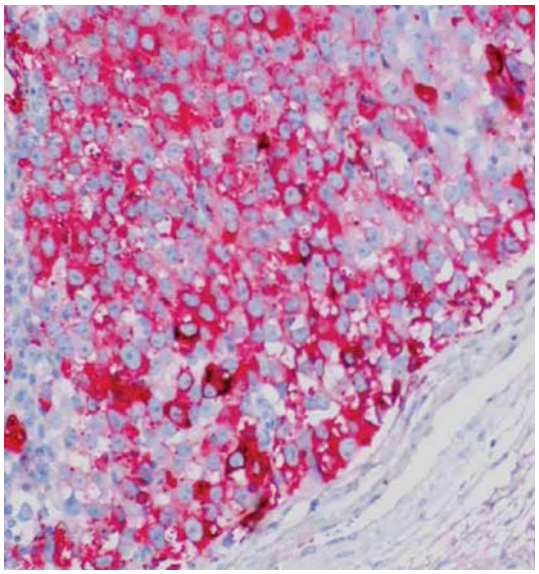

Fig. 17 Seminoma with strong expression of KIT (KIT *red*, ×100).

Treatment sensitivity and resistance

Like their normal counterparts, PGC and ESC, seminoma cells and EC cells have an open chromatin structure, and a hypersensitive DNA damage response. The latter characterized by inducibility of wild-type p53 jointly with the absence of p21-induced cell cycle arrest, whereby cells with damaged DNA are not repaired but eliminated due to a low threshold for apoptosis. This mechanism is a physiologic protection against propagation of repair errors via germ cells into the next generation or via ES cells into the developing embryo. The open chromatin structure in combination with a hypersensitive DNA damage response explains the high sensitivity of type II GCT for DNA damaging agents. As a consequence, Type II GCT are the solid tumors in adults with the highest sensitivity to DNA-damaging agents with cure rates of over 80% in disseminated disease. Nonseminoma lacks the exquisite sensitivity to radiotherapy of seminoma.

The chemotherapy sensitive germ cell/embryonic phenotype gets lost upon somatic differentiation into teratoma, as adult tissue stem cells are able to survive DNA damage by prolonged G1 and G2 arrest and proficient repair. This explains why characteristically the teratoma component survives chemotherapy of a Type II GCT as so-called residual mature teratoma. Primary and acquired resistance is relatively rare in type II GCT because of the low mutation rate in these tumors. In general, loss of germ cell- and embryonic phenotype and acquisition of somatic mutations are factors inducing treatment resistance. A final important mechanism causing resistance of type II GCT is further progression of teratoma- and YST-elements due to accumulation of mutations commonly found in adult cancers.

Type II GCT by anatomical site

Type II GCT of dysgenetic gonads in patients with disorders of sex development (DSD)

Gonadoblastoma is a rare lesion that develops in the dysgenetic gonad of patients with of DSD. At high risk are 46,XY patients with mutations in *WT1* (including Denys–Drash, Fraser, and WAGR syndromes), *SRY*, *SOX9*, *DHH*, *ARX*, *RR5A1*, or *TSPYL1*. These germ line mutations in the presence of Y-chromosomal sequences result in a dysgenetic testis.

- Pathology: Gonadoblastoma is most often caused via the developmental pathway. Mutations in genes involved in male gonadal development in the presence of GBY/TSPY result in a hypovirilized gonad allowing sustained coexpression of OCT4 and TSPY in gonocytes in undifferentiated gonadal tissue (UGT) (Fig. 18), later accompanied by overexpression of KITLG. Initiating somatic mutations, particularly in *KIT* are rare in the presence of GBY/TSPY; probably more frequent in its absence. The usual precursor of type II GCT in dysgenetic gonads is gonadoblastoma (Fig. 19), and much less frequently GCNIS; rarely gonadoblastoma and GCNIS are simultaneously present (Fig. 20). Gonadoblastoma may develop in streak gonads in the abdomen, and in dysgenetic testes in abdominal, inguinal and scrotal position. In 40% of cases gonadoblastoma is bilateral.

Microscopically, gonadoblastoma consists of solid sheets composed of two cell types: nonneoplastic immature granulosa cells, the niche cells, and germ cells, in various arrangements associated with small round depositions of basement membrane-like matrix, called Call-Exner bodies, or psammoma bodies when calcified (Fig. 19). Some of the germ cells resemble oogonia, others, the actual gonadoblastoma cells, have the same atypical morphology of transformed gonocytes as the cells of GCNIS and seminoma, with

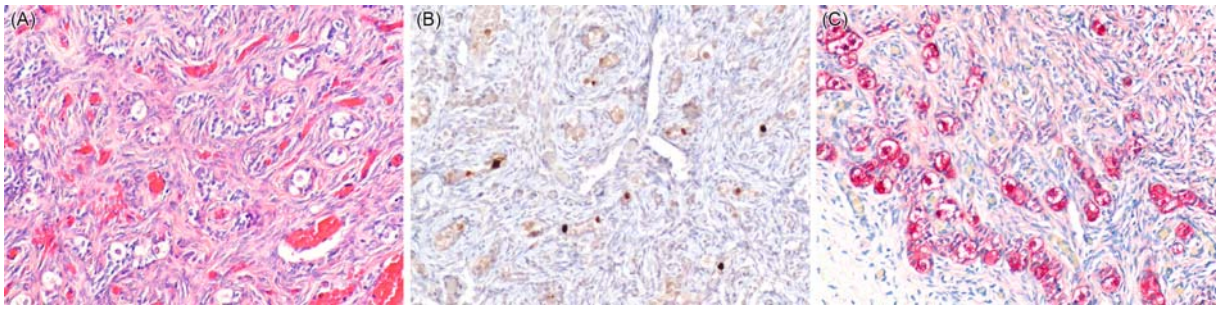

Fig. 18 Undifferentiated gonadal tissue (UGT) composed of strands of small stromal cells resembling granulosa cells, enveloping large pale cells, the germ cells (A: H and E, ×200); some of them, the gonocytes, express OCT4 (B: OCT4 *brown*, ×200); all germ cells express TSPY (C: TSPY *red*, ×200).

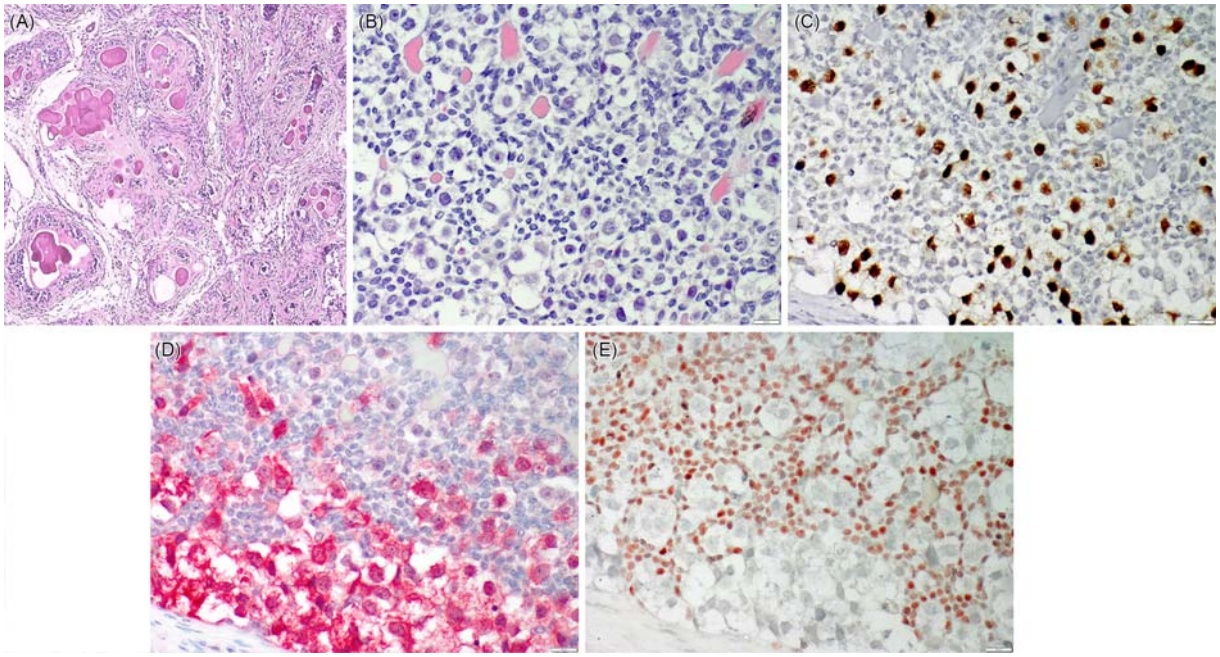

Fig. 19 Gonadoblastoma: areas of immature granulosa cells containing coarse, mulberry-like psammoma bodies and lager pale cells (A: H and E, ×50); Gonadoblastoma: oogonia and gonadoblastoma cells embedded in area of immature granulosa cells, as well as *pink-colored* Call-Exner bodies (B: H and E, ×200); gonadoblastoma cells express OCT4, oogonia do not (C: OCT4 *brown*, ×200); oogonia and gonadoblastoma cells express TSPY (D: TSPY *red*, ×200); the granulosa cells express FOXL2 (E: FOXL2 *reddish brown*, ×200).

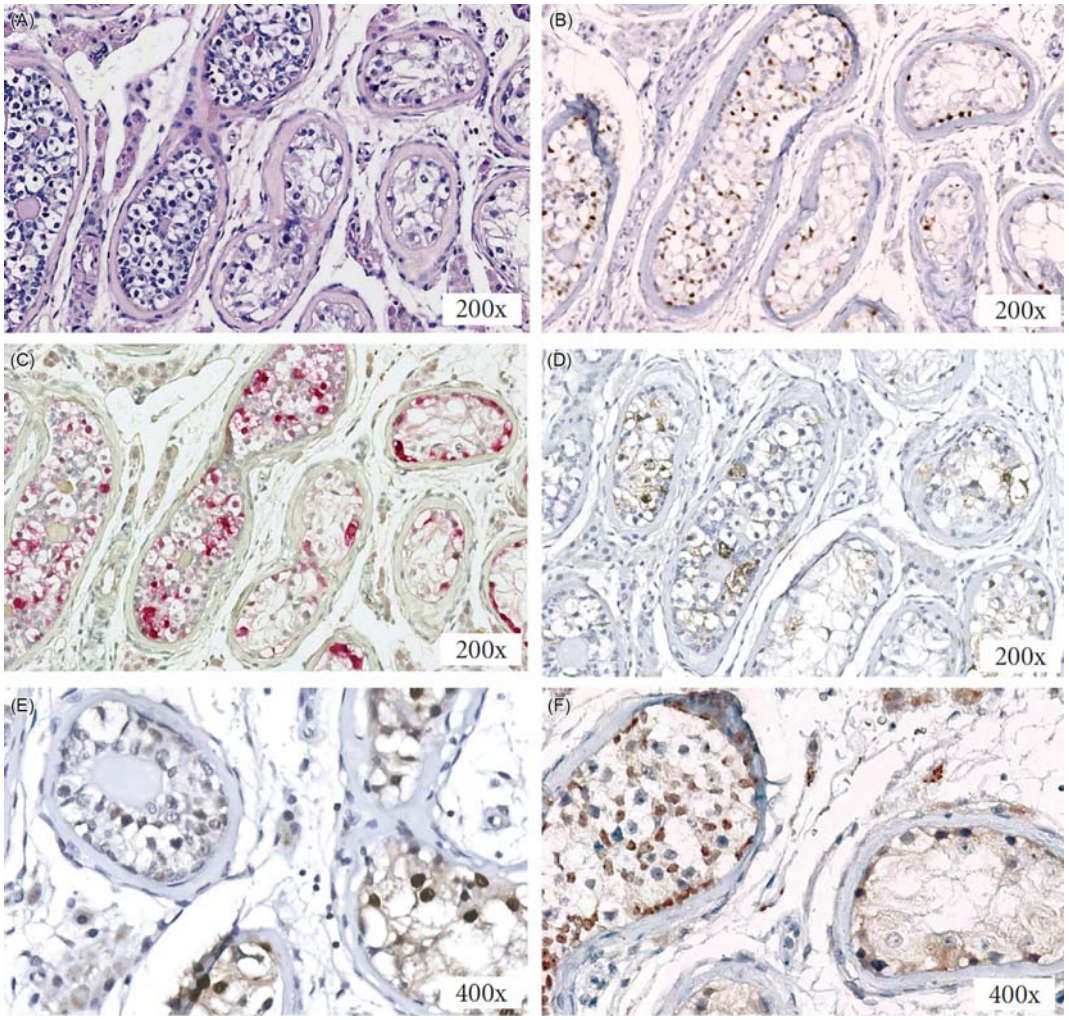

Fig. 20 Gonadoblastoma (left side of each photograph) and GCNIS (right side of each photograph) both within abnormal testicular tubules (A: H and E, ×200); both gonadoblastoma and GCNIS cells have nuclear expression of OCT4 (B: OCT4 *brown*, ×200); both express TSPY (C: TSPY *red*, ×200); the supportive cells express KITLG in gonadoblastoma and GCNIS (D: KITLG *brown*, ×200); Sertoli cells supporting GCNIS express SOX9 (E: SOX9 *brown*, ×400), whereas the granulosa cells supporting gonadoblastoma express FOXL2 (F: FOXL2 *brown*, ×400). Hersmus, R., Stoop, H., White, S. J., Drop, S. L., Oosterhuis, J. W., Incrocci, L., Wolffenbuttel, K. P., Looijenga, L. H. (2012). Delayed recognition of disorders of sex development (DSD): A missed opportunity for early diagnosis of malignant germ cell tumors. *International Journal of Endocrinology* **2012**, 671209.

enlarged angulated nuclei with large nucleoli and abundant clear cytoplasm. Immunohistochemically, the morphologically normal germ cells express early differentiation markers of oogonia, such as TSPY and VASA, and are negative for the pluripotency marker OCT4. The gonadoblastoma cells coexpress markers of gonocytes (e.g., OCT4, PLAP, AP-2gamma, and KIT), and of oogonia (TSPY and VASA). The immature granulosa cells express FOXL2, a key regulatory protein for ovarian development of the undifferentiated gonad (Fig. 19). In dysgenetic testes the tubules are lined by immature Sertoli cells expressing SOX9, the key regulator for testicular development (Fig. 20). Occasionally, tubules in transition zones between testicular and ovarian development may be lined by FOXL2 positive primitive granulosa cells. KITLG is also expressed in gonadoblastoma, probably both in the granulosa and gonadoblastoma cells (Fig. 20).

Gonadoblastoma cells will eventually outgrow the nonneoplastic oogonia, and by way of further progression become an invasive type II GCT: seminoma (80%), and upon reprogramming, nonseminoma (20%). Most mixed nonseminomas contain a seminoma component.

Type II GCT of the testis

- Epidemiology and risk factors
  Africa and parts of Asia have the lowest incidence figures of less than 0.5 for testicular type II GCT. The incidence is a factor 10–20 higher among most white Caucasian populations in Western societies. Worldwide, the incidence has increased in the last decades. In most Western and Northern European countries it has doubled. In the United States the incidence among Caucasians is 6.6 versus 1.2 in blacks. In both groups, the rates have increased in the past 30 years.

The large incidence differences among ethnic groups within the same society demonstrate the importance of genetic factors. However, the worldwide increasing incidence of testicular type II GCT, and the changing incidence among immigrant populations toward the country of destination, point to an important role of environmental factors, associated with Western lifestyle, favoring hypovirilization of the developing male embryo.

The strongest risk factors for testicular type II GCT are cryptorchidism (OR 4.3), previous inguinal hernia (OR 1.63), hypospadias, and impaired spermatogenesis. These conditions are considered part of the so-called testicular dysgenesis syndrome (TDS), a relatively mild disturbance of sex differentiation, due to hypovirilizing factors in utero. Other established risk factors are: previous testicular cancer, and a family history of testicular type II GCT.

- Genetic risk factors

  Familial risk is among the highest in cancers. The small size of affected families, usually a father and a son or two brothers, and the high risk in monozygotic compared to dizygotic twins are consistent with multiple autosomal recessive low-penetrance susceptibility genes. The first identified risk locus was the gr/gr deletion in azoospermia factor c region of Y, and recently a deleterious probably causative germline mutation in *PDE11A* was discovered in familial and sporadic cases. Both mutations explain only a few percent of the familial cases.

  GWAS have discovered variants in over 30 tumor-biologically plausible genes, which increase susceptibility for testicular type II GCT. The ones with the highest OR are *KITLG*, *BAK1*, *SPRY4* and *PDE11A*, which are involved in KIT/KITLG signaling, and thus in survival and proliferation of PGC/gonocytes. *DMRT1* is a niche factor involved in sex determination and regulation of meiotic division. These variants explain still only 20% of the excess familial risk compared to testicular type II GCT families. Obviously more low penetrance genes are involved, like variants in *TGFBR3* and *BMP7* and *AR*, which are associated with TDS. The different distribution of variants, such as in *KITLG* and *AR*, in Caucasian and black populations may partly explain the 20-fold ethnic difference in the incidence of testicular type II GCT.

  Homozygosity jointly for variants that target the PGC/gonocyte and those targeting niche cells substantially increase risk. For example, men with testicular type II GCT have a 14 times higher chance than controls to be homozygous for the two risk alleles, *KITLG* and *DMRT1*.

- Pathology

  The developmental pathway, due to hypovirilization of the niche of the gonocytes in the developing testis is the most important mechanism of initiation of type II GCT. The disturbed niche interferes with downregulation of OCT4 in gonocytes relocated from the center of the tubules to the prespermatogonial niche, thereby creating a window for coexpression of OCT4 and TSPY. In due time accompanied by overexpression of KITLG, which enhances proliferation of the maturation-disturbed prespermatogonia, and thereby promotes neoplastic transformation.

  The earliest changes, preceding overt GCNIS, are maturation delay, and pre-GCNIS, (**Figs. 21 and 22**) which have been studied in cryptorchid testes and androgen insensitivity syndromes.

  GCNIS is the common precursor of seminoma and nonseminoma of the testis (**Fig. 23**); it is bilateral in 3%–5% of the patients. This high rate of bilaterality is probably because the germ cell niche is disturbed in both testes as a consequence of TDS. Noteworthy, in DSD, where the disturbance of the niche is more severe, bilaterality of gonadoblastoma may occur in up to 40%. Supposedly GCNIS when left untreated, will always progress to an invasive type II GCT. By default GCNIS develops into intratubular seminoma (**Fig. 24**), whereby the lumen of the tubule is packed with GCNIS cells, often accompanied by lymphocytes, like in seminoma. Remarkably, necrosis is rare in intratubular seminoma. Apparently the tumor cells, like gonocytes, are well adapted to the low oxygen environment within the tubules. In general, intratubular seminoma becomes invasive by overextension and destruction of the seminiferous tubules.

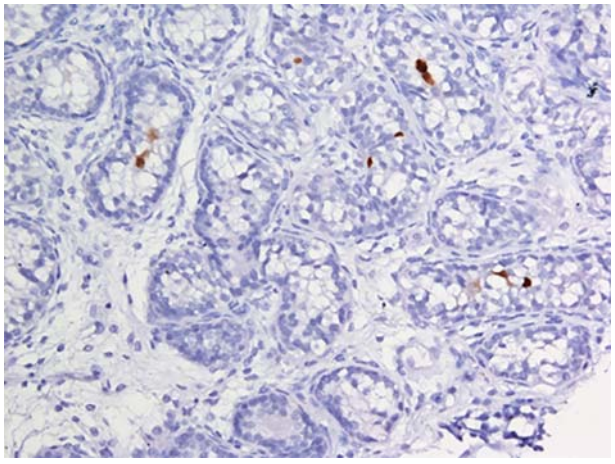

Fig. 21 Maturation delay: gonocytes located centrally in the tubules still express OCT4, although the infant is older than 6 months (OCT4 *brown*, ×200).

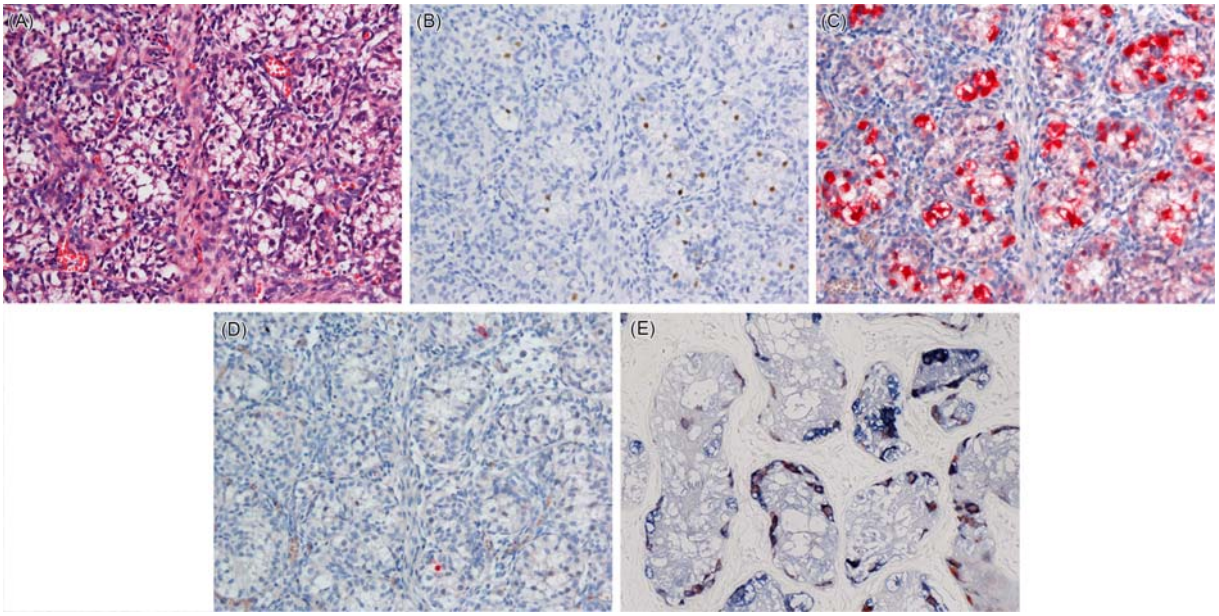

Fig. 22 Pre-GCNIS is characterized by coexpression of OCT4 and TSPY by germ cells located in the prespermatogonial niches and focal expression of KITLG. Immature tubules of a young boy contain gonocytes (centrally in the tubules) and prespermatogonia (peripherally in the tubules) (A: H and E, ×200); OCT4 is still expressed in the germ cells, not only centrally, but also in the periphery of tubules by germ cells in the prespermatogonial niches (B: OCT4 *brown*, ×200); all germ cells express TSPY (C: TSPY *red*, ×200); focal expression of KITLG (D: KITLG *red*, ×200). Double staining for OCT4 (*brown*) and TSPY (*blue*) demonstrates germ cells in the spermatogonial niches with coexpression of OCT4 and TSPY, consistent with pre-GCNIS (E, ×200).

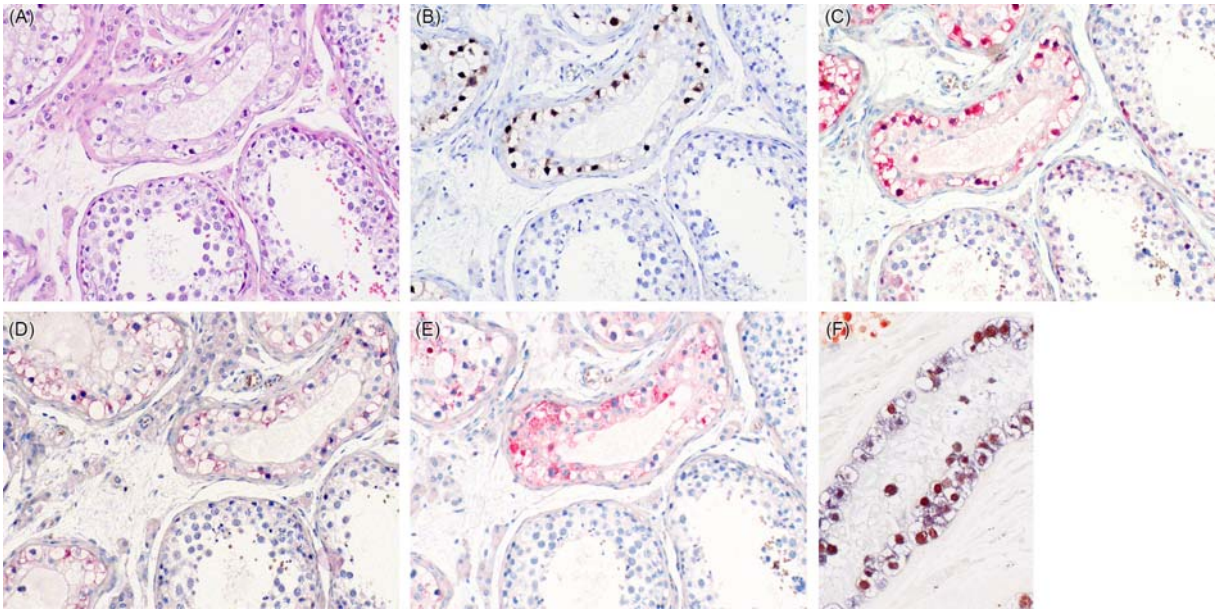

Fig. 23 In the upper left corner of the photograph are tubules with GCNIS, in the lower right corner tubules with spermatogenesis. The tubules with GCNIS have a narrower than normal caliber and a thickened wall; GCNIS cells have dark, enlarged, angular nuclei (A: H and E, ×200); GCNIS cells have nuclear expression of OCT4 (B: OCT4 *brown*, ×200), and membranous and cytoplasmatic expression of TSPY (C: TSPY *red*, ×200), as well as membranous expression of KIT (D: KIT *red*, ×200); the Sertoli cells diffusely express KITLG in a granular fashion (E: KITLG *red*, ×200); GCNIS cells consistently coexpress OCT4 (*reddish brown*, nuclear) and TSPY (bluish, membranous, and cytoplasmatic) (F, ×400).

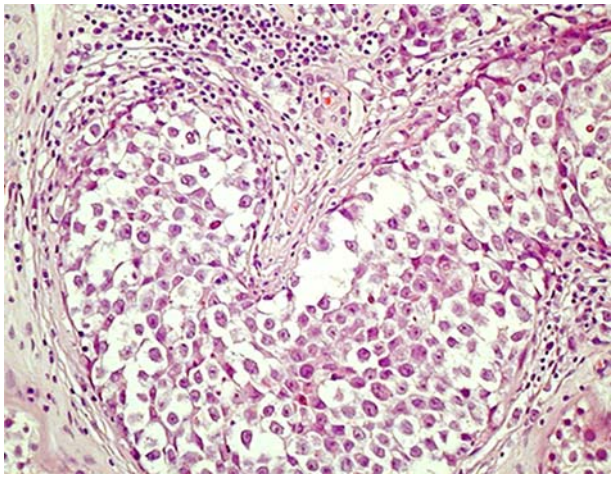

Fig. 24 Intratubular seminoma: seminiferous tubule packed with seminoma cells, extending the tubule (H and E, ×200).

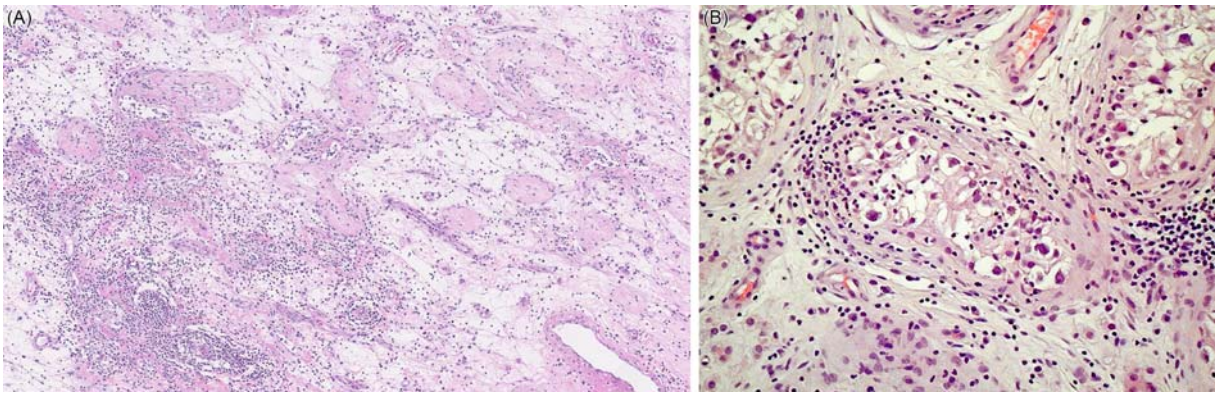

Fig. 25 The immune reaction of the host elicited by seminoma, apparent from the inflammatory cells, is capable of destroying invasive seminoma cells, and GCNIS cells within the seminiferous tubules, leaving fibrotic tubules and interstitial tissue (A: H and E, ×100); tubule with GCNIS, infiltrated by lymphocytes (B: H and E, ×200).

Upon invasion, seminoma invariably elicits an inflammatory host response, usually composed of lymphocytes, macrophages, plasma cells, and often a granulomatous reaction (Fig. 25), which may destroy tumor cells, leaving scar tissue. It is probably clinically relevant as in patients with AIDS the median age of seminoma is 25, 10 years younger than in the general population. Deviation from the default development of seminoma occurs when a seminomatous cell, either a GCNIS cell or an intratubular-, invasive- or metastatic seminoma cell, is reprogrammed to an EC cell, the totipotent stem cell of nonseminoma. One in three nonseminomas has a seminoma component, suggesting that reprogramming has occurred in an invasive seminoma (Fig. 26). Probably the remaining nonseminomas are due to reprogramming of a GCNIS- or an intratubular seminoma cell.

Virtually without exception intratubular nonseminoma has the morphology of EC. It is always partly necrotic (Fig. 27), apparently not adapted to the low oxygen intratubular environment. This relative anoxia may induce hypoxia factors, like MET, which triggers intratubular EC to invasion. Interestingly, upon invasion the EC cells often start to differentiate (Fig. 28). The intratubular environment seems to suppress differentiation of EC, while stromal factors stimulate differentiation. Candidate stromal factors are TGF-β, FGF, and BMP, which may derepress differentiation-promoting genes by removing polycomb repressive complexes recruited to the promotor sites of these genes by the pluripotency proteins OCT4, SOX2, and NANOG.

Type II GCT of the ovary

The incidence of ovarian type II GCT is about 20-fold lower than those of the testis. Ninety-five percent of ovarian type II GCT become manifest after puberty in women with a normal 46,XX karyotype, a couple of years earlier than in males, in accordance with the earlier onset of puberty in females. The remaining 5% are diagnosed before puberty in individuals with manifest or silent DSD. Overall, 6% are bilateral.

An established risk for (bilateral) ovarian type II GCT are various forms of DSD in phenotypic females who carry the GBY/*TSPY* region in their genome. As most studies of risk factors do not distinguish between type I and II GCT, the results have to be

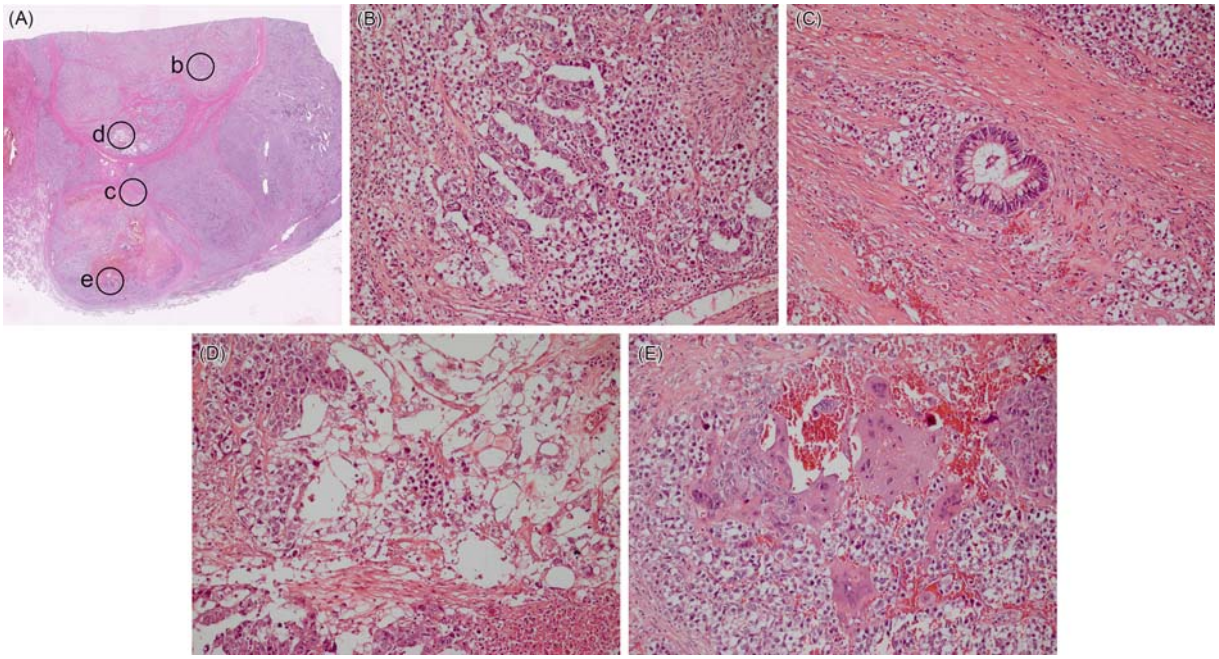

Fig. 26 Seminoma with reprogramming to EC, teratoma, YST, and choriocarcinoma (A: H and E, ×12.5). Embedded in seminoma are EC (B: H and E, ×200); teratomatous tubule lined with goblet cells (C: H and E, ×200); YST (D: H and E, ×200); choriocarcinoma (E: H and E, ×200).

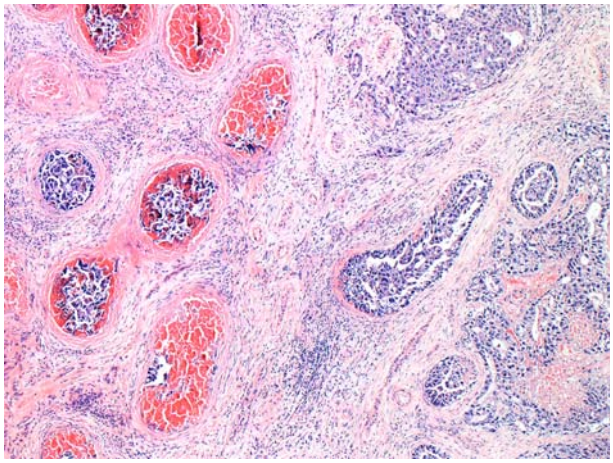

Fig. 27 Intratubular nonseminoma consists of EC only that is largely necrotic (pink staining material) (H and E, ×50).

interpreted with caution. Reported risks with the highest OR, such as exogenous hormones during pregnancy, maternal obesity and early regular menstruation after menarche, are related with hormonal regulation of reproduction.

An estimated 20% of ovarian type II GCT develop via the developmental pathway in women carrying GBY/*TSPY*: 6% with overt, and the remaining with clinically silent DSD. Ovarian seminomas in phenotypically and genotypically normal women have *KIT* mutations in about 50%. Only a minority of these being initiating, it leaves the pathogenesis of about three-quarters of ovarian type II GCT unexplained.

It is possible that in the ovary, the majority of type II GCT develop in the context of mild dysgenesis, comparable to TDS of the male, mainly caused by imbalances of factors regulating gonadal development and maintenance, such as FOXL2 (Fig. 29). Down-regulation of these factors during gonadal development, even only transiently, in the stage before oocytes become arrested in the prophase of meiosis I, would create a hypovirilized testis-like environment favoring disturbance of maturation oogonia/gonocytes and a window for the development of a type II GCT. However, due to the absence of GBY/TSPY, at a much lower rate than in males, or in DSD patients carrying GBY in their genome, who have an up to 70-fold risk of developing a type II GCT as compared to normal females.

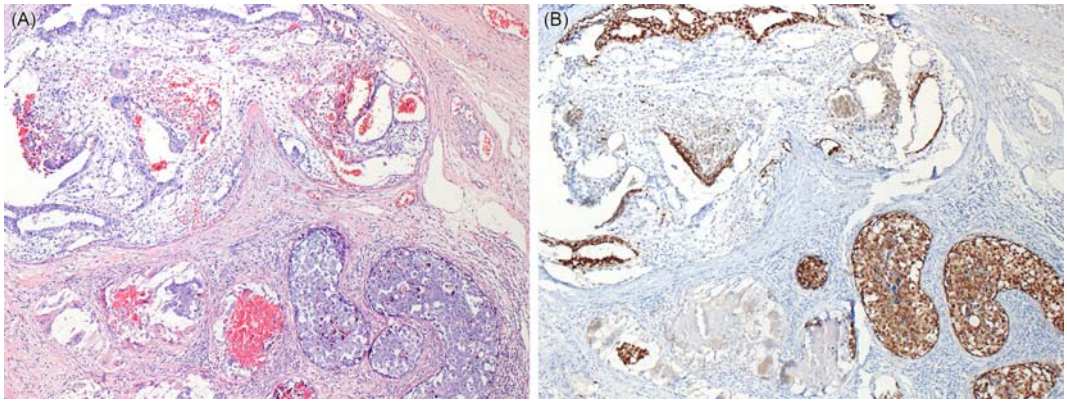

Fig. 28 Intratubular nonseminoma (right lower corner of the photograph) consisting of EC only, that starts to differentiate upon invasion (A: H and E, ×50; b, OCT4 *brown*, ×50). Oosterhuis, J. W. and Looijenga, L. H. J. (2017). Germ cell tumors from a developmental perspective: Cells of origin, pathogenesis and molecular biology; Emerging patterns. In Nogales, F.F. and Jimenez, R.E.(eds.) *Pathology and Biology of Human Germ Cell Tumors*, Berlin: Springer Nature, pp. 23–129.

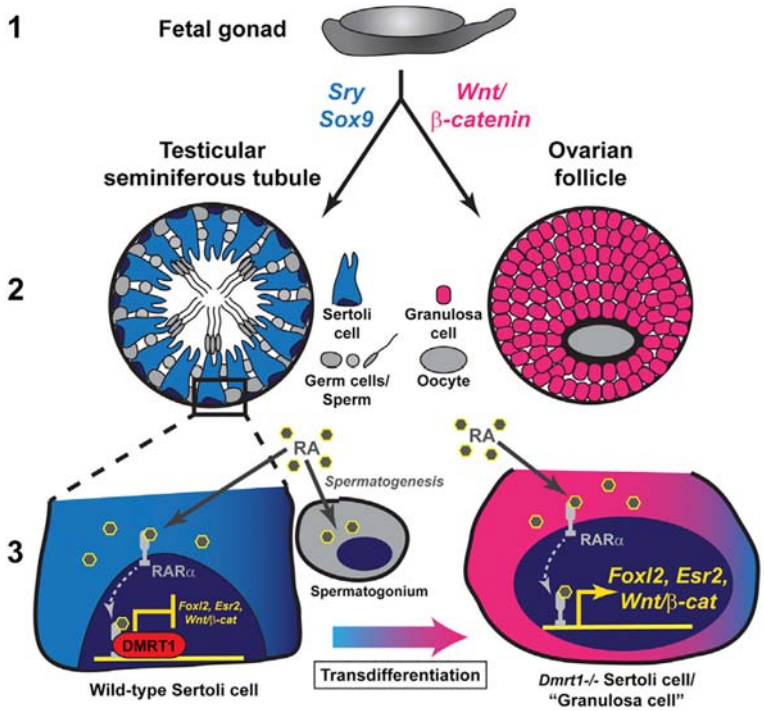

Fig. 29 Dmrt1 silences RA-dependent feminization genes to ensure postnatal sex maintenance during fetal sex determination (1), the bipotential gonad makes a choice between male (*blue*) and female (*pink*), largely guided by the presence or absence of Sry. The sexual differentiation machinery downstream of sex determination transforms the undifferentiated gonad into a mature testis or ovary (2), manifested in the formation of Sertoli-cell-containing seminiferous tubules in the male and granulosa-cell-containing ovarian follicles in the female. Postnatal sex maintenance within Sertoli cells (3) is achieved via the silencing of RA signaling-dependent feminization genes (such as Foxl2) by the transcriptional regulator Dmrt1. RA is thereby allowed to act in adjacent spermatogonia to promote spermatogenesis within the seminiferous tubule. In Dmrt1 mutant Sertoli cells, however, RA acting through RARa activates feminizing genes and reprograms the Sertoli cell into a granulosa-like cell through the process of trans-differentiation. DeFalco, T. (2014). DMRT1 keeps masculinity intact. *Developmental Cell* **29**, 503–504.

Type II GCT of the mediastinum

Mediastinal type II GCT constitute 50%–70% of extragonadal type II GCT. Both in whites and blacks over 95% occur in males, thus being male is the most important a risk factor. Mean age for seminomas is about 30 and for nonseminomas 25 years. Over 20% occur in individuals with Klinefelter's syndrome, who have a 67-fold risk compared to males without this condition. They present at median age of 17 (range 4–31), substantially younger than in non-Klinefelter patients. Klinefelter cases younger than 12 virtually always have precocious puberty, due to β-HCG produced by the tumor. In Klinefelter patients, increased levels of gonadotropins in

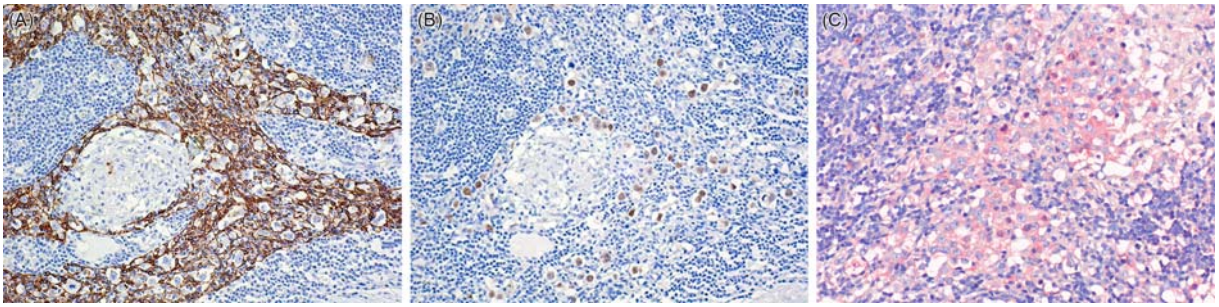

Fig. 30 Gonadoblastoma-like lesion in the thymus with seminoma cells enclosed by thymic epithelium (A: cytokeratin *brown*, ×200); the seminoma cells are OCT4 positive (B: OCT4 *brown*, ×200); thymic epithelium expresses KITLG (C: KITLG *red*, ×200). Oosterhuis, J. W., Stoop, H., Honecker, F., Looijenga, L. H. (2007). Why human extragonadal germ cell tumors occurin the midline of the body: Old concepts, new perspectives. *International Journal of Andrology* **30**, 256–263.

response to testicular atrophy may enhance malignant transformation of PGC in the thymus, explaining their 67-fold risk of these tumors compared to other males.

Mediastinal type II GCT originate from demethylated mis-migrated PGC that survived in the surrogate niche offered by thymic epithelium, shown to express KITLG, (Fig. 30), the critical factor for survival and proliferation of PGC. Primary mediastinal type II GCT are only localized in the anterior or antero-superior mediastinum within, or in association with the thymus. Apart from a somewhat higher proportion of pure YST and pure choriocarcinoma, the distribution of seminoma, and nonseminoma subtypes is similar as in the testicular type II GCT. In Klinefelter's syndrome the tumors are virtually always nonseminomas with 15% pure choriocarcinoma, and trophoblastic differentiation in 85%.

Of mediastinal nonseminomas 10%–20% develop a solid somatic-type malignancy. The distribution of the various histological types is largely similar to that in the testis, but angiosarcomas are more frequent. Hematologic malignancies, developing in 2%–6%, are uniquely associated with mediastinal YST. The most frequent types are megakaryoblastic leukemia, malignant and benign histiocytosis, and myelomonoblastic leukemia.

The (cyto)genetic aberrations are largely the same as in testicular type II GCT. Excess copies of chromosome X are partly due to Klinefelter cases.

Type II GCT of the central nervous system

- Epidemiology and risk factors
  The combined incidence of type I and II GCT of the brain is 0.143 for males and 0.046 for females in Japan and 0.118 for males and 0.030 for females in the United States. Probably more than 90% are type II.
  The overall male-to-female ratio of CNS GCT is about 4:1. The incidence of nonmalignant GCT is similar in males and females, 0.029 and 0.020, respectively. The male-to-female ratio for malignant GCT is 16:1 in the pineal region and 2.1:1 in the rest of the CNS. Being male is the most important a risk factor for Type II GCT of the CNS. More than half of all malignant GCT are located in the pineal region, virtually all of them type II.
  Type II GCT of the CNS can be familial and may cluster with type II GCT of the gonads and the mediastinum, sometimes in Klinefelter's and Down's syndrome. In Klinefelter's syndrome Type II GCT are the most frequent malignant CNS tumors, suggesting that it is a risk factor for these tumors.
- Anatomical localization
  Over 80% of type II GCT of the brain are located in the pineal gland, suprasellar region (neurohypophysial axis; occasionally within the neurohypophysis), hypothalamus, and the wall of the third ventricle. In these midline structures, the large majority are in male patients, malignant, and seminomas. Seminomas occur also in the basal ganglia, cerebral hemispheres, and in the posterior fossa. However, in these and other nonmidline anatomical sites, the proportion of females, nonseminomas and benign GCT (the latter probably of type I) is higher. In fact, type I GCT of the brain have an anatomical distribution resembling that of the type II nonseminomas. The anatomical distribution of type II GCT in Klinefelter's syndrome is similar to that in the general population. In Down's syndrome, where there is a high percentage of nonseminomas, the tumors lie most often outside the typical midline sites.
- Pathology
  The midline of the brain, in particular the pineal gland and the supra-sellar region, offers a niche where some mis-migrated, totipotent PGC can survive long enough to undergo transformation to a seminomatous precursor cell. Secretion of gonadotropins in the diencephalic centers at the inception of puberty may stimulate neoplastic transformation, and explain the young age of tumor manifestation.
  Eighty percent of type II GCT of the CNS are seminomas; most nonseminomas are mixed, followed by pure mature and immature teratoma, EC, YST and choriocarcinoma. Of the mixed tumors 75% have a seminoma component. Somatic-type malignancies rarely develop.

The strong male predominance suggests initiation via the developmental pathway with a crucial role for coexpression of OCT4 and TSPY. Probably only the minority of the tumors is initiated via somatic mutation of one of the genes involved in KIT signaling and downstream pathways (Fig. 15).

Eighty percent of the tumors developing in the midline is seminoma. Away from the midline type II GCT are rarer and more often nonseminomas. In these nonmidline sites, the conditions are supposedly less suitable for neoplastic PGC, favoring precursors that have undergone reprogramming to an ESC-like precursor, with a developmental potential in between the toti- and the pluripotent state. Indeed, the spectrum of histologies of type II nonseminomas of the brain (and to a lesser degree of the mediastinum) resembles that of type I GCT: relatively high proportions of pure (immature) teratoma, pure YST, and pure choriocarcinoma and rarely pure EC. Yet these tumors occur most often beyond the age of six and have the (cyto)genetic characteristics of type II GCT. In fact, in the brain, particularly away from the midline, there seems to be a gray area with a gradual transition between GCT of type I and II, featuring tumors that are type II by genotype and age but resembling type I by phenotype.

Klinefelter patients have the same distribution of type II GCT as non-Klinefelter patients, completely different from mediastinal type II GCT in Klinefelter's syndrome, where seminomas are virtually lacking.

In Down's syndrome, type II GCT of the brain are less frequently seminomas than in the general population (55%). The anatomical localization of the tumors is atypical, with only one in the pineal gland. Of five nonseminomas, four were YST and one teratoma.

- (Cyto)genetics

  Activating mutations in *KIT* (47%), *KRAS* (18%), and *NRAS* (6%) and inactivating mutations in *CBL* (6%), a negative regulator of KIT expression, are all mutually exclusive and occur most often in seminomas and mixed GCT that lack gain of 12p. The complementary character of these genetic events and their preferred occurrence in seminomas and mixed GCT indicate that they are probably not initiating but engaged in the progression of seminoma. The AKT/mTOR signaling pathway is activated in about 20% of cases, mostly by focal amplification of 14q32.33, containing the AKT1 locus, often in tumors lacking gain of 12p (Fig. 15).

Type III GCT (Spermatocytic Tumor)

Epidemiology

The incidence of spermatocytic tumor is 0.4 per million, without a significant increase over the past 20 years. The median age of clinical presentation is 55. In about 9% the tumor is bilateral.

Anatomical localization

Spermatocytic tumors occur only in the postpubertal testis, virtually always in scrotal position, and sporadically in a maldescended testis (Table 1).

Pathology

Spermatocytic tumor is a benign neoplasm, of which the cells resemble postpubertal germ cells with early, premeiotic differentiation. The nuclei appear in three size classes corresponding to A-dark spermatogonia (reserve spermatogonial stem cells) with the smallest nuclei with dense chromatin; A-pale spermatogonia (self-renewing stem cells) with intermediate and large paler nuclei with finely granular filamentous chromatin; B spermatogonia, and leptotene spermatocytes (Fig. 31). The tumor cells express

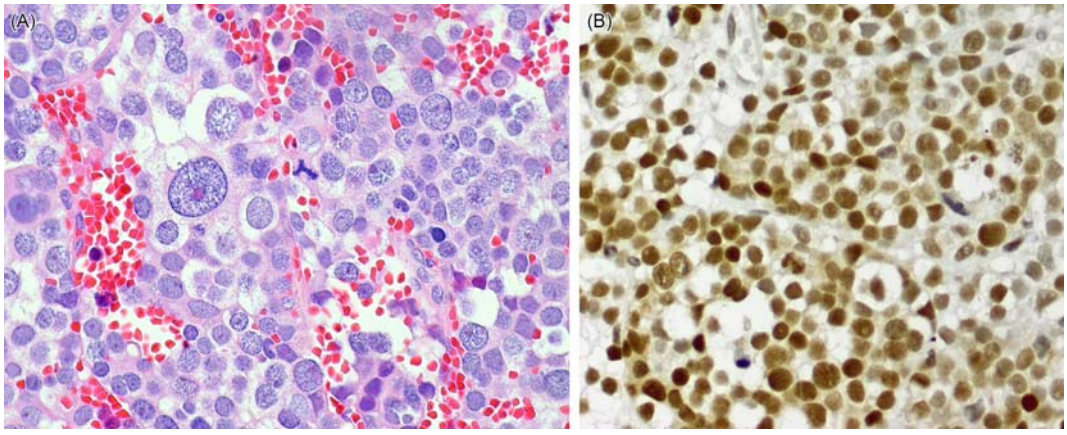

Fig. 31 Spermatocytic tumor with small dark nuclei, intermediate nuclei, and large nuclei with finely granular filamentous chromatin (A: H and E, ×400); the nuclei express DMRT1 (B: DMRT1 *brown*, ×400).

markers of these cell types, such as DMRT1, which is a diagnostically useful immunohistochemical marker (Fig. 31). Markers of gonocytes, such as OCT4 and PLAP have been switched off, and markers of meiosis are not yet expressed. Spermatocytic tumor lacks the characteristic host response of seminoma. Adjacent seminiferous tubules may contain intratubular spermatocytic tumor. The occasional finding of an exclusively intratubular spermatocytic tumor without an invasive component proves that the tumor has its origin within the seminiferous tubules (Fig. 32).

Exceptionally, the tumor is associated with a sarcomatous component, usually undifferentiated sarcoma, and rarely rhabdomyo- or chondrosarcoma. These are highly malignant and readily metastasize to regional lymph nodes or, blood–borne, to visceral organs.

Disturbance of the niche- and spermatogonial factors involved in the regulation of spermatogenesis are the factors driving tumorigenesis (Figs. 33 and 34). Like in the other types of GCT, in spermatocytic tumors, initiation is primarily due to

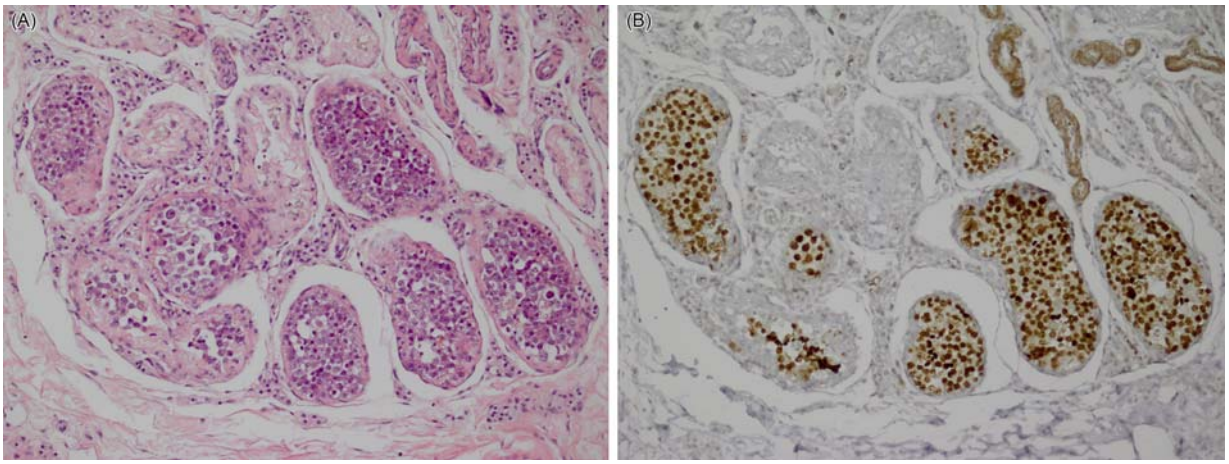

Fig. 32 Intratubular spermatocytic tumor (A: H and E, ×200); expressing DMRT1 (B: DMRT1 *brown*, ×200). Oosterhuis, J. W. and Looijenga, L. H. J. (2017). Germ cell tumors from a developmental perspective: Cells of origin, pathogenesis and molecular biology; Emerging patterns. In Nogales, F.F. and Jimenez, R.E.(eds.), *Pathology and biology of human germ cell tumors*, Berlin: Springer Nature, pp. 23–129.

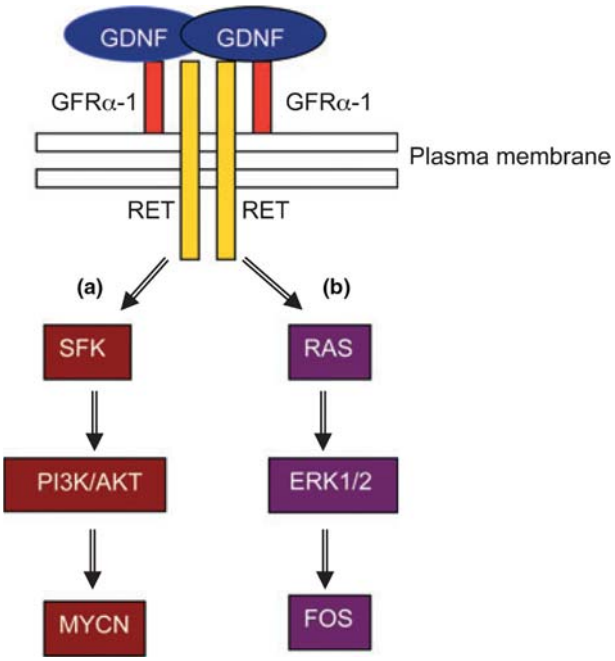

Fig. 33 Signaling pathways triggered by GDNF in spermatogonial stem cells. GDNF dimerizes and binds to the GFRA1/RET receptor complex. (A) Binding of GDNF activates RET, which triggers SRC-kinase phosphorylation and the downstream activation of PI3K/AKT. Ultimately the transcription factor MYCN is upregulated. (B) Binding of GDNF also can activate the RAS-mediated signaling pathway, which triggers ERK1/2 phosphorylation and upregulation of the transcription factor FOS. Waheeb, R., and Hofmann, M.-C. (2011). Human spermatogonial stem cells: A possible origin for spermatocytic seminoma. *International Journal of Andrology* **34**, e296–e305.

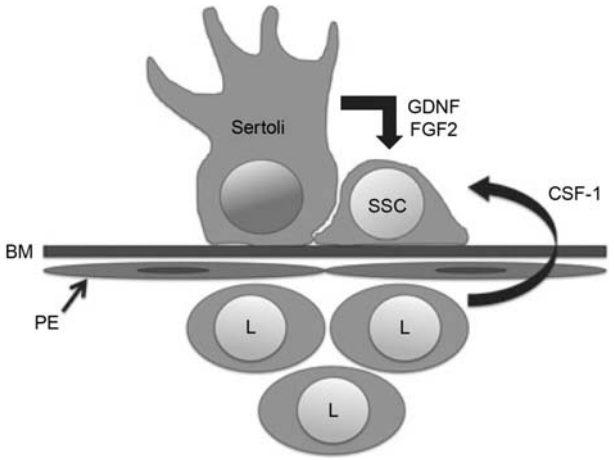

Fig. 34 A simplified scheme of the spermatogonial stem cell niche showing the main extrinsic factors driving spermatogonial stem cell (SSC) maintenance and self-renewal. Sertoli cells and spermatogonial stem cells (SSCs) are both attached to the basement membrane (BM). Sertoli cells provide for structural support and produce glial cell line-derived neurotrophic factor (GDNF) and basic fibroblast growth factor (bFGF) which are crucial for SSC self-renewal in vitro and in vivo. Leydig cells (L) and peritubular cells (PE) produce colony-stimulating factor-1 (CSF-1), also essential for self-renewal. Waheeb, R. and Hofmann, M-C. (2011). Human spermatogonial stem cells: A possible origin for spermatocytic seminoma. *International Journal of Andrology* **34**, e296–e305.

a developmental deregulation. Somatic mutations, and whole chromosome-aneuploidy are probably mainly progression related. The tumor promoting niche factors explain the high percentage of bilaterality of spermatocytic tumor.

(Cyto)genetics and epigenetics

Most spermatocytic tumors are (near)diploid, the second largest group is (near)tetraploid, and a few are peritriploid. The only consistent cytogenetic aberration is extra copies of chromosome 9 (Fig. 35). The candidate gene on this chromosome involved in tumorigenesis is *DMRT1* (Fig. 36). A small number of tumors, usually in the oldest half of the patients, have mutually exclusive, paternal age-related mutations in *FGFR3*, *HRAS* or *NRAS*. In 80% of spermatocytic tumors p53 is expressed.

Spermatocytic tumors have heterogeneous pattern of DNA methylation and histone modification, different from the regular patterns in normal spermatogenesis, probably because the tumor cells are deprived of regulatory niche factors.

Type IV GCT (Dermoid Cyst of the Ovary)

Epidemiology and risk factors

The dermoid cyst of the ovary is the most frequent GCT, with an estimated incidence between 10 and 15, occurring at the reproductive age (median age 30, range 10–90) (Fig. 37). Over 10% of the patients have bilateral tumors.

Anatomical localization

Dermoid cysts occur exclusively in the ovaries. On rare occasions, they become detached from the ovary and reimplanted in either omentum, fallopian tube, or Douglas' pouch. Tumors in the testis and extragonadal sites resembling dermoid cysts are type I GCT beyond infancy, with a developmental potential in between that of type I and type IV GCT.

Pathology

Dermoid cysts are derived from parthenogenetically activated primary oocytes (Fig. 38) that have escaped the normal, postpubertal regulation of meiotic arrest, and started uncontrolled meiosis, which explains why they occur at reproductive age. Genetic variants in the factors regulating meiotic arrest may be involved in proneness for bilaterality and familial occurrence of type IV GCT. Thus, it seems probable that, as in other GCT, the origin of type IV GCT is mainly determined by developmental factors, with a minor role for genetic events. Half of the dermoid cysts have the molecular characteristics of primary oocytes that have been parthenogenetically activated after meiosis I (Type-I), a quarter after meiosis II (Type-II), and the remaining quarter after endoreduplication (Type-III) (Fig. 39).

Dermoid cysts are completely mature teratomas, which present as a thin-walled cyst lined with epidermis with attached appendages and filled with sebaceous material and hairs. Usually one solid nodule (Rokitansky's protuberance) protrudes from the wall into the lumen of the cyst. It is mainly composed of cranial tissues: skin covered with hair (scalp), bone (skull), choroid plexus and glial tissue (intracranial tissues), retinal epithelium (eyes), teeth (jaw), and thyroid (neck). In fact, a dermoid cyst represents the rostral part of an attempted embryo turned inside out (Fig. 40). In addition, virtually any adult tissue can be present. Exceptional tumors are predominantly solid with highly organized structures resembling a fetus, however, lacking extraembryonic tissues, as do

dermoid cysts. Benign tumors, such as struma ovarii and carcinoids, may arise from organ anlages within a dermoid cyst. Somatic-type malignancies develop reportedly in 0.2%–3% of dermoid cysts, of which about 90% are squamous cell carcinomas. Dermoid cysts may sporadically contain immature foci, even more exceptionally combined with YST.

(Cyto)genetics and epigenetics

Virtually all dermoid cysts are diploid, a few percent have chromosomal abnormalities including trisomy for chromosomes 7, 8, 12, 15, and X. Trisomy for chromosomes 8, 12, and X may be shared by immature teratomas of the ovary. Somatic-type malignancies have the same genetic changes as their somatic counterparts. For example, malignant struma ovarii has the same *BRAF* point mutations as papillary carcinomas of the thyroid.

The genomic profile of dermoid cysts reflects the stage of meiosis of the oocytes from which they have originated. Most significantly, the chromosomes of dermoid cysts have an exclusively maternal imprinting (Fig. 41), inhibiting the development of trophoblast, like in the mouse gynogenote (Fig. 42). (Table 1).Thus, the developmental potential of type IV GCT corresponds to the 2C state, whereby, due to the exclusively maternal imprinting, only somatic tissues are formed.

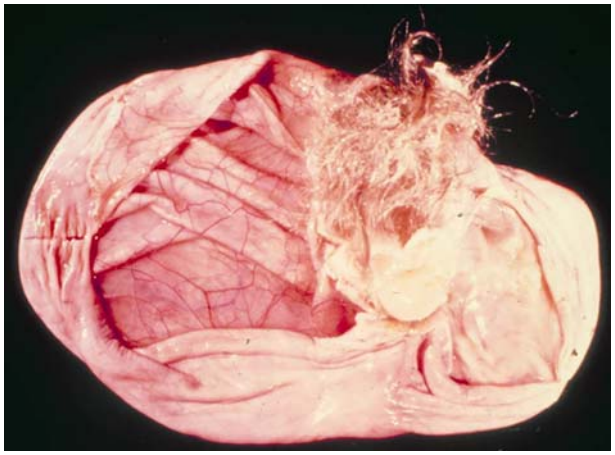

Fig. 40 Gross image of type IV GCT (dermoid cyst), fully developed hair on a scalp-like covering of Rokitansky's protuberance (dermoid hill).

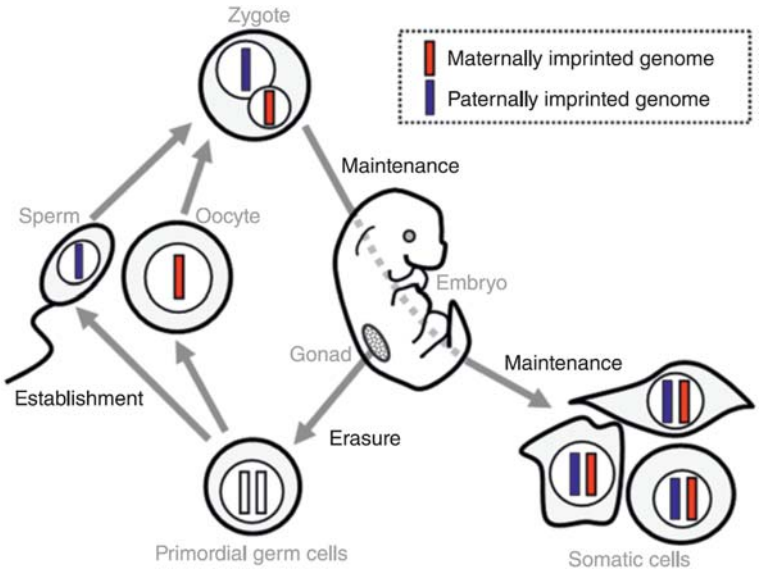

Fig. 41 Cycle of genomic imprinting (GI). Upon fertilization, the zygote acquires a haploid set of paternally imprinted chromosomes from the father and a haploid set of maternally imprinted chromosomes from the mother; the cells of the embryo therefore have a biparental GI pattern. In the germline, GI is erased; during spermatogenesis and oogenesis, respectively, paternal and maternal imprinting is reestablished. Hirasawa, R. and Feil, R. (2010). Genomic imprinting and human disease. *Essays in Biochemistry* **48**, 187–200.

Type V GCT (Molar Pregnancies)

Epidemiology and risk factors

The incidence of gestational trophoblastic disease, mostly complete hydatidiform moles, is 1 in 120 pregnancies in some parts of Asia and South America, a factor 10 higher than in Western societies. Risk factors are pregnancy at young or old age, prior gestational trophoblastic disease, Asian ethnicity, and possibly dietary deficiencies and low socioeconomic status.

Genetic risk factors are maternal mutations of *NALP7/NLRP7* on 19q13.4, causing abnormal imprinting with overexpression of the paternal genome, which results in recurrent familial biparental complete hydatidiform moles and reproductive wastage.

Anatomical localization

Molar pregnancies occur virtually always in the uterus, occasionally in a fallopian tube as an ectopic pregnancy.

Pathology

Complete hydatidiform moles are caused by androgenesis with two, rarely four, haploid sets of paternal chromosomes, arising from fertilization of an anuclear empty ovum by one 23,X sperm that replicates its chromosomes. Those with a 46,XY karyotype result from fertilization of an empty ovum by two sperm. Both mechanisms create a zygote with an exclusively paternal imprint, which

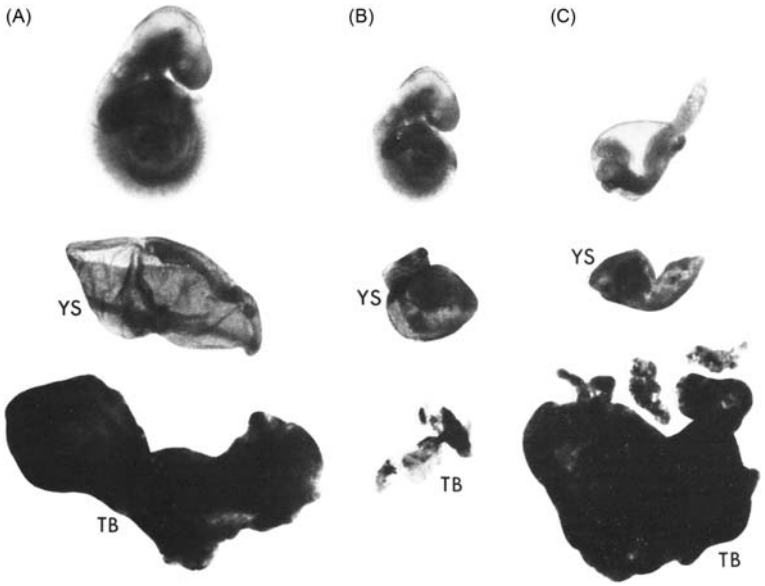

Fig. 42 Compare development of control embryo (A) with that obtained from eggs with two maternal genomes, gynogenotes (B), in which a small but well-advanced 25-somite embryo was the maximum development but with poor extraembryonic tissues. The eggs with two paternal nuclei, androgenotes (C), developed maximally to about the 6- to 8-somite stage but with extensive trophoblast development. YS yolk sac, TB trophoblast. Surani, M. A., Barton, S. C., Norris, M. L. (1986). Nuclear transplantation in the mouse: Heritable differences between parental genomes after activation of the embryonic genome. *Cell* **45**, 127–136.

gives rise to placental tissue only and no somatic tissues of the embryo proper, similar to experimentally produced mouse androgenotes (Fig. 42) (Table 1) The precursor cell of the hydatidiform mole has the 2C-state developmental potential, except for the ability to form somatic tissues of the embryo proper.

Consistent with this pathogenesis complete hydatidiform moles, type V GCT, are composed of hypertrophic, dysplastic placental tissue only, lacking somatic tissues of the embryo proper (Fig. 43). Thus, these growths are the mirror image of dermoid cysts, which are composed of somatic tissues only, and lack trophoblastic tissue. They progress to choriocarcinoma in 2%–3% of cases, possibly driven by hypomethylation-associated genomic instability.

Genetics and epigenetics

Complete hydatidiform moles are generally diploid with a 46,XX (90%) or 46,XY (10%) karyotype; rare cases are tetraploid.

Fig. 43 Gross image of hydatidiform mole, resembling a bunch of grapes, shown in an opened uterus. The individual grapes consist of hypertrophic, edematous placental villi.

Type VI GCT

Definition

Type VI GCT are defined as neoplasms resembling GCT as to their developmental potential. However, they are not derived from germ cells, but from somatic cells induced to pluripotency (Table 1).

Epidemiology and risk factors

As type VI GCT are a new concept, epidemiological data are scarce. With a median age of over 50, the patients are old for a germ cell tumor. Most type VI GCT develop in advanced cancers, in particular common epithelial cancer of the ovary; few arise de novo.

Anatomical localization

The anatomical distribution follows the various types of cancer in which of GCT components may develop, in particular of the ovary and stomach. Sinonasal teratocarcinosarcomas are virtually always located in the nasal cavity and/or ethmoid sinus. The few published de novo type VI GCT with balanced translocations were localized at atypical sites for GCT, certainly in view of the old age of the patients: retroperitoneum, posterior mediastinum, and inside the sacrum.

Pathology

Type VI GCT developing in somatic cancers may contain all elements of GCT apart from seminoma, either pure or in various combinations. Probably the most frequent types are YST and immature teratoma. Thus their developmental potential resembles that of type I GCT and the nonseminoma variant of type II GCT, like genetically engineered human induced pluripotent stem cells (iPSC) (Fig. 44).

(Cyto)genetics

Little is known on the genetics of GCT originated in somatic cancers. Overrepresentation of 12p has not been demonstrated. In a subpopulation of tumor cells of a nasal teratocarcinosarcoma an extra copy of 12p13 (a feature of type I GCT) was demonstrated by ISH.

The published de novo type VI GCT showed complex balanced translocations, with 6p21 being a common breakpoint in each of them; chromosome 12 was not involved. (Fig. 45) A nasal immature teratoma was diploid with a balanced translocation t(1;11)(q12;p15).

In type VI GCT developing in somatic cancers, various genetic and epigenetic changes may de-repress pluripotency genes. *MYC* might play a crucial role, since it is a central player in oncogenesis and pluripotency. Indeed, more aggressive cancers may express both the core pluripotency genes (OCT4, NANOG, SOX2, and KLF4) and MYC-centered networks.

The few cytogenetically characterized de novo type VI GCT suggest that breakpoints in certain chromosomal regions might activate the pluripotency program. The breakpoint in 6p21–22 in these tumors could involve OCT4. The overrepresentation of 12p13 in a sinonasal teratocarcinosarcoma may have led to overexpression of the pluripotency cluster NANOG, STELLAR, and GDF3.

Definition of a new entity of malignant extragonadal germ cell tumors. *Genes Chromosomes Cancer* **12**, 8–15.

GCT With Intermediate Phenotypes

Consistent with the plasticity of the developmental states of embryonic stem cells, there are intermediate phenotypes between the seven defined types of GCT.

There is continuum between multiple pregnancies, conjoined twins, parasitic twins, and type I GCT, with intermediate types between type 0 and type I GCT, which could arbitrarily be classified in either type.

Type I GCT and type II GCT have gradual transitions, in particular among prepubertal GCT of the mediastinum in Klinefelter's and among GCT of the brain in patients with Down's syndrome. Such tumors are genotypically type II but phenotypically resemble type I, suggesting that the genomic changes typical for type II, particularly gain of 12p, have occurred in a PGC that is still too heavily methylated to allow the full spectrum of the totipotent developmental potential of a type II GCT.

The type I GCT beyond infancy, composed of (immature) teratoma combined with dermoid cysts likely represent a transitional phenotype between type I and type IV GCT. It may be hypothesized that such tumors are derived from a precursor cell somewhere in between an oogonium and a type I oocyte, in which maternal GI is not yet completed.

There is at least one published case of a spermatocytic tumor that is intermediate between a type II and a type III GCT, in terms of morphology, chromosomal composition, and behavior: a seminomatous morphology, lacking lymphocytes, gain of 12p and chromosome 9, and metastasis.

Type VI tumors have developmental characteristics with features of type I GCT and type II nonseminomas, and intermediate phenotypes.

Conclusions

GCT are indeed one family of gonadal and extragonadal tumors derived from germ cells and their precursors. Their developmental potential/pathology is related to a developmental state rather than a specific cell of origin, as a particular originating cell may assume different developmental states, and different cell types may have the same developmental potential, in agreement with developmental state plasticity. A new concept is the type VI GCT, derived from somatic cells, most often cancer cells, induced to pluripotency.

Apart from type VI, most GCT are caused via the so-called developmental pathway: disturbance of niche-, and cell intrinsic factors that control the developmental potential of germ cells and their precursors. The somatic mutation pathway is much rarer; most mutations occur during tumor progression.

This developmental pathogenesis explains the strong familial component of most GCT, including clustering of different types of GCT, their frequent bilaterality, and their intact p53 response, which renders malignant GCT highly sensitive to DNA-damaging agents.

Having *TSPY*, located in the GBY region of the Y chromosome, is the most important risk factor for a type II GCT, regardless of anatomical site and phenotypic gender. Coexpression of OCT4 and TSPY in maturation delayed PGC/gonocytes emerges as a plausible factor for initiation of type II GCT via the developmental pathway.

Clinically it is important to differentiate between type I and IV teratomas, which are benign, and type II teratoma, which may look identical microscopically but behaves malignant.

Prospective Vision

For the advancement of the field of GCT it is important to reconsider the traditional site-oriented approach, which has led to the present confusing nomenclature, and blurred entities. GCT should rather be considered as one disease manifesting in different organs, like for example soft tissue tumors and lymphomas. This change will stimulate the development of a unifying, biologically plausible, and clinically relevant classification of existing and emerging entities, including tumors in the wake of clinical application of iPSC. Finally, it will provide a reliable basis for genotype/phenotype correlations carried out in joint efforts of basic scientists and clinicians.

Glossary

Akt/PI3K signaling pathway A signal transduction pathway involving the phosphatidylinositol 3-kinase (P13K) and protein kinase B (Akt) proteins that promotes survival and growth in response to extracellular signals.
Cytotoxic T-lymphocyte associated protein 4 (CTLA-4) A protein receptor that functions as an immune checkpoint and can downregulate immune response. It is over-expressed in tumor cells, thus helping them evade the body's immune system.
Epidermal growth factor receptor (EGFR) A transmembrane protein that is a receptor for members of the epidermal growth factor family of extracellular protein ligands. Mutations that lead to its over-expression are associated with various cancers including glioblastoma.
Glial fibrillary acidic protein (GFAP) A protein expressed by numerous cell types of the central nervous system including astrocytes, and involved in cell communication and the blood brain barrier. It is heavily expressed in glioblastoma.
Isocitrate dehydrogenase (IDH) An enzyme that catalyzes the oxidative decarboxylation of isocitrate, producing alpha-ketoglutarate and CO_2. Mutations in the isocitrate dehydrogenase gene IDH1 have been found in several brain tumors including glioblastoma and hold prognostic implications.
Mammalian target of rapamycin (mTOR) kinase A protein kinase that is involved in regulating cell growth, cell proliferation, cell motility and transcription, amidst other functions, and is implicated in the development of glioma.
Mitogen-activated protein (MAP) kinase A protein kinase involved in regulation of cell functions including proliferation, differentiation, mitosis, cell survival and apoptosis, and is implicated in the development of glioma.
O-6-methylguanine-DNA methyltransferase (MGMT) An enzyme encoded by the MGMT gene and is crucial for genome stability through its mechanism of repairing mutagenic DNA lesions and preventing mismatch and errors during DNA replication and transcription.
Phosphatase and tensin homolog (PTEN) gene The PTEN protein encoded by this gene acts as a tumor suppressor by negatively regulating the Akt/PKB signaling pathway.
Programmed cell death ligand 1 (PD-L1) A protein that suppresses the immune system by reducing proliferation and inducing apoptosis of T cells. Cancer cells upregulate expression of this protein and this may help them evade the body's immune system.
Telomerase reverse transcriptase (TERT) Subunit of the enzyme telomerase which comprises an important unit of the telomerase complex.
Tumor treating fields (TTF) Electromagnetic field therapy that applies low-intensity electrical fields to target areas containing proliferating tumor cells, impairing mitosis in these cells and thus selectively causing tumor cell death.
Vascular endothelial growth factor (VEGF) An important signaling protein that stimulates the formation of blood vessels.
World Health Organization (WHO) classification Classification of tumors of the central nervous system

History

In the mid-1800s German pathologist Rudolf Virchow coined the term "glioma" and became the first to attempt to classify this group of neoplasms. Glioblastoma, the most aggressive of these gliomas, was introduced by its name in 1926 by Percival Bailey and Harvey Cushing in their book "*A classification of the tumors of the glioma group on a histogenetic basis with a correlated study of prognosis*." The term was inspired by the fact that the tumor appeared to originate from primitive precursors—"glial cells"—and had a highly variable "multiform" appearance due to necrosis, hemorrhage, cysts, and blood vessels. Cushing and Bailey attempted to organize the gliomas into 10 groups, correlating with patient survival. Over the next few decades, various different classification systems were used until 1993, when the World Health Organization (WHO) introduced its grading system. Morphologic features continue to form the basis for classifying gliomas. Four distinct grades of glioma exist, with grades I representing circumscribed, generally slow-growing tumors and grades II, III, and IV representing diffusely infiltrating tumors with variable rates of growth. This classification was recently revised in 2016 and is discussed in greater detail below.

Epidemiology

Primary brain tumors have an incidence rate of 7 per 100,000 with a prevalence of almost 222 per 100,000 individuals. The incidence of primary brain tumors appears to be increasing over the last 30–40 years, especially in the elderly. Almost 35,000 new

diagnoses will be this year, and in 2017 alone, the condition will lead to almost 17,000 deaths. Of the primary brain tumors, 33% are malignant in nature. Glioblastoma is the most common form of malignant glioma, accounting for up to 70% of the cases. It is also the most aggressive and has the highest histological grade of the gliomas (WHO Grade IV). The typical age at presentation is between 45 and 55 years of age. Malignant gliomas including glioblastoma are almost twice as likely to occur in men than women, and twice as common in whites as in blacks.

Classification

The 2016 WHO classification of brain tumors categorizes glioblastoma by isocitrate dehydrogenase (IDH) status into IDH-wild type, IDH-mutant, and not-otherwise-specified subtypes. The IDH-wild type glioblastoma generally presents de novo (primary glioblastoma) in older (>50 years of age) patients, and 90% of glioblastomas fall into this subtype. These tumors exhibit epidermal growth factor receptor (*EGFR*) amplification and mutations, loss of heterozygosity of chromosome 10q, deletion of the phosphatase and tensin homolog (*PTEN)* on chromosome 10, and p16 deletion. The IDH-mutant glioblastoma typically present in younger patients with or without a previous diagnosis of a lower grade glioma that transforms to an aggressive, grade IV secondary glioblastoma. These have mutations in the p53 tumor suppressor gene, overexpression of the platelet derived growth factor receptor (PDGFR), abnormalities in the p16 and retinoblastoma pathways, and loss of heterozygosity of chromosome 10q. Primary and secondary glioblastomas differ at the molecular level, with differences in DNA copy number and their transcriptional patterns, but on a morphological level appear essentially identical. The glioblastoma NOS (not otherwise specified) is reserved for cases where the IDH status cannot be clarified further (**Table 1**).

A new variant to the 2016 classification is the epithelioid glioblastoma, which falls under the IDH-wildtype category. These tumors typically occur in children and young adults and are located in the cerebrum or diencephalon. They are characterized by large epithelioid cells with abundant eosinophilic cytoplasm and frequently have BRAFV600E mutations.

Etiology

The only environmental risk factor that has consistently demonstrated brain tumor risk has been exposure to therapeutic doses of ionizing radiation. Several studies have raised concern about cell phone usage and glioma, but to date the evidence overall has been inconsistent. These studies may be influenced by recall and selection bias. Diseases such as diabetes mellitus, hyperlipidemia, obesity, etc., have been evaluated and are not associated with any increased risk of developing glioblastoma. Epidemiological evaluations have noted that women have a lower glioma risk, and this protective effect is more obvious premenopause. However, the protective role of female hormones remains unclear and has still to be established conclusively. Head injury, diet, smoking, alcohol consumption, exposure to electromagnetic fields, prenatal exposure to drugs or medications, are some of the many factors that have been studied and the evidence has been minimal or inconclusive at best. Genetic factors have also been evaluated. While specific genetic polymorphisms are associated with specific types of gliomas, and may impact DNA repair and cell cycle regulation, patterns of occurrence are not always consistent with hereditary disease. Certain hereditary syndromes such as neurofibromatosis, Turcot and Li–Fraumeni syndromes are associated with increased brain tumor risk, but these account for a very small proportion of incident cases.

There is evidence that immunological factors that are related to allergic conditions and infections may have an impact on glioblastoma risk. Many studies evaluating risk of glioma in patients with allergic conditions (such as asthma or hay fever) or auto-immune diseases have found that risk of developing a glioma or glioblastoma is actually decreased in these conditions. Prior infection with certain viruses (herpes virus or varicella zoster virus, for instance) may also be associated inversely with adult glioma risk.

Table 1 Classification of glioblastoma under the 2016 WHO Guidelines

	Glioblastoma	
	IDH Wildtype	*IDH Mutant*
Type	Spontaneous, de novo	Transformation of lower grade glioma
Age distribution	Generally >50 years of age	Generally younger adults
Molecular characteristics	EGFR amplification	p53 Tumor suppressor
	Loss of heterozygosity of chromosome 10q	Gene mutations
	Deletion of PTEN	Overexpression of PDGFR
Prognosis	Worse	Better

Pathological Features

As already mentioned, glioblastoma is classified as WHO Grade IV, and thus has the highest grade of the malignant gliomas. Anaplastic astrocytomas, which are WHO Grade III, demonstrate high cell density, nuclear atypia, and mitotic activity on pathology. Glioblastoma is distinguished from the grade III pathology by the addition of abundant areas of endothelial proliferation or necrosis. Pseudopalisading necrosis may or may not be seen. IDH evaluation is routinely performed on all suspected glioblastomas, since the new classification system relies on knowing the wildtype or mutant status of the IDH gene. The tissue may also be evaluated for presence or absence of O-6-alkylguanine DNA alkyltransferase (*MGMT*) promoter methylation. Methylation of the MGMT promoter prevents gene transcription, reducing tumor cell DNA damage repair. Thus, methylation of the *MGMT* promoter makes the tumor cell more susceptible to chemotherapeutic agents that cause DNA damage, and subsequently, cellular death.

Cell of Origin and Signaling Pathways

Origins of glioblastomas and malignant gliomas have been explored since the first time the tumor was described by Dr. Harvey Cushing. Neural stem cells are proposed to be the primary origin of these tumor cells, primarily due to similarities in protein and cell surface marker expression. Neural stem cells have been known to express nestin, glial fibrillary acidic protein, and also a CD-133 cell surface marker that may lend properties of self-renewal to tumor cells.

Epidermal growth factor receptor (*EGFR*) and platelet derived growth factor receptor (*PDGFR*) are oncogenes that are often overexpressed in 40%–50% of primary glioblastomas. These likely create an autocrine loop that stimulates tumor proliferation. Moreover, several signal transduction mediators may impact the phosphatidylinositol-4,5-bisphosphate 3-kinase (*PI3-K*) pathways in these cells—these kinases are involved in cellular growth, proliferation, differentiation, and survival. These include the Ras-mitogen activated protein (*MAP*) kinase pathway and the mammalian target of rapamycin (*mTOR*) pathway. Mutation in or deletions of phosphatase and tensin homolog (*PTEN*), a tumor suppressor gene, may result in increased activity of the *P13-K* pathway also. Molecular therapeutics are currently targeting these pathways in an attempt to inhibit cell growth and encourage apoptosis of tumor cells.

Clinical Features and Diagnostic Approach

Primary brain tumor patients can present with either focal or generalized signs and symptoms. Headaches, nausea, vomiting, fatigue, confusion or altered/depressed mental status are more generalized and fairly nonspecific symptoms. Focal seizures, weakness and/or sensory loss of a particular side or limb, language and visuospatial difficulties are focal symptoms that may be more alarming and prompt earlier care.

Headache has been known to be the most common initial presenting symptom, as evaluated in many studies of patients with high grade primary brain tumor. A new diagnosis of headache or a distinct change in headache pattern in a patient older than 50 should be considered a red flag. Chronic, persistent headache with protracted nausea, vomiting, especially with positional worsening should also be evaluated carefully. This is also true for headaches that present in the morning, or wake the patient up from sleep, or are provoked by Valsalva maneuvers, coughing or straining.

When concerned, evaluation can generally be initiated with a contrast enhanced computed tomography (CT) scan of the head. At times it may be reasonable to go directly towards a gadolinium enhanced magnetic resonance imaging (MRI) scan if index of suspicion is high enough. An MRI can also provide many clues toward the nature of the tumor, based on location, presence and degree of enhancement, diffusion restriction, and perfusion, but definitive diagnosis is still made by pathological examination of tissue after excision or biopsy. Imaging in glioblastomas often reveals irregularly shaped borders, and a ring-shaped zone of contrast enhancement around a dark central area of necrosis. Significant peritumoral edema may be seen on fluid attenuation inversion recovery (FLAIR) sequences. Necrotic tumors will also have a high apparent diffusion coefficient (ADC). ADC may be also helpful in estimating cellularity of a tumor (**Fig. 1**).

Tumor perfusion, as measured by relative cerebral blood volume (rCBV), tends to be elevated in glioblastoma. Proton magnetic resonance spectroscopy or MRS can detect levels of metabolites. Areas with malignant gliomas show an increase in the choline peak and a decrease in the *N*-acetyl aspartate or NAA peak when using the MRS. Positron emission tomography (PET) is being increasingly investigated, but thus far the data are insufficient to support its use in routine evaluation of central nervous system tumors (**Fig. 2**).

Prognosis

Overall median survival is still less than 15 months in unselected patients and further reduced in the elderly population. Two-year survival rate in patients 65–74 years of age is only 8.9%, and only 3.2% for those greater than 75 years of age. Over the years, several factors have been demonstrated to be related to prognosis in glioblastoma patients. In addition to age, these include the Karnofsky Performance Status score, and the extent of resection.

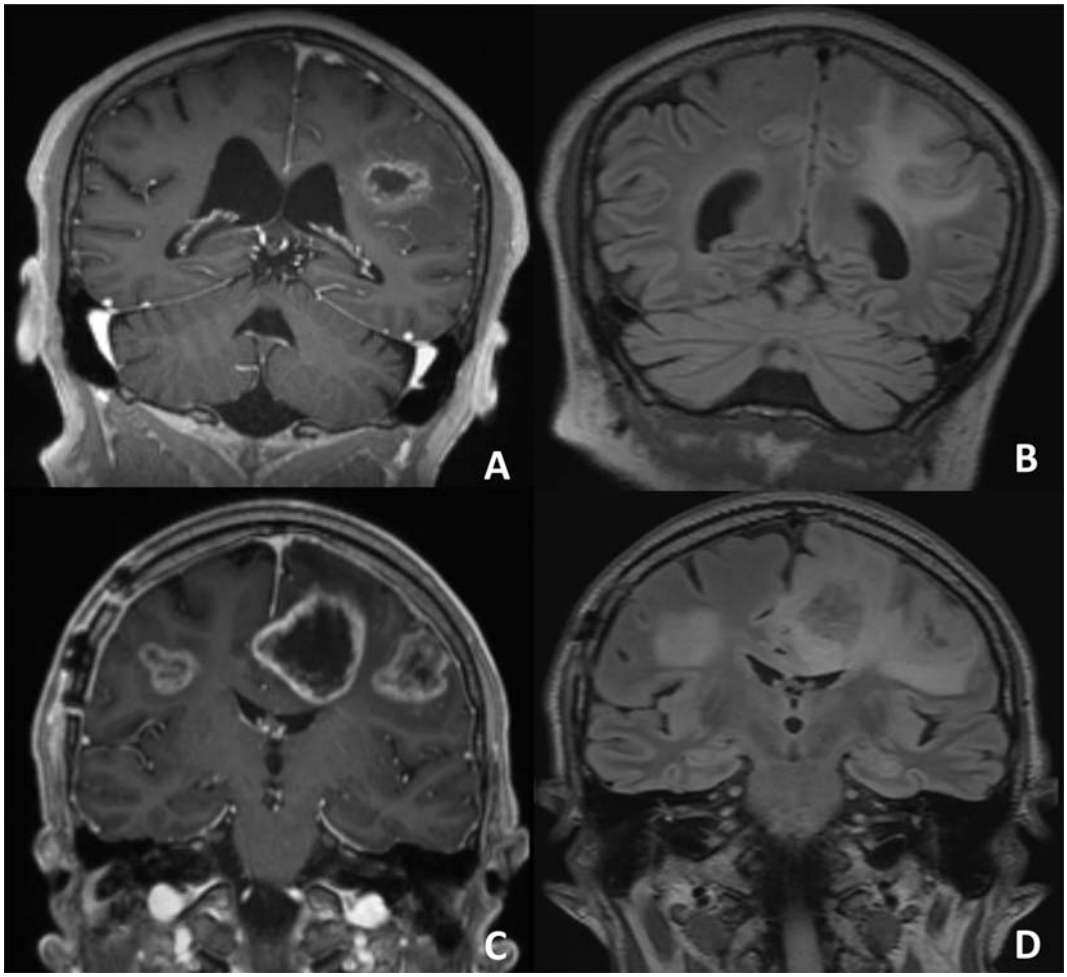

Fig. 1 Panel A and B Postcontrast T1-weighted and FLAIR MRI images showing left frontal lobe IDH wildtype glioblastoma; Panel C and D Postcontrast T1-weighted and FLAIR MRI images of a different patient with multifocal glioblastoma.

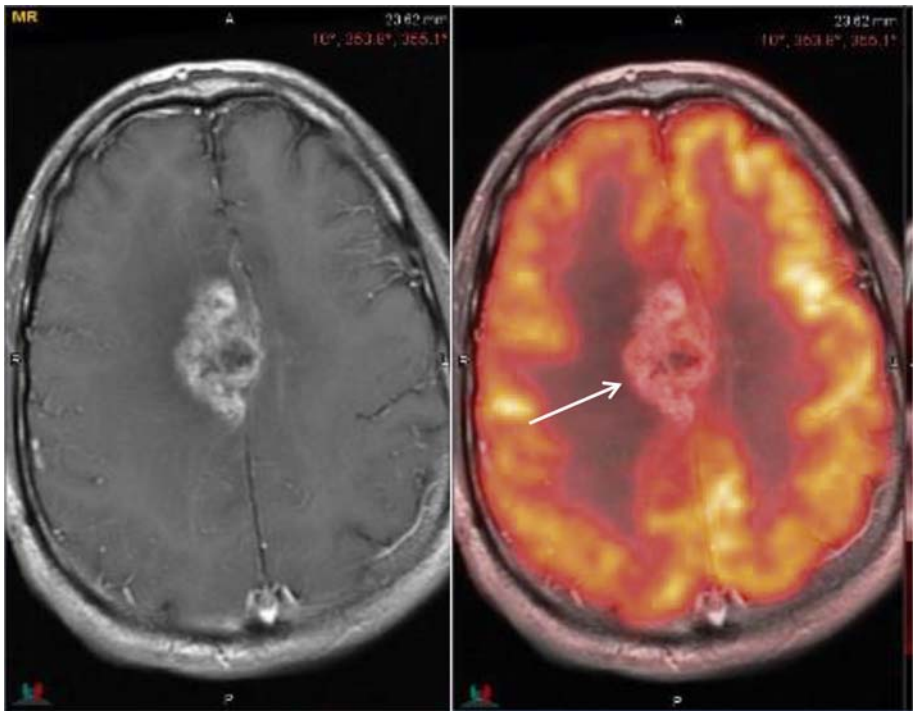

Fig. 2 PET/MRI of recurrent high grade glioma. *Arrow* points toward areas of increased uptake of radioactive label suggesting active disease.

Tumor IDH *mutation and MGMT* promoter methylation are extremely strong prognostic factors. Median survival of patients with IDH-mutant glioblastoma (which is a much smaller percentage) can be as high as 66.8 months in some cases. Similarly, patients with methylation of the *MGMT* promoter had a median survival of 21.7 months on standard of care versus 15.3 months for those with unmethylated *MGMT* promoter. A combination of MGMT promoter methylation and IDH1 mutation may have the best prognosis, thus, with an overall survival of up to 70 months in some series. It has also been noted that glioma patients with telomerase reverse transcriptase (TERT) mutations have poorer overall survival (**Figs. 3 and 4**).

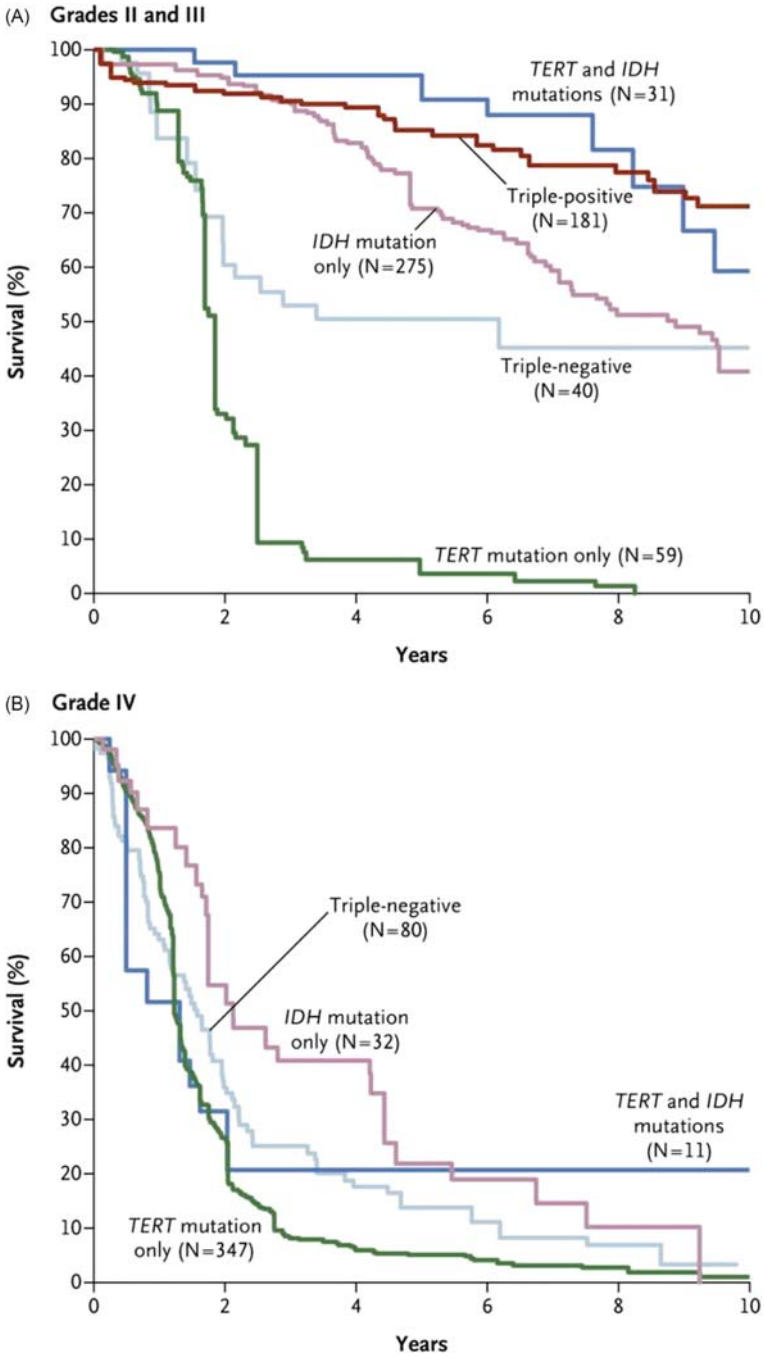

Fig. 3 Survival in glioblastoma by molecular subtype. Glioma patients with TERT mutations have poorer survival, while IDH mutations confer a survival benefit. Mutations of both TERT and IDH appears to be helpful for survival. From Eckel-Passow, J. E., Lachance, D. H., Molinaro, A. M., Walsh, K. M., Decker, P. A., Sicotte, H., et al. (2015). Glioma groups based on 1p/19q, IDH, and TERT promoter mutations in tumors. *The New England Journal of Medicine* **372**(26), 2499–2508.

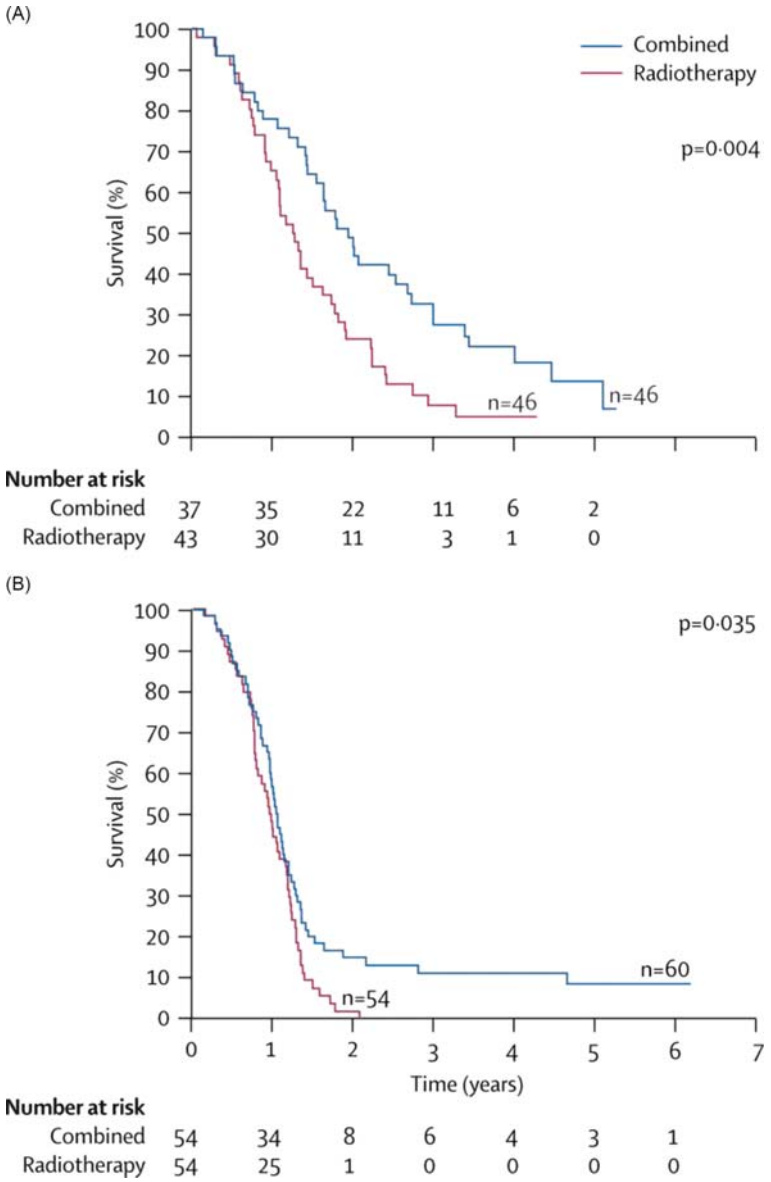

Fig. 4 Survival in glioblastoma by MGMT methylation status. Survival is longer with the combination of radiation therapy plus temozolomide in patients with either methylated or unmethylated tumors, but the treatment effect is found to be greater in patients with methylated tumors. From Stupp, R., Hegi, M. E., Mason, W. P., van den Bent, M. J., Taphoorn, M. J., Janzer, R. C., et al. (2009). Effects of radiotherapy with concomitant and adjuvant temozolomide versus radiotherapy alone on survival in glioblastoma in a randomised phase III study: 5-year analysis of the EORTC-NCIC trial. *Lancet Oncology* **10** (5), 459–466.

Treatment

There is currently no cure for glioblastoma. Whenever possible, patients should be offered a clinical trial as a part of their therapy plan. Maximal safe resection has been recommended as the standard of care for high grade gliomas such as glioblastoma. Various retrospective studies and meta-analyses have established that obtaining a gross total resection (GTR) when possible can improve outcomes including overall survival when compared to a subtotal resection or biopsy alone. Tumor location often dictates safety and feasibility of the resection, since morbidity of the surgery has to be balanced with the benefit from resection.

Radiation is the second pillar of therapy in glioblastoma. It should be initiated as soon as it is safe after surgical intervention, and is generally started between 3 and 6 weeks from surgery, barring any complications or infection. For patients who are younger than 65 with Karnofsky performance status greater or equal to 60, optimal dose fractionation for external beam radiation therapy after resection or biopsy is 60 Gy in 2-Gy fractions, delivered over 6 weeks. This schedule has been repeatedly demonstrated to have the maximal benefit. Elderly patients greater than 65 with a Karnofsky greater or equal to 50 are also advised external beam radiation therapy, but recent studies have demonstrated that hypofractionated radiotherapy has similar survival, lesser side effects, including

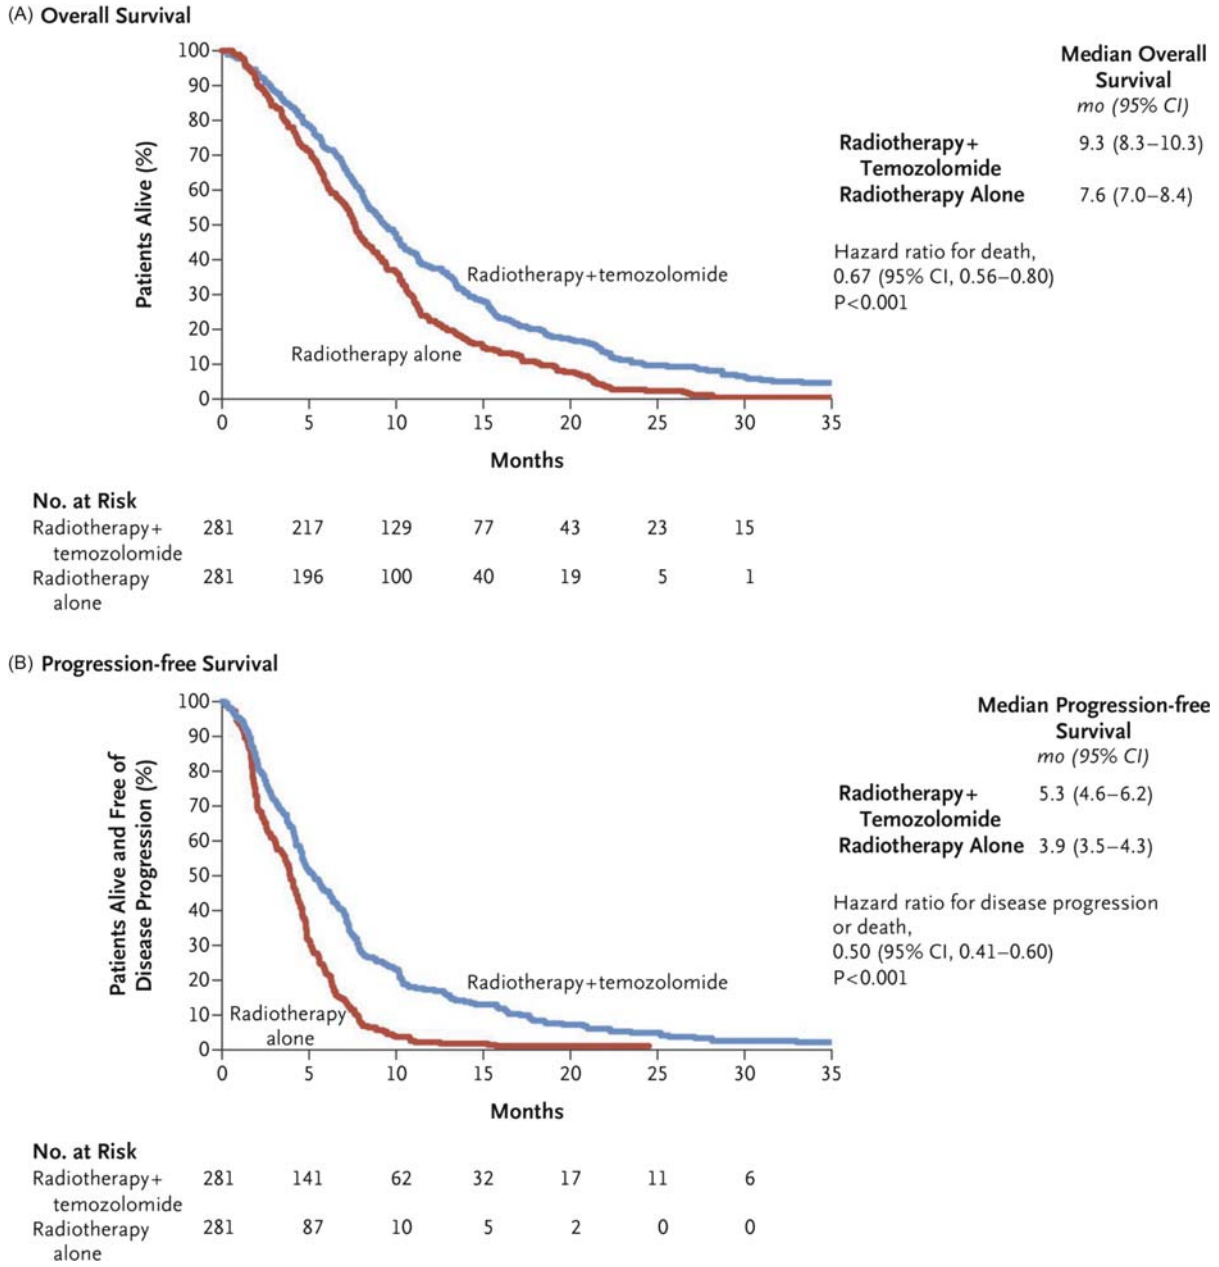

Fig. 5 Overall and progression-free survival in elderly patients treated with hypofractionated radiation in combination with chemotherapy. From Perry, J. R., Laperriere, N., O'Callaghan, C. J., Brandes, A. A., Menten, J., Phillips, C. et al. (2017). Short-course radiation plus temozolomide in elderly patients with glioblastoma. *The New England Journal of Medicine* **376**(11), 1027–1037.

lower steroid requirement during treatment. This is a dosing of 40 Gy in 15 fractions over 3 weeks instead of the schedule described above. Patients with poor Karnofsky performance status may receive hypofractionated radiotherapy alone, chemotherapy alone, or best supportive care. Partial brain radiation therapy is recommended, since no benefit has been seen with whole-brain radiation therapy. Radiation techniques involve using image guided radiotherapy and intensity modulated radiotherapy to deliver a high dose of radiation to the target area, while delivering a lower dose to the margin, thus sparing healthy surrounding tissue. While the evidence is weak, reirradiation to focal areas of recurrence with stereotactic radiosurgery or hypofractionated radiotherapy has been tried and may improve outcomes (Fig. 5).

Chemotherapy is the third and integrally important component of treatment. Prior to 2005, standard therapy consisted of maximal safe resection followed by radiotherapy and adjuvant carmustine, a nitrosourea. Significant survival benefit was not established with this regimen. In 2005, reported results using the "Stupp protocol" changed the management of glioblastoma patients. Patients receiving temozolomide, an oral methylating agent, with concurrent radiotherapy, followed by six monthly cycles of adjuvant temozolomide experienced prolongation of median survival by 2.5 months. Two year survival with this regimen

improved by 16%. In addition, temozolomide is taken orally, and is generally well tolerated. The more common side effects included fatigue, headache, nausea, gastrointestinal discomfort. Grade 3 or 4 cytopenias are uncommon. Following the results of this trial, standard of care for newly diagnosed glioblastoma transitioned to maximal surgical resection followed by radiotherapy, generally at a dose of 60 Gray given in 30 fractions over 6 weeks, with concomitant temozolomide at 75 mg/m^2 per day for the 42 days of radiotherapy. Four weeks after radiation, adjuvant temozolomide is given at 150–200 mg/m^2 on days 1–5 of each 28 day cycle, for 6 cycles. Treatment effect is greatest in patients with MGMT promoter-methylated tumors.

Carmustine wafers are another Food and Drug Administration (FDA) approved chemotherapeutic approach that may be undertaken with newly diagnosed glioblastoma at time of resection. Small polymers containing carmustine are implanted into the tumor bed, with the idea that slow release of the drug over the course of several weeks may kill residual tumor cells. Median survival has been seen to improve by approximately 2 months with integrated use of these polymers in newly diagnosed glioblastoma. These wafers do have significant limitations, and cannot be offered to every patient. Adverse effects in most studies include brain edema, seizures, wound-healing problems, infection, thrombosis, and intracranial hypertension.

The NovoTTF-100A system known as Optune was recently approved by the FDA for patients with recurrent and newly diagnosed glioblastoma. This is a portable, noninvasive device that generates low intensity, intermittent frequency alternating electric fields and delivers them via transducer arrays that are placed directly on the patient's scalp. The electrical fields, also called tumor-treating fields, have antimitotic effects by interfering with mitotic spindle cell formation and chromosomal segregation during tumor cell division. Usage compliance rates of >18 h a day are required for the best outcomes. Treatment begins in conjunction with temozolomide following completion of radiation therapy. When combined with temozolomide, median survival has been shown to improve to 20.5 months from 15.6 months with chemotherapy alone. Recent data from Stupp and colleagues indicate a 2 year survival rate of 43% in the TTF-treated group versus 31% in the group treated with standard of care alone. At 5 years, the difference remained—13% in the treatment group and 5% with standard of care alone.

Unfortunately glioblastoma almost always recurs. When it does recur, treatment options vary. Reoperation may be feasible and is often offered depending on the functional status of the patient and tumor (recurrence) location, size, and safety of the resection. There are no definitive data yet that the second surgery provides survival benefit, but it may be helpful to confirm the lesion is indeed recurrence and not radiation necrosis or inflammation. Radiotherapy for recurrent glioblastoma is controversial at this time and though frequently used, has not been established as having clear survival benefit. This is being evaluated in clinical trials. Stereotactic radiosurgery may be an option that can benefit these patients that have a small relatively well-circumscribed pattern of recurrence.

Carmustine wafers have been used in patients with recurrent glioblastoma with modest increase in time to progression. Several other chemotherapy agents have been assessed, including lomustine, procarbazine with lomustine, and vincristine (PCV), carboplatin, irinotecan, etoposide, and others. However, benefits of these agents are modest at best, with no evidence that any of the agents improves survival. Rechallenge with temozolomide has been studied, with inconclusive results.

Bevacizumab, a vascular endothelial growth factor (VEGF) inhibitor was approved for use in recurrent glioblastoma in 2009. It can be used as a single agent or in combination with the drugs mentioned above. Clinical trials thus far have demonstrated that bevacizumab may improve progression free survival, but does not improve overall survival. It does prove to be very useful in treating peritumoral edema and radiation necrosis in the appropriate patient, thus improving quality of life.

The NovoTTF-100A device has also been evaluated in patients with recurrent glioblastoma and compared with physician's choice of chemotherapy. There was no difference in outcomes between the two treatments.

General Medical Management

Apart from treating the tumor, patients with glioblastoma also require management of morbidity associated with their condition and/or its treatment. Seizures, peritumoral edema, venous thromboembolism, fatigue, headaches, and cognitive dysfunction are some of the most common problems encountered in care of the glioblastoma patient. Patients may also develop significant functional disability over the course of their disease.

Prevalence of seizures can be as high as 50% in glioblastoma patients. Patients with temporal lobe tumors and those with hemorrhage in the bed of the tumor may be at a higher risk of seizures. No statistically significant benefit has been seen thus far for the prophylactic use of antiepileptics in patients with tumors, even in those treated with a craniotomy for resection. Antiepileptics should only be started when patient has a clearly witnessed seizure or provides history that is concerning enough for a seizure. A single event is usually enough to start an antiepileptic in this high risk population, and an EEG is not always required if the clinical history is convincing.

The choice of antiepileptics is based on many considerations, including ease of dosing and tolerance, the side effects and the drug interactions. Generally, drugs that induce the hepatic cytochrome *p*-450 enzymes (such as phenytoin or carbamazepine) are avoided since they can increase the metabolism of many chemotherapeutic agents. Phenytoin should also be avoided in patients once patients have received cranial radiation, given higher risk of rash in this population. Levetiracetam, lamotrigine, pregabalin, and lacosamide are generally more preferred in this population. They appear to be better tolerated and have fewer drug interactions. Levetiracetam is perhaps the most frequently prescribed antiepileptic for this patient population. Side effects in a small percentage of people include irritability, aggression, hostility, suicidality, and depression. Lacosamide also has few drug interactions, and has fewer of these psychiatric side effects, but can have cardiac side effects and is quite expensive. Valproic acid in recent years has been

investigated for antiglioma properties in addition to anticonvulsant properties, as it may function as a radiosensitizer in glioblastoma patients. However, it does have side effects of teratogenicity, hyperammonemia, alopecia and weight gain, and thus has to be used in the appropriate patient.

Patients often complain of fatigue more than any other symptom, and can impact their overall sense of well-being. The disease as well as radiation and chemotherapy all contribute to this symptom. Management should include addressing reversible factors such as medications (anticonvulsants, opioids, antiemetics), diet and vitamin intake, sleep quality, anemia, and nutritional deficiencies. Aerobic exercise and steroids may improve fatigue. Psychostimulants such as modafinil and methylphenidate have been studied with mixed results, but may be appropriate for some patients.

Headache is experienced by up to 50% of patients with brain tumors and can get worse toward the end of life. Management of headache in glioblastoma depends on the stage of disease and overall functionality. Steroids may alleviate symptoms when edema is contributing but cannot be used indefinitely due to side effects. Antiinflammatory agents may be helpful when used in a limited manner to avoid overuse and kidney or gastrointestinal injury. Prophylactic agents such as gabapentin and topiramate may be beneficial but have side effects that may outweigh the benefits in some patients. At the end of life, opioids may be preferred, weighing the risk of sedation with pain control.

Peritumoral edema can be quite disabling, resulting in focal weakness and even coma. Steroids can treat and control edema in the glioblastoma patient, rapidly alleviating the symptoms. Steroids also work in alleviating nausea, treating headaches, and improving appetite. However, steroids also have significant side effects such as hyperglycemia, weight gain, myopathy, psychosis, delirium, and irritability. In an acute setting, the glioblastoma patient may be disabled by edema from the tumor. The goal should be to start with the lowest possible dose and taper down as quickly and safely as possible. Calcium/vitamin D supplementation and a proton pump inhibitor or histamine receptor blocker should be prescribed with the steroids for bone health and gastrointestinal prophylaxis, respectively. Bevacizumab may be another agent that can decrease peritumoral edema in these cases and reduce the need for steroids. Wider use for this indication, however, is limited due to high cost.

Glioblastoma patients are at an increased risk of venous thromboembolism. Anticoagulation therapy is recommended and safe for venous thrombo-embolism unless there is obvious systemic or intracerebral hemorrhage. Intratumoral hemorrhage rates in anticoagulated GBM patients are relatively low. Low molecular weight heparin can be safe and more effective than warfarin in this population, and is thus frequently used. Oral thrombin inhibitors have not yet been studied in this specific patient population; in fact, data on their safety and efficacy in cancer patients receiving chemotherapy at large is lacking.

Neurocognitive problems may be a presenting symptom of brain tumors or present later in the course of the disease. Impairment in executive functioning, memory, and attention are the areas where deficits are most commonly noted. Memantine has been trialed in a small group of patients—when initiated within 3 days of radiotherapy for 24 weeks, cognitive function over time may be better preserved. No other preventive interventions have been clearly established thus far. Several small studies have noted that methylphenidate at 10 mg twice a day can improve cognition and mood as well as functional status in high grade glioma patients, and can be taken with minimal adverse effects. Modafinil has also been seen to have a beneficial effect in speed of processing and executive function requiring attention in some studies. Fatigue and mood may also improve with this drug.

Prospective Vision

The neuro-oncology field, similar to the cancer therapy field at large, is in the midst of a variety of exciting new research that hopes to create new targeted therapy for primary brain tumors.

One of these areas is immunotherapy—agents developed for advanced systemic tumors have demonstrated significant clinical benefit but this has not yet been true for glioblastoma despite decades of research in the field. The T cell response is key in this process—antigens released from tumor cells at their death are presented to T cells by antigen presenting cells, which in turn prime the T cells against these antigens. Checkpoint pathways between the antigen presenting cells, tumor cells, and T cells, provide signals that activate or inhibit T cells and thus regulate this immune response. The brain, despite being highly protected by the blood brain barrier, does communicate with the immune system since we now know that activated cells are able to traffic through the barrier and the CNS lymphatic system also facilitates immune surveillance. The rationale is that antibodies to checkpoint inhibitors—specifically to cytotoxic T lymphocyte-associated antigen-4 (CTLA-4), programmed cell death protein 1 (PD-1), and programmed cell death-ligand (PD-L1)—could result in increased susceptibility of glioblastoma to an immune response. These are being investigated in clinical trials but at this point, a single phase III trial using one of these agents showed no benefit in the setting of recurrent glioblastoma, but numerous other clinical trials are in early stages and hold promise. Studies are also investigating the combination of these immunotherapies with established therapies, and with radiotherapy. One limitation is that we are still working on understanding how these specific pathways work in the brain and how glioblastoma specifically evades the immune system. It is important to ensure that these treatments will be safe in the CNS, where an intense immune response could have the potential of inflammatory damage to the brain. Assessing response in glioblastoma, and differentiating inflammation from progression, will also be key challenges.

Various vaccine-based therapies are also under investigation. One approach utilizes a mixture of autologous tumor cells with allogeneic glioblastoma cell populations that have been inactivated with irradiation. Vaccines with antigen-presenting dendritic cells primed ex vivo with glioblastoma antigens and peptide vaccines to enhance the immune response are in clinical trials. For

example, rindopepimut, an EGFRvIII peptide combined with an adjuvant, failed to demonstrate survival benefit in patients with newly diagnosed glioblastoma, but is currently being studied in combination with bevacizumab in patients with recurrent disease.

In recent years T cell therapy has gained a lot of attention in the field of oncology in general, and neuro-oncology is no different. Tumor infiltrating lymphocytes can be harvested, expanded in vitro and re-infused into the patient with the hope that a cytokine immune response will lead to cell death of the tumor. Engineered T cells—high avidity tumor specific transgenic T cells or TCR, and chimeric antigen receptor or CAR T cells—are being investigated specifically in glioblastoma.

Viruses that can infect tumor cells and lead to host cell death are an attractive concept. Various viruses are being investigated in phase I and II trials at this point, including herpes simplex virus-1, adenovirus, poliovirus, zika virus, measles virus, and parvovirus. However, many challenges must be overcome at this point. One is safety—only malignant tumor cells must be infected and healthy brain tissue surrounding the tumor margins must be spared. In addition, the likely immune response in the brain to the virus must protect the brain without irreversible inflammatory damage, and also not diminish the impact of the viral agent itself. This area continues to carry much excitement and hope for the future, as researchers continue to troubleshoot these aspects.

Advances in surgical and imaging techniques also hold promise for the future. While it has been established that maximal safe resection improves prognosis in glioblastoma, achieving that gross total resection has been a challenge on the operating table given limitations in visualizing tumor margins. To this end, advances in imaging have allowed for improved volumetric analyses and surgical planning. Fluorescence guided surgery ("tumor paint") has been noted to help improve extent of resection and in turn overall survival in advanced glioma. Intraoperative MRI guidance has also been used in several centers to achieve maximal resection with subsequent improvement in progression free survival. Other technologies increasingly available to the surgeon include cortical and subcortical stimulation mapping and intraoperative ultrasonography, techniques that can help preserve normal and essential brain tissue while helping resection of tumor.

The field of radiation therapy has had many exciting advances in recent years and we have learned more about what is both efficacious and safe for our patients. Proton beam radiotherapy has received significant attention in recent years for several malignancies, including glioblastoma. The hope is that proton therapy will offer the same or improved benefit with less toxicity since the radiation exposure to normal tissue is less than with conventional photon beam therapy. Trials investigating this in glioblastoma are on going. The future also holds promise with tractography and functional mapping to better diagnose and delineate anatomy. Diffusion tensor imaging tractography may be able to help differentiate between gross tumor and infiltrative margins, allowing for safer treatment. [^{18}F]-fluoromisonidazole has been used to identify hypoxic areas in tissue and is being explored as a means to identify specific different regions within the tumor and tailor treatment doses accordingly. Improved imaging techniques will continue to enable the radiation oncologist to provide the best treatment for the tumor bed, thus impacting overall and progression free survival.

Glioblastoma: Pathology and Genetics

Christian Hartmann, Medical School Hannover, Hannover, Germany

Introduction

Gliomas are a very diverse group of glial neoplasms and account for the great majority of tumors originating in the parenchyma of the central nervous system (CNS). Two main categories of gliomas are recognized: diffuse gliomas, by far the most frequent gliomas in adult patients and characterized by extensive infiltrative growth into the surrounding CNS parenchyma, and gliomas with a much more circumscribed growth pattern ("nondiffuse gliomas"). Traditionally, diffuse gliomas are further classified based on their microscopic similarities with (precursors of) glial cells and then designated as astrocytoma, oligodendroglioma, or mixed glioma/oligoastrocytoma. After assessment of the glioma type, a malignancy grade is assigned to these tumors based on especially the following histologic features: marked mitotic activity, florid microvascular proliferation, and necrosis. Diffuse astrocytic tumors showing marked mitotic activity, as well as necrosis and/or florid microvascular proliferation are diagnosed as glioblastoma. Glioblastomas account for about 15% of all primary CNS tumors and for over 50% of all gliomas. Even though extracranial metastases of gliomas are very rare, most glioblastoma patients die within 1–2 years after diagnosis, despite today's standard of care (surgery, radiotherapy, and chemotherapy). Many patients with a lower grade (WHO grade II or III) diffuse astrocytoma survive (much) longer, but virtually all these patients will eventually experience progression to glioblastoma resulting in fatality.

For a long time, microscopic evaluation has provided the gold standard for the diagnosis of gliomas, assessment of prognosis and formed the basis for therapeutic management. Multiple studies, however, showed that a purely histopathologic classification suffers from considerable inter- and intraobserver variability. Especially in the course of the last decade it became clear that molecular characteristics provide a more robust and objective basis for subtyping of diffuse gliomas. Indeed, in the revised 4th edition of the WHO classification of CNS tumors (published in 2016), classification of diffuse gliomas has fundamentally changed as for the first time presence/absence of particular molecular aberrations is now part of the definition of these tumors. After providing some essentials of the traditional, histopathology-based classification of glioblastomas, this review discusses novel insights in molecular characteristics of (different subgroups of) these neoplasms and how this information is now used for a combined histomolecular diagnosis. Furthermore, information is provided on how based on tools like expression profiling and methylation profiling additional subgroups can be recognized, while in the last part some future perspectives are given with regard to where the field is or may be heading.

From Histopathologic to Histomolecular Classification

For over a century, microscopic analysis of tumors of the CNS has been performed on histochemically, especially hematoxylin-and-eosin (H&E) stained sections, later on supplemented by electron microscopy and immunohistochemistry. Diffuse gliomas represent the vast majority of glial neoplasms in adult patients and are microscopically characterized by diffuse infiltrative growth within the CNS parenchyma, with tumor cells extensively invading individually or in small groups in the neuropil along myelinated fiber tracts and along blood vessels. This invasive growth may well extent over several centimeters outside the abnormal area as seen on magnetic resonance imaging (MRI) scans. Also, not infrequently the tumor cells of diffuse gliomas cross the corpus callosum, resulting in a "butterfly glioma" pattern on MRI. Especially in the less cellular areas of diffuse gliomas the matrix may consist of relatively intact preexistent gray and white matter with aggregation of neoplastic cells around neurons (perineuronal satelitosis), blood vessels, and under the pial membrane. Such "secondary structures of Scherer" are nearly pathognomonic of diffuse glioma. Occasionally, a diffuse glioma may present radiologically as multiple lesions (multifocal or multicentric glioma) resembling brain metastases or abscesses while it in fact concerns multiple foci of high cellularity, microvascular proliferation and/or necrosis in a widespread diffuse glioma.

Based on their histopathologic phenotype, diffuse gliomas are traditionally typed as astrocytic, oligodendroglial, or mixed oligodendroglial-astrocytic, and graded as WHO grade II (low grade), III (anaplastic), or IV (glioblastoma). Diffuse gliomas without mitotic activity, microvascular proliferation, and necrosis are graded as low-grade (WHO grade II). With increased mitotic activity, the diagnosis of anaplastic astrocytoma or anaplastic oligodendroglioma (WHO grade III) is rendered, while in astrocytic tumors the presence of necrosis and/or microvascular proliferation leads to a diagnosis of glioblastoma (WHO grade IV). In contrast, pure oligodendroglial tumors with necrosis and florid microvascular proliferation are still graded as WHO grade III. Necrosis in glioblastomas often consists of irregular, serpiginous foci surrounded by densely packed, somewhat radially oriented tumor cells ("palisading necrosis").

Glioblastoma is by far the most frequent and most malignant diffuse glioma and was previously called "glioblastoma multiforme" because of the often striking intratumoral cytologic and histologic heterogeneity. Furthermore, several histologic subtypes of glioblastoma are listed in the WHO 2016 classification, including the small cell variant of glioblastoma (predominantly showing small, relatively monomorphous tumor cells with little cytoplasm which may resemble anaplastic oligodendroglioma),

gliosarcoma (with a sarcoma-like, reticulin-rich component), giant cell glioblastoma (characterized by the presence of many large, multinucleated tumor cells), epitheloid glioblastoma (often apparently more circumscribed tumors showing prominent epitheloid or even rhabdoid morphology and thereby showing resemblance with metastastic carcinoma or melanoma), glioblastomas with primitive neuronal component (with nodular foci of primitive neuronal cells resembling embryonal tumor), and granular cell glioblastoma (with histiocyte-like cytoplasmic granularity and vacuolation). (Fig. 1).

Until the most recent World Health Organization (WHO) classification of CNS tumors published in 2016, the histologic diagnosis was the gold standard for classification of gliomas. In daily clinical practice, however, unequivocal typing and grading of gliomas can be difficult. For instance, because diffuse gliomas often show marked phenotypic heterogeneity with spatial differences in cellular phenotype, degree of anaplasia and mitotic activity there is a danger of underestimation of malignancy grade because of sampling error. Furthermore, the minimum diagnostic criteria of, for example, florid microvascular proliferation are not clear. Even identification of necrosis may be troublesome in biopsy samples that are small or poorly preserved, and in recurrent gliomas discrimination of native tumoral from therapy-induced necrosis may be difficult.

Meanwhile, since 2008 multiple studies showed that based on the presence or absence of mutations in the *isocitrate dehydrogenase 1* (*IDH1*) or *IDH2* gene and of complete, combined loss of the short arm of chromosome 1 and of the long arm of chromosome 19 (complete 1p/19q-codeletion) three major, clinically relevant subgroups of diffuse glioma can be defined. Indeed, the International Society for Neuropathology—Haarlem Consensus Guidelines and the subsequently published, revised 4th edition of the WHO classification of CNS tumors published in 2016 embraced this notion of an integrated histomolecular classification of diffuse gliomas, and the WHO classification nowadays recognizes the following three major molecular diffuse glioma subgroups:

- *IDH-wildtype*: most of these histologically represent astrocytic tumors, a large percentage belonging to the highest malignancy grade, that is, glioblastomas;
- *IDH-mutant and 1p/19q-non-codeleted*: these tumors also generally have an astrocytic phenotype, but a much larger percentage is at first diagnosis histologically lower grade/WHO grade II or III;
- *IDH-mutant and 1p/19-codeleted*: most of these are characterized by a prominent oligodendroglial phenotype of the tumor cells.

In this new classification, the presence of complete 1p/19q-codeletion in an IDH-mutant diffuse glioma is considered pathognomonic for oligodendroglioma, while IDH-mutant oligodendroglioma-appearing tumors lacking this event are reclassified as astrocytoma, IDH-mutant. Following this strategy, the diagnosis of oligoastrocytoma can be expected to largely disappear, except when additional molecular tests cannot be performed or do not provide unequivocal results; in that situation, not-otherwise-specified (NOS) should be added to the diagnosis to indicate that ideally such samples require further workup. Similarly, molecular studies have now also revealed that most cases previously diagnosed as glioblastoma with oligodendroglioma component (GBM-O) fit in one of the three categories just mentioned (i.e., can be diagnosed as glioblastoma IDH-wildtype, glioblastoma IDH-mutant, or as anaplastic oligodendroglioma IDH-mutant and 1p/19q-codeleted) and GBM-O has therefore been removed from the WHO 2016 classification as a diagnosis.

In the following paragraphs three molecularly defined groups of glioblastoma will be discussed in more detail: IDH-wildtype glioblastoma, IDH-mutant glioblastoma, and diffuse midline glioma H3 K27M-mutant. This last category was added in the

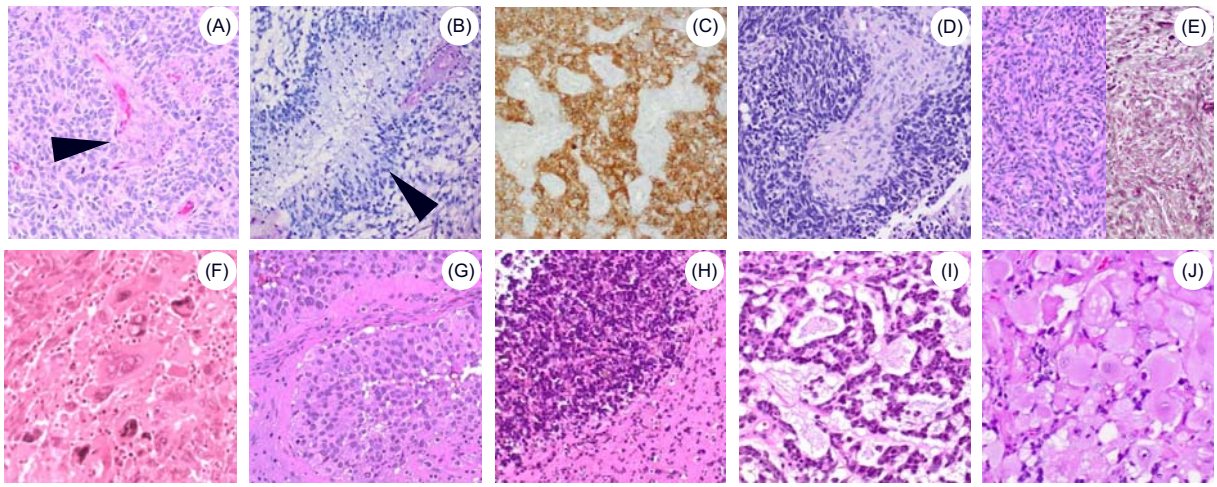

Fig. 1 Examples of histopathology of glioblastoma, including some histologic variants (=commonly accepted subtypes associated with particular clinical features) and patterns (=histological appearances without any currently identified clinical significance). (A) Florid microvascular proliferation (arrowhead); (B) palisading necrosis (arrowhead); (C) immunohistochemical demonstration of IDH1 R132H mutant protein in glioblastoma, IDH-mutant (molecularly defined entity); (D) small cell glioblastoma (pattern); (E) gliosarcoma (variant); (F) giant cell glioblastoma (variant); (G) epitheloid glioblastoma (variant); (H) glioblastoma with primitive neuronal component (pattern); (I) adenoid glioblastoma (pattern); (J) granular cell glioblastoma (pattern). Images A, B and D–J are from hematoxylin-and-eosin stained sections, apart from the right half of image E where a reticulin stain highlights the widespread presence of reticulin fibers in between the sarcomatoid tumor cells.

WHO 2016 classification as a separate entity. H3 K27M-mutant diffuse midline glioma generally occurs in children and should be located in the "midline" of the CNS (defined as brainstem, thalamus, cerebellum and/or spinal cord). Diffuse intrinsic pontine glioma (DIPG) is a frequent representative in this category.

Glioblastoma, IDH-Wildtype

The current WHO classification thus separates glioblastomas according to their IDH and H3 K27M status. Approximately 90%–95% of adult patients with glioblastoma have an IDH-wildtype (and H3 K27-wildtype) tumor. In most of these patients the tumor presents as a "primary glioblastoma," that is, a glioblastoma without clinical, radiological and/or pathological evidence of a lower grade precursor lesion. Data from large epidemiological cohorts are currently not yet available for IDH-wildtype versus IDH-mutant glioblastomas. The most recent CBTRUS report (published in 2017) on the occurrence of CNS tumors in the USA in the period 2010–14 still presents glioblastomas as one group. In the majority of patients IDH-wildtype glioblastoma is diagnosed in their 6th or 7th decade of life. Of note, many glioblastomas in childhood are also IDH-wildtype but the molecular underpinnings of these tumors is generally different from that in adult patients (see also paragraph on diffuse midline glioma, H3 K27M-mutant).

Large consortia such as the International Cancer Genome Consortium (ICGC) (https://icgc.org), The Cancer Genome Atlas (TCGA) (https://cancergenome.nih.gov), and the Chinese Cancer Genome Consortium (CCGC) (http://cancerdb.genomics.org.cn) have provided a wealth of new information on molecular alterations in different subgroups of glioblastoma. Different molecular classification schemes have been proposed over the last decade, some of these using a restricted set of molecular markers (such as IDH, H3 K27 and 1p/19q status), others using information on additional markers and/or on data obtained by global gene expression or methylation profiling analysis. Salient molecular aberrations in IDH-wildtype glioblastomas are: loss of chromosome 10 combined with gain of chromosome 7 (+7/−10), amplification of the epidermal growth factor receptor (*EGFR*) gene, mutation of the promoter of the telomerase reverse transcriptase (*TERT*) gene. These molecular markers will now be discussed in more detail. Additionally, in this paragraph some information will be provided on the methylation of the promoter of *MGMT* gene (encoding O^6-methylguanine-DNA methyltransferase). Of note, *MGMT* promoter methylation status is an epigenetic marker with predictive value for response to alkylating chemotherapy in patients with glioblastoma rather than a marker of use for assigning a particular WHO diagnosis to a glioma.

The vast majority of IDH-wildtype glioblastomas show (often whole chromosome) gain of one copy of chromosome 7 and loss of one copy of chromosome 10 (+7/−10). (**Fig. 2**) This aberration is considered as a very early event in the oncogenesis of glioblastomas. Several oncogenes that have been implicated in gliomagenesis are located on chromosome 7, for example, Cyclin Dependent Kinase 6 (*CDK6*), MET Proto-Oncogene (*MET*) and *EGFR*, while several tumor suppressor genes are located on chromosome 10, including Tet family member Tet Methylcytosine Dioxygenase 1 (*TET1*) and Phosphatase and Tensin Homolog (*PTEN*). It is still unclear, however, how exactly +7/−10 plays a role in gliomagenesis. With a reported mutation frequency of

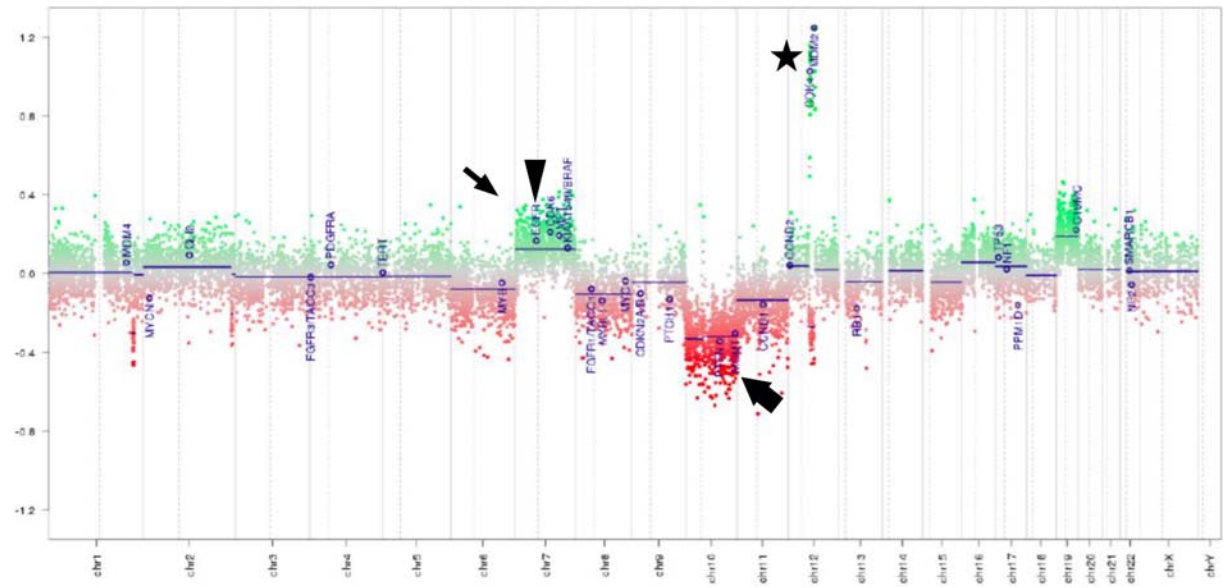

Fig. 2 Chromosomal copy number variation (CNV) plot of an IDH-wildtype glioblastoma based on Illumina EPIC/850k methylation profiling analysis. This glioblastoma shows +7/−10 in the form of whole chromosome 7 gain (thin arrow) combined with whole chromosome 10 loss (thick arrow). Additionally, amplification of *CDK4* and *MDM2* is present (asterisk), but high copy *EGFR* amplification is lacking (arrowhead). Of note, demonstration of +7/−10 and/or EGFR amplification in an IDH-wildtype diffuse astrocytic tumor of histologically WHO grade II or III is a very strong indication that the tumor will clinically behave as glioblastoma (WHO grade IV).

54%–84%, *TERT* promoter mutation is the most frequent mutation in IDH-wildtype glioblastomas. This gene encodes the telomerase, which induces the extension of the telomeres. Interestingly, the *TERT*-related mutations are thus not located in the coding area of the gene, but in the promoter, with approximately 80% of the C228T type, and 20% of the C250T type. The consequence of these mutations is an increased expression of telomerase by a factor of five. Glioblastoma patients with a *TERT* promoter mutation are older and tend to have a worse prognosis. Of note, IDH-mutant and 1p/19q-codeleted oligodendrogliomas also show a very high frequency of *TERT* promoter mutations but in those tumors this marker does not have a negative prognostic significance. In contrast, diffuse, IDH-mutant astrocytomas, including IDH-mutant glioblastomas, typically do not have *TERT* promoter mutation but an α-thalassemia/mental retardation syndrome X-linked (*ATRX*) mutation resulting in alternative lengthening of telomeres (**Fig. 3**).

Approximately 40% of all IDH-wildtype glioblastomas show amplification of the *EGFR* gene, and one-third to half of these *EGFR*-amplified tumors additionally show the *EGFRvIII* mutation variant. In this variant, exons 2–7 are deleted, and the consecutive loss of part of the extracellular domain of the receptor tyrosine kinase causes constitutive autophosphorylation and permanent activation of, for example, the PIK3 pathway, resulting in increased cell proliferation and resistance to apoptosis. Although the *EGFRvIII* mutation variant is often present in only a subset of the tumor cells, it has been demonstrated that cells expressing this variant can stimulate neighboring tumor cells by a paracrine mechanism. Furthermore, the in-frame deletion of the *EGFRvIII* mutation generates a neoepitope that can be detected with specific antibodies. Unfortunately, attempts to use this neoepitope for therapeutic vaccination have so far failed. In the TCGA RNAseq analysis of *EGFR*, glioblastomas with deletions of exons 12–13 and 14–15 were also found, but it remains to be seen if these variants are the consequence of aberrant splicing. In about 10% of the glioblastomas in the

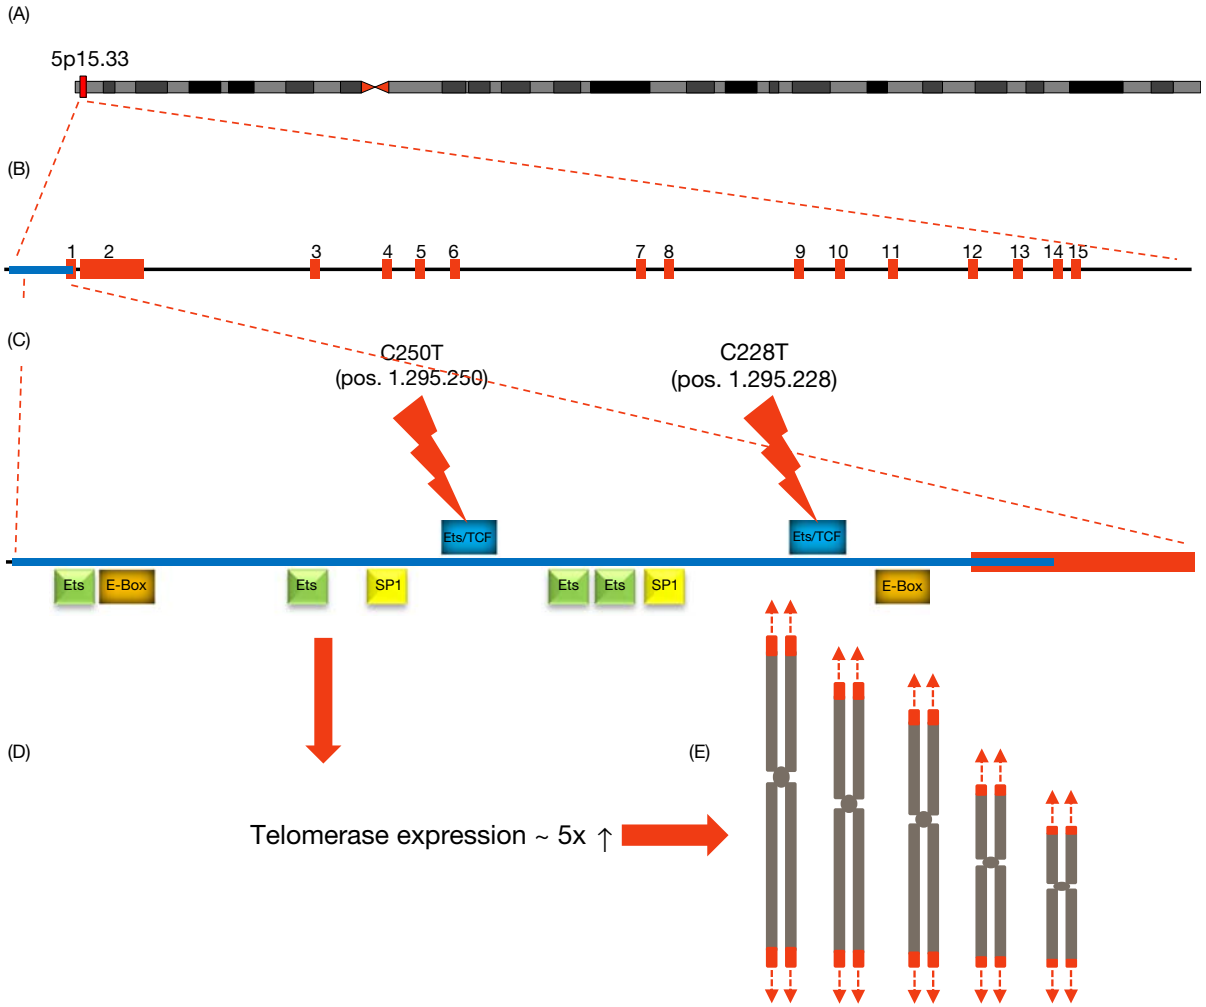

Fig. 3 Schematic illustration of *TERT* promoter mutation and its consequences. (A) The *TERT* gene is located on chromosome 5p15.33. (B) The *TERT* gene has 15 exons and a promoter (blue line), which partially extends into exon 1. (C) The *TERT* promoter has various transcription factor binding motifs (below the blue line); in IDH-wildtype glioblastomas, an additional Ets/TCF motif is frequently inserted by a C250T or a C228T mutation in the *TERT* promoter region. (D) this mutation results in increased translation of telomerase. (E) As a consequence, tumor cells are able to continue proliferating without critical telomere shortening forcing them into senescence or apoptosis.

TCGA series the mutation variant *EGFRvIV* (affecting exon 25–27) was found, and sporadically yet another mutation variant occurred as fusion between *EGFR* and adjacent genes. In somewhat over 10% of glioblastomas *EGFR* point mutations occur. In contrast to pulmonary cancer, *EGFR* point mutations in glioblastomas usually do not involve the kinase domain but the extracellular domain of the receptor tyrosine kinase. (**Fig. 4**) This difference may explain why studies with receptor tyrosine kinase inhibitors were negative in patients with glioblastoma. Neither *EGFR* amplification nor the combination with the *EGFRvIII* mutation variant has a clear prognostic significance in IDH-wildtype glioblastomas. However, demonstration of *EGFR* amplification, as well as of +7/−10 and/or *TERT* promoter mutation is a serious indication of high-grade malignancy in adults with IDH-wildtype diffuse astrocytic tumors to which based on histologic examination not (yet) a WHO grade IV can be assigned.

The *MGMT* gene encodes the O^6-methylguanine-DNA methyltransferase, a DNA repair enzyme which can transfer a methyl group from the O^6 position of a guanine nucleotide irreversibly to itself, thereby repairing the mutated DNA. The O^6-methylation or alkylation of guanine is a typical DNA mutation event induced by various mutagenic events. Application of alkylating drugs like temozolomide induces such O^6-guanine methylation as well, the therapeutic intention being to induce DNA mismatch, DNA-double-strand breakage and ultimately apoptosis in glioblastoma cells. MGMT expression is under control of a large CpG island in the gene promoter. In case of methylation of these CpG sites, MGMT expression is strongly reduced and cells have a limited capacity to repair drug-induced DNA damage. In approximately 40% of patients with IDH-wildtype glioblastomas the tumors demonstrate *MGMT* promoter methylation, thereby rendering this subgroup of patients relatively responsive to treatment with alkylating drugs. Because of this predictive value, recent guidelines of the European Association for Neuro-Oncology (EANO) recommend *MGMT* promoter methylation testing for certain groups of patients with high-grade gliomas.

Diffuse gliomas with a *H3F3A*, *HIST1H3B/C*, or *HIST2H3C* K27M mutation are typically found in midline structures in children (see separate paragraph below). Since the first description of these mutations it became obvious that such histone H3 mutations not affect only codon 27 but also codon 34. Glioblastomas with a H3 G34R or, less frequently, H3 G34V mutation are rare, occur mostly in the cerebral hemispheres, affect predominantly older children and young adults, and are associated with a somewhat better prognosis than patients with ordinary glioblastomas. H3F3A G34R/V-mutant tumors can also have the phenotype of a CNS embryonal

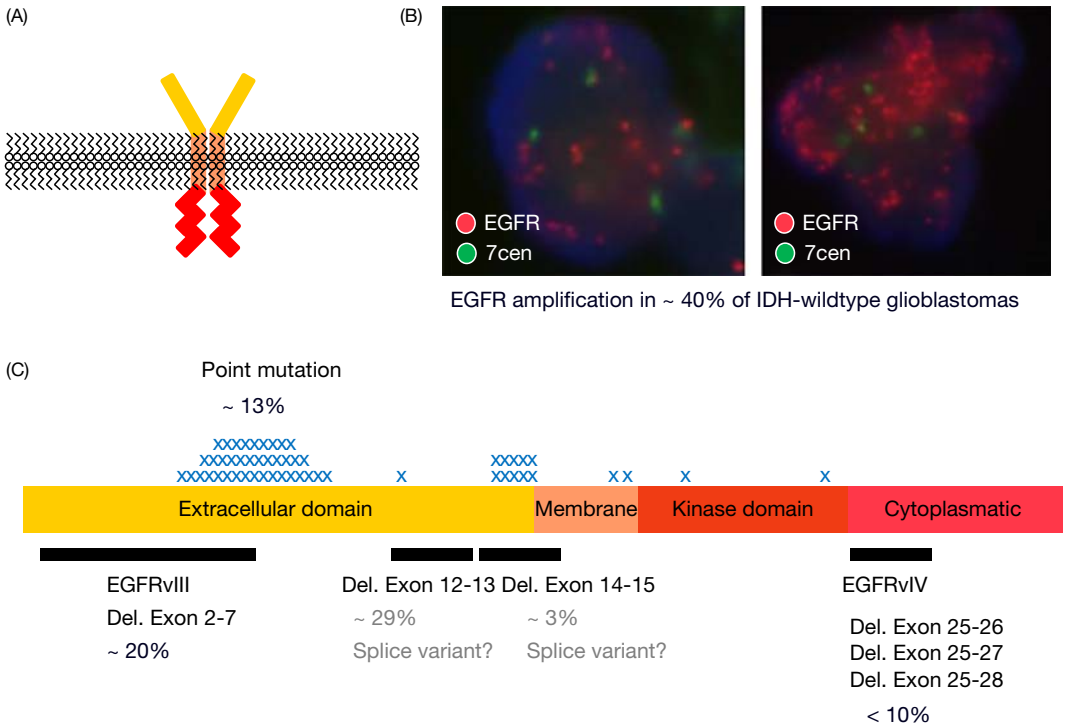

Fig. 4 Schematic illustration of involvement of the epidermal growth factor receptor (EGFR) in glioblastomas. (A) The EGFR protein normally has an extracellular domain (yellow), a domain in the membrane (orange), and an intracellular part (kinase domain and cytoplasmic end). (B) About 40% of all IDH-wildtype glioblastomas show high copy amplification of *EGFR*, here illustrated by FISH images of two different tumors; the centromere of chromosome 7 is marked by a green signal, and the fact that more than two green signals are visible indicates polyploidy of chromosome 7; the multitude of red dots represent the signal of the *EGFR* probe and reflect high copy amplification of this gene. (C) Schematic illustration of other mutation variants affecting the *EGFR* gene. Up to half of all glioblastomas with *EGFR* amplification additionally have a deletion of exon 2–7, leading to the *EGFRvIII* mutation variant which is constitutively active. The mutation variant *EGFRvIV* affects exon 25–27 and is found in about 10% of cases. The importance of the potential deletions of exons 12–13 and 14–15 is still unclear, these may in fact be mRNA splicing variants rather than genetic deletions. Approximately 13% of IDH-wildtype glioblastomas show point mutations in *EGFR*, mainly in the extracellular domain, and partly in combination with *EGFR* amplification.

tumor (formerly known as (supratentorial) CNS PNET), but no prognostic difference was found between high grade glioma versus embryonal histology. In contrast, the lack of amplification of oncogenes, and the presence of *MGMT* promoter methylation in such tumors was reported to be associated with better outcome. As these tumors seem to represent a discrete group, one can expect that they will be listed as a separate entity in a next edition of the WHO classification of CNS tumors.

Glioblastoma, IDH-Mutant

The establishment of IDH-mutant glioblastomas as a separate entity by the WHO classification was significantly influenced by the clinical concept of the existence of primary ("de novo") glioblastomas (diagnosed in patients without clinical, radiological and/or pathological evidence for a lower grade precursor lesion) and secondary glioblastomas (that apparently evolved from such a lower grade precursor lesion). After it was shown that the vast majority of primary glioblastomas are IDH-wildtype, while most secondary glioblastomas are IDH-mutant, and given the fact that "primary" glioblastomas with IDH mutation might represent cases in which the lower grade precursor lesion was missed, nowadays the terms primary and secondary glioblastoma are considered to be largely synonymous with IDH-wildtype and IDH-mutant glioblastoma, respectively.

In different studies the relative frequency of IDH-mutant glioblastomas varies between 6% and 13%. Patients with an IDH-mutant glioblastoma are on average significantly younger than patients with an IDH-wildtype glioblastoma, in a population-based study the mean age was 48 versus 61 years, respectively. In MRI imaging, patients IDH-mutant glioblastomas showed more rarely large central necrosis, less pronounced edema, more frequently cystic changes and more diffuse tumor infiltration than patients without this genetic alteration. IDH-mutant glioblastomas usually show the same genetic alterations as diffuse, lower grade (WHO grade II and III) astrocytomas, with especially *TP53* and *ATRX* mutations being present in a high percentage of cases. While *TP53* mutations also occur quite frequently in IDH-wildtype glioblastomas, *ATRX* mutations are typical for IDH-mutant astrocytomas/glioblastomas and functionally partially substitute *TERT* promoter mutations. IDH-mutant glioblastomas typically do not exhibit +7/−10 or EGFR amplification.

The gene *IDH1* (located on chromosome 2q33.3) encodes the cytoplasmatic (type 1) form of isocitrate dehydrogenase (IDH1), while the *IDH2* gene (located on 15q26.1) encodes IDH2 that is located in the mitochondria. Both proteins catalyze as homodimers isocitrate and NADP by an oxidative decarboxylation to α-ketoglutarate (α-KG) and NADPH. Only the much more complex IDH3, but not IDH1 and IDH2, has a functional role in the tricarboxylic acid cycle. IDH mutations only affect one of the two alleles (heterozygous deletion) and are generally "hotspot" mutations of *IDH1* codon 132 or of *IDH2* codon 172. *IDH1* mutations account for over 90% of the IDH mutations found in diffuse gliomas, with *IDH1 R132H* representing up to 90% of all *IDH1* mutations. The availability of a specific antibody against the IDH1 R132H mutant protein that can be applied on formalin-fixed, paraffin-embedded tissue thus enables reliable detection of the vast majority of IDH-mutant gliomas/glioblastomas by a simple immunohistochemical procedure in routinely processed glioma tissue (**Fig. 1**C).

Mutant IDH protein utilizes the physiological product α-KG as an educt and catalyzes it to 2-hydroxyglutarate (2-HG). As a result, the so-called "oncometabolite" 2-HG is present in excessive concentrations in affected tumor cells and induces a competitive inhibition of a large group of more than 60 different α-KG-dependent dioxygenases. From this point on, various dysfunctional pathways result of which the individual significance for neoplastic transformation is unclear (**Fig. 5**). The physiological function of TET2 comprises a large-scale demethylation of CpG sites in promoter regions of various genes, and impaired function due to IDH-mutant status results in a global hypermethylation of the genome, also described as the glioma CpG island methylator phenotype (g-CIMP). This situation may explain why the vast majority of IDH-mutant gliomas show hypermethylation of the *MGMT* promoter. The genomic hypermethylation also affects cohesin and CCCTC-binding factor (CTCF)-binding sites, thereby compromising binding of this methylation-sensitive insulator protein. This in turn leads to a disrupted chromosomal topology with enhanced PDGFRA activity. Furthermore, excessively increased 2-HG results in inhibition of KDM4A, whose functional failure leads to an increase in DEPTOR activity, which in turn causes mTOR pathway activation. As a further consequence of massively increased concentrations of 2-HG, competitive inhibition of the α-KG-dependent prolylhydroxylase was demonstrated, resulting in inhibition of the degradation of HIF1α.

Diffuse Midline Glioma, H3 K27M-Mutant

While in adult patients glioblastomas mostly are located in supratentorial parts of the CNS, in children glioblastomas occur relatively frequently infratentorially. A particular subset of such (mainly) pediatric tumors, the diffuse midline glioma, H3 K27M-mutant, was added to the list of diffuse gliomas in the WHO 2016 classification. Diffuse midline glioma, H3 K27M-mutant carries a mutation in either the *H3F3A*, *HIST1H3B/C*, or *HIST2H3C* gene and represents a WHO grade IV tumor. By definition, these tumors with a H3 K27M mutation should be (a) gliomas with (b) diffuse growth and (c) located in the midline (brain stem, thalamus, cerebellum, and/or spinal cord). Tumors that were previously diagnosed as diffuse intrinsic pontine glioma (DIPG) are a frequent representative of this group, with about 80% of the previously diagnosed DIPGs indeed carrying the H3 K27M mutation. Patients with a diffuse midline glioma, H3 K27M-mutant in the pons are on average younger than those with such a tumor in the thalamus (around 7 years and 11 years, respectively). In both children and adults, diffuse midline gliomas, H3 K27M-mutant that show WHO grade II or III phenotype generally still carry a grim (WHO grade IV-like) prognosis. Importantly, other glial CNS tumors (especially nondiffuse

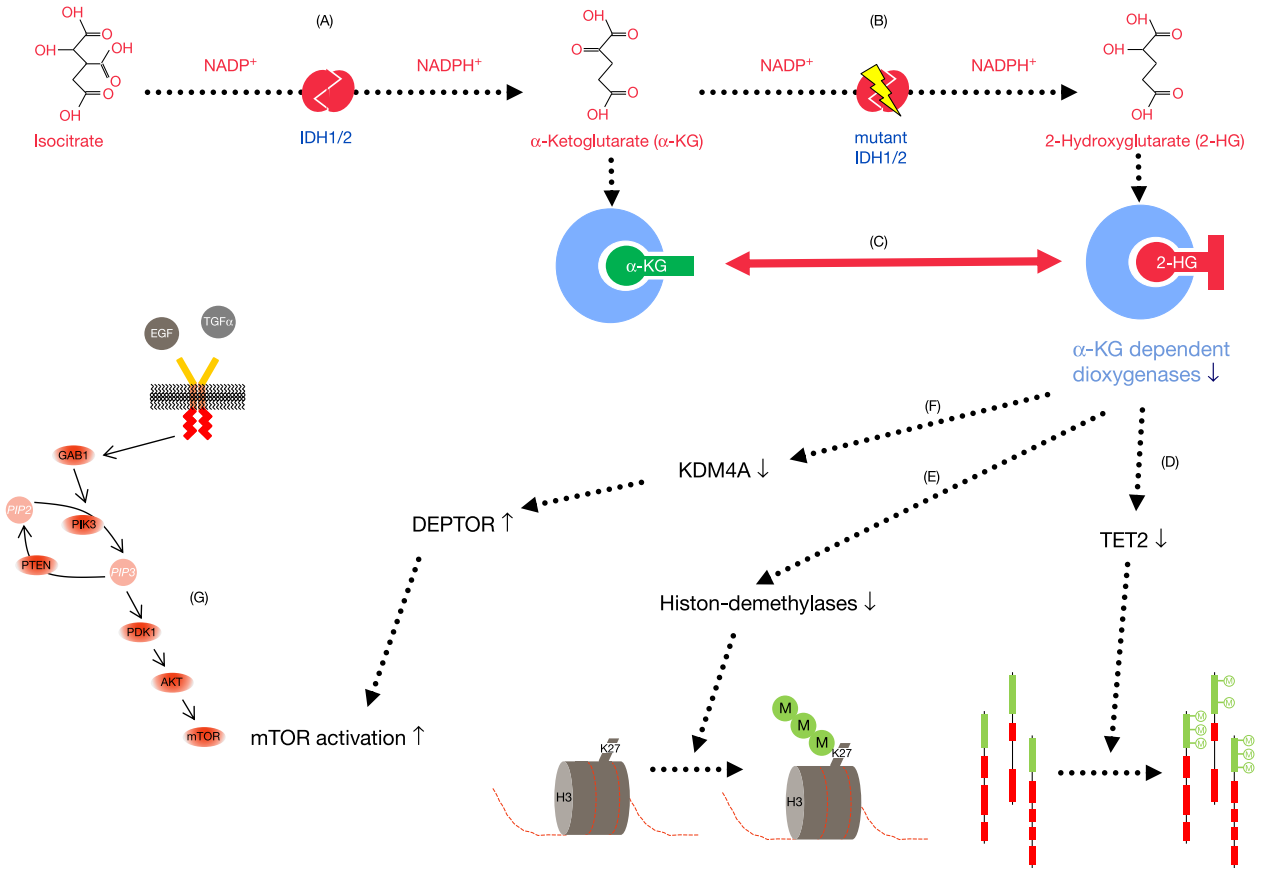

Fig. 5 Schematic drawing of mechanisms involved in the isocitrate dehydrogenase (IDH) pathway. (A) Normal IDH protein catalyzes isocitrate to α-ketoglutarate (α-KG); (B) mutant IDH protein utilizes the physiological product α-KG as educt and catalyzes it to 2-hydroxyglutarate (2-HG); (C) 2-HG occurs in excessive concentrations in affected tumor cells and is competitively inhibiting a large number of different α-KG-dependent dioxygenases (D–F); (D) by blocking the activity of the DNA demethylase TET2 a global CpG island methylator phenotype (g-CIMP) results; (E) by inhibiting the activity of histone demethylases for example H3 histone protein becomes trimethylated; (F) by inhibition of KDM4A, the activity of DEPTOR increases, which in turn causes mTOR pathway activation; (G) frequently occurring alternative route for mTOR pathway activation in cancer.

gliomas such as ependymomas and pilocytic astrocytomas, and nonmidline gliomas) may occasionally carry the H3 K27M mutation as well, but the prognostic impact of this mutation in such a nondiffuse and/or nonmidline glioma is unclear.

Up to now four different histone-encoding genes carrying H3 K27M mutations have been identified. By far the most frequently mutated gene is *H3F3A* (mutant in about 80% of H3 K27M-mutant diffuse midline gliomas and encoding histone H3.3), followed by *HIST1H3B* (mutant in about 20% of these cases and encoding histone H3.1). In less than 1% of the H3 K27M-mutant diffuse midline gliomas a mutation is found in *HIST1H3C* (encoding histone H3.1) or *HIST2H3C* (encoding histone H3.2). The functional consequences of H3 K27M mutations are not yet completely understood. A H3 K27M mutation results in an altered histone protein that cannot become trimethylated at position 27 anymore. When the DNA-trimethylating polycomb repression complex 2 (PCR2) encounters such a mutant oncohistone, it stops functioning and detaches itself from the DNA. As a result, there is a global reduction in histone trimethylation (loss of H3K27me3) in tumor cells with a H3 K27M mutation. A global change of the epigenome then results, with as a consequence abnormal cell cycle control, inhibition of autophagy and presumably also an increased resistance of the tumor cells to radiotherapy (Fig. 6). Like for the IDH R132H mutant protein, a highly specific antibody is available for H3 K27M mutant protein that allows for detection of the H3 K27M-mutant status of a (glial) tumor by a simple immunohistochemical test on formalin-fixed, paraffin-embedded tumor tissue. In this staining a H3 K27M-mutant glioma shows positive staining of tumor cell nuclei (with the negative nuclei of nonneoplastic (e.g., vascular) cells representing a negative internal control in the same slide).

Interestingly, *H3F3A* K27M mutations were reported to occur in diffuse midline gliomas in all anatomical structures of the midline, while *HIST1H3B* K27M mutations occur mainly in those originating in the pons. First data indicate that patients with *H3F3A* K27M mutation in their diffuse midline glioma usually have a worse prognosis than those with an *HIST1H3B* mutation. Furthermore, *HIST1H3B* mutations are very often combined with *ACVR1* mutations which have been reported as a slightly better prognostic factor as well. *PDGFRA* and *PIK3CA* mutations are interpreted as progression-associated genetic changes in diffuse midline gliomas with a *H3F3A* K27M mutation. *PIK3CA* mutations were reported as progression-associated changes in *HIST1H3B*-mutant tumors as well.

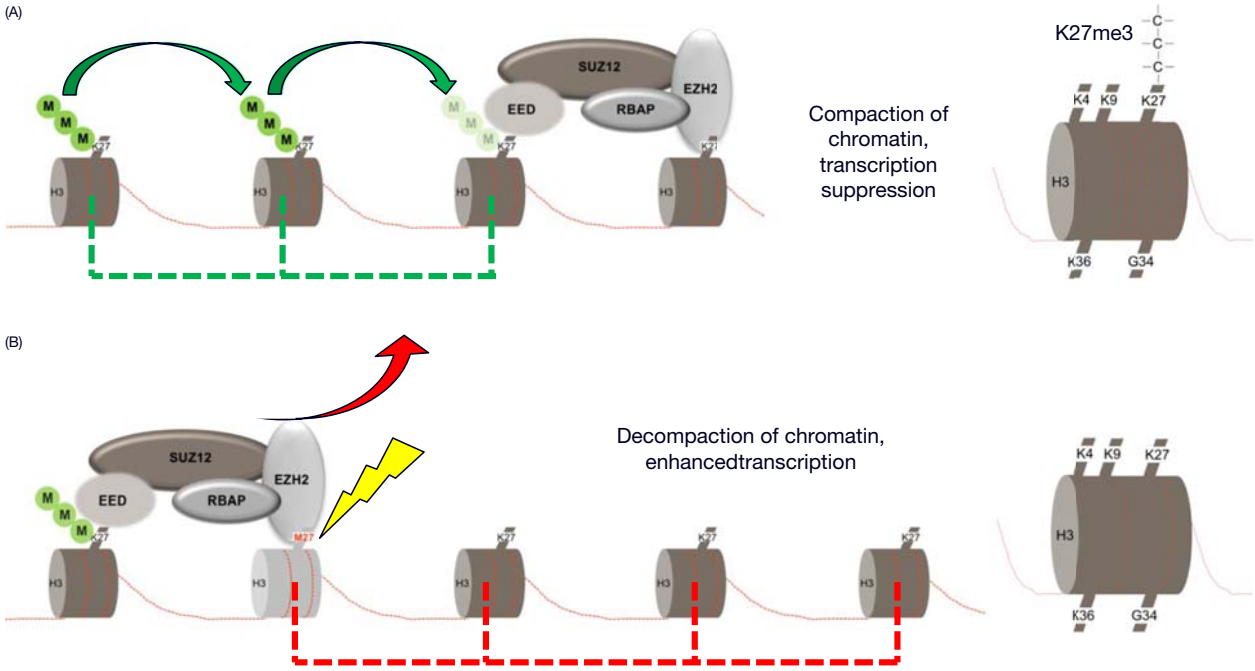

Fig. 6 H3 K27M mutation results in decompaction of DNA and promotion of transcription. (A) The polycomb repression complex 2 (PRC2, with EZH2, SUZ12, EED, RBAP as components) moves gradually along histones associated with DNA and establishes tri-methylation at the H3 K27 site of the histone tail (H3 K27me3), resulting in DNA compaction and transcription suppression. Presence of a H3 K27M mutation in the *H3F3A* or *HIST1H3A/B* gene obstructs this effect of PRC2 not only at the site of the mutant histone, but also at subsequent histones as further movement of the PRC2 complex is impaired. The focal presence of H3 K27M may thus cause more widespread blockage of H3 K27 trimethylation and, consequently, more widespread decompaction of DNA and promotion of transcription.

Glioblastoma Classification by Next Generation Molecular Technologies

Especially in the last two decades, technologies have become increasingly developed that not only enabled the investigation of individual molecular markers, but also the analysis of complex correlations on a molecular basis. In the field of neurooncology, this was achieved for the first time with the comparative genomic hybridization (CGH) technology, which was significantly improved by the array-CGH (aCGH) method. These assays allowed the detection of chromosomal gains or losses in gliomas. Another step forward was expression array analysis, for which RNA is extracted from tumor tissue and converted into cDNA. Subsequently, the expression pattern of a large number of genes can be determined on this basis.

Furthermore, different methods for next-generation sequencing (NGS) were increasingly used in neuro-oncology. While initially only small panels of genes were investigated, further development of the technique allowed for wider availability and higher efficiency of NGS and now analysis of entire (glioma) exomes and genomes are performed. The NGS technology also has been extended to the transcriptome of gliomas (whole transcriptome shotgun sequencing; RNAseq). Using RNAseq it is possible to determine both the expression and the mutations of the (glioma) genome. Another advantage of RNAseq is that fusion genes can be detected more effectively than with any other technology. Probably the most productive technology for classifying gliomas at present is the 450 K, or more recently, 850 K BeadChip methylation analysis. This platform generates detailed information on the epigenetic profile of a tumor as well as on chromosomal gains and losses. On the basis of these molecular high-throughput techniques, new subgroups of glioblastomas were identified. The following paragraphs present some examples of such newly recognized glioblastoma subgroups (Fig. 7).

Expression Profiling

Initial expression profiling studies revealed that glioblastomas can be distinguished from pilocytic astrocytomas, anaplastic astrocytomas or oligodendrogliomas, and that "primary" glioblastomas can be discriminated from "secondary" glioblastomas. Ordering the results of expression profiling using unsupervised clustering algorithms indicated patterns that correlated with diagnoses and malignancy grades assigned to the tumors based on histopathologic analysis. Meanwhile, several studies reported that the prognosis of patients with (astrocytic) gliomas could be more accurately predicted based on expression profiling than on morphologic evaluation.

Various attempts have been made to use expression profiling for the recognition of clinically relevant subgroups of histopathologically diagnosed glioblastomas. At first, three groups were described: proneural, proliferative and mesenchymal. In

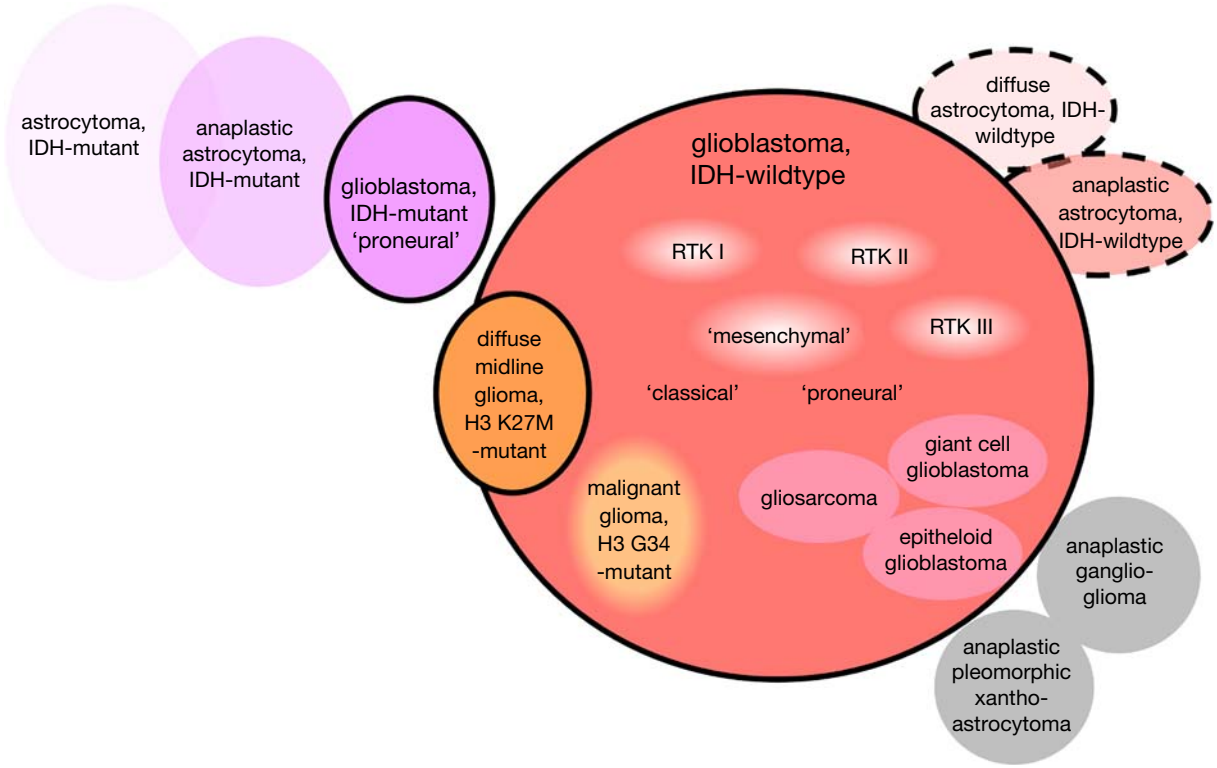

Fig. 7 Scheme of histologic and molecular categories of glioblastoma. The current WHO classification of CNS tumors lists three, partly molecularly defined groups of grade IV diffuse gliomas/glioblastomas (encircled by a solid line): (A) IDH-wildtype, by far the most frequent group in adults; (B) IDH-mutant, generally occurring in younger adults than IDH-wildtype glioblastomas and often the result of malignant progression of a previously diagnosed lower grade IDH-mutant astrocytoma; (C) H3 K27M-mutant diffuse midline gliomas (that are IDH-wildtype as well), typically but not only occurring in children. Of note, many tumors that are histologically diagnosed as lower grade (WHO grade II and III) IDH-wildtype diffuse astrocytomas (encircled by the dashed line in this figure) have molecular characteristics of and in fact clinically behave like IDH-wildtype glioblastomas (WHO grade IV). Meanwhile, the IDH-wildtype glioblastoma group is still a very heterogeneous one with different subgroups that can be recognized based on histology (e.g., gliosarcoma, giant cell glioblastoma, epitheloid glioblastoma), expression profiling (classical, mesenchymal, or proneural subtype), or methylation profiling (e.g., receptor tyrosine kinase type I (RTK I), RTK II, RTK III, mesenchymal). In the IDH-wildtype glioblastoma group, the H3 G34-mutant tumors already stand out as a distinct subgroup that may well be designated as a separate entity in the next WHO classification. Discrimination of high-grade "nondiffuse" gliomas like anaplastic pleomorphic xanthoastrocytoma or anaplastic ganglioglioma from especially the epitheloid variant of glioblastoma may be difficult not only because of histopathologic similarities but also because these tumors share the frequent occurrence of *BRAF* V600E mutation.

the proneural group, patients were generally younger and the tumors lacked *EGFR* amplification and *PTEN* mutation. In the proliferative and mesenchymal groups, on the other hand, the tumors typically showed the genetic profile of glioblastoma in (older) adult patients, including gain of chromosome 7 and loss of chromosome 10. Later on, based on in depth analysis of the large and complex data sets of the TCGA project, modification of expression profiling-based subgrouping of glioblastomas was suggested with recognition of four transcription types: proneural, neural, classic, and mesenchymal. These four subtypes were associated with different frequencies of mutations in especially *TP53*, *EGFR*, and *NF1*. More than 90% of IDH-mutant glioblastomas belonged to the proneural expression signature, and about 30% of glioblastomas with a proneural expression signature were IDH-mutant. Diffuse lower grade astrocytomas and oligodendrogliomas also typically had a proneural signature.

Later on, the neural transcription profile could at least partly be explained by the presence of relatively large amounts of non-neoplastic CNS tissue in the glioblastoma samples in this group. In other words, identification of this neural group may partly have been based on "selection-bias" towards the use of samples with relatively low tumor cell percentage, for example, from the periphery of a glioblastoma, rather than have a basis in a real profile of the tumor itself. Furthermore, using single cell analysis it was demonstrated that different transcription types can occur within one and the same glioblastoma. Also in a human glioblastoma xenograft model cells could be transformed from a proneural to a mesenchymal expression type by defined conditions. Such observations raised doubts about the stability of classification of glioblastomas by RNA-based transcriptional profiling. Yet another problem with expression profiling as a diagnostic tool in clinical practice is that in routinely processed, formalin-fixed, paraffin-embedded tumor tissue the integrity of RNA is significantly impaired. Ideally, for expression profiling tumor tissue should thus be fresh frozen.

Methylation Profiling

Analyzing the epigenome, and in particular the methylome of tumor cells has proved to be a robust and reproducible technology allowing for the analysis of even small, formalin-fixed, paraffin-embedded tissue samples of morphologically poor quality. The analysis of the methylome can be used to evaluate which epigenetic changes are evolving due to the induction and progression of tumors. On the other hand, part of the epigenetic imprinting remains stable from the original cell to the tumor cell, so that the analysis of the methylome provides information on the cell of origin of the tumor and can be used to classify tumors. Various technologies for global methylation analysis are available. The commercial Infinium BeadChip 450 K assay, later on replaced by the Infinium MethylationEPIC BeadChip 850 K assay, has found the broadest distribution and has been successfully used for subclassification of glioblastomas as well. With 850 K analysis, over 850,000 CpG sites are examined, which corresponds to about 3.5% genomic CpG coverage. An alternative approach is whole genome bisulfite sequencing (WBGS), allowing investigation of more than 26 million CpG sites, corresponding to a CpG coverage of more than 90%. The results of tumor DNA analysis using the 450 K and the WBGS method showed comparable results, indicating that different methods can be applied for robust characterization of the tumor methylome.

One of the first observations obtained with methylation profiling analysis of gliomas was the existence of a glioma CpG island methylator phenotype (g-CIMP) cluster. This "cluster #1" with g-CIMP signature encompassed most of the lower-grade diffuse infiltrating gliomas as well as a fraction of glioblastomas and was strongly associated with presence of an IDH mutation. For example, in the TCGA dataset 30 of the total number of analyzed glioblastomas (6%) carried an IDH mutation, largely overlapping with the 42 tumors that exhibited a g-CIMP phenotype (7.9%). In addition, two other methylation clusters of glioblastoma were found (#2 and #3) in which IDH-wildtype glioblastomas were grouped. Comparison of these three methylation clusters with the four established expression profiles of glioblastomas revealed that most glioblastomas with a proneural expression signature were found in methylation cluster #1 (g-CIMP), while glioblastomas with a neural, mesenchymal or classical expression signature were assigned to the other two methylation clusters without a particularly clear distribution pattern. Furthermore, tumors with a 1p/19q-codeletion ("g-CIMP-A") had a clearly different methylation profile compared to *TP53*-mutant gliomas ("g-CIMP-B").

A systematic classification of CNS tumors including glioblastomas on the basis of their methylation profile became possible due to the availability of the 450 K/850 K assay in combination with newly developed software, which is capable of unsupervised analysis of the complex results. Several closely collaborating research groups from Heidelberg have now established a comprehensive CNS tumor classifier based on methylation profiling and thereby became leaders in this field. In a first publication six glioblastoma subgroups were reported: (1) the IDH subtype, characterized by IDH mutations with a g-CIMP phenotype; (2) the H3 K27 subtype, consisting of tumors with, for example, an *H3F3A K27M* mutation; (3) the H3 G34 subtype of tumors with an *H3F3A G34R/V* mutation; (4) the RTK I or *PDGFRA* subtype; (5) the mesenchymal subtype; and (6) the classic, RTK II subtype. This RTK II subtype overlapped with methylation cluster #3 as described in the previous paragraph, subtypes 2–5 with methylation cluster #2, and subtype 1 with methylation cluster #1. The CNS tumor classifier was further refined by the analysis of a large number of additional tumors, and the current classifier (02/18) with version number 11b4 (https://www.molecularneuropathology.org/mnp/classifier/2) now lists the following nine glioblastoma methylation classes (ordered from highest to lowest median age of the patients in these classes):

- *Glioblastoma, IDH-wildtype, subclass RTK I PDGFRA*: these tumors are typically found in the cerebral hemisphere; the patients have a median age of 64 years; genetically, gain of chromosome 7 with or without *EGFR* amplification, loss of chromosome 10, and homozygous deletions of *CDKN2A* are typically present; also, amplification of *PDGFRA* is more common in this methylation class and the expression profile corresponds to the proneural subtype.
- *Glioblastoma, IDH-wildtype, subclass RTK II classic*: in this methylation class the tumors have a supratentorial location; the patients have a median age of 61 years; some gliosarcomas are grouped in this class; genetically, like in the previous methylation class, these tumors also show gain of chromosome 7 with or without *EGFR* amplification, loss of chromosome 10, and homozygous deletions of CDKN2A; additionally, around 40% of these tumors also have gains of chromosome 19 and 20.
- *Glioblastoma, IDH-wildtype, subclass mesenchymal*: these tumors typically grow supratentorially and the patients have a median age of 59 years; histologically this group includes gliosarcomas; genetically, gain of chromosome 7 with or without amplification of *EGFR*, loss of chromosome 10, and homozygous deletions of CDKN2A are observed; *NF1* mutations are enriched in this methylation class, which overlaps with the mesenchymal expression profile.
- *IDH glioma, subclass high-grade astrocytoma*: this class encompasses supratentorially located astrocytomas with an IDH mutation, which are often derived from a low-grade lesion and are associated with the g-CIMP phenotype; the median age of the patients in this class is 38 years; this methylation class corresponds to glioblastoma, IDH-mutant (and partially anaplastic astrocytoma, IDH-mutant) in the WHO classification.
- *Glioblastoma, IDH-wildtype, H3.3 G34-mutant*: this typically concerns supratentorial tumors with the morphological appearance of a glioblastoma or an embryonal tumor; the median age of the patient is 20 years; the tumors are *H3F3A* G34R/V-mutant.
- *Glioblastoma, IDH-wildtype, subclass midline*: this class represents glioblastomas growing in the midline regions of the brain and showing an epigenetic overlap with the methylation class diffuse midline glioma, H3 K27M-mutant but the tumors do not have the H3 K27M mutation; the median age of the patients in this group is 13 years.
- *Diffuse midline glioma, H3 K27M-mutant*: this class overlaps with diffuse midline gliomas, H3 K27M mutantas listed in the WHO 2016 classification; the median age of patients in this class is 12 years.

- *Glioblastoma, IDH-wildtype, subclass MYCN*: these tumors are mostly located supratentorially or in the posterior fossa; the median age of the patients is 11 years, and amplification of *MYCN* can be detected in 20%–30% of these tumors;
- *Glioblastoma, IDH-wildtype, subclass RTK III*: these tumors are found mainly in the cerebral hemisphere; the median age of the patients in this class is 9 years, and in this group *EGFR* amplification and deletions of chromosome 10 are frequent.

Further analysis of diffuse infiltrating gliomas in children with the morphological appearance of a glioblastoma allowed the identification of two further subtypes: tumors with the epigenetic profile pleomorphic xanthoastrocytoma (PXA)-like and low-grade glioma (LGG)-like. The tumors in this latter class are characterized by the absence of an IDH mutation. Patients from both subgroups showed a significantly better prognosis. A further analysis of supratentorial pediatric glioblastomas without H3 and without IDH mutation resulted in the identification of three methylation classes: (1) pediatric glioblastoma MYCN; (2) pediatric glioblastoma RTK1; and (3) pediatric glioblastoma RTK2. Patients with tumors in methylation class RTK1 and RTK2 showed a relatively good prognosis. The epigenetic pattern of the pediatric methylation classes RTK1 and RTK2 was different from the profile of the adult methylation classes RTK I and RTK II. Pediatric patients in methylation class MYCN, on the other hand, showed an exceptionally poor prognosis. *MYCN* amplification was relatively frequently found in this methylation class, but the majority of tumors did not exhibit such genetic alteration.

In addition to the actual classification as part of a methylation analysis, information on chromosomal gains and losses (e.g., complete 1p/19q codeletion versus partial deletion of (one of) these chromosome arms) and on the methylation profile of (the promoters of) individual genes such as *MGMT* is also provided. Methylation analysis also facilitates that different neuropathologists generate identical diagnoses, and it was reported that compared to traditional histopathologic evaluation the classification by methylation analysis enabled a better estimation of the prognosis associated with the investigated tumors. As the "Heidelberg CNS tumor classifier" is a self-learning system, identification of new, rare subgroups can be expected by adding methylation data of additional tumors. In other words: The more CNS tumors are examined by methylation profiling in this system, the better the classification of these tumors will be. Disadvantages of this approach are, however, that the necessary laboratory infrastructure is costly and that processing individual samples is relatively expensive as well. Furthermore, using the 450 or 850 K technology as described above creates a dependence on a single manufacturer, as it has not yet been conclusively proven whether transfer to another global methylation assay is possible without problems with preserving the established classifier.

Integrated TCGA Approach

As the Cancer Genome Atlas research network (TCGA) focused already in an early phase on glioblastomas, most of the data sets on these tumors are now completely available. An essential concept of the TCGA network was the integrated analysis of glioblastomas using various high-throughput assays. For example, many hundreds of clinically annotated glioblastomas were examined with regard to their protein expression, mRNA expression profile, methylation profile, mutation status and chromosomal alterations and the resulting data were combined. Fortunately, the results confirmed data from many previous studies with regard to the molecular characteristics of glioblastomas. Potential downsides of the TCGA approach are the retrospective approach, the heterogeneous therapy of the patients of which material was included, the potential bias resulting from the inclusion criterion of sufficient tissue for performing multiple high throughput analyses, the focus on adult patients and the bias towards patients that were treated predominantly in academic centers.

Fusion of the TCGA datasets from different high-throughput assays resulted in only a few relevant and new association patterns. It was not possible to identify individual molecular markers that could clearly be assigned to one of the different subgroups. At best, singular molecular markers were more common in one subgroup than in the other. For example, *NF1* mutations were frequently observed in glioblastomas of the mesenchymal expression profile. *PDGFRA* amplifications were found mainly in glioblastomas of the proneural signature, which did not correspond to the g-CIMP methylation profile. *ATRX* mutations and *MYC* amplifications were detected mainly in glioblastomas of the g-CIMP methylation profile, *CDK4* and *SOX2* amplifications in tumors of the proneural subtype, and amplifications of chromosomes 19 and 20 in the classical subtype.

Also, within the TCGA project, an attempt was made to characterize epigenetic glioblastoma subtypes at the methylation level. Six methylation groups of glioblastomas were identified (M1–6, with M5 being the g-CIMP subtype). In comparison to the Heidelberg glioblastoma methylation classes discussed above, the Heidelberg IDH-mutant subtype was found in group M5, the mesenchymal subtype especially in groups M1 and M2, the RTK II subtype in groups M3 and M4, and the RTK I subtype in group M6. Since only adult glioblastoma patients were included in the TCGA cohort, the Heidelberg subgroups K27 and G34, which mainly affect children and young adults, could not be identified.

When considering the frequencies of molecular aberrations in the cohort of glioblastoma patients investigated by the TCGA project, the *TERT* promoter mutation is the most frequent aberration (present in about 80% of the glioblastomas analyzed). A homozygous deletion of *CDKN2A* and an *EGFR* alteration were found in about 60% of the tumors, *PTEN* was altered in about 40%, and *TP53* in 35% of cases. Furthermore, amplifications in *CDK4* and mutations in *NF1* were found in about 14%, *PIK3CA* and *PIK3R1* mutations as well as *PDGFRA* amplifications in slightly more than 10% of the tumors. A surprisingly broad spectrum of *EGFR* alterations was detected (amplification, deletion, point mutation, fusion). Furthermore, it was noted that frequently several genes for tyrosine kinase receptors (*EGFR*, *PDGFRA*, *MET*, *FGFR*) were altered in a single tumor. While most of these observations confirmed the knowledge obtained in previous studies on the genetic changes in glioblastomas, the relatively high frequency of *NF1*

mutations came as a sort of surprise. However, since *NF1* is a very large gene, complete analysis of this gene using classic Sanger sequencing is complex, explaining that until the TCGA data became available limited reliable data on the involvement of *NF1* in glioblastomas were published.

When mapping the broad spectrum of mutations identified in the TCGA glioblastoma cohort into different tumor-relevant signaling pathways, it appears that these pathways are all frequently affected. Alterations in the PIK3CA/AKT and the MAPK signaling pathway were found in 90% of the investigated glioblastomas. In 66% of the tumors, combined alterations at the upper end of the signaling pathways were found by alteration of the receptor tyrosine kinase, and in almost 70% of the tumors either a *PTEN* or a *PIK3CA/PIK3R1* mutation was detected. Senescence/apoptosis regulation was affected in 86% of glioblastomas. The homozygous deletion of *CDKN2A/B* was predominant, followed by *TP53* mutations and deletions as well as amplification of *MDM2* and *MDM4*. In 79% of the investigated glioblastomas, the genes involved in cell cycle control were also impaired. Again, *CDKN2A/B* proved to be the leader in this respect, while other relevant genes of this signaling pathway were altered at significantly lower frequencies (**Fig. 8**).

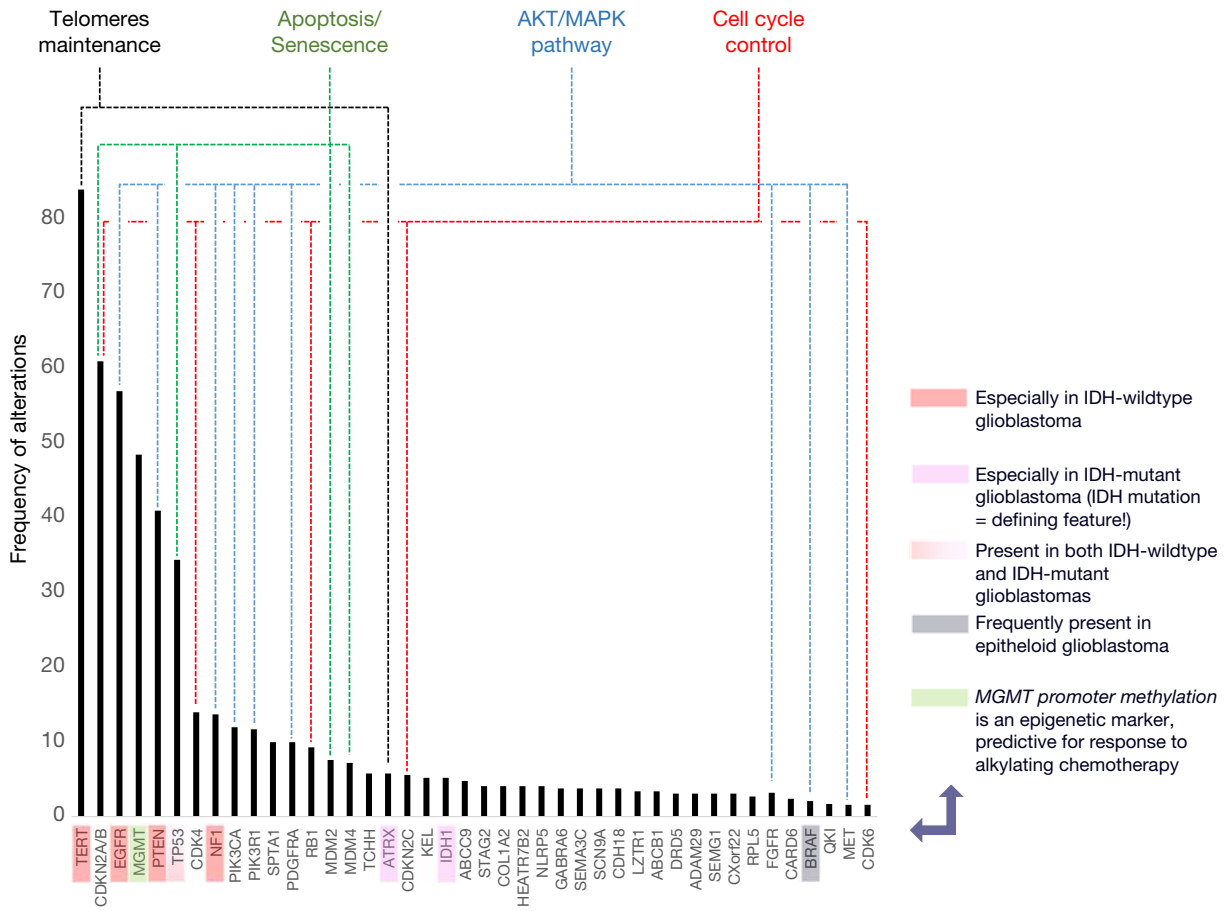

Fig. 8 Genes most frequently showing aberrations (mutation, loss, amplification, fusion) in glioblastomas according to The Cancer Genome Atlas consortium (TCGA; see https://cancergenome.nih.gov). Because the TCGA study focused on glioblastomas in adult patients, the H3 K27- and H3 G34-mutant tumors are not represented in this graph. Examples of genes (almost) exclusively affected in the IDH-wildtype versus IDH-mutant category of glioblastoma in adults are indicated by a light red versus light pink square (with presence versus absence of an IDH mutation in fact being the criterion based on which these two groups are discriminated). *TP53* is frequently involved in both molecular groups of glioblastomas (indicated by square showing both light red and light pink color). *BRAF V600E* mutation (highlighted by a gray square) is frequent in epitheloid glioblastoma as well as in histologic look-alikes such as anaplastic pleomorphic xanthoastrocytoma and anaplastic ganglioglioma (present in about 50% of these neoplasms). Many of the genes listed in this graph can be assigned to the cellular systems of telomere maintenance (black dashed lines), apoptosis/senescence (green dashed lines), the AKT/MAPK pathways (blue dashed lines) and the cell cycle control pathway (red dashed lines). *CDKN2A/B* belongs functionally to both the apoptosis/senescence and cell cycle control pathway. *MGMT* is also also included in this figure (highlighted in light green); about 50% of glioblastomas in the TCGA cohort showed *MGMT* promoter (hyper)methylation which serves as a marker indicating better response to alkylating chemotherapy; as a result of their glioma CpG-island methylator phenotype (g-CIMP) status, IDH-mutant glioblastomas generally have a methylated MGMT promoter, while in IDH-wildtype glioblastomas this is found in about 40% of the cases.

Prospective Vision

The introduction of molecular markers in the WHO 2016 definition of CNS tumors is a paradigm shift that allows for a more robust recognition of clinically relevant subgroups of glioblastoma. This change necessitates further study of what exactly the clinical behavior of these subgroups is and how additional molecular markers can be optimally used for the diagnosis of these newly defined categories. It is already evident that apart from assessment of IDH and H3 K27M mutation status, which are part of the definition of glioblastoma subgroups, analysis of other molecular markers such as mutation of *ATRX* and/or *TP53* (especially present in adult IDH-mutant glioblastomas in adults) or *TERT* promoter mutation (present in a large percentage of adult IDH-wildtype glioblastomas) may be helpful as well. For instance, in a situation where molecular tools for further characterization of glioblastomas are lacking, many cases can still be put in a particular molecular category based on immunohistochemical analysis of (surrogate) markers. Cytoplasmic staining of glioblastoma cells for IDH1 R132H mutant protein is, if the procedure was adequately performed, proof of an IDH1-mutant tumor. Obviously, lack of IDH1 R132H staining does not completely rule out an IDH-mutant tumor as other IDH1 and IDH2 mutant proteins (i.e., about 10% of all IDH-mutant gliomas) are not recognized by this antibody. Similarly, in the right context H3 K27M-mutant protein staining in tumor cell nuclei (with negative nuclei of non-neoplastic cells as an internal control) allows for unequivocal identification of a diffuse midline glioma, H3 K27M-mutant. As *ATRX*-mutant and *TP53*-mutant diffuse gliomas generally show lack of ATRX staining of tumor cell nuclei versus strong and extensive p53 staining of the nuclei these immunohistochemical markers may help to put a glioblastoma in a particular, molecular subgroup as well. It can be expected that the development of novel immunohistochemical (surrogate) markers will further facilitate making a "molecular diagnosis" without performing genetic testing.

Meanwhile, in many centers high-throughput technologies for sophisticated molecular classification become increasingly available in a routine diagnostic setting. Improved methods for extraction of RNA in sufficient quality and quantity from formalin-fixed, paraffin-embedded tissue may help to create a niche for expression profiling as a routine tool for the neuropathological diagnosis of glioblastomas. Application of such tools will provide more information on the presence and clinical importance of fusion genes (i.e., chromosomal alterations that are easily "lost" in DNA NGS). With *TERT* promoter mutations as a first example, another aspect that needs further elucidation is the importance of mutations in noncoding DNA segments. For some tumors there is already data on mutated super enhancers which may be located on chromosomes other than the relevant gene. Furthermore, it can be assumed that the classification of CNS tumors including glioblastomas will become increasingly better the more such tumors are examined at methylation level. As the "Heidelberg CNS tumor classifier" is a self-learning system, identification of new, very rare subgroups can be expected by adding further methylation data of additional tumors. Time will tell how exactly this classifier will eventually be used in the neurooncology community as a support tool for (or even alternative for) a histomolecular CNS tumor classification.

Much more information on the (epi)genetic, molecular, and protein characteristics of glioblastomas will certainly be acquired in the years to come and will help to acquire a more complete understanding of these tumors. For instance, it is now possible to interrogate individual tumor cells for their DNA, RNA and methylome characteristics, and the results so far underscore a high level of intratumoral heterogeneity. Another aspect that requires a better understanding is the relationship between tumor cells and their microenvironment (or of the host more in general), not in the least because of the so far disappointing results of antiangiogenic and immune-therapy approaches in patients with glioblastoma. Elucidation of how tumor cells change under pressure of (chemo-, radio-, immuno-)therapy may help to improve the efficacy of treatment of recurrent glioblastomas.

One can expect that sooner or later a plateau phase will be reached in our understanding of glioblastoma pathobiology. Meanwhile, it is increasingly possible to make a precise, sometimes even molecular diagnosis based on minimally invasive diagnostic approaches such as innovative imaging and liquid biopsies. Unfortunately, against the background of all the progress that has been made in elucidating the pathology and genetics of glioblastomas, the sobering reality so far is that the prognosis for glioblastoma patients has not substantially improved. It is thus time that the increased knowledge described in this chapter can be translated in therapeutic strategies that do improve the outcome for patients suffering from these tumors.

Glossary

Anabolism The biochemical processes in living systems to synthesize complex molecules from simpler molecules. An anabolic process usually requires energy input in the form of ATP or GTP.

Anaplerosis The biochemical processes that provides or replenish intermediate metabolites into a metabolic pathway. A common example is TCA cycle. During active biosynthesis, intermediate metabolites of the TCA cycle may be utilized and consumed for biosynthesis. Various mechanisms exist to replenish the metabolites of the TCA cycle.

Catabolism The biochemical processes in living system that break down of complex molecules to form simpler molecules. Catabolic reaction usually releases energy, which may be used to generate ATP and heat.

Chirality of amino acids Most amino acids assume either L- or D- chirality. Except for glycine which is achiral, all other proteinogenic amino acids are L-α-amino acids. To simply the discussion, we will omit the L-α prefix in the text unless other configuration is involved.

Cystine A dimer made of two cysteine molecules which form a disulfide bond between the sufhydro groups. This amino acid is usually imported into the cell by the cystine/glutamate antiporter (known as system Xc- or xCT) encoded by the *SLC7A11* gene in humans. After being uptaken into cells, a cystine molecule is converted into two cysteine molecules by reductive reactions.

Endoplasmic reticulum stress response An evolutionarily conserved cell response to the disturbances of the normal functions of the endoplasmic reticulum. The most common causes and consequences are accumulation of unfolded proteins in the ER lumen, also known as the unfolded protein response, and a disruption of calcium homeostasis.

Essential amino acids The amino acids that are required to support the metabolism of the living system, but the living system cannot synthesize them. Accordingly, essential amino acids have to be obtained by diet.

Homeostasis The ability of the living system to maintain a condition of equilibrium or stability within its internal environment when dealing with external changes.

mTOR Mechanistic target of rapamycin, also known as mammalian target of rapamycin, is the catalytic subunit of two protein kinase complexes (mTORC1 and mTORC2) that serve as the central sensors and integrators of multiple stimuli inputs. The best known stimuli are extracellular nutrient status, intracellular energy status and availability of growth factors. Based on the integration of the stimuli, mTORCs may regulate a variety of biological processes including cell survival, metabolism, proliferation, migration, autophagy and apoptosis.

Nonessential amino acids The amino acids that can be made by a living system, thus not being required to present in the diet.

Oncometabolite A molecule or metabolite produced by mutated metabolic enzymes and contribute to oncogenesis and tumor progression. An oncometabolite is commonly resulted from gain of function mutations which alter the normal function of a metabolic enzyme.

Abbreviations

AARE Amino acid responsive element
ALT Alanine aminotransferase
AST Aspartate aminotransferase
ATF4 Activating transcription factor 4
BCAA Branched chain amino acids
ER Endoplasmic reticulum
GCN2 General Control Non-derepressible 2
GDH Glutamate dehydrogenase
GLS Glutaminase
GSH Glutathione
IDH Isocitrate dehydrogenase
LAT1 Large neutral amino acid transporter 1

NF-κB Nuclear factor kappa B
TCA Tricarboxylic acid cycle
α-KG α-ketoglutarate

Introduction

Glutamine is one of the 20 amino acids used in protein translation processes. In plants, glutamine can be synthesized by glutamine synthetase, which uses glutamate and free ammonia as substrates and ATP as the energy source. Biochemically, the glutamine synthesis process is the major way to introduce inorganic nitrogen into organic molecules in the form of amino acids, which eventually are converted into proteins and other nitrogenous molecules and flux into higher organisms through food-chain or food-web. In addition to the dietary sources, in animals, multiple tissues can synthesize glutamine, and often use this synthesis as a way to dispose free ammonium ion, a metabolic waste. The most relevant glutamine-producing tissue is the skeletal muscle, accounting for about 90% of all glutamine synthesized. As one of the three amino acids that shuttle the toxic ammonium ion from extrahepatic tissues to hepatocytes, glutamine serves a special role in disposal of the nitrogenous waste through urea cycle. Since glutamine can be synthesized, at organism level glutamine is classified as a nonessential amino acid, and as such, its importance in anabolic pathways other than protein translation and nucleotide biosynthesis are often overlooked.

However, rapid proliferating cells including cancer cells, pathogen stimulated immune cells and various progenitor or stem cells have increased demand for glutamine, and often show glutamine dependent growth and proliferation. This increased demand usually excesses the needs for protein translation and nucleotide synthesis. In fact, most types of cancer cells cultured in vitro depend on high levels of supplemented glutamine. In those cells, most of the glutamine uptaken by cells are converted into glutamate through glutaminolysis catalyzed by glutaminase. More and more published studies support the notion that proliferating cancer cells use glutaminolysis to maintain the intracellular glutamate homeostasis to support a metabolic reprogramming associated with malignant transformation. The amido and amino groups from glutamine are crucial for the active nitrogen anabolism in proliferating cells, and the carbon skeleton from glutamine catabolism eventually contributes to the carbon pool, supporting ATP production, anaplerosis and lipid biosynthesis.

In this article, we will summarize the glutamine metabolism in cancer cells, focusing on biosynthetic roles of glutamine in proliferating cells as both a nitrogen source and a carbon source and the regulatory roles of oncogenic signaling.

Direct Roles of Glutamine and Major Enzymes

Glutamine is the most abundant one among all amino acids in circulation, including the proteinogenic or nonproteinogenic amino acids. Cells uptake glutamine through glutamine transporters, a transmembrane protein family consisting of multiple members. The structural–functional relationships and specific roles of these transporters under defined physiological or pathological conditions remain not well studied. However, SLC1A5 (ASCT2) may have special importance for cancer cells to uptake glutamine. Upon uptaken by cells, glutamine can be directly utilized for protein translation and nucleotides biosynthesis, two processes are described in details in most molecular biology textbooks. Intracellular accumulation of glutamine also provides a chemical potential for cells to uptake other nutrients. For example, leucine is an essential amino acid, and the uptake of leucine by the large neutral amino acid transporter 1 (LAT1) antiporter requires the simultaneous release of glutamine to the outside of cells. A summary of glutamine utilization in cells are outlined in Fig. 1.

Importantly, a major portion of intracellular glutamine will be converted into glutamate and an ammonium ion primarily in the mitochondria by the enzyme glutaminase. Part of the mitochondrial glutamate will be exported to cytosol to join the glutamate pool, and the other portion of glutamate is further converted into α-ketoglutarate by glutamate dehydrogenase and release ammonia. This interconversion between glutamate and α-ketoglutarate can also be catalyzed by aspartate transaminase (AST), but instead of releasing ammonia, this reaction transfers the amino group from glutamate to oxaloacetate and generates aspartate, another amino acid with special importance in nucleotide biosynthesis.

There are two genes encoding glutaminase, *GLS* and *GLS2*. *GLS* encodes for the kidney-type glutaminase (KGA), which is primarily expressed in the brain and kidney and plays a key role in synthesizing the neurotransmitter glutamate and maintaining acid–base balance in the kidney. *GLS2* encodes for the liver type glutaminase (LGA), which was originally considered liver-specific, but later found to be expressed in other tissues and cancer cells as well. Alternative splicing may result in multiple transcript variants which generate various glutaminase isoforms in different tissues and cancer cells.

Aspartate transaminases, better known clinically as glutamate-oxaloacetate transaminase (GOT), also have two isoenzymes in human: the cytosolic isoenzyme (cAST or GOT1) which primarily expresses in muscle and red blood cells, and the mitochondrial AST (mAST or GOT2) which primarily expresses in hepatocytes. The expression of both isoenzymes have been reported in different types of cancers.

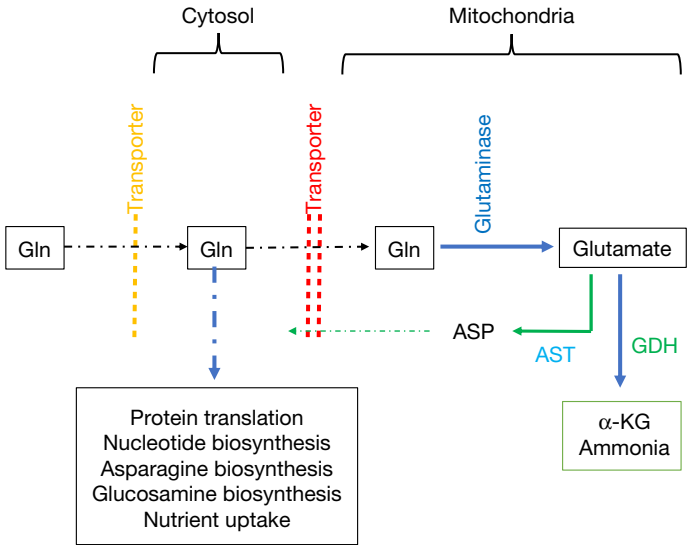

Fig. 1 Schematic drawing shows glutamine uptake, intracellular dynamics and direct roles in cell metabolism. Transporters and enzymes involved are marked with color text. *Dotted fine lines* show intracellular diamics or flux, and *solid lines* indicate biochemical conversion. *Gln*, glutamine; *Asp*, aspartate; *AST*, aspartate transaminase; *GDH*, glutamate dehydrogenase.

Indirect But Important Roles of Glutamine in Cancer Metabolism

Replenishing the pool of cytoplasmic glutamate by glutaminolysis is the most crucial role of glutaminolysis in cancer metabolism, particularly in nitrogen anabolism. In normal cells, various vitamin B6-dependent transaminases operate a glutamate-α-KG cycle, in which α-KG collects amino groups from excess amino acids doomed to be catabolized; on the other hand, when an NAEE becomes scarce, glutamate may donate the amino group to synthesize it (Fig. 2A). In cancer cells and other proliferating cells, to support proliferation, active biosynthesis, including many nitrogen anabolic processes in addition to protein translation, is necessary and sometimes can be rate-limiting for cell division. Particularly, these nitrogen-dependent biosynthetic processes consume large quantity of several amino acids that provide the nitrogen source, or carbon

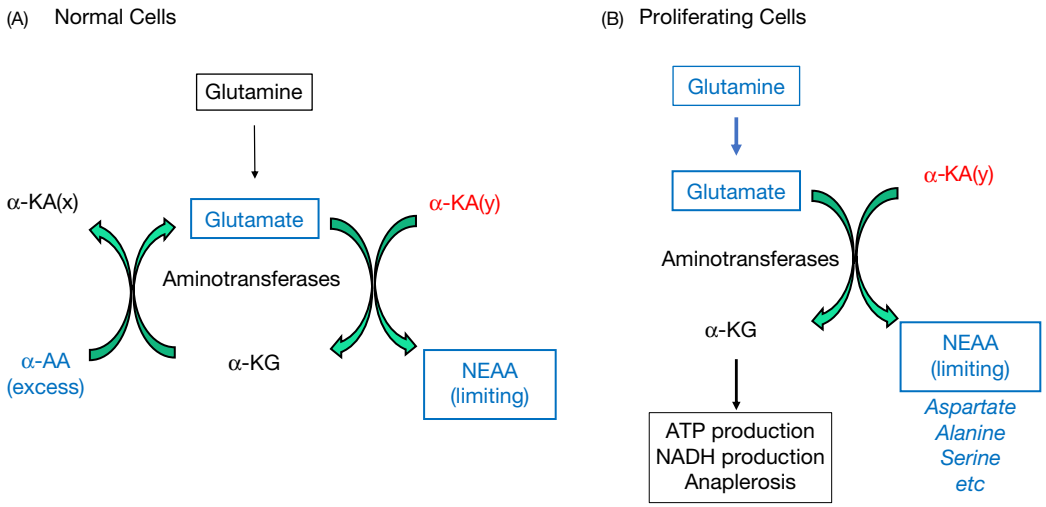

Fig. 2 Central role of glutamate in the homeostasis of nonessential amino acids in normal cells and proliferating cells. (A) In normal cells, the glutamate and α-KG cycle plays the key role to maintain a dynamic homeostasis of the intracellular pool of amino acids. Any amino acids in excess will be catabolized by transamination with α-KG first prior to feeding the carbon skeletons (ketoacids) into TCA cycle. Glutamate then can be used to synthesize any nonessential amino acid in need. (B) In rapid proliferating cells, active biosynthesis will consume most of the amino acids, particularly, some amino acids are consumed in large quantity. In this case, glutamine plays the important role in replenishing the glutamate pool consumed directly or indirectly in biosynthesis of nitrogenous molecules. Metabolites in blue indicate the flux of nitrogen.

source as well in some cases. Glutamate derived from glutaminolysis either directly participates in the biosynthesis, or indirectly provides the nitrogen source or carbon source by synthesizing these amino acids required in large quantity for the active biosynthesis (Fig. 2B). In turn, glutaminolysis provides the ultimate mechanism to maintain the cytosolic homeostasis of glutamate.

First of all, in addition to glutamine, glutamate, aspartate and glycine are well-known for their roles in de novo biosynthesis of nucleotides. Moreover, glycine is an important substrate for biosynthesis of heme, a prosthetic factor required for a variety of redox enzymes; and glutathione, an important molecule in maintaining the intracellular redox homeostasis. Similarly, serine plays multiple roles in proliferating cells, thus being required in large quantity. Serine cleavage provides important source of one carbon units for various reactions, including nucleotide synthesis, protein methylation, epigenetic control of gene expression etc. Serine also is a substrate for the biosynthesis of biomembrane by either serving as an alcohol head of phospholids, or the core structure of sphinosine (2-amino-4-octadecene-1, 3-diol). Collectively, to meet the needs for cell growth and division will consume considerable amount of serine in biosynthesis based on the stoichiometry. As such, glutamate is usually consumed as a substrate in large quantity through transamination to synthesize aspartate, glycine, serine and other nonessential amino acids actively participating in proliferative biosynthesis (Fig. 2B).

Most human cells maintain high levels of intracellular glutamate, and the cross-membrane glutamate gradient serves as a chemical potential to facilitate the uptake of key metabolites. The human *SLC7A11* gene encodes for a sodium-independent but chloride dependent cystine-glutamate antiporter well-known as system Xc- or xCT. SLC7A11 is highly expressed in astrocytes as well as in some types of cancer cells including lung, head and neck carcinomas. Cystine-glutamate antiporter uses the cross-membrane gradient of glutamate as an energy source, and couples the uptake of one molecule of cystine with the release of one molecule of glutamate to the outside of cells. The uptaken cystine in cells will be converted to two molecules of cysteine. In addition to participate in protein translation, as a special amino acid with thiol group, cysteine can be converted into methionine and participate in one carbon unit metabolism and in the biosynthesis of polyamines, a group of amines interacting with newly synthesized DNA and facilitating chromatin condensation. More importantly, cysteine is one of the critical substrate for the biosynthesis of glutathione, participating in the maintenance of redox homeostasis. The important role of glutamine metabolism in supporting glutathione biosynthesis is summarized in Fig. 3.

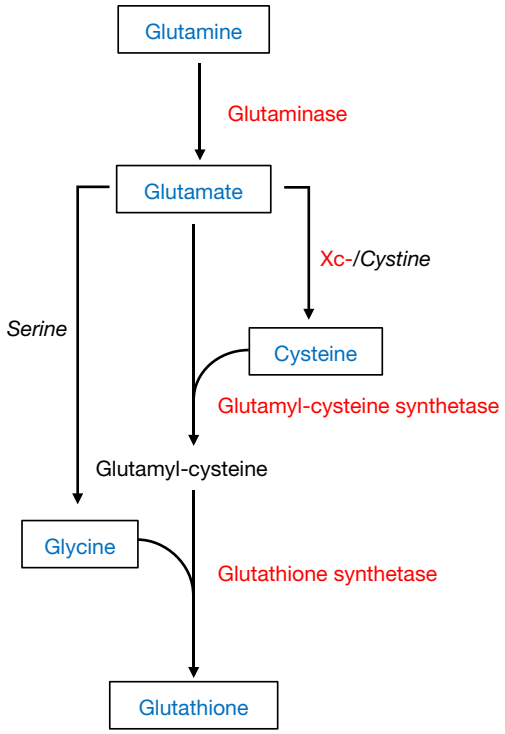

Fig. 3 Biochemical importance of glutamine in the biosynthesis of glutathione. Glutathione (GSH) is a tripeptide plays important role in protecting cells from damage caused by reactive oxygen or reactive nitrogen species, which may arise from cell metabolic processes, radiation or therapeutic drugs. Rapid proliferating cells require the biosynthesis of a large quantity of GSH to prepare for the cell division. The biosynthesis of GSH requires glutamate, cysteine and glycine as substrates. Glutamine plays important roles in maintaining the intracellular homeostasis of all three amino acids. Key amino acids are *boxed*. Enzymes and transporters involved are in *red*. Intermediate metabolites are indicated in *italics*.

Glutamine, Glutamate and α-Ketoglutarate Pathway in Carbon Metabolism

As the carbon skeleton derived from glutamine catabolism, α-KG joins the pool of reduced carbons and contributes to the carbon metabolism. As one of the metabolites of the TCA cycle, α-KG can be oxidized in TCA cycle as a fuel to generate NADH and FADH2, which transfers the electrons to electron transfer chain for ATP production. Moreover, α-KG also plays roles in anaplerosis to support the synthetic function of TCA cycle. Three metabolites of the TCA cycle have particular importance in supporting the proliferative biosynthesis thus being commonly withdrawn from the TCA cycle. Succinyl CoA is required as a substrate for the biosynthesis of Heme, an important cofactor needed for a variety of oxidoreductases. Oxaloacetate can be transaminated into aspartate in the mitochondria and exported to cytosol to support active protein translation and nucleotide biosynthesis. The citrate can be exported to the cytosol to replenish the cytosolic pool of acetyl-CoA and malate. Malic enzyme-catalyzed subsequent reaction utilizes malate as a substrate to produce cytosolic NADPH. Thereafter, both acetyl-CoA and NADPH are utilized for the biosynthesis of fatty acids, cholesterol and other molecules derived from the mevalonate pathway. In addition, α-KG can also directly undergo reductive carboxylation in the cytosol to generate citrate by the cytosolic $NADP^+$-dependent isocitrate dehydrogenase 1 (IDH1), providing another metabolic pathway generating acetyl-CoA and NADPH for lipogenesis in the cytosol.

As an excitatory neurotransmitter and the precursor of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA), glutamate is the most abundant amino acids in human brains. Although the role of glutamate in the physiology of central nerve system is apparently beyond the scope of this article, glutamate metabolism has a special importance in astrocytoma, glioma or glioblastoma, the major forms of brain malignancies derived from astrocytes or glial cells. These tumors frequently carry mutations in the gene encoding IDH1 or the mitochondrial IDH2, which render new enzymatic activity; for example, a common gain of function of IDH1 is to convert α-KG into D-2-hydroxoglutarate, an oncometabolite which competitively inhibits α-KG-dependent enzymes. Similar IDH1/2 mutations and oncogenic metabolism were found in other types of malignancies, including sarcomas, hematologic malignancies and colon cancers, adding a new level of twist of glutamine metabolism in cancer cells.

Glutamine in Maintaining mTORC Activity and Active Biosynthesis

As a crucial nutrient, glutamine maintains the activity of mTORC signaling pathways. It is well-known that the mTORC signaling pathways serve as master regulators of cell survival, proliferation and proper functioning. Proper mTOR signaling is important to suppress degradative processes such as autophagy and apoptosis. The mTOR kinase forms two multiprotein complexes, mTOR complex 1 (mTORC1) and mTOR complex 2 (mTORC2). In addition to upstream regulators, the availability of nutrients and growth factor signaling are crucial to maintain mTORC activity. mTORC1 is required for various biosynthetic activities including protein translation and lipogenesis, whereas mTORC2 facilitates cell survival, migration and invasion. Adequate mTORC activity is also important to limit degradative processes including autophagy. According to the above discussion of the metabolic roles of glutamine, it is obvious that glutamine is required in multiple aspects to maintain the mTORC1 activity; particularly glutamine utilization is critical to ensure the homeostasis of the intracellular amino acids pool, redox status and energy which are monitored by mTORC1. Knocking down glutamine transporter SLC1A5 not only inhibits glutamine uptake, but also suppresses mTORC1 signaling.

Glutamine Utilization Promoted by Oncogenic Activation and Loss of Tumor Suppressors

In cancer cells, active anabolism requires increased glutamine utilization, which is driven by the activation of oncogenes, the loss of tumor suppressors or other genetic alterations (Fig. 4). Altered expression of glutamine transporters, GLS and glutamate dehydrogenase has been linked to tumor cell growth and proliferation.

The first oncogene demonstrated to promote glutamine utilization is c-Myc. *MYC* encodes a protein containing the basic helix-loop-helix leucine zipper (bHLHZip) motifs. With this motif, c-Myc contributes to the genesis of human malignancy via a network of protein–protein interaction and DNA binding. In this network, c-Myc binds to Max, another bHLHZip family member, forming a heterodimer. The structure of Myc protein contains an unstructured N-terminal region which functions as transcriptional regulatory domain, and the C-terminal bHLHZip domain, which dimerizes with Max. The Myc-Max heterodimer recognizes the DNA sequence CACGTG which belongs to the *E*-box sites. The DNA binding recruits coactivator or corepressor complexes that modify the chromatin, thus regulating the expression of the downstream genes with E-box in their promoters. These genes regulate a wide range of cellular processes, including cell growth, proliferation, and tumorigenesis. Importantly, c-Myc lies at the downstream of, and is regulated in response to some upstream oncogenic signals. Studies showed that the upregulation of MYC drives glutamine utilization via upregulating glutamine transporters and metabolism enzymes such as GLS. The second reported oncogenic signaling pathway that drives glutamine utilization is HER2 (ErbB2). Activation of ErbB2 is frequently involved in breast cancer, ovarian cancer, gastric cancer and other cancers. The formation of homodimer or heterodimer of ErbB2 with other forms of ErbBs triggers its downstream signaling including MAPK/ERK, PI3K-Akt pathway, or nuclear factor kappa B (NF-κB). It has been demonstrated that ErbB2 drives glutamine utilization by activating GLS in breast cancers. Finally, AP1 (c-Jun/Fos) has been reported to promote glutaminolysis. c-Jun, as a transcription regulator, is derived from the proto-oncogene *JUN*. c-Jun modulates oncogenic Rho-GTPase signaling to enhance the expression and enzymatic activity of mitochondrial GLS in breast cancer, which facilitates cancer cell

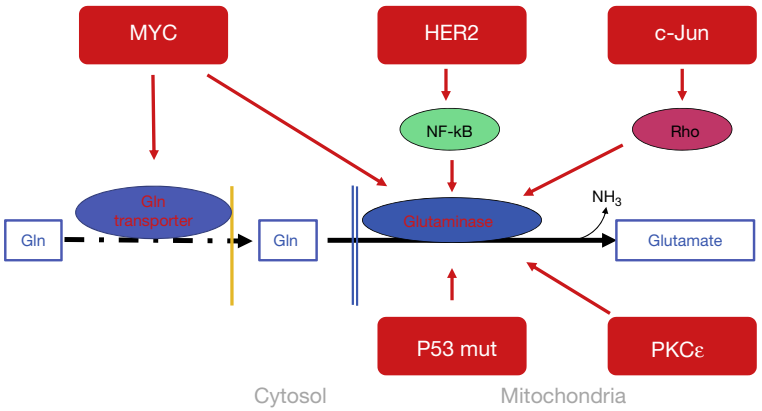

Fig. 4 Common oncogenic signaling pathways that promote glutamine utilization in cancer cells. Major oncogenic signaling pathways that promote glutamine utilization in cancer cells are shown schematically. Oncogenes or tumor suppressors were shown in *red boxes*.

metabolism and progression. More recently, a truncated isoform of glutaminase (GAC) expressed in some cancer cells was found to be activated by phosphorylation catalyzed by PKCε, providing a posttranslational mechanism to enhance glutamine utilization in cancer cells.

As a tumor suppressor, p53 suppresses the production of reactive oxygen species (ROS) through upregulating GLS2, which enhances the production of reduced glutathione. Exogenous GLS2 expression inhibits tumor growth in vivo, consistent with the tumor suppressive activity of p53. However, in some tumor cells, GLS2 is upregulated to promote tumor growth. In addition, another tumor suppressor, retinoblastoma protein (Rb) also regulates glutamine metabolism, and the loss of Rb drives tumor cells' dependency on glutamine, which also exemplifies a proliferation enhanced utilization of glutamine.

Responses of Cancer Cells to Glutamine Depletion

During tumorigenesis and tumor progression, cancer cells are frequently exposed to a poorly vascularized microenvironment which is often characterized by the lack of oxygen, glucose and glutamine. To survive in such a stressful microenvironment, tumor cells have obtained strategies to sense the lack of a specific nutrient and respond to the status by reprogramming cellular processes and metabolism. The general responses to stresses usually include the induction of autophagy, inhibition of mTOR activity, cell cycle arrest, endoplasmic reticulum (ER) stress response and activation of the heat shock system. Like other stress conditions, glutamine depletion triggers the above general responses as well (Fig. 5).

In addition to these general responses to stresses, cancer cells also develop metabolic reprogramming more specific to glutamine depletion (Fig. 5). These reprogramming include the decreased utilization of glucose, increased uptaking and utilization of other amino acids and enhanced recycling of ammonia. The decreased utilization of glucose is manifested by the decreased expression and activity of enzymes involving in both glycolytic and pentose pathways. The increased uptaking and utilization of other amino acids is highlighted by the enhanced expression of transporters for amino acids, such as branched chain amino acids (BCAA). Moreover, glutamine depletion also promotes the expression of transaminases for alanine (ALT) and branched chain amino acids. Recycling of ammonia in cancer cells is catalyzed by glutamate dehydrogenase, whose activity can be easily reversed by the alteration of substrate and/or product concentrations. Collectively, those metabolic reprogramming events triggered by glutamine depletion may either utilize alternative sources of nitrogen, or slow down global cell metabolism to conserve the nitrogen sources.

How cells monitor the glutamine availability remain illusive. Initially, the lack of essential or conditionally essential amino acids including cysteine and leucine induces an "integrated stress response" to amino acid depletion and redox stress, in which GCN2 senses the increased amount of nonaminoacylated tRNA. Nonaminoacylated tRNA binds with and activates GCN2. Like PERK in the ER lumen, activated GCN2 phosphorylates eIF2α, attenuating general protein synthesis but selectively translates ATF4, a transcription factor that binds to amino acid responsive elements (AARE) and regulates gene transcription involved in relieving the stresses caused by amino acid depletion. Later, it is found that glutamine depletion is sufficient to induce eIF2α phosphorylation and thus activates ATF4. This process may involve both GCN2 activation and the PERK kinase activity as a part of the ER stress responses. Considering glutamine's crucial role in biosynthesis of nonessential amino acids, glutamine depletion could lead to insufficiency of nonessential amino acids such as serine, glycine, aspartate which are required in large quantity in proliferating cells. In addition, glutamine depletion disrupted glutamate homeostasis may directly compromise GSH synthesis, and thereafter, the accumulation of redox stress facilitates the activation of ER stress, providing additional mechanism to activate ATF4. Activation of ATF4 may lead to transcriptional reprogramming and the relieving of stresses including nutrient depletion. In this aspect, it seems that the availability of multiple amino acids as a pool, instead of glutamine alone, is collectively sensed by multiple cellular mechanisms.

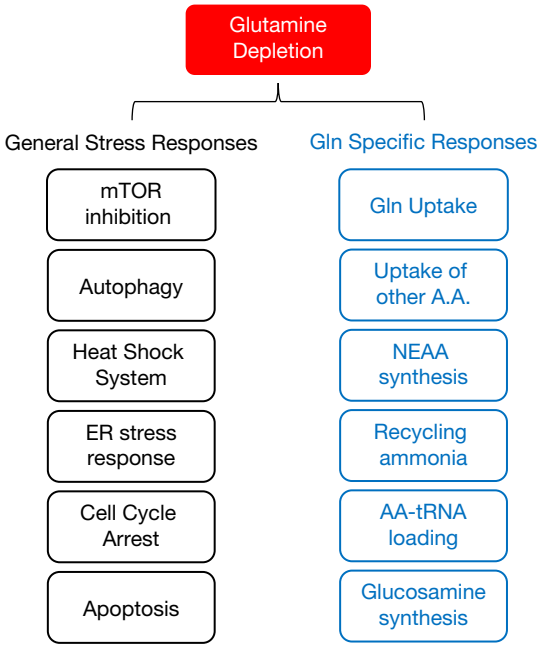

Fig. 5 Glutamine depletion triggeres general stress responses and glutamine depletion specific, adaptive metabolism. Glutamine depletion is a common condition that cancer cells may frequently encounter in vivo. Current studies indicate that glutamine depletion triggered cellular responses can be classified into two major categories: those not specific to defined stresses, and those specific to glutamine depletion. The responses specific to glutamine depletion generally tend to increase the ability or enzyme activities to reach a new homeostasis of a metabolite in scarce supply, indicative of compensatory strategies of cancer cells.

Prospective Vision

Cancer metabolism is characterized by increased glycolysis and active glutaminolysis, representing the enhanced utilization of glucose and glutamine respectively. Targeting cancer metabolism as potential novel therapies has been explored at various stages including basic research, preclinical and clinical stages in recent years. The initial success has been demonstrated by various trials targeting the glucose utilization pathways in cancers. Preclinical studies on the use of inhibitors of glutamine transporters or metabolic enzymes in order to block glutamine utilization also result in initial excitement. However, cancer cells may usually evolve the ability to adapt to nutrient depletion, which negatively affects the efficacy of various strategies to "starve" cancer cells. Accordingly, identification of critical adaptive strategies of cancer cells induced by nutrient depletion will potentially provide novel therapeutic targets. A combination of targeting both cancer metabolism and its adaptive strategy may provide therapeutic advantages and improve the efficacy.

Existing data from cultured cells indicate that whereas glutamine depletion suppresses glucose utilization, and that glutamine utilization may be limited by the availability of other nutrients such as glucose and oxygen, indicating a coordinated utilization of glutamine, glucose and molecular oxygen. Our unpublished observations show that glucose depletion suppresses c-Myc/Max, which indicates limited glucose supply may suppress glutamine utilization driven by Myc oncogene. Hypoxia-inducible factors (HIF-1, 2, collectively HIFs) are heterodimeric transcription factors which are activated primarily by hypoxia and serve as drivers of ATP production. Accordingly, HIFs are often activated by hypoxia and other biological stresses such as injury and infection to promote cell repair and defense. It has been reported that there is a functional interaction between the c-Myc and HIF pathways, and HIF activation counteracts the cell cycle promoting effect of c-Myc. A better understanding of the coordination of cellular response to nutrient depletion may provide new insight into the molecular and biochemical mechanisms of cancer cells' adaptation to a combined nutrient depletion which is more relevant to cancer metabolism in real patients.

Mechanistically, while the enzymes involved in glutamine utilization are well studied, and the metabolic flux of glutamine also has been extensively studied by combined isotope-tracking and mass-spectrometric analyses, the expression and regulation of glutamine transporters in cancers remain to be further clarified. Altered metabolic pathways or metabolites in cancers caused by gain-of-function mutations of metabolic enzymes remain to be further elucidated.

The Discovery of *H. pylori* as an Infectious Agent Within the Stomach

Helicobacter pylori has colonized and coevolved with its human host for millennia. The earliest direct evidence of *H. pylori* colonization can be seen from gastric biopsies taken from the Iceman, a 5300-year old mummy from the Copper Age, yet *H. pylori* colonization dates back at least 100,000 years. Indeed, conserved domains within the *H. pylori* genome can be used to mirror the paths of human migration out of Africa.

Although *H. pylori* was not officially discovered until 1983, spiral-shaped bacteria had been observed in human stomachs by German physicians as early as 1875. In 1899, a Polish physician named Walery Jaworski observed spiral shaped bacteria in sediments from gastric washings and named the organism *Vibrio rugula*. In his book entitled "*Handbook of Gastric Diseases*", Jaworski even implicated *V. rugula* as a causative agent of gastric disease. However, the observations of these scientists were forgotten until 1939–40 when physicians again observed "spirochaetes" within the human gastric mucosa of patients with and without gastric disease. Finally, in 1954 Palmer et al. examined over 1000 gastric biopsies and found no bacteria with spirochetal structure from their samples. They concluded that the stomach was a sterile organ and that any observed bacteria were oral contaminants that multiplied in postmortem specimens. Nonetheless, observations of bacteria within the human stomach persisted into 1975 when Steer and Colin-Jones observed Gram-negative bacilli in 80% of patients with gastric ulcer, yet they dismissed their observation as a possible contaminant of *Pseudomonas* (Fig. 1).

In 1983 Barry J. Marshall and John Robin Warren were the first to both observe and culture back an unspecified bacteria from the gastric epithelium among patients with chronic gastritis. To accomplish what their predecessors could not, Marshall and Warren had used a silver stain, which was unconventional for gastric specimens at the time, to observe the spiral-shaped bacteria. Furthermore, the conventional amount of time for bacteria recovered from the gastrointestinal tract to grow in the lab was only 2 days, after which the agar plates would be discarded if there was no bacterial growth. However, due to a fortunate accident whereby Marshall and Warren had accidentally left their agar plates in the incubator for 6 days over the Easter weekend, they were then able to recover their unspecified bacterium. They classified the bacterium not as a spirochete as others had described, but rather a species of *Campylobacter* due to its morphology. In 1984, they again published that this unspecified bacterium was recoverable from chronic active gastritis as well as peptic ulcers. The pair named this unspecified organism *Campylobacter pyloridis* due to its predominance within the gastric antrum. In 1989, 16S ribosomal RNA sequencing of *Campylobacter pyloridis* revealed that it was not a *Campylobacter* species, but rather a new bacterial species and subsequently renamed to *Helicobacter pylori*.

In 1983, the hypothesis that *H. pylori* could be the causative agent of peptic ulcer was not well received in the medical community despite a clinical trial demonstrating gastritis could be healed after bacterial eradication. One of the main obstacles in proving that *H. pylori* was the etiological agent of gastritis was the lack of a proper animal model to prove Koch's postulates. Therefore, after multiple failures in trying to infect rats, mice, and pigs, Barry Marshall chose to drink a pure culture of the bacterium and track his disease progression. Within 5 days he developed acute gastritis associated with the presence of many *H. pylori* until day 14 when his symptoms and the *Helicobacter* spontaneously subsided. By 1988, two independent follow-up studies published outside

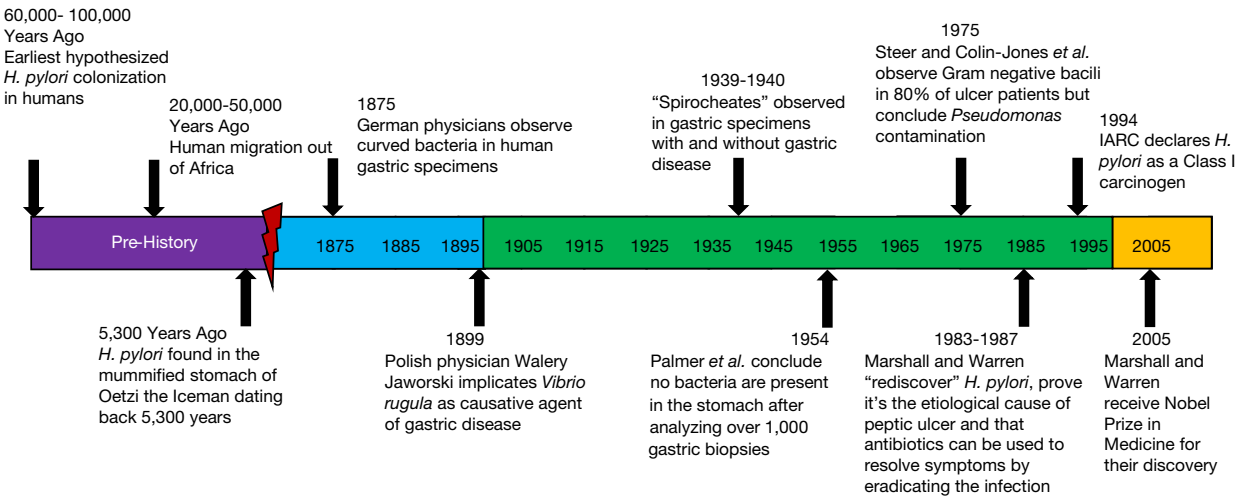

Fig. 1 Timeline of major events in the history of *H. pylori* from its coevolution with humans in prehistory to the revelation of its contribution to peptic ulcer disease and gastric adenocarcinoma.

the United States had shown that patients with duodenal ulcer and concurrent *H. pylori* infection could be cured with a regimen of antibiotics combined with bismuth. By 1991 the first study demonstrating the cure of duodenal ulcer was published in the United States. These clinical trials, combined with Marshall's proof of Koch's postulates, proved *H. pylori* as a causative infectious agent leading to gastroduodenal disease.

Since Marshall and Warren's discovery, *H. pylori* has been associated with a range of gastroduodenal disorders including gastric and duodenal ulcers, gastric adenocarcinoma, mucosa-associated lymphoid tissue (MALT) lymphoma, as well as non-Hodgkin lymphoma of the stomach. In 1994, the International Agency for Research on Cancer officially classified *H. pylori* as a class I carcinogen. Additionally, as a result of their work and subsequent scientific advancement of the field of gastroenterology, Marshall and Warren were awarded the Nobel Prize in Physiology or Medicine in 2005.

Bacteriology of *H. pylori*

Helicobacter pylori is the archetypal species of its genus. *H. pylori* is a Gram-negative, curved-rod or spiral-shaped microaerophilic organism that resides in the mucus gel layer above the gastric epithelium (Fig. 2). The genome size is approximately 1.7 Mbp with a G+C content of 35%–40%. Every strain of *H. pylori* is genetically distinct, possibly as an adaptation to the unique gastric conditions and immune response of each human host. In vitro, *H. pylori* colonies are translucent and uniformly sized (~1 mm). Each bacterium measures approximately 2–4 μm in length 0.5–1 μm in width, however in response to environmental stress, *H. pylori* may temporarily assume a smaller, coccoid shape until ideal growth conditions are restored. *H. pylori* harbor two to seven unipolar, sheathed flagella that measure approximately 3 μm in length and typically carry a distinctive bulb at the terminus. *H. pylori* strains are characteristically catalase, oxidase, and urease positive organisms. Urease productivity is critical for *H. pylori* survival, representing nearly 15% of the total expressed proteome. Urease is of particular importance because it is the foundation of both noninvasive and invasive clinical diagnostics for active *H. pylori* infection.

Virulence Factors

In order to sustain a persistent infection, *H. pylori* must liberate nutrients from the host while also evading the host immune response. To accomplish this task, *H. pylori* maintains an armamentarium of virulence factors which serve to both strategically

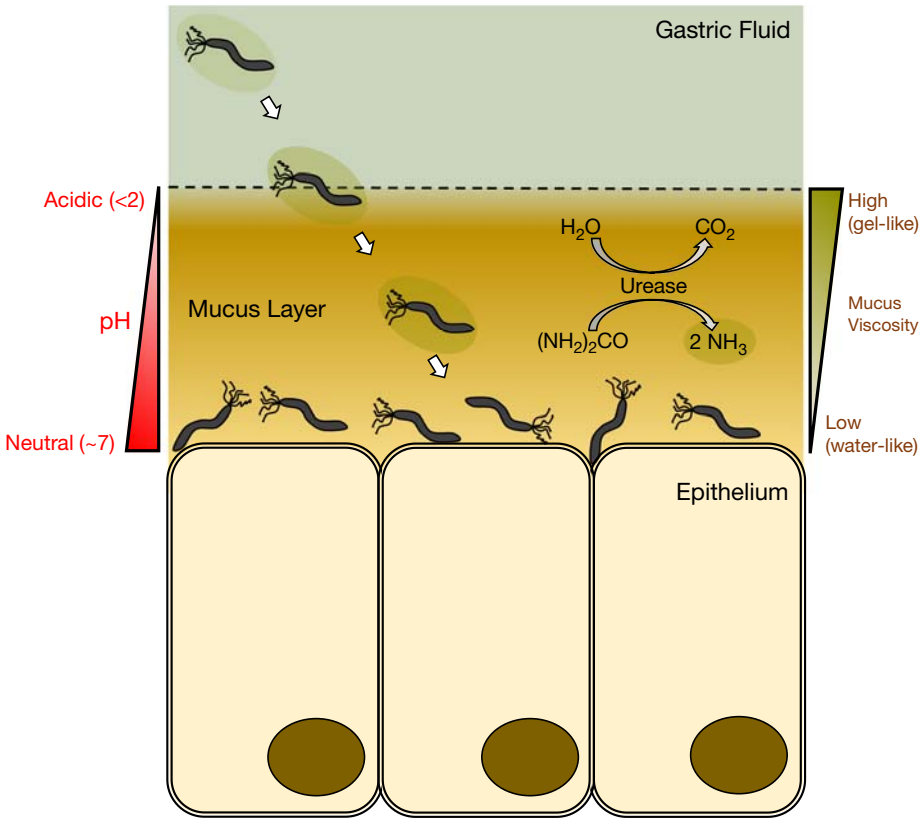

Fig. 2 Schematic representation of the natural niche of *H. pylori*. Upon initial colonization, *H. pylori* utilizes it flagella and urease to survive the acidity of the gastric lumen. Through chemotaxis, the bacteria migrate through the mucus gel layer to the border with the gastric epithelium where it can establish infection. The majority of colonizing bacteria are free swimming, while some will adhere to the gastric epithelium, inducing proinflammatory immune responses.

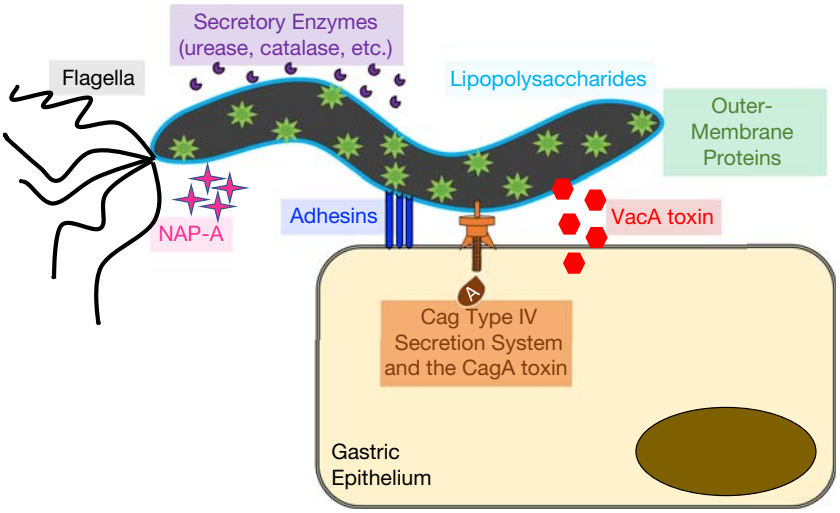

Fig. 3 Summary of *H. pylori* virulence factors that contribute to oncogenesis.

induce an inflammatory response to free nutrients sequestered by host cells while simultaneously shielding it from clearance by the immune response (Fig. 3).

Cag pathogenicity island

The cytotoxin associated gene pathogenicity island (*cag*PAI) is a highly proinflammatory, strain-specific virulence factor that significantly augments risk for gastric cancer and ulceration. Nearly 50% of all strains in the United Sates and 90% of stains from East Asia are cag^{+}. Genes within the *cag* pathogenicity island encode the structural components of a bacterial type IV secretion system (T4SS), a needle-like appendage that delivers microbial effectors into host cells (Fig. 4). The protein product of the terminal gene in the *cag* PAI is the CagA toxin, which is delivered into host cells following bacterial attachment. Once inside host cells, CagA can become tyrosine-phosphorylated at EPIYA amino acid sequence motifs and subsequently induce proinflammatory signaling pathways and cytoskeletal rearrangements. Intracellular CagA may also remain unphosphorylated, thereby inducing aberrant β-catenin activation, disruption of apical junction complexes, and a loss of cellular polarity. In vitro and in vivo experiments have also demonstrated that CagA can inhibit apoptosis and induce cellular proliferation, thus designating this toxin as a bacterial oncoprotein. The Cag T4SS can also deliver other effector molecules such as peptidoglycan from the bacterial cell wall, subsequently activating the innate immune receptor NOD1 and triggering further downstream proinflammatory signaling cascades. Lastly, nascent and ongoing studies have shown that *H. pylori* may also deliver its genomic DNA via the Cag T4SS into host cells to modulate innate immune responses.

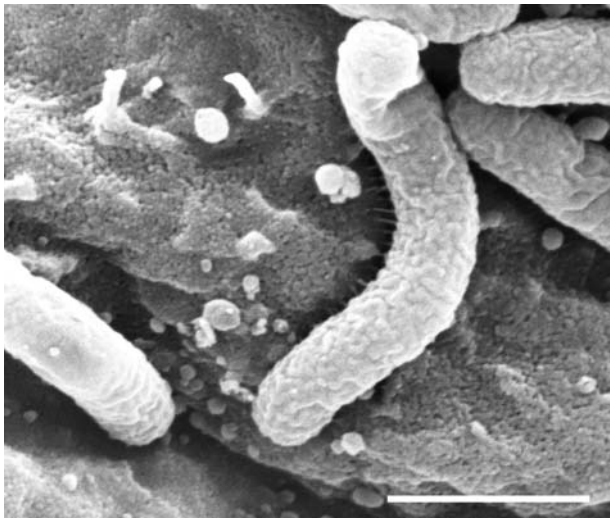

Fig. 4 Electron micrograph of *H. pylori* strain 26695 in coculture with human gastric epithelial cells. Numerous cag T4SS pili are visible at the bacteria–host cell interface. Scale bar represents 1 μm. Image courtesy of Dr. Carrie Shaffer, University of Kentucky.

Vacuolating toxin A

Vacuolating toxin A (VacA) is an *H. pylori* secreted protein that assembles into oligomers when in contact with host cell membranes. These oligomers assemble into selective anion channels that classically define VacA as a pore forming toxin. In addition to causing vacuolation, VacA pores can increase paracellular permeability to organic molecules, iron, and nickel within gastric epithelial cells, thereby liberating vital nutrients for *H. pylori* survival. The toxin can also damage mitochondria and induce apoptosis. To evade the adaptive immune response, VacA can also inhibit the expansion of bacterial protein-detecting T-cells and promote the differentiation of dendritic cells into a tolerogenic phenotype which subsequently trigger the development of regulatory T-cells. All *H. pylori* strains harbor *vacA* genes, however there is significant genetic variability within the *vacA* gene that influences its toxicity. The more virulent form of the toxin (s1m1 allelic variant) is associated with increased risk for both peptic ulcer as well as gastric adenocarcinoma.

Neutrophil activating protein A

The *H. pylori* NAP-A (synonymously called HP-NAP) is a highly conserved, secreted protein which acts as a chemoattractant for neutrophils. In response to NapA, these recruited neutrophils then produce oxygen radicals, cytokines, and chemokines involved in a strong T_H1 immune response.

Outer membrane proteins and adhesins

H. pylori adhesins decorate the outer membrane and facilitate a closer association between the bacterium and the gastric epithelial cell. This interaction is essential for successful colonization and allows for enhanced host cell exposure to bacterial virulence factors, resulting in greater inflammation and mucosal damage. Several of the major *H. pylori* adhesins include BabA, SabA, and OipA. BabA binds difucosylated $Lewis^b$ blood group antigens found on epithelial cells and mucins, and is the major adhesin involved in facilitating *H. pylori* colonization. It has two allelic forms, *babA1* and *babA2*; strains expressing *babA2* have been associated with increased *H. pylori* colonization density, higher levels of inflammation, and more severe gastric disease, particularly when coexpressed with CagA and VacA. SabA binds sialyated $Lewis^x$ antigens and is predominantly expressed in response to a chronically inflamed stomach. Strains expressing SabA are associated with increased risk for gastric cancer. OipA expressing strains have been associated with increased risk of both peptic ulcer and gastric cancer. Finally, from studies of serum antibody titers, two other uncharacterized *H. pylori* proteins, an outer membrane protein, Omp (*HP1564*) and the hypothetical protein encoded by the gene *HP0305* have been consistently associated with gastric cancer incidence.

DupA and tfs4

H. pylori species can encode multiple type IV secretion systems in addition to the *cag* system. These include the *comB*, *tfs3*, and *tfs4* systems. However, the *comB and tfs3* systems are involved in horizontal gene transfer between *H. pylori* strains and are thus not directly involved in *H. pylori* virulence. Similar to the *cag*PAI, the *tfs4* gene cluster encodes a T4SS and the duodenal ulcer promoting gene A (*dupA*). As the name suggests, $DupA^+$ strains were initially associated with duodenal ulcer disease, however not all studies have been able to demonstrate a positive association. Discrepancies may be due to differences in the expression of DupA alone compared to the expression of the entire *tfs4* gene cluster.

Strategies of Persistence and Immune Evasion

Although *H. pylori* engenders a robust immune response, it can maintain colonization for the lifetime of the host. To accomplish this feat, *H. pylori* employs a multitude of strategies to survive the hostile conditions of the human stomach and escape the immune response.

Physical barriers

Immediately after infecting its host, *H. pylori* must overcome multiple host defenses to initiate colonization in the human stomach. The basal pH of the gastric lumen is typically less than pH 2.0 and can rise to pH 5.5 after a meal in adults. However, *H. pylori* is not an acidophile and thus cannot survive long under this pH stress. To combat these conditions, nearly 15% of the total expressed *H. pylori* proteins are devoted to manufacturing enzymes designed to buffer the acidic environment. Below pH 6.5, *H. pylori* opens a channel in its cytoplasmic membrane to allow for urea produced by the host to enter the cytosol. *H. pylori* urease then catalyzes host urea into ammonia and carbon dioxide which act as buffers in the bacterial cytoplasm. Subsequently, the periplasmic enzyme α′carbonic anhydrase catalyzes the reversible reaction of hydrating the carbon dioxide released via cytoplasmic urease activity into bicarbonate, which then buffers the *H. pylori* periplasm.

Despite the capacity to buffer the acidic conditions found within the gastric lumen, *H. pylori* must also remain in the stomach after gastric emptying. Gastric epithelial cells are protected from acid in the gastric lumen by a mucus layer. The mucus layer is thick and gel-like nearest the lumen and gradually increases in viscosity as well as pH until it reaches the epithelial cell surface where it is highly viscous and has near-neutral pH. Through the use of chemotaxis and its unipolar flagella, *H. pylori* can identify this pH gradient and navigate away from the acidic lumen and toward the epithelial cell surface. *H. pylori* then resides within this viscous, pH neutral niche adjacent to the gastric epithelium where the majority are free swimming, while others adhere to gastric epithelial cells via adhesins and secrete effectors to induce the release of host nutrients (**Fig. 2**).

Innate immune response

Whilst the colonization of the mucus layer and gastric epithelium helps *H. pylori*, the interaction with the epithelial surface also triggers inflammatory responses designed to clear pathogens. However, *H. pylori* has evolved to limit its activation of the host immune response and even alter the response to become more tolerogenic.

Toll-like receptors (TLRs) orchestrate immune responses targeting invading pathogens and bridge innate with adaptive immunity via the detection of conserved pathogen associated molecular patterns (PAMPs). These PAMPs can originate from a wide array of molecules such as lipids, nucleic acids, and specific proteins that can be derived from organisms of bacterial, viral, or fungal origin. As TLRs are integral to the innate immune response, *H. pylori* has developed highly specific adaptations to its PAMPs such that it can avoid or reduce the intensity of their activation. *H. pylori* can activate TLR2 to subsequently trigger the expression of many antiinflammatory cytokines. Bacterial lipopolysaccharides (LPS) are recognized by TLR4 and can be highly immunogenic, yet *H. pylori* has subtle modifications within the structure of the lipid A core of its LPS that render it nearly undetectable. Furthermore, additional adaptations to *H. pylori* LPS make it less susceptible to destruction by cationic antimicrobial peptides. The natural ligand of TLR5 is flagellin; however, *H. pylori* flagellin is not recognized by TLR5 due to a mutation in the conserved domain of FlaA, which alters the domain where TLR5 binds. Recent studies have also shown that *H. pylori* DNA activates TLR9 to induce antiinflammatory responses during the initial stages of infection, however *H. pylori*-induced chronic activation of this receptor can eventually yield a proinflammatory response.

Phagocytosis is a key component of the host response to clear bacterial pathogens. Infection with *H. pylori* can recruit neutrophils, polymorphonuclear lymphocytes (PMNs), and monocytes. *H. pylori* can evade phagocytosis by PMNs and monocytes and even if engulfed, can use its virulence factors CagA and VacA to survive phagocytosis. Furthermore, phagocytes release reactive oxygen species (ROS) and nitric oxide to facilitate bacterial killing. Yet, *H. pylori* possess the enzymes catalase and superoxide dismutase to detoxify ROSs while *H. pylori* arginase protects it from the effects of nitric oxide.

Dendritic cells link innate and adaptive immunity. The c-type lectin receptors (CLRs) are a class of innate immune receptors expressed by dendritic cells that also recognize conserved bacterial motifs. DC-SIGN is the predominant CLR involved in detecting *H. pylori*, specifically the surface proteins Le^x and Le^y antigens. However, DC-SIGN engagement of *H. pylori* Le^x or Le^y antigens can induce antiinflammatory signaling cascades and can also block proinflammatory T_H1 cell recruitment. The *H. pylori* virulence factor CagA can further regulate DCs to favor a tolerogenic T_{Reg} immune response and also block $CD4^+$ T-cell differentiation into T_H1 types. The VacA toxin can also inhibit DC maturation by inducing cell cycle arrest. The *H. pylori* secreted virulence factor γ-glutamyl-transferase (GGT) blocks IL-6 production and favors IL-10 and IL-18 production in DCs, subsequently favoring the expansion of naive T cells into T_{Reg} cells to further suppress T_H1 and T_H17 effector functions.

Adaptive immune response

The adaptive immune response to *H. pylori* is predominantly mediated by $CD4^+$ polarized T-cells, namely T_H1 and T_H17 immune responses. As DCs bridge the innate and adaptive immune responses, the previously mentioned mechanisms by which *H. pylori* manipulates DC responses are also attributable to the manipulation of the adaptive immune response. However, *H. pylori* may use its virulence factors VacA and GGT to also directly inhibit T-cell functions as a means of persistence. VacA can traverse T-cell membranes where, once in the cytoplasm, it can impair T-cell activation and proliferation through a variety of independent mechanisms. GGT can inhibit T-cell proliferation through disruption of the Ras signaling pathway. GGT can also reduce the efficacy of T-cell responses by depriving cells of glutamine, which is required for the synthesis of the proinflammatory effector cytokines such as IL-2, IL-17, and IFNγ. Similarly, the *H. pylori* enzyme arginase can deplete levels of available L-arginine, which is required by T-cells for proliferation. Although *H. pylori* elicits strong T_H1 and T_H17 adaptive immune responses, it can persist within its human host by actively preventing these T cell responses from clearing the infection while also promoting the recruitment of antiinflammatory T_{Reg} cells.

The humoral immune response to *H. pylori* is robust yet mostly ineffective. Multiple in vivo murine studies have demonstrated that B-cell responses are entirely dispensable for bacterial clearance and that they may even be harmful to the host. Most infected individuals will mount IgG and IgA antibody responses typically directed toward membrane proteins, flagellin, urease, LPS, and chaperonin GroEL.

Epidemiology of *H. pylori* Infection

Transmission and Colonization

H. pylori almost exclusively colonizes the gastric mucosa of humans and is typically the only *Helicobacter* species found within the human stomach. Greater than half of the world's population is colonized with *H. pylori.* Infection is typically acquired during early childhood and the infection usually persists for the lifetime of the host if left untreated. Reinfection after successful eradication is rare among adults, occurring in less than 2% of patients per year. Increased risk for acquiring an *H. pylori* infection has been related to a mother with an *H. pylori* infection, non-white race, lower socioeconomic status, poor hygiene, residing in an area of high population density, greater number of siblings, and a lack of running water.

H. pylori strains can be recovered from saliva, gastric reflux fluid, diarrhea, and vomitus yet *H. pylori* does not survive passage through the intestine into normal feces. The mode of transmission remains unclear; intrafamilial case clustering as well as the

lack of a nonhuman reservoir suggest that close person–person contact is required for transmission. Therefore, the prevailing hypotheses posit that fecal–oral and/or oral–oral routes may be the most likely mode(s) of transmission, with children generally infected by their mother, older siblings, or classmates.

Geographical Variation

Currently, the global prevalence of *H. pylori* infection is approximately 50% where more-affluent countries generally have a lower prevalence (approximately 20%–40%) compared to low and middle-income countries where the prevalence can reach upwards of 80%. However, one notable exception is the East Asian region, where the more-developed countries of Korea, Japan, and China have historically maintained near developing-country levels of *H. pylori* prevalence (Fig. 5). Even within countries, racial and ethnic differences and variation in socio-economic status also influence the prevalence of infection. In the United States, for example, individuals of non-white race, including Asian Americans, African Americans, American Indians, and Hispanic Americans, have been found to have significantly higher prevalence of *H. pylori* than white Americans. Additionally, in both high- and low-*H. pylori*-prevalent countries, individuals of lower socioeconomic status are more likely to harbor the bacteria.

Temporal Trends

Over time, *H. pylori* prevalence has remained fairly stable and at a high level in developing and newly industrialized countries. In contrast, decreasing trends have been observed in many more-developed countries as living conditions have improved. In established industrialized nations, including the United States, Japan, and China, the declines in prevalence are beginning to slow and stabilize. Moreover, the decline of *H. pylori* prevalence in the United States appears limited to the white population.

The Role of *H. pylori* in Disease

Gastritis

H. pylori infection results in a robust, localized, immune response that activates proinflammatory signaling cascades in the gastric mucosa (gastritis). Nearly every person infected with *H. pylori* develops superficial atrophic gastritis that will last throughout the duration of their infection. The level of gastritis varies significantly per person, ultimately influencing the risk of disease progression.

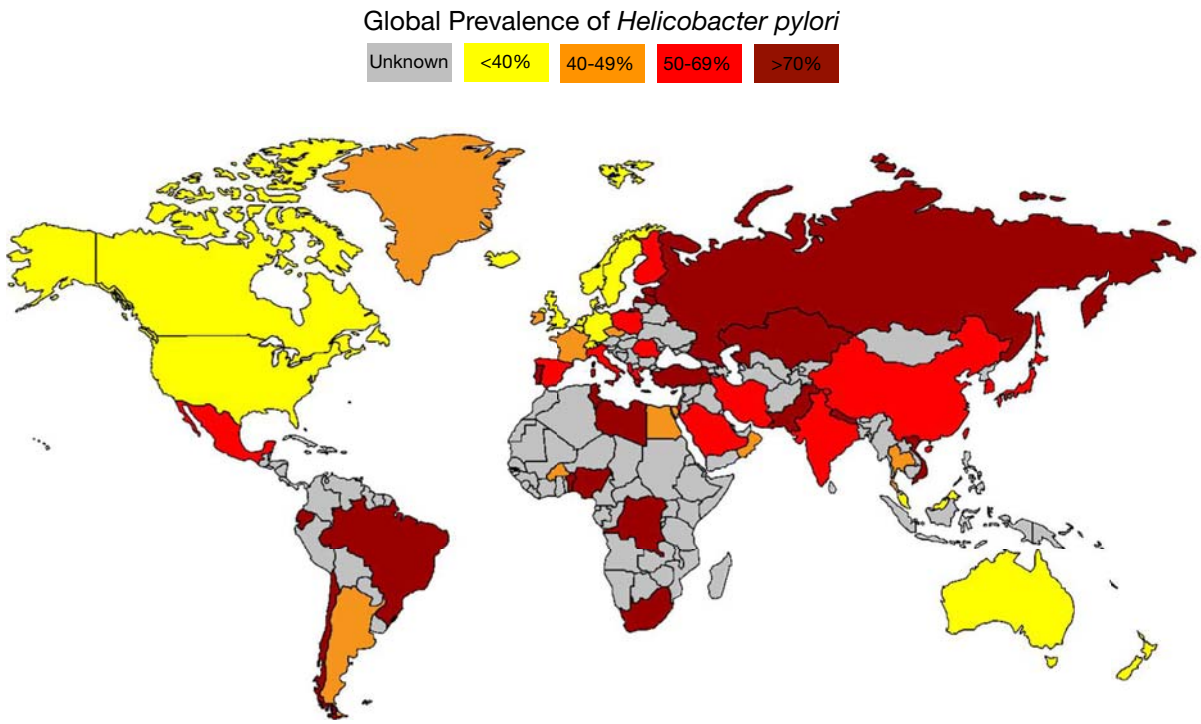

Fig. 5 Map demonstrating global prevalence of *H. pylori*. Prevalence estimates are based on data collected from January 1, 1970 to January 1, 2016. Adapted from Hooi, J. K. Y., Lai, W. Y., Ng, W. K., Suen, M. M. Y., Underwood, F. E., Tanyingoh, D., Malfertheiner, P., Graham, D. Y., Wong, V. W. S., Wu, J. C. Y., Chan, F. K. L., Sung, J. J. Y., Kaplan, G. G., Ng, S. C. (2017) Global prevalence of *Helicobacter pylori* infection: Systematic review and meta-analysis. *Gastroenterology***153**(2), 420–429. doi: 10.1053/j.gastro.2017.04.022. PubMed PMID: 28456631.

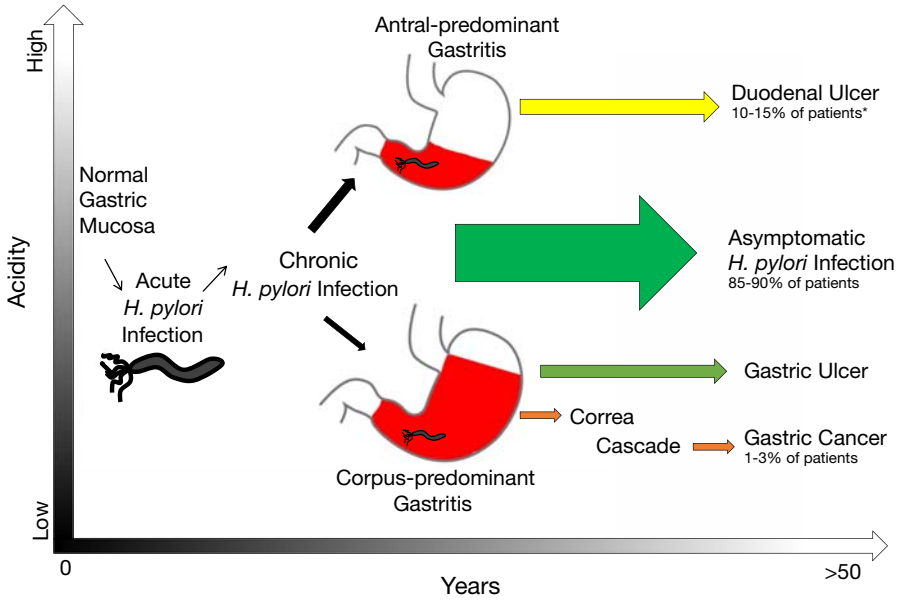

Fig. 6 Potential outcomes of *H. pylori* infection. *H. pylori* infection can persist for the lifetime of the host, causing alterations in the gastric environment and histology. Approximately 85%–90% of infected individuals will remain asymptomatic, only developing nonatrophic gastritis. However, a minority of infected patients can progress over the course of decades to either antral- or corpus-predominant gastritis, which can lead to peptic ulcer disease or gastric cancer. *Percent representative of patients progressing to peptic ulcer disease, including both gastric and duodenal ulcer.

While the majority of infected individuals remain asymptomatic with only chronic gastritis, some may progress further to a permanent loss of epithelial glands termed atrophic gastritis, a recognized risk factor for gastric cancer. Another determinant of disease outcome involves the pattern of gastritis within the stomach, although the drivers of each particular pattern remain unknown. Antral-predominant gastritis is associated with duodenal ulceration in contrast to corpus-predominant or pan-gastritis which are both associated with gastric ulcer and gastric adenocarcinoma (Fig. 6).

Peptic Ulcer Disease

Gastric and duodenal ulcers are mucosal defects that penetrate the muscularis mucosa and typically appear in areas where mucosal inflammation is most severe. Peptic ulcer disease is a chronic, relapsing disease that causes significant morbidity and mortality due to pain, bleeding and perforation of the gastric mucosa. Nearly 70% of all gastric ulcers and 95% of duodenal ulcers are attributable to *H. pylori* infection. However, eradication of *H. pylori* allows most peptic ulcers to heal and prevents further relapse.

Mechanistically, gastric ulcers originate from prolonged, intimate contact between *H. pylori* and the gastric epithelium. This interaction leads to continuous inflammation in the gastric antrum, thereby perpetuating mucosal breakdown, erosive gastritis, and eventually gastric ulceration. Conversely, the mechanism by which *H. pylori* promotes duodenal ulceration is not completely understood. The leading hypothesis is that *H. pylori*-induced high levels of gastric acid secretion in the antrum can eventually lead to replacement of intestinal-type tissue in the duodenum with gastric tissue. Subsequently, *H. pylori* can then colonize the areas of gastric metaplasia and together with elevated acid levels, ultimately promote ulceration in this locale.

MALT Lymphoma

Normal gastric mucosa does not typically contain lymphoid tissue, however colonization with *H. pylori* recruits mucosa associated lymphoid tissue (MALT). In very rare instances, the chronic expression of cytokines released by T-cells involved in combating *H. pylori* infection can ultimately support the uncontrolled growth and proliferation of a monoclonal population of B lymphocytes leading to MALT lymphoma. Almost all MALT lymphoma patients are *H. pylori*-positive, however this disease manifests in less than 1% of *H. pylori* infected individuals. If found early, *H. pylori* eradication can lead to complete remission in more than 80% of patients.

Gastric Adenocarcinoma

Infection with *H. pylori* is the single greatest risk factor for the development of noncardia gastric adenocarcinoma, with nearly 89% of cases attributable to infection. Due to its association with gastric carcinogenesis, the World Health Organization has classified *H. pylori* as a type I carcinogen. Among infected individuals, the risk of developing gastric cancer is between 1% and 2%. The

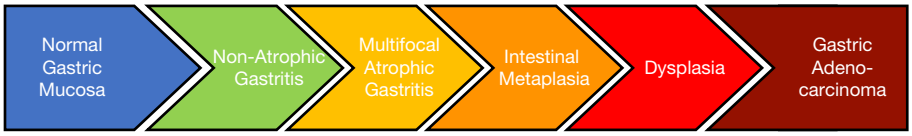

Fig. 7 Schematic of the Correa Cascade representing the histological progression from normal gastric mucosa to gastric adenocarcinoma.

progression from superficial gastritis to adenocarcinoma is a lengthy process taking 15–20 years to move through a series of progressive histological steps termed the Correa Cascade (Fig. 7). *H. pylori* eradication can reduce the risk for gastric cancer if therapy occurs prior to the onset of premalignant histological changes.

The chronic inflammatory process resultant from infection is the primary mechanism of *H. pylori*-induced carcinogenesis. *H. pylori* can decrease apoptosis and promote cell survival, which, in a highly proinflammatory environment rich in free radicals, can subsequently increase the likelihood of DNA damage and DNA mutations within host cells. In addition, the T_H17 immune response elicited by *H. pylori* can enhance carcinogenesis because the secreted cytokine profile favors angiogenesis and tumor invasiveness. *H. pylori* also induces a robust T_H1 response which does have antitumorigenic properties, however the tolerogenic T_{Reg} response also elicited by *H. pylori* to dampen the proinflammatory response can simultaneously inhibit antitumor activity.

Extragastric Diseases

Helicobacter pylori has been implicated in a variety of extragastric diseases due to its coevolutionary history with humans, its immunomodulatory properties, and its antigenic molecular mimicry. As of 2017, studies have been conducted investigating the role of *H. pylori* infection in diseases ranging from neurological disorders (including Alzheimer's and Parkinson's diseases) cardiovascular diseases, skin diseases, metabolic disorders (including type II diabetes, obesity and nonalcoholic fatty liver disease), and cancers occurring outside of the stomach (including colorectal and pancreatic), as well as a potential protective effect of *H. pylori* infection against allergy and autoimmune diseases (including inflammatory bowel disease and asthma) and esophageal diseases (including gastroesophageal reflux disease and esophageal adenocarcinoma). The epidemiological evidence linking the role of *H. pylori* to these diseases is not yet definitive and requires significant further investigation.

Treatment and Prevention Strategies

H. pylori Detection Strategies

The diagnosis of *H. pylori* was pioneered by Marshall and Warren in the 1980s, including serology and urease testing. Since then further tests have been developed and refined, each with specific advantages and disadvantages. These tests can be categorized into two groups: invasive tests based upon gastric biopsies collected during endoscopy to be used for histological analysis, bacterial culture, or molecular/biochemical assays; and noninvasive tests based on peripheral samples such as blood, stool, or saliva (Table 1). Typically in clinical practice one type of test is sufficient for diagnosis, however in laboratory research-based settings a combination of at least two tests are used to determine the status of *H. pylori* infection.

Noninvasive tests

Noninvasive tests for *H. pylori* include serology, urea breath test, and stool antigen testing. Serological methods are preferred for large epidemiological studies and can be used clinically for primary diagnosis of *H. pylori* infection due to its high sensitivity and specificity. However, serological methods are not useful in assessing successful eradication as *H. pylori* antibody titers fall gradually and can remain long after the infection is cleared.

In contrast, the urea breath test (UBT) can be used to detect primary infection and follow-up testing for successful eradication. The UBT involves ingestion of carbon labeled (^{13}C or radio-labeled ^{14}C) urea, and if *H. pylori* are present, the urea will be hydrolyzed yielding labeled carbon dioxide which can be detected in breath samples. The sensitivity and specificity range from 88% to 95% and 95% to 100%, respectively. False negatives can arise in patients who have recently taken proton pump inhibitors (PPIs), bismuth, or antibiotics or patients with active ulcer bleeding.

Stool antigen testing (SAT) is based upon an enzymatic monoclonal immunoassay that detects *H. pylori* antigens in feces. The detection of *H. pylori* antigens is representative of an active infection and can thus be used as tool for both primary diagnosis as well as confirmation of successful eradication. Similar to the UBT, the sensitivity and specificity are high (94% and 97%, respectively) and the results can be complicated by use of PPIs, bismuth, antibiotics, and peptic ulcer bleeds. In regions of low to intermediate *H. pylori* prevalence, the SAT is the most cost-effective diagnostic tool compared to serological assays and the UBT.

Invasive (endoscopy-based) tests

Endoscopy is not required solely for the purpose of *H. pylori* diagnosis, however if a patient has undergone an upper endoscopy and gastric biopsies retrieved, the biopsies can be used to assess *H. pylori* infection. Clinical diagnostic tests for *H. pylori* infection based on biopsies include urease testing, histology, or bacterial culture. Similar to the UBT, biopsy samples can be placed in medium

Table 1 Summary of diagnostic methods for the detection of *Helicobacter pylori* infection

Diagnostic method	*Specimen type*	*Application*	*Remarks*
Invasive methods			
Histology	Mucosal biopsy (at least 2)	Primary diagnosis	Pros: Also provides patient histology data (i.e., Inflammation, atrophy) Cons: Requires high expertise, multiple biopsies, high intra-observer variability
Culture	Mucosal biopsy	Primary diagnosis	Pros: Can be used to quantify antibiotic resistance, high specificity Cons: Low sensitivity and slow detection time
Rapid urease test	Mucosal biopsy	Primary diagnosis	Pros: Rapid results (~1 h), least expensive endoscopy-based method, kits commercially available Cons: Requires additional tests to confirm *H. pylori*
Noninvasive methods			
Urea breath test (UBT)	Breath sample	Primary and follow-up diagnoses	Pros: "Gold standard" of noninvasive tests. Cons: False negatives frequently occur in patients who have recently taken antibiotics or PPIs, or those who have an ulcer bleed.
Stool antigen test (SAT)	Stool	Primary and follow-up diagnoses	Pros: Most cost-effective option in populations with low to intermediate *H. pylori* prevalence Cons: False negatives frequently occur in patients who have recently taken antibiotics or PPIs, or those who have an ulcer bleed.
Serology	Serum	Primary diagnosis or indication of ever infection	Pros: Most cost effective for large population (epidemiological) studies Cons: Cannot discriminate between active and prior infection
Research-based methods			
PCR	Gastric juice, stool sample, mucosal biopsy	Research only	Pros: Highly specific, diversity of samples available for analysis, yields high amounts of microbe-specific data (i.e., Virulence factors, antibiotic resistance) Cons: Cost prohibitive for clinical use

containing urea and a pH reagent. The enzymatic breakdown of urea by *H. pylori* urease yields ammonia and bicarbonate resulting in a change in pH that is visualized by a color change of the pH reagent. Commercially available test kits yield a sensitivity and specificity of 90% and 95% respectively with results in about an hour. This test is the least expensive compared to other invasive tests and is thus the preferred method when endoscopy is used. Alternatively, biopsies can be assessed by histological examination for *H. pylori* with a hematoxylin and eosin stain (H&E) however the implementation of Giemsa, Steiner, or Warthin-Starry stains or through specific immunohistochemical means can make detection easier. Multiple biopsies from both the antrum and corpus should be examined as the density of *H. pylori* can be highly variable at different sites. Lastly, biopsies may be used for direct bacterial culture to diagnose *H. pylori* infection. Although this modality is highly specific and allows for simultaneous antibiotic resistance measurements, it is the least common diagnostic test because of its low sensitivity. The low sensitivity is attributable to the highly fastidious nature of *H. pylori*, which makes it difficult to recover and grow from biopsy specimens. Other uncommonly used diagnostic tests include PCR-based strategies on biopsy tissue or stool samples, however those are typically limited to research-only settings due to the high cost of the assay.

Treatment Strategies

Current guidelines in the United States state that when a physician chooses to test a patient for *H. pylori*, they should be unequivocally committed to eradication therapy if the patient tests positive. Although *H. pylori* is susceptible to many antibiotics in vitro, the gastric niche protects the bacteria from efficacious single-treatment therapies due to the low pH and the high viscosity of the mucus layer. In general, treatments for *H. pylori* involve an acid reducer such as a proton pump inhibitor (PPI) to reduce acid output with the addition of two antibiotics. First line treatment options for *H. pylori* include (1) clarithromycin triple therapy, (2) levofloxacin triple therapy, (3) Bismuth quadruple therapy (4) concomitant therapy (5) sequential therapy, (6) fluoroquinolone sequential therapy, or (7) hybrid therapy (**Table 2**). The most important predictors of successful *H. pylori* eradication are the choice of treatment regimen, patient adherence, and the sensitivity of the *H. pylori* strain to the combination of antibiotics. Unfortunately, the frequency of treatment failures is growing due to increasing antimicrobial resistance to clarithromycin and metronidazole. Four to six weeks after treatment, patients should be retested for *H. pylori* via UBT, SAT, or endoscopy-based methods. If the *H. pylori* infection is not successfully eradicated, second line therapies should be selected based upon which antibiotics were used in first-line therapies, as well as the local antibiotic resistances in the area. Metronidazole resistance is the most common, with 75% of strains in Africa and 46% in Asia and 30% of strains in Western countries demonstrating resistance. Recently, a new class of acid reducers termed potassium competitive acid blockers (P-CAB) have emerged as a more potent alternative to PPIs and may benefit

Table 2 Summary of *Helicobacter pylori* treatment regimens

H. pylori *treatment regimen*	*Drug(s)*	*Duration*
Triple therapy	(1) Either clarithromycin or levofloxacin (2) Amoxicillin (or other metronidazole) (3) PPI	10–14 days
Bismuth quadruple therapy	(1) Bismuth (2) Tetracycline (3) A Nitroimidazole (4) PPI	10–14 days
Concomitant therapy	(1) Clarithromycin (2) Amoxicillin (3) A Nitroimidazole (4) PPI	10–14 days
Sequential therapy	(1) Amoxicillin (2) PPI Followed by: (1) Amoxicillin (or fluoroquinolone) (2) Clarithromycin (3) A Nitromidazole (4) PPI	5–7 days 5–7 days
Hybrid therapy	(1) Amoxicillin (2) PPI Followed by: (1) Amoxicillin (2) Clarithromycin (3) A Nitromidazole (4) PPI	7 days 5–7 days

H. pylori eradication strategies. To date, P-CAB has been tested in triple therapy regimens and has shown to increase *H. pylori* eradication rates compared to PPIs, however its efficacy in quadruple, sequential or bismuth-containing therapies have not yet been studied.

Prospects of a Vaccine

As the complexity of *H. pylori* treatment increases and antimicrobial resistance continues to grow, a therapeutic vaccine could be a possible long-term solution to manage an *H. pylori* infection. Since *H. pylori* infection is acquired in early childhood and the possibility exists that infection may actually be beneficial in childhood, a therapeutic vaccine to eradicate the bacteria is the preferred strategy as opposed to prophylaxis. Formulations for vaccines have been attempted using whole cell lysates, outer membrane vesicles, as well as single or multiple purified antigens such as CagA, VacA, NapA, urease, and catalase. Some studies conducted in animals have shown that *H. pylori* vaccines can cure infection, while other studies have shown that *H. pylori* vaccination can augment the efficacy of antibiotic therapy and prevent recurrence. To date, progress on a human vaccine has been slow. The most recent study involved a phase 3 trial in China which demonstrated an approximately 70% protective effect of an orally administered *H. pylori* vaccine (based upon a recombinant urease B protein) in children aged 6–15 years, however the efficacy began to deteriorate after one year.

Population Screening

Interventional strategies such as eradication therapy, in conjunction with improved living conditions and hygiene across much of the world, have led to a significant decline in *H. pylori* prevalence over the recent decades. However, despite the decreasing prevalence of *H. pylori*, gastric cancer incidence is projected to rise as a result of changing population demographics. As such, there remains a need to reduce the number of future gastric cancer cases through eradication of *H. pylori*. Universal test and treat strategies among healthy, asymptomatic individuals within high gastric cancer-risk populations could reduce the incidence of gastric cancer in a cost-effective way. Furthermore, the cost-benefit of *H. pylori* eradication is increased when considering the benefit of reducing the incidence of other diseases such as peptic ulcer and dyspepsia. However, arguments against universal test and treat strategies include: (1) findings that *H. pylori* infection has been associated with other gastrointestinal and nongastrointestinal diseases where it may serve a beneficial role to the host; and (2) the impact of large-scale eradication therapy on antimicrobial stewardship remains unknown. Nonetheless, the growing consensus in the field suggests that population screening for *H. pylori* is a worthwhile endeavor to prevent premalignant and malignant gastric lesions.

Prospective Vision

H. pylori is the most successful bacterial pathogen worldwide, coevolving with its human host for millennia and infecting over 50% of the global population. Yet, it was not identified as a stomach pathogen until the late 20th century by the Nobel Prize-winning physicians Barry Marshall and Robin Warren. Their landmark discovery ultimately revolutionized the field of gastroenterology, providing an etiological cause for both peptic ulcer disease and gastric cancer. Laboratory investigations of this Gram-negative, spiral-shaped, microaerophilic organism have yielded the identification of numerous and highly specific virulence factors that enable its initiation and colonization in the mucus gel layer between the gastric lumen and the epithelial cell surface. Research has also illuminated many of the strategies employed by *H. pylori* to both persist in the highly inhospitable environment of the human stomach and to evade innate and adaptive immune responses. Simultaneously, in concert with improved hygiene and sanitary conditions around the world, clinical investigations have borne effective detection and treatment strategies that have contributed to the declining prevalence of this bacterium over the past several decades. Despite these advancements, *H. pylori* prevalence remains very high in developing nations and, as the global population continues to age, it is expected that we may still see an increase in lives lost from *H. pylori*-induced gastric diseases in the years ahead. As the diseases that result from *H. pylori* infection include not only those of the stomach but also potentially numerous extragastric diseases, noninvasive testing followed by eradication therapy for those in high-risk populations could significantly reduce the morbidity and mortality from this common bacterial pathogen.

Glossary

Cell cycle checkpoints Regulatory mechanisms at various phases of the cell cycle to ensure the correct completion of cellular processes crucial to the survival of a cell. Checkpoints are important for faithful DNA replication and the prevention of uncontrolled cell division.

Chromosomal instability A higher than normal rate of missegregation of chromosomes or parts of chromosomes during mitosis due to defective cell cycle quality control mechanisms.

Dysplastic nodule A focal nodular region (≥ 1 mm) showing nuclear atypia with increased fat or glycogen in a cluster of dysplastic cells. Dysplastic nodules are often associated with cirrhosis but without definite evidence of malignancy.

Edmondson-Steiner grading A 4-point scale describing the extent of differentiation of hepatocellular carcinoma cells and their resemblance of normal hepatocytes. It is the most widely used system for histologic grading of hepatocellular carcinoma.

Telomerase reverse-transcriptase A catalytic subunit of the enzyme telomerase, which maintains telomere ends by the addition of the telomere repeat TTAGGG. Reactivation of telomerase activity allows cells to overcome replicative senescence and to escape apoptosis.

WNT signaling pathways A series of signal transduction pathways responsible for passing signals into a cell through cell surface receptors. The three WNT signaling pathways described are the canonical WNT pathway, the non-canonical planar cell polarity pathway, and the non-canonical Wnt/calcium pathway.

Introduction

Liver cancer was responsible for an estimated 782,000 new cancer cases and nearly 746,000 deaths in 2012. Unlike most other malignancies, mortality from liver cancer has increased significantly over the past 20 years and the medical and economic burden of liver cancer will likely increase significantly in Western populations over the next decades. Of primary liver cancer cases, hepatocellular carcinoma (HCC) accounts for >90%. HCC is the sixth most common cause of cancer and third most common cause of death worldwide, accounting for nearly 10% of cancer deaths worldwide. Currently, curative treatment options for early-stage HCC detected by screening (one lesion <5 cm or up to three lesions <3 cm) involve resection and/or liver transplantation, with a >50% 5-year survival. Prognosis for patients with late-stage, inoperable HCC is poor with >90% mortality, particularly for cases associated with high serum α-fetoprotein (AFP) levels or *TP53* mutation. Until 2016, sorafenib, a multi-kinase inhibitor, remained the only approved systemic agent for HCC but only prolongs patient survival by 2.8 months. In 2017, regorafenib, a multi-kinase inhibitor, and nivolumab, a PD-1 inhibitor, were approved as second-line treatments following sorafenib, bringing the total number of approved systemic agents to three, far fewer than most other cancer types.

HCC shows great variation in incidence according to geographical regions. Around 80%–85% of HCCs are related to hepatitis B (HBV) and/or hepatitis C virus (HCV) chronic infection. In sub-Saharan Africa and South-East Asia, HBV chronic infection is endemic and accounts for the majority of HCCs diagnosed. In Western populations, however, the rising incidence of HCC is attributed to the increasing prevalence of chronic liver diseases associated with HCV infection, alcohol consumption, obesity and non-alcoholic fatty liver disease (NAFLD). Patients with hereditary diseases such as hemochromatosis or α-1-antitrypsin deficiency are also at increased risk of cirrhosis and fibrosis and, thus, of HCC. The male gender, exposure to aflatoxin B1 through dietary consumption and smoking are also known risk factors.

In about 80% of cases, HCCs arise in cirrhotic livers or in livers with advanced fibrosis. In fact, regardless of etiologies, liver cirrhosis is considered the major clinical risk factor. The 5-year cumulative risk for HCC in patients with cirrhosis ranges between 5% and 30%, depending on the cause (with the highest risk among those infected with HCV), region or ethnic group (17% in the United States and 30% in Japan) and stage of cirrhosis (with the highest risk among patients with decompensated disease). Although liver cirrhosis itself is not considered pre-malignant per se, there is increasing evidence to support a multistep model of hepatocarcinogenesis. Following hepatic injury resulting from one or more of HBV, HCV, excessive alcohol, exposure to aflatoxin B1 and/or other agents or conditions, necrosis develops followed by hepatocyte proliferation. Repeated cycles of this destructive-regenerative process lead to chronic liver condition that culminates in liver cirrhosis. Subsequently, hyperplastic nodules arise, followed by dysplastic nodules, resulting in the development of HCC. HCCs that occur in the absence of cirrhosis may present with unique clinicopathologic features, such as the fibrolamellar subtype that is predominantly diagnosed in young female patients.

Traditional pathology analyses have revealed the extraordinary histologic and phenotypic heterogeneity of HCCs. In fact, our understanding of HCC pathology is still evolving, with the last update of the WHO classification including substantial updates on the classification and diagnosis of early HCCs and lesions thought to derive from progenitor cells. From a diagnostic point

of view, the increased detection of small and early lesions in screening programs has highlighted the difficulties in distinguishing benign, precursor, and early HCC lesions. In addition, the advances in next-generation sequencing in recent years have also revealed the startling molecular heterogeneity of HCCs, with many deregulated pathways through an accumulation of somatic genetic and epigenetic changes in the cells.

Pathology of HCC

Precursor Lesions of HCC

Hepatocellular adenoma

Hepatocellular adenoma (HCA) is a benign neoplasm that sometimes undergoes malignant transformation into HCC. HCA is diagnosed predominantly in young women using oral contraceptives. Less commonly, it has been described in female patients with maturity onset diabetes of the young type 3, and in men using anabolic steroids, with glycogen storage disorders or receiving androgen treatment. Recently, metabolic syndrome, obesity and alcohol have also described as likely risk factors of HCA, in particular of the inflammatory subtype. Patients with HCA have normal liver function, but may occasionally have elevated serum AFP levels. Unlike other precursor lesions of HCCs, HCA is uncommonly associated with cirrhosis.

HCA is typically a large (up to 30 cm in diameter) tumor that resembles normal liver tissue microscopically but may display a pseudoglandular architecture. Large cell and fatty changes are often seen, but the cells have regular nuclei without atypia and mitoses are almost never present. In 20%–30% of cases, multiple HCAs may be present. The reticulin framework is usually present, bile ducts are absent and the sinusoids are usually compressed.

In general, the risk of transformation to HCC has been reported to be between 4% and 8%. Increased risk has been reported in male patients, patients presenting with large HCA (but not the number of HCAs), with pseudogland formation.

Molecular classification has divided HCA into several subgroups linked with distinct risk factors, clinical behaviors, histologic as well as imaging features: HNF1A-inactivated HCA, inflammatory HCA, *CTNNB1* exon 3-mutated HCA, *CTNNB1* exons 7 or 8-mutated HCA, sonic hedgehog HCA and unclassified HCA. *CTNNB1* exon 3-mutated HCA and sonic hedgehog HCA have been linked to high risk of malignant transformation and bleeding, respectively. Liver fatty acid-binding protein, serum amyloid A, C-reactive protein, prostaglandin D2 synthetase, glutamine synthetase, and β-catenin can be used either on biopsy or surgical specimen to classify HCA into these subclasses.

Transformed HCA typically appears as well differentiated HCC within the HCA with vascular invasion.

Dysplastic foci

Dysplastic foci are microscopic (<1 mm in diameter), uniform non-invasive lesions that differ from surrounding liver tissue based on morphology, cytoplasmic staining, nuclear size and cellular atypia. Dysplastic nodules are usually incidental findings and are usually found within cirrhotic nodules. Dysplastic hepatocytes within these foci may display large cell change, small cell change or iron-free foci.

Large cell change refers to hepatocytes with nuclear and cytoplasmic enlargement (thus retaining the nuclear/cytoplasmic ratio), associated with nuclear pleomorphism, multinucleation, and hyperchromasia. Large cell change may encompass dysplasia as well as reactive changes, and its precise role as an HCC precursor lesion is unclear. Studies reporting low cell proliferation, increased apoptosis and association with cholestasis support the notion that large cell changes are reactive changes. On the other hand, other studies have reported increased proliferation, telomere shortening and abnormal DNA content, including chromosomal copy number aberrations, leading to the hypothesis that large cell changes are indeed precursor lesions, especially in cirrhosis associated with HBV or HCV.

By contrast, small cell change refers to hepatocytes with decreased cell volume, mild nuclear pleomorphism, increased nuclear/cytoplasmic ratio, basophilic cytoplasm and hyperchromasia. Hepatocytes with small cell change typically show increased cell proliferation, inactivation of cell cycle checkpoint and telomere shortening. Morphologically, small cell change resembles well differentiated HCC. Importantly, while expansile small cell changes foci are considered dysplastic foci, a diffuse pattern is considered regenerative changes. Compared to large cell changes, small cell changes are considered more advanced.

Iron-free foci are proliferative lesions consisting of clusters of hepatocytes devoid of or low in iron content. Large or small cell change may be present. The precise clinical significance of iron-free foci is not clear, but it has been suggested that iron-free foci arising in livers with hereditary hemochromatosis are likely HCC precursor lesions.

Dysplastic nodules

Dysplastic nodules are larger than dysplastic foci and are defined as those ≥ 1 mm in diameter, usually around 1 cm in diameter. Dysplastic nodules are detectable macroscopically and sometimes radiologically. Similar to dysplastic foci, dysplastic nodules are also usually found on a cirrhotic background and may occur as single or multiple nodules. Macroscopically, dysplastic nodules are distinctly nodular lesions that differ from surrounding liver tissue based on color and texture, and may bulge from the surface of the liver (Fig. 1).

Dysplastic nodules are subdivided into low and high grades (LGDN and HGDN), with HGDNs associated with an increased risk of malignant transformation. LGDN shows minimal architectural atypia, mildly increased cell density, with normal to slightly elevated nuclear/cytoplasmic ratio, no mitoses and 1–2 cell wide cell plates. The borders of LGDN may be rounded

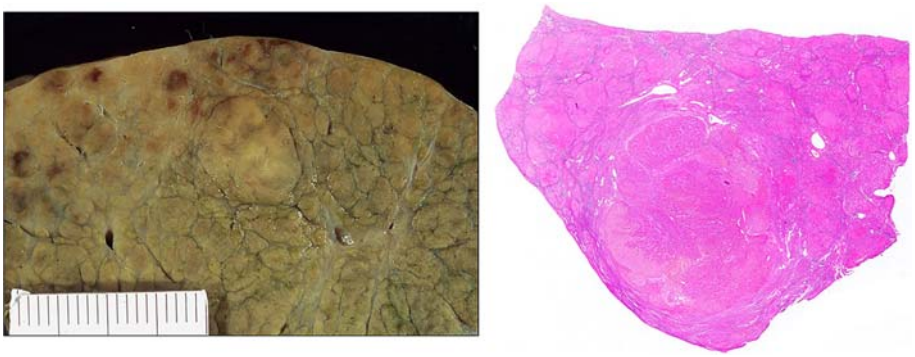

Fig. 1 Macroscopic and microscopic images of a dysplastic nodule. Macroscopic image of a liver dysplastic nodule taken during a routine procedure (*left*) and micrograph of hematoxylin and eosin stain (*right*).

but do not usually compress the adjacent liver tissue. Portal tracts and the reticulin network are retained. Steatosis and Mallory bodies may be present. Large cell change, but not small cell change, may also be present. However, histologic diagnosis of LGDN has not been found to be reproducible in practice, because of significant overlapping features with large regenerative nodule. By contrast, HGDN histologically and molecularly resembles HCC. In particular, HGDN displays significant architectural and cytologic atypia, including enlarged and irregular nuclei, nuclear hyperchromasia, peripheral location of the nucleus, occasional mitosis, thickening of hepatic cell plates (>2 cells), basophilic cytoplasm, formation of pseudoglands, focal loss of the reticulin network and resistance to iron accumulation. Small cell change is frequently seen in HGDN. Some of these features may be confined to foci within the HGDN. In HGDN, portal tracts may be few and sinusoidal capillarization is increased. Neoangiogenesis may be seen in dysplastic nodules, in particular in HGDNs, including the formation of unpaired arteries with no accompanying bile ducts. Dysplastic nodules usually show an isovascular or hypovascular appearance compared to surrounding tissues (Fig. 1).

Macroscopic Features of HCC

HCCs are highly heterogeneous macroscopically. HCC typically forms soft nodular masses that vary in color from gray to light brown to yellowish-green and are often punctuated by foci of hemorrhage and necrosis. HCC associated with cirrhosis typically presents as fibrous, encapsulated nodules while HCC not associated with cirrhosis is usually unencapsulated. HCC may also present as a single or as multiple nodules, with sizes from <1 to >20 cm. Indeed, compared to other tumor types, one of the distinguishing features of HCC is the frequent occurrence of multiple nodules. The multiple nodules of HCC may represent intrahepatic metastasis, in which malignant cells are disseminated from a single primary tumor to form additional tumor nodules, or may represent independent tumors. The distinction between these two scenarios is not trivial but has important clinical implications, given that intrahepatic metastases are likely to be more poorly differentiated and aggressive than independent, single nodules that do not disseminate. Extrahepatic metastases are most frequently identified in the lungs, the lymph nodes, bone and the adrenal glands.

The WHO 2010 guidelines divide HCCs into early HCCs and progressed HCCs. Early HCC refers to single, well differentiated, vaguely nodular tumor with poorly defined margins and of <2 cm in diameter, whereas progressed HCC refers to a single tumor >2 cm in diameter, or small (<2 cm), moderately differentiated HCC of distinctly nodular type or multiple tumors. Both vaguely and distinctly nodular HCCs usually occur in a cirrhotic liver, but vaguely nodular HCCs do not have well defined margins, whereas distinctly nodular HCCs are encapsulated. Compared to the distinctly nodular type, vaguely nodular type HCCs are usually smaller in size, represent a biologically earlier stage with more favorable prognosis and are rarely associated with intrahepatic metastasis.

Macroscopically, progressed HCC may be nodular, massive or diffuse. Nodular HCC may involve one or more nodules. Single nodular HCC is usually encapsulated and may show extracapsular growth around the nodule. Multinodular (or expansive) HCC is defined by the presence of multiple nodules throughout the cirrhotic tissues, usually with one dominant nodule, with satellite nodules in the proximity. Multinodular HCC is the most common type and are typically seen in association with cirrhosis. Massive (or infiltrative) HCC is a large dominant, poorly circumscribed tumor with ill-defined invasive borders and may be associated with smaller satellite nodules. Massive HCCs tend to be larger, are more frequently seen in non-cirrhotic livers and are associated with a poor prognosis. HCC can also be mixed nodular and massive. The less frequent diffuse (or cirrhotomimetic) HCC consists of many small nodules in a growth pattern that resembles regenerative nodules. Diffuse HCC can involve either a liver lobe or the entire liver, may be associated with macroscopic portal vein and/or hepatic vein invasion and is associated with a poor prognosis. On rare occasions, HCCs may display a pedunculated or protruded growth pattern, referring to extrahepatic growth with and without a peduncle, respectively.

Additional macroscopic features of HCC include the presence of necrotic areas, involvement of portal and hepatic veins and bile or fat production.

Microscopic Features of HCC

The most distinctive features of HCC are that HCC cells resemble hepatocytes and attempt to mimic the growth pattern of normal liver cells.

Early HCC is well differentiated and consists of tumor cells with increased nuclear/cytoplasmic ratio. Early HCC typically displays trabecular or pseudoglandular, or admixed, growth pattern. Relative to surrounding liver tissues, increased cell density is usually observed. Early HCC tends to be isovascular or hypovascular with varying numbers of portal tracts, and does not show vascular invasion. The reticulin framework is reduced but not lost.

The most common presentation of progressed HCC includes the following features: one or more well vascularized tumors with vascular invasion, prominent trabecular and pseudoglandular growth pattern with small cell change, cytologic atypia with increased mitotic activity, a lack of fibrous connective tissue between tumor cords and cells, fatty change, loss of the reticulin network, and an absence of Kupffer cells. Bile canaliculi are present and bile production is frequently observed. In progressed HCC, complete neovascularization with vascular infiltration is not uncommonly seen. However, there is substantial heterogeneity between and within HCCs in terms of their architecture, cytologic features and histologic grades.

HCC may display multiple architectural patterns: (1) trabecular (or sinusoidal) pattern where tumor cells grow in cords of variable thickness separated by prominent sinusoids lined by flat endothelial cells, with the trabeculae becoming thicker and contorted with dedifferentiation; (2) pseudoglandular (or acinar) pattern with a variety of abnormal, dilated bile canaliculi forming between tumor cells, often admixed with the trabecular pattern; (3) compact (or solid pattern) where tumor displays a trabecular phenotype but the tumor cells apparently grow in solid masses compressing the sinusoids and rendering the thick trabeculae inconspicuous by compression. Progressed HCC, in particular, sometimes display all three architectural patterns. Trabecular and pseudoglandular patterns are more frequently seen in well to moderately differentiated HCCs, whereas compact is more common in poorly differentiated HCCs (Fig. 2).

HCC may also display the following cytologic variants: (1) pleomorphic cells that vary in size, shape, nuclei and/or staining patterns and are often associated with the presence of multinucleated or mononuclear giant cells; (2) clear cells resulting from the accumulation of glycogen; (3) spindle cells with sarcomatoid differentiation; (4) fatty change, most frequently observed in early HCCs; (5) bile production seen as plugs in pseudoglands; (6) hyaline (Mallory-Denk) bodies with aggregation of intermediate filaments within hepatocytes; (7) pale bodies which are round to ovoid cells with cystically dilated endoplasmic reticulum containing amorphous and lightly eosinophilic accumulations; (8) ground glass inclusions which are hepatocytes with granular, eosinophilic cytoplasm mainly resulting from HBsAg positivity.

Histologic grade

HCC cells show variable degree of resemblance to normal hepatocytes, depending on the extent of differentiation. The most widely used system for histologic grading is the Edmondson-Steiner grading. Grade I tumors display abundant cytoplasm and minimal nuclear atypia that resembles normal liver. Grade II tumors show mild nuclear atypia with prominent nucleoli and hyperchromasia. Grade III tumors show moderate nuclear atypia with greater hyperchromasia, nuclear irregularity and granular cytoplasm. Grade IV tumors show marked nuclear pleomorphism, marked hyperchromasia, loss of trabecular pattern and are often associated with anaplastic giant cells. Most HCCs are of grades II or III.

It should be noted that HCCs often vary histologically even within a single nodule. Most primary cancer nodules < 1 cm are uniformly well differentiated (grades I/II). On the other hand, around 40% of nodules between 1 and 3 cm in diameter contain tumor cells of different histologic grades, with the less differentiated tumor cells concentrated in the central regions of the tumors. Although histologic grading in liver biopsies may be subjected to tumor heterogeneity, it has been shown that tumor grade in preoperative biopsy is correlated with the final grade on resection and predicts survival of the patients. Histologic grade in preoperative biopsy tends to be lower than the grade on resection. However, compared to several other clinicopathologic factors such as tumor size, tumor stage, vascular invasion and liver function, histologic grade is a relatively weak independent prognostic indicator.

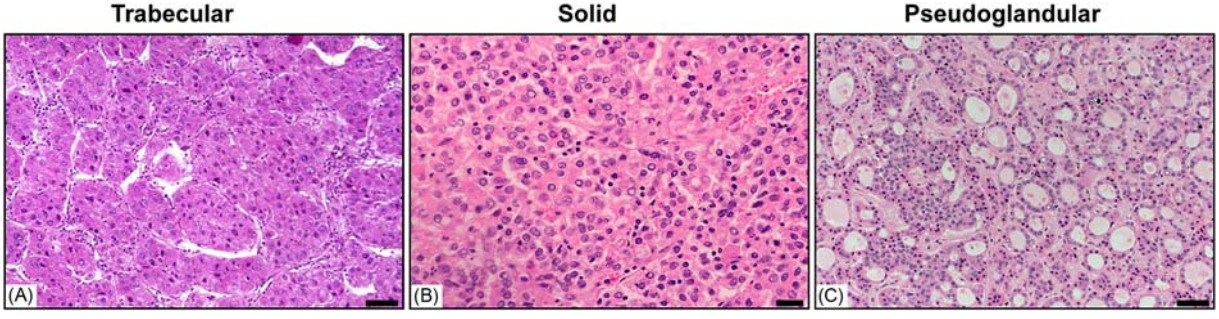

Fig. 2 Architectural patterns of HCC. Representative micrographs of the most common architectural patterns of HCC: (A) trabecular pattern (scale bar 50 μm), (B) solid pattern (scale bar 25 μm) and (C) pseudoglandular pattern (scale bar 50 μm).

Histologic variants of HCC

Fibrolamellar HCC is a rare variant of HCC, accounting for $<1\%$ of liver tumors. The majority of fibrolamellar HCC ($\sim 85\%$) is diagnosed in children and young adults <35 years old. Fibrolamellar HCC is characterized by well differentiated and eosinophilic tumor cells with prominent nucleoli growing between laminated collagen fibrous layers that show a lamellar pattern. This type of HCC is typically large and well circumscribed, grows with pushing borders and is often hyalinized. In some cases, fibrolamellar HCC resembles nodular hyperplasia, with a central scarred zone that is often calcified. Cytoplasmic inclusions are common, and may include Mallory bodies, pale bodies and/or cytoplasmic globules of variable positivity to PAS and immunoreactivity to anti-fibrinogen. In contrast to classical HCC, fibrolamellar HCC is reported to show abundant cytokeratin (CK) 7 and focal CK19 expression. Among the histologic variants of HCC, fibrolamellar HCC is unique as it is usually diagnosed in the absence of cirrhosis. Despite the usually large tumor size at diagnosis, fibrolamellar HCC has better prognosis than classical HCC, in part due to the fact that it is usually diagnosed in young patients not associated with primary risk factors and that the tumor can usually be resected surgically. Metastases are sometimes seen and most frequently seen in the peritoneum, the lungs and abdominal lymph nodes.

Sarcomatoid HCC is seen in $\sim 2\%$ in HCCs, alone or within classical HCC. Sarcomatoid HCC is fully or partially composed of spindle-shaped cells and shows bizarre anaplastic features that resemble those seen in leiomyosarcoma and fibrosarcoma. Giant cells may also be present. Patients with sarcomatoid HCC have been reported to show low serum AFP levels and frequently present with distant metastases. Sarcomatoid HCC has been associated with repeated chemotherapy and/or transarterial chemoembolization. Other clinical features are similar to classical HCC.

Scirrhous HCC accounts for $<5\%$ of HCCs and is characterized by the presence of diffuse fibrotic changes, alone or in conjunction with classical HCC. The tumor is usually large and unencapsulated with serrated border. Microscopically, the fibrosis is usually seen along the sinusoid-like blood spaces separating trabecular cell plates, often of >3 cells thick. Scirrhous HCC typically does not display prominent nucleoli and has granular eosinophilic cytoplasm. Scirrhous HCC is associated with hypercalcemia but not with bone metastasis. Scirrhous HCC is often misdiagnosed as post-therapy fibrosis, cholangiocarcinoma or metastatic tumors due to the presence of diffuse fibrosis. Scirrhous HCC differs from fibrolamellar HCC in terms of its lack of lamellar fibrosis and central scar, and the presence of cirrhosis.

The clear cell variant of HCC is characterized by the presence of tumor cells with clear cytoplasm due to cytoplasmic fat or glycogen. Predominant appearance of clear cell change is seen in up to 20% of HCCs and some degree of clear cell change can be found in up to 40% of HCC. The clear cell variant of HCC may display trabecular, pseudoglandular, solid or mixed architectural pattern. The clear cell variant is reported to be more frequently diagnosed in male patients.

Steatohepatic-type HCC is more frequently seen in patients suffering from non-alcoholic steatohepatitis and is characterized by the steatotic appearance in $>5\%$ of the tumor, including the presence of Mallory bodies, fibrosis, inflammation and the ballooning of hepatocytes. If present, the fibrosis usually displays a trabecular or a pericellular pattern. Inflammatory infiltrates, if present, usually consist of neutrophils, plasma cells and lymphocytes.

HCC with lymphoid stroma has been described in a few case reports and is defined by the presence of prominent inflammatory infiltrates. Lymphocytes make up the majority of the stroma, with the presence of some macrophages, plasma cells, neutrophils and/or giant cells. The T-cells are mostly CD4+. The existence of HCC with lymphoid stroma as a distinct entity is controversial, with some suggesting that the lymphoid stroma merely represents a regression phenomenon.

Differential Diagnosis of HCC

While the diagnosis of poorly to moderately differentiated HCC is usually straightforward, differentiating HCA and well differentiated HCC, or HGDN and well differentiated HCC presents significant diagnostic difficulty. The identification of surrogate markers to distinguish early HCC from pre-malignant lesions is also a major issue in clinical management. Additionally, metastasis from other organs may resemble primary HCC. Differential diagnosis of HCC involves the use of hematoxylin & eosin (H&E) stain, reticulin stain (loss of reticulin), and immunohistochemistry (IHC).

HCA versus well-differentiated HCC

Differential diagnosis of well differentiated HCC from HCA is based on a combination of increased mitotic activity, nuclei atypia, trabecular growth with thickened cell plates, vascular invasion, loss of the reticulin framework and the presence of bile ducts. HCA rarely occurs on a background of cirrhosis and are negative for glypican 3 (GPC3) and AFP. Mitoses are extremely rare in HCA. If mitoses are present, a diagnosis of HCC should be considered. CD34+ arterialized sinusoids are preferentially found in HCC.

High-grade dysplastic nodule versus HCC

Differential diagnosis between HGDN and well differentiated HCC is sometimes very difficult, given that they display very similar histologic features. Microscopically, stromal invasion is an important distinguishing feature of HCC but its identification is especially challenging in small biopsies. In a cirrhotic liver, stromal invasion may be difficult to distinguish from small clusters of hepatocytes within fibrous septae. Immunostains of CK7/9 that show a ductular reaction favors pseudoinvasion and therefore a diagnosis of HGDN. Elevated nuclear/cytoplasmic ratio, even when the nuclei do not show atypia, together with trabecular or pseudoglandular growth strongly suggest a diagnosis of well differentiated HCC. The complete loss of the reticulin framework is also considered one of the strongest indicators for a diagnosis of HCC.

Several IHC markers are used to distinguish HGDN and well differentiated HCC in cirrhotic livers. A panel of three markers GPC3, glutamine synthetase and heat shock protein 70 (HSP70) has been employed. GPC3 is an oncofetal protein that is not expressed in human livers but frequently reactivated in HCC, with cytoplasmic/membranous staining in >5%–10% of cells. Positivity of glutamine synthetase, a target of β-catenin signaling, increases from LGDN to HGDN to HCC. In HCC, glutamine synthetase may show diffuse cytoplasmic positivity in >50% of cells unrelated to vessels. HSP70 is negative in non-tumor hepatocytes and its positivity correlates with the grade of the HCC, in which it shows cytoplasmic or nuclear stain in >5%–10% of tumor cells. When two of the three markers are positive, the sensitivity and specificity for detecting well differentiated HCC in resection specimens are 72% and 100%, respectively. For the detection of small (<2 cm) early well differentiated HCC by core biopsy using a 20-21G needle, the sensitivity and specificity for 2/3 markers are 50% and 100%, respectively. Adding clathrin heavy chain to the panel of three markers increases the sensitivity and specificity for the detection of small early HCCs by core biopsy to 67% and 100%, respectively.

HCC versus metastasis

In patients without underlying chronic liver disease, the vast majority of malignant tumors in the liver is from non-liver origin, particularly in Western countries. The most common sites of origin are the breasts, the lungs, colon, and pancreas. While most metastases resemble their primary tumors histologically, certain types of tumors from non-liver origin, such as clear cell adenocarcinoma, clear cell renal cell carcinoma, melanoma, neuroendocrine tumor of the gastrointestinal tract and gastrointestinal adenocarcinoma with hepatoid features, may be difficult to differentiate from primary HCC. HCC typically lacks a desmoplastic stroma, the presence of which is typical of metastatic adenocarcinomas, although HCCs of the fibrolamellar and scirrhous subtypes may contain abundant stroma. The presence of bile production, the presence of multiple types of cytologic variants usually seen in classical HCC, and/or an absence of mucin in pseudoglands would suggest predominantly hepatic phenotype.

Immunostains of arginase 1, hepatocyte paraffin-1 antigen (HepPar-1, also known as hepatocyte specific antigen), polyclonal CEA (pCEA), CD10 and various cytokeratins may help determine if the tumors show hepatocellular differentiation. Arginase-1, HepPar-1, and pCEA are positive in normal liver and almost all well differentiated HCCs. HepPar-1 shows a granular, cytoplasmic (mitochondrial) pattern of staining in ~90% of HCC. HepPar-1 may also be expressed by tumors of the gastrointestinal tract, lung, pancreas and biliary tract but in these tumors, staining is usually weak or focal. pCEA shows a distinctive canalicular pattern of staining in HCC. A diffuse cytoplasmic pCEA staining pattern would favor a diagnosis of tumors other than HCC. However, sensitivity and specificity for both markers decline with the dedifferentiation of the tumor. CD10 is negative in adenocarcinomas but shows similar staining patterns to pCEA in HCCs. AFP shows a patchy and cytoplasmic staining pattern in ~50% of HCC and its staining increases with dedifferentiation. Cytokeratins CK7, CK19, and CK20 are usually negative in HCCs and one or more is frequently positive in adenocarcinomas. The presence of liver-specific proteins such as albumin would also suggest a liver origin. Interestingly, CK19 positivity in HCC seems to correlate with clinicopathologic features of tumor aggressiveness, more invasive characteristics, compared with CK19-negative HCCs through the upregulation of epithelial-to-mesenchymal transition-associated genes.

Combined hepatocellular-cholangiocarcinoma

Combined HCC-cholangiocarcinoma (CHC) is rare and accounts for <1% of malignant liver tumors. However, unlike HCC that is believed to have arisen from mature hepatocytes through a multistep process of hepatocarcinogenesis, CHC is thought to derive from a progenitor cell that differentiates into both hepatocytes and cholangiocytes. As its name suggests, combined HCC–CHC contains intimate mixtures of HCC and cholangiocarcinoma cells and includes tumors of transitional type in which the tumor cells display morphologic features intermediate of HCC and cholangiocarcinoma. CHC is usually positive for CK7 and CK19 although positivity is also occasionally seen in HCC. CHC must be also distinguished from collision tumors.

The WHO subclassifies CHC into the classical subtype and the subtype with stem cell features. The more common classical subtype consists of tumor cells with classical features of HCC and cholangiocarcinoma, in which the HCC component may be identified by cytoplasmic staining of HepPar-1 and canalicular staining of pCEA and CD10, and the cholangiocarcinoma component with CK7/19 and epithelial membrane antigen (EMA). Additionally, the cholangiocarcinoma component may be identified using D-PAS or mucicarmine stain to show mucin production and is usually associated with abundant desmoplastic stroma. CD133 and vimentin are usually negative. Both components can be well, moderately or poorly differentiated. Foci of intermediate HCC–cholangiocarcinoma phenotype may be present. However, we have to keep in mind that the concept of stem cell features in HCC is controversial and that the definitions in the 2010 WHO classification are not precise, leading to variable interpretations. Moreover, there are no reliable immunohistochemical markers to identify stem cells.

CHC with stem cell features does not produce mucin, shows high expression of CD133, EpCAM and vimentin, but less frequent expression of HepPar-1, thus recapitulating the features of progenitor cells. The subtype with stem cell features is further subclassified into typical, intermediate and cholangiolocellular subtypes, although the subclassification remains controversial. The typical subtype consists of mature hepatocytes with high nuclear/cytoplasmic ratio and hyperchromatic nuclei on the periphery. The peripheral cells stain positive for CK7/19, CD56, EMA, c-KIT, and EpCAM. The hepatocytes in the center of the tumor may show clear cell change. The intermediate subtype displays features intermediate between hepatocytes and cholangiocytes, consisting of small cells with hyperchromatic nuclei and scant cytoplasm. The cells are arranged in trabecular, solid nests or strands. CK7/19 and EMA positivity is frequent. The cholangiolocellular subtype consists of small cells with high nuclear/cytoplasmic ratio, hyperchromasia, and oval nuclei embedded in a fibrous stroma, and grows in an antler-like intersection pattern. Cellular atypia is usually mild. CK7/9 and EMA are positive and EpCAM and CD133 expression may be increased. The cholangiolocellular subtype was

previously considered a subtype of cholangiocarcinoma but at the moment is considered part of the spectrum of CHC with stem cell features.

Genetic Alterations in HCC

HBV Integration

Recent reports attribute over 50% of HCC cases worldwide to HBV infection, which is the major cause of HCC in East Asian and sub-Saharan countries. Compared with uninfected individuals, HBV carriers have 10- to 25-fold greater risk to develop HCC.

Integration of the HBV genome into the host genomic DNA occurs randomly in infected regenerating hepatocytes, is believed to be an early event in HBV infection and is involved in the development of HBV-related HCC. Whole genome sequencing studies of HBV-related HCCs have demonstrated that HBV genome integration occurs in approximately 80% of cases with a mean of 2.5 HBV integration sites per tumor. The HBx gene (encoding for the hepatitis B viral protein) is the HBV gene most frequently integrated into the human genome and the expression of the trans-acting wild-type and truncated HBx chimeric transcript has been shown to enhance transforming potential.

The first two integration sites in the human genome were described in the early 1990s when chimera sequences formed by the fusion of the HBV genome with the *RARB* or *CCNA* genes were identified. With the advancement of sequencing technologies, various additional integration sites have been described. The most recurrent HBV integration site is in the promoter region and within the gene body of the *TERT* gene, observed in ~20% of the HBV-associated HCC. HBV has also been reported to recurrently integrate into other cancer-related genes such as *SENP5*, *ROCK1*, *MLL4*, *CCNE1*, and *SOX2*. Furthermore, HBV integration sites within repetitive or non-coding sequences such as long interspersed nuclear elements (LINEs), Alu and the long terminal repeats of endogenous retroviruses have also been reported.

The precise mechanism of HBV genome integration in the development and the progression of HCC is under active investigation. Molecular studies have demonstrated that although HBV integration does not promote HBV replication, its integration into coding genes or their promoter regions may alter the expression of the target genes and increase genomic instability. Interestingly, HBV integration into the LINE1 region results in the generation of a chimeric transcript HBx-LINE1 detected in 21 of 90 (23%) tumors of HBV-related HCC patients and is significantly associated with poor survival of HCC patients.

Chromosomal Instability

Chromosomal instability (CIN) refers to a higher than normal rate of missegregation of chromosomes or parts of chromosomes during mitosis due to defective cell cycle quality control mechanisms, resulting in copy number alterations (CNAs) or aneuploidy. CIN is frequently a consequence of genetic or epigenetic alterations in genes involved in telomere maintenance, DNA replication, chromosome segregation or cell cycle checkpoints. In the context of HCC, the most frequent alterations that result in CIN include alterations in *TERT*, *TP53*, and *CDKN2A*.

CNAs cause dosage effects on the genes located in the affected genomic regions. The non-random distribution of CNAs in HCC suggests these CNAs, in particular focal amplifications and homozygous deletions, may lead to the overexpression of oncogenes or the loss of tumor suppressor genes. Indeed, profiling HCC using comparative genomic hybridization or single nucleotide polymorphism arrays has revealed recurrent chromosomal gains of 1q, 5p, 6p, 7q, 8q, 17q, and 20q and losses of 1p, 4q, 6q, 8p, 9p, 13q, 14q, 16p-q, 17p, 21p-q, and 22q. Analyses of focal amplifications have demonstrated recurrent amplifications targeting genomic regions of *TERT* (5p15.33), *VEGFA* (6p21.1), *MYC* (8q24.21), *CCND1* and *FGF19* (11q13.3), and *CCNE1* (19q12). On the other hand, genes reported to be homozygously deleted include *IRF2* (4q35.1), *CDKN2A* (9p21.3), *PTEN* (10q23.31), *RB1* (13q14.2), and *AXIN1* (16p13.3).

Among the most commonly gained regions in HCC are copy number gains of 1q and 8q, both in around 60%–70% of HCC. The minimal amplified region 1q21 has been linked to the early development of HCC (1q21-23) and to advanced metastatic HCC cases (1q21-q22). The region has been shown to contain potential oncogenes that when overexpressed may be involved in hepatocarcinogenesis. For instance, the gene *CHD1L* has been shown to be amplified and overexpressed in HCC but not in matching normal parenchyma. Additionally, expression of *CHD1L* is positively associated with vascular invasion and has been found to be an independent predictor of decreased disease-free survival (DFS) in HCC patients after surgical resection. Chromosome arm 8q contains the well-known oncogene *MYC*, a central regulator of malignant transformation in early hepatocarcinogenesis and has also been found to be significantly correlated with DFS and overall survival (OS) in patients with HCC.

On the other hand, 4q, 8p, and 17p are the chromosome arms most frequently lost. While how 4q loss contributes to hepatocarcinogenesis is not clear, it has been linked to high levels of serum AFP and is more frequently seen in poorly differentiated HCC. The loss of chromosome arm 8p have been extensively described in the HCC. A cluster of tumor suppressor genes on 8p have been identified, including the *DLC1*, *CCDC25*, *ELP3*, *SH2D4A*, and *SORBS3* genes, and the loss of these genes has been shown to be associated with metastasis and poor prognoses for HCC patients. On chromosome 17p is the *TP53* gene, one of the most frequently mutated genes in HCC.

Compared to focal amplifications and homozygous deletions, the biological effects of gains or losses of whole chromosomes or large genomic regions are more difficult to pinpoint. There remain many important questions regarding the identification of the genes in these large CNAs that are involved in hepatocarcinogenesis and their biological and clinical implications.

Genes and Pathways Altered by Somatic Genetic Alterations

Activation of the WNT/β-catenin pathway

The WNT/β-catenin pathway is of great importance in physiologic embryogenesis, zonation, and metabolic control in the liver. The WNT/β-catenin pathway can be classified into canonical and non-canonical pathways (based on the dependency of β-catenin). β-catenin, encoded by the *CTNNB1* gene, plays a pivotal role in the regulation of the canonical WNT signaling pathway. In the absence of WNT, cytoplasmic β-catenin protein is phosphorylated at serines 33, 37, and 45, and threonine 41 residues by the Axin complex (composed of Axin, APC, CK1, and GSK3) and then ubiquitinated and degraded by β-Trcp ubiquitin ligase. Activation of Wnt signaling induces the stabilization and translocation of β-catenin to the nucleus, where it associates with transcription factors of the TCF family and generates a functional complex able to transactivate several genes involved in the cell cycle control and proliferation, such as *MYC*, *CCND1*, *MT-CO*$_2$, and *MMP7*.

Dysregulation of the WNT pathway has been observed in 40%–70% of HCCs suggesting a major role of this pathway in HCC development. Processes WNT signaling regulates include angiogenesis, infiltration and metastasis by regulating the expression of angiogenic factors such as MMP-2, MMP-9, VEGF-A, and VEGF-C. The most common mechanism of β-catenin activation in HCC is through mutation of the *CTNNB1* gene, identified in about 40% of HCC. The majority of the *CTNNB1* mutations occurs at mutation "hotspots" in exon 3, specifically at the four phosphorylation sites. Mutation of serine/threonine residues results in impaired Axin/APC/GSK3b mediated degradation of β-catenin and the gain of oncogenic activity. HCCs with *CTNNB1* mutation display a specific transcriptomic profile with the overexpression of glutamine synthetase (encoded by *GLUL*) and leucine rich repeat containing G protein-coupled receptor 5 (encoded by *LGR5*), as well as increased expression of glutamine synthetase on the protein level. Other alterations that lead to an upregulation of WNT signaling include mutations or homozygous deletions of *AXIN1* (5%–15%), *AXIN2* (3%), and *APC* (1%–2%).

Several studies demonstrated a critical role of the deregulation of WNT/β-catenin signaling in hepatocarcinogenesis. HCV-positive HCC tends to be associated with frequent *CTNNB1* mutations. *CTNNB1* mutations have been found to be associated with macrovascular and microvascular invasion and increased tumor size. At the same time, HCCs characterized by the activation of the Wnt/β-catenin pathway exhibit specific features such as high differentiation associated with a homogeneous microtrabeculo-acinar pattern, low-grade cellular atypia, and cholestasis. Moreover, WNT/β-catenin signaling has been shown to play an important role in the activation of oval cells, considered to be hepatic stem cells, and HCCs with stem cell signatures have a more aggressive behavior. However, the clinical implications of *CTNNB1* activating mutations in terms of overall survival and disease recurrence have been contradictory. These findings demonstrate an essential role of the Wnt signaling in hepatocarcinogenesis and suggest that targeting this pathway may be promising for therapeutic options (**Figs. 3** and **4**).

Alterations in TP53 and cell cycle signaling pathway

TP53 is the most frequently mutated gene in human cancers. The p53 protein modulates multiple cellular functions, including transcription, DNA synthesis and repair, cell cycle arrest, senescence and apoptosis. Mutations in *TP53* can abrogate these functions, leading to genomic instability and progression to cancer. In HCC, *TP53* is one of the most frequent mutated genes and its

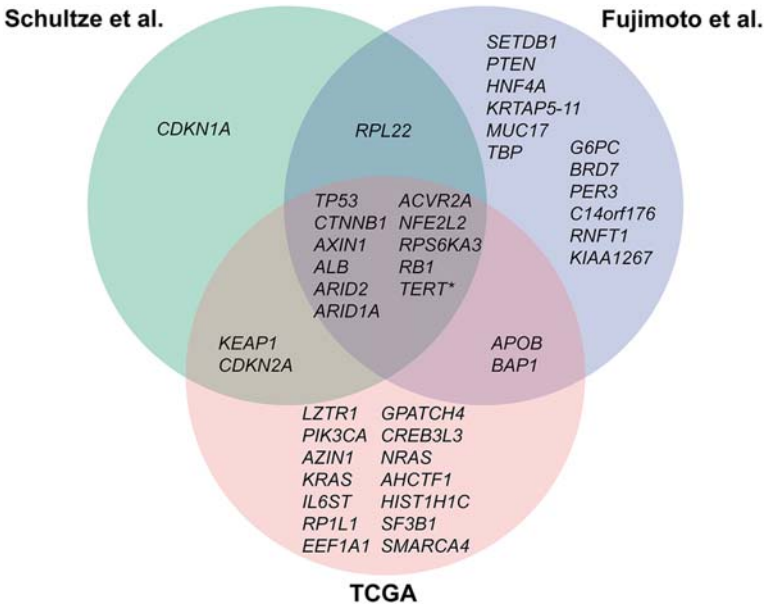

Fig. 3 Significantly mutated genes in HCC. Venn diagram illustrates the significantly mutated genes in HCC identified in three seminal studies that described in the genomic landscape of HCC. *Promoter region.

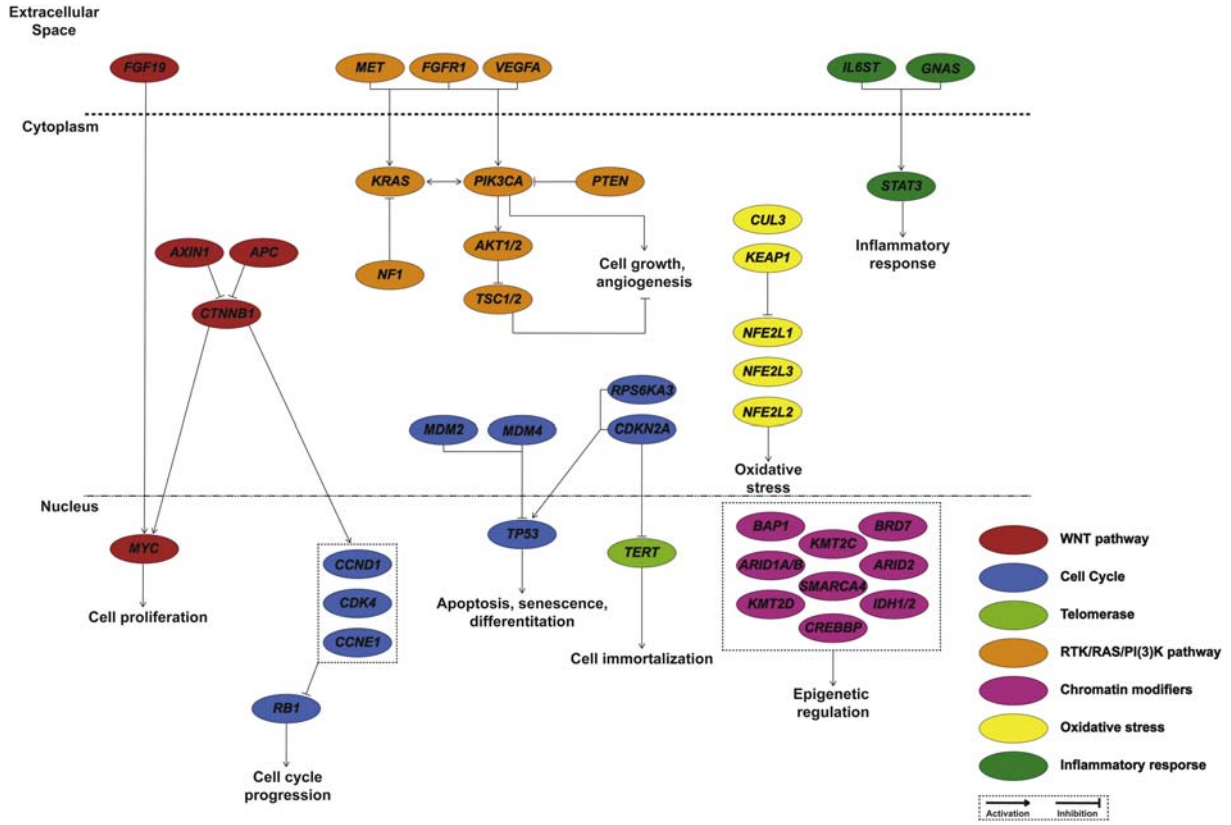

Fig. 4 Altered signaling pathways in HCC. Schematic representation of the major signaling pathways recurrently altered in HCC. Genes belonging to each pathway are represented and activating or inhibitory interactions between pathways are indicated with lines according to the legend.

mutational frequency is between 18% and 50%, depending on the geographic regions, etiological factors and carcinogen exposure, with more frequent *TP53* mutations in HBV-associated HCCs. Inactivating mutations in the *TP53* gene, or other components in the p53 pathway, may render hepatocytes susceptible to the effects of other carcinogens that activate oncogenic pathways and may also predispose to the development of HCCs with a more aggressive phenotype. For instance, *TP53*-mutant HCCs have been associated with features linked to poor prognosis, including high levels of serum AFP, high Edmondson grade, expression of stem-like markers, and activation of pro-oncogenic signaling pathways. Indeed, patients with *TP53*-mutant HCCs tend to have shorter OS and DFS.

The G1 to S phase of the cell cycle (retinoblastoma pathway) is often deregulated via homozygous deletion of *CDKN2A* (p21, 2%–12%) or *RB1* mutations (3%–8%) and is often associated with poor prognosis suggesting a role of the related pathway inactivation in tumor aggressiveness. Additionally, recurrent HBV integration into the *CCNE1* locus (5%) and amplification of the *CCND1/FGF19* locus (5%–14%) have been reported in HCC, both of which have implications in the regulation of cell cycle.

Not all *TP53* mutations in HCCs are equal. Dietary exposure to fungal aflatoxin B1 results in a specific *TP53* mutation that is rarely found in other cancers, namely the R249S mutation resulting from G>T transversion; this is considered to be a driver mutation since it is also found in the normal livers of patients exposed to aflatoxin B1. There is strong epidemiologic synergism between aflatoxin B1 exposure and chronic HBV infection in the induction of HCC, and it has been shown that, in patients infected with HBV, expression of HBx is associated with an approximately twofold increase in the incidence of G/C-to-T/A transversion mutations following aflatoxin B1 exposure (Figs. 3 and 4).

Alterations in the human telomerase reverse-transcriptase

The human telomerase reverse-transcriptase (*TERT*) gene encodes a rate-limiting catalytic subunit of telomerase, which maintains the length of telomeric DNA and chromosomal stability. Thus, *TERT* plays a pivotal role in cellular immortalization, cancer development and progression. Reactivation of telomerase activity allows cells to overcome replicative senescence and to escape apoptosis, both of which are fundamental steps in the initiation of malignant transformation. The interests in the role of telomerase maintenance in the development of HCC have grown since the discovery of *TERT* promoter hotspot mutations in HCC and other cancers. While telomere shortening is a feature of chronic liver diseases and cirrhosis, telomerase reactivation through *TERT* promoter mutations (30%–60%), amplifications (5%–6%) and HBV integration into the *TERT* promoter or the gene body of *TERT* (10%–15%) is associated with hepatocarcinogenesis. Two hotspot mutations c.-124C>T and c.-150C>T have been reported in HCC, and in particular the c.-124C>T mutation has now been shown to be the most common mutation in HCC, observed in

30%–60% of HCC. This mutation is in fact the most frequent mechanism of telomerase activation. The c.-124C>T and c.-150C>T mutations result in the formation of novel ETS transcription factor binding sites upstream of the *TERT* transcription start site, which leads to increased *TERT* transcript expression. *TERT* promoter mutations have been reported to be more frequent in HCV-associated HCC. On the other hand, compared to HCCs of other etiologies, HBV-induced HCCs are less likely to harbor *TERT* promoter mutations but may be deregulated by integration of HBV sequences into the *TERT* gene locus, which serves as a complementary mechanism for telomerase activation.

Deregulation of *TERT* has been suggested to be an early driver event in hepatocarcinogenesis. *TERT mRNA* has been reported to be detectable in the serum of patients with HCC with higher sensitivity and specificity than serum AFP, AFP-L3, and des-gamma-carboxy prothrombin (DCP) in the diagnosis of early stage HCC. Thus, measuring serum *TERT* mRNA levels may potentially be used as diagnostic tool for HCC detection at early stage. In fact, *TERT* promoter mutations have been suggested to be early driver mutations, given that *TERT* promoter mutations have been found in 30% of cirrhotic preneoplastic lesions. These findings suggest that *TERT* promoter mutations are among the earliest genetic alterations in hepatocarcinogenesis, occurring at preneoplastic stages and behaving as a "gatekeeper" during the malignant transformation sequence. It has also been suggested that telomerase inhibition may be a potential therapeutic target in treating HCC (**Figs. 3 and 4**).

Alterations in chromatin modifiers

Chromatin remodelers are epigenetic modifiers that play important roles in maintaining nucleosome positioning and thus in transcriptional regulation. Alterations in ATP-dependent chromatin remodeling complexes have been implicated in carcinogenesis, tumor heterogeneity and cellular response to therapy. Among others, the most frequently altered chromatin remodelers in human cancer are part of the SWI/SNF complex (20%). In fact, this complex has been associated with epigenetic modification including roles in maintaining nucleosome positioning and interacting with other chromatin modifiers. The SWI/SNF complex contains two main subunits, namely the BAF and the PBAF complexes. In HCC, inactivating mutations are frequently found in the *ARID1A* and *ARID1B* genes (4%–17%), encoding the AT-rich interacting domain containing protein 1A-B which are components of the BAF complex, and in *ARID2* (3%–18%), encoding the AT-rich interacting domain 2, a component of the PBAF complex. The frequent occurrence of inactivating mutations in the SWI/SNF complex suggests that the complex acts as a tumor suppressor. Although it has been suggested that alterations in the SWI/SNF complex modify chromatin structure and nucleosome position, the functional role of the mutations and the molecular mechanisms that result in the initiation and progression of HCC are not yet fully understood.

In addition to the SWI/SNF complex, recurrent somatic genetic alterations in the histone methylation family members *MLL* (3%–4%), *MLL2* (2%–3%), *MLL3* (3%–6%), and *MLL4* (2%–3%) or HBV insertions into the *MLL4* gene locus (10%) are also frequent in HCC. The MLL gene family encodes for proteins that modify histone methylation by adding and removing H3K4 methyl groups. As with alterations in the SWI/SNF complex, the functional significance of alterations in the *MLL* genes in hepatocarcinogenesis remains to be further elucidated (**Figs. 3** and **4**).

Alterations in genes involved in oxidative stress response

Oxidative stress pathway dysfunctions have been linked to carcinogenesis and the progression of cancer via the production of reactive oxygen species (ROS) that cause damage to proteins, DNA and lipids. One of the major oxidative stress pathways is the NRF2-KEAP1 signaling pathway, which is a regulator of cytoprotective responses to endogenous and exogenous stresses caused by ROS and electrophiles. In this pathway, NRF2 is the mediator of the oxidative stress response while KEAP1 is the negative regulator of NRF2 activity. Deregulation of the NRF2-KEAP1 signaling pathway prevents proteasome degradation of NRF2, which is physiologically induced by KEAP1/CUL3 complex ubiquitinylation. This results in epigenetic instability or altered chromatin status, leading to abnormal methylation of tumor suppressor genes.

In HCC, the NRF2-KEAP1 signaling pathway is altered by activating mutations of NRF2 (encoded by *NFE2L2*) or inactivating *KEAP1* mutations in 5%–15% of the cases. The role of the somatic mutations in these genes in cancer formation/development is, however, controversial. Studies carried out in rats have reported the presence of these somatic alterations in preneoplastic lesions and early HCCs. By contrast, mutations in *NFE2L2* and *KEAP1* in humans have only been observed in advanced HCC and not in premalignant nodules or early HCC, suggesting that these mutations are late genetic events in hepatocarcinogenesis in humans. Furthermore, mutations in *NFE2L2* or *KEAP1* are significantly correlated with the deregulation of the WNT/β-catenin pathway via *CTNNB1* or *AXIN1* mutations, suggesting that the NRF2/KEAP1 pathway may interact with WNT/β-catenin signaling to promote hepatocarcinogenesis (**Figs. 3 and 4**).

Deregulation of PI3K-AKT-mTOR and RAS/RAF/MAPK signaling pathways

The PI3K/AKT/mTOR pathway is an intracellular signaling pathway that plays a pivotal role in the cell cycle control. Phosphorylation of PI3K activates AKT which regulates several downstream molecules, including mTOR. Several factors may constitutively activate the PI3K/AKT/mTOR signaling pathway, such as EGF, shh, IGF-1, insulin, and CaM. On the other hand, PTEN, GSK3B and HB9 are inhibitors of the pathway. In many cancers including HCC, the PI3K/AKT/mTOR pathway is hyperactive, thus reducing apoptosis and promoting cellular proliferation.

Activation of the PI3K/AKT/mTOR pathway is a common feature of HCC and has been reported in 40%–50% of HCC. Pathway activation may be achieved through several distinct mechanisms. Activating mutations of *PIK3CA* are observed in 0%–2% of patients and inactivating mutations of *TSC1* or *TSC2* are observed in 3%–8% of patients. Furthermore, homozygous deletion of *PTEN* has been identified in 1%–3% of the HCCs. However, some HCCs with activation of PI3K/AKT/mTOR signaling have no

genetic alterations in the pathway. Indirect activation of the upstream insulin growth factor pathway has been proposed as an alternative mechanism to active the PI3K/AKT/mTOR pathway.

Genetic alterations in the RAS/RAF/MAPK pathway have also been implicated in the development of HCC, albeit rarer. Activating mutations in the RAS family genes (e.g., *KRAS*, *NRAS*) are rare (<2%). More common are inactivating mutations in *RP6SKA3*, encoding for the RAS inhibitor RSK2, identified in 2%–9% of HCCs. RSK2 is downstream of MAPK and is a negative regulator of RAS signaling. Inactivating RSK2 disrupts the negative feedback loop and results in the constitutive activation of the RAS pathway (**Figs. 3 and 4**).

Alterations in liver metabolic pathways

Liver is unique organ and has very different gene expression patterns compared to other organs. A number of genes highly expressed and/or only expressed in the liver have been found to be frequently mutated in HCC. Of these, *ALB* (encoding for albumin) and *APOB* (encoding for apolipoprotein B) have been found to be affected by mutations in 10%–15% of HCC. Mutations in *ALB* and *APOB* are dominated by inactivating mutations (i.e., nonsense, splice site and insertions/deletions), strongly suggesting a tumor suppressive role for these genes in liver. Indeed, *ALB* and *APOB*-mutant HCCs have been found to have reduced expression of the respective gene. It has been suggested that *ALB* and *APOB* mutations may be under positive selection to divert energy for other cancer-associated metabolic requirements. *HNF1A* and *HNF4A* (encoding for hepatocyte nuclear factors 1-alpha and 4-alpha) are each mutated in ~2% of HCC. Both encode for transcription factors essential for the transcription of a number of genes required for hepatocyte differentiation, with *HNF4A* regulating the transcription of *HNF1A*. Alterations in *HNF1A* and *HNF4A* are also preferentially loss-of-function alterations (**Figs. 3 and 4**).

Alterations in non-coding elements

Considering that protein-coding regions only account for 1%–2% of the human genome, it is not surprising that recent whole-genome sequencing studies of HCC and other cancers have revealed that the number of somatic mutations in non-coding elements far outnumber that in coding regions. The significance of the vast majority of the non-coding mutations is still unknown but several non-coding regions/genes have been identified to harbor elevated number of mutations. Besides the hotspot mutations in the promoter regions of *TERT*, an additional 10 promoter regions, including those of *TFPI2*, *MED16* and *WDR74*, and nine untranslated regions, including those of *BCL6* and *AFF4*, have also been identified as regions with significantly elevated number of mutations. Among these, mutations in the *TFPI2* (encoding for tissue factor pathway inhibitor 2, a serine proteinase inhibitor) promoter have been linked to lower expression of *TFPI2*, a gene reported to have tumor suppressive roles in several cancers. Finally, the long non-coding genes *NEAT1* (~20%) and *MALAT1* (~5%) are recurrently mutated in HCC. Both *NEAT1* and *MALAT1* encode for transcripts that are subnuclear structural components and regulate the transcription of cancer genes. In particular, *MALAT1* is upstream of p53 and is required for G1/S cell cycle progression. On the other hand, *NEAT1* expression is reported to be influenced by p53. Our understanding of the precise effect of mutations in non-coding elements is very preliminary and the functional impact of these alterations is currently under active investigation.

DNAJB1-PRKACA fusion gene in fibrolamellar HCC

Fibrolamellar HCC is a clinically and morphologically distinctive subtype that accounts for <1% of HCC. Unlike classical HCC, fibrolamellar HCC is usually diagnosed in young adults and is rarely associated with pre-existing liver disease or cirrhosis. Whole genome and transcriptome sequencing studies have identified a recurrent fusion gene resulting from a 400 kb deletion on chromosome 19 in 100% of fibrolamellar HCC. This in-frame chimeric transcript fuses exon 1 of the *DNAJB1* gene, which encodes for a member of the heat shock 40 protein family, to exons 2–10 of the *PRKACA* gene, which encodes for the adenosine 3′,5′-monophosphate (cAMP)-dependent protein kinase A (PKA) catalytic subunit alpha. Additional sequencing studies revealed no other highly recurrent genetic lesions in fibrolamellar HCC and the absence of the fusion in non-fibrolamellar HCC. These observations suggest that the fusion is pathognomonic of fibrolamellar HCC.

The gene fusion leads to the formation of a chimeric protein that differs from wild-type PKA in size. The functional catalytic domain and kinase activity are retained but the fusion protein lacks the domain that binds to the regulatory subunit of PKA. The functional role of this fusion transcript is still under investigation (**Fig. 5**).

HCC Susceptibility Loci

Germline polymorphisms module HCC risk. Genome-wide association studies have identified susceptibility loci in genes associated with signaling pathways known to be involved in carcinogenesis. These include *SOD2* and *MPO* involved in oxidative stress response, *TNFA*, *IL1B*, and *TGFB1* in inflammatory response, *MTHFR* and *XRCC3* in DNA repair, *MDM2* and *TP53* in cell cycle regulation, and *EGF* (epidermal growth factor).

The majority of the susceptibility loci associated with HCC development are linked to specific risk factors. For instance, single nucleotide polymorphisms (SNPs) of *GTSM1* and *GSTT1* are linked to aflatoxin B1 exposure and HBV infection. Also in HBV-positive patients, SNPs in *STAT4*, *TPTE2*, *DCL1* are associated with increased risk of HCC. In HCV-positive patients, however, polymorphisms in *MICA* (a gene involved in regulating immune response), *DEPDC5* (a gene in the mTOR pathway) and in the 5′ UTR of *EGF* have been reported as susceptibility loci. A *PNPLA3* polymorphism has been linked to HCC associated with fatty and alcoholic liver diseases. These associations suggest interaction between these SNPs, environmental factors and chronic infection.

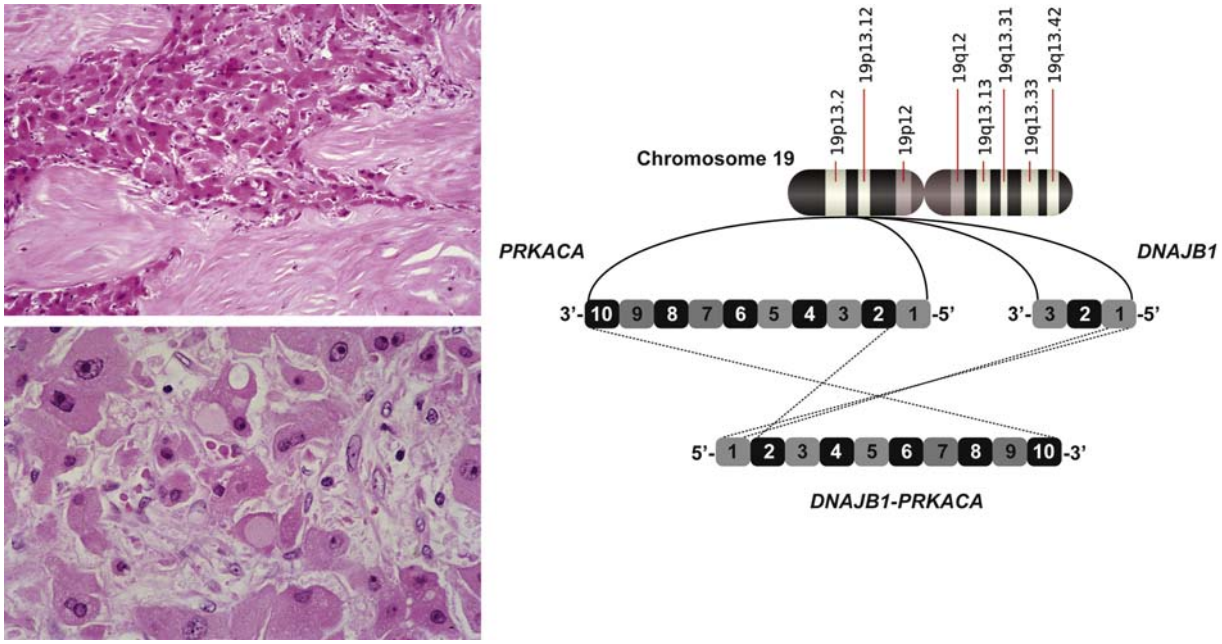

Fig. 5 Recurrent molecular alteration in fibrolamellar HCC. High power and low power micrographs of a fibrolamellar HCC (*left*) and a schematic representation of the major recurrent fusion gene *DNAJB1-PRKACA* present in nearly 100% of fibrolamellar HCCs (*right*).

Genetic Syndromes Associated With Increased Risk of HCC

Several rare monogenic syndromes have been linked to increased risks of hepatocarcinogenesis. The autosomal recessive α-1-antitrypsin deficiency results from mutations in the *SERPINA1* gene, a serine protease synthesized at high levels in the liver and responsible for the inhibition of neutrophil elastase. Glycogen storage disease type I, caused by the deficiency of glucose-6-phosphatase (G6Pase) activity results in excess glycogen storage in the liver and causes hepatomegaly, fasting hypoglycemia, lactic acidosis, hyperlipidemia, hyperuricemia, and growth retardation. Hemochromatosis is caused by a mutation in the *HFE* gene (most commonly single base mutation C282Y) and leads to the development of fibrous tissue at the site of iron deposition, causing liver dysfunction. Patients with hemochromatosis are at increased risk of developing hepatic cirrhosis followed by HCC. Acute intermittent porphyria (AIP) is a low penetrant autosomal dominant disease caused by mutation in enzymatic activity of hydroxymethylbilane synthase (*HMBS*), one of the enzymes in the heme biosynthesis pathway. AIP patients have an >30-fold increase in the risk of HCC compared to the general population. HCC in AIP patients are rarely associated with cirrhosis. Tyrosinemia type I is an autosomal recessive disorder caused by biallelic pathogenic variants in the *FAH* gene. The deficiency of the fumarylacetoacetate hydrolase enzyme leads to an accumulation of tyrosine catabolic intermediates, acute hepatic failure in infancy or chronic liver disease associated with cirrhosis and HCC development. Finally, HCC has also been reported in patients with familial adenomatous polyposis associated with *APC* germline mutation.

Conclusions

With sorafenib, regorafenib, and nivolumab still the only approved systemic therapies for HCC, the identification of additional therapeutic targets is crucial to improve the prognosis of HCC patients. On the one hand, the consensus on the classification between early and late HCCs is having an impact in the clinic to optimize clinical management. On the other hand, our evolving understanding of the genetic heterogeneity of HCC is beginning to reveal additional pathways and potential vulnerabilities that may be exploited in future studies. Integration of histopathologic and molecular analyses will provide further insight into the pathogenesis and genotype–phenotype interactions important in HCC.

Cancer Control From a Public Health Perspective

Incidence and prevalence of cancer have been increasing for most neoplastic diseases in the past decades, due to different causes, including the progressive aging of the population and the continuous improvement in diagnostic and treatment strategies, that, if not always able to cure, at least make people live longer and with an acceptable quality of life.

In this context, the healthcare assistance related to cancer, from screening to diagnosis, to cure or treatment, has become a very crucial, but challenging, public health topic.

Cancer is a multifactorial disease, whose pathogenesis is complex, but strongly driven by genetic modifications in the genome DNA. This makes cancer field of study of Public Health genomics, the field in epidemiology wherein molecular data at population scale are integrated into new strategies both from a personalized medicine and a public health perspective.

The completion of the human genome-sequencing project in 2003, and the further advances in numerous sectors of biotechnology, created great expectations about health benefits for several diseases, including cancer. Moreover, the decrease of the costs related to the DNA sequencing techniques has contributed to the spread of genetic testing in healthcare.

The genomic approach to cancer means a consistent reduction in terms of mortality, morbidity, and, therefore, a possible reduction of costs for the healthcare systems. Genetic testing may contribute to cancer control by identifying individuals at high risk of disease. Some monogenic subtypes of common cancers such as *BRCA*-related breast cancer and Lynch syndrome (LS) colorectal cancer (CRC) are autosomal dominant disorders with a risk of 50% for first-degree relatives of the index case to be affected. The identification of these hereditary forms of cancer that show high incidence, mortality rate, and that are potentially preventable or efficiently treatable is of critical public health importance because it changes cancer risk management options and enables patients and their at-risk family relatives to benefit from targeted intervention measures.

Hereditary Breast Cancer

Breast cancer is the most common malignancy in women, and one of the three most common cancers worldwide, with around 1,671,000 new cases diagnosed in 2012.

The majority of breast cancers show a multifactorial pathogenesis; however, approximately 30% of breast cancer cases occur in family clusters and up to 7% have a strong hereditary component.

Among affected women, the genetic variants of *BRCA1* and *BRCA2* (breast cancer susceptibility genes) account for up to the 30% of the genetic predisposition to breast cancer and show a high-penetrance pattern of hereditary predisposition. The prevalence of pathogenic variants of *BRCA* genes has been estimated as 1/800; however, a number of founder effects with higher prevalence have been observed in different populations as Ashkenazi Jewish, Swedish, Dutch, Hungarian, and Icelandic.

Mutations in these genes predispose women to develop cancer at a younger age than general population. In women, *BRCA1* or *BRCA2* mutations result in a 57%–65% or 45%–55% risk of developing breast cancer by age 70 years, and a lifetime risk of 39%–44% or 11%–18% of developing ovarian cancer (includes fallopian tube and primary peritoneal cancers), respectively. In men, the lifetime risk of breast cancer is 1.2% for *BRCA1* mutation carriers and 6.8% for *BRCA2* mutation carriers. Besides, carriers have a considerable risk to develop a contralateral breast cancer, after the first one.

In 2003 the European Council recommended the implementation of cancer screening programs for women aged 50–69 years. Also the U.S. Preventive Services Task Force and the American Cancer Society recommend that women aged over 50 years undergo regular screening mammography for the early detection of breast cancer. However, women with a *BRCA1* or *BRCA2* mutation may develop cancer at a younger age.

Identifying *BRCA* mutated women is important not only for cancer-affected women because of the prognosis and the related treatment choices but also for healthy carriers because of the different options in terms of primary and secondary prevention. According to international guidelines, surveillance of breast cancer in *BRCA* carriers includes monthly self-examinations, clinical breast examinations twice a year, and yearly mammograms and magnetic resonance imaging of breasts starting at age 25 or younger based on the earliest age at which breast cancer was diagnosed in the family. Screening for ovarian cancer is also recommended and preventive surgery (mastectomy and salpingo-oophorectomy) can be considered.

Considering the relevance of breast cancer, international communities are strengthening the efforts in order to implement adequate integrated diagnostic-therapeutic pathways for the affected women. In this context, breast units have a key role, coordinating high quality and appropriate assistance, taking care of patients in all the stages of their disease.

To date, according to the most recent international guidelines it is not indicated to perform a screening program for genetic testing of *BRCA* genes, neither in the general population nor in all women with breast cancer. In fact, the U.S. Preventive Services Task Force recommends to perform the genetic testing only in the presence of specific anamnestic criteria that identify the high-risk woman that might carry the *BRCA* mutations. Women with positive screening results should receive genetic counseling and, if indicated after counseling, *BRCA* testing.

Considering economic evaluations, there are good evidences in support of the implementation of dedicated screening pathways to identify high-risk women. According to a recent systematic review of the economical evaluations of *BRCA* screening strategies, family history-based genetic testing is potentially very cost-effective, but there was no evidence of cost-effectiveness for testing all the newly diagnosed cases of cancers.

Hereditary breast cancer is addressed as one of the main topics in cancer control policies and the implementation of prevention programs would reduce the burden of the inherited disease. In some countries public health genomics policies have already been formulated; however, the implementation of integrated pathways for the identification and follow-up of *BRCA* carriers is still at the beginning.

Hereditary Colorectal Cancer

CRC is the third leading cause of cancer death worldwide, accounting for 774,000 deaths in 2015, and with an estimated annual worldwide incidence of 1.4 million new cases. CRC ranked third in prevalence, after lung and prostate cancers, for men, and second, after breast cancer, for women.

Due to its high incidence rate, its long preclinical phase, its recognizable and tractable precursor, and the association between the tumor stage and mortality rate, CRC is a condition suitable for screening according to the criteria established by Wilson and Jungner as the "gold standard of screening assessment." The recommended screening can be performed through an annual or biennial fecal immunochemical test, or sigmoidoscopy every 5 years, or colonoscopy every 10 years. The burden of this disease could be dramatically reduced by screening, but CRC screening programs in many countries start at an age when the neoplastic process has already gone in hereditary forms of CRC, leading to a late-stage diagnosis for those patients.

Between 5% and 10% of CRC are hereditary forms, of which the most common is LS, that is associated with approximately 3%–5% of all CRCs.

LS, previously known as hereditary nonpolyposis CRC, is an autosomal dominant disorder caused by mutations in DNA mismatch repair (MMR) genes that have the role to maintain genomic integrity during DNA replication. Inactivation of MMR genes causes an increased mutation rate (genomic instability) and a microsatellite instability.

In individuals with LS, current CRC screening recommendations include colonoscopy every 1–2 years beginning at age 20–25 years. Annual transvaginal ultrasound of the uterus and ovaries and endometrial sampling are also recommended although efficacy is still debated as well as the utility of screening for other LS cancers. Furthermore, prophylactic surgery can be considered as an effective option for women with LS. Additionally, regular, long-term aspirin use is reported as a preventive measure to reduce incidence and mortality due to CRC and the most relevant impact of chemopreventive strategies is expected in patients with an hereditary predisposition as LS.

Hence, the identification of LS-related CRC can lead to beneficial outcomes in terms of survival for the patients, and in terms of prevention for their affected family members.

Several international guidelines recommend to screen for LS all newly diagnosed CRC patients, regardless the age or the clinical criteria. The first step of the screening is performed on tumor tissue through immunohistochemistry staining or the microsatellite instability molecular testing, two laboratory procedures with comparable sensitivity and specificity. In case of positive tumor test, the patient is referred to genetic services for counseling and germline testing for MMR mutations to establish the diagnosis of LS.

Moreover, economic evaluations documented the cost-effectiveness of the universal tumor screening strategy versus no screening because it reduces the costs related to morbidity and mortality from CRC from the early identification of LS-carriers among family members.

However, in resource-limited settings, a universal tumor screening could be hardly achievable. This strategy requires a multidisciplinary team (involving pathologists, surgeons, gastroenterologists, oncologists, geneticists, genetic counselors) that might be not available in all clinical contexts. Furthermore, genetic services are not always available in all clinical settings, and some laboratories could lack in resources, expertise, and quality assessment to perform all the required tests for tumor screening.

Implementation of Genetic Testing Programs in Health Care: Barriers and Future Challenges

The increasing evidence of genomic contribution to cancer onset and progression makes it a relevant part of research and public health which can no longer be overlooked.

The awareness of the health benefits of using genetic tests and family health history in clinical practice has been increasing, as underscored in the agenda items in Healthy People 2020: "Increase the proportion of women with a family history of breast and/or ovarian cancer who receive genetic counseling" and "Increase the proportion of persons with newly diagnosed colorectal cancer who receive genetic testing to identify Lynch syndrome."

In this framework, to make genetic testing for hereditary forms of cancer accessible to all the patients and their family members, when appropriate, as part of the routine diagnostic and therapeutic pathways, many barriers still need to be overcome.

The health professionals' lack of knowledge about genetic testing and their lack of confidence in interpreting familial patterns of disease are some of the most significant barriers to integrate genetic testing into cancer prevention. The lack of consensus and providers' awareness as well as specific guidelines for every country, that take into account the feasibility of different approaches in different contexts, have been associated with divergent referral and testing practices. The miscommunication between patient and physicians and the refusal of genetic counseling by the patients, due to a perceived lack of benefit, have to be also considered.

Therefore, further efforts are necessary to overcome the gap between expectations on genetics and clinical results. A promotion of genetic education and training for healthcare professionals is crucial to assure awareness of emerging issues and appropriate utilization of new genetic technologies, as well as measures to foster the public understanding of scientific developments in human genetics and associated ethical, legal, and social issues. Moreover, a reduction in financial, geographic, and cultural barriers to access genetic services, an optimal management of test-positive individuals, and a family support through integrated services will be crucial. A multidisciplinary team is usually involved in the screening pathways; therefore, a standardized plan should be created to drive their efforts in order to provide effective and equitable cancer assistance to all patients.

In conclusion, genetic research is rapidly increasing the opportunities for the detection of inherited cancer risk, but coordinated strategies in educating clinicians and policy makers and addressing public concerns are necessary to ensure that public health needs are satisfied through appropriate and sustainable healthcare services.

Hereditary Risk of Breast and Ovarian Cancer: BRCA1 and BRCA2☆

Claus Storgaard Sørensen, University of Copenhagen, Copenhagen, Denmark

Glossary

BRCA1 gene A breast cancer susceptibility gene located on chromosome 17q21, known to be mutated in families prone to a high incidence of early onset breast cancers and also ovarian cancers.

BRCA2 gene A gene mapped to chromosome 13q12-13; known to be mutated in families prone to a high incidence of early onset breast cancers and also ovarian cancers.

HBOC Hereditary breast and ovarian cancer (HBOC).

Homologous recombination repair (HRR) A DNA repair pathway acting on DNA double-strand breaks that uses the undamaged sister chromatid as template for error-free repair.

Locus heterogeneity A genetic term describing how variations in different genes cause the same disorder. The genes are not linked physically; examples are hereditary breast and ovarian cancer predisposition by BRCA1, BRCA2, partner and localizer of BRCA2 (PALB2) and TP53.

Variant of unknown significance (VUS) Variants in genes are classified according to their impact on the protein function, for example, BRCA1 function. A variant with an unknown clinical function owing to lack of functional or clinical data is classified as a VUS.

Characterization of BRCA1 and BRCA2

Fifteen years of analysis of large multigenerational families with a strong history of breast cancer led in 1990 to the identification of a gene on chromosome 17q12–21 that conferred a greatly increased risk of breast cancer in an autosomal-dominant manner. The gene itself, BRCA1, was cloned in 1994. The discovery of the complete sequence of a second such gene, BRCA2 on 13q12-13, was reported in 1995.

The protein-coding region of BRCA1 consists of 5592 bp in 22 exons that encode a protein of 1863 amino acids, and the protein-coding region of *BRCA2* consists of 10,254 bp in 26 exons that encode a protein of 3418 amino acids. Studies of the interactions of these proteins led to the conclusion that they are involved in the regulation of genomic stability and DNA repair. The BRCA1 and BRCA2 proteins interact through a third breast cancer tumor suppressor, PALB2 (partner and localizer of BRCA2) that serves as a major link. A key function of the BRCA1–PALB2–BRCA2 pathway is to secure proper and stable loading of the RAD51 protein at sites of DNA lesions such as DNA double-strand breaks. RAD51 is crucial for homologous recombination repair as well as for the protection of exposed DNA from undergoing excessive degradation during DNA replication. Mice lacking Brca1 and Brca2 (the murine homologues of *BRCA1* and *BRCA2*) undergo developmental arrest during embryogenesis. Furthermore, the modeling of mice with mutations in Brca1 and Brca2 revealed that such genetic changes display enhanced tumorigenesis. This can be modeled to take place in the murine breast tissue, particularly when combined with the TP53 loss. Mice homozygous for a truncating mutation of Brca2 that survive to adulthood have a wide range of defects, including improper tissue differentiation, absence of germ cells, and the development of lethal thymomas, and cultured embryonic fibroblasts from these mice are unable to repair radiation-induced DNA damage. Other studies suggest that mouse embryonic stem cells deficient in Brca1 are unable to carry out a transcription-coupled repair of oxidative DNA damage and are hypersensitive to ionizing radiation and hydrogen peroxide. Human *BRCA2*-defective cancer cells are also deficient in the repair of double-strand DNA breaks induced by ionizing radiation, although individuals with germline mutations in *BRCA1* and *BRCA2* do not appear to be hypersensitive to ionizing radiation.

Cancer Risk Due to Mutations in BRCA1 and BRCA2

Mutations in *BRCA1* and *BRCA2* are responsible for increasing the risk of breast cancer to between 56% and 87% for carriers by the age 70. The lower estimate of risk was derived from an analysis of a general population with little or no family history of cancer, and the higher estimate was derived from families with multiple women affected by breast cancer. The increased risk of breast cancer is observed not only over a woman's lifetime, but particularly at a young age, to 33%–50% before age 50 compared to the general population risk of 2%.

☆*Change History*: August 2017. Claus Sørensen has updated the text and references.
This is an update of Thomas S. Frank, Hereditary Risk of Breast and Ovarian Cancer: BRCA1 and BRCA2 in Encyclopedia of Cancer (Second Edition), edited by Joseph R. Bertino, Academic Press, 2002, Pages 381–385.

 https://doi.org/10.1016/B978-0-12-801238-3.65227-3

Mutations in *BRCA1* also confer a greatly increased risk of ovarian cancer of up to 44%, by age 70, whereas mutations in *BRCA2* increase this risk to approximately 27% compared to 1% for the general population of women. The age of onset of hereditary ovarian cancer is typically later than that of hereditary breast cancer, especially when associated with a *BRCA2* mutation.

Women already diagnosed with breast cancer are at a greatly increased risk of a second cancer of breast and ovary if they carry a mutation in *BRCA1* or *BRCA2*. Mutations in *BRCA1* confer a 64% risk of contralateral breast cancer by age 70, or 20% within 5 years of the initial diagnosis, whereas mutations in *BRCA2* increase these risks to about 50% by age 70, or 12% within 5 years of the first breast cancer. The risk of developing ovarian cancer after breast cancer is increased 10-fold to at least 16% compared to women with early onset breast cancer without such mutations. Mutations in both *BRCA1* and *BRCA2* also confer increased (albeit low) risks of some cancers of men, particularly male breast cancer. Mutations in *BRCA2* are responsible for an increased risk of prostate cancer (8% by age 70 and 20% by age 80), as well as an elevated but still low (2%–3%) risk of pancreatic cancer.

There is also a familial component in "triple-negative" breast cancer where cancer cells do not express the receptors estrogen, progesterone, and HER2/neu. About 10%–30% of women under the age of 60 diagnosed with "triple-negative" breast cancer will have a gene mutation in *BRCA1*. Triple-negative breast cancer has relatively poor prognosis, hence these women are also included in clinical genetic programs.

Assessment of Hereditary Risk of Breast and Ovarian Cancer

Genetic testing for mutations in *BRCA1* and *BRCA2* genes is no longer confined to research protocols, but is now clinically available to healthcare professionals. Mutations in the *BRCA1* or *BRCA2* genes can be identified through a blood or saliva test. DNA sequence analysis is generally acknowledged as the most sensitive method of analyzing these genes because more than thousand mutations have been described throughout the lengths of each. Sequence analysis detects the majority of clinically significant abnormalities in *BRCA1* and *BRCA2*. Large duplications and deletions in the respective genomic regions have also been reported for which clinical testing has become available.

Prior to genetic testing, a patient is generally provided pretest education and counseling regarding hereditary risk and genetic testing, including consideration of which relatives with whom the patient would share test results. Individuals who choose to be tested are asked to sign an "informed consent" form indicating that they understand the benefits and limitations of the test that they have chosen. An identified mutation in either *BRCA1* or *BRCA2* can usually be assumed to have been inherited from one parent or the other, as spontaneous germline mutations in either gene are rare. An individual who does not have a germline mutation in *BRCA1* or *BRCA2* at the time of birth cannot acquire one later in life so tests for mutations in these genes are normally performed only once in a person's lifetime. If a mutation is identified in HBOC predisposing genes, a tailored surveillance plan is developed based on the pattern of cancers associated with the specific genes and family history of cancer. This plan must be developed by a team of healthcare professionals and must include expertise in clinical cancer genetics.

Testing for mutations in the *BRCA1* or *BRCA2* genes may not be beneficial for the average woman since most breast and ovarian cancers are sporadic. Genetic testing for hereditary cancer risk is generally preceded by thorough assessment of an individual's family history in order to determine whether she (or he) is likely to carry a mutation responsible for hereditary cancer risk. The hallmarks of mutations in *BRCA1* and *BRCA2* include two or more family members on the same side of the family with breast cancer at an early age of onset (usually before age 50) or ovarian cancer at any age. Breast and ovarian cancer in the same individual or male breast cancer at any age also indicates the possibility of HBOC. In evaluating a family history for the possibility of hereditary cancer risk, it is important to equally assess the father's side of the family as well as the mother's, as half of women with a hereditary risk of breast and ovarian cancer inherited it from their father.

Mutations in *BRCA1*and *BRCA2* have been described throughout the world but are more prevalent in some populations than others, such as individuals of Ashkenazi Jewish descent (i.e., central and eastern European origin). Evaluation of hereditary cancer risk may be warranted for any Ashkenazi Jewish woman with early onset breast cancer or ovarian cancer at any age regardless of family history. Notably, identifying a *BRCA1* and *BRCA2* variant does not immediately suggest that the individual is a carrier of a pathogenic variant. Indeed, many variants of *BRCA1* and *BRCA2* have no clear disease linkage, which can be due to a documented lack of cancer predisposition, or, the individual may carry a rare or newly discovered variant. These variants of unknown significance (VUS) can constitute a major issue for the genetic counseling, and such result generally indicate that the individual should be monitored more carefully.

BRCA1 and *BRCA2* are not the only HBOC predisposing genes. Mutations in other genes may be associated with an increased risk of developing breast cancers, including mutations in the *PALB2*, *ATM*, and *CHEK2* genes. Another set of genes are involved in syndromes with more varied pattern of cancer types, which is including the Li–Fraumeni syndrome (*TP53* gene), Cowden syndrome (*PTEN* gene), and others. Thus, the pattern of cancers in a family can indicate the specific gene predisposing to hereditary cancer for that family.

To aid in optimal genetic analysis, new panels of multiple genes have been developed for testing in patients with a suggestive personal and family history. These panel tests include *BRCA1* and *BRCA2* and other genes that increase the risk of breast, ovarian, and other cancers. Panels may include 6, 20, 40, or more genes depending on the personal and family history. Thus, even if an individual has a negative test result for *BRCA1* and *BRCA2*, mutations in other genes may still be elucidated. These mutations can be relevant as BRCA1 and BRCA2 operate in complex pathways where locus heterogeneity can be observed. Thus, several gene products collaborate to maintain genome stability, and mutations in several such factors can lead to a BRCA1/2-like phenotype. Because these non-BRCA1/2 mutations are rare, accurate risk assessments may not be possible. However, if a genetic analysis indicates a potential pathogenic variant, prevention and screening strategies may still be initiated.

It is in principle possible to use massive in-depth sequencing (next-generation sequencing) of blood samples from individuals with suspected family history. However, this leads to the inclusion of vast number of genes with no clear link to HBOC, which makes it virtually impossible to use such massive data in the clinical genetic setting.

Hereditary Risk of Breast and Ovarian Cancer: Implications for Medical Care

Evaluation for hereditary cancer risk should occur in the context of the medical interventions available to address that risk. Management options generally include increased surveillance, prophylactic surgery, and chemoprevention (medications that reduce the risk of cancer). The risks and benefits of these options should each be considered not only for women who do not themselves have cancer, but also women with breast cancer who are at the risk of subsequent malignancy of the breast and ovary.

Elaborate guidelines have been developed to establish standardized and adequate clinical practices. These are based on expert opinions and are from organizations such as the National Comprehensive Cancer Network (NCCN), the National Institutes of Health and Clinical Excellence (NICE), and the European Society for Molecular Oncology (ESMO). The reader is referred to these (see references) for comprehensive and recently updated guidelines on initial risk assessment, genetic counseling, and testing.

Specifically, it is recommended that women with mutations in *BRCA1*or *BRCA2* perform monthly breast self-examinations, beginning at age 18. The female carrier then undergoes annual or semiannual clinician breast examinations from the age of 25. Annual screening MRI should be started from age 25 as well as annual mammography to commence from age 30. Increased surveillance may be implemented in association with chemoprevention. Tamoxifen, a selective estrogen receptor modulator, may reduce the risk of breast cancer in high-risk women and specifically reduces the risk of contralateral breast cancer in women with *BRCA1*or *BRCA2* mutations. It is thus likely, although not yet specifically demonstrated, that tamoxifen will reduce the occurrence of primary cancer in such women.

Several risk-reducing breast surgical techniques exist ranging from total to nipple-sparing mastectomy (NSM). Prophylactic mastectomy has been shown to reduce the risk of breast cancer in "high-risk" women by at least 90% with mutations in *BRCA1* or *BRCA2*. Bilateral risk-reducing total mastectomy is an option, however, this procedure is not the sole approach because of the efficacy of surveillance in detecting most early stage breast cancer and the high cure rate of breast cancers detected at an early stage. Prophylactic total mastectomy may be considered by women whose mammographic assessment is compromised by extensive fibrocystic change or by women whose perception of breast cancer has been affected by relatives or friends with the disease. Following NSM, there might be somewhat elevated residual risk due to breast tissue being left behind after surgery, however, such elevated risk is not clearly established. In any case, all aspects of surgical procedures should be carefully discussed with the individual carrier or patient.

Oral contraceptives reduce the risk of ovarian carcinoma by 50% in the general population and have also been associated with a 60% reduction in the risk of ovarian cancer in women with mutations in *BRCA1* and *BRCA2*. It should be noted that oral contraceptives may increase the risk of breast cancer for carriers.

Unfortunately, surveillance for ovarian cancer is often ineffective. Measurement of serum CA-125 is regarded as a quite unreliable screen for ovarian cancer and transvaginal ultrasound lacks specificity. Prophylactic oophorectomy should therefore be considered by women around age 35–40 with mutations in *BRCA1*or *BRCA2* as recommended by the clinical practice guidelines. Prophylactic oophorectomy is believed to reduce the risk of ovarian cancer in women with mutations in *BRCA1* and *BRCA2* by as much as 95% and also reduces their risk of breast cancer by nearly 50%.

A negative as well as a positive test result can have significant implications for patient care. If a mutation in *BRCA1* or *BRCA2* has previously been characterized in a relative, a negative result indicates that a woman is at the population risk of breast and ovarian cancer, despite having a strong family history of either or both diseases. It has also been shown that individuals who learn through genetic testing that they do not carry the mutation identified in their family have significant reductions in depressive symptoms compared with untested individuals.

Options exist for couples interested in having a child when they know that one of them carries a gene mutation that increases the risk for this or any other hereditary cancer syndrome. Preimplantation genetic diagnosis done in conjunction with in vitro fertilization is used to avoid the carrier chromosome. Thus, it allows both women and men who carry a specific known genetic mutation to have children who do not carry the mutation.

Summary

Inherited mutations in the genes *BRCA1* and *BRCA2* are associated with a significantly increased risk of breast cancer, particularly before age 50, as well as an increased risk of ovarian cancer. Laboratory analysis of these genes can determine whether a woman has inherited increased risks of breast and ovarian cancer. Identification of a hereditary risk of breast and ovarian cancer can facilitate the medical care of healthy mutation carriers, as well as those already diagnosed with cancer who are at risk of a second malignancy. Once a mutation has been characterized in a family, a family member whose test indicates that he or she did not inherit the mutation has no elevated risk of cancer despite the strong family history, and can therefore avoid unnecessary interventions that might have previously been considered appropriate. Clinical laboratory analysis of *BRCA1* and *BRCA2* can be used to assist in the identification and management of individuals with a hereditary risk of breast and ovarian cancer.

Prospective Vision

The identification of BRCA1 and BRCA2 as major HBOC factors has been crucial in the development of tailored clinical approaches to improve counseling and treatment of affected individuals. However, a number of unresolved issues still remain, including the detailed analysis and validation of VUS as well as the elucidation of non-BRCA1/2 genes contributing to a substantial number of HBOCs. The latter may even operate in the same functional pathways as BRCA1/2. Thus further understanding of genetic risk factors as well as nongenetic risk contributors are important to further advance the field. In this regard, ongoing international large-scale efforts aim at tackling these issues, and it is likely that comprehensive whole exome/genome studies will contribute in the near future. When coupled with functional assays to characterize and validate potential variant dysfunction, it is conceivable that HBOC clinical practices will be markedly improved within the coming decade.

HIV (Human Immunodeficiency Virus)☆

Jay A Levy and JoAnn C Castelli, University of California San Francisco, San Francisco, CA, United States

Glossary

Acquired immunodeficiency syndrome (AIDS) A disease of the immune system caused by HIV infection and characterized by increased susceptibility to opportunistic infections, certain cancers, and neurological disorders.

CD4 A cellular surface protein found on T cells as well as other cells. It functions as a receptor for HIV binding and facilitates recognition of the T-cell receptor to antigens bound to MHC class II complexes.

Cellular immunity The immune system response by a number of cellular components such as CD8 + T cells, CD4+ T cells, NK cells, neutrophils, macrophages, and dendritic cells. The effector function involves contact of the immune cells with infected cells or cancer cells.

Chemokines A class of proinflammatory cytokines that have the ability to attract and activate leukocytes. They can be divided into at least three structural branches—C, CC, and CXC—according to variations in a shared cysteine motif.

Cytokines Proteins secreted by leukocytes and some nonleukocytic cells that act as intercellular mediators. They are also produced by a number of tissue or cell types and generally act locally in a paracrine or autocrine manner.

Dendritic cells Immune cells, derived from bone marrow, with long, tentacle-like branches called dendrites. Among dendritic cells are the Langerhans cells of the skin and follicular dendritic cells in the lymph nodes. Most dendritic cells function as antigen-presenting cells that digest extracellular pathogens and present segments of protein (antigen) on the cell surface to induce a primary immune response.

Humoral immunity An antibody-mediated immunity involving secreted products of B cells that interact and neutralize extracellular pathogens.

Innate immunity A nonantigen specific immune system that is the first line of host defense against incoming pathogens and foreign substances. Unlike the adaptive immune system, the innate immune system response is not to a specific antigen nor does it usually have memory of previous exposure to an antigen. This immune system acts within hours to days whereas the adaptive immune system, reflected by humoral and cellular immunity, responds after days to weeks. The innate immunity plays a role in activating the adaptive immune system.

Lentivirus A genus of the family Retroviridae consisting of nononcogenic retroviruses that produce multiorgan diseases characterized by long incubation periods and persistent infection. Lentiviruses are unique in that they contain open reading frames between *pol* and *env* genes and in the 3′ *env* region.

Long terminal repeats (LTR) Identical DNA sequences, several hundred nucleotides long, found at either end of transposons and proviral DNA. LTRs are formed by reverse transcription of retroviral RNA. In proviruses, the upstream LTR acts as a promoter and enhancer, whereas the downstream LTR acts as a polyadenylation site.

Long-term survivors Individuals infected by HIV for many years who, without therapy, do not show any signs of the infection. They have a normal immune system reflected by normal CD4+ cell counts and low virus levels in the blood. Some are elite controllers who have had undetectable HIV in their plasma for several years.

Macrophages Large white blood cells found mainly in connective tissue and in the bloodstream that ingest foreign particles and infectious microorganisms by phagocytosis.

Retroviridae A family of viruses with a single-stranded RNA that, upon infection, generates a DNA copy via a viral reverse transcriptase; lentivirus is a genus in a subfamily.

Simian immunodeficiency virus (SIV) A member of the genus lentivirus that induces acquired immunodeficiency syndrome in monkeys and apes. SIV and HIV-2 exhibit close structural and immunologic properties and are 75% homologous.

T lymphocyte A subset of lymphocytes that develop in the thymus and circulate in the blood and lymphoid tissue. They orchestrate the response of the immune system to infected or malignant cells, either by lymphokine secretions or by direct contact. Helper T cells recognize foreign antigen on the surfaces of other cells, thus causing the stimulation of B cells to produce antibody and to cytotoxic T cells to destroy antigen-displaying cells.

 https://doi.org/10.1016/B978-0-12-801238-3.11085-2

The human immunodeficiency virus (HIV), is a retrovirus that gradually destroys the immune system and has caused the worldwide epidemic of acquired immunodeficiency syndrome (AIDS). In 1983, HIV was first isolated from AIDS patients and was later identified as the infectious agent responsible for the disease. Other reports indicated the presence of this agent in many populations, including healthy individuals. HIV is cytotoxic to CD4+ cells and does not transform them into malignant cells characteristic of HTLV infection. This infection of CD4+ cells appeared to contribute to the dramatic decrease in CD4+ cell numbers observed in AIDS patients. HIV can be transmitted to individuals through sexual contact, blood products, or via mother-to-child transmission before or shortly after birth. Consistent with this observation, the levels of infectious HIV virions are substantially higher in the peripheral blood and genital fluids of individuals with the greatest chance of transmitting the virus.

Stages of HIV Infection

The typical course of HIV infection begins with an acute infection characterized by the presence of increasing levels of infectious viral RNA in plasma and a transient decrease in CD4+ T lymphocytes. Within weeks to a few months, the amount of virus detected in the peripheral blood decreases as a result of immune responses, while the CD4+ T lymphocyte count returns to a near-normal level. The initial infection is often associated with a flu-like syndrome that occurs within weeks and is followed by a quiescent period characterized by a healthy clinical state. The length of this asymptomatic latent period is influenced by environmental, genetic, and immunologic factors as well as by the predominant virus type. In the final stages of the infection, which takes place after an average of 10 years, the viral load increases in the peripheral blood and lymphoid tissues. This phenomenon is accompanied by a major decrease in CD4+ cell numbers and the occurrence of opportunistic infection or cancer leading to a fatal outcome.

Genetic Structure and Products

HIV-1 and HIV-2 are grouped within the lentivirus genus as members of the Retroviridae family. The two types of AIDS viruses, HIV-1 and HIV-2, share up to 50% overall nucleotide homology and are similar in structure and cellular tropism. Based on virus genetic similarities, four major groups of HIV-1 (M, N, O, P) have been identified. Each group differs genetically by up to 30%. Within the HIV-1 group M there are at least 9 subtypes or clades that vary in sequence by about 15%. Most HIV infections worldwide involve HIV-1 clade C. For HIV-2, there are 2 groups and no clades. Most evidence suggests that the difference in pathogenicity of these various HIV isolates is determined by host specific factors (intrinsic or immune) rather than the particularly virus isolate.

The genomes of HIV-1 and HIV-2 consist of two identical single RNA strands enclosed within a cone-shaped core, surrounded by a glycosylated outer virion surface (Fig. 1). The 9.8-kb RNA genome contains a 5′ cap (Gppp), a 3′ poly(A) tail, and several open reading frames (ORFs). This genome codes for 15 major molecular products (Table 1). The longest ORF encodes for viral structural proteins, whereas smaller ORFs encode regulators of viral binding, fusion, replication, and assembly.

Structural Proteins

Env

The Env structural polyprotein, gp160, is produced from a long ORF transcript. Gp160 is cleaved into gp120 and gp41 in the endoplasmic reticulum. These proteins are highly glycosylated and can be expressed on either the cell or the virion surface. Interaction of the viral gp120 with the cellular receptor CD4 causes a conformational change that facilitates virus binding and entry. The gp120 protein forms trimeric structures that are anchored to the membrane of the virion by the viral transmembrane protein gp41. The

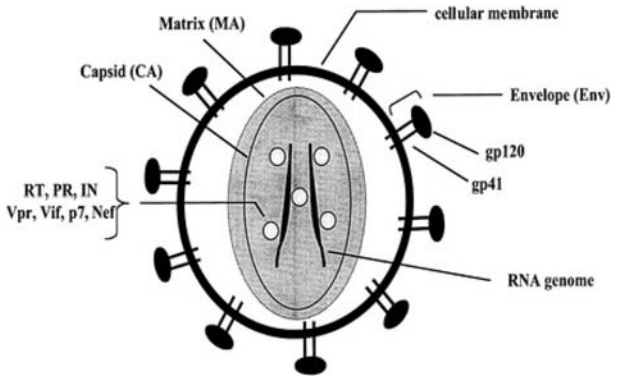

Fig. 1 Structure of the HIV virion. The HIV RNA genome is encapsulated in a capsid (CA) composed of p24 and is stabilized by a matrix protein, MA. The cellular lipid bilayer containing envelope glycoproteins completes the outer structure. Several proteins located inside the capsid are required for maturation and infectivity of HIV.

Table 1 HIV proteins and their functions

Protein	*Size (kDa)*	*Function*
Gag	p24	Capsid (CA) structural protein
	p17	Matrix (MA) protein-myristoylated
	p6	Role in budding
	p7	Nucleocapsid (NC) protein; helps in reverse transcription
Polymerase (Pol)	p66, p51	Reverse transcriptase (RT); RNase H–inside core
Protease (PR)	p10	Posttranslational processing of viral proteins
Integrase (IN)	p32	Viral cDNA integration
Envelope	gp120	Envelope surface (SU) protein
	gp41	Envelope transmembrane (TM) protein
Tat	p14	Transactivation
Rev	p19	Regulation of viral mRNA expression
Nef	p27	Pleiotropic, can increase or decrease virus replication
Vif	p23	Increases virus infectivity and cell-to-cell transmission; helps in proviral DNA synthesis and/or in virion assembly
Vpr	p15	Helps in virus replication; transactivation
Vpu	p16	Helps in virus release; disrupts gp160–CD4 complexes
Vpx	p15	Helps in infectivity

Adapted from Levy, J. A. (2007). HIV and the pathogenesis of AIDS (3rd ed.). Washington, DC: ASM Press.

gp120 surface protein has several loops highly variable in amino acid sequence (V1–V5) among viral strains. These regions primarily regulate the efficiency of virus entry and cellular tropism. The envelope also contains five constant regions (C1–C5) interspersed within its structure. Mutations in the V3 loop can decrease or alter infectivity and the fusion capabilities of HIV. One of the conserved regions of gp120, C4, has a complex folded structure that, if mutated, can affect conformational changes and thus the efficiency of virus binding to CD4. The C2 region of gp120 is important for interactions with CD4 and with gp41, to which gp120 binds by hydrophobic interaction. The gp41 protein mediates fusion and, along with gp120, cytotoxicity (see Section IVB).

PR, RT, and IN

Another long viral ORF generates precursor Gag and Gag-Pol transcripts, which can be transported to the cytoplasm for translation by free ribosomes into polyproteins. A ribosomal frameshifting event produces the Gag-Pol polyprotein $Pr160^{Gag\text{-}Pol}$ that can be proteolytically processed by the viral protease, PR. The autocatalysis of PR, a product of Pol, is activated in the presence of high $Pr160^{Gag\text{-}Pol}$ protein concentrations. The PR-mediated cleavage of $Pr55^{gag}$ and $Pr160^{Gag\text{-}Pol}$, during assembly of the virion, is necessary for the generation of infectious particles. In addition, PR processes the reverse transcriptase (RT) and integrase (IN) proteins from Pol and matrix (MA), p24, p9, and p6 proteins from Gag. Reverse transcriptase generates the complementary strand from the RNA genome producing the provirus cDNA form. Because RT is colocalized with the RNA genome in the capsid, some reverse transcription can occur in the viral particle before infection of the target cell. However, the completion of provirus production requires infection of the host cell and uncoating of the virion. Within the capsid, viral IN proteins are found along with MA and the accessory viral protein, Vpr. IN is required for integration of the provirus into the host genome.

MA, p24, p9, and p6

The Gag precursor protein $Pr55^{gag}$ is responsible for generating structural proteins required for virus assembly. Due to myristoylation of $Pr55^{gag}$, the protein can be targeted to the plasma membrane for the regulation of viral assembly at the cell surface. Proteolytic processing of $Pr55^{gag}$ by PR generates MA, p24, p9, and p6. MA is a myristoylated protein (p17) that forms a matrix assuring the structural integrity of the virion. The p24 protein is the major structural component of the cone-shaped core or capsid (CA) and can influence infectivity of the virion through interaction with cyclophilin A. The p9 protein is an RNA-binding protein in the core that protects viral RNA from nucleases and transports full-length viral RNA to the assembly complex. The p6 protein can assist in budding of the virion and affect infectivity.

Regulatory Proteins

Tat and Rev

The smaller ORFs generate viral regulatory and accessory proteins. These viral gene products, Tat, Rev, Nef, Vpu, Vpr, and Vif, can be spliced in the nucleus by cellular spliceosomes and transported to the cytoplasm for translation by membrane-bound ribosomes. Tat regulates viral transcription through interactions with specific cellular factors and TAR, the transactivation response element in the 5′ stem–loop region of the HIV RNA genome. Tat can also enhance, but is not required for, virus replication. The Rev protein regulates nuclear export of transcripts by interacting with a Rev responsive element (RRE) located in the viral *env*-coding region. Rev controls the ratio of unspliced to spliced transcripts, which is important for initiating virus assembly.

Accessory Proteins

Vif, Vpu, Vpr, Nef

In addition to regulatory proteins, several accessory proteins have important functions in the HIV replicative cycle. Vif increases virus infectivity, and Vpu, found in HIV-1 only, mediates downregulation of the CD4 molecule and enhances infectious HIV virion release from the cell surface. Vpr, a nuclear protein found in most HIV subtypes, regulates transport of the preintegration complex. Both Vpr and Vpx, a cytoplasmic protein found only in HIV-2 and SIV, affect assembly and budding, as well as enhance viral replication. Nef is a pleiotropic protein that can positively regulate virus replication in quiescent cells and mediate pathogenicity. Nef appears to affect T-cell signaling activity, resulting in altered or lower levels of cytokines, particularly IL-2. The role for Nef in the regulation of viral infectivity and pathogenesis is supported by the recovery of Nef mutants of HIV-1 from infected individuals with no evidence of disease progression. However, the full mechanism of Nef activity remains unclear.

HIV Replication Cycle

The infection cycle of HIV can be divided into four major stages: binding and entry, reverse transcription and integration, transcription and translation, and assembly and budding (Fig. 2). (Step 1) In the binding and entry stage, the HIV envelope protein, gp120, has a high-affinity interaction with the cellular surface protein, CD4, and specific cellular coreceptors, which facilitate fusion with the cellular membrane. Once inside the cell, viral CA protein p24 and cyclophilins mediate the uncoating of the HIV core and release of the RNA genome. (Step 2) In association with several structural proteins, the RNA genome is primed by viral tRNA-lysine and is reverse transcribed into a double-stranded cDNA. The MA and Vpr viral proteins target the preintegration complex, composed of viral cDNA and MA, Vpr, and IN, to the nucleus. Integration of the provirus occurs randomly in the cellular genome and is regulated by IN, which is capable of cleaving chromosomal DNA and mediating ligation of the provirus.

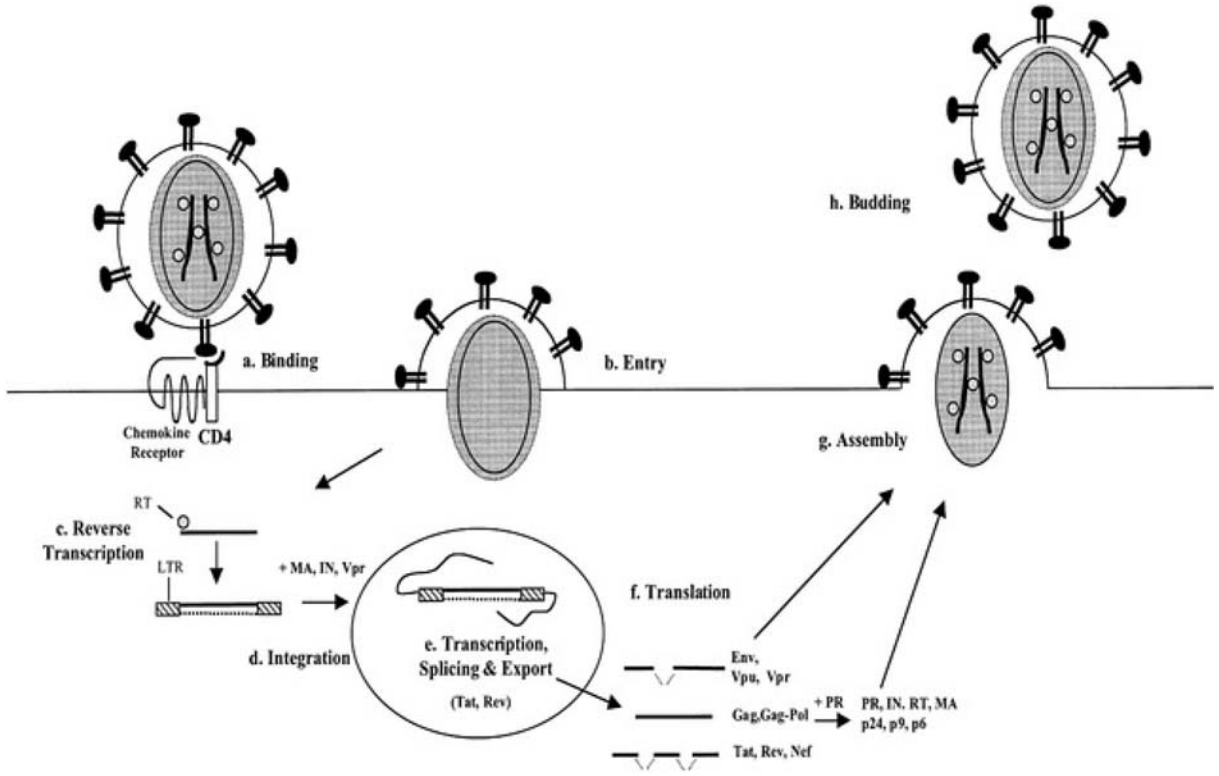

Fig. 2 Steps in the HIV replication cycle. HIV infection proceeds through several stages involving binding, entry, reverse transcription, integration, transcription, translation, assembly, and budding. (A) The HIV gp120 envelope protein binds CD4 on the cellular surface and specific chemokine receptors facilitate fusion with the cellular membrane. (B) Entry involves uncoating of the virion, releasing the capsid containing the viral RNA genome and viral proteins into the cytoplasm. (C) Virally encoded reverse transcriptase generates the RNA genome into double-stranded cDNA. (D) MA, IN, and Vpr mediate nuclear transport of the cDNA preintegration complex, and IN completes integration of the HIV cDNA into random sites of the host genome. (E) Transcription of viral genes is initiated at the 5′ LTR and requires Tat for optimal transcription. Splicing occurs in the nucleus, and the export of long viral transcripts is mediated by Rev. (F) Translation of viral transcripts in the cytoplasm produces viral products that assist in (G) assembly of the virion at the cell surface and the subsequent (H) budding from the cellular surface.

The HIV proviral cDNA is flanked by a 5′ LTR and 3′ LTR that regulate initiation of transcription and RNA termination, respectively, of regulatory enzymatic and structural genes. (Step 3) The 5′ LTR is composed of several regulatory sites for the transcription of viral genes by RNA polymerase II. NF-κB, Sp1, and TATA binding protein (TBP) are among some of the cellular factors that bind upstream of the 5′ LTR and assist in initiating viral transcription. The viral regulatory protein Tat is essential for increasing the rate of transcription. The regulation of splicing events, directed by the Rev protein, allows for the proper translation of many of the viral RNAs. Unspliced viral RNA can incorporate, at the cell membrane, into virus capsids that subsequently bud from the cell surface, incorporating the virus envelope expressed on the cell surface. (Step 4) During the budding process, proteolytic processing (mediated by the viral protease) brings about the maturation of the viral particle into an infectious virion.

Cellular Binding and Tropism

Cellular determinants of the host range include receptors for HIV binding and entry, such as the CD4 surface molecule, chemokine coreceptors, galactosyl ceramide, complement, and Fc receptors used when virus is complexed with antibody. However, high levels of productive infection are predominantly observed in CD4+ hematopoietic cells. The CD4 surface protein expressed by mononuclear phagocytes and helper T lymphocytes contains region D1 important for viral entry and cellular tropism. This CD4 molecule provides a docking site for, and induces a conformational change in, the envelope protein gp120, which exposes a site(s) for virus binding to coreceptors on the cell and fusion with the cell.

HIV: Cell Interactions

Coreceptors are necessary for efficient HIV virion attachment that leads to viral fusion and entry. Two such receptors are the G protein-coupled seven transmembrane chemokine receptors CXCR-4 and CCR5. Chemokine receptors have important roles in the trafficking of T lymphocytes and macrophages. In HIV infection, chemokine receptors are essential for HIV entry after initial binding to the CD4 surface molecule and are determinants of cellular tropism.

A morphologic hallmark of productive HIV infection in cultured cells is the presence of syncytia, a fusion of infected cells resulting in multinucleated cellular complexes, and subsequent cell death. All HIV isolates can replicate in CD4+ T lymphocytes and some are more cytopathic than others, as observed by the rapid formation of syncytia. Those HIV strains that replicate in established T-cell lines, as well as CD4+ lymphocytes, are the syncytia-inducing (SI) strains and utilize the CXCR-4 coreceptor, expressed on T lymphocytes. In contrast, non-syncytia-inducing (NSI) strains that also infect CD4+ lymphocytes grow well in macrophages using the CCR5 coreceptor. This receptor is expressed on monocytes, dendritic cells, T cells, and microglia. Additionally, some isolates are dual-tropic and can infect both cell types. Therefore, the diversity of HIV isolates and coreceptor expression can affect cellular tropism.

Evidence has shown that SDF-1, the natural ligand to CXCR-4, and the β-chemokines that bind to CCR-5 can suppress HIV replication in cell culture by blocking entry. These findings further support the importance of chemokine receptors in mediating HIV infection. Moreover, at the genetic level, homozygosity for a CCR5 allele with a 32-bp deletion, which affects CCR5 surface expression, confers resistance in some HIV-infected individuals to the NSI virus strains.

HIV can infect CD4 negative cells, although with less replication capacity, through alternate receptors. In brain cells and bowel epithelium, gp120 interacts with surface galactosyl ceramide at a site distinct from its CD4 receptor-binding region. Another mode of entry may involve Fc and complement receptors. These receptors can interact with the Fc portion of nonneutralizing antibodies that attach to HIV and can transport the virus into the cell.

Role of HIV Envelope Protein

HIV envelope proteins act as viral determinants of cellular binding and host range. Both gp120 and gp41 appear important in regulating the rate and efficiency of virus attachment and entry through defined conformational changes or glycosylation patterns. Specific regions in the V3 loop also influence the pathogenicity or syncytia-inducing capability of the virion. The V3 loop is particularly important for determining the host range. Additionally, cleavage of gp120 by cellular proteases may be an essential step for viral entry and facilitate gp41 fusion with the cellular membrane.

Virus Replication and Cytopathicity

The difference in virus production and cytopathogenicity in T cells and macrophages may correlate with the state of activation. Quiescent T lymphocytes expressing CD4 on the surface are very susceptible to HIV infection. However, until activated, they cannot elicit a productive infection or permit integration of viral DNA. In nondividing CD4+ macrophages, HIV infection can be productive with integration of viral DNA. Levels of virus replication are generally lower than in CD4+ lymphocytes but some NSI strains can be produced to high levels in macrophages. In some CD4 negative cells, HIV can enter but generally replicates to low levels. Differences in the intracellular factors influencing transcription, reverse transcription and virus production may account for the incapacity of some cell types to produce substantial amounts of virus (see below). In addition, virus entry or envelope processing can vary among cell types and affect the extent of viral replication.

Cytopathic Effects

The loss of CD4+ cells could be due to a variety of mechanisms, including syncytia formation, antibody-dependent cellular cytotoxicity, gp120-induced apoptosis, cytotoxic T lymphocyte (CTL) lysis of infected cells, or death of uninfected bystander cells by apoptosis, or necrosis. Syncytia formation (or cell:cell fusion) is followed by membrane damage, leading to "balloon cell" degeneration, or necrosis. As noted earlier, SI viruses are generally more cytopathic than NSI viruses, and the appearance of SI isolates in infected individuals strongly correlates with progression to AIDS. Regions on CD4 and gp120 can regulate syncytia formation and, therefore, toxicity to CD4+ cells. Programmed cell death, or apoptosis, in response to virus infection, appears to account in part for the decline in CD4+ cell numbers in individuals as they progress to disease. This process is increased with inflammation and cell activation. Direct infection of the cells is not needed to observe this effect. Many reports suggest that alterations in cytokine production can influence the rate of cell death by inhibiting survival cytokines (e.g., IL-2) or by directly inducing the death of uninfected bystander lymphocytes as well as infected cells. However, the pathway(s) leading to apoptosis in vivo is still unclear.

Cellular Latency

Cellular latency occurs following HIV provirus integration and is characterized by minimal transcriptional or translational activity of viral genes. Virus activation from a latent state is often the result of stimulation by mitogens, cytokines, or DNA-damaging agents. The regulation of viral latency remains elusive. Some of the cellular factors recruited to the LTR for the active transcription of viral genes include NF-κB, Sp-1, and TBP However, Rev, Tat, Vpu, and Nef have been implicated in mediating latency through their interactions with the LTR and replication cycle. Further understanding of the factors preventing induction of and reactivation from viral latency would be helpful for developing approaches to inhibit progression to disease. Activation of HIV from a latent state is a recent approach at bringing about a cure (see below).

Host Immune Responses to HIV Infection

The effect of HIV on the immune system heavily influences the pathogenesis of the infection. Some of the differences observed in immune responses to HIV infection can be associated with small genetic changes in the virus or differences in the host genome. Certain HLA genotypes (e.g., HLA-B57 B27 and B51) have been associated with long term survival and slow disease progression. Also HLA-KIR interactions can influence the natural killer (NK) cell anti-HIV activity. A humoral response to the initial acute infection is reflected by the production by B cells of anti-HIV antibodies. As a host response to HIV infection, some of these antibodies are able to neutralize the virus, generally blocking the epitopes responsible for binding and/or fusion of gp120 or gp41 to the target cell. Antibody-dependent cellular cytotoxicity (ADCC) is another host humoral antiviral response that targets specific HIV epitopes for destruction by interactions of antibody-coated infected cells with effector cells such as NK cells, neutrophils, or macrophages. In contrast, antibody-dependent enhancement (ADE) can potentiate HIV infection through complement or Fc receptors. A decreased concentration of inhibitors of complement in infected individuals suggests that the antibody-independent complement cascade pathway can be activated to lyse either the virus or the virus-infected cell. This and other innate immune responses may play a role in controlling HIV infection.

Natural Killer Cells

A component of the innate immune system, NK cells, can directly eliminate virus-infected cells. The cytotoxic mechanism is not MHC-dependent and potentially involves ADCC. In individuals progressing to disease, a loss in NK cell number and function, partly reflecting direct infection of these cells by HIV, alters the production of proinflammatory cytokines such as interferon-γ. A decrease in interferon-γ production can also interfere with CD8+ cell function.

CD4 + T Lymphocytes

The CD4+ cell number and proliferative responses are dramatically reduced during disease progression. Their loss is caused by several processes including direct infection, apoptosis, and immune cell killing. Dysfunctional T helper cells and a loss of CD4+ cells are characteristically observed during infection. Pronounced deficits in CD4+ cell function are manifested by a decreased proliferative response first to recall antigens, then alloantigens, and, in later stages, mitogenic stimulation. Lower levels of IL-2 production in addition to decreased IL-2 receptor expression are observed with progression to disease. Generally, CD4+ T helper cells produce higher levels of type 2 cytokines (IL-4, IL-5, IL-13) than type 1 cytokines (e.g., IL-2) during the course of symptomatic infection.

CD8 + T Lymphocytes

Unlike NK cells, CD8+ cells with cytotoxic function require MHC restriction and are antigen-specific. These cytotoxic T lymphocytes (CTL) eliminate virus-infected cells through perforin or Fas/FasL-mediated pathways. CD8+ T lymphocytes are critical for

controlling the dissemination of HIV in stages early in infection and before the appearance of antibodies. Importantly, an increase of CD8+ cells is observed during the asymptomatic stage of the infection, reflecting a response to infection as well as a compensatory reaction to the loss of CD4+ T helper cells.

Both transient and long-lived CTL populations, specific for viral proteins, such as Env, Nef, RT, and Gag gene products, are found in vivo. However, during the progression to disease, a decrease in the frequency of HIV-specific CTLs has been observed along with a decline in cytotoxic responses. Proposed mechanisms for the loss of function include the generation of viral mutants that escape CTL recognition, downregulation of MHC I molecules (potentially through viral *tat* or *nef* gene products), and decreased T helper cell function.

CD8+ cells can also exhibit noncytotoxic, non-MHC-dependent anti-HIV activity. This innate CD8+ cell noncytotoxic antiviral response (CNAR), which is not HIV isolate-specific, acts on all strains of HIV-1 and HIV-2, and is mediated, at least in part, by a factor secreted by CD8+ cells. This CD8+ cell antiviral factor (CAF) decreases HIV replication in CD4+ cells and in macrophages by acting on the HIV LTR to block virus transcription. Lower levels of viral RNA and protein are observed in infected cells exposed to CAF. The activity of CAF is distinct from chemokines and other known cytokines; its identity remains unknown. CNAR activity correlates directly with a healthy clinical state; CD8+ cells from asymptomatic individuals exhibit a greater capacity to suppress HIV replication than individuals progressing to disease. People infected for more than 10 years who are healthy and without therapy have a strong CNAR. Thus, this host innate immune response appears to be very important in controlling HIV infection.

Dendritic Cells

Dendritic cells and other antigen-presenting cells (APC) migrate in the peripheral blood and line mucosal surfaces. They are necessary, after interacting with infectious virus, for triggering subsets of antiviral effector cells. The replication of virus in these cell types is relatively low and stable and therefore they can remain for long periods of time as reservoirs releasing virus in the body. Because certain dendritic cells are believed to harbor virus, they can readily transfer HIV to T lymphocytes and contribute to the loss of CD4+ cells. Many of the functions of APCs, including presentation capabilities and cytokine regulation for the differentiation, survival, and maintenance of memory and naive T cells, are compromised in HIV-infected individuals. Because dendritic cells are among the first cell subset to encounter infectious HIV and are capable of modulating a broad range of lymphocyte functions, a further understanding of their role in HIV pathogenesis is of particular importance.

Intrinsic Anti-HIV Cellular Factors

When HIV infects a cell there can be differences in the extent of virus replication depending on intracellular intrinsic factors that have been identified. These include APOBEC3 G/F, Trim 5α, LD2, tetherin, MURR-1, and SAMHD1. APOBEC, a cytidine deaminase, causes mutations in the HIV genome affecting virus replication. The viral protein Vif can counter this anti-viral response by inducing APOBEC degradation. Trim 5α, a cytoplasmic protein, prevents the uncoating of the virus by binding to the capsid. LD2 has a similar effect in blocking HIV-2 replication after entry. Tetherin, a membrane protein, prevents budding of virus particles brought to the cell surface and can be countered by HIV Vpu. MURR-1 can affect viral transcription. Finally SAMHD1 blocks proviral synthesis during reverse transcription, particularly in monocytes and dendritic cells. This antiviral intrinsic effect can be countered by HIV Vpx which induces proteolytic degradation.

Cancers Associated with HIV Infection

HIV-infected patients and recipients of organ transplants show an increased prevalence of cancer particularly those associated with a viral infection (**Table 2**).

As seen in transplant patients, HIV infection leads to an immune deficiency that can decrease immune responses against cancer or increase immune responses associated with inflammation that are associated with cancer development (**Fig. 3**). It is estimated that about 40% of cancers in HIV-infected subjects can be attributed to viral infections. Herpes and papilloma viruses are responsible for cancers that were initially linked to the diagnosis of AIDS. The mechanism for the induction of malignancy involves initiation by the virus, promotion of cell proliferation, and cytokine production that leads to cellular karyotypic and genomic mutational events. Obviously the current vaccines against known viruses such as Hepatitis B and HPV should reduce the prevalence of these cancers.

Anti-HIV Approaches

Current therapeutic approaches to block HIV replication involve targeting the three viral enzymes reverse transcriptase, integrase and protease. These treatments have decreased plasma viral loads dramatically and increased the life expectancy for symptomatic individuals infected with HIV. Recent combination therapy approaches (using three drugs) have given infected people the possibility of living a near normal lifetime, although some treated subjects develop resistance to the antiviral drugs or toxic side effects

Table 2 Cancers associated with HIV infection

Cancer	*Virus*
AIDS-defining cancers	
Kaposi's sarcoma	KSHV (HHV8)
Non-Hodgkin's lymphoma	EBV
Invasive cervical cancer	HPV
Non-AIDS-defining cancers	
Anal Cancer	HPV
Hodgkin's disease (Hodgkin's lymphoma)	EBV
Adult T cell leukemia/lymphoma	HTLV
Melanoma skin cancer	
Liver cancer	Hep B; Hep C
Lung cancer	
Mouth and throat cancers	HPV
Testicular cancer	
Squamous cell and basal cell skin cancers	HPV?

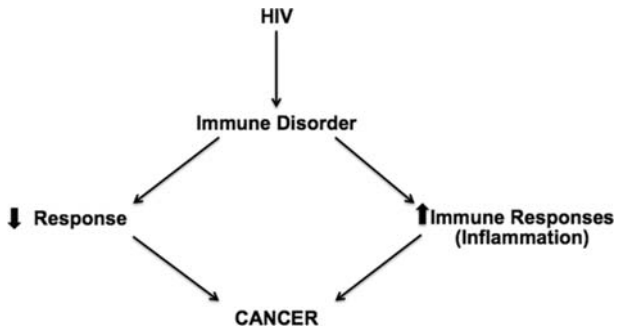

Fig. 3 HIV Infection and Cancer Development.

affecting tissues such as the kidney, liver, and pancreas. Most recently, combination HIV therapy can be delivered as one pill taken daily. That has reduced resistance by helping increase adherence. Also, because HIV infection often leads to the development of B-cell lymphomas and several central nervous system disorders, the extended life expectancies as a result of therapeutics could increase the prevalence of HIV-associated cancers and neuropathies.

With the success of antiviral drugs, many in the HIV field are advocating therapy for all infected individuals. Reducing the viral load by using anti-viral drugs can also markedly decrease the transmission rate. Thus the aim in some communities is to establish universal anti-HIV drug administration that could reduce transmission rates and overall prevalence of the infection.

In addition, the success of antiretroviral therapy (ART) has led to strategies to prevent HIV infection by preexposure therapy and to effect a cure. In the latter case, the drugs are used in attempts to rid the body of HIV completely or reduce HIV presence to a state in which there are no signs of the infection. Attempts at establishing a cure involve activation of HIV from latent cellular reservoirs so that the immune system can eliminate them, gene therapy in which the CCR 5 gene and other host genes required for HIV infection are deleted, as well as approaches to boost the immune system to control virus-infected cells and prevent HIV spread in the host. Short-term advances toward a cure have been reported but elimination of the virus that integrates into several different cells in the body presents a notable challenge. Many researchers are suggesting that combination antiviral therapies and immune enhancing drugs could lead to a "functional" cure in which ART will not be needed for a lifetime. The host immune system would control the virus as seen in healthy long-term infected individuals who have no detectable circulating virus or very low viraemia. Innovative approaches at enhancing antiviral immunologic responses can offer advantages to individuals infected with HIV, as the immune system can recognize a variety of viral subtypes and control infection in many different tissues of the body (e.g., bowel, brain).

Finally, the development of vaccines using antigenic components of HIV delivered through a variety of different modalities and with different adjuvants will be necessary for the prevention of infection. HIV is very variable and can be transmitted by infected cells as well as by free virus. The approaches needed for inhibiting all HIV isolates and for blocking an incoming infected cell, therefore, raise major challenges to the development of an effective vaccine.

It is hoped that by studying the cellular, molecular, and biochemical pathways involved in HIV replication and the effective immune responses that can control the virus, particularly in long-term survivors, optimal therapies and strategies for the prevention of HIV and AIDS can be developed.

Glossary

The HUGO (Human Genome Organization) Committee nomenclature is used throughout: genes are quoted in italics and capital letters, except for those encoding for immunoglobulins (IG) or the variable region of their heavy chains (IGVH) and T-cell receptor (TR), which are reported in ordinary capital letters. The gene products are quoted in ordinary capital letters.
The cluster of differentiation (CD) nomenclature of human leukocyte antigens is used through the text.
The terminology of the Revised 4th Edition of the World Health Organization: WHO Classification of tumors of hematopoietic and lymphoid tissues is used throughout.

Abbreviations

ABVD Adriamycin, bleomycin, vinblastine, dacarbazine
ALK Anaplastic large cell lymphoma kinase
CD Cluster of differentiation
EBER Epstein–Barr encoding region
HIV Human immunodeficiency virus
MW Molecular weight
OS Overall survival
PCR Polymerase chain reaction
PET Positron emission tomography
(R-)CHOP (Rituximab-)cyclophosphamide, hydroxydaunorubicin, oncovin, prednisone
WHO World Health Organization

Definition

Hodgkin lymphoma (HL) is usually characterized by the presence of a low number of neoplastic cells, either multinucleated (Reed–Sternberg cells, RSCs) or mononucleated (Hodgkin cells and variants, HCs), which are comprised in an overwhelming inflammatory background with variable cytological composition. RSCs, which measure about 60 μm in diameter, display a large rim of cytoplasm and two or more huge nuclei with central, inclusion-like nucleoli, often acidophilic at hematoxylin and eosin (H&E) (Fig. 1). HCs differ from RSCs by the presence of a single nucleus.

Historical Annotations

The tumor was first described by Sir Thomas Hodgkin in 1832 and subsequently named "Hodgkin's Disease" by Samuel Wilks. The histogenesis of the condition was a matter of debate for several decades, until the use of single cell micro-dissection allowed establishment of the monoclonal B-cell nature of the neoplastic cells. As a result of this finding the term "Hodgkin's disease" was abandoned in favor of "Hodgkin lymphoma," with as implication its inclusion among lymphoid neoplasms. On histological grounds, the Lukes and Butler classification became the reference in the mid-1960s, by distinguishing four varieties of HL (lymphocyte predominant, nodular sclerosing, mixed cellularity, and lymphocyte depleted), mainly based on the composition of the microenvironment. This classification still represents the basis for the diagnosis of HL, although some refinements have been introduced meanwhile. Nowadays, a major distinction is made between nodular lymphocyte predominant HL (NLPHL) and classical HL (CHL), each characterized by particular clinical, morphologic, immunophenotypic and molecular features. Accordingly, the Revised Edition of the WHO Classification has abandoned the unifying term "Hodgkin lymphoma" in favor of "Hodgkin lymphomas." CHL is further subdivided into four types: lymphocyte-rich (LR), nodular sclerosing (NS), mixed cellularity (MC), and lymphocyte depleted (LD). LRCHL was in the past lumped with NLPHL. However, although it shares architectural and microenvironmental features with the latter, it shows the morphologic and immunophenotypic profile of CHL.

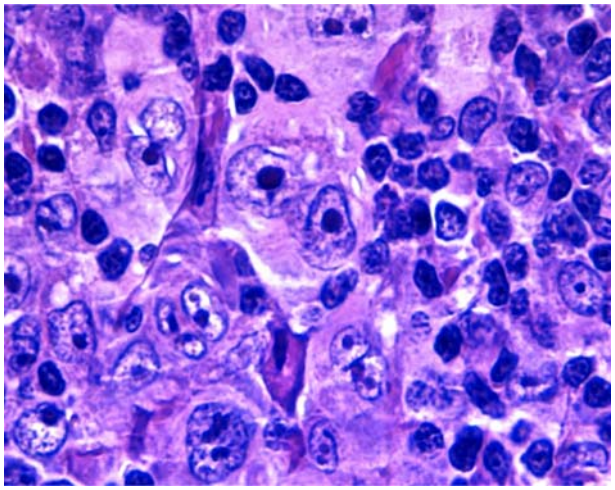

Fig. 1 Example of a binucleated Reed–Sternberg cell (center) surrounded by some mononucleated Hodgkin cells.

Epidemiological Notes

HL usually affects lymph nodes, except for NSCHL that can develop in the thymus. About 95% of HL cases belong to the classical category, the remaining 5% corresponding to NLPHL. In resource-rich countries, the latter more often occurs in males in the fourth decade of life. It has a rather indolent course with possible late recurrences and a spread that is closer to that of non-Hodgkin lymphomas. NLPHL can be concomitant with or preceded or followed by a peculiar modality of lymph node regression, known as progressively transformed germinal centers (PTGC). The latter, however, is not necessarily associated with NLPHL. CHL shows a bimodal age distribution with peaks in the second and seventh decades of life. It is more common in males, except for NSCHL that is more predominant among females. It has a distinct pattern of extension in the body, starting from a single node or group of adjacent nodes; this pattern represents the rationale for the staging procedures.

Lymphocyte Predominant HL

This form of HL has unique morphologic and immunophenotypic features. In 80% of cases it is characterized by the presence of nodules mostly composed of small B-lymphocytes (CD20+, CD79a+, PAX5+) with some epithelioid elements (CD68+/CD163+). Inside the nodules, which tend to expand and coalesce through time, producing a nodular and diffuse growth pattern, there are mononucleated cells measuring about 60 μm in diameter, which represent 1%–2% of the cell population (Fig. 2A–C). They show polylobated nuclei, with dispersed chromatin and multiple small nucleoli at times adjacent to the nuclear membrane, and a narrow rim of slightly basophilic cytoplasm. Because of the nuclear morphology, they were called "pop-corn" cells, a term that has been almost completely abandoned in favor of "lymphocyte predominant" cells (LPCs). RSCs are exceedingly rare and are usually detected only when serial sections are examined. LPCs express a complete B-cell phenotype (CD20+, CD75+, CD79a+, PAX5+, BOB.1+, OCT2+) as well as the leukocyte common antigen CD45 and—in most cases—epithelial membrane-antigen (EMA) (Fig. 3A–G). They also stain positive for BCL6 and IRF4 (Fig. 2J and K), which supports their derivation from a cell still residing in the germinal centers along with the presence of a high mutational load of the variable region of the immunoglobulin heavy chain genes (IGVH). In 10%–20% of cases, they express IgD and CD38, but not IgM or CD27 (Fig. 3G). This peculiar pattern is usually observed in young males and is associated with a more favorable course. A meshwork of follicular dendritic cells (FDCs) (CD21+, CD23+) is detected within the nodules. Importantly, LPCs lack expression of CD30 and CD15, which are characteristic of HRSCs of CHL. Furthermore, LPCs are typically surrounded by rosettes of follicular T-helper (FTH) lymphocytes (CD3+, CD279/PD1+, BCL6+, CD57+) (Fig. 3H and I). A few scattered CD30+ elements may be observed, which usually correspond to activated B-immunoblasts and only exceptionally have the typical LP morphology. The regular CD20 positivity of LPCs represents the rationale for treatment with Rituximab, either as monotherapy in low stage disease, which may be followed by maintenance therapy, or in combination with CHOP or ABVD in more advanced stages. Interestingly, the administration of Rituximab might prevent disease transformation.

Besides this classic nodular, B-cell rich appearance, LPHL can display some variant patterns: serpiginous/interconnected nodular, nodular with prominent extra-nodular LPCs, nodular with T-cell rich background, diffuse (T-cell rich B-cell lymphoma-like), and diffuse "moth-eaten" with B-cell rich background. The latter two variants correspond to the 20% of cases in which no nodular pattern is observed and may be difficult to distinguish from T-cell/histiocyte-rich large B-cell lymphoma (THRLBCL), also due to the absence of FDCs and the similarity in terms of gene expression profile between the two neoplasms. The following elements can help under these circumstances to reach a diagnosis: (1) the clinical presentation, which is aggressive with widespread disease

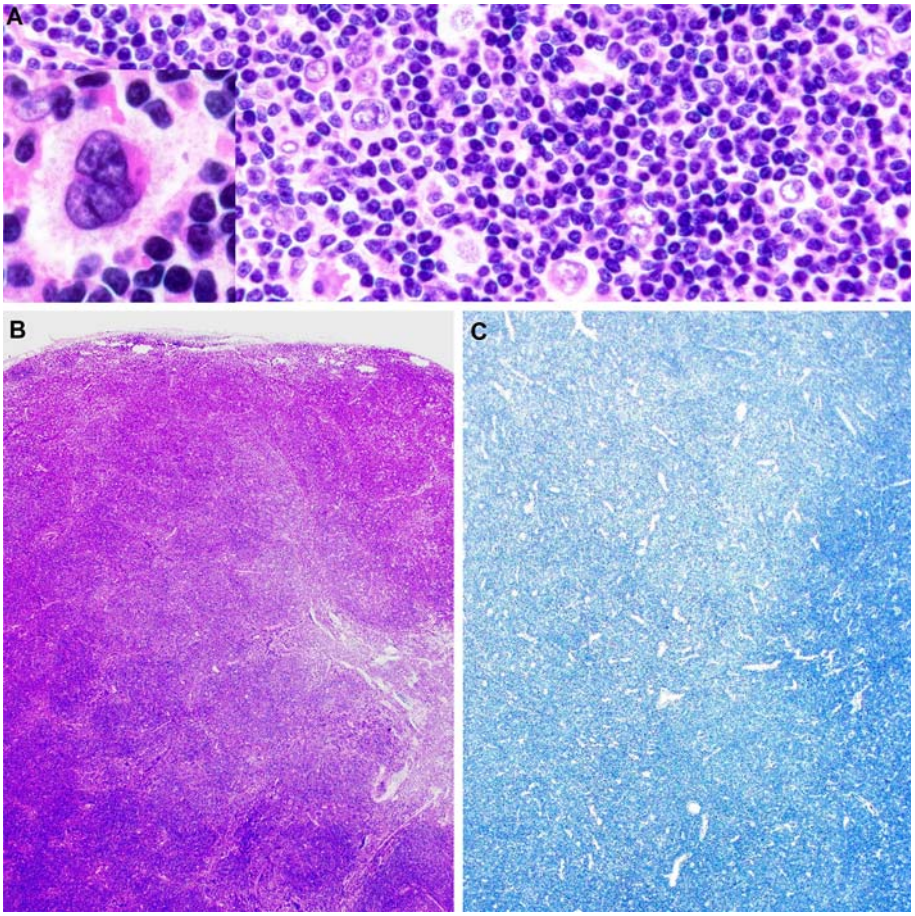

Fig. 2 So-called "lymphocyte predominant cells" (LPCs), scattered in a background rich in small lymphocytes (A, inset: nuclear detail of a LPC). Nodular lymphocyte predominant Hodgkin lymphoma may show a nodular (B) or diffuse growth pattern (C). These patterns are frequently coexistent in the same lymph node.

and systemic symptoms in THRLBCL; (2) the presence of CD279/PD1+ T-cell rosettes around otherwise canonical LPCs; (3) the expression of PU.1 and the negativity for LSP-1 in LPCs, the opposite pattern being observed in the neoplastic elements of THRLBCL; and (4) the presence of a residual nodule with the typical characteristics of NLPHL.

Molecular studies have shown that LPCs harbor clonally rearranged IGVH. As mentioned above, the clonal rearrangements can be easily detected in the DNA of single microdissected neoplastic cells, and the variable regions of IGVH carry a high load of somatic mutations indicative of ongoing mutational activity. Epstein-Barr virus (EBV) infection detected by EBER 1/2 in situ hybridization may be found in LPCs in 3%–5% of cases in both children and adults. EBV may be also present in bystander lymphocytes. *BCL6* rearrangements (involving IG, *IKAROS*, *ABR* and other partner genes) are present in about half NLPHL cases. Aberrant somatic hypermutations are found in 80% of cases, most frequently in *PAX5*, but also in *PIM1*, *RHOH/TTF*, and *MYC*. Mutations of the genes *SGK1*, *DUSP2*, and *JUNB* are also reported in about half of NLPHL cases by targeted next-generation sequencing (NGS). An increased risk of NLPHL has been noted in some families. PHL has also been identified in patients affected with Hermansky-Pudlak type 2 syndrome or autoimmune lymphoproliferative syndrome (ALPS) with mutations in *FAS*.

As previously mentioned, nodular and nodular and diffuse forms of NLPHL develop slowly, with frequent late relapses. It usually remains responsive to therapy and thus is rarely fatal, although in an advanced stage and higher age group it may behave more aggressively, as do histopathologic variants characterized by the presence of LPCs outside B-cell nodules or B-cell depletion of the microenvironment or THRLBCL-like transformation. Therefore, it is useful to mention these variant features in the pathology report. Progression to diffuse large B-cell lymphoma (DLBCL) has been observed in approximately 3%–5% of cases. In such cases the neoplastic cells maintain their typical immunophenotype. If localized, DLBCL associated with NLPHL generally has a good prognosis. NLPHL and the associated DLBCL are clonally related. Bone marrow involvement is rare in NLPHL and raises the possibility of THRLBCL, when there are only PD1/CD57-negative T-cells and no small B-cells in the background. Cases of NLPHL with bone-marrow involvement show aggressive clinical behavior. Advanced stage NLPHL responds poorly to the chemotherapy regimens traditionally used for CHL treatment but responds better to R-CHOP or regimens used to treat aggressive B-cell lymphomas.

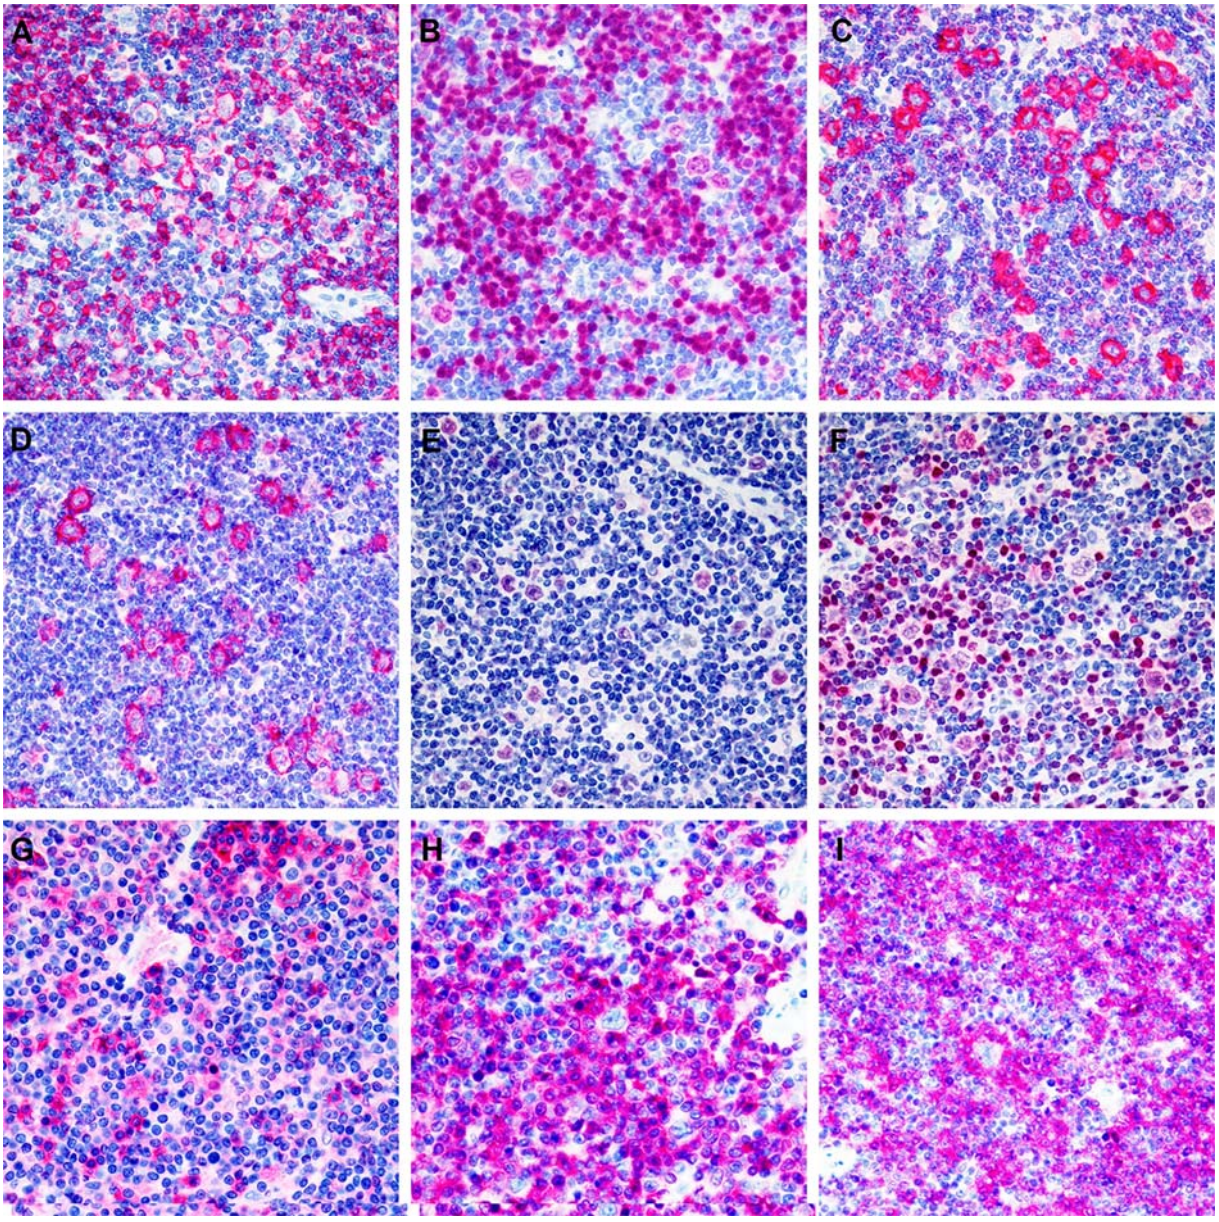

Fig. 3 Immunophenotypic features of nodular lymphocyte predominant Hodgkin lymphoma. LPCs are positive for CD20 (A), BSAP/PAX5 (B), CD75 (C), epithelial membrane antigen, EMA (D), BCL6 (E) IRF4/MUM1 (F), and, in a subset of cases, IgD (3G). LPCs are, as a rule, surrounded by small T-lymphocytes, which express CD3 (H) and PD-1 (I), with formation of rosette-like structures.

Classical HL

Morphology and Histotypes

Classical HL is characterized by the presence of typical HRSCs in a cellular milieu that varies depending on its histotype. Neoplastic cells can at times become smaller due to apoptotic changes: they are accordingly termed "dwarfs."

Lymphocyte-rich classical Hodgkin lymphoma

Lymphocyte-rich classical Hodgkin lymphoma (LRCHL) may proliferate in a nodular or, more rarely, diffuse pattern. The reactive component consists of small lymphocytes (mostly of B-cell origin) and some histiocytes with or without the formation of micro-granulomas. In this context, HRSCs are scattered through the nodules or more rarely located at their periphery (Fig. 4A). At times, residual germinal centers are seen within the nodules in an eccentric location. Neutrophils and eosinophils are absent. Based on morphological characteristics, in the past LRCHL was included in the setting of LPHL. With the advent of immunohistochemistry, it became clear that neoplastic cells had the typical phenotype of HRSCs (see below) and not that of LPCs. With the currently

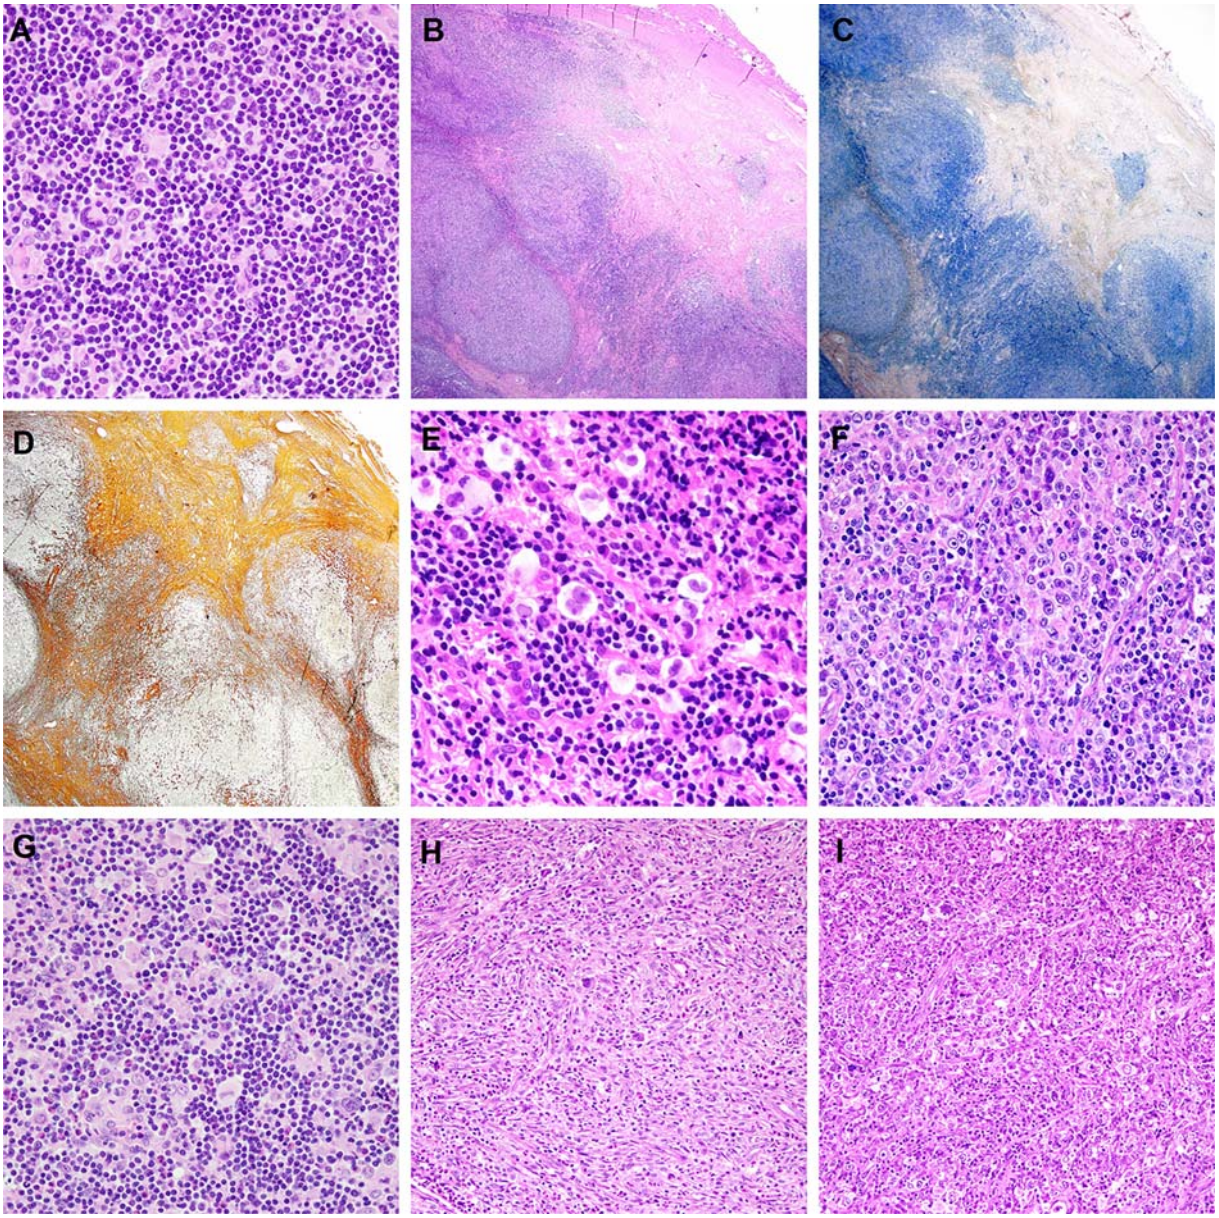

Fig. 4 Morphologic features of classical Hodgkin lymphoma (CHL). Lymphocyte rich CHL (A) displays scattered Hodgkin and Reed–Sternberg (HRS) cells in a background rich in small lymphocytes; eosinophils and sclerosis are not observed. Nodular sclerosis CHL is characterized by nodules surrounded by fibrous bands departing from a thickened lymph node capsule (B–D). The nodules contain variable amounts of small lymphocytes, eosinophils, macrophages, and plasma cells. HRS cells have a lacunar appearance and may be dispersed (BNLI type I, E) or form cohesive sheets (BNLI type II, F). Mixed cellularity CHL is distinguished by lack of sclerosis, frequent interfollicular growth and scattered classic HRS cells (G). Lymphocyte depletion CHL can show two different morphologic patterns: the fibro-histiocytic variant (H), that is characterized by a predominance of fibroblasts and histiocytes, with scattered HRS cells, and the sarcomatous variant (I) that is extremely rich in HRS cells. In both subtypes, the small lymphocytic component is extremely sparse.

available therapeutic approaches, LRCHL has a more favorable course than the other types of CHL, similar to that of LPHL. On the contrary, however, relapses are exceedingly rare.

Nodular sclerosing classical Hodgkin lymphoma

Nodular sclerosing classical Hodgkin lymphoma (NSCHL) represents about 70% of CHL cases in Western Countries, although its prevalence varies in different parts of the World. In contrast to the other types of CHL, it affects females more often than males and presents with a mediastinal mass (with possible features of bulky disease) in 80% of patients. At microscopic examination (Fig. 4B–D), NSCHL is characterized by nodules surrounded by collagen bands (birefringent on polarized light) that depart from a thickened lymph node capsule. The cellular composition of the nodules can significantly vary by mimicking the one of the other types of CHL

(LR, MC, and LD). Occasionally, only nodule formation is seen with minimal or absent fibrosis: this pattern is called the cellular phase of NSCHL. Neoplastic cells are mostly mononucleated and can acquire a "lacunar" appearance in improperly fixed material, consisting of the retraction of cytoplasm close to the nucleus with some thin connections to the cytoplasmic membrane, forming what look like small lacunae (Fig. 4E). The British National Lymphoma Investigation (BNLI) distinguishes two grades of NSCHL, which are potentially relevant for prognosis. Grade I corresponds to the presence of a small amount of scattered HRSCs in a composite cellular milieu, consisting of variable amounts of small lymphocytes, histiocytes, neutrophils, eosinophils, mastcells, and plasmacells. Grade II is assigned (Fig. 4F) when (1) >25% of the nodules show sarcomatous lymphocyte depletion, (2) >80% of the nodules show features of the fibro-histiocytic variant, or (3) >25% of the nodules show numerous bizarre, anaplastic-appearing Hodgkin cells without lymphocyte depletion. Following such criteria, approximately 15%–25% of NSCHL cases are classified as grade II. Grading is not mandatory for clinical purposes but has been applied in some clinical trials. However, it has become less relevant, due to advances in therapy which obscure differences seen in less effectively treated patients. Within the morphologic spectrum of NSCHL, the so-called "syncytial" variant merits to be mentioned. It is characterized by large aggregates of neoplastic cells within the nodules, resembling metastatic involvement by undifferentiated carcinoma. Immunohistochemistry is pivotal for the differential diagnosis as it is in the distinction between grade II NSCHL and ALK-negative anaplastic large cell lymphoma (ALCL) (see below).

Mixed cellularity classical Hodgkin lymphoma

In this variant, HRSCs can be easily found comprised in a mixed reactive population composed of lymphocytes (mainly T), histiocytes, plasma cells, neutrophils, and eosinophils (Fig. 4G). The normal lymph node structure is complete effaced, at times with sparing of some follicles with a germinal center. It should be differentiated from nodal peripheral T-cell lymphoma (PTCL), especially of the FTH-cell type, that can contain EBV-positive HRS-like cells. However, T-lymphocytes in mixed cellularity classical Hodgkin lymphoma (MCCHL) show a complete T-cell phenotype and do not homogeneously express FTH-related markers in contrast to those of FTH-PTCL. In addition, they do not display the large rim of clear cytoplasm that is characteristic of nodal FTH-PTCL.

Lymphocyte depleted classical Hodgkin lymphoma

Lymphocyte depleted classical Hodgkin lymphoma (LDCHL) includes two morphologic subtypes (Fig. 4H and I). The fibrohistiocytic subtype has a cellular milieu mostly consisting of fibroblasts and histiocytes. The sarcomatous subtype is extremely rich in neoplastic cells, which frequently form a palisade at the periphery of large necrotic areas but can also occur diffusely throughout sinuses. Immunophenotyping is pivotal to differentiate them from ALK-negative ALCL (see below).

Phenotype

HRSCs of CHL have a distinctive immunophenotypic profile. They strongly express CD30 in a characteristic dot-like and membrane-bound pattern, corresponding to the synthesis of the protein backbone (90 kDa MW) of the molecule, which is glycosylated in the Golgi apparatus (120 kDa MW) and then translocates to the cell membrane, where it acquires a transmembrane location (Fig. 5A). Ber-H2 is the reference antibody for immunohistochemical identification of CD30 and SGN30 is a humanized monoclonal antibody used for the construction of brentuximab-vedotin by conjugation with monomethyl auristatin E. The epitopes detected by these antibodies are located on the external domain of CD30, but are not shed in the circulation, in contrast to the CD30 epitopes that can be detected in peripheral blood. This is quite important, since CD30 is an important diagnostic and therapeutic target. CD30 is the target of specific immunoconjugates, administered either as monotherapy or in combination with chemotherapy with promising results, both in refractory cases or as first line treatment. In about 60% of cases HRSCs express CD15, also known as X-hapten, with a staining pattern similar to that of CD30 (Fig. 5B). This is one of the many molecules aberrantly expressed in at least 20% of HRSC cases, which include CD15, GATA3, TRAF1, ID2, ABF1, JUN, JUNB, AP-1, FLIP (CFLAR), JAK/STAT, STAT5, and the cytotoxic markers TIA-1, Granzyme B and perforin. It is assumed that these aberrant attributes facilitate the immune escape of neoplastic cells. A main feature of HRSCs is downregulation of the B-cell program and loss of most B-cell markers (see also section "**Molecular Characteristics**"), in spite of their B-cell derivation. In >90% of cases, they retain only the expression of the *PAX5* gene product, also known as BSAP (B-cell specific activator protein), although at a significantly lower intensity than normal B-cells (Fig. 5C). CD20 is expressed in about 30% of cases by a proportion of neoplastic cells with variable intensity (Fig. 5D). CD79a is detected in about 10% of cases with a staining pattern like CD20. The transcription factors BCL6, BOB.1, OCT2 and PU.1 are usually absent. At times, either BOB.1 or OCT2 may be expressed, which impairs the transcription of IG genes (Fig. 5E). CD45 and EMA are also defective (Fig. 5F and G). IRF4 and Ki-67 are expressed in most if not all cases of HRSC (Fig. 5H and I). Even though they express Ki-67, HRSC enter the cell cycle but do not proceed through due to abortive cytokinesis. BCL2 and TP53 are expressed by >50% and 25% of neoplastic cells in one third and 12% of cases respectively, which has been found of prognostic relevance (Fig. 6A and B). In 87% of cases, HRSCs express CD274/PD-L1 and CD273/PD-L2 a rationale for treatment with immune check-point inhibitors (e.g., nivolumab and pembrolizumab) (Fig. 6C). Copy number alterations of 9p24.1/*PDCD1/LG* contribute to robust PD-L1 and PD-L2 expression by HRSCs, although PD-L1 is also strongly expressed by reactive tissue macrophages. The combination of brentuximab-vedotin and nivolumab has recently been tested in relapsed or refractory CHL with promising results (82% overall response rate). In a small percentage of cases HRSCs may express one or more T-cell associated molecules. Intracytoplasmic and globular staining suggests passive absorption, but detection at the plasma

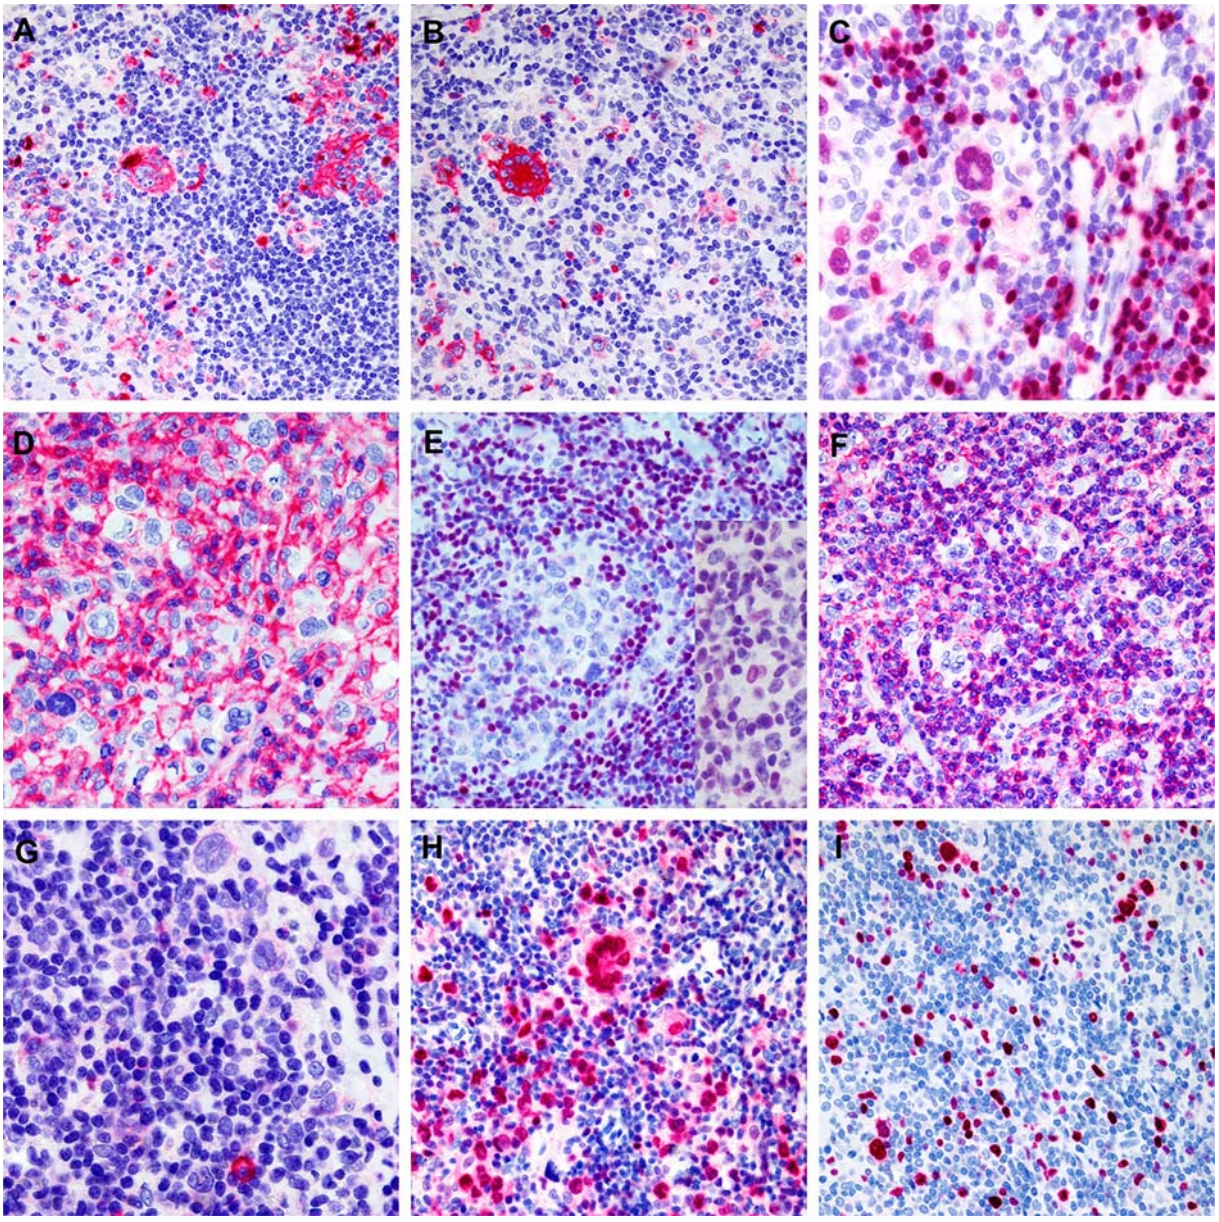

Fig. 5 Immunophenotypic features of classical Hodgkin lymphoma. HRS cells are positive for CD30 (A), CD15 (B) and, weakly, for BSAP/PAX5 (C). CD20 is negative or weakly expressed by a minority of cells (D). Furthermore, HRS cells are negative for CD45/LCA (E), OCT2 (F), BOB.1 (F inset) and EMA (G). Most cells are positive for IRF4/MUM1 (H) and for the proliferation marker KI-67 (I).

membrane level has been associated with IGVH gene rearrangements with polyclonal T-cell receptor (TR) (see section "**Molecular Characteristics**").

When a tumor is rich in neoplastic cells (NSCHL grade II or sarcomatous LDCHL), a differential diagnosis of ALK-negative ALCL should be considered. Expression of PAX5, IGVH clonal rearrangement, lack of TR clonality, and possible EBV infection will then favor a diagnosis of CHL.

Reactive cells in the microenvironment are important for cross-talk with neoplastic cells through cytokines and cytokine-receptors, and also convey prognostic information. The presence of macrophages (with cut-off values ranging from 5% to 25%), of T-lymphocyte subsets and of myeloid suppressor cells has been found of potential prognostic value, although conflicting data have been reported in the literature.

Numerous markers of HRSC or cells in the microenvironment have been proposed as prognostic indicators, and these have been compared with interim-PET for prediction of response to two cycles of ABVD treatment. In patients with a negative interim PET, expression of CD68 (>25%) and CD279/PD1 (diffuse or rosetting pattern) in microenvironmental cells, and STAT1 negativity in HRSC identify a subset of patients with a significantly lower 3-year progression-free survival (**Fig. 6**E and F).

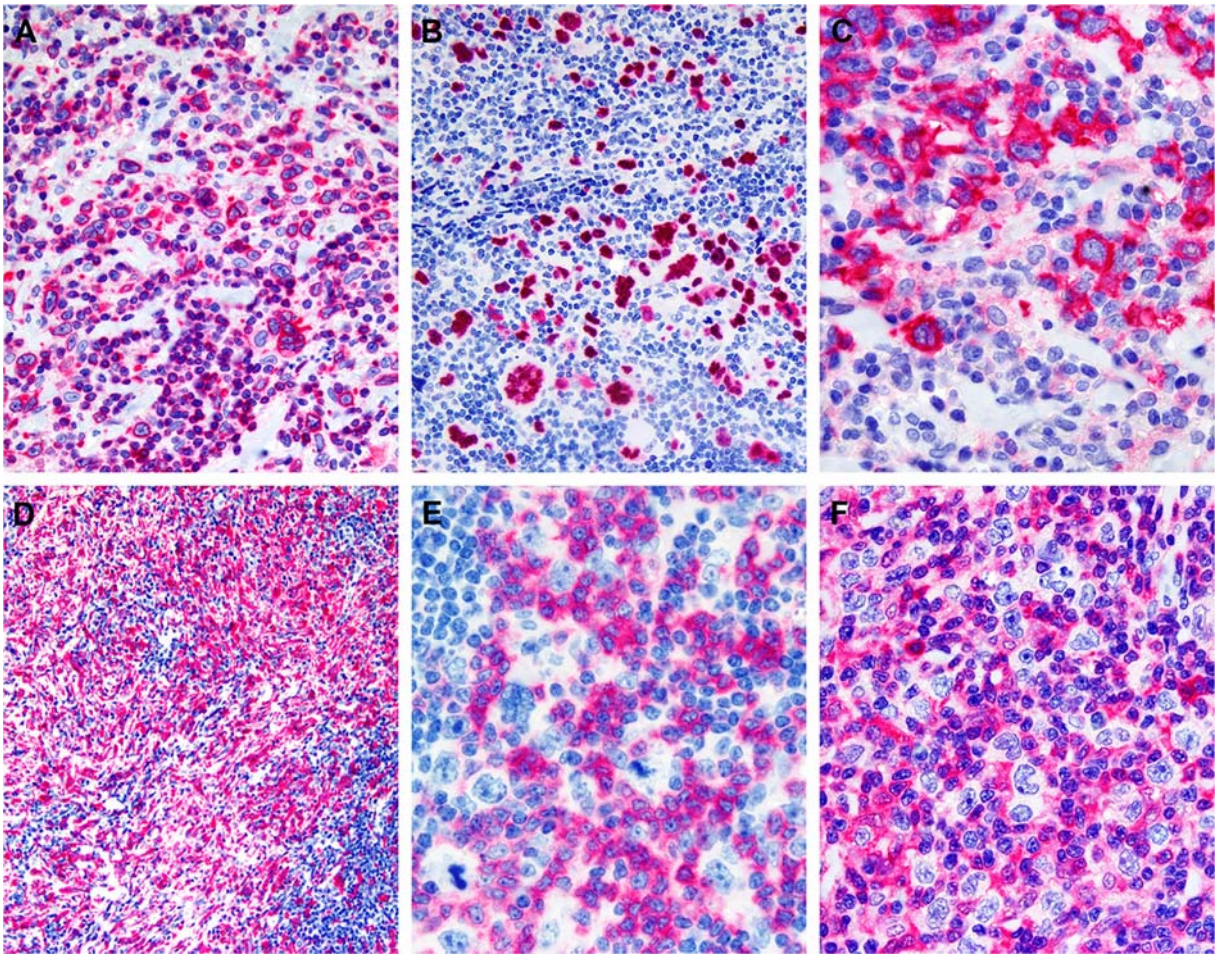

Fig. 6 Biologic prognostic markers in CHL. HRS cells can express BCL2 (A) and p53 (B). Expression above 50% and 25% of neoplastic cells represents an adverse prognostic factor. Positivity for PD1 ligand is found in HRS cells of most cases of CHL (C), and this can have impact on therapy choice. An increased macrophagic population above 25% of cellular background (D), as well as an increase of PD1-positive T-lymphocytes, with rosette formation (E) and down-regulation of STAT1 in HRS cells (F), are considered adverse prognostic factors.

EBV Infection

By in situ hybridization for EBER 1/2 and immunohistochemical detection of LMP1 and EBNA1 (latency II pattern) it has been convincingly shown that HRSC are EBV infected. LMP-1 expression is regarded as potentially implicated in the pathogenesis of the tumor because of its in vitro transforming capacity. Conceivably, EBV infection of a B-cell replaces one of the genetic alterations necessary for the development of CHL. The prevalence of EBV in HRSCs varies according to the histological subtype and epidemiologic factors. The highest frequency ($\sim$75%) is found in MCCHL, and the lowest (10%–40%) in NSCHL. In resource-poor regions and in patients infected with HIV, the rate of EBV infection is close to 100%. The type of EBV strain also varies between geographical areas. In resource-rich countries strain 1 prevails, and in resource-poor countries strain 2.

Cell of Origin

As previously mentioned, IGH gene rearrangement studies carried out by single cell microdissection provided convincing evidence that HRSCs of CHL are clonal and derived from germinal center B-cells, even if they lack morphologic or phenotypic similarities other than their PAX5/BSAP expression. In rare cases, HRSCs were reported to harbor clonally rearranged TR, indicating that cases with morphological features of CHL might be derived from T-cells. This issue remains unsolved, since differentiating between these exceptional cases and PTCLs, especially ALK-negative ALCL, can be very challenging.

Molecular Characteristics

HRSCs reveal clonal IGVH rearrangements in $>$98% of cases. As mentioned above, single cell microdissection is required to detect clonal rearrangements, as DNA extracted from the whole tissue specimens provides poor results. The rearranged IGVH of tumor cells

harbor a high load of somatic mutations (hypermutated), usually without signs of ongoing mutational activity. These findings support the view that in most if not all instances HRSCs are derived from a germinal center B-cell. Nonetheless, HRSCs have lost much of the B-cell specific expression program and have acquired B-cell inappropriate gene products, as described earlier. In addition, deregulated transcription factors in CHL promote proliferation and abrogate apoptosis of the neoplastic cells. The transcription factor NF-κB is constitutively activated in HRSCs, and there is altered activity of the NF-κB target genes, which regulate proliferation and survival, the AP-1 complex and the Janus kinase/signal transducers and activators of transcription (JAK/STAT) signaling pathway. Mutations of the JAK regulator *SOC-1* are associated with nuclear STAT5 accumulation in HRSCs, indicating blocking of the negative feedback loop of the JAK/STAT5 pathway. Even though TP53 may be overexpressed, mutations of *TP53* are rare or absent in primary CHL.

Classical cytogenetic and fluorescence in situ hybridization (FISH) studies show aneuploidy and hypertetraploidy, consistent with the multinucleation of the neoplastic cells; however, these techniques fail to demonstrate recurrent and specific chromosomal changes in CHL. Comparative genomic hybridization, however, shows recurrent gains of sub-regions on chromosomal arms 2p, 9p, and 12q and distinct high-level amplifications on chromosomal bands 4p16, 4q23-q24, and 9p23-p24. Special attention deserves the alterations at 9p24.1, since this region includes the genes encoding for CD274/PD-L1, CD273/PD-L2, and JAK2, which herald sensitivity to specific targeted therapies as highlighted above in the "**Phenotype**" section.

Gene expression profiling (GEP) studies have confirmed all these findings, including global down-regulation of the B-cell program, and highlighted similarities between CHL and primary mediastinal large B-cell lymphoma (PMBL). PBML show overexpression of genes encoding for CD274/PD-L1, CD273/PD-L2 and JAK2, due to 9p24.1 alterations. The similarities between the signature of CHL and that of PMBL are not surprising, which is a reflection of the gray-zone between the two neoplasms. In the Revised WHO Classification, the latter condition for which the term "B-cell lymphoma unclassifiable with features intermediate between CHL and DLBCL" is used, corresponds to two different conditions: a tumor showing CHL morphology but complete B-cell immunophenotype or a tumor with the PMBL morphology but a CHL immunophenotype. By profiling HL cell lines and micro-dissected HRSCs two molecular subgroups of CHL were identified, associated with differences in activity of transcription factors of *NOTCH1*, *MYC*, and *IRF4*. Moreover, HRSCs displayed deregulated expression of several genes potentially highly relevant to lymphoma pathogenesis, including silencing of the apoptosis-inducer *BIK* and of *INPP5D*, an inhibitor of the PI3K-driven oncogenic pathway. In further GEP studies, using mRNA extracted from HRSCs micro-dissected from formalin-fixed, paraffin-embedded tissues, a macrophage-like signature in HRSCs significantly correlated with treatment failure. *CSF1R* is a representative of this signature, and its expression by mRNA in situ hybridization was significantly associated with progression-free and overall survival. A combined score of CSF1R in in situ hybridization and CD68 in immunohistochemistry was found to be independently predictive for progression-free survival in multivariate analysis. In one study, a 23-gene outcome predictor was generated, which identified a 29% difference in in 5-year overall survival between the high- and low-risk groups population in a validation cohort. The predictor was claimed to be superior to the International Prognostic Score and CD68 immunohistochemistry, but this was not confirmed in two later studies.

Whole exome sequencing on purified HRS cells has revealed inactivating *B2M* mutation as the most frequently detected gene mutation in CH. This leads to loss of major histocompatibility complex class I (MHC-I) expression. The absence of B2M protein in HRSCs has been associated with lower stage of disease, younger age at diagnosis, and better overall and progression-free survival. In a further study, fusions involving *CIIITA* (MHC II trans-activator) in 15% of CHL cases caused down-regulation of HLA class II expression and overexpression of CD274/PD-L1 and CD273/PD-L2.

Some novel gene loci have been identified as being associated with increased risk for the development of CHL. An association between rs6903608 and EBV-negative cHL was confined to the nodular sclerosis histological subtype. Other associations involving HLA Class I have been identified in EBV-positive CHL, mainly mixed cellularity subtype. These observations confirm the relevance of histological subtyping of CHL, and differences between EBV-positive and EBV-negative cases.

It has recently been reported that sequencing of circulating cell free (cf)DNA in CHL patients provides a surrogate for the mutational landscape of HRSCs obtained by micro-dissection. Genes recurrently mutated in $>20\%$ of CHL cases include *STAT6* (37.5%), *TNFAIP3* (35%), and *ITPKB* (27.5%), and are clustered in major pathways, including NF-κB, PI3K-AKT, cytokine and NOTCH signaling, and immune evasion. The mutational landscape of newly diagnosed and chemorefractory CHL largely overlaps. Refractory CHL does not show an increased rate of *TP53* mutation (see above). In contrast, *TET2* mutations, including newly acquired mutations, are more frequent in refractory CHL, which is potentially important for therapy choice. Longitudinal studies in patients relapsing under/after chemotherapy or brentuximab vedotin, of paired pre-treatment/relapse tumor tissue samples, have shown that recurrent tumor cell clones branch from ancestral clones through acquisition of specific mutations, while preserving the mutational landscape of the ancestral clone. Conversely, in patients under nivolumab maintenance therapy, ancestral clones were replaced by completely novel clones.

Conclusions

Only once the goal of curing all HL patients has been reached, the long journey begun by Sir Thomas Hodgkin can be concluded.
