
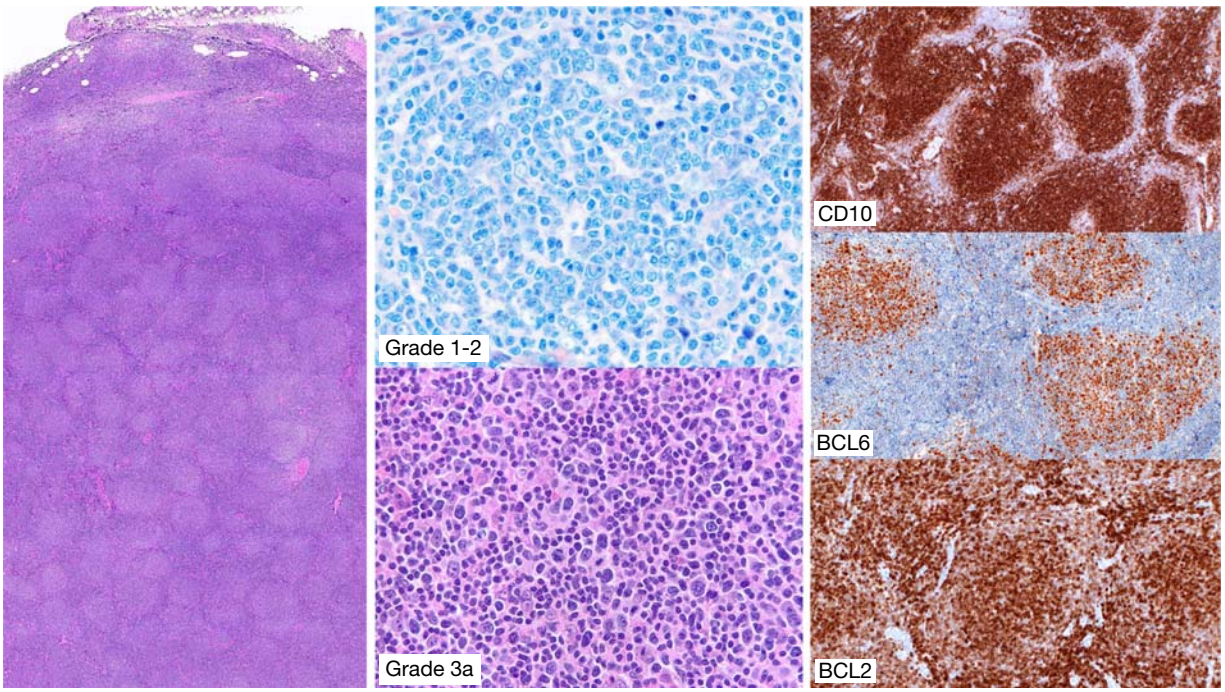

Fig. 7 Follicular lymphoma. At low-power view, lymph node parenchyma is replaced by multiple small nodular structures; this lymphoproliferation extends beyond the capsula into the adjacent fat. A Giemsa stain and hematoxylin & eosin stain illustrate to the high-power view of two cases, one grade 1–2 follicular lymphoma, comprising <10 centroblasts per high-power field, and a grade 3a case, comprising an admixture of centrocytes with numerous centroblasts (>15 large cells/hpf). The typical immunophenotype of follicular lymphoma is CD10+, BCL6+, BCL2+.

patient outcome, and a prognostic model, named m7-FLIPI, that links seven mutations including five with epigenetic functions, to patient prognosis has been proposed.

A small proportion of FL do not have *BCL2* gene rearrangement and do not express BCL2. In particular grade 3 FL tend to be negative for BCL2 more frequently than grade1–2 cases, and purely diffuse FL are typically negative for *BCL2* translocation, while showing recurrent 1p36 deletion (containing *TNFRSF14*), a feature common to all forms of FL. Various other chromosomal gains and losses affecting multiple chromosomes are frequently encountered as well. Abnormalities of 3q27 and/or *BCL6* rearrangement are found in about 5%–15% of the cases.

In situ follicular neoplasia (ISFN)

In situ follicular neoplasia (ISFN) designates partial or total colonization of germinal centers by light-chain restricted clonal B cells harboring the *BCL2* translocation characteristic of FL, and strongly expressing BCL2 and CD10 in otherwise reactive lymph nodes. It is thought to be the tissue equivalent of circulating FL-like B cells that are detected in the blood of otherwise healthy individuals. ISFN is detected in about 2% of randomly selected reactive lymph nodes; if found incidentally with no evidence of concurrent FL by staging, the risk of subsequent FL is $<5\%$.

Duodenal-type FL

Duodenal-type FL is a variant of FL with very indolent behavior: it involves the duodenum as small polyps and is typically diagnosed incidentally in women undergoing upper gastrointestinal endoscopy for other reasons; the lymphoma is usually purely follicular and grade 1–2, harboring a *BCL2* rearrangement, with an immunophenotype similar to that of nodal FL, frequent expression of IgA and of the intestinal homing receptor alpha4beta7 integrin. There is a very low risk of progression to nodal disease.

Testicular FL

Testicular FL occurs in children or less commonly in adults, and usually consists of grade3 lesions that are negative for BCL2 and lack *BCL2* rearrangement. It is usually diagnosed on surgical excision of a testicular mass and has a very good prognosis.

Pediatric-type FL

Pediatric-type FL is an uncommon form of nodal FL occurring in children or young adults, most often presenting as localized disease involving cervical lymph nodes. Cytologically, the lesions are composed of large blastic cells (grade3) and have a high proliferation index, which contrasts with the very indolent behavior. Pediatric FL lacks *BCL2*, *BCL6* or *IRF4* translocations, often features deletions of 1p36, and about half of the cases have deletions and mutations of *TNFRSF14*, and/or *MPA2K1* mutations.

Primary cutaneous follicle center lymphoma (PCFCL)

Primary cutaneous follicle center lymphoma (PCFCL) is a cutaneous lymphoma composed of centrocytes, centroblasts and large multilobated cells, showing a follicular, follicular and diffuse, or purely diffuse growth pattern. It usually presents as localized skin lesions on the head, forehead or scalp. PCFCL is positive for B-cell antigens and expresses BCL6, but CD10 is variably detected., BCL2 immunohistochemical expression is usually negative or faintly positive, and *BCL2* rearrangement is generally absent. Grading is not applied to FCFCL; the proliferation fraction may be high, especially in diffuse cases composed of large cells, and the prognosis is excellent.

Mantle Cell Lymphoma (MCL)

Mantle cell lymphoma (MCL) is an aggressive lymphoma of middle-aged to older adults (median survival 3–5 years) with a marked male predominance (75%). It accounts for about 7% B-NHL. Most patients have disseminated disease at diagnosis, with lymphadenopathy, hepatosplenomegaly and bone marrow and blood involvement. Extranodal involvement, especially of the gastrointestinal tract (lymphomatous polyposis), is common.

MCL is typically composed of a monotonous population of small to medium-sized lymphoid cells, with slightly irregular or "cleaved," nuclei which may have a diffuse, nodular, mantle zone, or mixed pattern in lymph nodes (**Fig. 8**). The blastoid variant, composed of cells resembling lymphoblasts with fine chromatin and a high mitotic rate, and the pleomorphic variant, which comprises many large irregular cells with prominent nucleoli, are considered more aggressive cytological variants. A marginal zone variant may morphologically mimic marginal zone lymphoma. MCL is not graded but the mitotic count or proliferation index have an important prognostic impact.

MCL cells strongly express sIgM and IgD, more often lambda than kappa light chains and are positive for B-cell antigens; most cases coexpress CD5, and CD43, and they usually lack CD23, CD10 and BCL6. Nuclear expression of cyclin D1 is present in $>95\%$ of the cases and represents the hallmark of the disease. Expression of SOX11 is detected in most cases including the rare subset of cyclinD1-negative MCL. MCL has unmutated or only minimally mutated IGHV regions, consistent with an origin from naïve B cells.

The t(11;14)(q13;q32) (involving *CCND1* gene) is present in $>95\%$ of the cases is the primary genetic event and results in overexpression the cyclin D1, a protein involved in the regulation of the cell cycle transition between the G1 to the S phase not normally expressed in lymphoid cells. Deregulated expression of cyclin D1 overcomes the cell cycle suppressive effect of RB and p27 but is not sufficient in itself to induce MCL. Abnormal SOX11 is thought to be another important pathogenic factor. MCL also carries numerous chromosomal aberrations—gains and losses—and some of these aberrations may correlate with an aggressive clinical

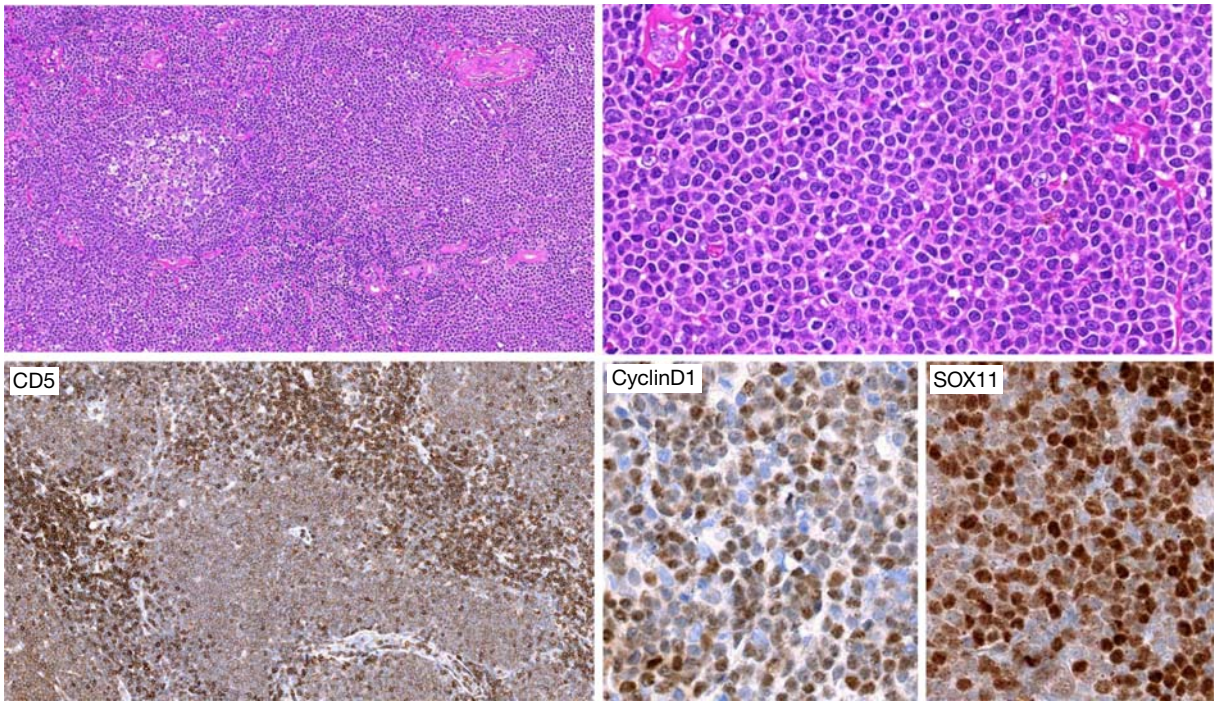

Fig. 8 Mantle cell lymphoma. A medium-power view of a lymph node involved by mantle cell lymphoma (upper left panel) shows a residual germinal center surrounded by a monotonous lymphoproliferation of small lymphoid cells; the upper right panel shows the cytological features of the lymphoid cells, of small size with irregular nuclei (classical variant of mantle cell lymphoma). By immunochemistry, the lymphoma cells are faintly positive for CD5, and most nuclei show expression of cyclin D1 and SOX11.

parameters. Mutations in genes involved in cell cycle and other pathways, including *ATM*, *KMT2D* (*MLL2*), *NOTCH1/2* are found in a variable proportion of the cases. Mutations of *TP53* and homozygous deletions of *CDKN2A* are commonly found in highly proliferative cases. A small subset of the cases are negative for cyclinD1 and lack *CCND1* translocation; about half of these cases carry an alternative *CCND2* or *CCND3* translocation.

In addition to the usual nodal MCL, two subsets of MCL with an indolent behavior, namely in situ mantle cell neoplasia and nonnodal, leukemic MCL are now recognized.

In situ mantle cell neoplasia

In situ mantle cell neoplasia designates the presence of cyclinD1-positive B cells harboring a *CCND1* translocation, in the mantle zones of otherwise reactive lymph nodes. This condition is very rare (much less frequent than in situ follicular neoplasia) and carries a very low risk of progression to overt MCL. Compared to classical MCL, in situ lesions tend to be CD5-negative and are variably positive or negative for SOX11.

Leukemic nonnodal MCL

Leukemic nonnodal MCL is defined by clinical presentation of MCL with blood and bone marrow involvement, sometimes splenomegaly, and no significant lymphadenopathy. Leukemic cells are usually small, positive for cyclin D1, carry the t(11;14) translocation, but tends to be negative for SOX11 and have hypermutated IGHV regions. Despite a usually indolent clinical course, which can remain stable for many years, these cases may transform, sometimes to a pleomorphic blastoid morphology. Routes of transformation include *TP53* mutations or other oncogenic events.

Diffuse Large B-Cell Lymphoma (DLBCL)

DLBCL accounts for about one-third of B-NHL and represents the most common type of lymphoma. It is defined as a neoplasm of medium to large B cells more than twice the size of small lymphocytes, with a diffuse growth pattern. DLBCL encompasses marked biological heterogeneity. It may occur de novo or as a high-grade transformation of a small B-cell lymphoma. Median age at presentation is in the 7th decade, but may occur at any age. Patients typically present with a rapidly enlarging mass, with B symptoms in one-third of the cases. About 50% have localized disease involving nodal or in up to 40% of the cases various extranodal sites. Overall, $>30\%$ of the patients will not respond to therapy or will relapse with resistant disease. The International Prognosis Index (IPI) stratifies patients into risk groups and is predictive of outcome.

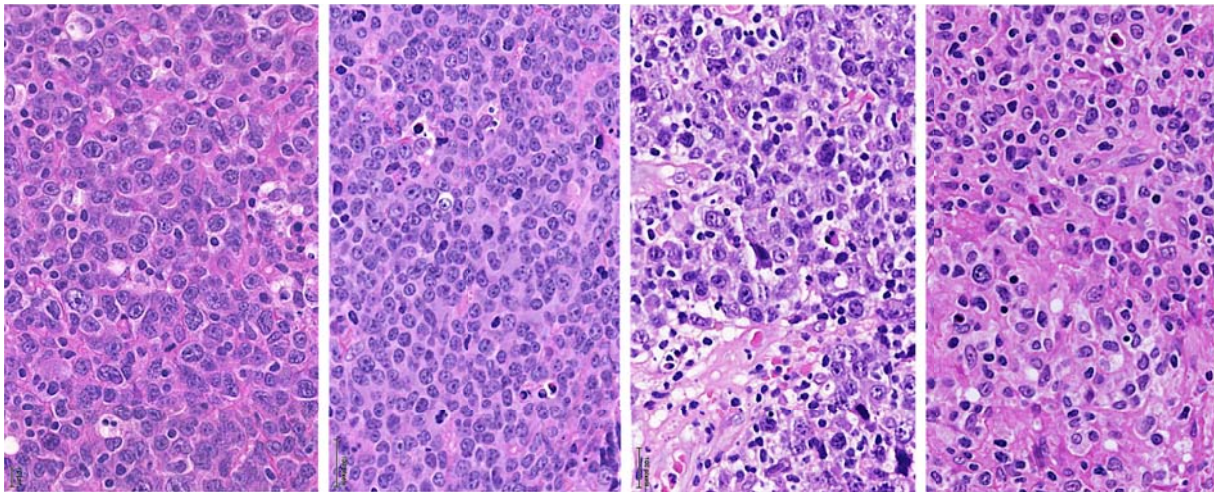

Fig. 9 Morphological variants of diffuse large B-cell lymphoma.

Diffuse large B-cell lymphoma, not otherwise specified (DLBCL-NOS)

In its usual form, DLBCL is a diffuse proliferation of large lymphoid cells that may be classified as centroblastic (most common variant, may be monomorphous composed entirely of centroblasts, or polymorphous comprising an admixture of centroblasts and immunoblasts), immunoblastic (comprising >90% immunoblasts, i.e., large lymphoid cells with a centrally located nucleolus), or anaplastic (composed of large pleomorphic cells that are often CD30+ and tend to form cohesive sheets with a sinusoidal pattern of growth)(Fig. 9). Immunoblast-rich tumors have been found to have a worse prognosis in several studies. Bone marrow involvement in DLBCL seen in about 15% of the cases may appear either as a large-cell infiltrate, or slightly more often as an infiltrate of small atypical B cells ("discordant" marrow involvement); the latter is not associated with a worse prognosis than cases without marrow involvement.

DLBCL express CD45, one or more B-cell-associated antigens (CD19, CD20, CD22, CD79a), PAX5, and often surface with or without cytoplasmic Ig (IgM > IgG > IgA). Therapy of B-cell lymphoma with chimeric antibodies against CD20 can result in the loss of CD20 antigen expression. About 5%–10% of de novo DLBCLs (i.e. excluding Richter's syndrome) express CD5. CD5+ DLBCLs are reported to occur in elderly women, with a predilection for extranodal involvement, especially bone marrow and spleen and to be associated with shorter survival in comparison with CD5+ tumors. CD30 expression is seen in 10%–20% of the cases, especially those with anaplastic morphology. Ki67 proliferation index is usually >40% and may be >90%. Expression of BCL2 is reported in 50%–80% of the cases, and about 30%–40% of the cases are MYC-positive. Approximately one-third of the cases express CD10, 70% express BCL6, and 50% are positive for MUM1/IRF4; unlike normal B cells, DLBCL frequently coexpresses BCL6 and MUM1.

Evaluation of DLBCL gene expression profiles by cDNA microarray techniques identified three molecularly distinct subtypes of DLBCL: the GCB subtype, characterized by the expression of genes normally expressed by GC B cells and showing ongoing somatic hypermutation; the ABC subtype, characterized by the features of BCR-activated B cells entering plasmablastic differentiation, showing activation of the NF-kappa B pathway, upregulation of genes involved in plasmacytic differentiation, and no ongoing hypermutations; and an unclassified group (15%–30% of the cases) (type 3). Patients with GC-like DLBCLs have better outcomes than those with activated B cell-like and type 3 DLBCLs. Different immunohistochemistry-based algorithms based the expression of markers associated to one or the other signature, have been developed as surrogates to microarray-based gene expression profiling in order to define the molecular subtypes; one of the most commonly used is the Hans algorithm, relying on the expression of three markers (CD10, BCL6 and MUM1/IRF4).

Compared to other lymphomas, DLBCL shows a higher degree of genomic complexity, harboring between 50 and >100 lesions per case. The most frequent recurrent cytogenetic aberration consists of rearrangement of *BCL6* at the 3q27 locus in about 30% of the cases, both of GCB and ABC subtypes. In addition, *BCL6* is the target of somatic mutations abrogating its promoter regulatory sequences in its 5′ untranslated region in 70% of the cases, and BCL6 expression is deregulated in many cases as the consequence of mutations in other genes that are normally involved in regulating its function and activity or its degradation. Altogether there is ample evidence that BCL6 deregulation is an essential pathogenic event common to both molecular subtypes. Inactivating mutations and deletions of the histone acetyltransferases *CREBBP* and *EP300*, and the histone methyltransferase *KMT2D* (*MLL2*) are also highly recurrent in both molecular subtypes and may favor tumor development by reprogramming the cancer epigenome. The immune surveillance pathway is frequently impaired through genetic loss of *B2M* or *HLA-I* genes or loss of the gene encoding CD58 ligand, allowing to escape from cell-mediated cytotoxicity. Mutations of *TP53* gene are detected in about 20% of DLBCL, in both molecular subtypes, and are associated with clinical drug resistance and poor outcome. Translocations of *BCL2* and

MYC occur in about 20%–25% and 10% of cases respectively, and almost exclusively in GCB-DLBCL. These also harbor gain-of-function mutations of *EZH2* in 20%–25% of the cases. Constitutive activation of the NF-kappaB pathway is the hallmark of ABC-DLBCL, the underlying mechanisms being heterogeneous and including gain-of-function mutations in signal transduction components of the BCR, and toll-like receptor pathways (*CD79B*, *CARD11*, *MYD88*), and loss-of-function mutations in *TNFAIP3* (*A20*). ABC-DLBCL is also characterized by defective plasma cell differentiation caused by lesions deregulating *BCL6* and inactivating *PRDM1/BLIMP1*.

T-cell/histiocyte-rich large B-cell lymphoma (T/HRLBCL)

This variant of DLBCL comprises $<10\%$ large neoplastic B cells (which may resemble the neoplastic cells of nodular lymphocyte predominance Hodgkin lymphoma or even Reed–Sternberg cells of classical Hodgkin lymphoma) scattered in a background of nonneoplastic T cells with or without histiocytes. T/HRLBCL usually presents with advanced-stage disease with nodal, splenic and bone marrow involvement. Immunophenotypic studies are essential to distinguish this variant from peripheral T-cell lymphoma and Hodgkin lymphoma.

Plasmablastic lymphoma

Plasmablastic lymphoma was initially described as a tumor occurring in the oral cavity in HIV-infected patients but since then similar lesions have been reported in other anatomical sites as well as in non-HIV+ individuals. The tumor cells are immunoblastic in morphology, with or without plasmacytoid differentiation, with a plasmacytic phenotype. They are negative for CD45 and CD20, negative or weakly positive for PAX5, may be positive for CD79a, and are positive for MUM1/IRF4 and CD138. EBV is detected overall in 60%–75% of the cases, including the majority of HIV-associated cases. *MYC* rearrangement, usually to an *IG* locus, is detected in about half of the cases and translates into strong MYC positivity by immunohistochemistry.

ALK-positive large B-cell lymphoma

This a very rare aggressive lymphoma is composed of large immunoblast-like B cells expressing ALK and featuring a plasma cell immunophenotype (weakly positive for CD45, lacking expression of CD20 and PAX5, positive for IRF4/MUM1 and CD138) with expression of EMA (Epithelial Membrane Antigen) and cytoplasmic IgA. CD30 is usually negative. ALK expression is usually granular and cytoplasmic, reflecting expression of the CTCL-ALK fusion protein.

Primary mediastinal (thymic) large B-cell lymphoma (PMBL)

PMBL comprises 7% of large B-cell lymphomas and 2.4% of all NHL. This lymphoma has clinical, morphological, molecular and genetic features distinct from usual DLBCL. PMBL tends to occur in young patients (median age of about 35 years), and affects women more commonly than men. Patients present with an anterior mediastinal mass originating in the thymus, with symptoms related to local invasion. Relapses tend to occur in distant extranodal sites such as central nervous system and the gastrointestinal tract. PMBL is associated to a better prognosis than GCB and ABC-DLBCL subtypes.

PMBL is cytologically heterogeneous, but clear cells, multilobated nuclei and compartmentalizing sclerosis are common features. The neoplastic cells express the B-cell antigens CD19, CD20, and CD79a but frequently lack surface immunoglobulin (Ig), despite expression of the appropriate transcription factors and have defective expression of HLA class I and/or class II molecules. A minority of cases are positive for CD10; BCL6 staining is found in more than half of the cases, and IRF4/MUM1 is expressed in the majority of cases. Most cases are BCL2+. Most cases express CD30 (at variable extent and intensity), CD23, the MAL antigen, and programmed cell death ligands (PD-L1 and PD-L2).

PMBL has a unique gene expression signature that differs from that of other DLBCL and partly overlaps with that of classic Hodgkin lymphoma, and reflects activation of the nuclear factor-κB and the Janus kinase-signal transducer and activator of transcription (JAK/STAT) signaling pathways. This not only supports PMBL as a distinct clinicopathologic entity, but also the concept of "gray zone" lymphomas with features overlapping between those of PMBL and classical Hodgkin's lymphoma. Overexpression of the MAL gene is a characteristic feature of the PMBL signature that is not found in DLBCL arising in other sites. MLBCL has been postulated to derive from medullary thymic asteroid B cell. PMBL cells have isotype-switched IG genes with a high load of somatic mutations without evidence of ongoing mutations.

BCL2, *BCL6* or *MYC* rearrangements are extremely infrequent, but half of the cases harbor rearrangements or mutations of the *CIITA* transactivator resulting in downregulated HLA class II molecules, creating an immune-privileged phenotype. PMBL also exhibits gains at 9p24, including the *JAK2/PDCD1LG2/PDCD1LG1* locus in 70% of the cases, an aberration that explains the overexpression of PD-L1 and PD-L2 in PMBL. About half of the cases have gains at 2p16 including *REL* that encodes a transcription factor of the nuclear factor-kappaB family and *BCL11A*. Constitutive activation of the JAK/STAT signaling pathway results from *JAK2* amplifications, frequent inactivating mutations of *SOCS1* and *PTPN1*, and *STAT6B* mutations.

Primary central nervous system lymphoma (PCNSL)

PCNSL is a rare and aggressive lymphoma that is confined to the brain, eyes, spinal cord, or leptomeninges without systemic involvement. PCNSL can develop in immunosuppressed (HIV/AIDS, organ transplant, immunosuppressive agents) or immunocompetent patients. PCNSL in immunocompetent patients is rare and represents 4% of all intracranial neoplasms. The outcome is worse than for non-CNS DLNCL.

Pathology reveals highly proliferative large lymphoid cells disposed in an angiocentric growth pattern, diffusely infiltrating the CNS. By immunohistochemistry to identify DLBCL molecular subgroups, most PCNSLs are nongerminal center subtype. Accordingly, frequent recurrent mutations in *MYD88* and *CD79B* are identified in PCNSL. Many cases have defective HLA class I and/or class II antigen expression. Moreover, PCNSL exhibit frequent 9p24.1 copy-number alterations and infrequent translocations of 9p24.1 and associated increased expression of the programmed cell death protein 1 (PD-1) ligands, PD-L1 and PD-L2, suggesting that immune evasion might play a role in PCNSL.

Primary cutaneous DLBCL, leg type (PCLBCL)

PCLBCL represents $<5\%$ of primary cutaneous lymphomas, and arises in older patients, with a median age at presentation >70 years. Clinically, patients present with solitary or multiple rapidly growing bluish-red nodules or plaques, which may be ulcerated, usually on one or, rarely, both legs.

Histologically, the dermis is infiltrated by dense, diffuse sheets of centroblasts and immunoblasts, often extending into the subcutis. PCLBCL is typically positive for pan-B-cell markers, CD10−, BCL6+, MUM1+, BCL2+, IgM+, and shows an ABC signature by gene expression profiling. Genetic alterations within the NF-kappaB pathway, include mutations in MYD88 in 60% of the cases, or less commonly, mutations in CD79B or CARD11. Translocations of *BCL2* do not occur but amplifications of the locus at 18q21 likely explains the usually intense BCL2 expression. Loss of *CDK2NA/CDKN2B*, by deletion and/or promoter methylation occurs in $>50\%$ of the cases and associates with a poor outcome.

Large B-cell lymphoma with IRF4 *rearrangement*

Large B-cell lymphoma with *IRF4* rearrangement is characterized by strong expression of MUM1/IRF4, usually as a consequence of *IRF4* rearrangement. This is an overall rare lymphoma, affecting predominantly the pediatric age group, consisting of a follicular and/or diffuse proliferation of large B cells and manifesting as tumors in the tonsils or Waldeyer ring or head and neck lymph nodes. The outcome is favorable.

Intravascular large B-cell lymphoma

This entity consists of a disseminated intravascular proliferation of large B cells involving small blood vessels, without an obvious extravascular tumor mass or leukemia, maybe related to defective expression of homing receptors. The central nervous system, kidney, lung, and skin are commonly involved, and patients present with symptoms related to organ dysfunction secondary to vascular occlusion. Many reported cases are diagnosed at autopsy.

EBV-positive large B-cell lymphomas

Several EBV-positive DLBCL entities are recognized: EBV-positive DLBCL, not otherwise specified (**Fig. 10**); EBV-positive mucocutaneous ulcer; lymphomatoid granulomatosis; and DLBCL associated with chronic inflammation.

EBV-positive DLBCL-NOS

EBV-positive DLBCL-NOS occurs in older patients where age-related immunodeficiency is thought to represent the predisposing conditions, but also in younger patients without known immunodeficiency. Peculiar morphologic features that are frequently encountered include the presence of large very atypical lymphoid cells, resembling those seen in Hodgkin lymphoma, a variable inflammatory background sometimes mimicking T-cell/histiocyte-rich large B-cell lymphoma, and areas of geographic necrosis. The neoplastic cells have an activated immunophenotype, frequent CD30 expression, and express a type II or type III EBV latency program. The disease is aggressive in older individuals but has a good prognosis in younger patients.

EBV-positive mucocutaneous ulcer

EBV-positive mucocutaneous ulcer manifests as superficial ulcerated lesions in the skin, oral mucosa, gingiva or mucosal sites in patients with age-related or iatrogenic immunosuppression. The course is typically indolent and some lesions may spontaneously regress.

Lymphomatoid granulomatosis (LyG)

Lymphomatoid granulomatosis (LyG) is an angiocentric and angiodestructive EBV+ large B-cell lymphoma with a T-cell-rich background. Necrosis is common. Patients typically present with extranodal disease, most commonly involving lung, CNS, and/or kidneys. Evidence of past or present immunosuppression may be found. LyG is graded (1 to 3) according to the number of large B cells, which correlates with clinical aggressiveness.

DLBCL associated with chronic inflammation

DLBCL associated with chronic inflammation occurs in the setting of chronic longstanding inflammation, like pyothorax, osteomyelitis, metallic implant insertion, or chronic skin ulcers. LDBCL associated with chronic inflammation forms tumor masses and is usually localized. The tumor may show plasmacytic differentiation and not uncommonly coexpress T-cell antigens. A type III EBV latency is characteristic. *TP53* mutations and *MYC* amplifications are common.

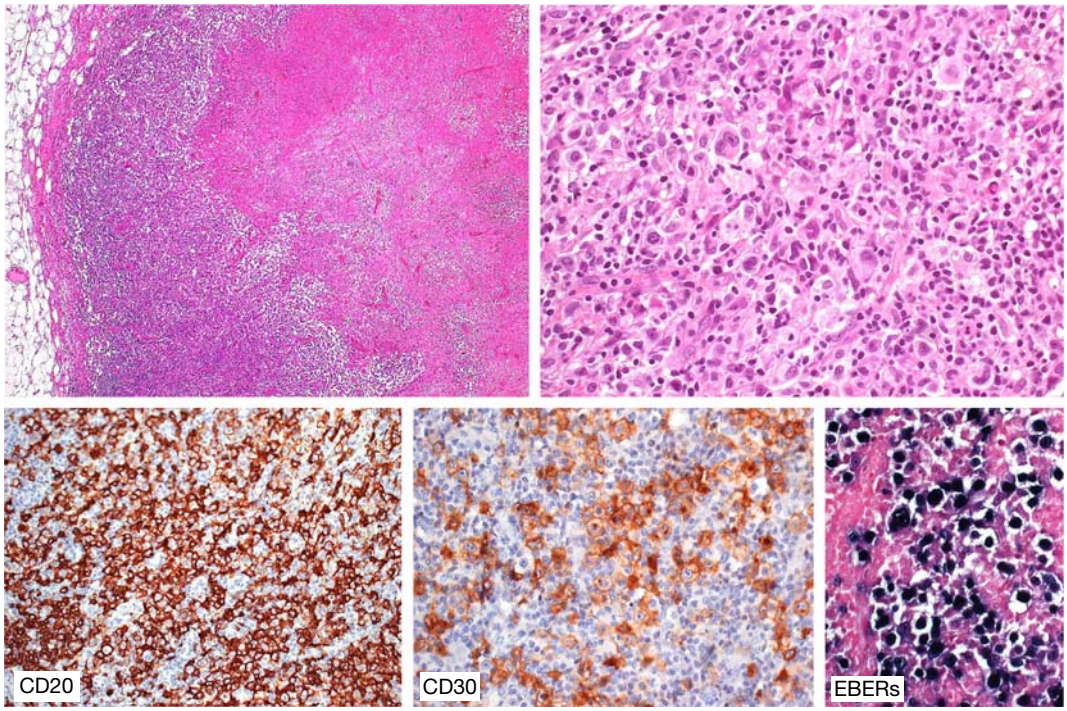

Fig. 10 EBV-positive diffuse large B-cell lymphoma, not otherwise specified. A low-power view of the lymph node (upper left panel) shows a diffuse lymphoproliferation associated to large areas of geographic necrosis. A closer view (upper right panel) shows a polymorphous infiltrate comprising many large lymphoid cells, including some resembling Reed–Sternberg cells, admixed with an inflammatory infiltrate. The atypical lymphoid cells are positive for CD20, coexpress CD30, and EBV infection is demonstrated by EBERs in situ hybridization.

Primary effusion lymphoma (PEL)

This rare and aggressive disease originally identified in AIDS patients, may also occur in other clinical settings. Patients present with effusions in serous cavities, generally with no formation of tumor masses. Rare HHV8+ DLBCLs may occur as solid tumor masses and are designated "extracavitary PELs." PEL is composed of large, often pleomorphic cells. They are usually CD45+ but lack expression of B-cell antigens and sIg and are often positive for MUM1 and CD138 as well as for CD30. The tumor cells are characteristically infected by the human herpesvirus-8 (HHV8) and most cases are coinfected with EBV. The gene expression profile of PEL shows features intermediate between those of immunoblasts and plasma cells, suggesting a plasmablastic derivation. The genome of PEL is complex.

Burkitt Lymphoma (BL)

Burkitt lymphoma (BL) is a well-defined aggressive B-cell lymphoma with characteristic morphological, immunophenotypical and molecular features with a simple karyotype and a homogeneous gene expression profile. Three distinct forms of BL are recognized: endemic BL (primarily found in Africa), sporadic BL (comprising 30% of pediatric lymphomas in western countries), and immunodeficiency-associated BL (most often affecting HIV+ patients). In all groups, the majority of patients are male. Patients present with rapidly growing often extranodal tumor masses. In endemic cases, the jaws and other facial bones are often involved. In sporadic cases, the majority of patients present with abdominal tumors. Immunodeficiency-related cases more often involve lymph nodes, and both these and sporadic cases may present as acute leukemia. BL is highly aggressive but potentially curable; intensive chemotherapy results in cure rates of up to 90%.

BL cells are monomorphic, medium-sized, with round nuclei, multiple nucleoli, and basophilic cytoplasm with small lipid vacuoles that are best seen on cytological smears (Fig. 11). There is a very high rate of proliferation and a "starry-sky" pattern is imparted by macrophages that have ingested apoptotic tumor cells. Some cases may show more pleomorphism or evidence of plasmacytic differentiation.

The immunophenotype, with expression of pan B-cell antigens, germinal center markers CD10 and BCL6 and lack of BCL2 protein, is quite constant and part of the definition. Strong MYC protein expression is detectable in the majority of neoplastic cells by immunohistochemistry. The proliferation rate, as assessed by MIB1 staining, should be close to 100% of tumor cells. More than 90% of BL show translocations of the *MYC* oncogene, usually with the immunoglobulin heavy chain locus, and, less frequently, with the light-chain loci. Immunoglobulin heavy and light-chain genes are rearranged, with somatic mutations in most cases and intraclonal heterogeneity, consistent with their putative derivation from early follicular blasts.

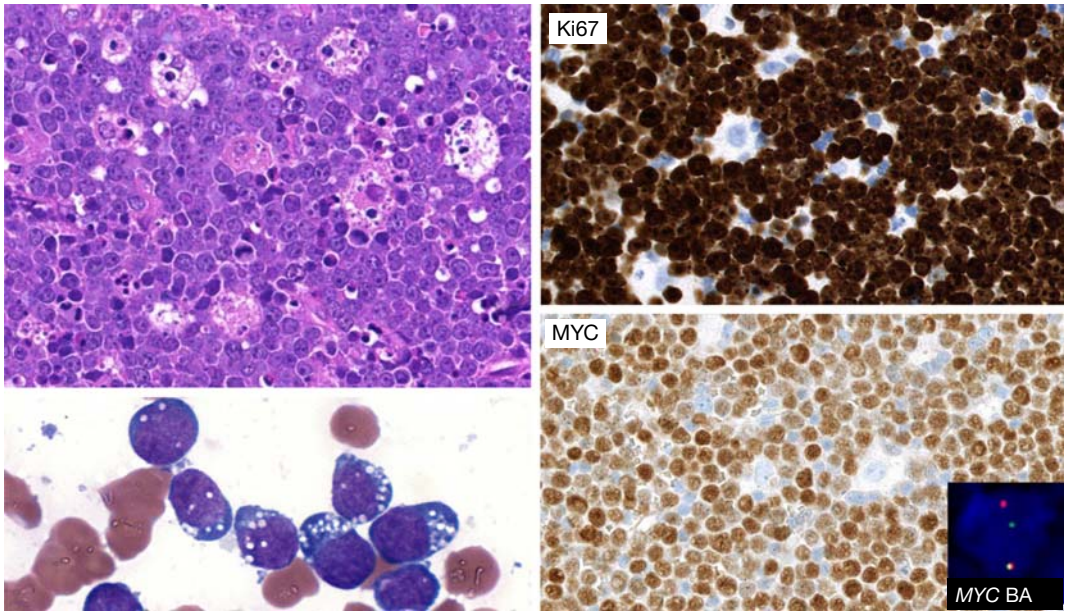

Fig. 11 Burkitt lymphoma. The histological and cytological features of a typical case are depicted in upper and lower left panels. Burkitt lymphoma is characterized by a very high proliferation fraction (almost 100% nuclei are Ki67 positive). MYC overexpression occurs as a consequence of a *MYC* rearrangement (inset, FISH using a break-apart probe for the *MYC* locus, showing a one red, one green and one yellow pattern, indicative of a *MYC* break).

Most cases have a translocation of MYC from chromosome 8q to either the IGH region on 14q—t(8;14)(q24;q32)—or IGK or IGL loci on 2q—t(2;8)—or 22q—t(8;22). Virtually all endemic cases contain EBV genomes, as do 25%–40% of sporadic and immunodeficiency-associated cases. In EBV-positive cases, the tumor cells contain clonal viral episomal genome, and display a type I latency program of gene expression (EBERs and EBNA1 expression). The exact role of EBV in the pathogenesis of BL is not understood. Next-generation sequencing analyses have revealed mutations of the transcription factor *TCF3* or its negative regulator *ID3* resulting in activation of the BCR signaling, in about 70% of the cases, and other mutations observed at lower frequency in various genes including *CCND3*, *TP53*, and *RHOA*. In general, cases that are EBV-positive tend to harbor a lesser number of mutations.

Recent studies have identified rare cases fulfilling the morphological and phenotypical criteria of BL and showing a similar gene expression profile, but lacking *MYC* translocations. In some of these cases, recurrent alterations of 11q23, namely high level gains including 11q23.2-q23.3 and telomeric losses of 11q24.1-qter were identified. Their clinico-pathological spectrum is slightly different from BL with more frequent nodal disease, higher morphological variability, lower levels of MYC expression and more complex karyotypes. The characteristic gain/loss pattern of 11q is associated with overexpression of *PAFAH1B2* and loss of *ETS1*.

High-Grade B-Cell Lymphoma

High-grade B-cell lymphoma with *MYC* and *BCL2* and/or *BCL6* rearrangements, and high-grade B-cell lymphoma, not otherwise specified, were introduced in the most recent WHO classification to encompass a group of highly aggressive lymphomas, that in the past were in part categorized as unclassifiable B-cell lymphoma with features intermediate between diffuse large B-cell lymphoma and Burkitt lymphoma. Patients with high-grade B-cell lymphomas tend to have a very aggressive clinical disease with extensive tumor dissemination, often with bone marrow involvement, elevated LDH, rapid progression and poor response to standard therapy.

High-grade B-cell lymphomas may morphologically resemble DLBCL, have features intermediate between DLBCL and Burkitt lymphoma (high proliferation fraction and a starry sky appearance, with cells larger or more pleomorphic than the spectrum of classical Burkitt lymphoma or a morphology resembling Burkitt lymphoma with a discordant immunophenotype, typically strong BCL2 expression), or have a blastoid morphology. A sizeable fraction of high-grade B-cell lymphomas with *MYC* and *BCL2* and/or *BCL6* rearrangements, also simply termed "double hit" or "triple hit" lymphomas, represent transformed follicular lymphomas. *MYC* plus *BCL2* double hit lymphomas are usually GCB and those with *MYC* and *BCL6* rearrangement are usually ABC. High-grade B-cell lymphomas NOS by definition do not have double or triple hits, but a significant proportion carries a *MYC* rearrangement (alone).

Mature T/NK-Cell Neoplasms

Neoplasms of mature NK or T cells (PTCLs) show important variations in their geographic distribution: while comprising approximately 10% of all lymphomas in Western world, in Asia, where EBV-associated extranodal NK/T-cell lymphoma (and adult T-cell

leukemia/lymphoma) are more frequent, they represent up to 20% of lymphomas. Most entities are clinically aggressive with a dismal prognosis.

Many distinct T/NK-cell diseases have a broad range of cellular composition, from pleomorphic small cells to anaplastic large cells; immunophenotypic profiles may vary within a disease category, while similar antigen combinations may be found across different entities; and the genetics of many of these diseases is heterogeneous with few diagnostic abnormalities. Thus the delineation of mature NK/T-cell neoplasms into entities along the WHO scheme is not as sharp as for the B-cell tumors, in regard to the numerous T-cell subsets and their functional plasticity, and reflecting the fact that, despite the cell of origin being a major determinant of PTCL biology, the cellular derivation of many PTCL entities is heterogeneous or remains poorly characterized (Fig. 12). There are currently >25 different T-cell neoplasms (Table 1), which broadly segregate into leukemias (summarized in Table 5), lymphomas with predominant nodal involvement, extranodal, or cutaneous manifestations. Peripheral T-cell lymphoma, not otherwise specified (PTCL-NOS), angioimmunoblastic T-cell lymphoma (AITL), and the anaplastic large-cell lymphomas (ALCL), are the most frequent T-cell lymphoma entities with somewhat varying incidence between the Americas, Asia, and Europe.

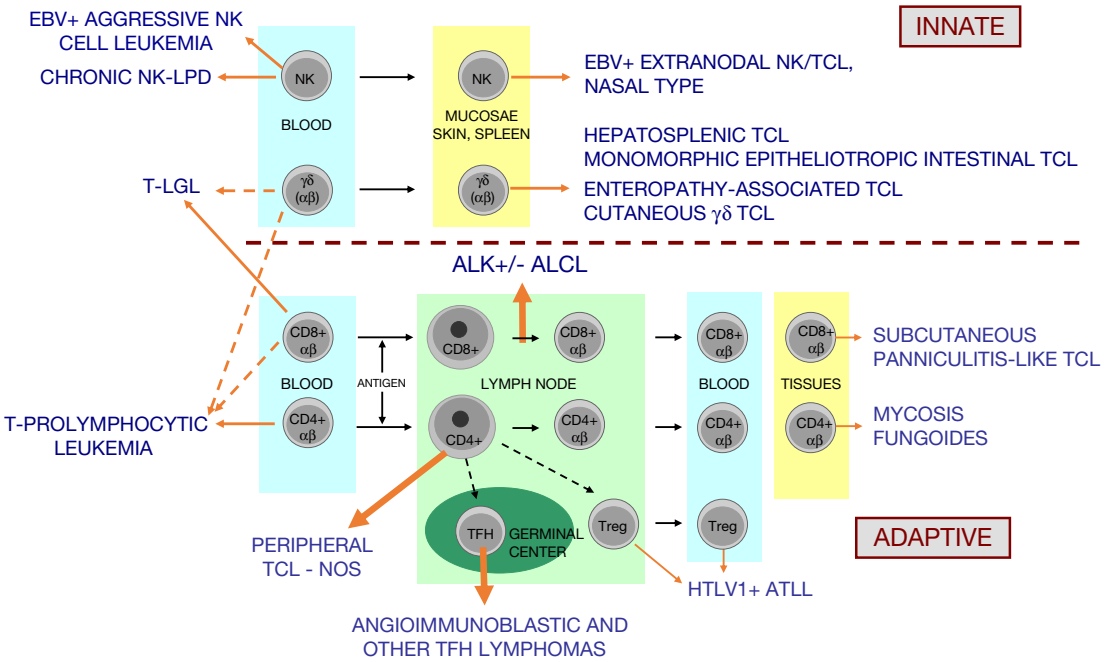

Fig. 12 Cellular derivation of PTCLs from normal T-cell and NK-cell subsets. Normal mature T cells either express the αβ or γδ isoforms of the T-cell receptor (TCR) and both express surface and cytoplasmic CD3. Alpha–beta T cells comprise CD4+ (mainly helper) and CD8+ (mainly cytotoxic) subsets. Gamma–delta T cells (CD4−CD8− or CD4−CD8+) comprise <5% of T cells and are preferentially distributed in the skin, mucosae, and to the splenic red pulp. NK cells are distinguished by the absence of TCR rearrangement and membrane TCR expression. NK cells share some markers with T cells such as CD2, CD7, CD45RO, and cytoplasmic (but not surface) CD3. NK cells are usually CD4−CD8− but may be CD8+, and they express one or several of the "NK-associated" antigens (CD11b, CD16, CD56, CD57, NK receptors), which are, however, not entirely specific. Both NK cells and activated cytotoxic T cells express cytotoxic proteins, T-cell intracellular antigen (TIA)-1 (a marker of cytotoxic cells in general), perforin and granzyme B (both expressed upon activation and not in the resting stage). Functionally, the majority of αβ T cells recognizing the antigen in a MHC-restricted fashion in the presence of an antigen-presenting cell, are part of the adaptive immune system, which features specificity and memory of the immunological response, whereas NK cells, a subset of the γδ T cells and a minor subset of αβ T cells are part of the innate immunity. Reflecting the paucity and distribution of normal γδ T cells, γδ PTCLs comprise rare, mostly extranodal cytotoxic malignancies, with aggressive behavior and poor outcome. The WHO classification comprises three lymphoma entities usually derived from γδ T cells, that are hepatosplenic T-cell lymphoma, monomorphic epitheliotropic intestinal T-cell lymphoma, and primary cutaneous γδ T-cell lymphoma. In addition minor subsets of other entities (T-LGL, NKTCL, EATL) as well as a small minority of PTCL, NOS, also have a γδ phenotype. Mature naïve T cells, either CD4+ or CD8+, are found in the thymic medulla, in the circulation and in the paracortex of lymph nodes; some may give rise to cases of T-cell prolymphocytic leukemia (T-PLL) and some peripheral T-cell lymphomas. Antigen-dependent reaction occurs in the paracortex of lymph nodes, and many peripheral T-cell lymphomas (peripheral T-cell lymphomas not otherwise specified, PTCL-NOS; angioimmunoblastic T-cell lymphoma, AITL; anaplastic large-cell lymphoma, ALCL) appear to correspond to proliferating peripheral T cells. From the immunoblastic reaction come antigen-specific T cells of either CD4 or CD8 type, as well as memory cells, that may recirculate and home to peripheral tissues. Some cases of peripheral T-cell lymphomas are thought to correspond to effector T cells. Mycosis fungoides (MF) corresponds to a mature, effector CD4+ T cell; T-cell large granular lymphocyte leukemia (T-LGL) to a mature effector CD8+ cell and many extranodal T-cell lymphomas to cytotoxic T cells. Gamma/delta T cells are usually CD8+; they constitute a minority of circulating T cells and have a predilection for homing to the spleen, skin and mucosae. These cells are thought to give rise to most cases of hepatosplenic T-cell lymphomas as well as some enteropathy-associated T-cell lymphomas (ETCL) and a subset of subcutaneous T-cell lymphomas (SPTCL). Natural killer (NK) cells appear to derive from a common progenitor with T cells. Immature NK cells are thought to be the precursor to blastoid NK-cell lymphoma/leukemia. Some types of LGL leukemia and extranodal T/NK lymphoma appear to correspond to mature NK cells.

Table 5 Features of leukemic/disseminated mature T/NK-cell neoplasms

Entity	*Morphology*	*Cell derivation*	*Functional features*	*Virus*	*Genetics*
T-cell PLL *Aggressive (1–2 years survival)*	Prolymphocyte (or small-cell or cerebriform variants)	αβ T cell (CD4 + CD8 − or less commonly CD4 + CD8 + or CD4 − CD8 +) sCD3 + CD5 − CD7 +	Noncytotoxic	No	Inv(14)(q11;q32), t(14;14) (*TCL1*), t(X;14) (*MTCP1*) *JAK1-JAK3* mutations (35%) *STAT3-STAT5B* mutations (35%)
T-cell LGL leukemia *Indolent*	Large granular lymphocyte	αβ T cell (CD8 ≫ CD4) more rarely γδ T cell) sCD3 + CD5 −/+ CD7 + CD16 + CD56 + CD57 +	Cytotoxic (A)	No	*STAT3* mutations (30%) *STAT5B* mutations (rare)
Chronic LPD of NK cells *Indolent*	Large granular lymphocyte	NK-cell (CD4 − CD8 −) sCD3 − CD5 − CD7 − CD16 + CD56 + CD57 +	Cytotoxic (A)	No	*STAT3* mutations (30%)
Aggressive NK-cell leukemia *Aggressive to fulminant*	Similar to but larger than large granular lymphocytes	NK-cell (CD4 − CD8) sCD3 − CD5 − CD7 − CD16 +/− CD56 + CD57 −	Cytotoxic (A)	EBV	6q21–23 deletion
Adult T-cell leukemia/lymphoma *Acute and lymphomatous: aggressive; chronic and smoldering: protracted course*	Flower cells (blood); pleomorphic cells (tissues)	αβ T cell (CD4 + CD8 −) sCD3 + CD5 + CD7 − CD25 + CD30 −/+	T regulatory (FOXP3 +)	HTLV1	14q31.1 fragile site deletion (*NRXN3* locus) (60%) *PLCG1* and *PRKCB* mutations (about 35% each) *CARD11, VAV1, FYN* mutations (25%, 20% and 5%) *CD28* amplifications, mutations and fusions *CCR4* truncating mutations (25%) Prominent CpG island DNA hypermethylation

T-PLL: T-cell prolymphocytic leukemia; T-LGL: T-cell large granular lymphocyte leukemia; NK-LGL: NK-cell large granular lymphocyte leukemia; ATLL: adult T-cell leukemia/lymphoma; Cytotoxic: denotes TIA-1, perforin, and/or granzyme expression; +/−: > 50% positive; −/+: < 50% positive.

Nodal Lymphomas Derived From Follicular Helper T Cells

Nodal lymphomas derived from follicular helper T cells (TFH cells) (see Glossary) is an umbrella term to embrace a large group of PTCL that have in common an immunophenotype overlapping with that of normal TFH cells, and share a similar genetic landscape. Angioimmunoblastic T-cell lymphoma (AITL), a disease entity encompassing systemic symptoms, biological abnormalities (such as anemia or hypergammaglobulinemia), usually generalized lymphadenopathy and a polymorphous infiltrate in lymph nodes with prominent proliferation of vessels and follicular dendritic cells, represents the prototypic and most common TFH-PTCL entity (Fig. 13). The two other nodal TFH-derived PTCL entities are: follicular T-cell lymphoma (FTCL), which is rare and defined by a predominantly follicular growth pattern and PTCL of TFH immunophenotype (TFH-PTCL), designating a subset of PTCL "unspecified" by morphology showing expression of a TFH phenotype. Worldwide, AITL is the second most common PTCL after PTCL-NOS, with the highest prevalence in North America and Europe. In France, AITL currently represents >35% of newly diagnosed noncutaneous PTCLs, largely outnumbering PTCL-NOS.

AITL usually diffusely involves lymph nodes and comprises a relatively small proportion of neoplastic cells (medium-sized atypical cells with clear cytoplasm), admixed to an abundant reactive microenvironment composed of small lymphocytes, histiocytes or epithelioid cells, B-cell immunoblasts, eosinophils, and plasma cells. The neoplastic cells are mature CD4+CD8− T cells, frequently show aberrant loss or reduced expression of one or several T-cell antigens and express several markers of T_{FH} cells (CD10, CXCL13, CXCR5, CD154, CD279/PD-1), CD278/ICOS (inducible T-cell costimulatory), SAP (SLAM-associated protein), BCL6, and/or c-MAF. The presence of large B-cell blasts, often infected by EBV is a feature common to AITL and other nodal T_{FH} lymphomas. Accordingly, the gene expression signature of AITL comprises a strong microenvironment imprint, with overexpression of B-cell- and FDC-related genes, chemokines/chemokine receptors, and genes related to extracellular matrix and vascular biology; conversely the neoplastic cell signature, quantitatively minor, is enriched in genes normally expressed by T_{FH} cells. The TFH phenotype and functionality of AITL neoplastic cells likely explains the peculiar pathological and biological traits of the disease, with the secretion of various soluble factors by TFH cells promoting recruitment, activation and differentiation of other cell types, for example CXCL13 promoting B-cell expansion and plasmacytic differentiation, causing hypergammaglobulinemia and Coombs-positive hemolytic anemia commonly found in AITL patients.

Broadly, the numerous recurrent genetic aberrations that have been recently identified in AITL and other TFH lymphomas interfere with two major processes: T-cell receptor (TCR) signaling pathway, and DNA methylation. Among the genes related to TCR

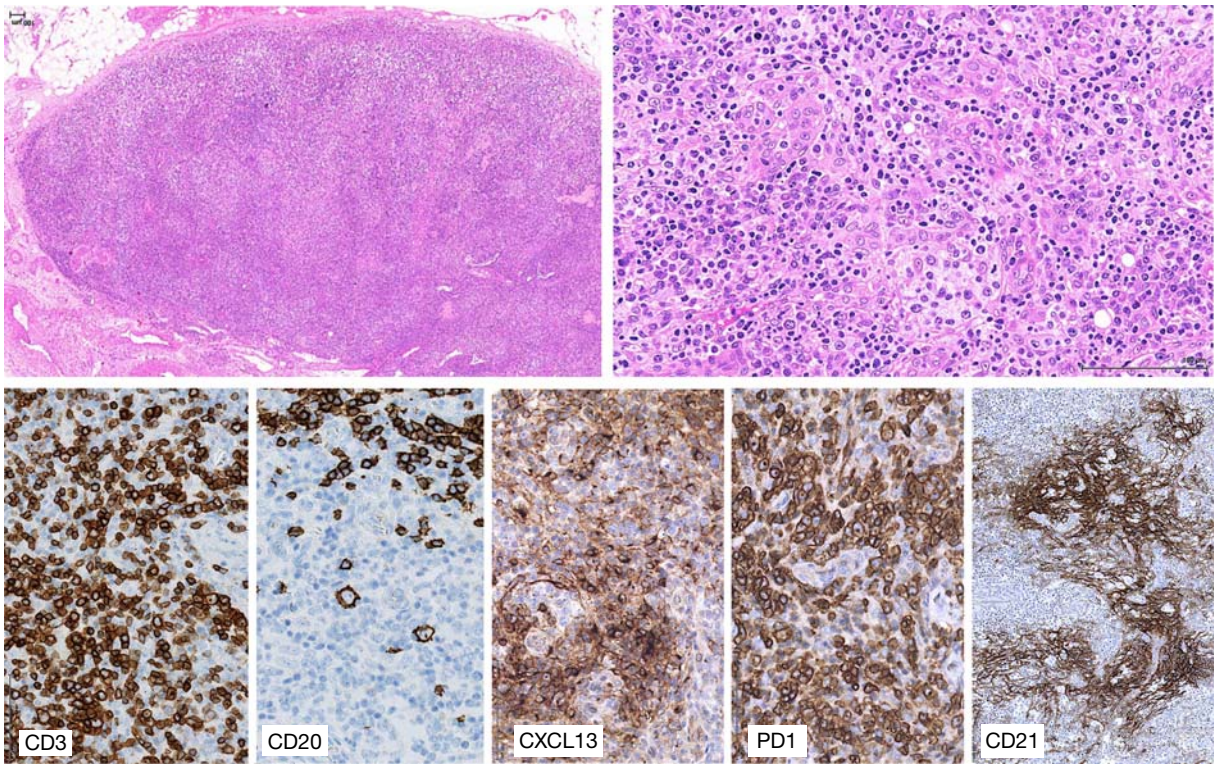

Fig. 13 Angioimmunoblastic T-cell lymphoma. A low-power view of the lymph node (upper left) shows a diffuse obliteration of the architecture, with a somewhat pale appearance. A higher magnification (upper right) shows abundant high endothelial venules, and a polymorphous cellular infiltrate comprising atypical medium-sized lymphoid cells with clear cytoplasm, that represent the neoplastic component. Most cells are CD3+ while CD20 highlights scattered large lymphoid cells. CXCL13 and PD-1 highlight a T_{FH} immunophenotype in the neoplastic component. CD21 shows an irregular proliferation of follicular dendritic cells which is characteristic of that entity.

signaling pathway, *RHOA*, which encodes a small GTPase is the most frequently mutated (60%–70% of the cases). Most mutations are hotspot generating p.Gly17Val RHOA dominant-negative variant which specifically binds to guanine nucleotide exchange factor VAV1, an interaction enhancing the adaptor function of VAV1, and ultimately leading to increased TCR signaling. In addition, activating mutations in genes encoding proximal TCR signaling elements (FYN), costimulatory receptors (CD28), or key intracellular effectors of signal transduction (PLCG1, PI3K, CTNNB1, GTF2I) are detected in up to half of TFH-PTCLs. Oncogenic TCR activation may also result from gene fusions, that is, the rare t(5;9)(q33;q22) translocation producing an ITK-SYK chimeric protein, and overall infrequent gene fusions involving *CD28* with *CTLA4 or ICOS*. The second group of genes frequently altered are involved in DNA methylation: *TET2*and *DNMT3A* harbor mono- or biallelic inactivating mutations distributed along their coding sequences in 50%–75% and 20%–30% of TFH-PTCLs, respectively. In addition, about 20%–30% of AITLs have gain-of-function missense *IDH2* mutations at the R172 residue which induces the production of an oncometabolite (hydroxyglutarate), which inhibits various deoxygenases including TET2 and histone demethylases. In AITL, *DNMT3A* and *IDH2* mutations almost always occur in association with *TET2* mutations, in contrast with myeloid neoplasms where they are usually mutually exclusive. While *RHOA* and *IDH2* mutations are present in tumor cells only, *TET2* and *DNMT3A* mutations have been found also in hematopoietic progenitors. In most cases, *RHOA* mutations are observed in *TET2* mutated tumors, with the allelic burden for *TET2* or *DNMT3A* mutations being higher than for *RHOA*, suggesting cooperation between impaired RHOA function preceding TET2 loss of function contributing to AITL pathogenesis.

Anaplastic Large-Cell Lymphomas

Anaplastic large-cell lymphoma (ALCL) encompasses four disease entities that differ by their clinical presentation and genetic features: anaplastic lymphoma kinase (ALK)-positive and ALK-negative (systemic) ALCLs, each accounting for 7%–8% of PTCL, primary cutaneous ALCL (pcALCL) and breast implant-associated ALCL (BI-ALCL) (**Fig. 14**). ALCLs share a common core of morphological and immunophenotypical features: they are composed of large anaplastic cells, including so-called "hallmark cells" characterized by an eccentric kidney- or horseshoe-shaped nucleus and a prominent Golgi region; they are homogeneously strongly positive for the activation marker CD30; they often present a cohesive pattern of growth and sinusoidal dissemination in the lymph nodes; they frequently exhibit so-called "null" immunophenotype with defective expression of the TCR/CD3 and of many T-cell antigens, despite a T-cell genotype; and usually express cytotoxic-associated antigens.

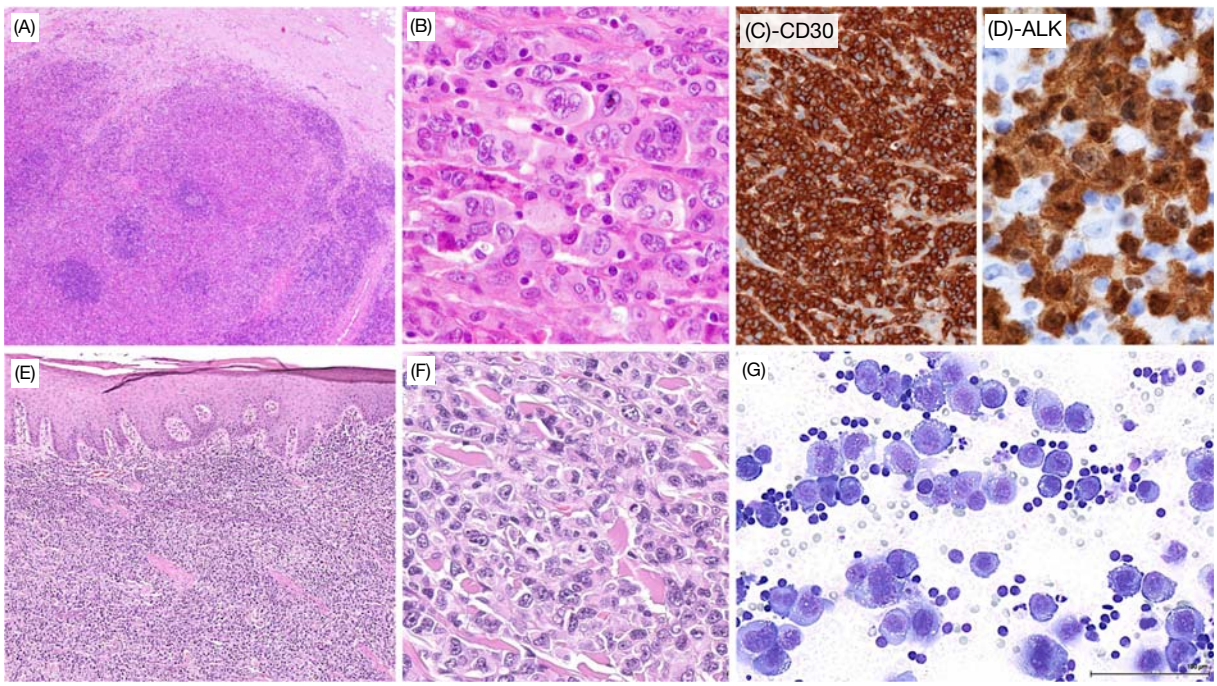

Fig. 14 Anaplastic large-cell lymphomas. ALK-positive anaplastic large-cell lymphoma (upper panels): low-power view of the lymph node shows a fibrous thickening of the capsule, and partial obliteration of the architecture (A); at higher magnification, the neoplastic cells are very large, sometimes gigantic, with horseshoe-shaped or multilobulated nuclei (B); the tumor cells are strongly positive for CD30 (C) and show nuclear and cytoplasmic positivity for ALK (D) which is indicative of t(2;5) (NPM–ALK) translocation. Primary cutaneous anaplastic large-cell lymphoma (lower left panels): the lesion is characterized by a diffuse lymphoproliferation occupying the dermis and sparing the epidermis (E); the neoplastic cells are large and grow in diffuse cohesive sheets; nuclei are irregular; mitotic figures are seen (F). Breast implant-associated anaplastic large-cell lymphoma (lower right panel): Giemsa stain of a cytological smear of seroma associated BI-ALCL, comprising large pleomorphic cells with abundant cytoplasm (G).

ALK+ ALCL

ALK+ ALCL preferentially affects children and young adults. Overall ALK+ ALCLs are aggressive neoplasms with good response to therapy and a significantly better survival as compared to ALK-negative ALCL (perhaps as a result of the younger age of ALK+ ALCL patients) and other PTCLs. Among the variety of *ALK* translocations, which induce the expression of chimeric fusion proteins having constitutive ALK tyrosine kinase activation, the most common fuses *ALK* gene @2p23 to the *nucleophosmin* gene (*NPM*) @5q35. The type of translocation determines the subcellular distribution of ALK but has no prognostic significance. ALK oncoproteins represent the major oncogenic driver in ALK+ ALCL: in vitro, constitutively activated ALK chimeras induce cellular transformation, enhance cell proliferation and survival, and account for the silencing of the T-cell phenotypic markers. These properties result from engagement of multiple signaling pathways, including the JAK/STAT and the PI3K/Akt pathways. No etiologic agent has been linked to ALCL, but there have been case reports of systemic ALK+ ALCL presenting with skin lesions occurring after an insect bite, suggesting the possible role of inflammatory mediators released upon the bite in eliciting lymphoma development. A recent study presented a model of peripheral ALCL pathogenesis where the malignancy is initiated in early thymocytes, before TCR β-rearrangement, which is bypassed in CD4/NPM–ALK transgenic mice following NOTCH1 expression. However, TCR is required for thymic egress and development of peripheral murine tumors, yet TCR must be downregulated for T-cell lymphomagenesis. These observations suggest that children affected by ALCL may harbor thymic lymphoma-initiating cells capable of seeding relapse after chemotherapy.

ALK-negative ALCL

ALK-negative ALCL tends to occur in older individuals than ALK+ ALCL, and to have more preserved T-cell immunophenotype, with less frequent expression of cytotoxic molecules. ALK− ALCL by definition contains no *ALK* translocation and is negative for ALK protein expression. While distinct signatures have been derived from the comparison of ALK+ and ALK− ALCL, other studies have also evidenced much commonality in RNA or protein expression in ALK+ and ALK-negative ALCL, and in ALK-negative ALCL and a subset of PTCL, NOS with strong CD30 expression. ALCL, irrespectively of ALK status, is molecularly distinct from other PTCLs and express a distinct set of transcripts, including CD30 (*TNFRSF8*), *BATF3*, and *TMOD*, and demonstrate low expression of genes associated with TCR signaling.

Two types of recurrent translocations were discovered in ALK− ALCL by massive parallel sequencing: (1) the most frequent rearrangements involving the 6p25.3 locus which are rather specific to ALK− ALCLs (both systemic and primary cutaneous), and virtually absent in other PTCL entities, and involve either *IRF4* or *DUSP22* (which encodes a dual-specificity phosphatase that inhibits TCR signaling) with various partners; (2) the less frequent *TP63* rearrangements encoding fusion proteins homologous to ΔNp63, a dominant-negative p63 isoform that inhibits the p53 pathway, which have been found also in PTCL-NOS. The most common rearrangement resulting from inv(3)(q26q28), fuses *TP63* to *TBL1XR1*. Rearrangements of *DUSP22* and *TP63* in ALK- ALCL are mutually exclusive and detected in 19%–30% and 7%–8% of the cases, respectively. *DUSP22*-rearranged ALCLs have a prognosis similar to ALK+ ALCL, while, conversely, *TP63* rearrangements are associated with a poor outcome (17% 5-year OS). Cases lacking all three genetic markers have an intermediate prognosis. In addition there are diverse mechanisms convergent to induce constitutive oncogenic activation of the JAK/STAT pathway in a substantial proportion of ALK− ALCL including occasionally co-occurring activating mutations of *STAT3* and *JAK1*, and recurrent gene fusions involving a transcription factor (*NFKB2* or *NCOR2*) with tyrosine kinase genes (*ROS1* or *TYK2*). Thus, STAT3 activation represents a shared oncogenic mechanism in both ALK+ and ALK− ALCLs.

Primary cutaneous (pc)ALCL

Primary cutaneous (pc)ALCL is the second most common cutaneous T-cell lymphoma (after mycosis fungoides). pcALCL presents as solitary or less commonly multiple skin nodule(s) or tumor(s) that may regress and recur, and usually carries a good prognosis. Its pathological and genetic features overlap with those of systemic ALK− ALCL, including rearrangements of *DUSP22* in up to 30% of the cases, rearrangements of *TYK2* in 13% of the cases, occasional *STAT3* mutations and rearrangements of *TP63*.

Breast implant-associated ALCL (BI-ALCL)

Breast implant-associated ALCL (BI-ALCL) is a very rare form of ALK-negative ALCL that arises in association with various kinds of breast implants with an estimated risk of one case per 500,000 to 3,000,000 women with breast implants. Most cases are confined to the periprosthetic effusion and capsule have excellent outcomes, while a minority of patients present with a breast tumor mass, which is an adverse prognostic factor. Information on the genetics of BI-ALCL is essentially limited. Next-generation sequencing findings in a few primary cases consistently showed either no alteration or a small number of somatic alterations, including activating mutations of *STAT3* or *JAK1*. *DUSP22* and *TP63* rearrangements were not found in a reported series.

Peripheral T-Cell Lymphoma, Not Otherwise Specified (PTCL-NOS)

PTCL-NOS comprises a heterogeneous group of mature T-cell neoplasms, which do not qualify for any other specific entity. PTCL-NOS make up to 40% of mature T-cell malignancies in historical series, but their relative frequency in more recent registries is lower now that cases with of a TFH immunophenotype are considered in the group of AITL-related PTCLs.

Lymph nodes usually are diffusely involved and cytology is typically pleomorphic, with predominantly smaller or larger cells. Reactive eosinophilia and/or histiocytes may be prominent. Many cases are CD4+CD8−, a subset are CD4−CD8+, and more rarely tumors are either double-negative or -positive for CD4 and CD8. Most cases derive from α/β T cells, a minority are of γδ

derivation, or TCR-silent. CD30 is often detected in a variable proportion of tumor cells. Up to 50% of PTCL-NOS are EBV-positive usually in a small subset of cells, likely bystander B cells, and this feature has been associated with a poor survival. A subset of PTCL-NOS, most commonly CD8+, feature a cytotoxic immunophenotype which in general correlates with a poorer prognosis.

Gene expression profiling has identified two subgroups of PTCL-NOS characterized by high expression of either *GATA3* or *TBX21* transcription factors and downstream target genes, associated with different prognosis. These findings can be translated to routine immunohistochemistry: PTCL-NOS with high expression of GATA3 or TBX21/T-bet appear to be essentially nonoverlapping and the high GATA3 group was shown to portend a significantly worse prognosis in two independent series.

Conventional cytogenetics and comparative genomic hybridization have shown recurrent genetic aberrations and imbalances, usually complex, but have not allowed to capture specific driver alterations. Very rare recurrent translocations involve breaks in the TCR genes. The t(6;14)(p25;q11.2) translocation involving the *IRF4* locus, has been reported in clinically aggressive cytotoxic PTCL. Expression and constitutive activation of PDGFRα and SYK tyrosine kinases appear to represent features common to many PTCLs, and although their role in lymphomagenesis remains poorly understood, they represent novel potential therapeutic targets. The mutational landscape of PTCL-NOS is not fully characterized; targeted sequencing analyses have highlighted a heterogeneous pattern of alterations including recurrent mutations in epigenetic mediators, regulators of signaling pathways, and tumor suppressor genes.

Extranodal NK/T-Cell Lymphoma (ENKTCL)

ENKTCL, nasal type (ENKTCL) represent the prototype of EBV-positive NK- or T-cell neoplasm (**Fig. 15**, upper panels). ENKTCL is not exceptional in western countries, but predominantly affects middle-aged men in Asia, Mexico and South America. It presents as tumors or destructive lesions in the nasal cavity, maxillary sinuses or palate, and despite a localized presentation in most patients, tends to relapse locally or at other extranodal sites, such as the skin, with an overall 40%–50% 5-year survival rate. "Extranasal NK/T-cell lymphomas" otherwise similar to the nasal NKTCL, may present in other localizations, especially in the skin, gastrointestinal tract, or testis, with a more adverse clinical outcome. Aggressive NK-cell leukemia, also EBV-associated and derived from NK cells, is regarded as the systemic form of NKTCL.

ENKTCL cells usually express cytoplasmic CD3 (CD3ε+), are CD2+,CD5− CD7+ CD16+/− CD56+, with an activated cytotoxic profile. Consistent PD-L1 expression by neoplastic cells was reported in the majority of the cases. Most cases are derived from NK cells and have a germline *TCR* configuration; however, in some series up to more than half of the cases derived from clonal T cells, with a $\gamma\delta$ or more rarely $\alpha\beta$ TCR configuration.

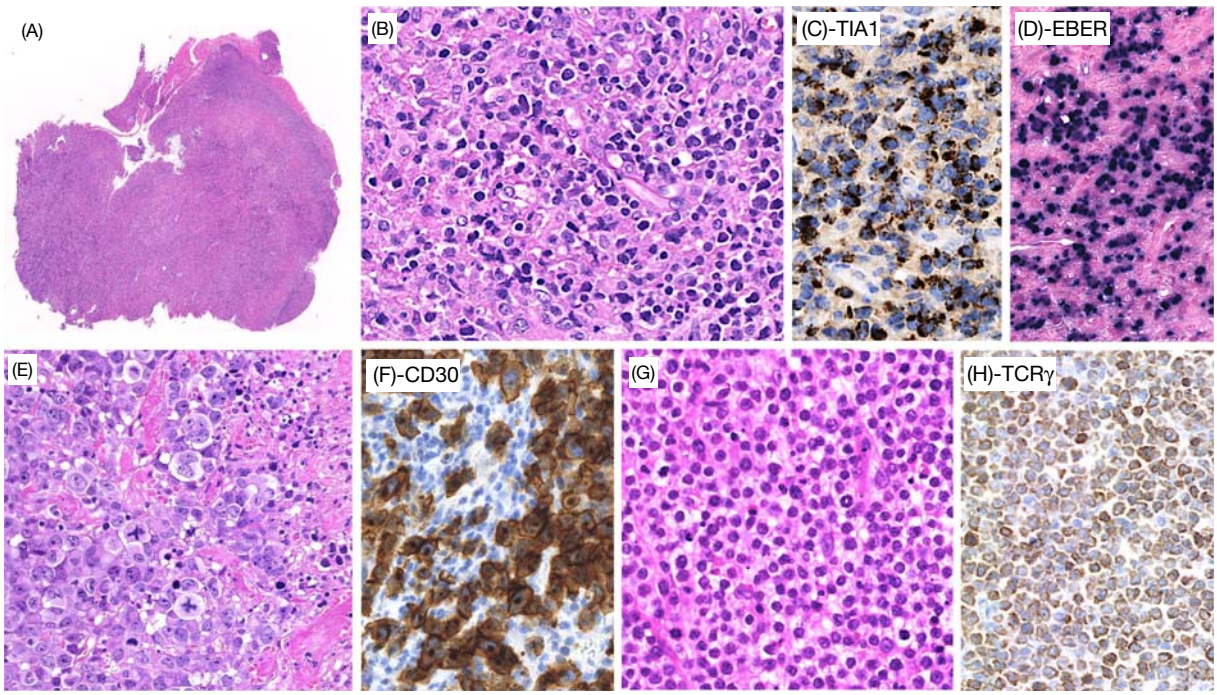

Fig. 15 Extranodal NK/T-cell lymphomas. Extranodal NK/T-cell lymphoma, nasal type (upper panels): this low-power biopsy shows a piece of sinonasal mucosa, with surface ulceration, diffuse necrosis and focal areas of viable tumor (A); the latter comprises an admixture of atypical lymphoid cells, including large cells (B); the tumor cells are positive for TIA1 (C) and EBV (D) as demonstrated by in situ hybridization with EBER probes. Intestinal T-cell lymphomas (lower panels): enteropathy-associated T-cell lymphoma composed of large cells with anaplastic morphology, associated to necrosis (E) and showing strong expression of CD30 (F). Monomorphic epitheliotropic intestinal T-cell lymphoma comprising a monotonous proliferation of small to medium in size lymphoid cells with pale cytoplasm (G) and showing TCR-gamma membrane expression (H).

By definition, all cases are associated with EBV, with a type II latency program (expression of EBERs, LMP1 and EBNA2). EBV is clonally present in an episomal form and exerts oncogenic effects through the production of cytokines such as IL-9 and IL-10, and the upregulation of IP10/MIP2 chemokines that may contribute to vascular damage and secondary necrosis. TNFα production may explain the common hemophagocytic syndrome. Partial deletion of chromosome 6 (6q21-25) is a recurrent aberration in ENKTCL. Several candidate tumor suppressor genes, such as *PRDM1*, *ATG5*, *AIM1* and *HACE1*, are mapping to that region and their inactivation by deletion and/or methylation might be involved in lymphomagenesis. Compared to normal NK cells, ENKTCL is characterized by activation of PDGFRA and of the AKT, JAK/STAT, MYC and nuclear factor-kappaB pathways. While ENKTL consistently shows nuclear localization of p-STAT3, very different results have been published regarding the actual frequency of activating *JAK3* mutations in this disease. Based on whole exome or large gene panel sequencing, the most frequent mutations have been found in *BCOR* (a corepressor acting selectively with the POZ domain of BCL6 (21%, loss-of-function mutations), *DDX3X* (a RNA helicase, mutated in 16% of the cases, and recurrently methylated as well), *TP53* (15%) and *STAT3* (13%).

Intestinal T-Cell Lymphomas

Primary intestinal T-cell lymphomas derived from intraepithelial T lymphocytes overall account for 5%–8% of PTCLs (**Fig. 15**, lower panels). These diseases tend to occur in adults, usually manifest with single or multiple lesions/tumors in the small intestine, and have a poor prognosis. They include two entities: enteropathy-associated T-cell lymphoma (EATL), and monomorphic epitheliotropic intestinal T cell lymphoma (MEITL).

EATL is most common overall, especially in Northern Europe where celiac disease is more prevalent. EATL occurs as a complication of gluten-sensitive enteropathy, but in up to half of the patients, it is the first manifestation of enteropathy. EATL is composed of pleomorphic, medium to large, occasionally anaplastic lymphoid cells, often comprises necrosis and an inflammatory infiltrate rich in histiocytes and eosinophils. The neoplastic cells are usually CD3+, CD5−, CD4−, CD8−, CD30+ CD56−, have an activated cytotoxic immunophenotype and usually express TCRαβ+ and the intraepithelial homing integrin CD103.

MEITL lacks the association to celiac disease in the majority of cases and is overall very rare, but represents the more prevalent intestinal T-cell lymphoma type in Asian-Pacific studies. It comprises a monomorphic proliferation of medium-sized cells, without necrosis and inflammation spreading to the adjacent mucosa with marked epitheliotropism. The neoplastic cells are usually CD3+, CD5−, CD7+, CD4−/CD8+, CD30−, CD56+, with an activated cytotoxic immunophenotype. Aberrant expression of CD20 or other B-cell markers is seen in some cases. MEITL appears heterogeneous in terms of TCR expression with the majority of cases being of γδ origin.

EATL and MEITL share common recurrent chromosomal imbalances (chromosome 9q gains with almost mutually exclusive losses of 16q12.1, gain of chromosome 7 and losses of 8p22-23.2, 16q21.1, 11q14.1- q14.2 and 9p21.2-p21.3), and also distinctive genetic alterations. MEITL is characterized by significantly more frequent gains of the *MYC* oncogene locus and less frequent gains of chromosomes 1q and 5q as compared with EATL. Additionally the loss of 3p21.31 has been reported as recurrent in MEITL but not in EATL.

A few studies have examined the mutational landscape of these lymphomas. Whole exome sequencing analysis of MEITL led to the discovery of highly recurrent alterations of the tumor suppressor *SETD2* gene encoding a nonredundant H3K36-specific trimethyltransferase, in the majority of the cases (14/15) (93%). *SETD2* alterations were often biallelic, mainly by loss-of-function mutations and/or loss of the corresponding locus (3p21.31). *SETD2* alterations are found in both γδ and αβ-expressing tumors and consistently correlated with defective SETD2 expression and H3K36 trimethylation. In a subsequent study, *SETD2* alterations were identified in a small percentage of EATL as well. In a T cell-specific *SETD2* knockout mouse model, an expansion of γδ T cells was observed. Interestingly, *SEDT2* is also most frequently mutated gene (about one-third of the cases) in Hepatosplenic T-cell lymphoma, an entity having in common with MEITL to be highly aggressive and often derived from γδ T cells. In another study from Asia, *GNAI2* was mutated gene in 24% of MEITL cases. Both EATL and MEITL harbor recurrent mutations in both the JAK/STAT and in MAPK (*TP53*, *BRAF* and *KRAS)* signaling pathways with *STAT5B* and *JAK3* most frequently mutated. In MEITL mutation-induced alterations in the JAK-STAT pathway, mainly affecting *STAT5B* (60%–65%), *JAK3* (35%–46%) and *SH2B3* (20%), are almost constant.

Hepatosplenic T-Cell Lymphoma (HSTL)

HSTL mostly derives from γδ T cells of the splenic pool with vδ1 gene usage, but there are rare cases with an αβ phenotype and similar clinicopathologic and molecular features. HSTL predominantly affects young male adults and may arise in the setting of chronic immune suppression or prolonged antigenic stimulation, particularly in solid organ transplant recipients or in children treated by azathioprine and infliximab for Crohn's disease. The disease typically presents with hepatosplenomegaly, thrombocytopenia and systemic symptoms, without lymphadenopathy or peripheral blood involvement.

HSTL comprises a monotonous infiltrate of atypical medium-sized lymphoid cells, with a prominent sinusoidal pattern in the splenic red pulp, liver and bone marrow. The usual immunophenotype is CD3+ CD5− CD56+ CD4−/CD8− TCRγδ+ with a nonactivated cytotoxic profile. Irrespective of TCR cell lineage, HSTL has a unique gene signature, with elevated levels of transcripts of *SYK*, NK-cell-associated molecules and oncogenes (*FOS* and *VAV3*), and low expression of the tumor suppressor AIM1 due to promoter hypermethylation.

The majority of the cases carry an isochromosome 7q, and trisomy 8 and loss of a sex chromosome seem to be associated with progression of the disease. Deep sequencing analyses have highlighted frequent mutations in epigenetic modifiers in 62% of cases, most commonly *SETD2* but also *INO80*, and *ARID1B*. Other frequent abnormalities include activating mutations of *STAT5B* (31%) and *STAT3* (9%), and of *PIK3CD* (9%).

Conclusion

Lymphoid neoplasms are a diverse group of tumors arising from cells of the immune system. The normal counterpart of many but not all of these tumors can be recognized. With available techniques, a large number of clinically and biologically distinct tumors can be defined; in daily practice fewer than 10 of these make up the majority of the cases seen by clinicians and pathologists. New genetic data are enhancing our ability to define clinically relevant subsets of heterogeneous groups such as diffuse large B-cell lymphomas. Recognizing distinct diseases is important for future progress in understanding the pathogenesis of diseases and in defining optimal therapies.

Nonsmall-Cell Cancers of the Lung: Pathology and Genetics

Erik Thunnissen, VU University Medical Center, Amsterdam, The Netherlands
Egbert F Smit, Netherlands Cancer Institute, Amsterdam, The Netherlands

Glossary

APOBEC family Is a family of enzymes with cytidine deaminase function that catalyze the deamination of cytidine to uridine in the single stranded DNA substrate. Beside antiviral function they also have mutagenic effect later in oncogenesis.

Comparative genomic hybridization Is a molecular technique to screen chromosomes for discrete chromosomal regions, of which the copy number has increased or decreased; that is, gained or lossed compared to the standard of two alleles (one maternal and one paternal allele in each nucleus). For pathology diagnosis this technique is now replaced by *shallow sequencing*, providing similar information with less input material.

Mutational load of a neoplasm Is the cumulative result of all acquired mutational changes in a tumor, since the first division of the cell.

Next generation sequencing Is a term covering high-throughput (multiple parallel) sequencing technologies, enabling the identification of coding-sequence alterations down to single-base-pair resolution with a fairly high level of precision and accuracy in a short period of time (days). Coverage is a term used in next generation sequencing denoting the number of reads in a sample for a given DNA fragment.

Synthetic lethality An occurrence in which the disruption of two or more gene products leads to cell death, but the inhibition of either one alone does not.

Transcriptome alterations Analyses in tumor specimens have led to several important observations regarding the effects of DNA-sequence alterations on RNA transcripts, splice-site mutations, and gene fusions.

Whole exome sequencing Is a transcriptomics technique for sequencing all of the protein-coding genes in a genome (which is called the exome). The size of the exome in humans is approximately 1% of the genome and covers approximately 30 million base pairs.

Whole genome sequencing The process of determining the complete DNA sequence of an organism's genome at a single time. The size of the human genome is 3 billion base pairs.

Pathology of Nonsmall Cell Lung Carcinoma

Introduction

Until the beginning of the 21st century, the pathological classification of lung cancer for guiding of systemic treatment was quite simple: a division existed in small cell lung carcinoma and the other carcinomas (nonsmall cell lung cancer, NSCLC), each having their own (but different) chemotherapy treatment. NSCLC is a nondescriptive term that comprises the large majority of malignant lung tumors and several histologic subtypes, including squamous cell carcinoma, adenocarcinoma and large cell or undifferentiated carcinoma. Pulmonary carcinoid, mesothelioma, mucoepidermoid carcinoma, and other rare forms of lung tumors are considered separately from this general SCLC and NSCLC classification. The World Health Organization (WHO) classification of 2004 and earlier classifications for decades had been based on resection specimens but this has been influenced by two developments. One was the finding in several clinical studies that in some histological categories (adenocarcinomas (AdC) and large cell carcinomas) a chemotherapeutic agent (pemetrexed) worked better than other chemotherapic agents, but less optimal than in squamous cell carcinomas (SqCC). In parallel, it was discovered that genetic alterations which drive tumorigenesis (driver mutations, like *EGFR* activating mutations) were predominantly found in adenocarcinomas and their presence predicts the response to small molecule inhibitor treatment. The latter development opened a new dimension in pulmonary pathology, since after the diagnosis of lung cancer an additional (predictive) test was needed that is, a test that, when positive, directs toward alternative treatment. As a result the pathological diagnosis of lung cancer has become a multistep process, beginning with morphology on routine hematoxylin and eosin stain (H&E) and immunohistochemistry (IHC), to discriminate benign from malignant processes and metastases from primary lung cancer. In case of primary nonsquamous NSCLC, this will be followed by molecular characterization. We will first discuss the diagnostic process and subsequently the predictive procedures.

Small Sample Diagnosis

Squamous cell carcinoma is recognized by signs of squamous differentiation, that is, keratinization or intercellular bridges. In contrast, adenocarcinomas present different patterns: acinar, micropapillary, rarely papillary, solid component with intracellular

mucin, and/or lepidic growth (i.e., growth along alveolar walls). Large cell carcinoma is a diagnosis by exclusion: it is a carcinoma that has no characteristics fitting small cell carcinoma, adenocarcinoma, or squamous cell carcinoma. Thus, in morphological terms large cell carcinoma is an undifferentiated carcinoma. The diagnosis of large cell carcinoma is only made on resection specimens, because resection specimens provide larger fragments of the tumor for examination. If histological criteria characteristic for adenocarcinoma or squamous cell carcinoma are focally present (arbitrarily in $>10\%$), the tumor is diagnosed accordingly. Biopsies invariably are of small size, and as a consequence the proportion of cases without distinct differentiation by H&E stain is as high as 30%–40%. This morphological pattern in biopsies is called "nonsmall cell carcinoma, not otherwise specified" (NSCLC-NOS, a term only used on biopsies). In daily practice approximately 70%–80% of all lung cancer diagnoses are made on small samples, the proportion of NSCLC-NOS is relatively high and this diagnosis does not provide any direction for decisions on systemic treatment. To provide arguments for therapy decisions, additional markers have to be added in the diagnostic process, as elaborated in the 2015 WHO classification of lung cancer. A set of three markers is used, pointing either to squamous cell carcinoma (immunohistochemistry strongly positive for p40 (or p63) in all undifferentiated tumor cells) or adenocarcinoma (immunohistochemistry for TTF-1 positive in most tumor cells in 60%–70% of adenocarcinomas, and histochemical mucin stain, which may be complementary to TTF-1), as shown in Fig. 1. The use of this marker panel reduces the NSCLC-NOS category to $<10\%$, and reliably can be used for guiding treatment.

Genetics of Nonsmall Cell Lung Carcinoma

Introduction

Since the discovery of DNA it became gradually clear that acquired (somatic) DNA changes in DNA are fundamental to tumor development. In lung cancer, smoking (local pollution) is the main cause of the acquired (somatic) changes. The somatic driver changes roughly corroborate with the histologic subtypes, but several additional (also called passenger) mutations are responsible for a tremendous diversity. Lung cancer is not one disease, but turns out to be a spectrum of different diseases. In this article the general mutational process in carcinogenesis is discussed and subsequently the somatic changes related to the different histological subtypes.

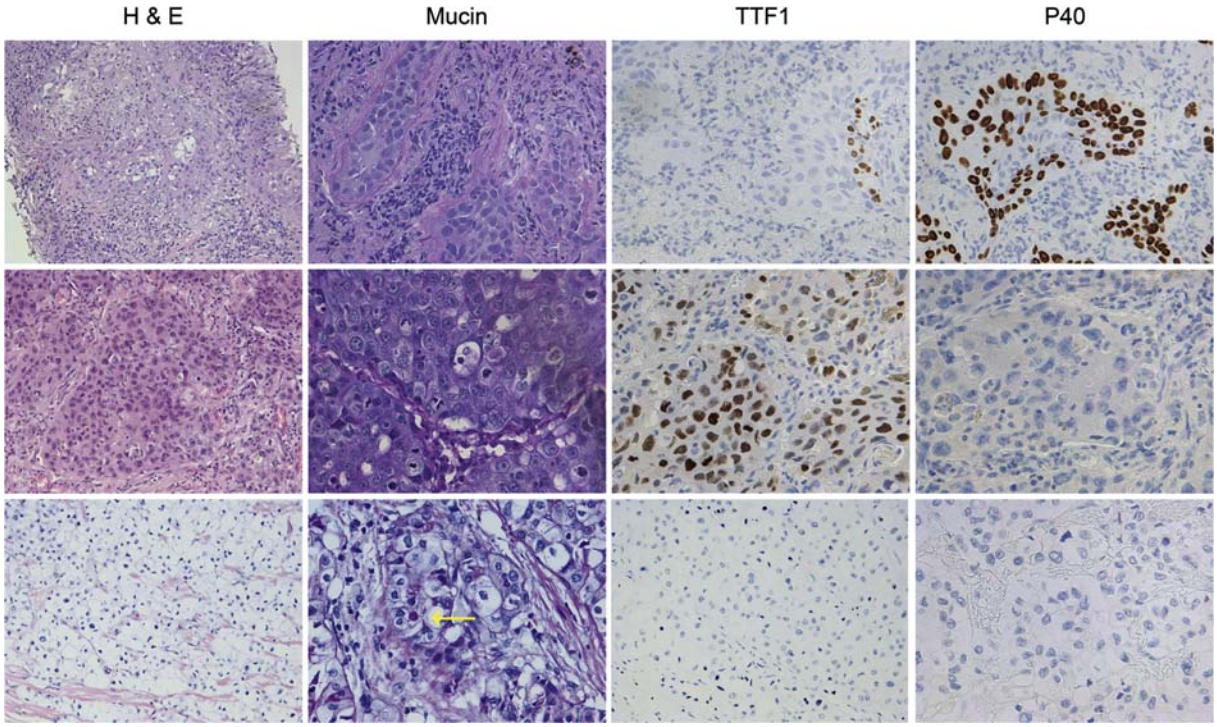

Fig. 1 For three different lung cancer cases (three rows) of nonsmall cell lung carcinoma not otherwise specified (NSCLC-NOS) the results of additional stains is shown. The top row shows positivity for p40 for a diagnosis of nonkeratising squamous cell carcinoma. The two rows below show adenocarcinoma based on positivity for TTF1 and mucin, respectively. H&E at $100\times$ and additional stains at $200\times$ magnification. In case of lack of morphological clues for the distinction between squamous cell carcinoma and adenocarcinoma on routine histological staining, or when the pathologist is in doubt, additional diagnostic stains are requested. The left panels show staining patterns and the diagnoses with which these are associated. The right panels list the predictive tests per diagnostic category. ESMO guideline indicates that molecular testing is only recommended in adenocarcinomas and NSCLC-NOS and not in patients with SqCC, except for never/former light smokers (<15 pack years).

General Somatic Changes

Smoking is the major cause of lung cancer (85% of cases). For the remaining 15%, environmental exposure, for example, diesel fumes, is likely to be responsible. With each inhalation, about 10^{14} oxidant molecules leave a cigarette, of which 10^{7} reach the lungs. These toxic components may enter airway cells and are then modified by cellular enzymes which metabolize xenobiotics, which facilitates excretion via liver and kidneys. There is some variability of the genes encoding the enzymes involved in the xenobiotic metabolism in the human population, leading to minor interindividual differences in enzyme activity. Variants of the involved genes are associated with the risk of the development of lung cancer. Some of the xenobiotics metabolites bind to DNA, creating so called DNA adducts which may result in DNA mutations. The original DNA sequence can be maintained through the removal of DNA adducts by DNA repair enzymes. DNA repair is a highly accurate process which is responsible for more than 3000 repairs per nucleus per day. Genes encoding for DNA repair enzymes also show some level of variability in the polulation, which is associated with variations in DNA repair enzyme activity. This provides a partial explanation to the fact that while many heavy smokers get lung cancer, some do not. The long latency period between smoking and the development of lung cancer (25–30 years) is one of the reasons why it has been difficult to convince smokers to quit smoking. The average life expectancy of heavy smokers is 10 years less than that of nonsmokers, due to cardiovascular and (chronic obstructive) pulmonary disease and to cancer of the lung and of other organs. The failure of epidemiological data to convince heavy smokers to quit has given rise to more personal approaches in the "quit smoking" campaigns, for example with the message that each smoked cigarette reduces life expectancy with approximately 15 min. Awareness that "smoking each cigarette is a mini-suicide attempt" may be more effective as an incentive to stop smoking.

Even though DNA repair is highly accurate, errors do occur. A single nucleotide repair error will change a single nucleotide, known as a point mutation. Point mutations may be in noncoding DNA or may not be associated with a change in the quality of the encoded protein. Such "passenger mutations" will not result in any noticeable damage. However, when a mutation in a protein coding gene changes the characteristics of the encoded protein this may profoundly impact cell behavior. Mutations in genes encoding proteins that stimulate cell proliferation, known as potential oncogenes, can convert such a gene in *a dominant oncogene* which drives uncontrolled cell proliferation (dominant because mutation of only one allele is responsible for the effect). Mutations may also be in genes inhibiting cell proliferation. Failure to repair double strand breaks may be responsible for rearrangement of some DNA strands. For tumor suppressor genes both alleles need to be mutated or functionally impaired to become oncogenic. Yet another possibility during rearrangement is the fusion between parts of two different genes, leading to a fusion protein, which may have an oncogenic driver function.

The mean somatic mutation rate in malignant tissue from the lungs of tobacco smokers is 8–10 mutations per megabase (1 million base pairs), regardless of the histologic subtype. In nonsmokers the somatic mutation rate is 10 times lower.

At nucleotide level three patterns of mutations are discerned. In smoking related lung cancer a frequent early nucleotide change is a cytosin to adenine transition (C > A), also called the "smoking signature." A similar pattern may also occur in nonsmokers, if exposure happens to similar toxins by, for example, occupational exposure. The second signature is an age related change: C > T transition at CpG sites. The third arises during cancer progression, during which additional mutations from cytosine to guanine or thymidine (C > G or C > T) develop. This pattern is associated with APOBEC enzyme-mediated mutagenesis creating the so called "APOBEC signature." Interestingly, despite maintained carcinogen exposure, tumors from smokers showed a relative decrease in smoking-related mutations over time compared to the APOBEC related mutations, which indicates that further expansion of the genetic derangement/chromosomal instability occurs. Interestingly, cessation of smoking for a longer period is associated with a reduction of the smoking signature. This implies that the tumor mutation spectra in former smokers reflects not only quantity of smoking exposure, but also time since smoking cessation.

The general assumption is that DNA mutations develop stochastically, but nonetheless the distribution of mutations is not random over the whole genome, as the folding of DNA in chromatin varies between cell types. In morphological terms, heterochromatin in a nucleus contains densely packed DNA strands, while euchromatin contains transcriptionally active DNA which is more loosely packed and more vulnerable to DNA adduct formation.

Regarding molecular oncogenesis of lung cancers, it is assumed that following early (tabacco related) mutations genome doubling occurs, along with chromosomal instability responsible for gain or loss of chromosomes chromosomal frangments, responsible for so called "copy number alterations." The pattern of copy number alterations, visualized by comparative genomic hybridization, shows some similarities between adenocarcinomas and squamous cell carcinomas, but also many differences, allowing to distinguish between these two categories in approximately 80% of the cases. In line with genomic instability as one of the hallmarks of cancer, in squamous dysplasia, the morphologically recognizable premalignant precursor lesion of respiratory epithelium, the presence of abundant copy number alterations mark progression to squamous cell carcinoma. Dysplasia without abundant copy number variation remain stable or even regress. Abundant copy number alterations in precursor lesions are not reversible.

Cell of Origin

The epithelium of the respiratory tract consists of basal, parabasal, neuroendocrine, ciliated, goblet cells, type I and type II pneumocytes. Depending on the cell type, some genes will be active, while others will be silent. Inhaled toxic components may affect any cell and cause a mutation, which raises the question whether the various cell types of the respiratory tract differ in sensitivity for mutagenesis. Ciliated cells and type II pneumocytes are terminally differentiated cells, which will undergo apoptosis at the end of their

life-span and will then be replaced freshly matured cells derived from local stem cells. In such terminally differentiated cells a mutation will not initiate cancer. In contrast, if a mutation develops in a cell with inherent proliferative capacity (e.g., basal, neuroendocrine, alveolar type II, and Clara cells), this may be the initial molecular event responsible for malignant transformation of a cell that might become the cell of origin of a tumor. Oncogenesis, however, requires the accumulation of multiple mutations in genes responsible for vital cellular functions (e.g., regulating cell proliferation and apoptosis).

The question of cell of origin of lung cancer has been studied by introducing specific gene mutations in specific cell types in mouse models, including exposure to toxins. Cell-of-origin appeared to be associated with the histopathological characteristics of the resulting tumor. The neuroendocrine cell appears to be the cell of origin of small cell lung cancer. For KRAS mutated adenocarcinomas Clara cells or alveolar type II cells serve as the initiating cell type. Of note, basal cells, Clara cells and alveolar type II pneumocytes may also serve as initiating cell types for squamous cell carcinoma, with SOX2 activation as the event responsible squamous differentiation.

Surprisingly, only 10% of the smoking population develops lung cancer and that even after a long latency period, in spite of the enormous daily toxic burden of a regular smoker. This is (at least in part) due to the efficacy of the DNA repair process as well as the fact that many mutations will occur in terminally differentiated cells which will not become cancer initiating cells.

Clonal Development

Once the cell has acquired a sufficient number of mutations conferring autonomic growth, autonomous clonal expansion will occur. During this process all cells of the clone will contain the same set of initiating mutations. To reach the volume of a detectable tumor (>0.5 cm) at least 30 doubling cycles have to be accomplished. With a tumor volume doubling time for malignant tumors varying between 50 and 400 days, the time it takes to develop a detectable tumor is counted in years. During this time frame additional mutations will have developed but not necessarily in all tumor cells. When samples from different regions of a large tumor are extensively studied with whole genome and/or exome sequencing, different parts of the tumor will show different mutational profiles, even though the set of initiating mutations is retained. Mapping these regions analogous to a phylogenetic tree structure, mutations present in all regions of the tumor are called "trunk mutations," heterogeneous mutations present in only some regions of the tumor are called "branch mutations," and mutations that are present only in one region of the tumor are called "private branch mutations." Trunk mutations are acquired early on during carcinogenesis while branch mutations have occurred later. Private branch mutations discovered with high sequencing depth might confer significant growth advantage, resulting in clonal expansion and this will turn them into branch mutations. This concept illustrates ongoing accumulation of somatic genome aberrations due to genome instability, continued background mutagenesis (age-related signature), and genetic drift. Intratumor heterogeneity is manifested in multiple subclones that coexist in different regions of one tumor.

Somatic Genome Changes in Adenocarcinoma

Comprehensive analysis of the genomic landscape of adenocarcinomas identified a very high number and a large variety of somatic gene aberrations, including mutations and/or copy number alterations (76%), as listed in **Table 1**. Some genes are frequently affected, but in most of the listed genes aberrations occur at a frequency $<10\%$. Affected genes are usually abnormally active in one or more cellular signaling pathways. We will discuss gene aberrations in adenocarcinomas, including those affected in AdC as well as in SqCC, according to functional categories. Some genes fit into more than one functional category, and for reasons of simplicity have been put together under the heading "deregulated proliferation."

Deregulated Apoptosis

TP53 is a tumor suppressor gene, implying that both alleles need to be aberrant for the carcinogenic effect. An important physiological function of p53 is detection of DNA damage which affects transcription of downstream targets, leading to growth arrest and apoptosis. When one allele of *TP53* is mutated and the other allele is lost, p53 is inactive which permits continuation of cell growth and cell survival in spite of DNA damage. *TP53* is the most frequently mutated gene in NSCLC, and in addition it is most frequently (92%) associated with mutations of other genes.

Deregulated Receptor Tyrosine Kinases

EGFR (ERBB1) is a transmembrane protein with receptor tyrosin kinase function. EGFR is activated by ligand binding and subsequent dimerization, which activates autophosphorylating capacity of the intracytoplasmic domain. This results in conformational changes of the protein, which activates downstream signaling via RAS (see *KRAS*). In AdC, EGFR mutations in the intracellular domain confer driver oncogene properties to the protein, as it is activated without ligand-binding. This results in oncogenic activities largely similar to those of *KRAS* mutations.

ERBB2, previously called her2/neu, is a member of the EGFR growth factor receptor family. Signaling promotes cell proliferation and opposes apoptosis and requires tight control. In AdC deregulation (mutation, amplification, and overexpression) the tight control is lost and oncogenic effect occurs.

Table 1 Gene aberrations in pulmonary *adenocarcinomas*, with aberration frequency

Gene	Also in SqCC	Aberration	
		M%	Lesion type
TP53	Yes[a]	54	
EGFR		10–50[b]	
KRAS		30–10[b]	
Keap 1		15	
STK11		14	
SMARCA4		9	L
RBM10		6	
RB1	Yes	5	L
ARID1	Yes	7	L
CDKN2A	Yes[a]	4	L
PIK3CA	Yes[a]	5	
NF1	Yes	10	
ALK		2–3	F
ROS1		1	F
BRAF		1–8	
ERBB2		2–4	
MET		1–3	A
ATM		8	
SETD2		5	
FTSJD1		4	
SMAD4		3	L
ARID2		5	L
NTRK1		0,1	F

M%: frequency of gene aberrations, including mutations, small insertions/deletions, and chromosomal rearrangements.
Lesion type other than point mutations: *F*, fusion; *G*, gain; *L*, loss in CNV analysis; *A*, amplification.
[a]Higher frequency in SqCC than in AdC.
[b]In western countries prevalence for *EGFR* 10%–15% and for *KRAS* 25%–30%, while in eastern countries prevalence for *EGFR* is 30%–60% and for *KRAS* 10%.

The *MET* gene (tyrosine-protein kinase Met or hepatocyte growth factor receptor) encodes for the c-MET protein. The c-MET protein plays a role in embryogenesis and is expressed on epithelial cells, but also some mesenchymal cells (endothelial cells, neurons, hematopoietic cells, melanocytes, and neonatal cardiomyocytes). In cancer two changes are relevant: amplification and deletion of exon 14. This exon contains an ubiquitin binding site. Deletion maintains an active c-MET protein with continuous activation of oncogenic pathways (RAS, PI3K, STAT3, b-catenin) and neoangiogenesis.

The *NTRK1-3* genes encode for proteins belonging to the tropomyosin kinase receptor family. The proteins have prosurvival and differentiation functions. Fusions occur at low frequency in several cancer types, and lead to constitutive oncogenic tropomysin kinase activity, also via MAPK pathway.

Deregulated Proliferation

KRAS is a dominant oncogene. When one allele is mutated it translates into a continuously active protein, resulting in persistent downstream signaling of the RAF/MEK/ERK pathway. This stimulates cell proliferation. It also activates the PI3K/AKT pathway, which stimulates cell survival (e.g., protein synthesis, cell motility).

The *RB1* gene codes for the retinoblastoma protein, a transcription repressor inhibiting cell growth. When pRB is phosphorylated it becomes inactive, allowing cell cycle progression. *Rb1* mutations result in an inactive protein, likewise allowing cell cycle progression. *RB1* is mutated at high rates in SCLC, and much lower in squamous cell carcinomas and adenocarcinomas.

CDKN2A gene (cyclin-dependent kinase inhibitor 2A) encodes for two proteins, p16 and p14arf, through an alternative reading frame. Both are cell cycle regulating tumor suppressor proteins; p16 inhibits CDK4 and CDK6 and thereby activates pRb, while p14arf activates the p53 tumor suppressor. Mutations will allow cells to continue to cycle.

PIK3CA encodes the phosphatidylinositol-3-kinase catalytic subunit alpha, that has a role in cell cycle control, differentiation, cytoskeleton reorganization, and intracellular trafficking. In lung cancer activation of the PI3K pathway allows uncontrolled cell proliferation.

The *NF1* gene encodes the protein neurofibromin, a negative regulator of the RAS signal transduction pathway. A germline *NF1* mutation is responsible for neurofibromatosis. The role of somatic *NF1* mutations in lung cancer is not clear; they may be driver mutations, but may also contribute to therapy resistance.

In NSCLC the *ALK* gene is involved in chromosomal translocation, resulting in a fusion gene. There are different fusion partners. The fusion gene is transcribed as fusion protein, containing the kinase domain of *ALK*. The fusion protein results in abnormal ALK signaling, which stimulates cell growth. Wild type ALK protein is normally not expressed in the lung. Screening for ALK aberrations in NSCLC can therefore be performed by immunohistochemical staining for the ALK protein.

The *ROS1* gene is also involved in chromosomal translocation in NSCLC. There are several different fusion partners (*CD74*, *EZR*, *FIG1*, *CCD6C*, *KDELR2*, *LRIG3*, *SDC4*, *SLC34A2*, *TPM3*, and *TPD52L1*). Transcription of the fusion gene usually contains the kinase domain of ROS1. This leads to constitutive activation of MAP kinase ERK, PI3K, mTOR, JAK, and STAT pathways. Like ALK, ROS1 can be detected using immunohistochemistry, but ROS1 staining may be positive in nonmalignant cells (e.g., type II pneumocytes).

BRAF is part of the RAS signal transduction pathway. Mutations result in activation of the MAPK pathway which stimulates cell growth.

SMAD4 (mothers against decapentaplegic homolog 4) also known as DPC4 (deleted in pancreatic cancer-4) is member of the SMAD protein family, that functions as signaling molecules downstream of the TGFβ receptor and so modulate gene transcription. SMAD4 activates the expression of genes that inhibit cell growth. In NSCLC *SMAD4* is inactivated by homozygous deletion or mutation.

Deregulated Oxidative Stress

KEAP1 encodes the Kelch-like ECH-associated protein 1 (KEAP1). KEAP1 interacts with NRF2 in the cytoplasm and has a repressive effect on NRF2. In lung cancer, mutations in *NRF2* and *KEAP1* are mutually exclusive.

STK11 encodes serine/threonine kinase 11, a cytoplasmic protein that functions as upstream kinase of adenosine monophosphate-activated protein kinase. It is involved in cell polarity and a necessary element in cell metabolism, required for maintenance of energy homeostasis, especially in a low energy state. Mutations in *STK11* lead to disorganization of cell polarity and facilitates tumor growth under energetically unfavorable conditions.

Deregulated DNA Repair/Chromatin Modeling

The SWI/SNF family is a multisubunit chromatin remodeling complex, including two mutually exclusive ATPase activities (SMARCA2 and SMARCA4). These reposition nucleosomes, which has an impact on gene expression. Mutations have been found most commonly in the SMARCA4 subunit but also in other subunits, and are thought to confer functional specificity (ARID1A, ARID1B, PBRM1, and ARID2). In NSCLC, loss of SMARCA4 can be demonstrated using immunohistochemistry and this is associated with a high mutation rate.

ATM is a gene encoding a serine/threonine protein kinase, that senses the presence of oxidative DNA damage, including double-strand DNA breaks, and facilitates subsequent repair. Insufficient DNA repair increases genome instability and contributes to cancer progression.

SETD2 protein is a histone methyltransferase, specific for lysine-36 of histone H3. Methylation of this residue prevents inappropriate transcriptional initiation, supports repair of damaged DNA, and regulates pre-mRNA splicing. Mutations of *SETD2*, or mutations at or near lysine-36 of histone H3, are associated with cancer development.

Deregulated Transcription

RBM10 encodes for an RNA binding protein involved in alternative splicing. Somatic alterations in *RBM10* lead to loss of function.

FTSJD1 (also known as *CMTR2*) was recently discovered and encodes an enzyme that methylates the ribose of the second transcribed nucleotide of messenger RNA and small nuclear RNA. In lung cancer frame shift mutations of *FTSJD1* have been found.

Somatic Genome Changes in Squamous Cell Carcinoma

Comprehensive analysis of the genomic landscape of SqCC identified a very high rate and a large variety of somatic gene alterations, both mutations (74%, with a mutation rate per megabase of 3–10 times more than in other cancers) and/or copy number alterations (76%). Consequently, most SqCCs (95%) have potentially targetable molecular alterations and almost two-thirds (>70%) have two or more alterations. This high rate of molecular changes reflects the mutagenic effects of tobacco in this strongly smoking-associated histological subtype. Some of the most significant somatic alterations of lung SqCCs identified in the Cancer Genome Atlas Research Network (TCGA) and in several studies are listed in **Table 2**. The genes carrying aberrations in squamous cell carcinomas only, excluding those that can be mutated in AdC as well as SqCC (which have been discussed earlier), are summarized

Table 2 Gene aberrations in *squamous cell carcinomas* of the lung with aberration frequency

Gene	Also in AdC	Aberration	
		M%	Lesion type
TP53	Yes[a]	51–81	92% co-mutations
MLL2		20	
PIK3CA	Yes[a]	3–16	G (34–43)
CDKN2A	Yes[a]	9–18	L (22–29) Me+(21)
NFE2L2		15	
KEAP1		12	
PTEN		8–10	L (17)
NOTCH1		8	
RB1	Yes	7	
DDR2		4	
FAT1		7	
RASA1		6	
CUL3		5	
PASK		4	
SOX2		21	G (21)
TP63		16	SNP (16)
FGFR1		16–21	G (16–22)
F (3)			
FGFR2		2–3	F (3)
FGFR3		2–3	F (3)
EGFR		7–14	G (7–14)
PDGFRA/KIT		8	G (8)
CCND1		14	G (14)
MET	Yes	3–21	G (3–21)
NF1	Yes	8	
ARID1A	Yes	5	
NOTCH1		5	

M% = frequency of gene aberrations, including point mutations, small insertions/deletions, chromosomal rearrangements.
Lesion type if not (only) point mutations (frequency in % of other lesion types) *F*, fusion; *G*, gain; *L*, loss in CNV analysis; *SNP*, single nucleotide polymorphism; *Me+*, gene silencing due to promoter hypermethylation.
[a]Higher frequency in SqCC than in AdC.

according to functional categories. Genes that fit into more than one functional category have been combined where appropriate under "deregulated proliferation."

Deregulated Receptor Tyrosine Kinases

FGFR 1-3 are proto-oncogenes and encode fibroblast growth factor receptor proteins, that belong to the fibroblast growth factor receptor family. FGFR proteins are involved in several signaling pathways including phospholipase C/PI3K/AKT, Ras subfamily/ERK, protein kinase C, and STAT. FGFR alterations as a rule are gain-of-function changes (amplification/fusion), but the exact mechanism is not always clear.

PDGFRa gene encodes platelet-derived growth factor receptor, a cell surface tyrosine kinase receptor. PDGFR proteins are involved in several signaling pathways including phospholipase C/PI3K/AKT, Ras subfamily/ERK, protein kinase C, and STAT3. Alterations of *PDGFR* in cancer include amplification, mutations, and rearrangements making the receptor constitutively active, and alternative *PDGFR* splicing.

NOTCH1 Notch homolog 1, translocation-associated (Drosophila), also known as NOTCH1, is a human gene encoding a single-pass transmembrane receptor, that belongs to the NOTCH family. In lung embryogenesis NOTCH1 is expressed in pluripotent progenitor cells in human bronchial epithelium. NOTCH1 suppresses multiple pathways, and when functionally disturbed it impacts on cancer-associated processes including proliferation, cell survival, epithelial–mesenchymal transition, metastasis, and angiogenesis.

PASK encodes the PAS domain-containing serine/threonine-protein kinase, which is involved in nutrient signaling. *PASK* mutations have recently been reported in lung cancer. The downstream oncogenic mechanism is unclear.

DDR2 discoidin domain-containing receptor 2 (also known as CD167b) encodes a receptor tyrosine kinase. Mutations are oncogenic, but the downstream mechanism is unclear.

Deregulated Proliferation

The *CCND1* gene encodes the cyclin D1 protein that belongs to the cyclin family, which show periodicity in protein abundance during the cell cycle. Cyclin D1 is required for progression through the G1 phase of the cell cycle. Constitutive overexpression of cyclin D1 leads to increased growth.

NFE2L2 (nuclear factor erythroid-derived 2-like 2, also known as Nrf2), encodes a basic leucine zipper (bZIP) protein. This transcription factor regulates the expression of antioxidant proteins that protect against oxidative damage triggered by injury and inflammation. Aberrant activation of the NRF2 signaling pathway has an oncogenic effect, because of crucial functions in cell survival and proliferation.

PTEN is a tumor suppressor gene which encodes phosphatase and tensin homolog protein, and functions as tumor suppressor through negative regulation of the Akt/PKB signaling pathway. Its inactivation in cancer leads to increased cell proliferation and reduced cell death.

RASA1 encodes p21 protein activator 1 or RasGAP (Ras GTPase activating protein), which is part of the GAP1 family of GTPase-activating proteins. RASA1 is located in the cytoplasm and stimulates GTPase activity of normal RAS p21, acting as suppressor of RAS function, thereby allowing control of cellular proliferation and differentiation.

FAT1 a tumor suppressor gene encoding a protein that is a member of the cadherin superfamily. FAT1 is expressed in fetal epithelium and has a supporting role in controlling cell proliferation.

Deregulated Oxidative Stress

CUL3 is a tumor suppressor gene encoding a core scaffolding protein in an E3 ubiquitin ligase complex that includes KEAP1 and RBX1, which plays a role in the oxidative stress response pathway. Loss of *PTEN* and *CUL3* synergize to activate NFE2L2 signaling. The oncogenic mechanism is unclear, possibly decreased production of superoxide might be protective for tumor cells.

Deregulated Migration

P63 encodes the transformation-related protein 63, that is part of the p53 gene family. P63 is expressed in the basal layer of most stratified epithelia and plays a role in epithelial development and differentiation. Even though p63 expression is used in the diagnostic process of NSCLC to make a diagnosis of SqCC, strictly speaking p63 is not a marker of squamous differentiation. *TP63* is frequently amplified and overexpressed of in a variety of epithelial cancers, which has led to the assumption that this protein behaves as an oncogene. Reduction of p63 expression levels has been associated with epithelial mesenchymal transition and metastasis.

SOX2 encodes a protein (sex determining region Y-box 2, SRY), that is a member of the Sox family of transcription factors. SOX2 is essential for maintaining self-renewal, or pluripotency, of undifferentiated embryonic stem cells. SOX2 is frequently amplified in SqCC and its overexpression activates cellular migration and anchorage-independent growth.

Deregulated DNA Repair/Chromatin Modeling/Transcription

MLL2 is a tumor suppressor gene encoding histone H3 lysine 4 (H3K4) mono-methyltransferase, that colocalizes with lineage determining transcription factors on transcriptional enhancers and is essential for cell differentiation and embryonic development. Mutations occur in several cancer types. The oncogenic mechanism is not clear. One possibility is that in situations of transcriptional stress RNA polymerase II malfunctions (pausing, stalling, and backtracking), resulting in abnormalities in early replicating fragile sites within the chromosome. In NSCLC, most genes are affected in $< 10\%$ of the cases except for *TP53*, which is frequently mutated in NSCLC. Development of malignancy does not require aberrations in all of these genes. Genes such as *TP63*, *SOX2*, and *PIK3CA* reside in the same chromosomal region (chromosomal region 3q) and co-amplification of these three genes with *FGFR1* amplification (chromosomal region 8p12), may lead to cross-activation.

Predictive Biomarkers in Nonsmall Cell Lung Carcinoma

Once the diagnostic process has been completed, predictive testing is a second equally important step that needs to be performed in patients with advanced lung cancer. The outcome of predictive testing is essential for the choice of drug treatment. This may also include information on xenobiotic metabolism, which influences drug dosage. For practical purposes this article will only discuss NSCLC testing for the choice of drug. Predictive testing does not only assess acquired genetic changes (**Table 3**), but also includes expression of specific proteins. The prevalence of aberrations in many of the relevant genes is low and therefore many tests (10 to almost 100) need to be performed to have even a single positive result, directing the choice for a patient toward a specific drug. This makes predictive testing rather expensive.

Most genome alterations occur in nonsmokers. Rearrangements of *EGFR*, *ALK*, and *ROS1* are predominantly found in young patients. *ALK* and *ROS1* alterations occur in adenocarcinomas with a solid or cribriform growth pattern and/or the presence of signet ring cells. *KRAS* mutations are most frequent (they occur in nearly 30% of NSCLC), predominantly in smokers, but they

Table 3 Genes examined for predictive testing in NSCLC

Gene	*Histology*	*Alteration*	*Frequency (%)*	*Method(s)*
EGFR	Adenocarcinoma	Mutation	10–60	Sanger sequencing/NGS
ALK	Adenocarcinoma	Rearrangement	2–5	IHC, FISH, NGS
ROS1	Adenocarcinoma	Rearrangement	1	IHC, FISH, NGS
BRAF	Adenocarcinoma	Mutation	1–3	Sanger sequencing/NGS
ERBB2	Adenocarcinoma	Mutation	2–4	Sanger sequencing/NGS
MET	Adenocarcinoma	Amplification	1–3	ISH
MET	Adenocarcinoma	Mutation	1–3	Sanger sequencing/NGS
PD-L1	NSCLC	Expression	20–30	IHC

IHC, immunohistochemistry; *FISH*, in situ hybridization; *NGS*, next generation sequencing.

are not (yet) targetable. An important role of the pathologist is to characterize the tumor and choose the tumor sample for testing. This includes testing for responsiveness to immune checkpoint inhibitors. As in about 80% of NSCLC patients only small cell/tissue samples are available (small biopsies or cytology specimens), the pathologist needs to make most efficient use of the tumor specimens and prioritize the analyses. The pathologist will select tissue for DNA extraction to be used for next-generation-sequencing (NGS), will assess chromosomal rearrangements using fluorescence in situ hybridization (FISH) and will also assess PD-L1 expression, to select patients for treatment with PD1/PD-L1 inhibitors.

NSCLC tissues are heterogeneous and composed of a mix of nonneoplastic stromal cells (immune cells, fibroblasts, endothelial cells) and neoplastic cells. This implies that tumor DNA is "diluted" with nontumor DNA from the stromal compartment. Any molecular test needs to be sufficiently sensitive (analytical sensitivity) to detect a mutation: when a molecular test can detect a minimum of 10% of mutated DNA, assuming that the mutation is heterozygous this will require the presence of 20% of malignant cells in the sample. When the fraction of neoplastic cells is lower, macro- or microdissection can be used to arrive at a higher fraction of tumor DNA. Morphological assessment of the percentage tumorcells in a sample, on H&E stained sections on both sides of the series of sections used for DNA extraction, is mandatory for reliable results.

For most PCR-based NGS techniques, a minimum of 5–10 ng of total DNA (including DNA from neoplastic and nonneoplastic cells) is required, which is equal to approximately 1000 cells in formalin-fixed and paraffin-embedded tissue material. Hybrid capture-based NGS technologies, necessary for RNA sequencing, require 100–200 ng of RNA or DNA, which may not be attainable in up to one third of small biopsy samples.

EGFR

The first responses to EGFR tyrosin kinase inhibitors in NSCLC were observed in metastatic patients who no longer responded to conventional treatment. Sequencing of the *EGFR* gene in these tumors led to the discovery that the gene sequence coding for the intracytoplasmic domain of EGFR contained activating mutations in exons 18–21, notably 15–18 base pair deletions in exon 19 and point mutations in exon 21 (p. L858R). Progression free survival improved, compared to standard chemotherapy, which resulted in approval of gefitinib, erlotinib, and afatinib for first-line treatment of *EGFR*-mutated advanced NSCLC. However, after a few months to a few years progression occurred, indicating resistance to treatment. Second and third generation EGFR inhibitors have been developed (such as osimertinib, designed against a resistance mutation T790M).

ALK Rearrangement

Anaplastic lymphoma kinase (*ALK*) gene rearrangements in NSCLC result in expression of ALK fusion-proteins with strong oncogenic properties. Screening for ALK rearrangement can be done by immunohistochemistry, which requires limited equipment and is available in pathology laboratories worldwide. The method allows detection of the presence of the fusion protein even in a small number of tumor cells. Interpretation of ALK stained sections is quite straight forward, as ALK protein is not expressed in normal epithelial lung tissue. Other nonneoplastic cells will stain, such as light dot-like cytoplasmic staining in alveolar macrophages, nerve and ganglion cells, epithelial cells of bronchial glands, extracellular mucin, and necrotic tumor areas. In case of doubt, Fish can be used to confirm a rearrangement. ALK positive NSCLC is treated with ALK-inhibitors crizotinib and ceritinib and the results are superior to those of standard chemotherapy. Recently, alectinib has been shown to be superior to crizotinib.

ROS1 Rearrangement

Rearrangements of the *ROS1* gene have been discovered recently and can be found in 1%–2% of lung cancer patients. Treatment with Crizotinib has been approved for *ROS1* rearranged NSCLC patients. Data on the predictive value of immunohistochemical staining for ROS1 are still evolving. *ROS1* rearranged tumors invariably show diffuse cytoplasmic staining, varying significantly in intensity. At low staining intensity a *ROS1* rearrangement might not be found by FISH as more cases stain positive by immunohistochemistry than are amplified by FISH. An additional issue is expression of ROS1 in normal reactive pneumocytes and

macrophages. Current guidelines suggests screening for ROS1 by immunohistochemistry and subsequent confirmation of immunohistochemically positive cases by FISH or any molecular method.

PD-L1

PD-L1 expression on tumors cell is one of the mechanisms of immune evasion, since this inhibits functional activity of cytotoxic lymphocytes which will then not attack tumor cells. For NSCLC, PD-L1 expression by immunohistochemistry is the first predictive biomarker for checkpoint blocking immunotherapy. Interpretation of PD-L1 immunohistochemistry requires familiarity with expression patterns, since PD-L1 is expressed on dendritic cells, macrophages, mast cells, T and B lymphocytes, endothelial and tumor cells. Currently, there are no universally accepted test protocols. Results may be different depending on the used antibody, thresholds for calling a test positive have not been universally validated and to what extent immunostaining of immune cells rather than tumor cells needs to be taken into consideration has not been clarified. This is exemplified by the observation that of patients with negative PD-L1 staining by immunohistochemistry who received anti-PD-1/PD-L1 treatment, as many as 9% will still have a clinical response. This may be due to heterogeneity in PD-L1 expression, with some subclones completely negative while others strongly positive. A form of sampling bias may also be involved: PD-L1 immunostaining will as a rule be performed on the sample on which the initial diagnosis was made. Chemotherapy may have affected PD-L1 expression, which might be resolved by taking a biopsy of the recurrent tumor. This is, however, not always feasible.

Other Emerging Biomarkers

New targeted therapies gave encouraging results in early phase clinical trials for NSCLC patients with *BRAF*, *HER2*, or exon 14 *MET* mutations, and *RET* or *NTRK* rearrangements.

Development of Resistance

Although treatment targeting EGFR, ALK, and ROS1 has proven a major step forward in lung cancer management, in most patients at some point in time a relapse occurs. Biopsy of the recurrent lesion, especially after tyrosine kinase inhibitors targeting EGFR, has provided insight into resistance mechanisms. Apparently, under the selection pressure of targeted therapy, drug sensitive tumor cells undergo apoptosis or at least become quiescent, while other tumor cells survive and continue to proliferate. The mechanisms determining resistance are not yet fully understood but three mechanisms have been proposed. Firstly, the target gene of the inhibitor may acquire an additional mutation, which reduces the binding affinity of the drug to the target, or may be amplified. After treatment with EGFR tyrosine kinase inhibitors (gefitinib, erlotinib, and afatinib), the most frequent resistance mechanism is a second mutation in exon 20 (p. T790M, occurring in $\sim$50% of secondary resistant cases). This mutation changes protein conformation at the ATP binding site, which is also the EGFR TKI binding site, resulting in constitutive activation. Remarkably, the proportion of tumor DNA carrying T790M is usually lower than that of the initial driver mutation. When the fraction of tumor cells is close to the detection threshold and the initial driver mutation was barely detectable, in such a situation it may be difficult to exclude a T790M. The relevance of rebiopsy after a recurrence is underscored by the development of a drug (osimertinib) specifically against EGFR with the T790M mutation. Rebiopsy should be included as standard of care in a setting of targeted therapy.

Secondly, activation of alternative pathways such as mutation or amplification of *ERBB2* or *MET* may bypass the originally targeted pathway.

Thirdly, histological transformation, for example, of NSCLC to small cell lung cancer or epithelial mesenchymal transition may develop (**Fig. 2**).

As ALK targeting treatment is more recent, less is known about the mechanism(s) involved in the development of secondary ALK resistance. Treatment with the first generation ALK inhibitor crizotinib has resulted in secondary resistance and in about 30% of the cases a second acquired mutation or occasional amplification have been found (**Fig. 3**). Even against second generation ALK inhibitors resistance develops and in such cases in 45% additional ALK resistance mutations have been reported.

Further elucidation of mechanisms involved in development of resistance is important. To this end it is important to obtain tissue samples at the time of disease progression. Liquid biopsies and ever more sensitive sequencing methods will help to better document mechanisms of resistance to targeted therapies in lung adenocarcinoma.

Prospective Vision

Molecular analysis of a tumor tissue sample has traditionally been highly informative but to obtain a tissue sample usually requires an invasive procedure. A less invasive method is taking a blood sample (what is now customarily called a liquid biopsy) as in the circulation tumor cells but also free circulating DNA and RNA are present. Analysis of a blood sample is rapid, precise, easy to interpret and might provide information relevant for therapeutic management of the patient. The quantity of circulating free DNA is low, which currently limits extensive testing and the liquid biopsy momentarily is used to obtain information on specific molecular events such as EGFR T790M mutation, which when found has direct impact on therapy choice. Isolation of circulating tumor cells requires sophisticated equipment and low numbers of circulating cells render clinical application less informative. It remains to be seen which position the liquid biopsy will ultimately will take in the molecular analysis toolbox.

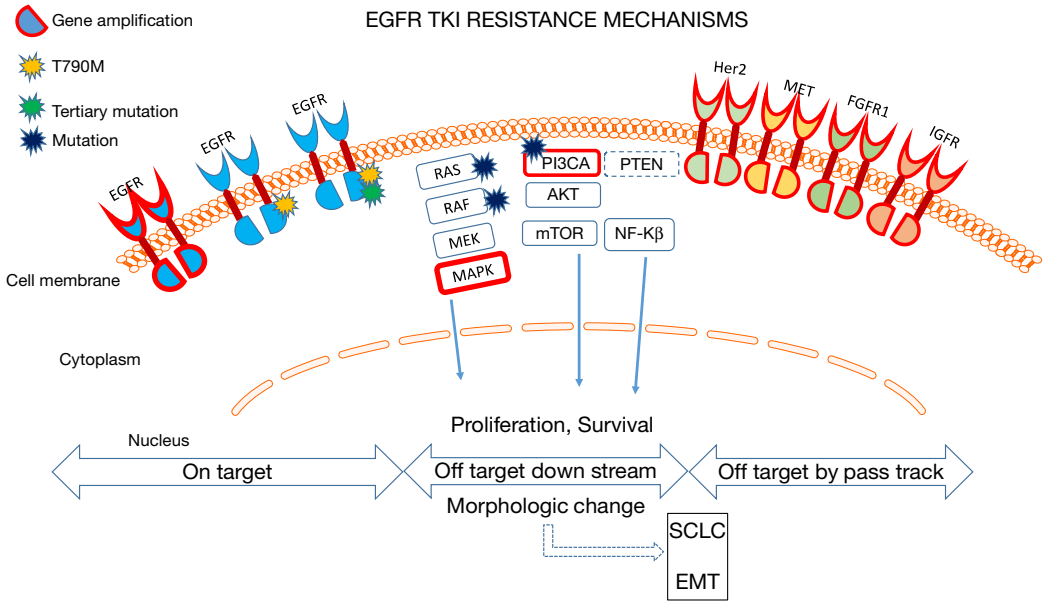

Fig. 2 EGFR resistance.

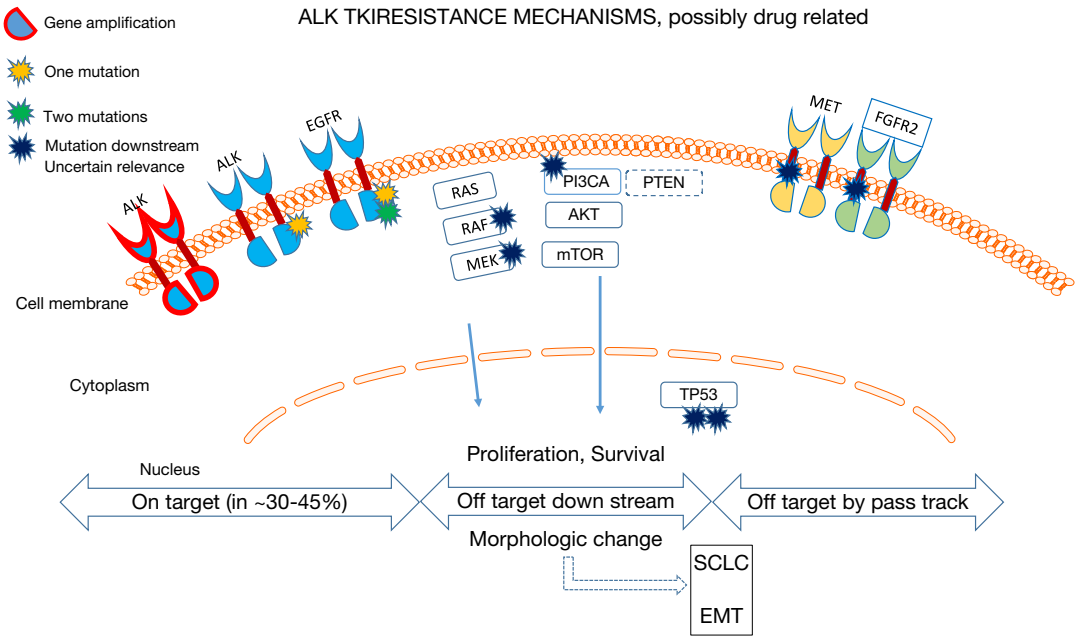

Fig. 3 ALK resistance.

In an immunotherapeutic perspective, testing for expression of PD-L1 is gradually entering into clinical practice. Although this immunohistochemical test currently provides the best information, it is likely that more discriminative testing modalities will be developed. As the mutation rate in NSCLC is high, many neo-antigens will be generated driving an antitumor immune response. A surrogate marker for response to PD-L1 blocking therapy may be the tumor mutational burden, which can also be determined on a liquid biopsy. It is likely that more markers will emerge to provide a more comprehensive and specific appreciation of the antitumor immune status of individual patients, to be used in decisions on modalities of immunotherapy.

In the future, pathologists will be required to provide detailed three dimensional assessment of tumor morphology and the host response to the tumor but also information on the mutation status of the tumor tissue, allowing clinicians to target molecular aberrations with high specificity as well as choosing immunotherapeutic modalities with the highest likelihood of response.

Obesity and Cancer: Epidemiological Evidence

Yikyung Park, Washington University School of Medicine, St. Louis, MO, United States

Glossary

Abdominal obesity Also known as central obesity, is the status that excessive body fat is accumulated around the stomach and abdomen. Waist circumference is commonly used as an indirect measurement of abdominal obesity.

Body mass index (BMI) Defined as body weight in kilograms divided by the square of height in meters (kg/m^2). For adult over 20 years old, normal or healthy weight is defined as BMI 18.5–24.9, overweight is BMI 25–29.9, and obesity is BMI $\geq$ 30. The obesity category is further classified as class I (BMI 30–34.9), class II (BMI 35–39.9), and class III (BMI $\geq$ 40) obesity.

Obesity Status of abnormal or excessive fat accumulation that may impair health.

Obesity Definition and Measurements

Body Mass Index

Obesity is defined as excessive fat accumulated in the body. A most commonly used tool to assess obesity is the body mass index (BMI), a simple index of weight-for-height. It is defined as a body weight in kilograms divided by the square of height in meters (kg/m^2). In 1832, Adolphe Quetelet (1796–1874), a Belgian astronomer, mathematician, and statistician, found that normal body weight in kilograms was proportional to the square of the height in meters in adults. In 1972, Ancel Keys found that the Quetelet index (kg/m^2) was strongly correlated with body adiposity measured by skinfold thickness and body density measurements in men in Europe, United States, South Africa, and Japan. Later studies also found that BMI was strongly correlated with more direct measures of body fat obtained from bioelectrical impedance, densitometry (underwater weighing), dual energy X-ray absorptiometry, computed tomography, or magnetic resonance imaging.

Since Keys renamed the Quetelet index to the BMI, BMI has been the most practical, inexpensive, and easy-to-measure method to screen for weight category. For adult over 20 years old, weight categories recommended by the World Health Organization (WHO) are underweight (BMI $<$ 18.5), normal or healthy weight (BMI 18.5–24.9), overweight (BMI 25–29.9), and obesity (BMI $\geq$ 30). The obesity category is further classified as class I (BMI 30–34.9), class II (BMI 35–39.9) and class III (BMI $\geq$ 40) obesity. Studies found that for the same BMI, percent of body fat differs by sex, age, and race/ethnicity. It has been debated whether the cut-off points for overweight and obesity are lower for Asian populations. For reporting purposes to facilitating international comparisons, it is recommended to use the additional cut-off points of 23, 27.5, 32.5, and 37.5 kg/m^2.

For children and adolescents, overweight and obese are based on age- and sex-specific growth standard. WHO definition for overweight and obesity in children under 5 years of age is weight-for-height greater than 2 and 3 standard deviations, respectively, above WHO Child Growth Standards median. For children aged between 5 and 19 years, overweight is BMI-for-age greater than 1 standard deviation above the WHO Growth Reference median, and obesity is greater than 2 standard deviations above the WHO Growth Reference median.

BMI has been widely used to examine the relationship between body fatness and diseases, including cancer, in numerous epidemiologic studies. Because people tend to over-report their height whereas underreport their body weight, BMI calculated from self-reported height and weight in observational studies may be lower than their actual BMI. However, the difference between self-reported BMI and measured BMI was negligible and did not introduce substantial bias in epidemiologic evaluation of body fatness and cancer association in large epidemiologic studies.

Waist Circumference

Waist circumference is also widely used as an indirect measurement of body fatness, particularly for central or abdominal obesity. Waist circumference is typically at the natural waist, just above hipbones. However, some studies measured at umbilicus or naval. People tended to underreport their waist circumference, in part, due to difficulties in measuring circumference around the waist. Waist circumference is positively correlated with visceral adipose tissue that is more metabolically active than subcutaneous fat. A consensus on the cut-off points for high risk for metabolic complications (e.g., diabetes, hypertension, cardiovascular diseases) is $>$102 cm in men and $>$88 cm in women. However, lower cut-off points have been proposed for Asians.

Imaging-Based Methods

There are several imaging methods that assess body fatness more accurately than BMI. Bioelectrical impedance analysis (BIA) measures body fatness as well as lean mass by assessing the impedance or resistance to a small electric current passed across body tissues. The greater the fatty tissue, the greater the resistance to the current. However, the bioelectrical impedance analysis

 https://doi.org/10.1016/B978-0-12-801238-3.65037-7

depends on individual's hydration status. The dual-energy X-ray absorptiometry (DXA) measures bone mineral density as well as fat and fat-free mass. Magnetic resonance imaging (MRI) and computed tomography (CT) can assess total body fat as well as visceral and subcutaneous adipose tissue, separately. However, these imaging-based methods are expensive and not readily available in clinics and studies. Also, there is no standardized visceral adipose tissue assessment method used across studies.

Prevalence of Obesity

The global prevalence of obesity tripled between 1975 and 2016 and increased in all age groups and every country. Age-standardized prevalence of obesity (BMI $\geq$ 30) increased from 3.2% in 1975 to 10.8% in 2014 in adult men, and from 6.4% to 14.9% in adult women. Overweight and obesity has increased not only high-income countries but also in low- and middle-income countries, particularly in urban areas. In 2016, 671 million adults were obese, and 1.3 billion adults were overweight while 125 million and 213 million children and adolescents aged 5–19 years were obese and overweight, respectively. If this trend continues, child and adolescent obesity is expected to surpass underweight by 2022, and one out of five adults in the world will be obese by 2025.

Obesity and Cancer

In 2016, the International Agency for Research on Cancer (IARC)WHO convened a Working Group to review extensive evidence on the effect of obesity on cancer risk. The Working Group reviewed more than 1000 epidemiologic studies and also experimental studies and concluded that excess body fatness causes cancer of the esophagus (adenocarcinoma), gastric cardia, liver, gallbladder, pancreas, colon and rectum, kidney, thyroid, breast (postmenopausal), endometrium, and ovary as well as meningioma and multiple myeloma.

Another independent group of investigators also conducted an umbrella review of 95 meta-analyses that reported the association between body fatness and cancer in cohort studies. After a rigorous evaluation for strength and validity of reported associations in meta-analyses, the umbrella review also made similar conclusions that current evidence supports the positive association of obesity with esophageal adenocarcinoma, multiple myeloma and cancers of gastric cardia, biliary tract system, pancreas, colon, rectum, kidney, ovarian, endometrium (premenopausal women), and breast (postmenopausal) cancer.

Similarly, recent reports from the World Cancer Research Fund that evaluate and summarize a body of evidence on obesity in relation to cancer concluded that obesity increased the risk of esophageal adenocarcinoma, gastric cardia, colorectal, gallbladder, pancreas, liver, kidney, thyroid, endometrial, postmenopausal breast, and ovarian cancer and multiple myeloma.

Head and Neck Cancer

Head and neck cancer includes cancers in oral cavity, pharynx, and larynx. Earlier case-control studies suggested that obesity was inversely related to the risk of head and neck cancer, particularly among smokers and alcohol drinkers. However, case-control studies have significant methodological limitations such as selection bias and reverse causality, which may lead to an inverse association between obesity and risk of head and neck cancer. Healthier patients were more likely to participate in a case-control study, and obese patients may already have significant weight loss before cancer diagnosis, thus have lower BMI at the study entry and misclassified as having normal weight. Also, given that smoking is a strong risk factor for head and neck cancer, and smokers tended to have lower BMI than nonsmokers, the inverse association observed in smokers suggested residual confounding (i.e., incomplete adjustment) by smoking.

Later, a large pooled analysis of 20 prospective cohort studies found that obesity was associated with modestly increased risk of head and neck cancer in never smokers. Every five unit increase in BMI was associated with 15% increased risk of head and neck cancer in never smokers. There was no association between BMI and head and neck cancer in former or current smokers. In addition, abdominal obesity assessed by waist circumference was related to a higher risk of head and neck cancer in never and former smokers.

Esophageal Cancer

Esophageal cancer is the six leading cause of cancer death in the world. The most common types of esophageal cancer are squamous cell carcinoma that arises from the epithelial cells lining of the esophagus and adenocarcinoma that arises from glandular cells in the lower third of the esophagus. There is strong evidence that obesity increases the risk of esophageal adenocarcinoma, but not squamous cell carcinoma. Obese individuals had two to threefold increased risk of esophageal adenocarcinoma compared with normal weight individuals. It is hypothesized that obesity increases intragastric pressure, which subsequently relaxes the lower esophageal sphincter, exposing the lower esophagus to gastric acid and increasing the risk of gastro-esophageal reflux disease. Thus, the effect of obesity on esophageal cancer is mediated by gastro-esophageal reflux disease. However, a positive association between obesity and esophageal cancer was found in people with a history of gastro-esophageal reflux disease as well as those without the disease, suggesting an independent effect of obesity on esophageal cancer.

In addition, waist circumference and waist-to-hip ratio are related to a significantly increased risk of esophageal cancer. Every 10 cm increase in waist circumference is related to approximately 80% increased the risk of esophageal adenocarcinoma. Increase in waist-to-hip ratio (per 0.1 unit) was associated with a twofold increase in esophageal adenocarcinoma risk.

Stomach Cancer

Stomach (gastric) cancer is the third leading cause of cancer death in the world and more common in eastern and central Europe, Asia, and central and South America. The effect of obesity on gastric cancer differs by subtypes defined by the tumor location—cardia and noncardia. The cardia region is the top of the stomach, close to the esophagus, and the noncardia region is the main area of the stomach. Noncardia stomach cancer is associated with *Helicobacter pylori* infection. A body of evidence supports that obesity increases the risk of stomach cancer in cardia and is not related to the risk of stomach cancer in noncardia. Obesity is related to about 1.5- to 2-fold increase in the risk of cardia stomach cancer. The positive association between obesity and cardia gastric cancer was consistently found in studies conducted in Asia, Europe, and North America.

Interestingly, emerging evidence suggests that adolescent obesity is associated with an increased risk of noncardia stomach cancer in mid-life. Compared with people with normal weight at age 16–19 years, people who were obese at age 16–19 years had 1.8 times higher risk of noncardia stomach cancer in later adulthood in a cohort of over 1.7 million Israeli men and women who underwent health examinations at the age of 16–19 between 1967 and 2002.

Colorectal Cancer

An extensive body of literature showed that body fatness was associated with increased risk of colorectal cancer in both men and women. There is a clear dose–response relationship between BMI and colorectal cancer. Compared with normal weight individuals, overweight individuals had 10%–15% increased risk of colorectal cancer, and obese individuals had approximately 30% increased risk of colorectal cancer. The association between obesity and colorectal cancer is stronger in men than in women. The positive association with obesity was found in all subtypes by tumor locations—proximal and distal colon and rectal cancer.

Abdominal (central) obesity measured by waist circumference is also related to significantly increased risk of colorectal cancer. Every 10 cm increase in waist circumference is related to approximately 6%–15% increased risk of colon cancer and 2%–6% increased risk of rectal cancer. Weight gain during adulthood is also associated with higher risk of colorectal cancer. Five kilograms increased in weight gain during adulthood was related to a 6% increased risk of colon cancer. Accumulating evidence also indicates that being overweight or obese at adolescence and young adulthood are associated with an increased risk of colorectal cancer in later life.

Liver Cancer

Liver cancer is the second leading cause of cancer deaths and the fifth most common cancer in men and the ninth in women in the world. Hepatitis B or C virus infection and heavy alcohol use are well-known risk factors for liver cancer. Causes of liver cancer differ among populations and geographical locations. However, convincing evidence exists for the harmful effect of obesity on liver cancer in all populations and geographic regions, including Asia, Europe, and America. In general, obesity almost doubles the risk of liver cancer. Compared with normal weight individuals, obese individuals have 1.5- to 2-fold increased risk of liver cancer. The positive association between obesity and liver cancer is stronger in men than in women. A recent large pooled analysis of 14 US based prospective cohort studies found the positive association between obesity and liver cancer in people with sera-negative for hepatitis, but not in people with sera-positive for hepatitis, suggesting the role of obesity in liver cancer may differ by viral hepatitis infection status.

Waist circumference, marker of central obesity, was also related to a higher risk of liver cancer. A recent study examining BMI measured at age 17–19 years in Swedish men in 1969–96 found that the late adolescence BMI was related to the risk of liver cancer in later life. Compared with normal weight (BMI 15.5–22.5), overweight and obesity in late adolescence were associated with 1.5- and 3.5-fold, respectively, increased risk of liver cancer in later adulthood.

Gallbladder Cancer

Although gallbladder cancer is rare, it is the most common tumor among biliary tract cancers. Earlier studies, although small, suggested that body fatness was associated with increased risk of gallbladder cancer. Recently, a large pooled analysis of prospective cohort studies found a clear link between obesity and gallbladder cancer. Compared with normal weight, overweight and obesity were related to 27% and 64%, respectively, increased risk of gallbladder cancer.

Central obesity measured by waist circumference was also positively associated with risk of gallbladder cancer. Every 5 cm increase in waist circumference was related to 9% increased risk of gallbladder cancer. Obesity at adolescence or young adulthood (18–21 years) was also associated with higher gallbladder cancer risk in later life.

Pancreatic Cancer

The increased risk of pancreatic cancer in obese men and women is well established. Obese individuals are more likely to be diagnosed with pancreatic cancer at younger age. There is a clear dose–response relationship between BMI and the risk of pancreatic cancer. Compared with normal weight people, obese people had 1.5–2 times higher risk of pancreatic cancer. Also, abdominal (central) obesity is associated with an increased risk of pancreatic cancer. Every 10 cm increase in waist circumference was related to approximately 23% increased risk of pancreatic cancer.

The link between obesity and pancreatic cancer was also confirmed in a study using the Mendelian randomization approach that eliminated confounding by diabetes and other metabolic risk factors. When obesity-associated single-nucleotide polymorphisms (SNPs) found in the large genome-wide association studies were used as an unconfounded marker of obesity (i.e., genetic instrument for BMI), the risk of pancreatic cancer increased by 34% per 4.6-unit increase in BMI.

Studies also have found that obesity in late adolescence and young adulthood was associated with increased risk of pancreatic cancer in late life. Every five unit increase in young adulthood BMI was associated with 18% increased risk of pancreatic cancer in later life.

Lung Cancer

The role of obesity in lung cancer is inconsistent. Many studies reported that higher BMI was associated with lower risk of lung cancer. However, the inverse association between BMI and lung cancer was likely due to residual confounding (i.e., incomplete adjustment) by smoking in the analysis. Smokers who are at high risk for developing lung cancer tend to have lower BMI than nonsmokers of the same age and sex. Therefore, obesity may appear to be protective against lung cancer. When the obesity and lung cancer relation was examined in smokers and nonsmokers, separately, obesity was not associated with lung cancer in nonsmokers but was related to a lower risk of lung cancer in smokers. A Mendelian randomization study of obesity and lung cancer using a genetic score for BMI as instrumental variable to eliminate reverse causation and reduce confounding found that the genetic risk score for obesity was associated with increased risk of lung cancer.

In addition, waist circumference—a proxy for abdominal obesity—was positively associated with lung cancer. Each 10 cm increase in waist circumference was associated with a 10% increased risk of lung cancer in both smokers and nonsmokers. Indeed, a genetic risk score for obesity in the GAME-ON consortium was positively associated with lung cancer, suggesting that the observed inverse associations with BMI may be noncausal.

Melanoma and Nonmelanoma Skin Cancer

The association between obesity and melanoma is less clear. Some studies found that obesity was related to an increased risk of melanoma, particularly in men, but not in women, while others found no association between obesity and melanoma. Sun exposure and skin type are important risk factors for melanoma, but most studies did not adjust for these factors, raising concern about residual confounding (i.e., incomplete adjustment) in the analyses. It has been suggested that obese people tended to spend less time outdoors and avoid sunbathing compared with normal weight people. Studies that adjusted for sunlight exposure observed a positive association between obesity and risk of melanoma in women.

In contrast, although limited, studies suggested that obesity was related to a lower risk of nonmelanoma skin cancer, including squamous cell carcinoma and basal cell carcinoma, even after controlling for sun exposure or UV radiation susceptibility. More studies with measures of sun exposure or sun-seeking behaviors are needed to investigate the role of obesity in melanoma and nonmelanoma skin cancer.

Breast Cancer

Obesity is an established risk factor for postmenopausal breast cancer in women. Five unit increase in BMI increases risk of postmenopausal breast cancer by approximately 15%. The effect of obesity on breast cancer is stronger in postmenopausal women who never used the exogenous hormones (i.e., hormone replacement therapy) than those who used. The effect of obesity on breast cancer also differs by tumor hormone receptor status (i.e., estrogen and progesterone receptor). Obesity is associated with 1.5- to 2-fold increased risk of both estrogen and progesterone receptors positive breast cancer, but not with both estrogen and progesterone receptors negative breast cancer. Weight gain during adulthood or after menopause also increased risk of postmenopausal breast cancer, especially among women who never used hormone replacement therapy.

On the other hand, obesity is related to a lower risk of premenopausal breast cancer. The inverse association with premenopausal breast cancer seems to be restricted to estrogen receptor-positive breast cancer. Triple-negative breast cancer that lacks expression of estrogen and progesterone receptors and human epidermal growth factor receptor 2 (HER2) tended to be diagnosed at younger age and have aggressive disease course. Several studies have shown that higher BMI and greater waist circumference are associated with a two to three times increased risk of triple-negative breast cancer among premenopausal women.

Interestingly, accumulating evidence suggests that obesity is related to an increased risk of breast cancer in men as well. Studies found that obesity was associated with approximately 30% higher risk of breast cancer in men. Also, obesity during adolescence or early adulthood was related to an increased risk of breast cancer in men.

Cervical Cancer

Cervical cancer is the fourth most common cancer in women in the world and is caused by persistent infection of human Papilloma Viruses (HPV). However, the majority of women with HPV do not develop cervical cancer, and other environmental factors are required for cancer to develop. Cervical cancer screening is effective in detecting precancerous lesions that can be treated and cured before they develop into cancer. The association between obesity and cervical cancer is not clear. Some studies found a weak but significantly positive association between obesity and cervical cancer while others found no association. Most of these studies did not have cervical cancer screening information that may have confounded the association.

Recently, a large retrospective cohort study of over 900,000 women who underwent cervical cancer screening (i.e., cytology and human papillomavirus DNA testing) found that overweight and obese women had an increased risk of cervical cancer. The positive association between obesity and cervical cancer was consistently found in HPV positive women as well as in HPV negative women. Obesity was also related to an increased risk of both subtypes—glandular and squamous. However, the study found that the increased risk of cervical cancer in obese women was likely due to low efficacy of cervical cancer screening in obese women, resulting in underdiagnosis of precancerous lesions, thus increased risk for cervical cancer.

Endometrial Cancer

Obesity is a well-established risk factor for endometrial cancer. There is a clear dose-response relationship between BMI and endometrial cancer. Every five unit increase in BMI is associated with 50% increased risk of endometrial cancer. The positive association between obesity and endometrial cancer was found in premenopausal and postmenopausal women and in hormone replacement therapy users and nonusers. The detrimental effect of obesity on endometrial cancer tended to be stronger in women who never used hormone replacement therapy than those who used. Obesity was also related to an increased risk of type I (mostly endometrioid adenocarcinomas) and type II (nonendometrioid such as serous, clear cell, and carcinosarcoma) endometrial cancer. Mendelian randomization study also found that genetic risk scores for BMI was positively associated with the risk of endometrial cancer.

Abdominal (central) obesity assessed by waist circumference is also associated with increased risk of endometrial cancer. Every 5 cm increase in waist circumference was related to a 13% higher risk of endometrial cancer risk. Weight gain in adulthood also increases the risk of endometrial cancer, particularly in women who never used hormone replacement therapy. Obesity at young adulthood (age 18–25 years) is also associated with higher risk of endometrial cancer later in life.

Ovarian Cancer

Emerging evidence suggests that obesity is related to a modest increase in the risk of ovarian cancer, particularly in premenopausal women. Every five-unit increase in BMI is associated with approximately 10% increase in ovarian cancer risk. The positive association between obesity and ovarian cancer is stronger in premenopausal women than in postmenopausal women. Some studies suggest that obesity is related to certain subtypes of ovarian cancer such as low-grade serous and invasive endometrioid and mucinous tumors.

Abdominal obesity assessed by waist circumference is also related to a small increase in the risk of ovarian cancer. Every 10 cm increase in waist circumference was associated with a 6% increase in ovarian cancer. Weight gain in adulthood seems to increase risk of ovarian cancer, especially in postmenopausal women who never used hormone replacement therapy. Interestingly, studies also found that obesity at young adulthood (age 18–29) was associated with higher risk of ovarian cancer at later life.

Prostate Cancer

Findings from earlier studies that examined the association between obesity and the risk of prostate cancer were inconsistent. Studies conducted in North America found no or inverse association between obesity and prostate cancer, whereas European studies found a weak but significantly positive association. It was postulated that the differential rate of prostate-specific antigen (PSA) screening between these regions was attributable to the inconsistent findings. PSA screening that resulted in a diagnosis of early-stage less aggressive cancer was common in North America, but not in Europe. Therefore, European studies tended to have advanced and fatal prostate cancer.

When the obesity and prostate cancer relation was examined by prostate cancer aggressiveness—nonadvanced, advanced, and fatal prostate cancer in later prospective cohort studies, a clear pattern emerged. Obesity was associated with an increased risk of advanced or fatal prostate cancer. Every five unit increase in BMI was related to approximately 8% increased risk of advanced prostate cancer. The risk of advanced prostate cancer also increased by 12% per 10 cm increase in waist circumference. In contrast, obesity was associated with a lower risk of nonadvanced prostate cancer.

Recent studies suggest that the relation of obesity to prostate cancer differs by molecular subtypes of tumor as well. Two studies found that obesity was inversely associated with risk of TMPRSS2:ERG (T2E)-positive prostate cancer, but not in T2E-negative prostate cancer.

Bladder Cancer

The association of obesity with bladder cancer is less certain. A meta-analysis of prospective cohort studies found a weak but significantly positive association between obesity and bladder cancer. Given that smoking is an established risk factor for bladder cancer, and smokers tended to have lower BMI than nonsmokers, most studies of obesity in relation to bladder cancer may have suffered from residual confounding (i.e., incomplete adjustment) by smoking. A large prospective cohort study found a positive association between waist circumference and bladder cancer, but it was limited to men.

Kidney Cancer

There is convincing evidence that obesity increases risk of kidney cancer (mostly renal cell carcinoma). The effect of obesity on kidney cancer is independent of hypertension that is another established risk factor for kidney cancer. In general, obesity is associated with a 1.5- to 2-fold increased risk of kidney cancer in both men and women. Abdominal obesity assessed by waist circumference is also positively related to the risk of kidney cancer. Every 10 cm increase in waist circumference increased risk of kidney cancer by approximately 11%. Weight gain in adulthood is also associated with increased risk of kidney cancer.

On the other hand, several studies that examined the association between obesity and cancer survival in kidney cancer patients found a contradicting result. Patients who were obese at the time of kidney cancer diagnosis tended to have better survival compared with patients with normal weight at cancer diagnosis. It was suggested that obese patients were more likely to have indolent tumors, leading to better survival.

Brain Tumors

Meningioma is slow-growing brain tumor that arises in the membranes surrounding the brain and the spinal cord. Although a limited number of studies examined obesity in relation to meningioma, they consistently found that obesity was associated with increased risk of meningioma. Overall, compared with normal weight individuals, obese individuals had a 1.5-fold increased risk of meningioma. In contrast, obesity is not associated with risk of glioma, the most common intracranial tumor that starts in the glial cells of the brain or the spine.

Thyroid Cancer

Obesity has been consistently associated with modestly increased risk of thyroid cancer. Every five unit increase in BMI was related to a 6% increase in thyroid cancer risk. The positive association between obesity and thyroid cancer was found in both men and women, but it tended to be stronger in men than in women. Obesity was related to an increased risk of all major histological types of thyroid cancer except medullary thyroid carcinoma. Similarly, abdominal obesity measured by waist circumference was associated with a higher risk of thyroid cancer. Emerging evidence also suggested that young adulthood obesity was related to approximately 13% increased risk of thyroid cancer in later life.

Non-Hodgkin Lymphoma

Non-Hodgkin lymphoma is a cancer originated from the lymph system, a part of immune system. The most common non-Hodgkin lymphoma subtypes are diffuse large B-cell lymphoma, follicular lymphoma, and chronic lymphocytic lymphoma/small lymphocytic lymphoma. Earlier studies on obesity and non-Hodgkin lymphoma reported inconsistent results. Some studies found a weak to moderate positive association between obesity and non-Hodgkin lymphoma whereas others found no association. When each subtype of non-Hodgkin lymphoma was examined separately, it became clear that obesity was related to an increased risk of diffuse large B-cell lymphoma, but not other subtypes. Compared with normal weight people, obese people had approximately 25% increased risk of diffuse large B-cell lymphoma. Recent studies also suggest that obesity during adolescence or young adulthood is associated with a higher risk of diffuse large B-cell lymphoma in later life.

Multiple Myeloma

Multiple myeloma is a rare but fatal malignancy. Mounting evidence indicates that obesity is related to an increased risk of multiple myeloma in men and women. A large pooled analysis of 20 prospective cohort studies found that obesity was associated with approximately 20% increased risk of multiple myeloma, compared with normal weight. The positive association of obesity with multiple myeloma seems to be stronger for obesity at adolescence or young adulthood (age 18–21 years). Waist circumference was also related to a higher risk of multiple myeloma, suggesting the harmful effect of abdominal obesity.

Leukemia

The role of obesity in leukemia is less clear. Limited evidence suggests that obesity is associated with a modestly increased risk of leukemia. The positive association with obesity was found for all leukemia subtypes such as acute myeloid leukemia, acute lymphoblastic leukemia, chronic myeloid leukemia, and chronic lymphocytic leukemia.

Obesity at Adolescence or Young Adulthood and Cancer

Emerging evidence suggests that excess body weight in early life increases risk of cancer in later life, particularly those known to be related to obesity in late adulthood. Due to the methodological challenges in ascertaining height and body weight in childhood, adolescence, and young adulthood and following participants for several decades for cancer outcomes, a limited number of studies examined the association between obesity in early life and cancer risk in later life. Some studies linked historical mandatory health examination data (e.g., for military service) to a national cancer registry data, and others collected self-reported recalled height and weight at early life period.

Although limited, studies consistently found that obesity at adolescence or young adulthood was associated with increased risk of stomach, colorectal, liver, gallbladder, pancreas, and thyroid cancer and diffuse large B-cell lymphoma and multiple myeloma in late adulthood. In contrast, obesity at early life was related to a lower risk of both premenopausal and postmenopausal breast cancer.

Weight Gain During Adulthood and Cancer

On average, young adults gain approximately 0.5 kg per year, which is translated into approximately 10 kg weight gain or 3.1–3.5 BMI increase during 18 years. Most people move into a higher BMI category by middle age. People who experienced early and rapid weight gain at young adulthood are more likely to continue to gain weight throughout the adulthood. The weight gain during adulthood is mostly due to increase in body fat, particularly around the waist. It is postulated that weight gain during adulthood, which can be measured easily, is a good surrogate of body fatness. A meta-analysis of studies of adult weight gain and cancer found that adult weight gain was associated with postmenopausal breast, endometrial, and ovarian cancer and cancers in colon and kidney. The increased risk of female cancers tended to be higher among hormone replacement therapy nonusers than among users. In general, every 5 kg weight gain during adulthood was related to approximately 10% increased risk of cancers.

Intentional Weight Loss and Cancer

A body of literature provides convincing evidence that obesity increases risk of numerous cancers. However, whether or not intentional weight loss reduces cancer risk is unclear. It is, in part, due to the difficulties in intended weight loss and long-term maintenance of weight loss in large observational studies. Therefore, bariatric surgery patients who had significant and sustained weight loss represent a unique population to examine the effects of long-term intentional weight loss on cancer risk.

Studies found that intentional weight loss by bariatric surgery in morbidly obese individuals was related to a lower risk of cancer. Compared with people with severe obesity but no bariatric surgery, people who received bariatric surgery had approximately 30% lower risk of cancer overall. The risk reduction was more pronounced for obesity-related cancers. There was a 40% risk reduction for postmenopausal breast cancer, 60% reduction for endometrial cancer, 40% reduction for colon cancer, and 50% reduction for pancreatic cancer in people who underwent bariatric surgery compared with those who did not.

Obesity Paradox in Cancer Survival

In contrast to the harmful effect of obesity on most cancers, some studies found that obesity was related to a lower risk of cancer death among cancer survivors. This obesity paradox (i.e., obese people live longer) was suggested in some studies of survivors of colorectal cancer, renal cell carcinoma, diffuse large B-cell lymphoma, and melanoma. Several methodological limitations in studies were proposed to explain the observed inverse association between obesity and cancer survival.

First, residual confounding (i.e., incomplete adjustment) due to inadequate or unmeasured confounders such as smoking, comorbidities, socioeconomic status, and lifestyle factors may cause a spurious positive association between BMI and cancer survival. Second, given that weight loss often precedes cancer diagnosis and is associated with an increased risk of mortality in cancer survivors, reverse causation may have occurred in the analysis. The third is a collider stratification bias that occurs in data analysis stratified by a variable affected by exposure and outcome. For example, obese people may have developed cancer due to obesity or smoking whereas normal weight people developed cancer due to smoking in the absence of obesity. Therefore, obese cancer patients are less likely to be smokers, while nonobese cancer patients are more likely to be smokers. Because smoking is a strong risk factor for mortality, obese patients appear to have lower mortality risk than nonobese patients in the analysis of cancer survivors.

In addition, although BMI is the most commonly used measurement to define obesity, BMI may not well represent body fatness in cancer survivors who often experienced changes in body weight and body composition. Studies that measured body fat mass and muscle mass using computed tomography images found that overweight cancer patients tended to have a normal body composition whereas normal weight cancer patients had low muscle mass, similar to underweight. Thus, cancer patients with normal weight at diagnosis may have different body composition compared with normal weight noncancer individuals. The common BMI category may not applicable to cancer patients. Lastly, there are significant heterogeneities in study design and methods, including time of BMI ascertainment (e.g., few months to years before or after cancer diagnosis), adjustments of potential confounders, and

duration of follow-up. These limitations in current literature contribute to inconsistent findings. More studies are needed in this emerging field.

Biological Mechanism

There are several biological mechanisms that may explain links between obesity and increased risk of cancer.

Sex Hormones

Estrogen has been hypothesized to play a role in mostly female cancers such as breast, endometrial, and ovarian cancer. Estrogen is predominantly produced in the ovary, but after menopause, it is produced primarily in adipose tissue through a cellular pathway involving the enzyme aromatase that converts androgens to estrogen. Postmenopausal obese women have higher concentration of total and free circulating estrogen levels compared with normal weight women. Women with higher concentration of circulating various estrogen metabolites and lower concentration of sex hormone binding globulin had an increased risk of postmenopausal breast cancer.

Animal and experimental studied showed that estrogen promotes tumor growth; stimulates cellular proliferation; inhibits apoptosis via estrogen receptor-α agonism; and induces vascular endothelial growth factor and angiogenesis. Estrogen is also suggested to promote free-radical mediated DNA damage, genetic instability, and mutation. Selective estrogen receptor modulators (SERMs) such as tamoxifen and raloxifene and aromatase inhibitors are effective breast cancer treatments by blocking the effects of estrogen.

In men, obesity was related to high estrogen, low testosterone, and low sex hormone binding globulin levels, which led to greater availability of estrogen. The majority of male breast cancer is estrogen receptor positive.

Insulin and Insulin-Like Growth Factor-1

High levels of insulin and insulin-like growth factor (IGF)-1 have been hypothesized to promote the development of cancer. Obesity is positively associated with circulating levels of insulin and IGF-1. Many obese people are insulin resistance and develop type 2 diabetes. Circulating insulin binds to the insulin receptor on the cell surface and promotes hyperactivity of phosphatidylinositol-3-kinase (PI3K)/Akt/mammalian target of rapamycin (mTOR) and mitogen-activated protein kinase (MAPK) signaling pathways that stimulate cell growth and cell proliferation. Metformin that is a type 2 diabetes medication increases insulin sensitivity and activates the AMP-activated protein kinase (AMPK) pathway, thereby counteracting the PI3K/AKT/mTOR signaling pathway. Metformin has been suggested as a chemopreventive agent for cancer prevention.

Chronic Inflammation

Obesity is a common cause of chronic inflammation, both systemically and at the tissue level. Obesity is associated with systemic chronic inflammation markers such as C-reactive protein, tumor necrosis factors (TNFs), interleukin (IL)-1β, IL-6, IL-8, and vascular endothelial growth factor. TNF-α, IL-1β, and IL-6 promote tumor growth in mouse models of obesity, and IL-6 and CRP have been associated with the development and progression of breast tumors. Also, chronic inflammation in the tissue microenvironment such as pancreatitis and gallstone are known risk factors for pancreatic and gallbladder cancer, respectively.

Adipokines

Adipose tissues, particularly white adipose tissue, also secrete various cytokines, known as adipokines that modulate the chronic inflammatory state. Leptin and adiponectin are the most studied adipokines in relation to cancer and play opposing roles in cancer. Leptin is a proinflammatory adipokine while adiponectin is an antiinflammatory adipokine. Leptin activates cell proliferation and multiple signaling pathways including the PI3K, MAPK, and Janus kinase/signal transducers and activators of transcription (JAK/STAT) pathways. Leptin can also induce IL-6 production, suggesting its contribution to the systemic inflammation.

On the other hand, adiponectin inhibits cell growth, increases apoptosis, and activates AMPK that induces cell cycle arrest and inhibits mTOR activity, therefore plays a protective role in cancer. Obesity is associated with higher leptin level and lower adiponectin level. It is suggested that adipose tissue in tumor microenvironment is also a rich source of pro-inflammatory mediators, stimulating tumor growth, and is more relevant than total body fatness to local tumor development.

Microbiome

Emerging studies suggest that microbiome also play a role in obesity and vice versa. The microbiome is microbes such as bacteria, bacteriophage, fungi, protozoa and viruses that live inside and on the human body. Growing evidence indicates that microbiomes in guts predispose individuals to obesity, and obesity also changes the gut microbiota, creating environment prone to

carcinogenesis. Studies showed that microbiomes were related to proinflammatory and immunosuppressive responses. It has been hypothesized that the microbiome in gut affects multiple pathways by which obesity acts on cancer.

Burden of Obesity on Cancer

Assuming that obesity causes cancer, it is estimated that approximately 4% of all new cancers in the world in 2012 was due to high BMI ($\geq$25 kg/m^2). The cancer burden attributable to obesity varied by cancer site in men and women. The population attributable fraction that is a contribution of obesity to a cancer is approximately 30% for esophageal, 10% for colon, 8% for pancreatic, and 18% for kidney cancer in men and 30% for endometrial, 10% for postmenopausal breast, 8% for colon, 8% for pancreatic, and 25% for kidney cancer in women. Also, approximately 10%–13% of cancers in liver, gallbladder, and gastric cardia and 7%–9% of multiple myeloma were attributable to high BMI in both men and women. It is estimated that the global increase in obesity prevalence since 1980s contributed to 25%–32% of obesity-related cancers in 2012.

Obesity also attributed to 120.1 million disability-adjusted life-years in 2015, which made the obesity one of the largest contributors to global disability-adjusted life-years. The cancer burden, including the disability-adjusted life-years, due to obesity is likely to increase if the obesity prevalence continues to rise worldwide.

Future Directions

Although convincing evidence indicates that obesity increases risk of numerous cancers, several challenges remain to advance the understanding of body fatness and weight management in the cancer control continuum.

Accumulating evidence suggests that body fatness in adolescence or early adulthood is associated with increased risk of several cancers at later life. People who experienced excessive weight gain at early life are more likely to keep their excess weight or gain even more weight throughout adulthood. Therefore, body fatness in early life could be an indicator of life-long exposure to obesity. Even though we do not know the biologically relevant time period for obesity to cause cancer, considering a long latency period of cancer, obesity in early life may play a role in carcinogenesis during adulthood, leading to cancer diagnosis at later life. However, there are gaps in the understanding of the effect of obesity at different life course and duration of obesity on cancer risk. In addition, whether intended weight loss at mid-life lowers cancer risk in later life is less clear. More studies are needed to investigate the time course of weight management-either gain or loss- in a life course and its effect on cancer development as well as cancer survival after diagnosis.

The role of obesity in cancer survival is the emerging area of interest. The inconsistencies in the current literature on the effect of obesity on survival among cancer patients indicate the need for a comprehensive examination of body composition, including both body fat mass and muscle mass, in relation to cancer survival. However, there are no practical and standardized methods to measure body composition in large-scale observational studies. A practical and economical method to assess body composition is needed to close a significant gap in understanding of the role of body fatness in cancer survival. Future research on the effect of body fatness and body composition after cancer on patients' overall health and well-being is warranted.

With increasing recognition of tumor heterogeneities in cancer, more and more cancers are reclassified into subtypes according to their molecular characteristics. It is hypothesized that the etiology of one molecular subtype of cancer differs from other subtypes. Further research to understand the role of obesity, including its biological pathways, in the etiology of each molecular subtype of cancer may contribute to find more effective cancer prevention strategies, including development of chemopreventive agents and targets for cancer treatment.

Given the increasing trend in obesity prevalence worldwide, the burden of obesity on cancer is likely to increase continuously. As obesity is a preventable and modifiable risk factor for cancer, obesity prevention and management can contribute significantly to cancer prevention. More efforts are needed to develop multilevel but personalized and sustainable approaches for a healthy lifestyle that maintains healthy weight and prevents weight gain throughout individual's life-course.

Oncology Imaging

Stefan Delorme and Michael Baumann, German Cancer Research Center (DKFZ), Heidelberg, Germany

Advances in Technology

Computed Tomography

Computed tomography (CT) continues to be the workhorse in oncology imaging, since it is fast, extremely reliable, and can be performed in patients who are severely ill, suffer from pain, require monitoring of vital functions, or even mechanical ventilation. Following the first publication of the principle in 1990 (Kalender et al., 1990), spiral CT was rapidly introduced, followed by the implementation of multirow detectors. In contemporary scanners, the beam geometry is cone-shaped to cover an array with 64 to >300 detector rows. The rotation time of the tube now lies below 1 s, in some scanners at 250 ms. As a result, large ranges can be scanned in few seconds time, and thin slices (<1 mm thickness) can be obtained without significantly increasing the radiation exposure to the patient. Neighboring primary slices will be merged to generate slices in the 3–5 mm range, which are less degraded by image noise than the primary thin slices and are required for assessing soft tissue. The primary image stack is almost isotropic, that is, the voxels (volume elements) have similar diameters in all three dimensions. Therefore, sagittal or coronal images can be reconstructed from the primary data stack.

The speed of acquisition permits to obtain images during a defined phase of contrast enhancement following intravenous injection. Dynamic scanning to quantitatively assess the microcirculation is also possible but used less often, because repeated scans will cause significant radiation doses.

Radiation dose is an increasing issue even in oncology, since more than half of patients with cancer can be expected to become long-term survivors. CT now offers numerous options for dose reduction:

Dose modulation: The tube current needed to avoid significant image degradation by noise depends on the radiation absorption by the tissue in the gantry. The absorption is typically low for the neck (because it is slim) or the mid-chest (containing the lungs) and high for the shoulder region or the abdomen. For dose modulation along the body axis (in z direction), the image noise is measured in real time, and the tube current is adjusted in order to keep the noise in a target range. This can be combined with dose modulation during tube rotation, where the tube current is changed as the tube rotates around the patient. The rationale for this is that in a given area the absorption will depend on the direction of the beam in the transverse plane. For the shoulder region, for example, it will be lower for a sagittal than for a transversal beam direction, where the shoulders, clavicles, and vertebral bodies lie in one line and will all be passed by the same beam. Obviously, the tube current will not be based on image noise (because the image does not yet exist) but rather on the beam intensity directly at the detector.

Adjustment of tube voltage and dual-energy CT: The tube voltage determines the maximal beam energy and is around 120 kV in standard diagnostic protocols. However, the optimal voltage is always a tradeoff: The contrast between either bone (that contains calcium) or iodine-based contrast media and soft tissue will increase if the voltage is lowered to 80 kV or even 70 kV. At the same time the radiation dose will decrease significantly, as long as the tube current remains unchanged, and the image noise will increase. In body regions with little radiation absorption, the increase in image noise will be more than compensated by the gain in contrast, resulting in an increase in the contrast-to-noise ratio. Low-kV protocols can be used for angiographic protocols in the head, neck, chest, or abdomen, but also for nodule detection in the lungs. For abdominal CT, however, where the contrast resolution is at a premium, and the X-ray absorption is about the highest in the body, low-kV protocols still play less a role, except for children and very lean adults.

Postacquisition data processing: Users of darkroom software for private digital pictures know how image noise can to some degree be reduced without degrading contrast or resolution, and the same is possible for medical images. Nevertheless, the iterative reconstruction algorithms used on CT platforms do more than that. If applied to image data, they are a way of image postprocessing, but advanced algorithms are applied to raw data and are therefore an entirely different way of reconstructing images than conventional, filtered back-projection. They are powerful tools that should be used carefully, and can compensate for the increase in image noise caused by lowering tube current or voltage (**Fig. 1**). Many radiologists are still reluctant using them, because iteratively reconstructed images often have an unnatural, plastic-like appearance. Nevertheless, it will have to be learned that image aesthetics are at least not the sole criteria to wisely choose the scanning technique. This unconsidered, raw data processing also permits to reduce artifacts due to metal implants or highly concentrated contrast media, for example, in the subclavian or anonymous vein.

Dual-energy CT (DECT) is not a new development, but only in the past 10 years has it become routinely applicable. It consists of scanning the same slice with different tube voltages, fully or almost simultaneously. The way of accomplishing this differs by manufacturer—two tubes arranged in a 90 degree angle, rapid switching between voltages in a single tube, or separation of the components of the energy spectrum in different layers of the detector ring. The rationale is that tissues or substances in the body (typically soft tissue, fat, and either calcium or contrast medium) not only differ by X-ray absorption (which is the classical principle behind X-ray or CT imaging), but that they are different with regard to which part of the X-ray spectrum is more strongly absorbed. If the same region is passed by beams of different energy, or if two regions of the energy spectrum are retrospectively extracted, the contribution of two substances to the absorption may be calculated. This principle has been used since decades for dual-energy X-ray absorptiometry (DEXA), a method for measuring bone density. Here, the dual-energy principle was used to extract the contribution of bone and nonbone to the X-ray absorption. Since for DEXA, only a sagittal beam was used to scan the lumbar spine, the X-ray absorption

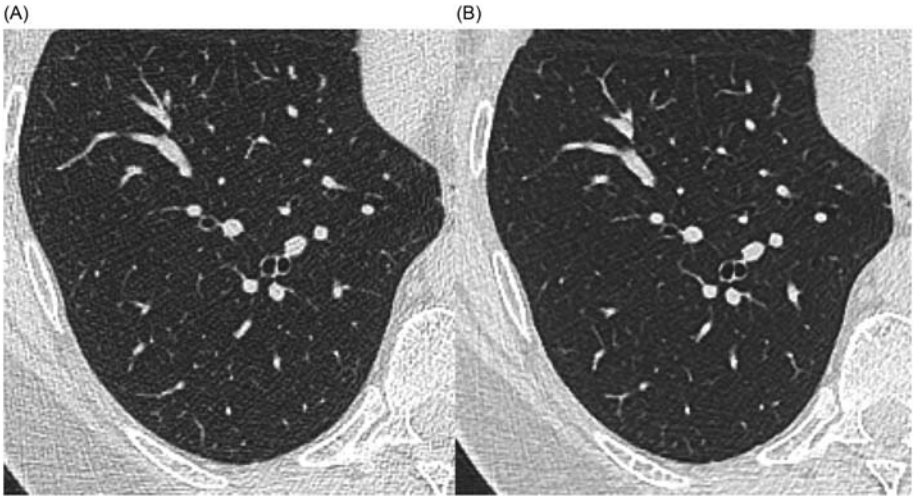

Fig. 1 CT of the lung reconstructed with standard filtered back projection (A) and raw data-based iterative reconstruction (B). Note the reduced noise artifacts on the iteratively reconstructed images. Iterative reconstruction can be used either to generate images with less noise, or to lower the tube current (and thereby the radiation dose to the patient), ending up with the same contrast-to-noise ratio as it would be with standard filtered back projection in combination with standard tube current.

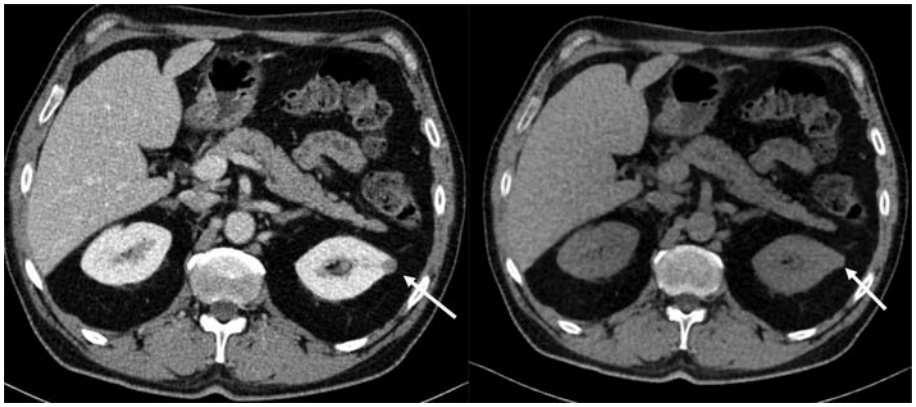

Fig. 2 Dual energy CT: CT of the kidneys with i.v. contrast medium (A) shows a small, hypodense lesion in the left kidney (*arrow*). Whether or not there is any contrast uptake in that lesion is crucial for discriminating a neoplasm from for example, a hemorrhagic cyst. Virtual native contrast (VNC) images (B) are retrospectively calculated from the simultaneously acquired Data obtained with different tube voltages, to exclude the attenuation caused by iodine. In this example, the density values on postcontrast and VNC images are identical, so that the suspicion for malignancy is low. Ultrasound confirmed a cyst.

by soft tissue and fat would otherwise have made bone density measurements impossible. In its first years, DECT has been used mainly for enhancing CT angiography, and only recently for oncological questions, particularly for assessing tissues such as bone marrow, where calcium, fat, and soft tissue are present in one voxel and cannot be resolved in space. A very practical, every-day application is calculating virtual native scans (Fig. 2). This means that only a postcontrast scan is obtained, and the dual-energy data are used to remove the attenuation caused by iodine. This obviates separate unenhanced scans and contributes to reducing the radiation dose. The logical continuation of DECT will be spectral CT, where each photon is measured for its energy. Today, only prototypes exist, and where the future clinical role of spectral CT is difficult to foresee.

Magnetic Resonance Imaging

Higher field strengths

For long, the field strengths were in the range from 0.2 T (particularly with open permanent magnets) to 1.5 T (closed superconducting magnets), with 1.5 T being most frequently used for oncological applications. 3 T magnets are now widely being used, mainly in hospitals or large outpatient facilities that operate them together with 1.5 T scanners. The advantages of 3 T over 1.5 T lies in a higher signal-to-noise ratio and a better quality of morphological images, which is of particular value in studies of the brain and spinal cord as well as in the pelvis. For prostate imaging at 1.5 T, for example, endorectal coils were used in the past to achieve

sufficient image quality, which made it an unpleasant procedure that was not happily accepted by patients. Since the introduction of 3 T scanners (and also fundamental improvements with 1.5 T ones), endorectal coils could be abandoned, which strongly increased the acceptance of the method. Nevertheless, increasing the field strength comes at a price. First, the forces to ferromagnetic implants are higher, and safety is even more an issue. Second, the radiofrequency that is transmitted by the body coil is 128 MHz instead of 64 MHz, and the heat deposition is higher than with 1.5 T, so sequence protocols need to be adapted not to exceed the specific absorption rate (SAR) limit. For both reasons, there are increasing compatibility issues with any kind of implants, be they stents, ports, shunts, bony implants with metal rods, and of course active medicinal products like insulin pumps or cochlea implants. Therefore, patients are expected to provide information about any implants already when making their appointment, so the clarification of compatibility issues (including inquiries, web searches, etc.) can be done beforehand.

Beyond safety issues, high field strengths may indeed degrade image quality because susceptibility artifacts are more pronounced than with lower field strengths. They will arise either in presence of metal or blood degradation products (where they may indeed improve the detection of small hemorrhages) or at tissue–air interfaces. Here, magnetic field inhomogeneities, if not compensated by "shimming" (geometrically adjustment of the magnetic field) the scanner, may, for example, cause difficulties in spectral fat suppression. Particularly in the lower neck and upper thoracic aperture such problems are common, because the geometry of the tissue–air interface (the skin) is so complex that it cannot be compensated by the shimming procedure, which is always rigid in all space directions.

Ultra-high field (UHF) MRI scanners (with e.g., 7 T or more) are so far only experimental. Technical challenges are paramount, some extrapolated from those with 3 T, some entirely new. For the brain, the results may nevertheless be stunning, but only as a result of meticulous refinements of the applied sequences. The potential of UHF MRI lies, for example, in the exploitation of susceptibility effects, imaging nonhydrogen nuclei, chemical characterization of tissue, all not yet ready for routine use. For the body trunk, the protocols are still in their infancy.

Whole-body MRI

Classically, MRI was designed for examining regions of the body, covering a field of view along the body axis (z direction) of about 40–50 cm. Modern scanners now come with an array of receive coils (the radiofrequency is transmitted by the "body coil" that is built into the scanner itself) that can cover the body all the way from the vertex to the feet. With this arrangement, the body can be scanned entirely, usually adding multiple coach positions to another and then composing for example, coronal or sagittal images to display the entire body (**Fig. 3**). Thanks to rapid MR sequences, this can be achieved in 30–45 min time, depending on which image contrasts are needed, and on whether i.v. contrast agents will be used. Obviously, this is a valuable tool for whole-body staging of metastatic disease or hematological neoplasms. Nevertheless, the images are complex, and the workload for the radiologist reading the entire body scan with several weightings and scan directions without missing relevant findings is much higher than with whole-body CT. Without a systematic workflow, relevant findings may easily be missed.

Functional imaging techniques

Dynamic contrast-enhanced MRI (DCE MRI) implies repetitive T1-weighted 3D image stacks being acquired over the same region with high temporal resolution before, during and after pump-controlled infusion of a gadolinium-based contrast agent, in order to assess tissue microcirculation. Using pharmacokinetic models, parameters can be extracted that reflect the relative blood volume in tissue, and the exchange rate of the contrast agent between the central and peripheral compartment, the latter consisting of both the terminal capillary intravascular as well as the extravascular space. The exchange rate is determined by both capillary perfusion and trans-capillary substrate exchange. DCE MRI is most frequently used for MR mammography and prostate imaging for discriminating benign from malignant lesions. Nevertheless, since spatial resolution is at a premium in both instances, the temporal resolution will not permit pharmacokinetic calculations. Therefore, the protocol may be termed multiphasic rather than dynamic, and instead of parameters, the shape of the time-intensity curve (e.g., continuously ascending, early peak followed by either a washout or a plateau) will be visually assessed. DCE MRI must be discriminated from dynamic susceptibility contrast MRI (DSC MRI). Here, a sharp contrast bolus is given, and T2*-weighted images are dynamically acquired to measure a drop in signal intensity which is induced by the presence of gadolinium inside and its absence outside the microvessels. Using indicator dilution models, the tissue perfusion can be calculated directly, provided there is no extravasation of the contrast agent. DCS MRI is standard of care for stroke imaging but can also be used for example, low-grade gliomas, where the blood–brain barrier is not disturbed.

With diffusion-weighted MR imaging (DWI), a series of magnetic gradients is applied to induce a signal loss in areas where extracellular water molecules are free to move randomly. The strength and duration of the gradients determine (expressed by the so-called B-value) the degree of diffusion-weighting. Since images are basically T2-weighted, the signal intensity of tissue depends on both its T2-signal intensity and diffusion restriction. Based on two or more signal intensities obtained with different B-values, the apparent diffusion coefficient (ADC) can be calculated, often represented in ADC maps generated from images obtained with different B-values (**Fig. 4**). More advanced techniques will account for the complexity of the interstitial space (e.g., diffusion kurtosis imaging) or the differential contribution of tissue perfusion and water diffusion to the signal (using, e.g., the intravoxel incoherent motion (IVIM) model; Le Bihan et al., 1988). Moreover, assessing the movement of water molecules separately for three dimensions may serve to assess the preferential direction of anisotropic structures, such as neural tracts.

As a rule, diffusion is restricted in tissues where cells are densely packed, as is often the case in malignant tumors (Chenevert et al., 2000). Although this is not specific, DWI has become an invaluable adjunct in oncologic imaging and can be used either to assist in the differential diagnosis of unclear lesions (e.g., in MRI of the prostate), or, in combination with a suppression of

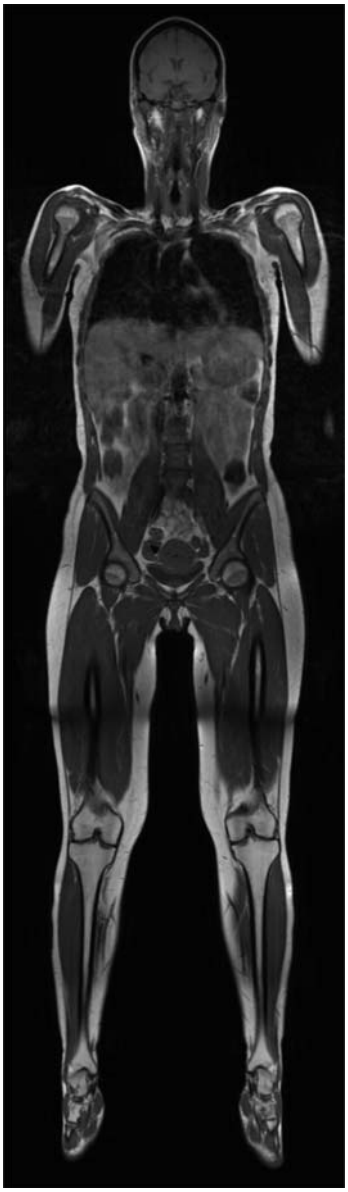

Fig. 3 Native whole-body MRI in a patient with asymptomatic multiple myeloma. Since the longitudinal field of view of clinical MRI scanners is typically 40–50 cm, image stacks are obtained stepwise, as the couch is advanced into the scanner, and then "stitched" together to generate, for example, coronal T1-weighted images as in this example. This patient has a typical, diffuse infiltration pattern with hypointensity of the bone marrow (owing to the replacement of fat by cell-dense tissue) in the vertebrae, the pelvis, the humeri and femora, sparing the epiphyses.

the background signals (from e.g., muscles or fat tissue), to generate whole-body overview images where only diffusion-restricted structures are displayed (**Figs. 9 and 12**). Such images resemble those from FDG-PET studies (sometimes they are called "poor man's PET") and are helpful to attract the reader's attention to suspicious finding, and then retrieve and further assess them on morphologic images.

Susceptibility-weighted MRI (SWI) uses sequences where signal voids arise in presences of differences in magnetic susceptibility, for example, in presence of contrast agents (in DSC MRI, see above), melanin, or blood degradation products. SWI sensitively detects microhemorrhages arising in brain metastases either spontaneously or as a result of treatment. Very typical intratumor susceptibility signals have been found in high-grade gliomas and helped to discriminate them from primary central nervous system lymphoma (Kickingereder et al., 2014).

Gadolinium chelates have been used as contrast agents in MRI since the 1980s. They are injected intravenously and are distributed in the intravascular and extracellular space (except for the brain, where they remain intravascular) and renally eliminated, like iodine-based contrast agents that are used for CT or fluoroscopy. One contrast agent (Gd-EOB-DTPA) is partly taken up by hepatocytes and excreted in the bile, and is therefore approved as a liver-specific contrast agent.

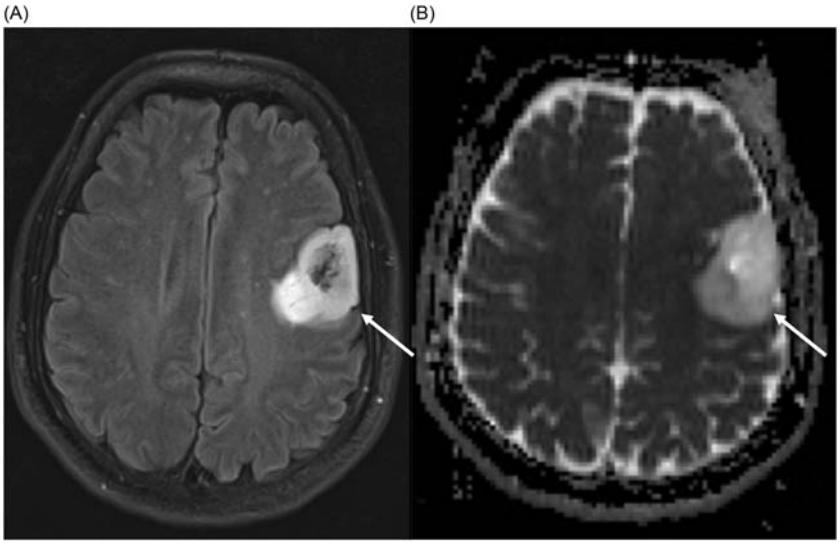

Fig. 4 Anaplastic astrocytoma in the left cerebral hemisphere, visible on a T2-weighted MR image with free water suppression (A) ("fluid-attenuated inversion recovery," FLAIR) and a parameter map showing the apparent diffusion coefficient ADC (B). The tumor is T2-hyperintense and shows increased water diffusion compared to the unaffected brain. Functional imaging techniques like diffusion-weighted imaging may assist in both differential diagnosis of suspicious tumors and in the delineation of the gross tumor volume for radiotherapy planning.

Gadolinium chelates are generally well tolerated, but risks are associated with free gadolinium being liberated from the chelator. In the 1990s, it became obvious that scleroderma-like skin changes (nephrogenic systemic fibrosis, NSF) occurred in patients with renal insufficiency who had received high or repeated doses of gadolinium chelates. Thanks to clear guidelines on the use and exclusion criteria for MRI contrast agents, hardly any NSF cases have occurred since. Only recently, however, gadolinium deposits were found in the dentate nucleus of the brain, visible as hyperintensity on T1-weighted, native images, and also proven in post mortem specimens, and have also to be expected elsewhere. There has been a clear association with both the cumulative amount of contrast agent given and also the type of chelators that have been used. Gadolinium is mainly released from linear chelators, whereas macrocyclic chelates are obviously so stable that the amount of liberated gadolinium is negligible. There is a clear move to using macrocyclic agents only, although no clinical sequelae of CNS deposits are known so far—and will be difficult to prove. The consequences for manufacturers may be serious, since some linear contrast agents that have been very successful until now will probably disappear from the market, except for the liver-specific Gd-EOB-DTPA, for which there is currently no macrocyclic alternative.

This in mind, there is continuing interest in techniques for tissue characterization, some being in use since long (e.g., spectroscopy, blood oxygen level-dependent (BOLD) neurofunctional MRI), others newly developed (MRI with hyperpolarized oxygen, chemical exchange saturation transfer (CEST) imaging). Mostly, they still require either specialized equipment such as ultra-high field scanners or an intense support by basic scientists or physicists, but some may evolve to become part of clinical protocols in future, as it has happened with diffusion-weighted imaging.

Ultrasound

Ultrasound (US) is one of the most underestimated imaging techniques, for numerous reasons, the most important ones being that it requires much skill and dexterity to be carried out, and that it will usually not yield volume-covering image stacks that can easily be reviewed by a second reader. It is sad to say that its being applied by numerous insufficiently educated users has damaged its reputation, triggering further, potentially costly and invasive measures. In the hand of a skilled and trained examiner, ultrasound is a powerful, versatile and fast imaging tool that is capable of solving many issues or at least guide further imaging studies. In the near field, with high frequencies, its spatial resolution is unsurpassed. Its contrast and resolution have been constantly improved over years, a kind of a "silent revolution".

The most striking development in the past years has been the introduction of ultrasound contrast media, along with specific contrast-specific imaging techniques. They consist of gas-filled microbubbles 1–10 μm in size with a soft shell that are suspended in water and injected intravenously. The most frequently used compound contains sulfur hexafluoride with a soft phospholipid shell. Originally, they were developed as signal enhancer for Doppler applications, but along with the official approval that became unusually protracted, the spectral and color Doppler techniques improved so substantially that the substances became almost obsolete for the originally intended use. However, the physics were deeply investigated, to reveal three different mechanisms of interaction between ultrasound waves and microbubbles, depending on the acoustic pressure: At very low intensities, the microbubbles act as simple scatterers and increase the echo intensity of the blood—as originally intended. At high intensities (i.e., those usually applied for B-mode and Doppler ultrasound), the positive and negative pressure forces cause the bubbles to rupture and emit

an acoustic signal, an event that is termed a "stimulated acoustic emission" (SAE). An SAE can be detected by the ultrasound probe and will be encoded either in a B-mode or in a color Doppler image. Thus, SAEs are a way to generate contrast-specific images, because their intensity is comparably high, but since they accompany the bubble's death, they are very short-lived. SAE imaging cannot be performed as a real-time examination, as would be desirable. At low intensities (about 10% of the usual output power), an interesting interaction occurs: Microbubbles have an own resonance frequency at which they expand and contract, dependent on their diameter. In case of resonance between transmitted ultrasound pulse and microbubble, this will vibrate at that frequency. As a happy coincidence, this is the case for microbubbles between 1 and 10 μm in diameter (i.e., that easily flow in the blood stream) and ultrasound in the usual diagnostic frequency range (between 1 and 20 MHz). The vibration is too low in amplitude to emit a signal, but the backscattered echo of the bubble will be distorted in shape when compared to the transmitted signal. In other terms, it will contain higher-frequency components, that is, second or higher harmonics. This is a peculiarity that not shared by backscatter from tissue and is now being used to separate echoes from microbubbles and tissue, using either high-pass frequency filters, sequences of inverted pulses, or both, and generate images that show the pattern of contrast enhancement. Although low-MI imaging (MI = mechanical index) does go along with some bubble destruction, enough bubbles will survive to enable real-time scanning for about 5 min.

Other than gadolinium- or iodine-based contrast media used for MRI or CT, ultrasound contrast agents remain strictly intravascular. Once the bubbles perish, the phospholipids are metabolized, and the gas is exhaled via the lungs. The absolute quantity of gas is in the range of few micro liter. Ultrasound contrast media are extremely well tolerated; allergic reactions may occur but are exceedingly rare, and so are nonallergic toxicities. They are contraindicated in advanced cardiac failure because fatalities had been observed in this context, but in absence of a plausible pathomechanism it can be assumed that these were coincident and caused by the disease itself rather than due to the compound.

The main application of contrast-enhanced ultrasound (CEUS) is to work up unclear liver lesions, where it has been shown to be diagnostically equivalent to CT or MRI (**Fig. 7**). Sonographic access provided, CEUS is the most sensitive method to detect even weak perfusion in tissue in anybody region.

Ultrasound is an exquisite method to guide a biopsy needle or an ablation device in real time and verify its correct placement, without exposing the physician to ionizing radiation as would be the case with fluoroscopic and sometimes CT guidance. It permits to directly visualize the progress of thermal ablation, and CEUS can be used to examine whether viable parts of the target have remained. If a lesion that was detected with CT or MRI is not visible in ultrasound, because it is for example, isoechogenic, the relevant image stack from the corresponding modality can be matched, using anatomical landmarks and an electronic positioning system attached to the transducer. The device is then guided via a split screen or an image overlay showing both the ultrasound and the CT or MRI images reconstructed in identical planes. Such systems are available either as additional equipment or readily implemented in high-end ultrasound machines. Such fusion-guided procedures are widely performed for example, liver or prostate lesions.

Current ultrasound research is focused on, for example, elastography, motion registration, or molecular imaging. Tissue elasticity can be assessed by analyzing the deformation of tissue upon movement of the transducer. More advanced techniques use a "push" pulse that causes tissue deformation and shear waves, both of which can be analyzed using ultra-fast techniques. Elastography may assist in detecting firm lesions that are isoechogenic to their surroundings, or in the differential diagnosis of otherwise unclear lesions, and is being used clinically for example, for assessing thyroid nodules or for detecting breast lesions. Current research is directed at using ultrasound for motion detection in the context of image-guided radiotherapy (IGRT). Ultrasound also offers possibilities for molecular imaging. Microbubbles can, for example, be attached to specific ligands or antibodies. The signal from stimulated acoustic emissions is so strong that every single bubble can be detected. However, such applications are limited to intravascular targets. Another approach is to make use of Bell's effect: Short laser pulses directed into the tissue will induce heat-induced, pulsatile tissue expansions and thereby the emission of an acoustic signal. Depending on whether monochromatic or spectral lasers are used, such optoacoustic imaging scan can be tailored to targets with known absorption peaks (e.g., melanin, oxygenated or de'oxygenated hemoglobin) or even dyes that are attached to specific ligands. Ultrasound for IGRT or molecular ultrasound imaging are still in their preclinical phase of development.

Positron Emission Tomography

The most important developments in positron emission tomography (PET) have been improvements of detector technology, the introduction of hybrid scanners and the development of specific tracers.

The principle of PET lies in the detection of two 511 keV photons emitted in opposing directions during an annihilation event from a collision of a positron (an antimatter particle emitted from isotopes like 18-fluorine, 11-carbon, or 68-gallium) and an electron. Positron-emitting isotopes are either chemically bound or chelated with substrates and are so used to map biochemical processes or specific markers in tissue. The main component of a PET scanner consists of a ring detector array that form its gantry. Whenever two coincident photons are registered, their source will be assumed to lie anywhere on the "line of response" connecting the two detector crystals. In modern "time of flight" scanners, a time lag between the two signals can be discriminated to better locate the annihilation event on the line of response and improve the spatial resolution. To quantify the tracer distribution in a 3D dataset, the raw data have to undergo a correction for attenuation and scatter. Attenuation correction is based on a transmission scan that would originally be acquired using a germanium source rotating around the patient.

Today, almost all PET cameras are part of PET/CT hybrid scanners. Only recently, PET/MR combinations are on the market, but only few of them have been installed so far. In the simplest case, the CT component will be used to obtain a low-dose transmission scan as the basis for the attenuation correction and as a map to locate the tracer distribution anatomically. However, the combination has the potential to fully exploit the diagnostic capabilities of both PET and contrast-enhanced multidetector spiral CT. The CT and PET scan are obtained after each other, and anatomical mismatches may be inevitable close to the diaphragm, in the abdominal viscera (in case of vivid peristalsis), or may occur in case of patient movements. Since the PET measurements take several minutes per bed position, the corresponding CT data cannot be acquired in a breathhold as would be done in normal CT examinations.

For PET/MR combinations, there are different solutions: (1) Shuttle systems with a PET/CT and an MRI scanners, with a couch system that can be docked to both machines, (2) two separate scanners (one MRI scanner and one PET camera) placed opposed to each other and connected by a common, rotatable couch table, (3) a PET detector insert inside a standard MRI gantry, and (4) a fully integrated, dedicated PET/MR hybrid machine. Besides technical challenges associated with such a construction (replacement of photomultipliers by photodiodes that do not interfere with the influences from the MRI scanner), specific issues need to be solved, since an MRI scan will obviously not contain radiodensity data as they would be needed for attenuation correction. Air and compact bone, for example, are both signal void on MRI scans. Therefore, one or several MRI sequences are used to create an attenuation map, using prior knowledge and empirical radiodensities. Furthermore, additional objects in the gantry like radiofrequency coils or ear protectors will not be contained in the obtained images but have to be accounted for. The developments in this regard are still ongoing.

Despite these challenges, PET/MR promises various improvements that are currently being explored. For various anatomical regions, MRI, not CT, is the morphologic imaging modality of choice—for example, the central nervous system, the pelvis, or parts of the musculoskeletal system—and is therefore preferable as an anatomic reference for the PET data. Fully integrated PET/MR scanners offer the possibility to measure PET and MRI data simultaneously and thereby perform a motion correction. This will improve both the anatomical location of the tracer uptake and also its quantification. Finally, PET/MR combines two highly versatile functional imaging modalities, which to compare is of high scientific interest.

The most widely used and best evaluated tracer is 18-fluorine-labeled deoxyglucose (FDG), a glucose analogue that is being used for staging and therapy monitoring of many tumors like lung cancer, lymphoma, malignant melanoma, multiple myeloma (**Fig. 13**), and others. Limitations arise from a high FDG uptake in for example, inflammatory lesions or healthy brain (which limits the value of FDG for imaging brain tumors) as well as a low FDG avidity in some common (prostate cancer) or less common (e.g., neuroendocrine) tumors. However, the past years have seen the development of additional tracers that are meanwhile being used clinically. The most important to mention are 68-Ga-DOTA-TOC (a somatostatin analogue taken up by neuroendocrine tumors or meningiomas), radiolabeled PSMA (prostate-specific membrane antigen) ligands for prostate carcinomas and its metastases, or amino acids for brain tumors. In addition to 11-C-methionin, 18-F-ethyl-tyrosine is now increasingly being used. In patient with advanced metastatic disease, DOTA-TOC or PSMA PET can serve to estimate whether sufficient dose may be achieved by radionuclide therapy, using the same substances as carriers.

Medical Image Computing

The era of films and lightboxes is definitely past. Even in private offices, images are stored and viewed digitally, and can be transferred to third parties for reading or consultation. There exist companies that have a team of radiologists on their payroll, whose task it is to read imaging studies performed anywhere on the globe. The availability of digital imaging data has triggered a plethora of applications designed to assist the reader, facilitate image handling and storage; some even promise to take over the radiologist's intellectual task, that is, to interpret the studies. Whether or not this may happen is mere speculation. Among numerous applications for analyzing, viewing and demonstrating images, two have immediate impact on imaging for cancer, automatic lung nodule detection and tools for response evaluation.

On plain X-ray films, even experienced readers will only detect nodules 1 cm in diameter or larger, and still miss many, because of overlying structures like ribs, vessels, etc. Therefore, CT is the method of choice for detecting lung nodules. Still, the presence of cross-sectioned vessels makes reading it a challenging task. One way of improving the conspicuity of lung nodules is to obtain thin primary slices (1 mm) and then create maximum intensity projections (MIP) in craniocaudal direction out image stacks of, for example, 10 primary slices. That way, vessel cross-sections will retain their strand-like or oval shape, whereas nodules will stand out as spherical structures.

Software solutions exist that analyze thin-section CT series of the lungs to find nodules in the lung and discriminate them from vessels. Some are implemented on the platforms of CT scanners and can be configured to add annotated images and transfer them to the PACS. Others will run on dedicated standalone workstations. Meanwhile, such software is reliable but will also yield false positive findings. So the user will have to cross-check the search results. Important to realize is that a nodule has to be surrounded by ventilated lung in order to be detected. Nodules with contact to the pleura, wedge-shaped sessile densities in the subpleural lung or masses with contact to the mediastinum will not be automatically detected, nor will be hilar masses.

Response evaluation

Clinical trials in oncology beyond phase I will often require an objective assessment of the tumor burden, usually based on imaging studies. Various evaluation criteria are being used, depending on the type of tumor and treatment, the most common ones being the Response Evaluation Criteria In Solid Tumors (RECIST), the International Working Group criteria for lymphomas, and the RANO

(Response Assessment in Neuro-Oncology) criteria for brain tumors. For immunotherapy, criteria have been adapted to better account for pseudoprogression or delayed response as may be encountered with this type of treatment. Apart from the RANO criteria, a response assessment in metastatic disease implies a heavy workload and requires a meticulous documentation to ensure that the index lesions that are followed are indeed identical. Originally, spreadsheets were used, but turned out to be impractical and error-prone. Software solutions that assist in this task are of invaluable help in any imaging facility involved in clinical trials. Such programs will use a dedicated, PACS-like user interface, provide a database for all measurements, measurement tools for diameters, areas, volumes, and suggest a timepoint response according to guideline's criteria. Additionally, they provide tools for measuring standardized uptake values in PET studies to support the response assessment.

It has to be said clearly that response criteria have been defined to support clinical trials, and so have been all related software tools. Neither were intended to serve as a basis for clinical decisions in routine oncology, and indeed they are too rigid for this purpose. Nevertheless, they are sometimes being used accompanying (rather than influencing) clinical decisions, as part of a quality assurance routine.

Imaging for Treatment Planning and Guidance

Both radiotherapy and percutaneous interventions use imaging for planning and guidance. For radiotherapy, the gross tumor volume (GTV) as well as the organs at risk will be defined using the imaging method and windowing on which the tumor is best to discriminate from its uninvolved surroundings, most often CT. Its advantage is that it is unaffected by spatial distortion that may accompany MRI measurements, but for MRI sequences are as well available that are corrected for spatial distortion. Image registration may be used to overlay CT, MRI, or PET images and improve the GTV delineation. PET in particular is a valuable adjunct to assess the presence of tumor in an otherwise unclear structure (i.e., a lymph node level), but for precise delineation of the GTV it should be used with caution, because the apparent borders between normal and abnormal can be strongly influenced by windowing.

Besides uncertainties regarding the true tumor extent and positioning (accounted for by the clinical and planning target volume), inter- and intra-fractional motion can cause underdosage to the tumor and overdosage to normal tissue. While issue of intra-fractional motion is still far from having been solved, movement or variations in positioning between treatment sessions can be detected by daily imaging in treatment position, using either an in-room CT or a cone-beam CT implemented in the linear accelerator, and corrected by for example, repositioning or alternating treatment plans (image-guided radiotherapy, IGRT). Hybrid installations of MRI scanners and linear accelerators, where image guidance would be feasible based on MR images are about to be installed, so that hardly any experiences exist in this regard. Nevertheless, MR guidance has been shown possible based on scans obtained in a standalone scanner, using a slim, custom-developed fixation device with integrated, MR-visible, stereotactic markers (Bostel et al., 2018).

Apart from endovascular interventions (e.g., chemoembolization), percutaneous biopsies or tumor ablations (using radiofrequency, microwaves, cryotherapy, or alcohol) are usually performed under ultrasound or CT guidance, depending on which method best shows the target and is best suited for its location—and is best mastered by the physician. MRI-guided interventions are only rarely performed, and if at all only in open scanners. For lesions that are best seen on MR images, image fusion is the best option. This has successfully been used for example, patients with elevated serum PSA and previous negative biopsies. Here, MRI including DWI and DCE MRI was used to locate suspicious areas in difficult to reach locations, and then to biopsy them under fusion ultrasound guidance.

Imaging the Primary Tumor

The choice of imaging techniques depends on the anatomical site to be imaged, available technology, and local expertise. Following the EU directive 97/43/EURATOM, several European countries, among them the United Kingdom and Germany, have published referral criteria (The Royal College of Radiologists, 2012; Strahlenschutzkommission, 2010) for imaging studies that have meanwhile undergone several revisions. Originally, they served radiation protection purposes, but have in the meantime evolved into up-to-date guidelines that are both scientifically founded and pragmatic in the context of availability and cost-effectiveness. Many of the recommendations in this article will follow the British and German referral criteria as well as the current oncological guidelines, for example, available from the German Arbeitsgemeinschaft Wissenschaftlicher und Medizinischer Fachgesellschaften (AWMF, www.awmf.org).

CNS Tumors

The annual mortality from primary CNS tumors is declining since the mid-1990s and in 2012 it was 2.89/100,000 (mortality) for women, and 4.43/100,000 for men (Becker and Wahrendorf, 1998). The treatment is multimodal and includes resection (if possible), radio- and chemotherapy as well as antiangiogenic, targeted or immune-stimulating agents.

The primary imaging modality for both primary brain intra- and extraaxial brain tumors as well as brain metastases is clearly MRI, including postcontrast T1-weighted sequences. Compared to CT, MRI is more sensitive and permits a better delineation of the gross tumor volume for radiotherapy planning. CT may be used whenever MRI is contraindicated and in addition to MRI in

radiotherapy planning or for detecting calcifications in oligodendrogliomas. T2-weighted sequences in MRI should include fluid-attenuated inversion recovery (FLAIR) sequences, where the signal from cerebrospinal fluid is suppressed (**Fig. 4**). FLAIR images are best suited to depict perifocal edema and low-grade components with an intact blood–brain barrier that will not take up contrast medium. Supplementary MRI investigations may be diffusion-weighted sequences (**Fig. 4**), dynamic susceptibility contrast (DSC) sequences or 1H spectroscopic imaging that may assist in depicting otherwise occult anaplastic foci in low-grade tumors and guide biopsies. 1H spectroscopy has proven valuable in irradiated patients for discriminating radiation-induced alterations from recurrences. In doubtful cases, amino acid PET/CT (using, e.g., 18-F-ethyl-tyrosine) may be used to assist in the delineation of vital foci, the choice of a biopsy site, and differentiation between treatment-induced changes and recurrences. 68-Ga-DOTA-TOC PET/CT is a specialized investigation for meningiomas and may aid in discriminating them from other meningeal tumors and in planning surgery or radiotherapy. In the follow-up of treated gliomas, MRI remains the primary investigation. Here FLAIR sequences play a pivotal role in detecting recurrences, since treatment with VEGF antibodies (e.g., Bevacizumab) may mask recurrences on contrast-enhanced images (Wen et al., 2010).

Head and Neck Tumors

Tumors of the upper aerodigestive tract are typically caused by chronic alcohol and tobacco consumption in combination, human papillomavirus (HPV) being another, independent risk factor. Apart from laryngeal cancer that causes hoarseness in early stages already, head and neck cancer in other locations may cause little or nonspecific symptoms, if at all. Often, a palpable metastatic lymph node will be the first clinical sign. The aggressiveness and metastatic pattern differ widely, depending on the site of the primary tumor. Whereas oropharyngeal cancer often presents with a pattern of rather few, morphologically unambiguous lymph node metastases, carcinoma of the hypopharynx rather may cause numerous micrometastases—which limits the diagnostic accuracy of lymph node imaging. The annual mortality (excluding laryngeal cancer) in 2012 was 5.34/100,000 in men, and 1.28/100,000 in women (Becker and Wahrendorf, 1998). Treatment is multimodal and includes chemoradiotherapy alone or preoperatively, resection where feasible, as well as targeted or immune-stimulating drugs, depending on the site of the primary tumor and the TNM stage.

For all palpable abnormalities in the neck or salivary glands, ultrasound is the immediate imaging modality of choice to verify the finding, learn which anatomical structure it belongs to, and, if necessary, to plan the next diagnostic steps. Often, the findings are typically benign, and no further measures are necessary.

For pharyngeal or laryngeal tumors the role of imaging is restricted to local and regional staging, whereas the diagnosis itself is made by endoscopy and biopsy. For assessing the depth of invasion, contrast-enhanced CT is accurate and reliable. MRI is the method of choice for nasopharyngeal tumors, but not for cancer of the oro- or hypopharynx or the larynx, where motions due to breathing and swallowing often degrade the image quality. For lymph node staging, CT and ultrasound are used in combination. The discrimination between metastatic and inflammatory lymph nodes (which often accompany head and neck cancer) remains a problem with all imaging modalities. Ultrasound, using high-frequency transducers (>14 MHz) has a superb spatial resolution, compared to CT and MRI, and allows to assess the normal intranodal anatomical structures (hilum, peripheral hyperplastic follicles, vascular architecture) as well as a lymph node's shape, and should be part of every regional staging for head and neck cancer. FDG PET/CT is of clear value for lymph node staging and being used depending on local standards and resources. It is an important adjunct in assessing the treatment response after neoadjuvant treatment prior to lymph node dissection. If used in radiation therapy planning for head and neck cancer, FDG PET/CT may help to significantly reduce the target volume in the majority of patients and thereby reduce radiation-induced toxicities (Wang et al., 2015).

Thyroid Tumors

Nodular goiters are common and endemic in areas with low iodine concentration in drinking water, and most nodules are benign. In fact, the annual incidence of thyroid carcinoma in 2014 was 3.7/100,000 in men, and 8.9/100,000 in women (Gesellschaft der epidemiologischen Krebsregister in Deutschland e.V. (GEKID), 2014), whereas the mortality in 2012 was 0.35/100,000 in men and 0.29/100,000 in women (Becker and Wahrendorf, 1998), which indicates that the cure rate is in the range of 90% or higher. This results from the fact that after thyroidectomy and modified neck dissection, the standard surgical procedure, radioiodine ablation using 131-J is highly effective in eradicating not only local remnants but also distant metastatic disease of follicular and papillary thyroid carcinoma. It will not work, however, if iodine is not (primarily in anaplastic or medullary thyroid carcinoma, MTC) or no longer be taken up, as may occur by dedifferentiation. Hence, the prognosis of anaplastic or secondarily dedifferentiated carcinoma is poor. For the same reason, distantly metastatic MTC is impossible to control definitely, but apart from highly aggressive variants, MTC will progress only slowly, over decades rather than years.

The primary task in the workup of thyroid nodules is to spare as many patients as possible invasive measures without missing the relatively few ones who have thyroid carcinoma, with the diagnostic tools ultrasound, 99-m-pertechnetate scintigraphy, cytology from fine needle aspiration, accompanied by serum levels for T3, T4, TSH, and calcitonin for the rare cases of medullary thyroid carcinoma. The tumor marker thyroglobulin is used only to screen for recurrences in patients post thyroidectomy and radioiodine ablation; in all other patients, its serum levels are of no diagnostic use. As a rule, hypoechogenic and scintigraphically cold nodules more than 10 mm in diameter should undergo fine needle aspiration, be followed up with ultrasound if the biopsy is benign, and rebiopsied in case of further growth. Recently, Tc-99m-MIBI scintigraphy has been used for nodules that are cold in pertechnetate

scintigraphy, and a persisting MIBI uptake after 120 min may be an additional indicator of malignancy. Still, under which circumstances MIBI scintigraphy should be performed remains to be determined. For preoperative nodal staging, additional ultrasound is the method of choice. Computed tomography plays almost no role for locoregional staging, since iodine-containing contrast agents are contraindicated. After thyroidectomy, radioiodine scintigraphy is the primary method for restaging, in combination with ultrasound. As long as any metastases continue to take up iodine, additional imaging studies will serve for morphologic workup of suspicious scintigraphic findings. Tumors that do not or no longer take up iodine (in case of secondary dedifferentiation, anaplastic, or medullary carcinoma), contrast-enhanced CT or MRI will be used in addition to ultrasound. FDG PET/CT is reserved for secondarily dedifferentiated carcinoma or anaplastic carcinoma.

Ten percentage of thyroid cancers are medullary carcinomas. Here, contrast-enhanced CT and ultrasound of the neck and abdomen are usual methods for staging as well as follow-up for patients who continue to have elevated serum levels for calcitonin or CEA. FDG PET/CT may be used in aggressive variants of the disease; slowly progressing tumors, the majority of cases, rather take up 18-F-DOPA, and PET/CT may be used to detect distant metastases. However, PET/CT studies for medullary carcinomas should be reserved for patients in whom positive findings would result in surgical resection. In late stages, this is only rarely the case.

Lung Tumors

For no other tumor, the etiology (smoking) is as well understood as for lung cancer, although nonsmokers with lung cancer are not infrequently seen, particularly at older age. There is now increasing awareness that the second-most important cause, exposition to radon (with an average annual dose of 1 mSv, depending on the geographic region), as it is being released for example, from building materials, is far from being under control. Lung cancer is a common and fatal disease, the annual mortality in 2012 being 32.08/100,000 in men and 14.5/100,000 in women (Becker and Wahrendorf, 1998).

The treatment depends on whether the patient has small-cell (SCLC) or nonsmall-cell lung cancer (NSCLC). SCLC is considered a systemic disease, even if no metastases are detected at staging. For NSCLC, surgical resection is restricted to patients without contralateral (N3) mediastinal and more distant metastases, often preceded by neoadjuvant chemo- and immunotherapy (in some centers, ipsilateral mediastinal (N2) nodal metastases already will rather trigger nonsurgical treatment). In all other stages, the patients are treated with chemoradiation, and here as well, targeted drugs and immune checkpoint inhibitors play an increasing role.

Many patients who are diagnosed with lung cancer have a plain chest X-ray as their first imaging study, being performed for more or less specific symptoms. In case of highly suspicious clinical symptoms (e.g., hemoptysis, dyspnea, recurrent nerve palsy) or X-ray findings (e.g., hilar mass, pneumonia irresponsive to antibiotics) and for staging the disease, cross-section imaging is needed. For diagnosing and staging lung cancer, contrast-enhanced CT remains the primary imaging modality of choice, supplemented by ultrasound of the abdomen, the neck, and the supraclavicular fossa. CT has to include the range between the lung apexes and both adrenal glands, but a complete scan of the abdomen in the portal phase of contrast enhancement will definitely make sense, considering that a baseline scan may be helpful to assess findings that are seen during the later course of the disease. In small cell lung cancer, a contrast-enhanced MRI of the brain is mandatory and may only be replaced by CT in case of contraindications to MRI.

MRI of the chest has no clear advantages over CT, with few exceptions. In tumors in the superior sulcus (Pancoast tumors), MRI, particularly in coronal orientation, is indicated to assess its depth of invasion into the cervical structures and its relationship to the cervicobrachial plexus. Moreover, MRI may be the only modality to delineate a tumor against a surrounding atelectasis, which may be important for the GTV or for response assessment.

Ultrasound of the chest may supplement CT in suspected chest wall invasion, particularly when MRI is unavailable. Endobronchial ultrasound is a specialized investigation and usually a guidance tool for transbronchial biopsies of suspicious lymph nodes.

FDG PET/CT is primarily indicated for characterization of singular pulmonary nodule undetermined in CT and for staging of nonsmall-cell lung cancer, which is highly FDG-avid in almost all cases, whenever radical surgery is intended. It may detect unsuspected mediastinal lymph node or distant metastases and identify patients who are no candidates for surgery. Those patients will usually undergo radiotherapy with selective nodal irradiation, and an available PET/CT study facilitates the delineation of the nodal GTV. If PET is unavailable, a bone scan may be used to screen for skeletal metastases. If they are suspected, their impact on bone stability needs to be assessed, often with X-ray films or CT. Of note, bone scintigraphy may be false negative (or cause a hard to detect "cold lesion") whenever there are large destructions of bone without reactively increased bone turnover. Pure bone marrow metastases may be negative as well, if they do not cause alterations to the mineralized bone.

There is an ongoing discussion on using low-dose CT for early detection of lung cancer in risk populations, that is, in current or former smokers (**Fig. 5**). Indeed, the largest prospective trial so far, the American National Lung Cancer Screening Trial (NLST) on more than 53,454 participants, comparing low-dose CT against chest X-ray, achieved a 20% reduction of lung cancer, and a 6.7% reduction in all-cause mortality in the screening group (Aberle et al., 2011). At least in some European trials, including the German LUSI trial (Becker et al., 2015), a similar mortality reduction was achieved, but due to smaller sample size, they still need to be meta-analyzed. The results from the largest European trial, NELSON from the Netherlands, are about to be published. While the hazards from radiation exposure are minimal (the effective dose is below 2 mSv and lies in the range of the annual dose from environmental sources), false positive findings are of concern, since they may trigger full-dose CT or PET/CT studies as well as invasive chest procedures. Furthermore, the issue of possible overdiagnosis and overtreatment (i.e., finding and treating lung cancer that, if left alone, would not have caused symptoms or been fatal) is unresolved. Since the NLST lacks a postscreening observation phase, other than some European trials, the question will remain open until the latter have been concluded. Upon a recent European position

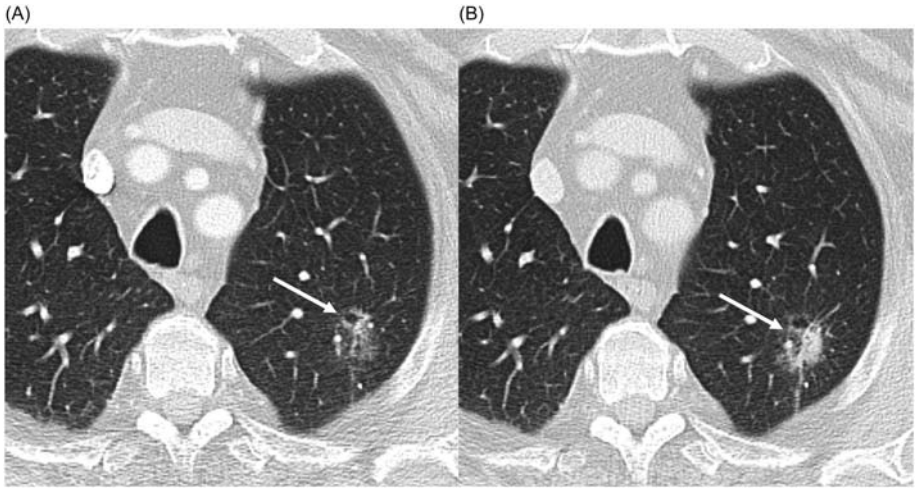

Fig. 5 Low-dose CT scans of the lung in a participant of the German "Lung Cancer Screening and Intervention" study (LUSI), 6 months apart. The initial scan (A) shows a ground-glass opacification (*arrow*) that at follow-up (B) has increased in size and density, and would now be termed "part-solid." Subsequent video-assisted thoracoscopy (VATS) with biopsy revealed lepidic adenocarcinoma with invasive foci.

statement calling for an implementation of lung cancer screening (Oudkerk et al., 2017), concerns have been raised that lung cancer were inadequate, arguing that smoking prevention would the more effective measure to reduce lung cancer mortality. In any case, it should be considered that quitters will remain at increased risk for the next 10–15 years.

Gastrointestinal Tumors

Barium-enhanced fluoroscopy, formerly the standard imaging method for tumors of the gastrointestinal tract, has become obsolete, except for few indications, like verifying or ruling out an esophageal stenosis as a cause of dysphagia, or examining the colon proximal to a stenosis that cannot be passed with the endoscope. Contrast-enhanced CT is now the imaging modality of choice, since due to the speed of acquisition peristalsis will no longer impair the image quality. MRI may be used as well, but is more susceptible to motion artifacts, and is inferior to CT in detecting lung metastases. It is, however, preferable in the aftercare for patients with a good long-term prognosis, to spare them a significant radiation dose that would otherwise accumulate over the years of follow-up. It can then be supplemented by native low-dose CT studies of the lung.

To assess the wall of hollow organs, some distension should be achieved, since nondistended or contracted bowel segments may easily mimic a mass. Most commonly, 1 to 1.5 L of water are administered either orally for the esophagus or stomach, or rectally for the large bowel, in combination with i.v. butylscopolamine—a technique commonly termed "Hydro-CT."

Esophageal cancer

Squamous cell and adenocarcinoma of the esophagus are different in many respects. Whereas squamous cell carcinoma may be located at any level, and its most important cause in the western world is tobacco and alcohol consumption, adenocarcinoma is most frequently induced by gastroesophageal reflux, intestinal metaplasia (Barrett's esophagus) being the typical precancerous change. The annual incidence for esophageal cancer in 2014 was 9.6/100,000 in men, and 2/100,000 in women (Gesellschaft der epidemiologischen Krebsregister in Deutschland e.V. (GEKID), 2014); the 2012 mortality was 4.78/100,000 in men, and 1.07/100,000 in women (Becker and Wahrendorf, 1998).

As with all gastrointestinal tumors, the diagnosis is routinely obtained by endoscopy and biopsy. Nevertheless, patients with dysphagia may in first instance have a barium swallow to verify whether a stenosis is present at all, and if so, where it is located. Not infrequently, esophageal carcinomas may grow mainly in the submucosa, so that mucosal abnormalities may not be very obvious at endoscopy. For staging, both contrast-enhanced CT and endoscopic ultrasound are primarily indicated. With endoscopic ultrasound (EUS), the layers of the esophageal wall can be nicely discriminated, and tumors can be diagnosed to either be confirmed to the mucosa and submucosa (T1), invade the muscular layer (T2), or breech the adventitia (T3 or T4). A discrimination between T3 and T4 (invasion of adjacent organs) is difficult, however, because EUS high-frequency probes are limited in penetration. Lymph nodes directly adjacent to the esophagus can be assessed and biopsied under endoscopic ultrasound guidance, if a suitable device is available. A precise discrimination of T stages lower than T4 may be of limited relevance for planning surgery, but is required prior to and after neoadjuvant therapy to assess the response to treatment. The strength of CT lies in the assessment of the overall extent of the tumor, a possible T4 stage with invasion into adjacent organs (e.g., trachea, left atrium, great vessels, thoracic vertebrae), and lymphatic and distant spread. CT is insensitive, however, in discriminating T1, T2, and T3 stages. Since both downstream and upstream lymph nodes may be involved, the neck, chest, and at least upper (if not the entire) abdomen has to be included. A postoperative CT study should be obtained as a baseline for follow up, because surgically induced alterations may

otherwise be hard to interpret and to discriminate from a recurrence. FDG PET/CT is not used routinely but in difficult cases, during staging as well as follow-up. If done, its CT part should be carried out as a full diagnostic protocol, including intravenous contrast, and not only in native, low-dose technique for attenuation correction and anatomical orientation.

Stomach cancer

For gastric cancer, the incidence and mortality have been constantly decreasing over the past decades, the 2012 mortality being 5.89/100,000 in men, and 3.14/100,000 in women, compared to almost 10-fold values around 1950 (Becker and Wahrendorf, 1998). Possible reasons among others are the consumption of fresh or refrigerated rather than nitrite-pickled food, or more effective treatment for chronic gastritis (including *Helicobacter*-associated disease). Nevertheless, gastric cancer is still a fatal disease once lymph node or distant metastases are present. According to the Laurén classification, tumors of the intestinal type are to be differentiated from diffuse tumors that lack adhesion molecules and may infiltrate the gastric wall in a single-cell pattern and extend far beyond what is evident clinically or at imaging. If resectable, it is treated by gastrectomy and lymph node dissection. Superficial tumors (T1a) may undergo endoscopic resection. If the resection has been radical, adjuvant chemotherapy is usually not given. In absence of distant disease, definite radiochemotherapy is a possible attempt at a cure. If distant metastases are present at the time of diagnosis, chemotherapy is indicated, and surgical procedures mainly serve to prevent symptoms, mainly obstruction.

The diagnosis is established by endoscopy and biopsy. To not miss a diffuse gastric carcinoma, special staining like PAS is needed to detect signet cells. For staging, hydro-CT and abdominal ultrasound, and endoscopic ultrasound are the imaging modalities of choice, CT mainly to detect a T3 or T4 stage, lymph node or distant metastases as well as a peritoneal spread and ascites. Nevertheless, a discrimination of an extension beyond the gastric wall (T3) may be difficult to discriminate from reactive inflammatory changes that often accompany gastric and also other gastrointestinal tumors, and lymph node metastases, especially those directly adjacent to the gastric wall, may be too small to appear suspicious or even be detected. Diffuse gastric carcinoma, not surprisingly, may show no circumscribed mass at all and be missed or grossly underestimated, and even a peritoneal dissemination may occur before a true gastric mass is apparent. CT has to cover the entire abdominal cavity, since peritoneal deposits may be present in the pelvis (a Krukenberg's tumor is an ovarian metastasis due to stomach cancer), and also the chest and infrahyoid neck, not to miss a Virchow's gland, a lymph node metastasis in the left venous angle. MRI is a special investigation to resolve open issues after CT and endoscopic ultrasound. FDG PET/CT is not routinely used for local staging but may be applied during aftercare for otherwise unclear lesions. Again, due to its single-cell infiltration pattern, diffuse gastric cancer will easily escape detection with PET/CT, and so will its metastases.

Cancer of the small bowel and appendix

Malignant tumors of the small bowel and appendix have in common that they are comparatively rare and usually inaccessible to endoscopy. If suspected clinically, contrast-enhanced hydro-CT in combination with abdominal ultrasound is usually the first imaging modality being used, but MRI is a good alternative, either in hydro technique as with CT, or, as a special investigation, with administration of a methyl-cellulose solution via a nasojejunal tube ("MR Sellink"), as it has been established for example, Crohn's disease. MR is especially useful if diffusion-weighted sequences are included that may highlight and draw the reader's attention to small lesions that would otherwise have escaped detection.

If PET/CT is being used, it should be carried out with CT as a full diagnostic, contrast-enhanced protocol. It should be considered that tumors of the small bowel or appendix not uncommonly have a neuroendocrine differentiation, in which case they may fail to take up FDG. 68-Ga-DOTA-TOC would then be a possible alternative.

Colorectal cancer

Colorectal cancer is among the three most common cancers and cancer-related causes of death in both sexes. Its mortality is on the decline, however. In 2012, it was 13.7/100,000 in men, and 8.2/100,000 in women (Becker and Wahrendorf, 1998). Its diagnosis is based on endoscopy and biopsy.

Colon and rectal cancer are fundamentally different regarding treatment protocols, and therefore also the required imaging procedures.

If no distant metastases are present, colon cancer is always treated by radical resection. The only imaging studies required preoperatively according to current guidelines are chest X-ray and abdominal ultrasound, to rule out lung or liver metastases. For rectal cancer, neoadjuvant as well as definite radiotherapy play a major role. As a consequence, thin-section MRI of the pelvis (CT in case of MRI contraindications) and endoscopic ultrasound are required to determine the distance of the tumor from the mesorectal fascia and diagnose possible perirectal lymph node metastases (**Fig. 6**). Their presence or absence is one criterion for the choice duration and fractionation of the neoadjuvant radiochemotherapy protocol. For both colon or rectal carcinoma, abdominal CT is indicated if there is suspicion of metastases, for example, at abdominal ultrasound. CT or MRI colonography are special investigations where the colon is inflated with air (or liquid endoluminal contrast agents with MRI). The tumor may so be seen as mural thickening and mass, and the depth of invasion into the wall or the surrounding be assessed. Additionally, 3D rendering virtual reality techniques can be used to generate colonoscopy-like views, allowing the user to "fly through" the lumen. The added value of CT or MRI colonography is obvious, but, considering the radiation dose, it should be reserved for resolving open questions that might influence clinical decisions, or rare cases where complete colonoscopy is not possible. Virtual colonoscopy may be used as an adjunct, but can neither replace CT or MR colonography or classical endoscopy, nor should it be used as a nonenhanced low-dose

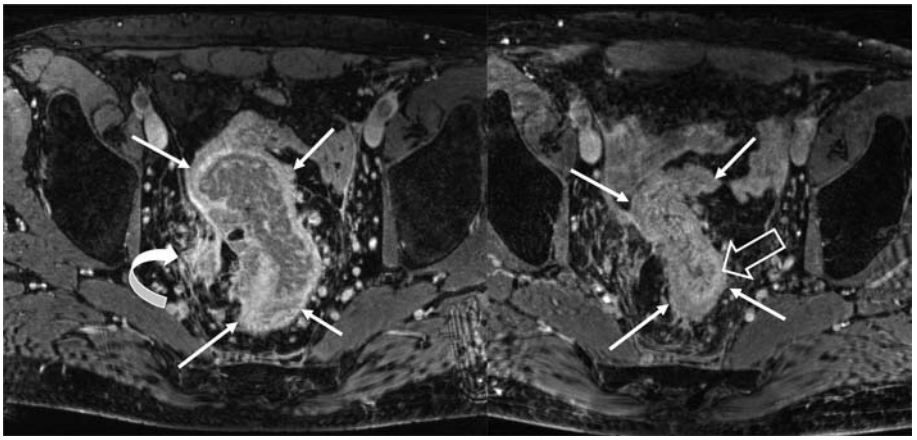

Fig. 6 Pelvic high-resolution MRI in a patient with locally advanced rectal cancer. On fat-suppressed, contrast-enhanced T1-weighted images at the time of diagnosis (A), there is a large rectal mass (*bold arrows*) with streaky infiltration into the mesorectal fat, and a broad extension to the mesorectal fascia (*curved arrow*), along with multiple enlarged lymph nodes within the mesorectum as well as along the pelvic wall. After neoadjuvant radiochemotherapy (B) there is marked remission of the tumor (*bold arrows*) as well as the extension to the mesorectal fascia and the lymph nodes. Note the recovery of the mural architecture in the rectal wall, the mucosa now being visible against the less enhancing submucosa (*open arrow*).

protocol for only visualizing the mucosal surface. Whether or not such techniques may in future be used as an alternative to colonoscopy for colon cancer screening is an open question. Currently, they clearly not being recommended for this purpose.

FDG PET/CT may have a peculiar role in colon cancer: Presacral tissue densities after primary treatment for rectal cancer often represent scar tissue, but their differential from presacral recurrences is often difficult. Here, a high uptake of FDG will point toward a recurrence as the cause. Furthermore, unlike in most other tumors, resection of metastases is an option in colorectal cancer, because there is a reasonable possibility that the visible metastases are the only ones. Whenever they are planned to be respected, a whole-body FDG PET/CT is a sensible choice to rule out additional metastases in other locations, that would prohibit such aggressive measures.

Hepatic Tumors

Focal hepatic lesions are an extremely common clinical problem, because they are frequent and also benign in most cases. The commonest tasks in which imaging studies are required are:

- To differentiate incidental liver lesions, usually detected by abdominal ultrasound,
- To stage for liver metastases in patients being diagnosed with for followed up for extrahepatic primary tumors,
- To diagnose and stage a suspected primary liver tumor.

Most incidentally detected liver lesions are benign (cysts, pseudotumors, hemangiomas, focal nodal hyperplasias, etc.). As a rule, the diagnosis of a simple cyst or a pseudotumor (e.g., focal sparing in fatty liver) should be made with ultrasound alone, without any further imaging or follow-up. Similarly, a lesion with the typical appearance of a hemangioma at ultrasound in a patient without a cancer history or risk factors should be definitely diagnosed with ultrasound, and have a single, final follow-up ultrasound for example, after 3 or 6 months. If one is unsure, it is better to refer the patient to someone more experienced with the technique than to order additional imaging studies. These are reserved for unclear cases, or for patients who have cancer in another location. If an additional CT or MRI would be performed anyhow (e.g., to stage a primary tumor in the abdomen), its protocol may be adapted in order to clarify the liver lesion. If not so, contrast-enhanced ultrasound (CEUS) would be first choice, because it implies no ionizing radiation, and in best case can be performed in the same session without leaving the patient in worries for longer time (**Fig. 7**). In large trials, CEUS has been found diagnostically equivalent to contrast-enhanced CT (Seitz et al., 2009; Strobel et al., 2009). If CEUS is unavailable or fails to resolve the issue, contrast-enhanced MRI including diffusion-weighted imaging is preferable over CT, at least in the interest of radiation protection. Furthermore, liver-specific contrast media are available in MRI, that may assist in differentiating liver lesions. In unclear cases, nuclear medicine studies (hepatobiliary or blood-pool scans) provide additional information to make the probable diagnosis.

When staging for liver metastases, the choice of the imaging method depends on the primary tumor and the a-priori risk for metastases. In many cases, CT or MRI of the liver will be included in the imaging protocol for primary staging, but should be supplemented by an abdominal ultrasound—if possible, after the CT or MRI, to help clarify unclear lesions, such as cysts or hemangiomas. It should be remembered that in cancer patients benign liver lesions are as frequent as in healthy persons.

Most primary liver tumors are either peripheral cholangio- or hepatocellular carcinomas (HCC). While HCC is common in Africa or the far east, following the endemic presence of hepatitis B virus and the exposure to aflatoxins, it is less common in Caucasians, mostly associated with alcoholic or nonalcoholic liver cirrhosis and/or chronic hepatitis B or C, or, less frequently, hereditary

Fig. 7 Longitudinal section of the right liver lobe during contrast-enhanced ultrasound (CEUS) in a patient with malignant melanoma. Unenhanced B-mode ultrasound of the liver had been normal. In the portal phase of contrast enhancement, there is a hypoenhancing, subdiaphragmal nodule (*arrow*), that progressed at follow-up and disappeared after immunotherapy, and was therefore diagnosed as a liver metastasis. As a rule, CEUS is equally sensitive and specific to CT or MRI, sonographic access provided.

hemochromatosis. It is a highly vascularized tumor with a strong tendency to invade portal venous branches, giving it the typical pattern of a strong contrast enhancement in the arterial phase of injection (which is uncommon in cholangiocarcinoma and most liver metastases) and a contrast washout in later phases. The primary treatment, depending on the number and size of lesions as well on the remaining liver function, consists of resection, local radiofrequency tumor ablation, or, in eligible patients, liver transplantation. In transplant-eligible patients, chemoembolization via a supraselective angiographic catheter or radiofrequency ablation may serve to prevent further tumor growth until a donor organ becomes available ("bridging"). In clinical trials, photon or particle radiation therapy are being evaluated. In case of irresectability or recurrence, sorafenib is effective for palliation and prolonging survival.

Cholangiocarcinoma usually shows a strong fibroplasia with only scarce vessels in its center. Cholangiocarcinomas are best imaged and staged with MRI (CT, if MRI is contraindicated) in combination with abdominal ultrasound. Imaging studies should be used to guide the biopsy to the vital periphery and avoid the desmoplastic reaction in the tumor's center, where it may be false negative. Owing to the aggressiveness of the tumor, both the entire abdomen and the chest (using contrast-enhanced CT) should be imaged.

For HCC, valid imaging studies are crucial: The presence of a lesion with typical enhancement pattern in a single imaging modality in a patient at high risk is accepted as proof of HCC, without the need for a biopsy. The modality may be contrast-enhanced CT or MRI, or contrast-enhanced ultrasound, all of which are seen as equivalent. Only in unclear cases either an additional imaging modality or biopsy is needed. Imaging also serves to diagnose multifocal lesions as well as portal venous invasion, that may preclude surgical resection.

Pancreatic Tumors

Ductal adenocarcinoma of the pancreas is one of the most fatal cancers. Although it is not exceedingly frequent, it is the fourth-most common cancer-related cause of death in men and women, and its frequency is on the slow rise. Smoking is a risk factor, but on the whole, there is no clearly definable risk population, and no effective and acceptable measures are available for early detection. Radical surgery is the only chance for a cure. The role of imaging is to enable a diagnosis as early as possible, but since the symptoms are unspecific at the beginning, ultrasound is the only modality that can be recommended to be used generously—knowing that its effectiveness in detecting pancreatic cancer in a resectable stage is yet unproven. In unclear findings, suspicious biochemical findings, suspicious and persistent pain (especially a combination of epigastric and middle back pain) in combination with limited sonographic access, contrast-enhanced CT or MRI are to follow. CT is used most frequently, because it will reliably image the entire abdominal cavity, and the chest if needed. MRI is equally capable, but more expensive and less well tolerated by the patient. Whenever the pancreas is well visible at sonography, contrast-enhanced ultrasound is a reliable and safe procedure to prove or rule out a focal pancreatic lesion, because pancreatic adenocarcinoma is almost always hypovascular compared to the normal parenchyma. It would clearly deserve to be used more frequently and could so obviate CT or MRI studies for unclear sonographic findings.

Endocrine tumors of the pancreas are an entirely different entity and may be found in patients with type I multiple endocrine neoplasia. Whereas some produce insulin, glucagon, gastrin or vasoactive intestinal peptide (VIP) and are therefore being suspected

because of endocrine symptoms (e.g., hypoglycemia, recurrent peptic ulcers, or watery diarrhea), a significant portion will be non-secreting. The probability of a malignant variant depends on the endocrine type and is highest in gastrinomas. Their morphology is often different from adenocarcinoma; typically they will be sharply delineated and hypervascular. As in other locations in the body, endocrine tumors of the pancreas express somatostatin receptors and can thus be detected by somatostatin analogs, using for example, octreotide scintigraphy or 68-Ga-DOTA-TOC PET/CT.

Tumors of the Kidney, Ureters, and Bladder

Renal carcinoma is a less common cause of cancer-related death. Its mortality in 2012 was 5.3/100,000 in men, and 2.2/100,000 in women (Becker and Wahrendorf, 1998). Its growth rate is highly variable, and symptoms like flank pain, or gross hematuria usually indicate advanced local disease. Apart from rare disorders like von Hippel–Lindau disease, there are no known risk constellations. Although no screening program exists, the most renal tumors are nowadays found incidentally on occasion of an abdominal ultrasound for any reason. As a result, most patients with renal cancer will be definitely cured. Apart from metastases to the lymph nodes, lung, and bones, two findings are peculiar: Renal cell carcinomas tends to invade the renal vein, extending along the inferior vena cava until above the diaphragm. Furthermore, pancreatic metastases may occur, even as a late recurrence, long after primary therapy. The treatment is almost exclusively surgical, whenever possible by kidney-preserving procedures, otherwise by nephrectomy.

Two kinds of space-occupying lesions in the kidney are definitely benign—cysts and angiomyolipomas. Cysts can be confidently diagnosed at ultrasound if they exhibit typical features. This, however may be difficult in case of limited sonographic access, so that contrast-enhanced CT or MRI may be necessary for clarification. The other entity, angiomyolipoma, has a typical morphology at ultrasound (high echogenicity, sharp delineation), but as state of the art, a second imaging modality (usually native CT) is required to prove the presence of significant amounts of fat in the lesion.

As a rule, all focal renal lesions that are neither simple cysts nor angiomyolipoma are suspicious and should be respected, because the majority of them will be malignant, and no imaging modality is capable of excluding this.

Cancer of the renal pelvis, ureters, and bladder are entirely different clinically and in etiology. Typically, they are caused by chronic exposition to carcinogens, most importantly smoking, but also for example, aniline dyes. Therefore, as many as 50% of patients may have recurrences or second neoplasms of the urothelium at the time of diagnosis or in the later course. Hematuria is the leading symptom in 75% of patients. The treatment is mainly surgical, but superficial bladder tumors might be locally ablated via cystoscopy. In advanced bladder tumors not undergoing cystectomy, instillation of BCG has successfully been used to temporarily control the disease.

CT or MRI may be limited to the kidneys if only carried out to rule out a malignant lesion. Whenever the ultrasound findings are highly suspicious for malignancy, or gross hematuria is the chief symptom, the heart should be included, to detect a possible thrombus in the vena cava, as well as the entire abdomen including the bladder. Furthermore, the urine collecting system has to be assessed for possible neoplasms as a cause for hematuria. Therefore, scan timing in a renal CT or MRI protocol will differ from that in a standard abdominal one. A baseline native scan (either acquired prior to contrast infusion or, if DECT is being used, as a virtual native scan) is needed, to detect a weak contrast enhancement in a focal lesion. An arterial phase is optional and often omitted. The most important will be a scan in the phase when both renal cortex and medulla are enhanced, which is later than the usual portal phase, that is, 120 s post infusion. Finally, a CT urography, with contrast filling of the collecting system is obtained after 5 min. The same timing will apply if MRI is used instead of CT.

For bladder cancer, ultrasound as well as cystoscopy are the primary examinations, and contrast-enhanced MRI whenever invasion of the muscular layer or extension beyond the bladder are suspected. As a rule, the entire urine collecting system including renal calices and pelvis as well as ureters needs to be examined with CT or MRI urography, due to the high prevalence of simultaneous second neoplasms, if not plain X-ray films with retrograde contrast filling of the ureters or ureteroscopy are performed on occasion of cystoscopy.

Prostate Cancer

Prostate cancer is the most common malignant tumor in men. Although there has been a steep rise in incidence, its annual mortality is slowly declining, being about 11/100,000 in 2012, indicating that the rising incidence is mainly a screening artifact due to the frequent measurement of PSA in serum. This means that there is a significant risk of overdiagnosis and overtreatment, if not measures are taken to identify high-risk and low-risk cancers and manage them adequately. In this process, imaging plays a pivotal role, using four tools: Endorectal ultrasound-guided biopsies, MRI, MRI/ultrasound fusion biopsies, and PET/CT or PET/MRI with radiolabeled PSMA ligands.

First, patients with suspected prostate carcinoma will undergo systematic endorectal, ultrasound-guided biopsy and, if positive, nodal and skeletal imaging for staging, and then treatment: Radical prostatectomy, definite intensity-modified or particle radiotherapy, or, in case of metastases, antihormonal therapy. In case of negative biopsies despite elevated or increasing serum PSA levels, or to stage biopsy-proven prostate carcinoma for local extracapsular extension, multiparametric MRI is the method of choice. It combines T1- and T2-weighted imaging with diffusion-weighted imaging (including calculated maps for the apparent diffusion coefficient) and DCE MRI. 1H spectroscopy is no longer standard part of the protocol. Depending on the morphologic and functional features, possible lesions may be classified according to their probability of malignancy, using, for example, the PI-RADS that was published in its 2nd version in 2015 (American college of radiologists, 2015). Using commercial image fusion system,

suspicious lesions may be targeted and biopsied under ultrasound guidance from a perineal approach, although they may be invisible at ultrasound. This is particularly useful to reach suspicious lesions that may have been missed by standard systematic biopsies because of their location (e.g., ventrally).

The development of a PET ligand to the prostate-specific membrane antigen (PSMA) has been a revolution in prostate imaging, since it enables to locate metastases even in otherwise unsuspicious structures, like normal-size lymph nodes. The first available F18-labeled PSMA-compounds and the currently distributed tracers labeled with 68-gallium are excreted in the urine. The excreted tracer in the urinary bladder may hinder the detection of local recurrent tumors in close proximity to the bladder. However, 18-fluorine-labeled tracers that are not primarily renally excreted will soon be available. This might not only facilitate the detection of prostate carcinoma but also support the delineation of the gross tumor volume for radiotherapy planning. Optimally, for imaging the prostate itself using PSMA ligands, PET/MRI hybrid scanners would be preferable over PET/CT machines.

Tumors of the Uterus and Ovaries

Uterine tumors may be either endometrial adenocarcinoma or cervical squamous cell carcinoma, with an annual mortality of 2/100,000 and 1.9/100,000, respectively. They may be treated by resection or radiochemotherapy, depending on the local stage and presence or absence of nodal or distant metastases. Cervical carcinomas, if locally advanced or recurrent, can be devastating regarding quality of life. The diagnosis is typically made by either abrasion (corpus) or cone excision (cervix), supported by bimanual palpation and endovaginal or endorectal ultrasound for local staging. MRI is primarily indicated for staging both tumors locally, and should include the entire abdominal cavity to detect spread to retroperitoneal lymph nodes—that would be considered distant, not regional. The main target feature when imaging corpus tumors will be the proportion of the uterine wall occupied by the tumor. For cervical tumors, particular attention is paid to an infiltration of the parametria, the bladder, and the rectum, and the downwards extension into the vaginal wall. FDG PET/CT is a specialized investigation in cases where the presence or absence of metastases remains unclear.

Ovarian cancer accounts for 5/100,000 deaths per year and is often diagnosed in an advanced, incurable stage. Due to the high prevalence of benign, and mostly cystic masses, the confident exclusion of ovarian cancer may be highly challenging, endovaginal ultrasound being the primary imaging modality of choice. Here, the presence of solid or papillary components, thick septa or strong vascularization at color Doppler will argue in favor of malignancy. For MRI as a problem solver, recommendations have recently been released (Forstner et al., 2017), that pay particular attention to DCE MRI and diffusion-weighted imaging for discriminating unclear masses. Nevertheless, laparoscopy and biopsy are indicated early, not to miss the disease in a curable stage. Once the diagnosis of ovarian cancer has been made, staging has to be completed, preferably by abdominal ultrasound and CT of the chest and abdomen. Bone scans are usually not required, because bone metastases due to ovarian cancer are extremely rare.

Breast Cancer

Breast cancer is the commonest tumor in women and with an annual mortality of 16.1/100,000 also their leading cause of cancer death. Besides eradicating the disease, all treatment approaches strive at limiting resection as much as possible. This in mind, imaging is directed at enabling a diagnosis as early as possible, and at visualizing the true extent of the tumor inside the breast, in order to guide breast-conserving surgery. Mammography screening programs are in action in most countries, but despite rigorous quality assurance and training of the readers, only about 50% of all women who finally undergo biopsy for a screening-detected lesion will in fact have cancer.

Besides the introduction of digital mammography and constant improvement of ultrasound technology, three developments need mentioning that have significantly influenced detection and staging of breast cancer, or can be expected to do so: Digital tomosynthesis, DCE MRI, and diffusion-weighted MR imaging. Digital tomosynthesis is a technique where the breast remains fixed between the detector and the compression plate, and the tube is being moved over an angle of up to 50 degrees while the beam is on. From the data, stacks single slices (e.g., 1 mm thick) can be reconstructed, which permits an improved delineation of nodules and masses against other overlying structures. This is possible without significant radiation dose penalty, and additionally conventional mammography images can be extracted, whose quality is apparently not inferior to that of a normal mammogram (Zuley et al., 2014). DCE MRI has been investigated since the early 1990s, and has now become part or the routine. Its role as a problem solver for unclear lesions is limited, and biopsy under imaging guidance is clearly the best way toward a reliable diagnosis. Nevertheless, it contributes significantly to assessing the extent of even complex shaped tumors, multifocal or multicentric lesions, and even DCIS components are visible owing to their contrast uptake, especially if they are high-grade (**Fig. 8**). Other clear indications are breasts with implants (where neither mammography nor ultrasound make sense), and suspicious lesions post treatment, where scars have to be differentiated from residual or recurrent tumor. Diffusion-weighted images, finally, are difficult to obtain in good quality, owing to motion and magnetic field inhomogeneity along the complex-shaped tissue–air interface. Nevertheless, when fine-tuning and quality assurance are thoroughly carried out, the images will reliably highlight malignant foci against a signal-void background (**Fig. 9**). In a prospective study, an abbreviated (<10 min) protocol applied for women scheduled for biopsy due to screening-detected, suspicious lesions, diffusion-weighted imaging was sensitive and specific enough to possibly spare women without breast cancer a biopsy, with extremely few true cancers being missed (Bickelhaupt et al., 2015). Such protocols do not require any contrast agent and are short enough to be used on large scale. Whether or not they might be used instead of screening mammography in the future, is yet undetermined.

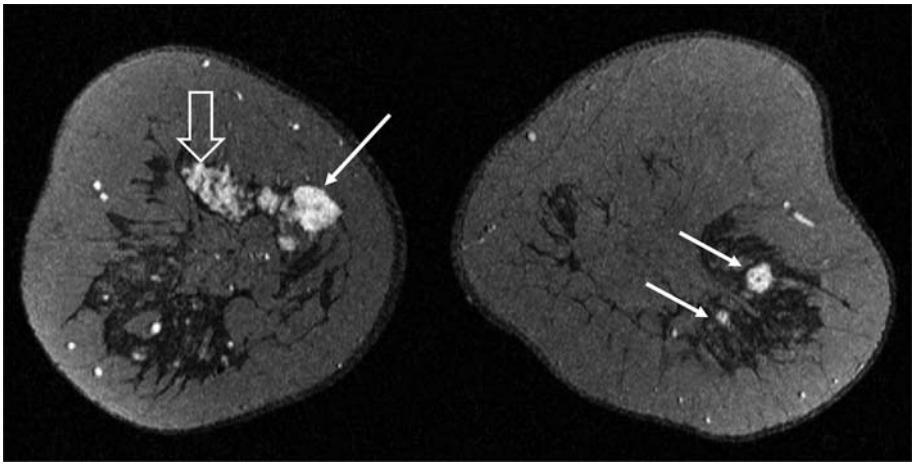

Fig. 8 Dynamic contrast-enhanced T1-weighted images in a patient with multifocal and bilateral breast cancer. Note the solid, circumscribed nodules (*bold arrows*) that correspond to invasive foci. Additionally, there is an extensive in-situ component that is visible as a less intense, inhomogeneous area of contrast enhancement with a segmental configuration (*open arrow*).

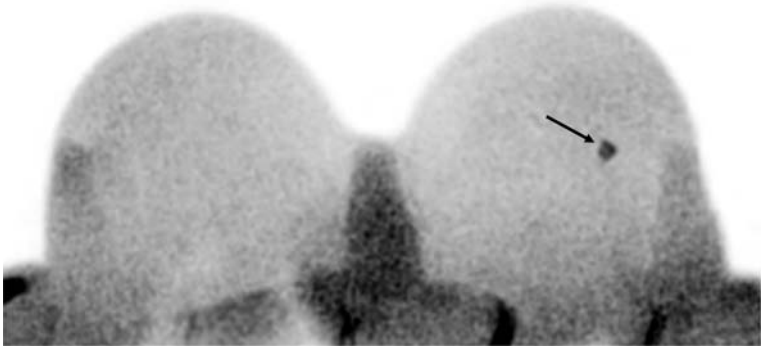

Fig. 9 Craniocaudal projection of axial diffusion-weighted images with background suppression in a participant of the German mammography screening program who had been recalled for a suspicious (BI-RADS 4) mammography finding in the left breast. The projection image permits to check the breasts for lesions with restricted diffusion at a single glance. In this case, the mammography finding corresponds to a lesion less than 10 mm in diameter that was histologically confirmed to be a ductal invasive carcinoma. Hematologic and Lymphatic Neoplasms

Leukemia is being diagnosed based on blood and bone marrow samples. Other than myeloid ones, lymphatic leukemias are often accompanied by lymph node and sometimes extranodal masses that will be seen in imaging studies. In chronic lymphoid leukemia, which is in fact an indolent non-Hodgkin lymphoma, imaging is part of staging and follow-up. For malignant lymphomas, imaging of the neck, chest, and abdomen is mandatory to stage the disease and to assess its response to treatment (Cheson et al., 2007), usually by a combination of abdominal and cervical ultrasound and contrast-enhanced CT. In patients with a favorable long-term prognosis, particularly young ones, it is recommended to replace CT by MRI, at least for the abdomen. Furthermore, FDG PET/CT is recommended in guidelines for Hodgkin lymphoma and those non-Hodgkin lymphomas that are typically FDG-avid. It may supplement primary staging, but its most important role is to assess the presence or absence of viable lymphoma at an interim staging and/or after completion of the primary treatment. Especially when there was bulky disease at diagnosis, macroscopic residuals will persist after treatment that may or may not contain viable lymphoma tissue. Increased FDG uptake in these lesions almost invariable heralds a recurrence and also indicates an unfavorable prognosis. Furthermore, FDG PET/CT may be indicated whenever there is suspicion of recurrence during the later course.

Multiple myeloma, formally a non-Hodgkin lymphoma, is a monoclonal plasma cell disorder that arises primarily in the bone marrow and interacts with osteoclasts and osteoblasts in a specific fashion. It may cause destructions to mineralized bone, along with anemia, hypercalcemia, and renal damage, which are indications for systemic treatment. There are, however, asymptomatic precursor stages, namely monoclonal gammopathy of unclear significance (MGUS) and smoldering multiple myeloma (SMM), that are at risk for progression into a symptomatic stage, but do not yet require treatment. Together with biochemical and bone marrow diagnostics, imaging plays a pivotal role for decisions on treatment. For assessing the integrity of mineralized bone, the previously used plain X-ray skeletal survey are now being substituted by noncontrast whole-body CT, because the latter is more

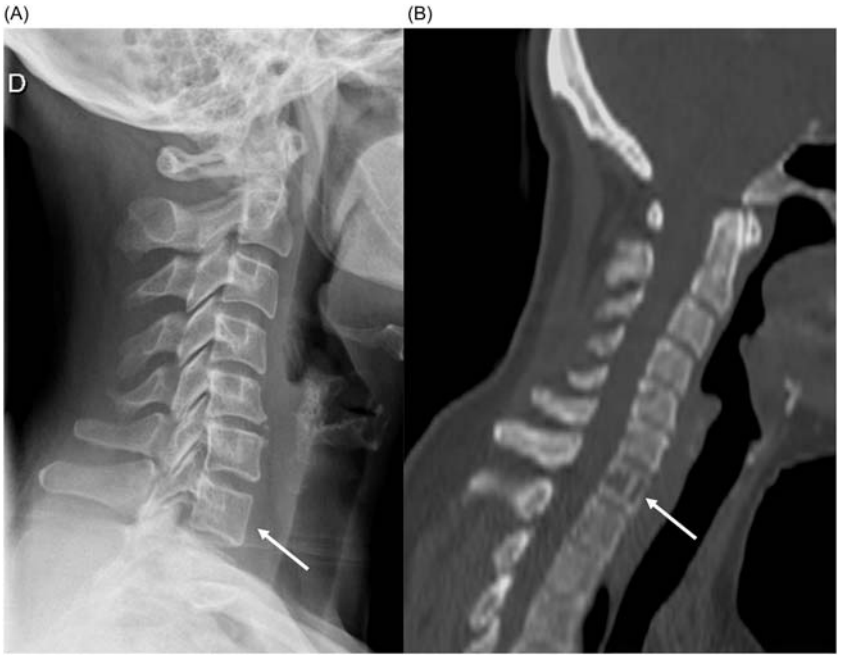

Fig. 10 Lateral X-ray plain film of the cervical spine (A) in a patient with smoldering multiple myeloma and so far without end organ damage. A sagittal reconstruction from an unenhanced, low-dose CT obtained within 4 weeks (B) shows a lytic bone lesion (*arrow*) that is invisible on plain films. The patient is therefore upstaged to symptomatic multiple myeloma, where systemic treatment is indicated.

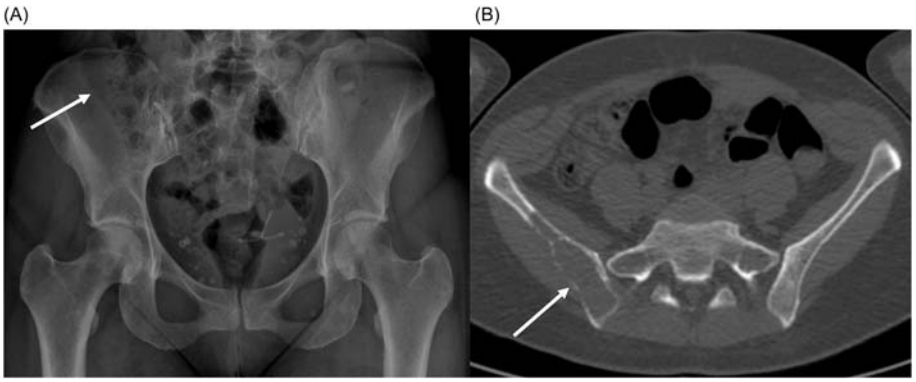

Fig. 11 Pelvic X-ray film (A) and CT (B) in a patient with multiple myeloma. On CT, a large destructive lesion in the iliac bone (*arrow*) is easily detected and was originally missed on plain films. Retrospectively, one can discriminate the vertical contour of the lesion (*arrow* in A), but it was obscured by overlying bowel gas.

sensitive and specific for bone destructions (**Figs. 10 and 11**), and its findings are of proven prognostic significance (Hillengass et al., 2017). For assessing the bone marrow and possible extraosseous myeloma foci, noncontrast whole-body MRI is now standard and is capable of detecting diffuse or focal bone marrow lesions that still have left the cortical and cancellous bone intact. According to the revised criteria of the International Myeloma Working Group, the presence of more than one focal bone marrow lesion is an indication to treatment, even if the mineralized bone remains intact (Rajkumar et al., 2014). FDG PET/CT is a valid modality for detecting focal myeloma infiltrates, but its sensitivity for diffuse bone marrow involvement is variable and probably dependent on the density of infiltration. If it is used, the CT data should be acquired using a full diagnostic protocol and enable a reliable assessment or the mineralized bone—and so to spare the patient an additional skeletal CT. Whole-body diffusion-weighted imaging is now a standard supplement to MRI in many centers and is extremely useful to facilitate the detection of diffuse and focal lesions, even in unusual locations (**Fig. 12**).

Tumors of the Bones and Soft Tissue

Primary bone and soft tissue malignancies are relatively rare tumors. The modality of choice to approach the diagnosis depends on the location. For primary bone tumors, diagnostic criteria applied to plain X-ray films have been established over many decades and

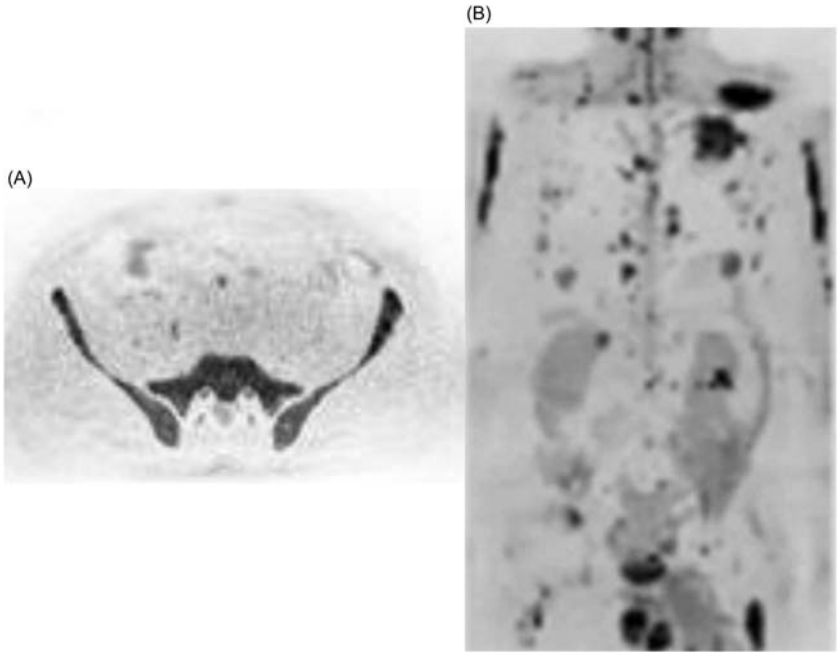

Fig. 12 Diffusion-weighed imaging (DWI) in plasma cell diseases. A transverse section at the level of the pelvis shows a diffuse infiltration pattern (A). A frontal projection image in a patient with a multifocal infiltration pattern, with lesions (B), for example, in the left scapula, left upper chest wall, both humeri, left femur, and numerous others.

remain valid. The first task of the reader is to identify tumor-like lesions where a biopsy should not be performed, because it is either unnecessary or even likely to yield falsely suspicious histologic findings that result in invasive measures ("do not touch lesions"). Of the remaining, some can be confidently diagnosed based on the plain film morphology, location, and patient's age, but in some the diagnosis will remain unclear until resection. Considering that such tumors are rare, and there are few radiologists who are truly experienced, it is strongly advised to seek an expert's opinion and to consult an orthopedic surgeon even before a biopsy is attempted. CT and MRI are valuable adjuncts for making the diagnosis, but their most important role is to delineate the true extent of the tumor, beyond what is visible on plain films.

For primary soft tissue tumors, MRI, CT, or ultrasound again serve to identify typically benign entities (e.g., lipoma), and to identify the organ or compartment of origin. If not the entity is evident from the lesion's imaging morphology (e.g., liposarcoma) or location, the contribution of imaging, including PET/CT, to making the diagnosis is limited. Such tumors will be respected, taking care of their integrity, in order not to contaminate the operation bed. Following up an unclear soft tissue mass is definitely inadequate.

Imaging Distant Disease

Usually, regional lymph nodes will be assessed when imaging the primary tumor, as outlined above, and some protocols also account for the most common distant metastases. In special situations, imaging is mainly dedicated to detecting distant disease. The most important applications are:

- Whole-body imaging: PET/CT is a valid method for lymph node as well as distant metastases, using FDG, PSMA ligands, DOTA-TOC or other tracers, depending on the histology. Diffusion-weighted MRI is sensitive for distant as well as lymph node metastases, but in the latter it is not specific for malignant involvement. Like metastases, reactively altered lymph nodes have a high signal. For brain metastases, neither FDG PET/CT nor diffusion imaging are valid, because of the brain's high FDG uptake and physiologic diffusion restriction.
- Detecting lung metastases: The modality of choice is CT. If for any reason no information about soft tissue is needed, it can be performed without contrast medium and in low-dose technique, which will keep the effective dose below 2 mSv, usually even lower.
- Detecting lymph node metastases: MRI contrast media dedicated to lymph node imaging have been on the market, but have been unsuccessful there and meanwhile withdrawn. For superficial lymph nodes, high-frequency ultrasound (14 MHz or higher) is clearly the best and cheapest method, but requires a skilled and experienced examiner.
- Detecting liver metastases: Usually, the liver is included in the primary imaging protocol. If examined alone, contrast-enhanced ultrasound is the first method to suggest, because it is sensitive, specific, and cost-effective. Alternatives are contrast-enhanced CT

or MRI including diffusion-weighted sequences. FDG PET/CT may be limited in value because of the moderately high background uptake of the liver itself.

- Detecting CNS metastases: The method of choice is clearly contrast-enhanced MRI, which is superior to all competing modalities. If meningeal spread is suspected, longitudinal, contrast-enhanced images of the entire spinal canal are added.
- Detecting skeletal metastases: 99m-Tc-Bisphosphonate bone scan continues to be the standard but has shortcomings in highly lytic lesions (e.g., due to thyroid or renal cancer) because the bony structures are either completely destroyed or the metastases induce no reactively increased bone turnover. The same may apply to pure bone marrow deposits. PET/CT with NaF-18 is an alternative to bone scans whenever 99m-Tc is unavailable but has the same limitations.
- Cancer of unknown primary (CUP) is a special indication. Usually, the origin of the resected tumorous tissue will be tried to discriminate from the pathological workup of the biopsy. If this is unsuccessful, the imaging methods are tried to be wisely chosen, along with for example, an endoscopic search. PET/CT is often included but may be unsuccessful if the tracer is not being taken up, or the assumed primary tumor is very small, as for example, in malignant melanoma. By the same token, in widespread disease with a high tumor load, it will be difficult to discriminate the metastases from the tumor of origin.

Response Monitoring

A tumor's response to treatment is generally attributed to a reduction in size, which is the sole criterion in almost all formal response criteria, including those for immune therapy. Powerful software tools are clinically approved that support physicians in formal response assessment in clinical trials. However, reduction in size occurs relatively late in the course of the treatment, with few exceptions like some lymphomas, where one can assume that treatment-induced apoptosis rather than necrosis is the predominant response mechanism. Therefore, functional features have been and are being explored to mirror or predict treatment response. The best evaluated one is the FDG uptake in PET/CT (Fig. 13), which in many tumors has been shown to be reduced much earlier than any changes in tumor size become apparent. The enhancement of contrast agents, that can easily be picked up in

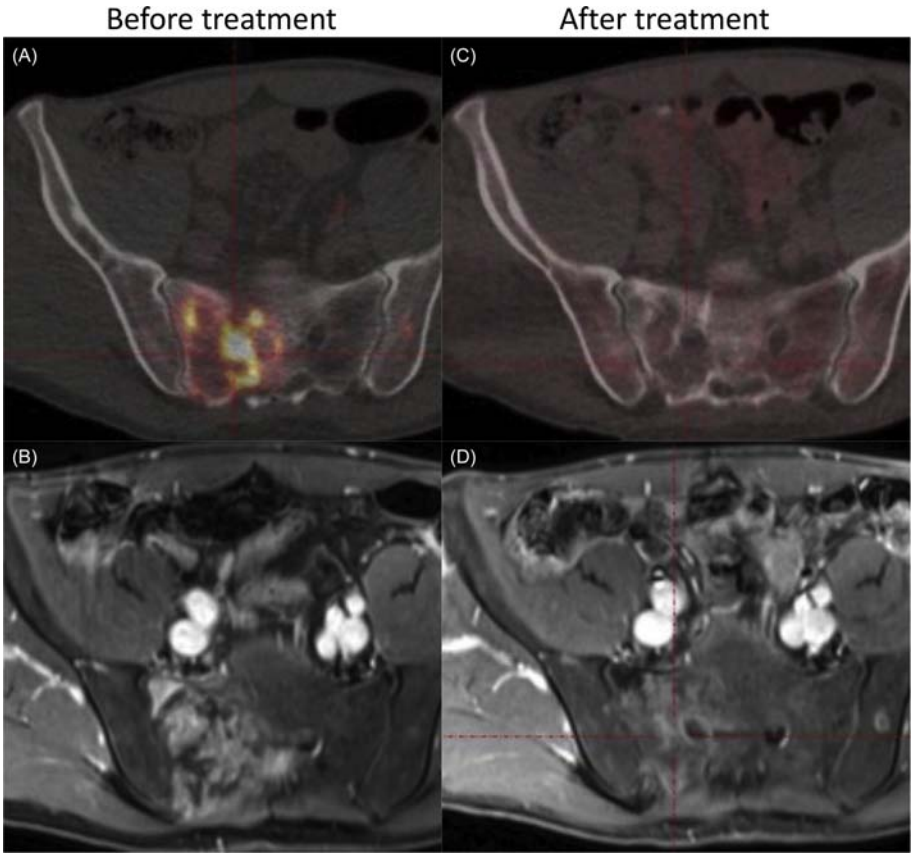

Fig. 13 FDG-PET/CT (A and C) and contrast-enhanced, fat-suppressed T1-weighted MRI (B and D) in a patient with a large, destructive myeloma infiltrate in the right sacral bone, obtained before (A and B) and after (C and D) high-dose chemotherapy with stem cell support. Initially, there is intense contrast enhancement and marked FDG uptake, both being markedly reduced after treatment. Courtesy of Dr. Bettina Beuthien-Baumann, Heidelberg.

contrast-enhanced ultrasound, CT or MRI, or can be formally quantified in dynamic MRI, is another criterion and is for example, being used for gastrointestinal stroma tumors (GIST), or hepatocellular carcinomas. Changes in diffusion-weighted imaging are further, possible criteria that are being investigated. Nevertheless, the current state is that the disappearance or non-progression of lesions remains the chief response criterion, and that functional interim tests for deciding upon a preterm change in treatment regimen are rarely in action, with rare exceptions. In this context, FDG-PET/CT is being used in malignant lymphoma for response assessment after primary chemotherapy, and increasingly for interim staging during treatment. Whether or not these studies will contribute to decisions regarding the therapy regime, is still open.

Acknowledgments

The author wishes to cordially thank Dr. Bettina Beuthien-Baumann for her support in the field of nuclear medicine, and for her very helpful discussion of this manuscript.

Opisthorchis viverrini, *Clonorchis sinensis*, and Cholangiocarcinoma

Catherine de Martel and Martyn Plummer, International Agency for Research on Cancer, Lyon, France

Opisthorchis viverrini (O. viverrini) and *Clonorchis sinensis (C. sinensis)* are trematode (flatworm or fluke) parasites belonging to different species, but members of the same family, Opisthorchiidae. They are found in specific endemic areas in Eastern Asia and the Russian Federation. Because these flukes establish chronic infection within intrahepatic bile ducts, they are also commonly called "liver flukes". Both species are similar in morphology, life cycle, and mode of transmission. After years of chronic infection, the damage caused by the parasites may lead to the development of the bile duct cancer cholangiocarcinoma (CCA), which is the second most common primary liver cancer after hepatocellular carcinoma and bears a very poor prognosis. In 1994, the International Agency for Research on Cancer (IARC) classified *O. viverrini* as carcinogenic to humans (group 1 in the scale used by IARC to assess strength of evidence); *C. sinensis* was only classified as probably carcinogen to humans (group 2A) due to the limited number of human studies published at that time. In 2009 however, new data had become available and allowed the classification of *C. sinensis* in group 1 as well, with sufficient evidence in humans to conclude that both parasites cause CCA in endemic regions.

Geographical Distribution and Burden of Infection

Within areas of Eastern Asia and the Russian Federation, the geographic pattern of liver fluke infection is very uneven (Fig. 1), but high rates are more likely seen in rural than urban environments, especially in wetlands and agricultural areas. Prevalence of liver

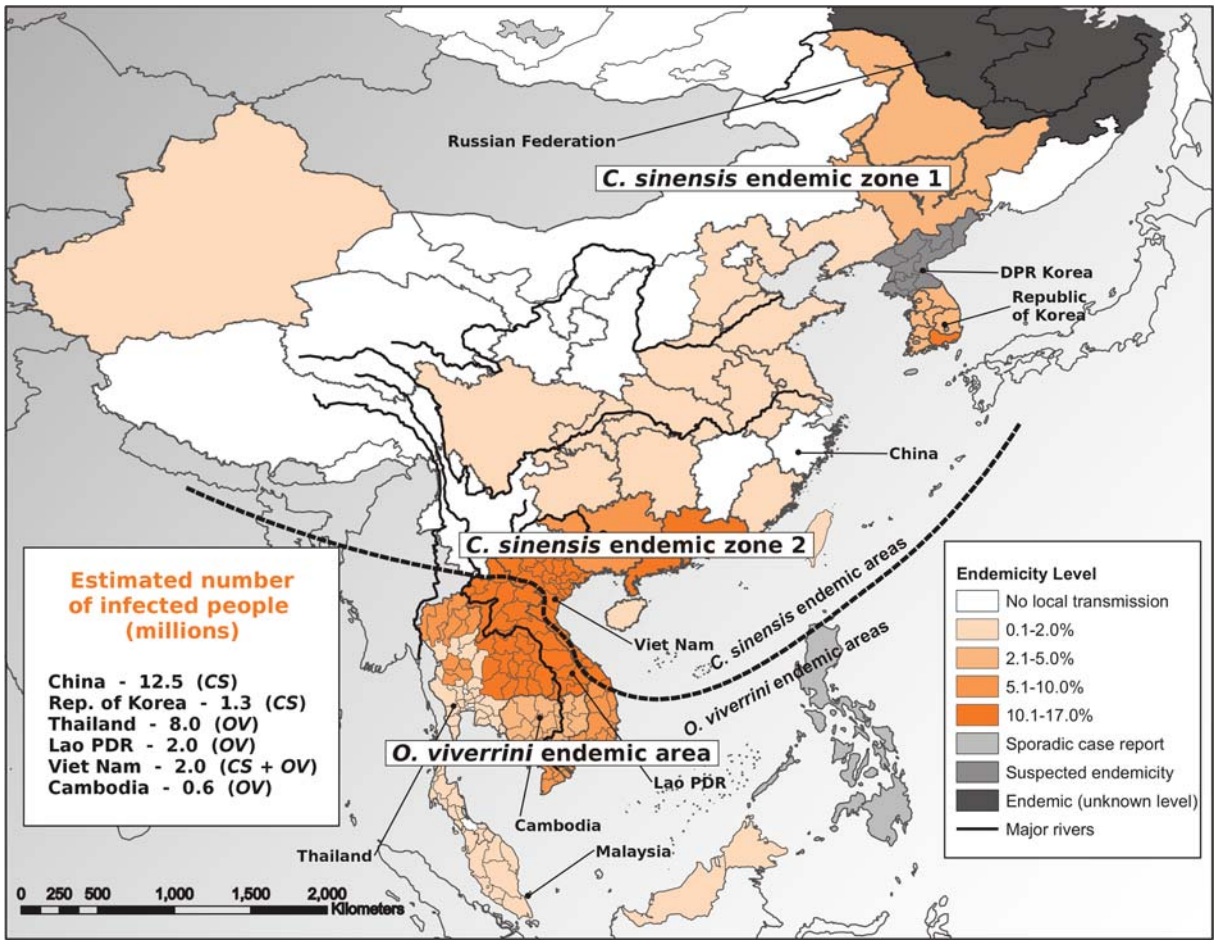

Fig. 1 Prevalence of liver flukes in Eastern Asia. Modified from *Opisthorchis Viverrini* and *Clonorchis Sinensis*. *IARC Monograph*, **100B**, 345. http://monographs.iarc.fr/ENG/Monographs/vol100B/index.php. Courtesy of Dr. Song Liang, Department of Environmental and Global Health, College of Public Health and Health Professions, University of Florida, USA, who did the art work based on data provided by the Working Group.

fluke infection depends on the distribution of fresh water, specific intermediary hosts (snail and fish), and local customs of eating traditional dishes made of raw or undercooked fish. Men are more frequently infected with liver flukes than women, especially in areas where *C. sinensis* infection is endemic: in these areas, the prevalence sex ratio (M/W) is around 2.0 whereas it is only around 1.2 for *O. viverrini* infection. Precise estimates of the number of infected people are extremely difficult to obtain as epidemiological studies are few and patchy, and the disease occurrence shows high variation within small geographical areas. For example, the results of field surveys in Kampong Chan province, Cambodia for the prevalence of *O. viverrini* showed that endemic villages (population prevalence of 30%) and non-endemic villages (population prevalence of 0%) coexisted within a distance of only 9 km, whereas the raw freshwater fish consumption rates were very high in all villages. Nationwide surveys prove very difficult to undertake, until the complex human and environmental factors that influence the distribution of liver fluke infection in endemic areas are fully understood.

C. sinensis

The world burden of *C. sinensis* infection is much higher than that of *O. viverrini*, as the parasite is found in a much wider area. *C. sinensis* is endemic in Eastern Asia, namely in China, the Republic of Korea, northern Viet Nam and eastern parts of the Russia Federation (see **Fig. 1**). It is also probably endemic in the Democratic People's Republic of Korea, and possibly in Malaysia. Although *C. sinensis* was highly prevalent in Japan decades ago, it is now extremely rarely seen there. Rare cases have also been reported in some other countries or areas as a result of tourism or immigration. In Viet Nam, *C. sinensis* is endemic in northern provinces, whereas *O. viverrini* is detected in central provinces.

Estimates of the total number of people infected with *C. sinensis* in the world have risen from 7 million in the 1990s to 15 million in 2004. This increase is due to several factors: population growth in major endemic areas during this period, the expansion of freshwater fish aquaculture, and better performing food distribution networks. One should add to these factors the difficulty for the elderly to modify their cultural habit of consuming undercooked or raw fish, while the young also become progressively accustomed to this habit. More recent estimates advance a total number varying between 12.5 and 35 million infected people worldwide, acknowledging that these numbers might only reflect the tip of the iceberg.

China alone bears the main burden of *C. sinensis* infection (over 80%). The parasite is found in 25 provinces but the population prevalence varies considerably, ranging from sporadic in some provinces (0.1% in Shandong or Sichuan provinces) to highly prevalent in others (70% in some areas from Guangdong province). The two main endemic areas are situated in the Southeast (Guangxi and Guangdong provinces) and in the Northeast (Heilongjiang province) (see **Fig. 1**). Note that some areas such as Hong Kong or Shanghai are not endemic for the parasite, but infections may still be acquired there—as in other non-endemic areas of China—by eating raw fish transported from endemic areas.

O. viverrini

O. viverrini is highly endemic in the northeastern region of Thailand, in Cambodia, in Southern regions of the Lao People's Democratic Republic, and in central Viet Nam (see **Fig. 1**). The number of people infected in these countries is estimated to be around 8 million in Thailand and 2 million in the Lao People's Democratic Republic. No national prevalence data are available in Viet Nam, but several hotspots for the infection have been recognized in the center of the country, including Nam Dinh and Ninh Binh provinces, with population prevalence of around 30%. Similarly, four Cambodian provinces (Takaev, Kandal, Kampong Cham, and Kampong Thom) have been identified as endemic areas of *O. viverrini* infection in a study conducted between 2006 and 2012 in five provinces, but nationwide surveys are still lacking, and other endemic area are yet to be precisely described.

Life Cycle of the Parasites

As food-borne trematodes, *O. viverrini* and *C. sinensis* have similar life cycles (see **Fig. 2**). People that have a habit of eating raw or uncooked freshwater fish constitute the final hosts for the worms, but so do a wide range of wild or domestic fish-eating animals such as dogs, pigs and cats. The elaborate life cycle of the parasite involves two separate intermediate hosts living in fresh water.

Adult liver flukes may live in their final hosts for years: in absence of treatment, their lifespan in humans can be as long as 25–30 years. Laid eggs are produced in the biliary tract by hermaphrodite adult worms (up to 4000 eggs per worm per day) and then eliminated with feces. If eggs happen to fall into freshwater reservoirs, they may then be ingested by specific aquatic snails, which constitute the primary intermediate hosts; eggs hatch into the snail as miracidiae, that is, ciliated larvae, and after a 90 days cycle of reproduction, cercariae, that is, free swimming larvae, escape from the snail into the water and adhere to the flesh of susceptible fish species, secondary intermediate hosts. Cercariae penetrate the subcutaneous tissues and muscle of the fish and slowly mature as metacercariae, its final larval form, within 45 days. The life cycle ends when definitive hosts (i.e., humans or other mammals) catch and eat raw or undercooked infected fish. Through gastric acidic digestion, the metacercariae separate from the fish, excyst in the duodenum of the host and migrate into intrahepatic bile ducts where they develop into adult worms.

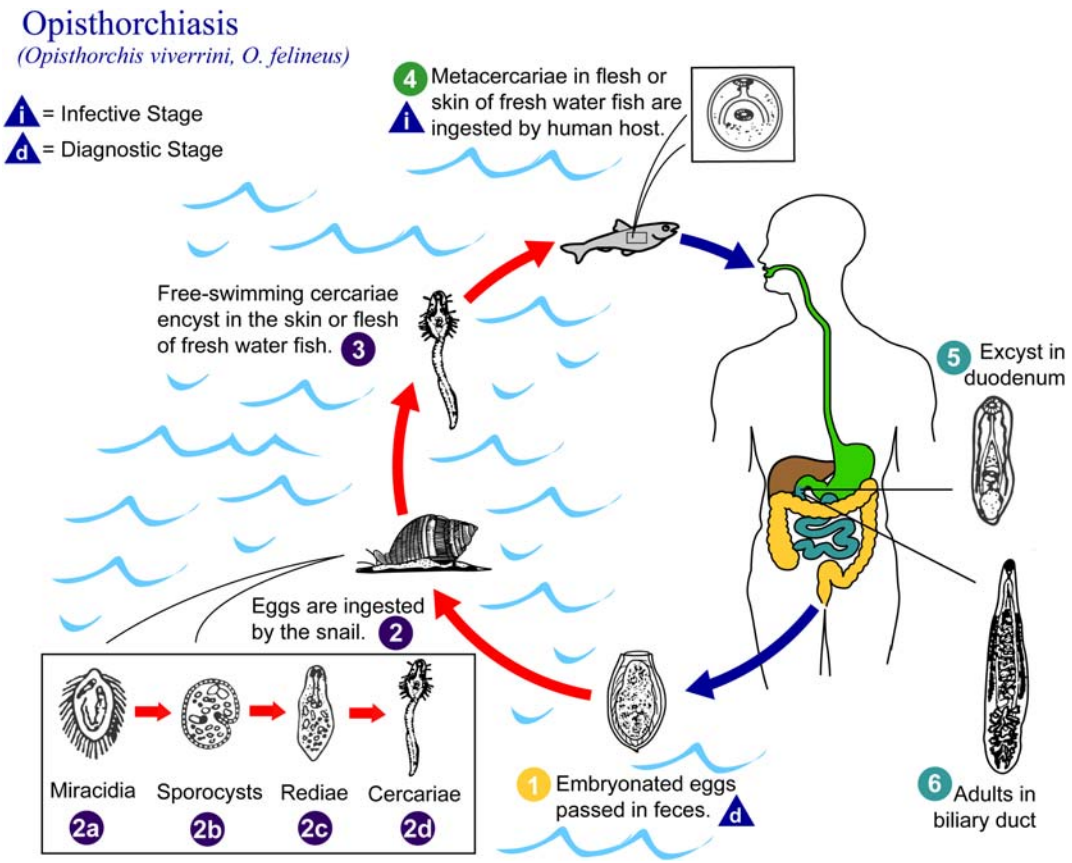

Fig. 2 Life cycle of *O. viverrini* and *C. sinensis*. From Centers for Disease Control and Prevention. https://www.cdc.gov/dpdx/opisthorchiasis/index.html and https://www.cdc.gov/dpdx/clonorchiasis/index.html. Courtesy of Alexander J. da Silva, PhD, and Melanie Moser.

Clinical Symptoms and Complications

O. viverrini and *C. sinensis* share the same clinical manifestations. The variations described in different geographical areas are more likely to reflect the duration and intensity of infection or the nutrition and comorbidity affecting the host than differences due to the species.

Clinical symptoms are related to the intensity of the infection. Infections involving < 100 adult worms are usually asymptomatic, but even in heavily infected hosts, only 10% show clinical manifestations. Common symptoms are unspecific and intermittent and may include asthenia, insomnia, pain in the right upper abdominal quadrant, nausea, anorexia, headache, dizziness, weight loss and diarrhea. If undertaken, abdominal ultrasound examination may show an enlarged gallbladder, and the presence of sludge and/or gallstones. Periductal fibrosis seen as periportal echoes along the intrahepatic biliary trees is also a common ultrasonographic feature in chronic liver fluke infections. In children, heavy infection may lead to slower growth or developmental retardation.

A small percentage of patients might develop complications, ranging from cholecystis, cholangitis, and pancreatitis, to cholangiocarcinoma. More typical symptoms of these complications may include fever, jaundice, hepatomegaly and liver tenderness.

Liver Flukes and Cholangiocarcinoma

The most severe complication of chronic liver fluke infection is the development of CCA. Many pathways could be implicated as the pathogenesis of the infection encompasses several factors. These include mechanical injuries of the biliary ducts by the suckers of the feeding worms; biliary obstruction by the adult parasites leading in turn to stasis and subsequent bacterial infections, including possibly colonization by *Helicobacter* species; chronic inflammation and excessive immune response from the host; and carcinogenic actions of the parasite's metabolic products such as Ov-GRN-1 secreted by *O. viverrini*, which can stimulate angiogenesis, suppress apoptosis, and promote tumor invasion.

Epidemiological studies (including correlation ecological studies, case series, and case control studies), animal studies (mostly in hamsters), and mechanistic evidence strongly indicate that liver flukes are causally related to CCA. Various attempts to quantify the

number of CCA cases attributable to liver flukes in Asia range from 1300 cases to 7000. All the authors who tried this exercise acknowledged that the estimate they provided was most probably well under the true number.

Pooled relative risks (RRs) from the available case control studies were estimated to range from 4 to 8 for both parasites. However, the RR of cholangiocarcinoma might be substantially underestimated by some methods of exposure assessment (i.e., detection of eggs in feces, or patient history self-testimony), both in the population, and in case control studies. Some evidence for this underestimate comes from the contrast between analytical and descriptive epidemiology. For example, the RR between 4 and 8 for *C. sinensis* from pooled case control studies is unable to account for the 60-fold variation in cholangiocarcinoma incidences between geographical regions. It is therefore probable that all statistical methods are underestimating the true burden with currently available data.

Diagnosis of Liver Flukes Infection

Liver fluke infection is suspected on the anamnestic description of recurrent clinical symptoms and raw fish consumption; blood cell count showing an elevated count of eosinophils—white cells whose function is to neutralize invading microbes, primarily parasites, and dilatation of the peripheral intrahepatic bile ducts shown by ultrasound, computed tomography or magnetic resonance imaging scans. Confirmation of diagnosis relies on different types of diagnostic techniques. In most areas, the diagnosis is mainly based on detection of eggs in feces by microscopy, usually using the Kato Katz technique. Trained parasitologists are however needed to make the identification. Even then, because the eggs are similar in size and are all oval and operculated, *C. sinensis* eggs cannot sometimes be differentiated from other Heterophyidae (e.g., *Haplorchis*, *Heterophyes*, etc.) or Opisthorchiidae eggs. The World Health Organization (WHO) has recommended the Kato Katz technique in areas with moderate to high endemicity (i.e., where the proportion of infected individuals is $>10\%$–50%). Where the prevalence is lower, the low specificity of this technique makes it less appropriate; more specific tools should be used, such as immunodiagnostic techniques and molecular methods. Of note, because endemic areas overlap with areas of high prevalence of hepatitis B virus infection, which shares some of its unspecific symptoms, liver fluke infection might be misdiagnosed as viral hepatitis, and coinfection of the flukes and the virus frequently happen in the same individuals. Whether liver flukes and hepatitis B virus co-infection have a synergistic effect on the development of CCA or hepatocellular carcinoma is plausible but has been little studied to date.

Individual Treatment and Population Control

Currently, the major strategies for community prevention and control encompasses fecal examination and treatment of individual cases with praziquantel, a highly effective broad-spectrum trematocidal and custodial drug. The recommended dose is 25 mg/kg three times daily for 2–3 days. A single dose of 40 mg/day has been used in preventive chemotherapy programs and resulted in 95% cure rate of light infections, but only 89% and 69% in intermediate and heavy infections, respectively.

For the purposes of public health control, WHO recommends carrying out community screening and diagnosis at the district level, and implementing preventive chemotherapy with praziquantel at a dosage of 40 mg/kg, single administration, as indicated in Table 1.

When treatment is delivered, information, education, and communication (IEC) should be given to the population to enhance sustainability by avoiding constant reinfection. Education may be a real challenge in areas where raw fish consumption is a strong tradition, or where people wrongly believe that drinking alcohol or consuming spicy food can prevent infection. No vaccine candidate has yet shown efficacy in animal models, and the control of human disease through vaccination is not an option in the near future. Environmental control is equally challenging and may encompass many measures including prevention of fecal contamination of fresh water, or, in the future, innovative techniques such as GIS-Based spatial identification of risk areas for liver flukes, or oral vaccination of the secondary intermediate hosts (fish) using probiotics.

Table 1 WHO recommendations for community diagnosis

District	*Prevalence of infection in the sample population*[a]	*Action to be taken*	
		Type of intervention and target population	*Interval of re-treatment*
High risk	≥ 20	Universal treatment (MDA)—Treat all individuals in the district	12 months
		Option 1: universal treatment (MDA)—Treat all individuals in the district	24 months
Low risk	<20	*Option 2*: targeted treatment—Treat all individuals in the district who report habitually eating raw fish	12 months

[a]The Kato-Katz thick smear technique should be used.Abbreviation: MDA, mass drug administration.

Oral Squamous Cell Carcinoma

Definition

A carcinoma with squamous differentiation arising from the mucosal epithelium. Recognized subtypes are: verrrucous carcinoma, basaloid squamous cell carcinoma, papillary squamous cell carcinoma, spindle cell squamous cell carcinoma, adenosquamous carcinoma and lymphoepithelial carcinoma. Subtypes only will be discussed regarding their pathologic features as they are with a few exceptions morphological variants without any proven relationship with other clinicopathological variables.

Burden

Squamous cell carcinoma represents $>90\%$ of cancers in the oral cavity. With respect to epidemiology, specific geographical regions must be considered separately, because there is a marked variation in incidence. A high incidence of oral cancer is found in southern Asia with age-standardized incidence rates of >10 cases per 100,000 population per year. Worldwide, oral cancer incidence is higher among males (5.5 cases per 100,000 population per year) than females (2.5 cases per 100,000). Most oral cancers occur in patients aged 50–70 years.

Risk Factors

Smoking is by far the most important cause of oral cancer. Alcohol consumption interacts synergistically with smoking, resulting in a more than additive risk. In some parts of the world, the use of areca nut whether or not mixed with other substances represents an important risk factor. In contrast to the oropharynx, oral cavity squamous cancers only rarely harbor high-risk HPV.

Pathology

Most cancers of the oral cavity and mobile tongue are moderately or well differentiated; poorly differentiated squamous cell carcinoma is less frequent. Well-differentiated OSCC is characterized by nests, cords, and islands of large cells with pink cytoplasm, prominent intercellular bridges, and round nuclei, which may not be obviously hyperchromatic. Dyskeratotic cells and squamous pearls are prominent. Well-differentiated tumors tend to invade in large islands, whereas less-differentiated tumors tend to have small islands and dispersed individual cells at the invasive front (Figs. 1 and 2).

Pathology of Subtypes

Verrucous Carcinoma

Verrucous carcinoma consists of blunt projections and invaginations of well-differentiated squamous epithelium, composed of one to several layers of basal cells and an expanded layer of spinous cells that lack cytological atypia. There is marked surface keratinization. Mitoses are rare and confined to the basal cell layer, and there are no abnormal mitoses. Verrucous carcinoma invades the stroma with a well-defined pushing border (Fig. 3). Verrucous carcinoma has a better prognosis than conventional oral squamous cell carcinoma.

Basaloid Squamous Cell Carcinoma

Basaloid squamous cell carcinoma consists of rounded nests with smooth borders and peripheral palisading. Gland-like foci with basophilic myxoid or mucoid material are common and mimic true gland formation. A variable degree of nuclear pleomorphism is present, and high mitotic activity, apoptosis, and necrosis are common. Also, comedonecrosis may be present. Stromal hyalinization is characteristic; it can be linear between and around nests and nodular within nests. Keratinization occurs abruptly adjacent to

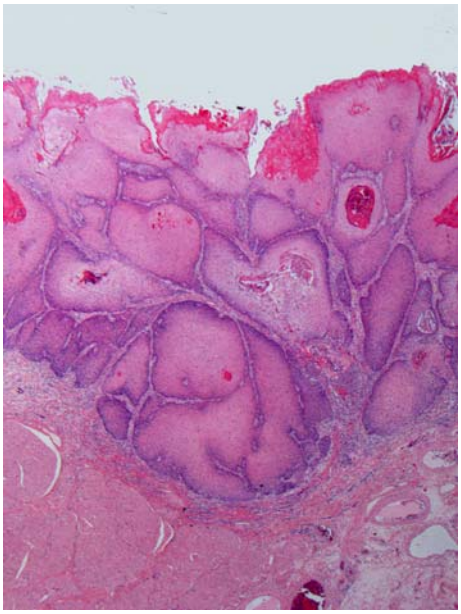

Fig. 1 Well-differentiated OSCC arises from the surface epithelium and invades the submucosal tissues as large keratinizing tumor nests.

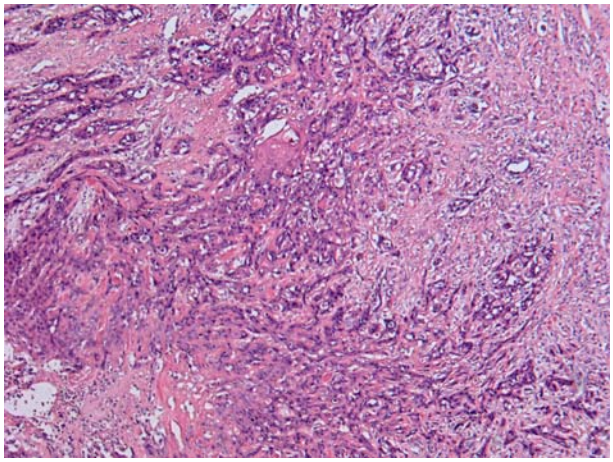

Fig. 2 Poorly-differentiated OSCC lacks significant keratinization and irregularly infiltrates the stroma as small cords or individual cells.

basaloid cells (Fig. 4). Whether basaloid squamous cell carcinoma has a worse prognosis than conventional squamous cell carcinoma is an issue that has not yet been definitely settled.

Papillary Squamous Cell Carcinoma

Papillary squamous cell carcinoma is characterized by a papillary growth pattern, with thin fibrovascular cores covered with malignant epithelial cells (Fig. 5). Two types of surface epithelium are described: one resembles high-grade keratinizing epithelial dysplasia, and in the other, the epithelial cells are immature and basaloid, with no evidence of maturation or keratinization. This type of squamous cell carcinoma has a better prognosis than conventional squamous cell carcinoma, primarily due to low-stage presentation, with a low metastatic potential.

Spindle Cell Squamous Cell Carcinoma

Spindle cell squamous cell carcinoma typically grows as an exophytic mass with a predominantly ulcerated surface, sometimes containing remnants of dysplastic squamous epithelium and frequently showing areas of transition from squamous cells to malignant spindled or pleomorphic tumor cells with hypercellularity, necrosis, atypical mitotic figures, and hyperchromatic nuclei (Fig. 6). Some cases exhibit heterologous mesenchymal differentiation in the form of malignant bone, cartilage, or skeletal muscle.

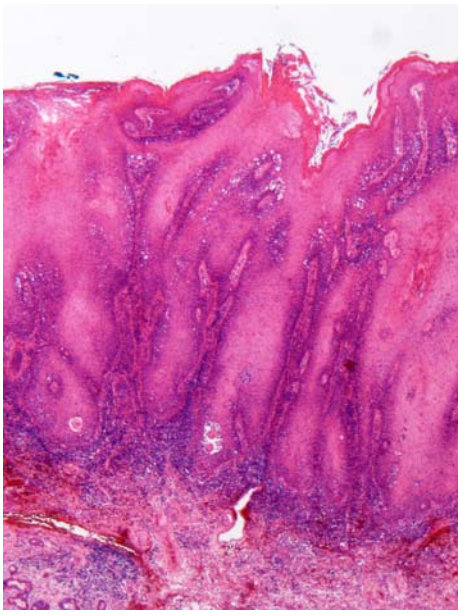

Fig. 3 Verrucous carcinoma exhibits prominent surface keratinization and a broad, pushing pattern of stromal invasion.

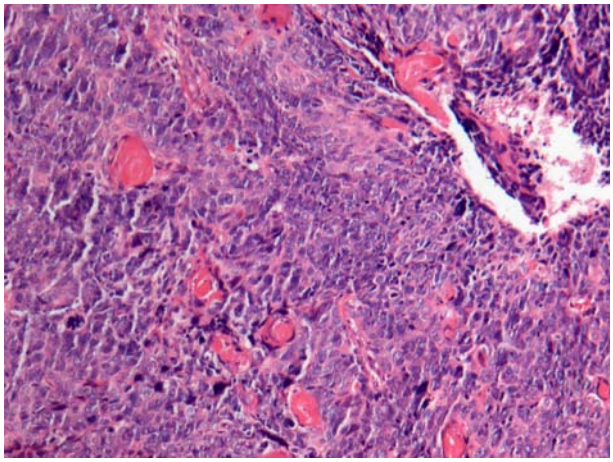

Fig. 4 Basaloid squamous cell carcinoma consists of basaloid cells with high nuclear:cytoplasmic ratios demonstrating abrupt keratinization.

Occasionally, spindle cell squamous cell carcinoma may have deceptively bland appearance, mimicking reactive myofibroblastic proliferation or granulation tissue. The prognosis of this subtype does not differ from conventional squamous cell carcinoma.

Adenosquamous Carcinoma

Adenosquamous carcinoma shows both squamous and glandular differentiation. The adenocarcinoma consists of cribriform and tubuloglandular structures and tends is mainly restricted to the deeper parts of the tumor (Fig. 7). This subtype is rare in the oral cavity, with larynx and hypopharynx being more common sites. Prognosis is worse than for conventional squamous cell carcinoma.

Lymphoepithelial Carcinoma

Lymphoepithelial carcinoma is a squamous cell carcinoma subtype morphologically similar to non-keratinizing nasopharyngeal carcinoma, undifferentiated subtype. The tumor is characterized by large cells with round to oval vesicular nuclei, and large central nucleoli. The neoplastic cells generally have scant amphophilic or eosinophilic cytoplasm. Unlike in the nasopharynx, lymphoepithelial carcinoma in the oral cavity appears to be unrelated to EBV. Lack of data on outcome precludes any firm statements.

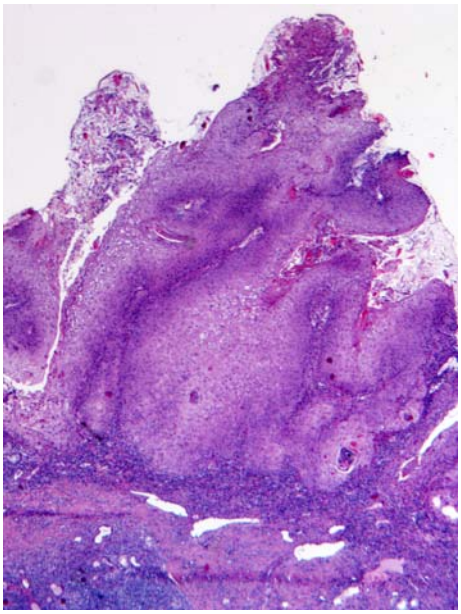

Fig. 5 Papillary squamous cell carcinoma grows as exophytic fronds of malignant squamous epithelium surrounding fibrovascular cores.

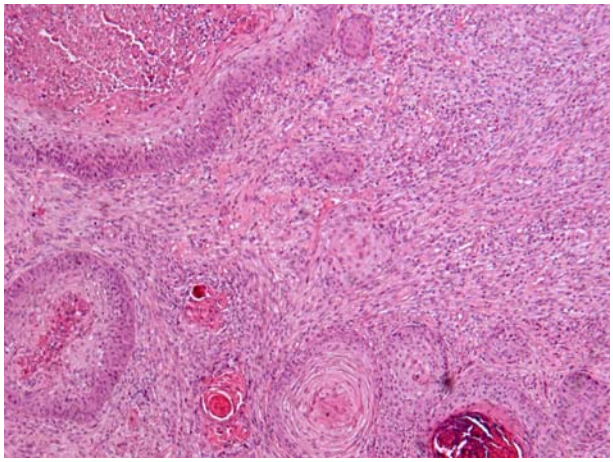

Fig. 6 Spindle cell squamous cell carcinoma has a component of conventional squamous cell carcinoma and a separate component of undifferentiated malignant spindle cells.

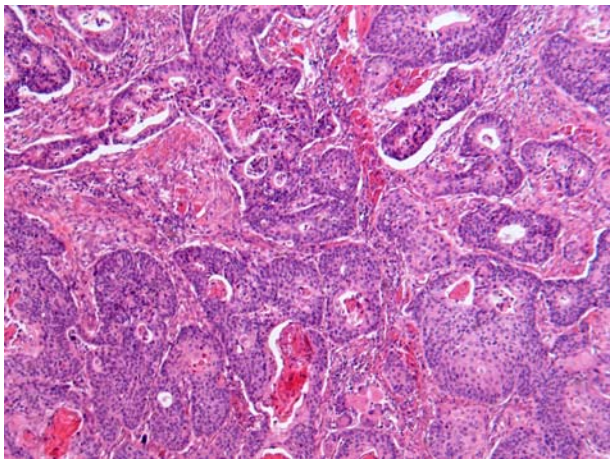

Fig. 7 Adenosquamous carcinoma demonstrates clear-cut glandular differentiation, particularly in the deeper portions of the tumor.

Molecular Pathology and Genetics

Most OSCCs are genetically unstable with chromosomal loss at 3p, 8p, 9p, 17p and gains at 3q and 11q. These changes may extend for some distance from the clinical lesion, underpinning the clinical phenomenon of field cancerization. Genes reported to have a role in OSCC (e.g., *TP53*, *CDKN2A*, *PTEN*, *HRAS*, *PIK3CA*, and *NOTCH1*) are mutated with sufficient frequency to support their potential role as drivers in cancer development.

Microenvironment Including Immune Response

Data regarding the immune microenvironment of oral squamous cell carcinoma is limited. A few studies have reported a subset of these cancers expressing the immune checkpoint receptor PD-L1.

Staging and Grading

Most cases of oral squamous cell carcinoma are moderately differentiated. There is no clear relationship between grading and prognosis. There are some indications however that evaluation of the invasive tumor front may have some prognostic relevance, with growth in tiny strands being worse than invasion in a pushing border. Staging is done conforming the most recent UICC guidelines (8th edition).

Prognostic and Predictive Biomarkers

An important prognostic factor is the status of surgical resection margins. Resection margins clear of tumor are associated with a lower recurrence rate and a better survival. An adequate margin of resection has not been precisely defined, but for oral squamous cell carcinoma margins of 5 mm are generally believed to be adequate.

Other significant prognostic factors are tumor size, nodal status, and distant metastasis. Histological risk factors associated with a worse prognosis include a non-cohesive growth pattern at the invasion front, perineural and lymphovascular invasion, bone invasion, and tumor thickness >4 mm. High-grade dysplasia at a mucosal margin correlates with local recurrence and second primary tumors. Extracapsular spread from metastasis in the neck, two or more positive nodes, and involvement of lower neck worsen prognosis. Conventional histological grading correlates poorly with clinical outcome.

Prospective Vision

Current research on oral squamous cell carcinoma has included work on improving early detection through screening saliva or serum for biomarkers, refining risk progression models particularly for low-stage cancers that behave unpredictably, and investigating novel treatment strategies like targeted therapies and immune checkpoint inhibition to improve a prognosis that has largely remained unchanged for decades.

Oropharyngeal Squamous Cell Carcinoma

Definition

Oropharyngeal squamous cell carcinoma is an epidemiologically, pathologically, and clinically distinct form of head and neck squamous cell carcinoma associated with high-risk HPV.

Burden

The incidence of oropharyngeal carcinoma has risen over the past three decades. Most patients are middle-aged males.

Risk Factors

Oropharyngeal squamous cell carcinoma is caused by high-risk HPV, with type 16 responsible for $>90\%$ of all cases. Oral sex is an established risk factor for oral HPV infection.

Pathology

HPV associated oropharyngeal squamous cell carcinoma generally exhibits a distinctive non-keratinizing morphology (Fig. 8). The tumor originates in the crypt epithelium and grows beneath the surface epithelial lining as nests and lobules. Tumor nests are often embedded in lymphoid stroma, and may be penetrated by lymphoid cells. Similar to squamous cell cancer of the oral cavity, the

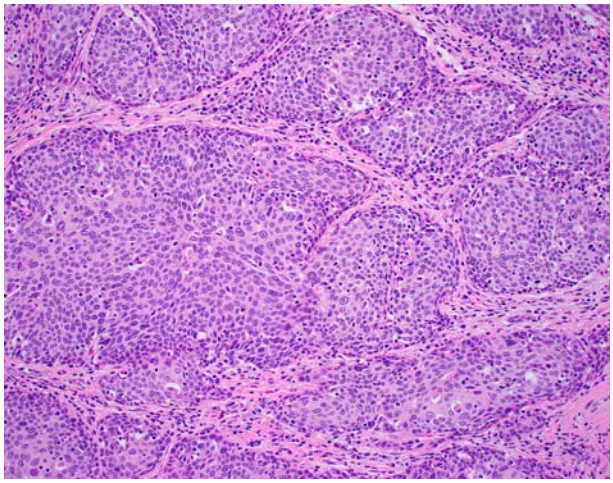

Fig. 8 HPV associated oropharyngeal squamous cell carcinoma grows as lobules of primitive cells with high nuclear:cytoplasmic ratios and limited keratinization.

morphological spectrum includes variants with papillary, adenosquamous, lymphoepithelioma-like, and spindle cell features. The clinical behavior of these morphological variants is the same as for the cases showing the typical histomorphology.

Molecular Pathology and Genetics

HPV oncoproteins E6 and E7 inactivate p53 and RB by targeting them for protein degradation, thus disabling the protective effects of these tumor suppressor genes. Oropharyngeal HPV-driven cancer has a gentic profile that differs from smoking-driven squamous cell carcinomas, with fewer mutations overall and fewer *TP53* mutations, but more frequent *PIC3CA* mutation or amplification and occasional *TRAF3* mutations not seen in HPV-unrelated tumors.

Microenvironment Including Immune Response

HPV associated oropharyngeal carcinomas arise from the specialized tonsillar crypt epithelium. These crypts have a distinct and complex immune environment that is not fully understood. As one important example, the immune checkpoint receptor PD-L1 is selectively expressed in the tonsillar crypt epithelium, seemingly creating an immune-privileged site where the effector function of virus-specific T cells is downmodulated, facilitating immune evasion by HPV.

Staging and Grading

Histologic grading is not currently advocated. Staging is done conforming the most recent UICC guidelines (8th edition).

Prognostic and Predictive Biomarkers

HPV associated oropharyngeal squamous cell carcinoma shows a better prognosis than the HPV negative tumors seen at this site but more commonly in the oral cavity. This improved prognosis is diminished in smokers with HPV associated oropharyngeal squamous cell carcinoma.

Prospective Vision

Future research directions in HPV associated squamous cell carcinoma research include early detection (made challenging by a lack of pre-malignant epithelial changes), novel treatment strategies like de-escalation radiation therapy or immunotherapy, and the long-term effects of routine HPV vaccination on the incidence of these carcinomas.

Glossary

Alveolar ridge One of the two jaw ridges either on the roof of the mouth between the upper teeth and the hard palate or on the bottom of the mouth behind the lower teeth.
Erythroplakia Chronic, red, generally asymptomatic lesion or patch on the mucosal surface that cannot be attributed to a traumatic, vascular, or inflammatory cause.
Extranodal extension Extension of metastatic carcinoma from within a lymph node through the fibrous capsule and into the surrounding connective tissue.
Interstitial brachytherapy Radioactive material inserted directly into body tissue.
Leukoplakia A white patch or plaque on the mucosal surface that cannot be rubbed off and may represent hyperplastic or dysplastic tumors.
Retromolar trigone A paired triangular area situated posterior to the third mandibular molars on the left and right sides of the oral cavity.

Introduction

The oral cavity consists of the oral vestibule and oral cavity proper. Its primary function is to serve as the entrance of the alimentary tract and to initiate the digestive process. It also serves as a secondary respiratory conduit, a site of sound modification for the production of speech, and a chemosensory organ. The development of a primary malignancy within the oral cavity as well as subsequent cancer treatment can affect these normal functions.

While cancers of the oral cavity only account for approximately 2% of all new cancer diagnoses in the United States, it is the most common site of all head and neck cancers (Siegel et al., 2017). In India, oral cavity cancer is among the three most common malignancies, accounting for over 30% of all reported malignancies in the country due to the high prevalence of chewing and smoking various carcinogens (Sankaranarayanan et al., 2005; Coelho, 2012). Surveillance Epidemiology and End Results (SEER) program data estimate 32,670 cases of cancer of the oral tongue, mouth, and oral cavity for 2017 in the United States (Siegel et al., 2017). An estimated 300,400 new cases and 145,400 deaths from cancer of the oral cavity and lip occurred worldwide in 2012 (Torre et al., 2015). Oral cavity cancer incidence rates worldwide have increased in many countries with tobacco epidemics that are currently peaking, but incidence rates have declined significantly among both males and females in areas where tobacco use peaked previously (Warnakulasuriya, 2009; Chaturvedi et al., 2013; Franceschi et al., 2000; Simard et al., 2014). Incidence rates for oral cancer sites related to human papillomavirus (HPV) infections are increasing in some countries, hypothesized to be in part due to changes in oral sexual behavior (Chung et al., 2014; **Fig. 1**).

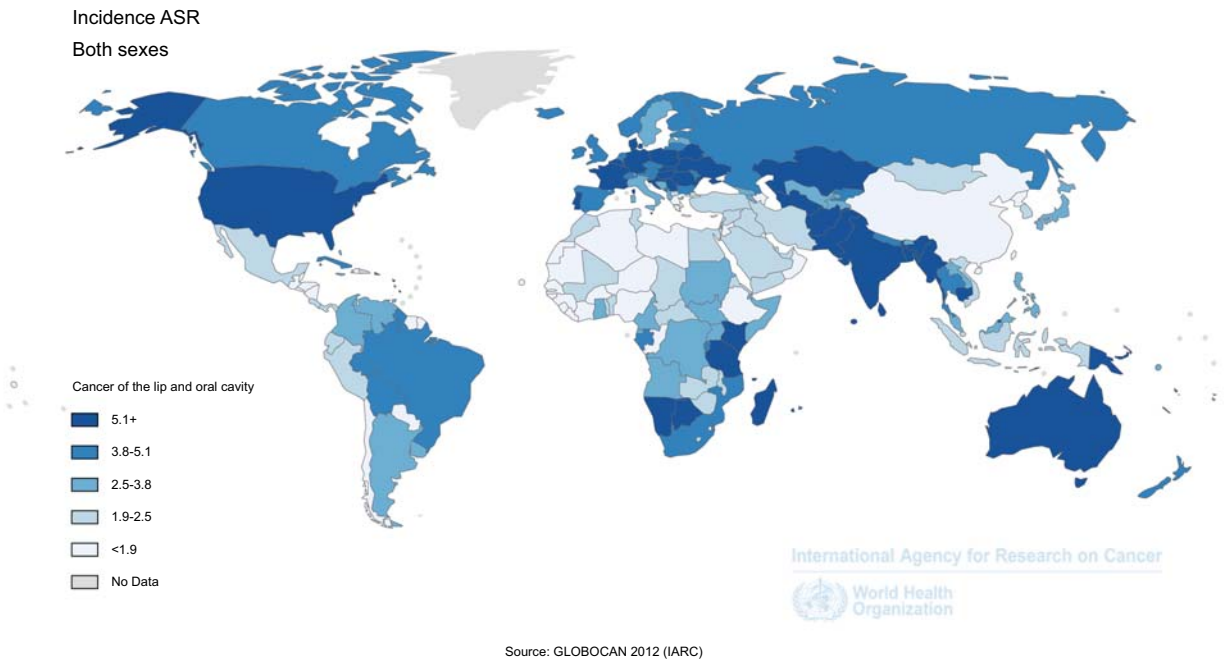

Fig. 1 Incidence of oral cavity cancer by country. Reproduced with permission from Ferlay, J., Soerjomataram, I., Ervik, M., Dikshit, R., Eser, S., Mathers, C., Rebelo, M., Parkin, D.M., Forman, D. and Bray, F. (2013). Lyon, France: International Agency for Research on Cancer; Available from: http://globocan.iarc.fr, accessed on 24 Nov 2017.

Subsites within the oral cavity from which a primary malignant neoplasm can develop include the lips, oral tongue, floor of the mouth, hard palate, retromolar trigone, alveolar ridge, buccal mucosa, and very rarely the teeth. Classification of tumors by subsite is useful because patterns of spread, specific treatment, and clinical outcomes vary for each specific subsite.

Anatomy

The oral cavity begins anteriorly at the junction of the skin and vermilion border of the lips. The roof, or superior portion, of the oral cavity extends posteriorly to the junction between the hard and soft palate. The floor, or inferior portion, of the oral cavity extends posteriorly to the V-shaped sulcus terminalis. Other than the mandibular periosteum, there is no other finite fascial plane to inhibit a tumor's extension and invasion in the oral cavity. The specific anatomic subsites of the oral cavity are outlined in the following sections (Fig. 2).

Lips

The lips are the anterior most aspect of the oral vestibule. The lips begin externally at the well demarcated transitional zone between the facial skin and the vermillion surface of the lips known as the vermilion border. The vermillion surface is separated into an outer darker dry vermilion and an interior pale wet vermilion. The upper and lower lips connect to one another by the labial commissure. The orbicularis oris muscle comprises the substance of the lips and is innervated by the buccal branches of the facial nerve. Upper lip sensation is provided by the infraorbital nerve, which is a branch of the maxillary division of the trigeminal nerve, whereas lower lip sensation is provided by the mental nerve, which is a branch of the mandibular division of the trigeminal nerve. The first echelon draining lymphatics of the lower lip are the submental, submandibular, subdigastric, and rarely facial nodes. Mental foramen adenopathy is rare and indicates mental nerve involvement. The first echelon draining lymphatics of the upper lip are the submandibular nodes and occasionally preauricular, parotid, and buccal nodes. The second echelon draining lymphatics for both lips are the upper anterior cervical nodes, though occasionally direct spread may occur.

Oral Tongue

Only the anterior two-thirds of the tongue are considered part of the oral cavity. The terminal sulcus, situated in a V-shaped configuration immediately posterior to the circumvallate papillae, demarcates the division between the oral tongue (i.e., anterior two-thirds) and the base of tongue (i.e., posterior one-third). The oral tongue can be subdivided into four anatomic areas: the tip, lateral borders, dorsal surface, and ventral surface. The fibrous septum divides the tongue into right and left halves. The oral tongue mucosa covers paired intrinsic and extrinsic muscles. There are four paired intrinsic muscles which alter the shape of the tongue during speech and swallowing: superior longitudinal, inferior longitudinal, vertical, and transverse muscles. There are three paired extrinsic muscles of the oral tongue which allow for protrusion, retraction, and side-to-side movement: genioglossus, hyoglossus, and styloglossus. Motor innervation is provided entirely by the paired hypoglossal nerves. General sensation of the anterior two-thirds of

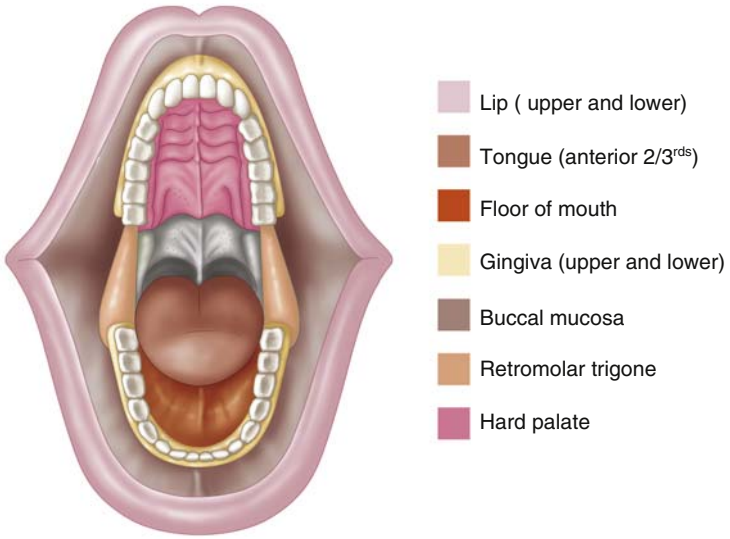

Fig. 2 Anatomic sites of the oral cavity. From Montero, P. H. and Patel, S. G. (2015). Cancer of the oral cavity. *Surgical Oncology Clinics of North America* **24**(3), 491–508.

the tongue is supplied by the lingual nerve, a branch of the mandibular division of the trigeminal nerve. Taste fibers from the anterior two-thirds of the tongue travel in the chorda tympani branch of the facial nerve. The glossopharyngeal nerve provides both sensation and taste to the circumvallate papillae and posterior third of the tongue. The blood supply to the oral tongue is primarily via the lingual artery, with primary drainage into the internal jugular vein via the lingual veins. The first echelon draining lymphatics for the anterior portion of the oral tongue are the submandibular, subdigastric, and anterior middle cervical nodes, with the tip of the tongue also draining to the submental nodes. The first echelon draining lymphatics for the posterior portion of the oral tongue are the submandibular and subdigastric nodes. Typically anterior tumors tend to spread lower in the neck than posterior tumors. Additionally, tumors located on the lateral third of each half of the oral tongue tend to spread ipsilaterally, whereas tumors located more medially tend to spread bilaterally. Skip metastases to inferior cervical lymph nodes have also been commonly reported for anterior oral tongue cancers (Byers et al., 1997; Woolgar, 1997; **Fig. 3**).

Floor of Mouth

The floor of mouth is bounded anteriorly and laterally by the lower gingiva, medially by the oral tongue, and posteriorly at the insertion of the anterior tonsillar pillar into the oral tongue. The mylohyoid, genioglossus, and geniohyoid muscles comprise the muscular floor of the oral cavity. This region is divided into right and left halves by the lingual frenulum and contains the ostia of the submandibular and sublingual salivary glands. The sublingual glands lie immediately beneath the floor of mouth mucosa and are separated by the genioglossus and geniohyoid muscles. The submandibular glands lie on the external surface of the mylohyoid muscle near its insertion to the mandible and terminate at Wharton's (submandibular) ducts, which are approximately 5 cm long and course between the sublingual gland and genioglossus muscle before exiting near the anterior floor of mouth at midline bilaterally. Motor innervation is provided by the hypoglossal nerves, whereas sensory innervation is provided by the lingual nerve. The first echelon draining lymphatics are the submandibular and subdigastric nodes. Lymphatic spread to the submental nodes is rare. The second echelon draining lymphatics are the middle and lower anterior cervical nodes.

Pitfalls in the staging of cancer of oral cavity cancer. *Neuroimaging Clinics of North America* **23**(1), 27–45.

Hard Palate

The hard palate is the roof of the oral cavity and separates this site from the nasal cavity. It extends posteriorly and medially from the maxillary alveolar ridge to the posterior edge of the palatine bone, creating a semilunar arch shape. The bony structure is formed by the palatine processes of the maxilla and the horizontal plates of the palatine bones. Centrally, the periosteum is covered by a firmly attached mucosa, while peripherally there is a minimal submucosa containing vasculature, which may result in an increased risk of spread. The hard palate is continuous with the soft palate posteriorly, which is excluded from the oral cavity proper. Vascular supply is provided by the greater palatine artery, which anastomoses with the nasopalatine artery. Veins from the hard palate terminate in the pterygoid venous plexus. The hard palate is innervated by the greater palatine and nasopalatine nerves, two branches of the maxillary division of the trigeminal nerve, both of which initially pass through the pterygopalatine ganglion. The paired greater palatine arteries and nerves, along with secretomotor fibers to the salivary glands on the posterior hard palate, enter the oral cavity via the greater palatine foramen located medial to the third molar. The nasopalatine nerve descends through the incisive foramen to supply the most anterior parts of the hard palate. The first echelon draining lymphatics are the submandibular or upper deep cervical nodes. The midline hard palate may drain bilaterally. Retropharyngeal nodes may rarely be involved (Fig. 4).

Alveolar Ridge

The superior (maxillary) and inferior (mandibular) alveolar ridges include the alveolar processes and overlying mucosa. The mucosa covering the inferior alveolar ridge extends from the lower gingivobuccal sulcus to the floor of the mouth, and further extends posteriorly to the ascending ramus of the mandible. The mucosa covering the superior alveolar ridge extends from the upper gingivobuccal sulcus to the junction of the hard palate, and further extends posteriorly to the upper end of the pterygopalatine arch. General sensory innervation of the maxillary and mandibular gingiva is from branches of the maxillary and mandibular divisions of the trigeminal nerve, respectively. The lymphatic drainage of the alveolar ridges is to the submental, submandibular, upper deep jugular, and retropharyngeal nodes.

Teeth

Teeth extend from within the alveolar ridges and erupt from the gingiva. Teeth are divided into four quadrants using descriptors of right versus left and mandibular versus maxillary. In adults, each quadrant has two incisors, one canine, two premolars, and three molars going from medial to lateral. Going from outside to inside in cross-section, teeth are made of enamel, centrum, dentine, and pulp—the latter containing the vessels and nerves. The mandibular teeth are innervated by the inferior alveolar nerves, whereas the maxillary teeth are innervated by the superior alveolar nerves. The first echelon draining lymphatics are the submandibular nodes, except for the incisors which drain directly to submental nodes. Odontogenic tumors are exceedingly rare and are typically only locally invasive. They will not be discussed further in this article (Fig. 5).

Retromolar Trigone

The retromolar trigone, as the name suggests, is a paired triangular area situated posterior to the third mandibular molars on the left and right sides of the oral cavity. The base of each triangle is formed by the third mandibular molar, and the apex is in continuity with the maxillary tuberosity located posterior to the third maxillary molars. The retromolar trigone is bounded laterally by the gingival buccal sulcus and medially by the anterior tonsillar pillar. Branches of the mandibular division of the trigeminal nerve provide sensory innervation to this area. The predominant lymphatic drainage from the retromolar trigone is to the upper deep jugular nodes, though there may be some drainage into periparotid and retropharyngeal nodes.

Buccal Mucosa

The buccal mucosa is comprised of the mucosal surfaces of the cheeks and lips, which form the anterolateral boundaries of the oral vestibule. It is contiguous with the mucosa that lines the floor of mouth and alveolar ridges. There are approximately 800–1000 minor salivary glands located throughout the buccal mucosa as well as other parts of the contiguous oral mucosa. The ostia of Stensen's (parotid) ducts are located within the buccal mucosa at the parotid papillae across from the second maxillary molars. Innervation is predominantly supplied by the buccal nerve, a branch of the mandibular division of the trigeminal nerve, but the superior portion is also innervated by the superior labial branches of the infraorbital nerve. Lymphatic drainage of the buccal mucosa is complex. The inferior and medial parts usually drain to submandibular nodes, whereas the lateral and upper parts may drain to parotid, buccinator, or preauricular nodes.

Epidemiology and Etiology

The epidemiology of oral cavity cancer strongly reflects exposure to various environmental agents. The most frequently cited risk factor for oral cavity cancer is tobacco, including smoking cigarettes, cigars, or pipes or using smokeless tobacco (Danaei et al.,

2005). Concomitant alcohol consumption acts synergistically and greatly increases the risk of developing an oral malignancy (Hashibe et al., 2009). Betel nuts, commonly chewed in Southeast Asia and India, also have high tumorigenic potential in the oral cavity (Coelho, 2012). Other reported risk factors for oral cavity cancer include gutka, supari, bidi, paan, vitamin A deficiency, and chronic irritation from poor oral hygiene or syphilis (Mahapatra et al., 2015; Chinn & Myers, 2015). High-risk strains of HPV, a sexually transmitted infection, are believed to be contributing to a steady increase in a subset of neoplasms originating from the oral cavity, particularly in patients younger than the historical average (Chocolatewala & Chaturvedi, 2009; Patel et al., 2011). For lip cancer, in particular, ultraviolet radiation is an established risk factor (Perea-Milla Lopez et al., 2003). Rarely, oral cavity cancer may occur as a secondary malignancy many years after prior radiotherapy to the head and neck. In the absence of these known risk factors, certain genetic syndromes such as Fanconi anemia and dyskeratosis congenita have strong associations with the development of oral cavity cancer (Prime et al., 2001).

The lip is the most prevalent site of oral cancer in several geographical areas worldwide, accounting for 25%–60% of all oral cavity cancer cases (Antoniades et al., 1995; Moore et al., 1999). Host and environmental factors associated with lip cancer include fair skin, cumulative and early sunlight exposure, skin reaction to sun exposure, outdoor occupations, genetic predisposition, immunosuppression, low socioeconomic status, and possibly viruses such as the Herpes simplex virus (HSV) and HPV (Perea-Milla Lopez et al., 2003). The lower lip, which is far more frequently affected than the upper lip, receives more direct exposure to solar ultraviolet radiation which causes DNA damage (**Fig. 6**).

The oral tongue is the second most common anatomic subsite of oral cavity cancer. The remaining anatomic subsites, in descending order of frequency among over 3,300 *de novo* oral cavity cancers treated at a single United States cancer center from 1970 to 1999, include the floor of mouth, retromolar trigone, alveolar ridge, palate, and lastly buccal mucosa (Chen & Myers, 2001). The median age at diagnosis of these malignancies is around age 60, and they are more common in males. Although rare in the United States, carcinoma of the buccal mucosa is the most common malignancy of the oral cavity in Southeast Asia because of the widespread use of betel nut.

About one in every 50 malignancies diagnosed in the United States originates in the oral cavity (Siegel et al., 2017). At a similar rate, nearly one in every 50 malignancies diagnosed in the United States is believed to be caused by HPV (Siegel et al., 2017; Klopp et al., 2014). Avoidance of the previously described known carcinogens and optimal skin protection from ultraviolet radiation has led to a decrease in the incidence of oral cavity cancer in many parts of the world (Chaturvedi et al., 2013; Franceschi et al., 2000). Prevention of most HPV-associated malignancies is thought to be possible by HPV vaccines (Kurdgelashvili et al., 2013). Since mid-2006, HPV vaccination has been recommended for females aged 11–12 years and through 26 years if not previously vaccinated (Markowitz et al., 2016). HPV vaccination is now routinely recommended at age 11 or 12 regardless of sex and recommended for males aged 13 through 21 years if not previously vaccinated (HPV Vaccine Recommendations, 2017). Rapid reductions of upwards of 90% of HPV 6/11/16/18 infections and genital warts were demonstrated after introduction of the quadrivalent HPV vaccination programs in young women in Australia, Europe, North America, and New Zealand (Garland et al., 2016). HPV-associated cancer rates are subsequently expected to decline and the full public health potential is not yet realized because carcinogenesis after HPV infection may require several decades to become manifest.

However, benefits of HPV vaccination may have less of an impact on oral cavity cancers than other HPV-related malignancies. A meta-analysis of 17 studies demonstrated a weaker association between HPV and cancer of the oral cavity compared to cancer of the oropharynx (Hobbs et al., 2006). After testing archival tissue from 2670 patients diagnosed between 1993 and 2005, HPV DNA was detected in 32% of oral cavity cancers in contrast to 90%–99% of invasive and in situ cervical cancers and 70% of oropharyngeal cancers (Saraiya et al., 2015). A meta-analysis reported a lower prevalence of HPV in oral cancer at 24% (Combes & Franceschi, 2014). Despite these HPV DNA prevalence rates for oral cavity cancers, recent international studies suggest that HPV rarely plays a driving role in oncogenesis because HPV mRNA or p16 is detected in as few as 3%–5% of oral cavity cancers (Castellsague et al., 2014). Nevertheless, certain oral cavity subsites such as the floor of mouth and tongue seem to be predominantly infected by HPV (Hübbers & Akgül, 2015). Therefore, the clinical significance that HPV vaccines will have on oral cavity cancers in particular remains to be seen.

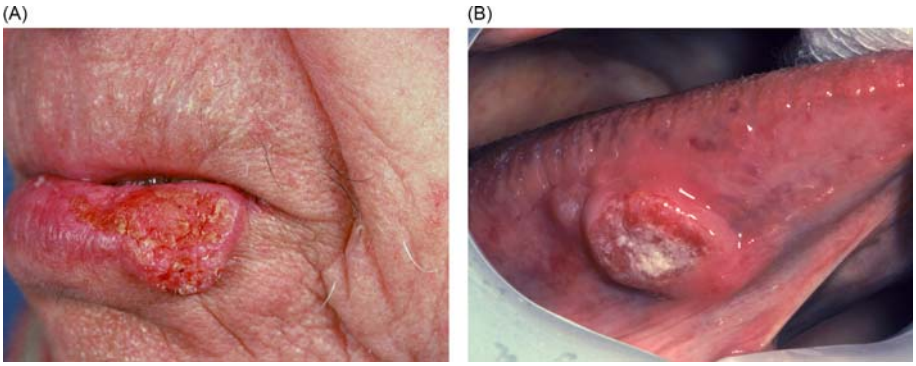

Fig. 6 (A) Oral squamous cell carcinoma of the inferior lip. (B) Oral squamous cell carcinoma of the right ventral tongue. Images appears with permission from VisualDx.

Most public health efforts have focused on prevention of oral cavity cancer by minimizing exposure to known carcinogens rather than screening. Increased regulation and public education on the harmful effects of tobacco, for example, has led to decreasing rates of smoking in many developed countries (Warnakulasuriya, 2009; Chaturvedi et al., 2013; Franceschi et al., 2000; Simard et al., 2014). There is no routine screening for cancer of the oral cavity, but special attention should be given to those at high risk based on the before-mentioned risk factors. In a regional United States oral cancer detection program in the Boston area, the diagnosis of early-stage disease increased from 20% to 33% over a 3-year period when investigators stressed the importance of routine oral examination. Furthermore, screening for and identification of leukoplakia may lead to not only earlier oral cavity cancer detection, but also reduced mortality based on a SEER analysis (Yanik et al., 2015). This was confirmed by an oral visual inspection program in India which screened over 87,000 individuals with a reduced mortality rate ratio of 0.79 in those who screened positive (Sankaranarayanan et al., 2005).

Patients with oral cavity cancer are at an elevated risk of developing a second primary cancer, likely because of field cancerization (Day & Blot, 1992). In a meta-analysis of over 40,000 patients with head and neck cancer, patients with carcinoma of the oral cavity had the highest rate of second primary cancers (Haughey et al., 1992). A retrospective review of 851 patients with head and neck cancer between 1978 and 1990 identified an 18% probability of developing a second metachronous malignancy at 5 years for patients with oral cavity cancer (Schwartz et al., 1994).

Natural History

Premalignant Lesions

Actinic keratosis is the earliest clinically recognizable manifestation of lip cancer. Leukoplakia and erythroplakia are common gross clinical descriptors of benign, premalignant, and malignant lesions seen throughout the intraoral cavity. Leukoplakia, or a white patch or plaque that cannot be rubbed off, may represent hyperplastic tumors or dysplastic tumors (Mehanna et al., 2009; **Fig. 7**). Hyperplastic tumors spontaneously regress 30%–40% of the time and have a low risk for malignant transformation. In contrast, dysplastic tumors rarely spontaneously regress and have a higher risk for malignant transformation. Microscopic features of dysplastic leukoplakias include abnormal orientation of cells, nuclear hyperchromatism, increased mitosis, and a high nuclear-cytoplasmic ratio. Erythroplakias, or bright red velvety plaques, rarely spontaneously regress and have a higher malignant transformation rate than leukoplakias (Shafer & Waldron, 1975). Oral homogeneous erythroplakias have been histopathologically documented to show 51% invasive carcinoma, 40% carcinoma in situ, and 9% mild or moderate dysplasia (Reichart & Philipsen, 2005). Another premalignant disorder prominent in Southeast Asia due to betel nut chewing is oral submucous fibrosis (Wollina et al., 2015; **Fig. 8**).

Pathology

Squamous cell carcinoma is the predominant histopathologic type of cancer in the oral cavity. Oral squamous cell carcinoma can present as several histologic variants including basaloid, verrucous, papillary, adenoid, acantholytic, cuniculatum, pseudoglandular, spindle cell, sarcomatoid, and adenosquamous (Pathak et al., 2014). Verrucous carcinomas are typically low grade, slow growing, and rarely metastasize despite the tendency to invade deep tissues (Chen & Myers, 2001; Candau-Alvarez et al., 2014). The buccal mucosa is the most common site for verrucous carcinoma. Basaloid was once believed to be a more aggressive variant, but the largest reported series of basaloid squamous cell carcinoma of the oral cavity to date demonstrates that this histology carries a comparable prognosis to conventional-type oral squamous cell carcinoma (Fritsch et al., 2014). Spindle cell carcinoma, on the

Fig. 8 Oral submucous fibrosis associated with oral cancer of the right buccal mucosa. From Jian, X., Huang, X., Liu, D., Xu, P., and Liu, X. (2013). Analysis of clinical symptoms and signs in cases of oral submucous fibrosis which have transformed into squamous cell carcinoma. *Open Journal of Stomatology* **3**, 235–240.

other hand, accounts for $<1\%$ of all tumors of the oral cavity and tends to be aggressive, with reported median overall survival times of <1–2 years (Ellis & Corio, 1980; Su et al., 2006).

Nonsquamous histologies cumulatively represent $<10\%$ of all oral cavity neoplasms (Daley & Darling, 2003). Examples of these nonsquamous histologies are listed in **Table 1**. The most common nonsquamous histology of the lip is basal cell carcinoma. Excluding the lip, malignancies of the minor salivary glands are the next most common type of oral cavity tumors behind squamous cell carcinoma. These tend to occur on the hard palate, and adenoid cystic carcinoma is the most common histology (Weber et al., 1989).

The third most common type of malignancy of the intraoral cavity is lymphoma. Most lymphomas in the head and neck arise not in the oral cavity, but rather in Waldeyer's ring which comprises the tonsils, base of tongue, and nasopharynx (Guevara-Canales et al., 2013). The oral cavity is the primary site of approximately 2%–4% of all extranodal lymphomas, and this location is more common in patients with acquired immunodeficiency syndrome (AIDS) than the general population (Kobler et al., 2005; Silva et al., 2016). Another neoplasm frequently seen in the oral cavity among AIDS patients is Kaposi's sarcoma (Fatahzadeh & Schwartz, 2013).

Table 1 Nonsquamous cell malignant tumors of the oral cavity

Cells or tissue of origin	*Cancer name*	*Usual age group*	*Prognosis*
Melanocytes	Melanoma	Adults	Very poor
Salivary glands	Many types	Adults	Good to poor
Fibroblasts	Fibrosarcoma	Young adults	Intermediate to poor
	Malignant fibrous histiocytoma	Older adults	Intermediate to poor
Myofibroblasts	Myofibrosarcoma	Adults	Intermediate to poor
Fat cells	Liposarcoma	Adults	Intermediate to poor
Skeletal muscle	Rhabdomyosarcoma	Children and adolescents	Intermediate
Smooth muscle	Leiomyosarcoma	Adults	Poor
Peripheral nerves	Neurosarcoma	Young adults	Very poor to poor
	Malignant granular cell tumour	Adults	Poor
Synovial cells	Synovial sarcoma	Adolescents and young adults	Poor
Endothelial cells	Angiosarcoma	Elderly people	Very poor
	AIDS-related Kaposi's sarcoma	Young adults	Poor
	Classic Kaposi's sarcoma	Elderly men	Good
Lymphocytes	Lymphoma	Adults and children	Good, intermediate or poor
Plasma cells	Plasmacytoma	Adults	Good to intermediate
	Multiple myeloma	Older adults	Poor to very poor
Bone cells	Osteosarcoma	Children and young adults	Intermediate to poor
	Parosteal osteosarcoma	Children and adults	Good
Cartilage cells	Chondrosarcoma	Adults	Intermediate
Odontogenic cells	Various carcinomas and sarcomas	Adults	Poor
Metastatic tumours	Breast, lung, prostate, kidney, thyroid	Adults	Very poor
	Leukemic infiltrate	Children and adults	Variable

From Daley, T. and Darling, M. (2003). Nonsquamous cell malignant tumours of the oral cavity: An overview. *Journal of the Canadian Dental Association* **69**(9), 577–582.

Other malignant histologies presenting in the oral cavity include adenocarcinomas, melanoma, ameloblastoma, plasmacytoma, multiple myeloma, teratoma, various sarcomas, and metastasis from other primary tumors (Gholizadeh et al., 2016; Gupta et al., 2012; Kolekar et al., 2016; Shah et al., 2010; Benoist & van Looij, 2013). Mucosal melanomas generally have a worse prognosis than cutaneous melanomas. Fortunately, melanoma of the oral cavity represents $<1\%$ of all melanomas (Smyth et al., 1993).

Important histopathologic prognostic factors include depth of invasion, worst pattern of invasion, perineural invasion, lymphovascular invasion, and extranodal extension (ENE). Greatest depth of invasion is measured from the horizon of the basement membrane closest to the intact squamous mucosa and dropping a "plumb line" from the horizon. Worst pattern of invasion score 5 is when satellite dispersion is ≥ 1 mm from neighboring satellites, and is significantly predictive of poor outcome. Perineural invasion and lymphovascular invasion should both be subclassified as either intratumoral or extratumoral, as well as focal or multifocal. Histopathologic designations of ENE include none (i.e., not present), microscopic (i.e., ≤ 2 mm of ENE), and macroscopic (i.e., >2 mm or gross ENE).

Patterns of Spread

About 90% of all squamous cell carcinomas of the lip start on the sun-exposed lower lip vermilion (Fitzpatrick, 1984). Basal cell carcinomas, alternatively, are more common on the upper lip. The commissures are rarely sites of disease origin. The disease may spread along the lip to involve the buccal mucosa or spread deeply to involve the gingiva, mandible, and in advanced cases the mental nerve (Baker & Krause, 1980). Lymphatic invasion and nodal positivity occurs in about 5%–10% of lip cancer cases overall. This rate is higher for bulkier and more advanced tumors. Draining lymphatics and therefore sites of nodal spread for upper versus lower lip tumors, as well as all other intraoral primary tumors, are specified in the prior Anatomy section (**Fig. 9**).

Squamous cell carcinomas of the oral tongue tend to originate on the lateral and ventral surfaces of the tongue. Most lateral tumors tend to be located on the middle and posterior thirds of the oral tongue. Dorsal tumors are rare and tend to occur in the posterior midline. Tumors on the tip of the tongue are usually diagnosed early. Local invasion into surrounding structures generally occurs late, but when it occurs, it can spread anteriorly or laterally into the floor of mouth and mandible; posteriorly into the glossotonsillar sulcus, retromolar trigone, tonsillar pillars, and base of tongue; and deep into the oral tongue musculature. Clinical nodal positivity ranges from 15% to 80%, the highest risk of nodal metastases among all oral cancer subsites, and is dependent on the size of the primary tumor and depth of invasion (Rusthoven et al., 2008; Almangush et al., 2015). For patients with clinically positive nodes, the risk of occult contralateral nodal disease is about 30%. Cancers of the anterior oral tongue have been documented as being able to skip levels II–III and spread directly to level IV (Byers et al., 1997; Woolgar, 1997).

Carcinomas of the floor of mouth, in contrast to oral tongue cancer, generally invade into surrounding structures early. About 90% of tumors start within 2 cm of the anterior midline floor. The tumors spread anteriorly into the lower gingiva and lower lip; posteriorly into muscles at the root of the tongue; laterally into the gingiva and along the mandibular periosteum or through the cortex in advanced stages; and deep into the genioglossus, geniohyoid, and sublingual gland. The mylohyoid acts as a barrier to deeper extension, until the tumor is more advanced, such that disease spreads along the muscle, escapes the oral cavity, and emerges in the neck near the angle of the mandible mimicking an enlarged lymph node. Lymphatic invasion and clinical nodal positivity range from 10% to 55% and are directly correlated to T-stage. For patients with clinically positive nodes, the risk of occult contralateral nodal disease is about 50%.

Most gingival tumors, roughly 80%, arise on the lower gingiva. Carcinomas of the alveolar ridge and retromolar trigone tend to invade bone early. Tumors of the lower alveolar ridge and retromolar trigone also have a high propensity of lymph node metastasis, second only to oral tongue carcinomas among all oral cavity subsites. Tumors of the inferior alveolar ridge may access the mandibular canal and the inferior alveolar nerve, whereas tumors of the superior alveolar ridge may invade into the maxillary antrum or floor of the nose. Tumors of the superior alveolus are less likely to metastasize to the neck than tumors of the inferior alveolus.

Carcinomas of the buccal mucosa commonly arise on the lateral walls, adjacent to the lower molars. One route of progression is into the gingivobuccal gutters, and ultimately invasion of the gingiva and bone can arise. Alternatively, they can invade the buccinator muscle, extend to the buccal fat pad, and invade subcutaneous tissues. More advanced tumors can even go on to involve the parotid gland and facial nerve. The likelihood of clinical nodal positivity at the time of diagnosis is approximately 10%–30%, and the risk of subclinical disease is between 5% and 15%. Bilateral neck involvement is rare for this subsite. The risk of nodal involvement increases to 60% for more advanced stage tumors (i.e., T4).

The hard palate has a relatively dense mucoperiosteum that is relatively resistant to invasion from hard palate carcinomas. Carcinomas of the hard palate can invade superiorly into the nasal cavity through the incisive fossa where the primary and secondary palates are fused. Furthermore, these tumors may invade into the surrounding gingiva and maxillary alveolar process, posteriorly into the soft palate, and posterolaterally through the greater palatine foramina into the pterygopalatine fossa which communicates with the skull base. The rate of nodal involvement at the time of diagnosis is about 13%–24% with a risk of subclinical involvement of 22% (**Fig. 10**).

The superior deep jugular nodes are the most frequently involved sites of lymphatic metastasis by cancers of the oral cavity. Approximately 25% of patients with carcinoma of the oral cavity will have occult nodal metastases. Contralateral metastases are more common in tumors that approach or cross the midline. In general, cervical lymph node involvement from oral cavity primary sites is predictable and orderly, spreading first to upper, then middle, and subsequently lower cervical nodes.

Hematogenous invasion is generally a rare initial presentation for oral cavity cancer. The lungs are the most common site of distant metastases; skeletal and hepatic metastases occur less often. Mediastinal lymph node metastases are considered distant

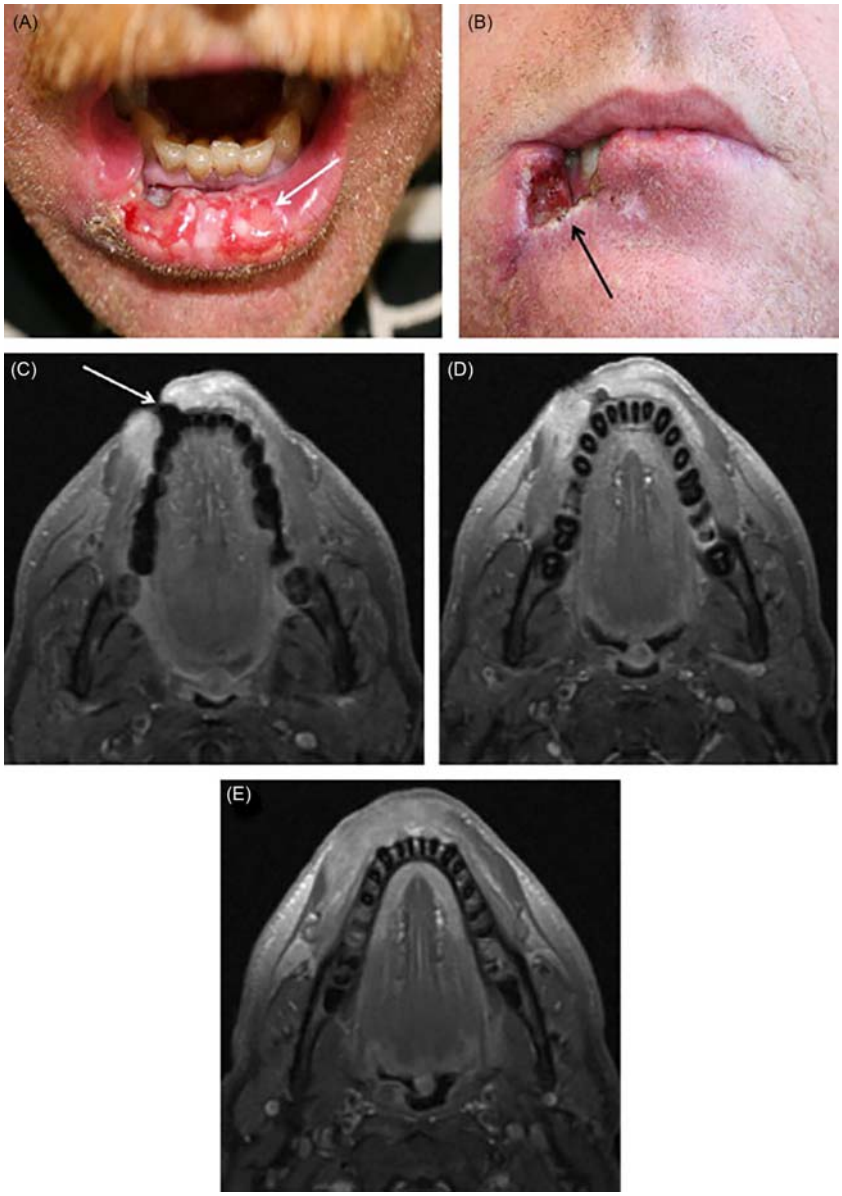

Fig. 9 Lip carcinoma. (A, B) Photographs show extensive ulceration and infiltration with erythroleukoplakia of the right lower lip and labial mucosa. Extension across the midline is seen intraorally (*white arrow* in A) and ulceration with breakdown of the skin is seen extraorally (*black arrow* in B). (C, D, E) Axial postcontrast T1-weighted images from superior to inferior show an enhancing mass extending from the skin surface to the buccal surface of the mandible, without evidence of bone invasion. Note the area of ulceration superiorly (*arrow* in C). From Hagiwara, M., Nusbaum, A., Schmidt, B. L. (2012). MR assessment of oral cavity carcinomas. *Magnetic Resonance Imaging Clinics of North America* **20**(3), 473–494.

metastases, except level VII or anterior superior mediastinal lymph nodes cephalad of the innominate artery. An increased risk of distant metastasis is associated with a higher burden of lymph node involvement, advanced primary tumor stage, and recurrent disease.

Presentation and Diagnosis

Clinical Presentation

Although the oral cavity is an anatomic region readily accessible to visual inspection and palpation, many patients present with advanced-stage disease because of vague and initially painless symptoms. About 30%–40% of patients with cancer of the oral cavity harbor cervical lymph node metastases at the time of diagnosis.

The most common presenting symptom for cancer of the oral cavity is a nonhealing lesion. Similarly, persistent pain in the mouth that does not resolve is also very common. Other presenting signs and symptoms include persistent leukoplakia or

Fig. 10 Left hard palate mucoepidermoid carcinoma. (A) Axial contrast-enhanced CT shows 2-cm enhancing mass with fairly well-circumscribed borders (*arrow*) in the left hard palate. Well-circumscribed borders are common in minor salivary gland malignancies, making it difficult to differentiate them from benign minor salivary gland tumors. (B, C) Bone window from axial CT images (at the level of the hard palate (B) and just above) show asymmetric widening of the left greater palatine foramen (*arrow*), compatible with perineural tumor extension. (D) Bone window from axial CT images shows extension of abnormal widening to the left pterygopalatine fossa (*arrow*). An MR image is needed to assess for proximal intracranial extension to determine if this tumor was resectable. From Aiken, A. H. (2013). Pitfalls in the staging of cancer of oral cavity cancer. *Neuroimaging Clinics of North America* **23**(1), 27–45.

erythema, difficulty chewing or swallowing, limited tongue mobility, bleeding, odynophagia, trismus, constant halitosis, globus sensation, otalgia, loose teeth, ill-fitting or uncomfortable dentures, voice changes, weight loss, numbness, and persistent or enlarging masses in the mouth and/or neck despite antibiotics.

Otalgia suggests involvement of cranial nerves V, VII, IX, or X—though the auriculotemporal branch of the mandibular division of the trigeminal nerve is the most commonly involved in oral cavity primary tumors (Scarbrough et al., 2003). Facial numbness may suggest involvement of the trigeminal nerve. Hypoesthesia of the lower lip and teeth is often from malignant penetration of the mandible and perineural spread along the inferior alveolar nerve. The presence of trismus may indicate invasion into the pterygoid musculature.

The differential diagnosis of lip cancer includes actinic cheilitis, leukoplakia, herpes simplex, syphilitic chancre, keratoacanthoma, hemangioma, and fibroma. The differential diagnosis for an oral tongue cancer includes granular cell myoblastoma, pyogenic granuloma, and hypertrophied papillae. The differential diagnosis for other intraoral cancers includes leukoplakia, candidiasis, and lichen planus.

Diagnostic Evaluation

Patients who present with cancer of the oral cavity should undergo a comprehensive history and physical examination. A detailed history of present illness should specifically evaluate for any of the aforementioned symptoms and identify carcinogenic risk factors, such as tobacco, alcohol, or betel nut use. A complete past medical history should be performed to take into account comorbid illnesses when creating an ideal treatment plan. A family medical history should be obtained to evaluate for inheritable genetic mutations. A full review of systems should be performed to evaluate for concurrent illnesses or systemic manifestations of the disease.

A meticulous physical examination of the head and neck should be performed, with particular focus on the oral cavity. This typically begins with a full inspection of the oral cavity in good lighting. Bimanual palpation of the oral cavity can help assess extent of induration, fixed tissues, and bony involvement. A thorough palpation of the neck is important to assess regional nodal disease.

Evaluation of other areas of the aerodigestive tract for synchronous primaries and functional deficits can be performed by indirect pharyngolaryngoscopy using small mirrors and/or direct pharyngolaryngoscopy using a flexible fiberoptic scope.

The next important step in diagnostic evaluation is biopsy to confirm malignancy. Histopathologic sampling can be performed by fine needle aspiration with or without ultrasound guidance, core needle biopsy, incisional biopsy, or exfoliative cytology. Immunohistochemistry staining can be performed on core needle and incisional biopsy specimens. Tumor HPV status can be determined using various testing platforms, including HPV DNA in situ hybridization, HPV RNA in situ hybridization, HPV polymerase chain reaction, and p16 immunochemistry (Duncan et al., 2013). The immunohistochemical staining for p16 is inexpensive, has near universal availability, and is relatively straightforward to interpret (Singhi & Westra, 2010; Lydiatt et al., 2017; **Fig. 11**).

Imaging modalities that may be used for staging, treatment planning, and posttreatment monitoring include X-ray, ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET). A chest CT is helpful to exclude lung metastases or identify a synchronous primary lung cancer, especially in patients with a significant smoking history. A head and neck CT, ideally with IV contrast, is the most commonly used modality to determine the extent of soft-tissue and bony involvement as well as to identify occult disease in the neck. The "puffed-cheek" maneuver during CT scanning may be helpful to better visualize and assess extent of invasion for buccal and gingival mucosa primary tumors (Weissman & Carrau, 2001). If CT scanning is not available, then panoramic radiographs can be used to demonstrate mandibular invasion. MRI may be used in cases of contrast allergy, poorly visualized lesions on CT such as from significant dental artifact, to establish the extent of primary tumor, and evaluating for perineural spread. Ultrasound may be used to screen for enlarged lymph nodes that are not clinically detectable, and in experienced hands the accuracy of ultrasound when combined with fine needle aspiration may be superior to CT or MRI for staging the neck (van den Brekel et al., 1993). PET-CT is highly sensitive in staging of patients with squamous cell carcinoma of the head and neck, but it is insensitive to evaluation of patients with glandular tumors, low volume tumors, and cystic metastases (Escott, 2013; Johnson & Branstetter, 2014). A prospective cohort study demonstrated that PET-CT based staging had a significantly higher detection rate of distant metastasis or synchronous cancer compared to other combined modalities (Rohde et al., 2017).

The presence of ENE, which is associated with worse outcome, is most commonly diagnosed pathologically, but it may also be identified on physical exam and imaging. Clinically, ENE may be diagnosed by the presence of a matted mass of nodes, involvement of overlying skin or adjacent soft tissues, or clinical signs of nerve invasion. Radiographically, ENE may be diagnosed by an indistinct nodal margin, irregular nodal capsular enhancement, or infiltration into adjacent fat or muscle.

Basic blood tests such as complete blood count, comprehensive metabolic panel, and liver function tests are useful to determine overall health and underlying organ function. These can diagnose anemia, malnutrition, kidney disease, or liver disease. Occasionally basic labs may also suggest metastatic disease to the liver or bone. These labs in combination with complete past medical history can also guide appropriate treatment, such as surgery or preferred systemic agent based on predicted treatment-related toxicity. Other diagnostic tests to consider in certain patients include electrocardiogram and pulmonary function tests prior to surgery. Candidates for radiation therapy should ideally undergo dental evaluation prior to initiation of treatment. Additionally, many patients benefit from multidisciplinary referrals to nutritionists and speech therapists.

Staging

Historically, cancers of the oral cavity were predominately staged based on the size of the primary tumor; invasion into surrounding structures; the size, laterality, and number of nodal metastases; and the presence or absence of distant metastatic disease. The American Joint Committee on Cancer (AJCC) 8th Edition introduced two new parameters in oral cavity staging: depth of invasion and

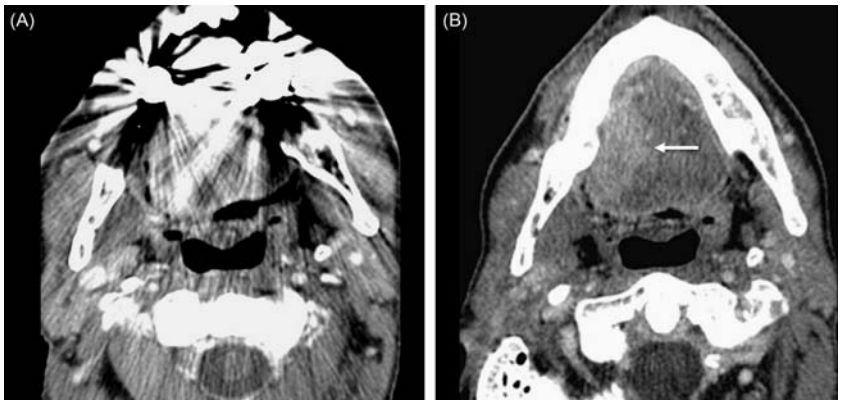

Fig. 11 Usefulness of reangled images to visualize squamous cell carcinoma of the right oral tongue. (A) Axial CT through the oral cavity is nondiagnostic because of dental amalgam and extensive streak artifact. (B) Delayed and reangled axial contrast-enhanced CT image shows a large enhancing right oral tongue mass (*arrow*), effacing the right sublingual space. From Aiken, A. H. (2013). Pitfalls in the staging of cancer of oral cavity cancer. *Neuroimaging Clinics of North America* **23** (1), 27–45.

ENE. Effectively, depth of invasion will increase the T category by 1 for each 5 mm of tumor depth until ≥10 mm. Pathological presence of ENE will increase the nodal category by 1 to either N2a or N3b depending on the size, laterality, and quantity of nodes involved.

Management

General Management

Treatment goals for cancer of the oral cavity include eradication of malignancy, preservation or restoration of form and function, avoidance or minimization of treatment sequelae, and prevention of second cancers. The ideal treatment to achieve these goals, whether as single modality or in combination, depends on various disease-, treatment-, provider-, and patient-related factors. Examples of these respective factors include tumor stage and location; potential treatment morbidity and convenience; multidisciplinary team expertise and available technology; and patient performance status and comorbid disease. A multidisciplinary approach is paramount in the optimal management of patients with cancer of the oral cavity. Multidisciplinary evaluation prior to treatment disposition helps to ensure consensus recommendations are made and to facilitate interdisciplinary coordination of care.

Early stage oral cavity tumors (e.g., T1-T2, N0-N1) are generally managed with single modality locoregional treatment consisting of surgery or radiation therapy. Surgery is generally preferred, but radiation therapy is appropriate when overall health or functional status precludes an operation, when there is an anticipated poor functional or cosmetic outcome, or simply when a patient declines surgery. For patients with locally advanced oral cavity tumors (e.g., T3-T4, N2-N3), upfront surgery followed by adjuvant radiation therapy with or without concurrent chemotherapy is generally preferred. However, in patients unable to undergo surgical resection, definitive chemoradiotherapy has been shown to be a reasonable option.

Prognostic and Predictive Factors

A series of nomograms and retrospective analyses have identified factors associated with recurrence and survival. One such nomogram predicts preoperative prognosis in patients with oral cavity squamous cell carcinoma and was designed after reviewing demographic, host, and tumor characteristics of 1617 patients treated primarily with surgery at a single-institution tertiary care cancer center between 1985 and 2009 (Montero et al., 2014). The most influential predictors of both recurrence and cancer-specific mortality probability were tumor size, nodal status, subsite, and bone invasion. A retrospective analysis of a single United States institution's 35-year experience treating 230 primary invasive squamous cell carcinomas of the oral cavity with surgery and postoperative radiotherapy (PORT) demonstrated that the following variables were significant on multivariate analysis for locoregional control: positive margins, vascular invasion, perineural invasion, extracapsular extension, and T stage (Hinerman et al., 2004).

One of the consistently reported prognostic factors for oral cavity cancers is depth of primary tumor invasion, which is associated with occult cervical metastases, especially in oral tongue cancer. Although the oral cavity subsites, study designs, and techniques for measuring depth of invasion varied significantly, a review of >50 studies identified tumor thickness/depth of invasion as predictive of nodal involvement and survival (Pentenero et al., 2005). A multicenter international study of patients with T1-T2, N0 oral tongue squamous cell carcinoma identified depth of invasion and worst pattern of invasion as strong predictors for locoregional recurrence and cancer-related mortality (Almangush et al., 2015). Consequently, the authors proposed that multimodality treatment should be utilized for early-stage oral tongue carcinomas with depth of invasion ≥4 mm or with a growth pattern characterized by small cell islands or satellites. This was supported by a meta-analysis, which analyzed sixteen studies consisting of 1136 patients with oral cavity squamous cell carcinoma to assess the predictive value of tumor thickness for cervical lymph node involvement (Huang et al., 2009). The optimal tumor thickness cutoff point was <4 mm, yielding a negative predictive value of 95.5% for cervical lymph node involvement.

Additionally, the pattern of pathologically involved cervical lymph nodes is associated with patient outcomes. An analysis of prognostic factors in 255 patients with oral cavity squamous cell carcinoma with ENE identified level IV and V nodal metastases and tumor depth ≥12 mm as independent predictors of 5-year survival (Liao et al., 2011; **Fig. 12**). These factors divided patients into three prognostic groups. In the low-risk group (no level IV/V metastases and tumor depth <12 mm), intermediate-risk group (no level IV/V metastases and tumor depth ≥12 mm), and high-risk group (level IV/V metastases present), the 5-year overall survival rates were 50%, 28%, and 10%, respectively.

Surgery

The overall health and functional status of the patient are important determinants in choosing between surgical and nonsurgical approaches. Surgery is generally preferred as definitive treatment of the primary tumor because it is expeditious, convenient, and offers pathologic information to guide treatment of the neck and adjuvant therapy. General principles of surgery include adequate exposure, wide negative margins (e.g., 1–2 cm mucosal margins and 1 cm bone margins), proximal transection of clinically-involved nerves, evaluation of the neck (elective vs. therapeutic), and tracheostomy if postoperative edema and airway obstruction are anticipated (**Fig. 13**).

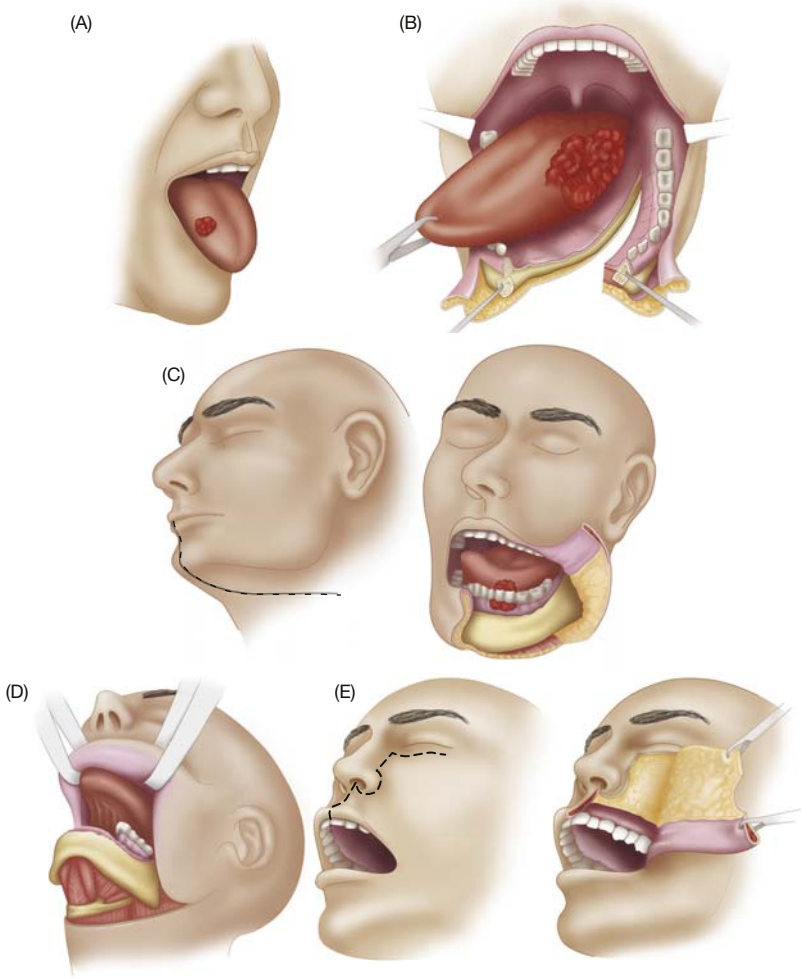

Fig. 13 Various surgical approaches: (A) peroral, (B) mandibulotomy, (C) lower cheek flap, (D) visor flap, and (E) upper cheek flap. From Montero, P. H., Patel, S. G. (2015). Cancer of the oral cavity. *Surgical Oncology Clinics of North America* **24**(3), 491–508.

Surgical management of the primary tumor

For early-stage lesions of the oral cavity, a transoral method of approach to resection generally provides adequate exposure to obtain negative margins. For advanced or poorly visualized tumors, a mandibulotomy or pull-through technique is often utilized for floor of mouth, tongue, and mandibular pathology while a Weber-Ferguson incision or mid-face degloving may be necessary for

maxillary or palatal lesions. When compared to open approaches, transoral approaches lead to shorter hospitalizations, and decreased tracheotomy and PEG dependence (Moore et al., 2012; White et al., 2010). Of note, most of the functional outcomes research on transoral versus traditional approaches pertains to oropharyngeal carcinoma but can be extrapolated to the oral cavity.

For lip cancers, surgical excision with intraoperative margin analysis with immediate reconstruction is the preferred method of treatment. For lesions involving up to one-third of the lip, excision with primary closure is generally performed. If the proposed excision involves up to two-thirds of the lip, local flaps are required for reconstruction. In general, regardless of the reconstruction needed (e.g., Abbe flap, Estlander flap if the oral commissure is involved, Karapandzic flap, radial forearm free tissue transfer with or without palmaris tendon suspension, etc.), wide local excision is indicated.

For cancers that involve the alveolar ridge, resection of a portion of the mandible is sometimes indicated (Genden et al., 2005). Given that the mucosa is densely adherent to the underlying periosteum, it is not uncommon to see bony erosion. While mandibular invasion is associated with decreased overall survival, medullary space invasion (rather than cortical invasion) is associated with decreased disease-specific survival and overall survival (Li et al., 2017). A marginal mandibulectomy, or rim resection of only the alveolar process or the lingual cortex of the mandible, is oncologically safe as long as the tumor abuts or only superficially invades the mandible (Chen et al., 2011; Patel et al., 2008). Physical exam findings (such as fixation and paresthesias) and imaging (CT or MRI) should be used to determine extent of surgical resection preoperatively (Van Cann et al., 2008; Nomura et al., 2005). In dentulous patients, in additional to erosion and infiltration of the bone, the tumor can migrate through the dental socket into the mandible, especially in the setting of dental extractions (Genden et al., 2005). When there is clinical or radiographic evidence of medullary space involvement, a segmental mandibulectomy is indicated. Of particular importance when determining extent of surgery is the status of the mental/inferior alveolar nerve. Clinical or radiographic findings that are concerning for involvement will require a more aggressive resection to obtain microscopically uninvolved bone, marrow, and nerve margins (**Fig. 14**).

Wide local excision (i.e., partial glossectomy) is the treatment of choice for small tumors confined to the tongue without significant posterior extension. In more advanced cases (e.g., deep extension to the extrinsic tongue muscles or involvement of the floor of mouth), a more invasive approach to the tumor is necessary to provide negative margins. The extent of resection (i.e., amount of oral tongue and floor of mouth mucosa) and the approach needed play a significant role in the reconstruction. Small transoral resections of the oral tongue can be closed primarily or left open to heal through secondary intention. Larger defects can be reconstructed with a split-thickness autograft if there is limited floor of mouth involvement. If significant portions of the floor of mouth are involved, one must be concerned about tethering and the associated functional consequences such as dysarthria and dysphagia. If a significant amount of floor of mouth mucosa is resected, local, regional, or free flap reconstruction with thin pliable tissue is necessary to preserve tongue mobility. Regional flaps like the submental island flap can be used for reconstruction without effecting oncologic safety (Kramer et al., 2015; Rigby & Hayden, 2014; Howard et al., 2014).

Cancer of the buccal mucosa can generally be excised via transoral approach. The buccinator muscle can be resected along with the primary lesion to provide an appropriate deep margin. Larger and more advanced tumors may require a more extensive ablation (e.g., resection of the pterygoids, subcutaneous fat and overlying skin with a resultant through-and-through defect, etc.) and reconstruction.

Small, early-stage lesions of the hard palate can also be removed through a wide local excision with the periosteum as an appropriate deep margin. If the periosteum or the underlying bone is involved, similar to an alveolar ridge lesion, resection of the bone via a maxillectomy is necessary. An inferior or subtotal maxillectomy may be necessary to obtain negative margins. If the nasal cavity or maxillary sinus is entered as a consequence of tumor ablation, the amount of connection will dictate reconstruction. Obturators, local flaps, or free flap reconstruction (bony vs. soft tissue) are all viable options with differing risks and benefits (**Fig. 15**).

Advances in reconstructive surgery, together with improvements in our understanding of the physiology of swallowing and in speech rehabilitation, have helped to reduce the morbidity associated with surgery in the oral cavity. Surgical reconstruction may be

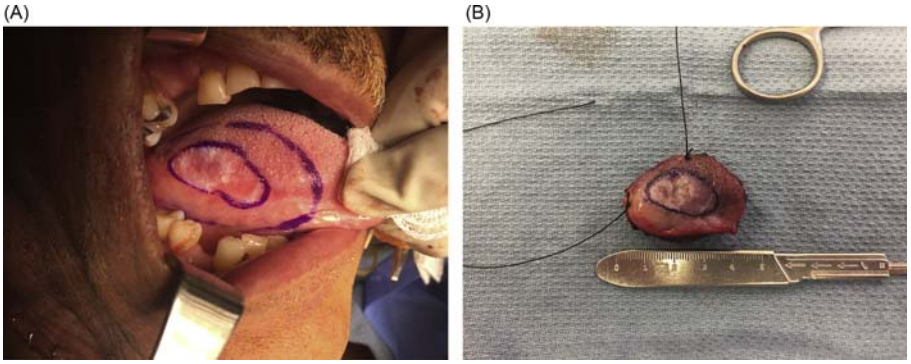

Fig. 14 (A) cT1 squamous cell carcinoma of the right lateral tongue, marked circumferentially with a 1-cm margin. Margin analysis: Squamous cell carcinoma of the oral cavity. *Oral and Maxillofacial Surgery Clinics of North America* **29**(3), 259–267.

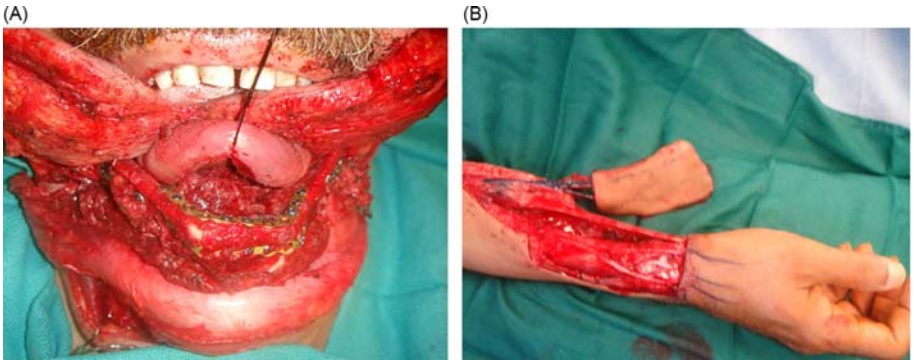

Fig. 15 Fibular (left) and radial forearm (right) free flaps are two common flaps used in oral cavity reconstruction after major resections. From Montero, P. H. and Patel, S. G. (2015). Cancer of the oral cavity. *Surgical Oncology Clinics of North America* **24**(3), 491–508.

performed after confirmation of complete resection with negative surgical margins. The reconstructive ladder ranging from primary closure or secondary intention to free tissue transfer must be employed with special consideration to long term swallowing, speech, and breathing. Small surgical defects of the oral tongue may not require reconstruction and therefore are often allowed to heal by secondary intention while a similarly sized defect of the floor of mouth could lead to debilitating tethering, dysphagia, and dysarthria. Larger or complex defects may be reconstructed by a combination of primary closure, split-thickness skin graft, vascularized cutaneous free flap, regional myocutaneous flap, or microvascular free flap (Urken et al., 1994). Reconstruction of a segmental defect of the mandible is a complex topic that is beyond the scope of this article (**Fig. 16**).

Surgical management of the neck

More than 90% of occult metastatic disease from oral cavity cancer involves nodal groups I–III (submental, submandibular, upper, and middle jugulodigastric nodes), thus a selective neck dissection removing these levels (formerly known as a supraomohyoid neck dissection) is oncologically sound, especially in the clinically N0 neck. Elective supraomohyoid neck dissection has been shown to improve survival rates compared to primary tumor resection alone in early stages of oral squamous cell carcinoma (Brazilian Head and Neck Cancer Study Group, 1998; Kligerman et al., 1994; D'Cruz et al., 2015). In particular, patients with T1-T2, N0 oral tongue cancer with tumor thickness >4 mm had significant improvement in disease-specific survival with elective neck dissection compared to observation. Because of the survival advantage and the poor salvage rate, elective neck dissection has been the standard of care (Abu-Ghanem et al., 2016).

In general, elective neck dissection in the clinically N0 neck is indicated when there is at least a 20% chance of lymph node involvement. The lower lip has a low risk of occult metastasis and therefore does not require elective neck dissection (Ozturk et al., 2015; Gary et al., 1995). A systematic review and meta-analysis demonstrated that the overall rate of cervical metastasis from a maxillary squamous cell carcinoma was 31%, with increasing risk as T-stage advances (Zhang and Peng, 2016). Patients with a primary tumor that involves the oral tongue, floor of mouth, mandibular alveolar ridge, or buccal mucosa present with an increased risk of occult cervical metastasis and should therefore be considered for an elective neck dissection (Capote et al., 2007; Fasunla et al., 2011). Based on lymphatic drainage pathways, midline tumors should be treated with bilateral neck dissections.

Recently, results were published on the first 500 patients enrolled on a prospective, randomized controlled trial evaluating the effect of elective node dissection (i.e., ipsilateral neck dissection with the primary surgery) versus therapeutic node dissection (i.e., neck dissection following nodal relapse) on survival in patients with lateralized T1-T2 squamous cell carcinomas of the oral cavity

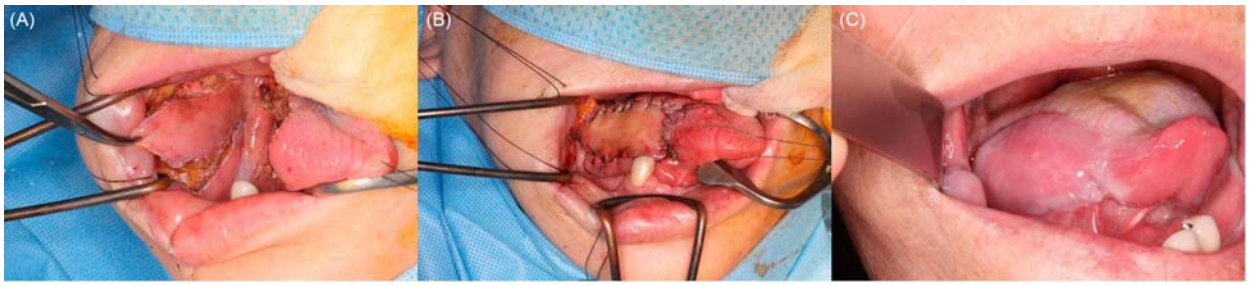

Fig. 16 After partial glossectomy, a posterior-based buccinator myomucosal flap (based on buccal artery) was harvested (A) and sutured to the residual tongue (B). Photograph taken 6 months postoperatively reveals healthy condition of the transplanted flap without shrinkage (C). From Ahn, D., Lee, G. J., and Sohn, J. H. (2017). Reconstruction of oral cavity defect using versatile buccinator myomucosal flaps in the treatment of cT2–3, N0 oral cavity squamous cell carcinoma: Feasibility, morbidity, and functional/oncological outcomes. *Oral Oncology* **75**, 95–99.

(D'Cruz et al., 2015). After a median follow up of 39 months, elective neck dissection resulted in higher rates of 3-year overall and disease-free survival than therapeutic neck dissection with similar rates of adverse events in the elective-surgery and therapeutic-surgery groups (6.6% and 3.6%, respectively).

A systematic review and meta-analysis comparing elective neck dissection with observation in patients with clinically node-negative, early-stage T1-T2 oral tongue squamous cell carcinoma showed that elective neck dissection can significantly reduce the rate of regional nodal recurrence and improve disease-specific survival in this population (Abu-Ghanem et al., 2016). A meta-analysis on selective versus comprehensive neck dissection in oral squamous cell carcinoma patients with clinically node-positive necks showed that selective neck dissection achieves similar regional control, disease-specific survival, and overall survival compared with comprehensive neck dissection (Liang et al., 2015).

Overall, there is increasing evidence that elective neck dissection in oral cavity carcinoma, even early stage, reduces regional recurrence rates, disease specific survival, and improves overall survival compared to observation alone (D'Cruz et al., 2015; Fasunla et al., 2011) (**Table 2**).

Sentinel lymph node biopsy is a less invasive procedure than neck dissection which is routinely used for other nonoral cavity sites of primary malignancy. A German prospective consecutive cohort analysis first correlated sentinel lymph node positivity with survival in early oral cavity and oropharyngeal cancer (Broglie et al., 2013). The authors found that the 3-year overall survival in patients with a negative sentinel lymph node was 98% compared to 71% in sentinel lymph node positive patients. Similar differences were seen in disease-specific survival (95% vs. 76%) and disease-free survival (98% vs. 73%). In addition, they identified correlation between the presence of isolated tumor cells or micrometastases and survival. Other authors have reported the sensitivity and negative predictive value of sentinel lymph node biopsy for oral cancer staging as 71% and 94%, respectively (Rigual et al., 2013). Further research to validate these findings may lead to changes in patterns of care based on the utility of the sentinel lymph node biopsy.

Adjuvant Therapy Following Definitive Surgical Resection

Following surgical resection, patients with pathologic features such as advanced primary T stage (T3-T4), lymphovascular space invasion, perineural invasion, positive margins, multiple pathologically involved cervical lymph nodes, and ENE have been shown to be at high-risk for locoregional recurrence (Cooper et al., 1998). PORT, frequently in conjunction with chemotherapy, results in a decreased risk of locoregional relapse for these patients (Lavaf et al., 2008; Maccomb, 1957). A nomogram constructed using data from 590 patients treated at a United States cancer center and validated using data from 417 patients treated at a Brazilian hospital can be used to help decide adjuvant treatment; however, limitations of the nomogram include the lack of important pathologic variables including ENE, perineural invasion, and lymphovascular space invasion, as well as the nonuniform use of radiation therapy between the construction and validation cohorts (39.5% vs. 60.4%) (Gross et al., 2008). More recently this group has created and validated an online nomogram using data from >1400 patients to estimate locoregional failure-free survival with and without PORT (Wang et al., 2013). Factors predictive of a locoregional control benefit from PORT include high N stage, low T stage, positive margins, young age, and female sex.

Adjuvant radiotherapy is preferred over preoperative radiotherapy based on Radiation Therapy Oncology Group (RTOG) 7303, which demonstrated that PORT provided superior locoregional control (70% vs. 58%) when compared to preoperative radiotherapy in patients with advanced head and neck cancer. Overall survival was unaffected by the timing (Tupchong et al., 1991). PORT provides the advantage of avoiding delay in implementation of surgical resection and obtaining complete pathologic staging of the tumor. However, postoperative wound complications may delay the initiation of PORT, and the regional hypoxia that can accompany the postoperative state may diminish the effectiveness of PORT compared to that achievable under conditions of full oxygenation.

Table 2 Types of neck dissections

	Lymph nodes excised	*Other structures excised*	*Structures preserved*
Radical neck dissection	Levels I–V	Sternocleidomastoid muscle, internal jugular vein, spinal accessory nerve, submandibular gland	
Modified radical neck dissection type I	Levels I–V	Sternocleidomastoid muscle, internal jugular vein, submandibular gland	Spinal accessory nerve
Modified radical neck dissection type II	Levels I–V	Internal jugular vein, submandibular gland	Sternocleidomastoid muscle, spinal accessory nerve
Modified radical neck dissection type III	Levels I–V	Submandibular gland	Sternocleidomastoid muscle, internal jugular vein, spinal accessory nerve
Supraomohyoid neck dissection	Levels I–III	Submandibular gland	Sternocleidomastoid muscle, internal jugular vein, spinal accessory nerve

From Montero, P. H., Patel, S. G. (2015). Cancer of the oral cavity. *Surgical Oncology Clinics of North America* **24**(3), 491–508.

Overall treatment time has been shown to be a critical factor in tumor control for cancers of the head and neck, including those of the oral cavity. Improved outcomes have been demonstrated when all radiation therapy is completed within 40 days for oral tongue cancer (Mendenhall et al., 1989). For patients with advanced head and neck cancer treated with combined modality therapy, the overall time from surgery to the completion of radiation therapy has been shown to be inversely related to prognosis. Multiple phase III prospective trials have demonstrated that the cumulative duration of combined modality therapy drives locoregional control and survival (Ang et al., 2001; Rosenthal et al., 2017). Significantly improved outcomes have been reported when the treatment package time was <85 days, and the treatment package time had a greater impact on locoregional control and survival than the dose of radiation administered (Rosenthal et al., 2017). High-risk patients who had a prolonged delay between surgery and PORT had an improved outcome with an accelerated fractionation schedule compared with those irradiated once daily (Ang et al., 2001).

Adjuvant chemoradiotherapy

Cisplatin-based chemotherapy combined with PORT has been compared to PORT alone for medically fit head and neck cancer patients in multiple randomized studies. These studies demonstrated statistically significant (Bernier et al., 2004; Bachaud et al., 1996; Fietkau et al., 2006) or strong statistical trends (Cooper et al., 2004) for improved locoregional control and disease-free survival with the addition of chemotherapy to PORT. Two of these studies demonstrated a statistically significant improvement in overall survival (Bernier et al., 2004; Noronha et al., 2018), while the others have shown numerically improved but not statistically significant survival improvements (Fietkau et al., 2006; Cooper et al., 2004). Of note, at least one quarter of patients in both the European Organization for Research and Treatment of Cancer (EORTC) 22931 and RTOG 9501 studies had oral cavity cancer, 26% and 27% respectively. A pooled analysis of the latter two trials demonstrated improved overall survival with the addition of concurrent chemotherapy to PORT for patients with positive margins and/or ENE (Bernier et al., 2005).

More recently, the final results of the Oral Cavity Adjuvant Therapy (OCAT) trial comparing multiple adjuvant treatment strategies (conventionally fractionated radiation with five fractions per week vs. altered fractionation with six fractions per week vs. conventional chemoradiation with weekly cisplatin 30 mg/m^2) in patients with resectable high-risk, locally advanced oral cavity cancer (stage III/IV and at least ENE, involvement of 2 or more regional lymph nodes, microscopically positive margins, extensive soft tissue or skin involvement requiring major reconstruction, perineural invasion, or lymphovascular space invasion) were presented (Laskar et al., 2016). No significant difference in locoregional control, disease-free survival, or overall survival was noted between the treatment arms. Planned subgroup analysis showed that chemoradiotherapy with weekly cisplatin resulted in improved locoregional control, disease-free survival, and overall survival compared to conventional radiation for patients with T3-T4, N2-N3 disease with ENE. There was no apparent difference in toxicity or radiotherapy compliance among the three regimens. The results of this trial have to be interpreted carefully, as most of the patients developed oral cavity cancer from betel nut chewing. Therefore, it is not clear if these results can be extrapolated to other areas where oral cavity cancer typically results from other risk factors. Also, a majority of the patients on the trial had gingiva/buccal tumors, so it is not clear if these results can be extrapolated to patients with oral tongue or floor of mouth cancers (**Fig. 17**). Additionally, the chemotherapy regimen utilized (30 mg/m^2 of weekly cisplatin) is considered to be suboptimal (see below), which may account for the lack of difference in outcomes between treatment arms.

Concurrent chemotherapy regimens for adjuvant chemoradiotherapy

Many consider bolus cisplatin (100 mg/m^2) given every 3 weeks with radiation therapy to be the standard of care for cancers of the head and neck; however, the optimal chemotherapy schedule is unknown. Bolus cisplatin (100 mg/m^2) schedules were tested in the previously mentioned RTOG 9501 and EORTC 22931 studies (Bernier et al., 2004; Cooper et al., 2004). A French randomized trial (Bachaud et al., 1996) utilized 50 mg weekly cisplatin, while the ARO 96-3 trial (Fietkau et al., 2006) employed cisplatin 20 mg/m^2 and 5-fluorouracil 600 mg/m^2 on days 1–5 and 29–33. A phase III randomized trial comparing the use of bolus cisplatin (100 mg/m^2) to weekly cisplatin (40 mg/m^2) with concurrent adjuvant radiation therapy in patients with high-risk (ENE, positive surgical margins, or pN2-N3) squamous cell carcinoma of the oral cavity demonstrated no difference in overall or locoregional recurrence free survival at 1 year (Tsan et al., 2012). A recently reported study in patients with head and neck cancer ($>90\%$ with oral cavity cancer) receiving adjuvant or definitive concurrent chemoradiotherapy compared cisplatin delivered 30 mg/m^2 weekly versus 100 mg/m^2 every 3 weeks (Noronha et al., 2018). Bolus cisplatin (100 mg/m^2) was found to improve locoregional control, which was the primary endpoint; however, many consider the weekly cisplatin regimen of 30 mg/m^2 utilized in this trial to be suboptimal.

The role of carboplatin-based chemotherapy regimens given concurrently with PORT versus PORT alone remains poorly defined. Randomized studies have been attempted, but unfortunately these studies were closed early before their accrual goals were met. Preliminary results revealed no significant benefit in locoregional control, disease-free survival, or overall survival from combining carboplatin with PORT (Expert Panel on Radiation Oncology-Head and Neck et al., 2011).

RTOG 0234 is a phase II trial of high-risk postoperative patients (positive margin, ENE, and/or ≥ 2 pathologically involved cervical nodes) randomized to PORT in combination with cetuximab (400 mg/m^2 loading dose followed by 250 mg/m^2 weekly) and weekly docetaxel (15 mg/m^2) or to PORT with cetuximab (400 mg/m^2 loading dose followed by 250 mg/m^2 weekly) and weekly cisplatin (30 mg/m^2) (Harari et al., 2014). Published results from this study compared favourably to outcomes seen in similar patients treated with PORT and cisplatin (100 mg/m^2 every 3 weeks) on RTOG 9501. It should be noted that almost half of the patients enrolled on RTOG 0234 (46.8%) had cancers of the oral cavity. Based on these findings, RTOG 1216,

Fig. 17 Contrast-enhanced CT axial image in a 55-year-old male smoker with squamous cell carcinoma of the tongue demonstrates an enhancing soft tissue mass involving the left oral tongue (*white arrows*) with extension to the midline. There is also a large necrotic-appearing left level 2 lymph node (*black arrow*) consistent with nodal metastasis. From Meesa, I. R., Srinivasan, A. (2015). Imaging of the oral cavity. *Radiologic Clinics of North America* **53**(1), 99–114.

a randomized phase II/III trial, was designed to determine the effectiveness of docetaxel with or without cetuximab relative to cisplatin in the setting of adjuvant PORT.

Currently, no randomized phase III data exist regarding the use of other chemotherapy agents in the postoperative setting for head and neck cancer. As a result, many consider cisplatin 100 mg/m^2 every 3 weeks to be the standard.

Adjuvant radiotherapy dose, volume, and modality

The optimal adjuvant radiotherapy dose is not well established. Most of the randomized studies which demonstrated a benefit of concurrent chemoradiotherapy in the adjuvant setting utilized doses of 60–66 Gy in 2 Gy daily fractions to high-risk areas (primary tumor bed with a positive margin, or nodal regions with ENE) and doses of 50–54 Gy in 2 Gy fractions to areas at risk for microscopic involvement. In three of the four randomized studies investigating adjuvant chemoradiotherapy, doses $>$65 Gy were prescribed to high-risk areas (Bernier et al., 2004; Bachaud et al., 1996; Fietkau et al., 2006), while the other study, RTOG 9501, utilized a dose of 60 Gy with or without an optional 6 Gy boost (Cooper et al., 2004). Despite the fact that little evidence exists to support the higher PORT doses used in these randomized trials over the doses established from PORT-alone dose-finding studies (63 Gy for ENE and 57.6 Gy for all other areas), we recommend similar dosing schedules as the randomized trials given that they were associated with significant overall survival benefits in patients with ENE and positive margins.

Frequently, the radiotherapy treatment volume used in the adjuvant setting for head and neck cancer encompasses the primary tumor site and the bilateral cervical lymph node regions, yet it is unclear whether both always need to be included. For patients with completely resected primary tumors and negative margins whose only indication for PORT is pathologic cervical lymphadenopathy, some clinicians would recommend therapy only to the neck. Similarly, for patients who have undergone a comprehensive neck dissection with pathologically uninvolved cervical lymph nodes and have only a positive margin in the primary tumor bed as their sole indication for treatment, clinicians may recommend PORT to the tumor bed only. Another setting where a less comprehensive radiation volume may be recommended is for patients with well-lateralized primary tumors where the reported patterns of progression suggest that this may be appropriate (Expert Panel on Radiation Oncology-Head and Neck et al., 2011).

Intensity modulated radiation therapy (IMRT) is the recommended treatment modality for head and neck cancers whenever high-dose, curative-intent irradiation is administered, whether definitively or adjuvantly (Mell et al., 2005). The benefits of IMRT are further discussed later in this article in the IMRT subsection of Definitive Radiation Therapy.

Definitive Radiation Therapy

Historically, the oral cavity has been divided into subsites, as the location of the primary tumor would determine the radiation modalities that could be utilized to deliver dose. As external beam radiotherapy delivery techniques have improved, these distinctions have become less clinically relevant. For early stage oral cavity cancer, radiotherapy alone can result in excellent local control and survival rates; however, local control decreases with more advanced tumor stage (**Fig. 18**).

The optimal dose fractionation schedule for patients receiving definitive radiotherapy alone for oral cavity cancer has not yet been established. Randomized data (Beitler et al., 2014; Overgaard et al., 2003; Overgaard et al., 2010) and meta-analyses (Budach et al., 2006; Bourhis et al., 2006) support an overall survival benefit with the use of accelerated fractionation or hyperfractionated radiotherapy, such that some form of altered fractionation should be utilized with treating oral cavity cancer patients with radiotherapy alone. One multi-institutional, international, randomized study comparing an accelerated regimen of 66–70 Gy delivered in 2 Gy daily fractions 6 days per week to the same dose delivered 5 days per week found improved locoregional control (42% vs. 30%, $p = .004$), disease-free survival (50% vs. 40%, $p = .03$), and a trend toward improved overall survival (35% vs. 28%, $p = .07$) with accelerated fractionation (Overgaard et al., 2010). When analysed with respect to HPV status, accelerated fractionated radiotherapy resulted in improved local control for both p16-positive (hazard ratio [HR] 0.56 [95% confidence interval (CI) 0.33–0.96]) and p16-negative tumors (HR 0.77 [95% CI 0.60–0.99]) (Lassen et al., 2011). However, when a more intensive accelerated regimen of 1.8 Gy twice daily to 59.4 Gy was compared to 70 Gy in 2 Gy fractions in stage III/IV head and neck cancer patients, no statistically significant benefits were seen in terms of locoregional control or overall survival (Poulsen et al., 2001). It is unknown if the lack of benefit seen was due to the regimen used, or due to inclusion criteria as the benefit for acceleration in some randomized studies was less significant for those with stage IV disease as well as those with a larger nodal disease burden (Overgaard et al., 2010).

The meta-analysis of radiotherapy in carcinoma of the head and neck (MARCH) Collaborative Group pooled 15 randomized studies (including 6515 patients, 13% with oral cavity cancer) and compared standard fractionation to either accelerated or hyperfractionated radiotherapy. Altered fractionation schedules were associated with an 8.5% absolute reduction in local failure and a 3.4% absolute improvement in 5-year overall survival. Further analysis demonstrated no significant interaction of tumor site on overall survival or tumor control. Heterogeneity in the patients included on the accelerated and hyperfractionated trials did not allow for direct comparisons, but patients treated with a hyperfractionated radiotherapy regimen were noted to have an 8.2% absolute improvement in overall survival at 5 years compared to only a 2% absolute improvement in those treated with an accelerated fractionation schedule (Bourhis et al., 2006). This meta-analysis was updated recently with increased patient numbers and follow up, and it confirmed the earlier finding that altered fractionation was associated with an improvement in overall survival, with an absolute benefit of 1.2% at 10 years (Lacas et al., 2017). This benefit also appeared to be limited to patients receiving hyperfractionated therapy, with an absolute benefit in overall survival of 3.9% at 10 years.

RTOG 9003 compared standard fractionation (70 Gy in 2 Gy/day fractions), hyperfractionation (81.6 Gy in 1.2 Gy/fraction, twice-daily), split-course accelerated fractionation (67.2 Gy in 1.6 Gy/fraction twice-daily with a 2 week rest after 38.4 Gy), and accelerated fractionation with a concomitant boost (72 Gy in 1.8 Gy/fraction for 14 fractions followed by 1.8 Gy morning and 1.5 Gy afternoon boost to gross disease) for patients with cancers of the head and neck, excluding only nasopharynx; however, only about 10% of patients had oral cavity cancer (Fu et al., 2000). In the initial report, locoregional control was improved with hyperfractionation and accelerated concomitant boost as compared to the standard fractionation. A trend toward improved disease-free survival for patients treated with hyperfractionation (37.6% vs. 31.7%, $p = .067$) or accelerated concomitant boost (39.3% vs. 31.7%, $p = .054$) was also noted. With longer follow up, patients receiving a hyperfractionated regimen demonstrated

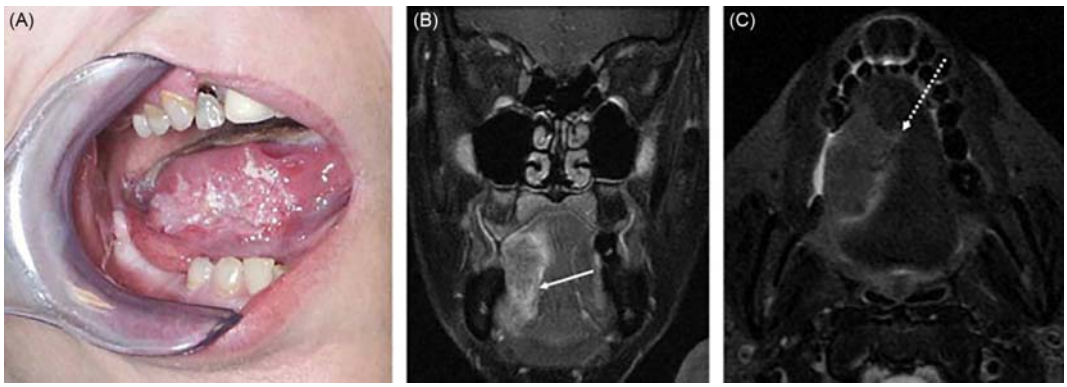

Fig. 18 Right lateral tongue squamous cell carcinoma crossing midline, with involvement of the genioglossus muscles. (A) Photograph shows an extensive area of mucosal irregularity and leukoplakia involving the right lateral tongue. The patient was unable to move the tongue due to tumor infiltration and pain. Coronal T1-weighted postcontrast fat-saturated (B) and axial STIR (C) images show a T2-hyperintense enhancing mass in the right tongue. The coronal image shows inferior extension into the floor of mouth/sublingual space (*solid white arrow* in B) and medial involvement of the genioglossus muscle. The axial image shows extension across the midline (*dashed arrow* in C). From Hagiwara, M., Nusbaum, A., and Schmidt, B. L. (2012). MR assessment of oral cavity carcinomas. *Magnetic Resonance Imaging Clinics of North America* **20**(3), 473–494.

improved overall survival (HR 0.81, p = .05) when patients were censored at 5 years (Beitler et al., 2014). Hyperfractionated patients also exhibited less late toxicity when compared to accelerated fractionated patients. Most notably, in patients who were disease-free at 5 years, only 4.8% of hyperfractionated patients had feeding tubes versus 13.0% of patients receiving accelerated fractionation with concomitant boost. It is difficult to determine the clinical significance of these toxicity data today since all of patients in the RTOG study were treated with parallel-opposed fields and the blocking techniques were rudimentary with only minimal sparing of the parotid glands and pharyngeal constrictor muscles. Currently, contemporary IMRT and image-guided radiotherapy (IGRT) techniques allow for increased sparing of these structures, which likely significantly reduces late treatment-related morbidity.

Intensity modulated radiotherapy

Intensity modulated radiotherapy (IMRT) has been widely adopted for the treatment of head and neck cancers (Mell et al., 2005). Retrospective single institution (Studer et al., 2007; Studer et al., 2012) and SEER-Medicare (Beadle et al., 2014) analyses have shown significant improvements in local control and cause-specific survival, respectively, with the use of IMRT in oral cavity cancer patients. Helical tomotherapy and volumetric modulated arc therapy (VMAT) are advanced forms of IMRT. While theoretical consideration of second cancers exists with IMRT (Hall, 2006), this technology has the ability to minimize normal organ exposure to radiation. This is particularly important for oral cavity cancer patients as pharyngeal constrictor dose is associated with dysphagia (Eisbruch et al., 2004; Caudell et al., 2010) and dose to the parotid, submandibular, and minor salivary glands are associated with xerostomia (Nutting et al., 2011). In addition, IMRT has the potential to decrease acute dermatitis. A prospective, randomized trial demonstrated the beneficial impact of IMRT on the reduction of xerostomia in patients with cancer of the oropharynx or hypopharynx, using the late effects of normal tissues scale, unstimulated and sodium citrate stimulated parotid saliva from each parotid orifice and the floor of mouth, and patient-reported quality of life (Nutting et al., 2011; **Fig. 19**).

Brachytherapy

Brachytherapy is the placement of radioactive materials in close proximity to or inside of tumors and was developed prior to IMRT or the use of concurrent chemotherapy. It allowed practitioners to deliver a tumoricidal dose of radiation to tumors in the head and neck while minimizing mandibular dose. Improved external beam radiotherapy planning and delivery techniques as well as a recognition that the incidence of osteoradionecrosis resulting from brachytherapy is significantly underreported, has resulted in a substantial decrease in the utilization brachytherapy for oral cavity tumors. Historically, brachytherapy's role in oral cavity cancer has been to boost the dose to gross disease following external beam radiotherapy. Typically, catheters are implanted under general anesthesia in the operating room, and as such oral cavity brachytherapy is a highly operator-dependent procedure (**Fig. 20**). Given the historically poor locoregional control rates for oral cavity tumors treated with external beam radiotherapy alone, intensifying the treatment with brachytherapy makes logical sense. Higher rates of locoregional control have been achieved using an integrated treatment approach of external beam radiotherapy directed at the primary and bilateral neck, followed by a brachytherapy boost (Harrison, 1997).

Complications of brachytherapy for oral cavity tumors can include mucosal ulceration, soft tissue necrosis, and osteoradionecrosis of the mandible (YamazakI et al., 2013). The risk of complications appears to be related to the technique of implantation, but may reach as high as 30%. Quality of life analyses comparing a combined regimen of brachytherapy plus external beam radiotherapy to surgery followed by PORT favored the combination of brachytherapy and external beam radiotherapy, suggesting that in experienced hands this is a reasonable treatment method for head and neck carcinoma (Levendag et al., 2004). There is limited information regarding the use of brachytherapy and chemotherapy concurrently, and as such this approach should be avoided outside of a formal trial setting.

Brachytherapy guidelines

The American Brachytherapy Society (ABS) has published guidelines for the use of high dose rate (HDR) brachytherapy for head and neck cancer, including specific guidelines for oral cavity tumors (Nag et al., 2001). The ABS panel members advise that whenever possible, a spacer be constructed and inserted at the time of the HDR treatment to reduce doses to normal tissues such as the mandible and mucosa of the palate. The relative risk of normal tissue injury for lesions near the mandible, such as the floor of mouth, is greater than for oral tongue, where the bone is not contiguous with the target volume. The interval between external beam radiotherapy and brachytherapy should be minimized (within 1–2 weeks, depending on the degree of recovery from mucositis), and the total duration of combined radiation therapy should be kept as short as possible (ideally <8 weeks) to minimize tumor cell repopulation. Expert panel evidence, as well as single institution series, recommend external beam radiotherapy doses of 40–50 Gy to the primary tumor (or 45–60 Gy when the neck is treated for microscopic disease) followed by a HDR brachytherapy boost of 2.7–3.0 Gy per fraction for 6–7 doses with locoregional control of implanted tumors reaching 80%. Similar to the ABS, the European Brachytherapy Group (GEC) and European Society for Therapeutic Radiology and Oncology (ESTRO) developed joint guidelines for the use of brachytherapy in the treatment of head and neck carcinoma based on consensus recommendations given the lack of randomized trial data (Mazeron et al., 2009; Kovács et al., 2017). For oral cavity tumors, these guidelines recommend 46–50 Gy of external beam radiotherapy followed by a 15–30 Gy low dose rate brachytherapy boost or equivalent HDR dose. In order to minimize overall treatment time, HDR brachytherapy is often administered as two fractions per day separated by at least six hours.

Concurrent chemoradiotherapy for locoregionally advanced oral cavity cancer

Although surgical resection followed by adjuvant radiation with or without chemotherapy is preferred for patients with large infiltrative primary tumors of the oral cavity, definitive concurrent chemoradiotherapy has been shown to be a reasonable option for patients who are unable to undergo surgical resection. In addition, surgical resection may be possible but not recommended for certain patients given the associated surgical morbidity and likely necessity of adjuvant chemoradiotherapy, which has a similar toxicity profile to definitive intent chemoradiotherapy (Fig. 21).

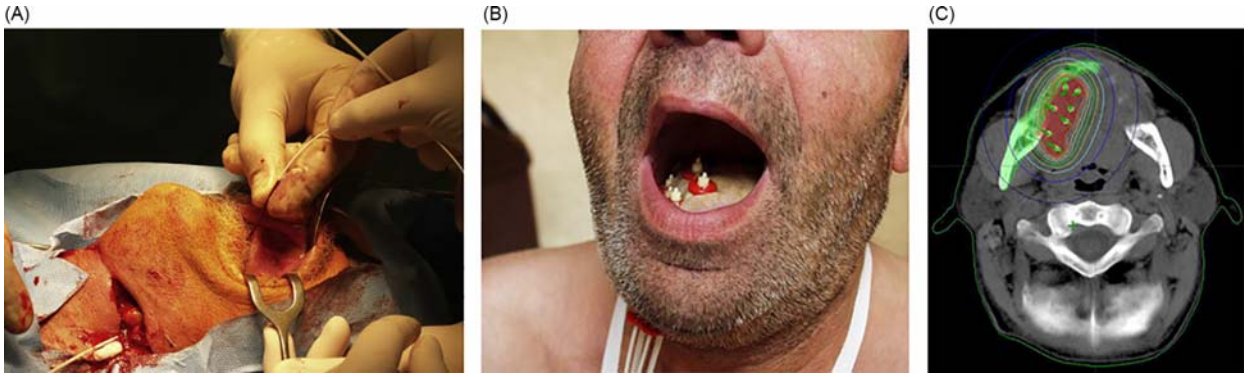

Fig. 20 (A) Technique of afterloading catheters insertion. (B) Implantation of afterloading catheters. (C) CT-based planning of dose distribution. From Tuček L, Petera J, Sirák I, Vošmik M, Doležalová H, Brokešová S, Hodek M, Kašaová L, Paluska P. (2011) Hyperfractionated high-dose rate brachytherapy in the treatment of oral tongue cancer. *Reports of Practical Oncology and Radiotherapy* **16**(6), 243–247.

Multiple studies have demonstrated a benefit with concurrent chemoradiotherapy in the definitive treatment of head and neck cancer, including oral cavity cancer (Adelstein et al., 2003; Brizel et al., 1998; Wendt et al., 1998). However, the use of concurrent chemoradiotherapy for patients with locoregionally advanced oral cavity cancer without distant metastasis is based primarily on the results of the meta-analysis of chemotherapy in head and neck cancer (MACH-NC), which demonstrated a 6.5% absolute improvement in overall survival at 5 years from the use of concurrent chemoradiotherapy compared to radiotherapy alone (Pignon et al., 2009). However, the beneficial effects of chemotherapy appeared to decrease with age. Patients with age >70 years did not derive a significant benefit, likely because more advanced age is associated with increasing frailty and more competing risks of mortality. Subgroup analysis demonstrated the benefit of adding chemotherapy to locoregional treatment alone for patients with oral cavity cancer, with a HR of 0.87 (95% CI 0.80–0.93) and an absolute improvement in 5-year overall survival of 5.1% (Blanchard et al., 2011). While this meta-analysis did not show a significant interaction between chemotherapy timing (adjuvant, neoadjuvant, vs. concomitant) and survival for oral cavity primaries, this may only be a consequence of a lack of power.

There are no randomized trials of chemoradiotherapy versus radiotherapy alone in the definitive treatment of patients with oral cavity cancer. A multiinstitution retrospective analysis investigated the outcomes of patients with locally advanced oral cavity cancer treated with definitive chemoradiotherapy on protocols between 1994 and 2008 and demonstrated 5-year overall and progression-free survival rates of 66% and 67%, respectively (Stenson et al., 2010). This cohort was updated recently to include patients treated up to 2014 and demonstrated 5-year overall and progression-free survival rates of 63% and 59%, respectively (Melotek et al., 2016). Five-year locoregional and distant control were reported as 79% and 87%, respectively. Long-term toxicities of this regimen were acceptable, with crude rates of osteoradionecrosis and sustained need for a feeding tube of 19% and 14%, respectively. A separate study from the same institution reported the outcomes of patients with oral cavity cancer treated on protocol with chemoradiotherapy using IMRT and demonstrated estimated 5-year locoregional progression-free survival, disease-free survival, and overall survival of 71%, 76%, and 76%, respectively (Pederson et al., 2011). By contrast, another single institution series of oral cavity cancer patients treated with definitive chemoradiation between 1990 and 2011 reported worse outcomes with a 3-year disease-specific survival of 38% and actuarial 5-year overall survival of 15% (Scher et al., 2015). A recent National Cancer Database (NCDB) analysis reported a 3-year overall survival of 38% for patients with locally advanced oral cavity squamous cell carcinoma treated with definitive concurrent chemoradiotherapy (Spiotto et al., 2017). Notably, patients treated with chemoradiotherapy were more likely to be older than 60 years old, have more comorbidities, and have more advanced primary tumor and/or nodal stage compared to patients treated surgically with PORT.

Concurrent chemoradiotherapy regimens

The associated toxicities of concurrent chemoradiotherapy have stimulated the search for the optimal chemotherapy regimen. Cisplatin given every 3 weeks at 100 mg/m^2 is often cited as the standard regimen. For oropharyngeal cancer, the Groupe d'Oncologie Radiothérapie Tête et Cou (GORTEC) randomized study demonstrated an overall survival advantage using a carboplatin/5-fluorouracil regimen specifically chosen to avoid cisplatin-related tinnitus, renal dysfunction, and emesis (Calais et al., 1999). Randomized studies comparing alternative cisplatin dosing schedules (such as 30–40 mg/m^2 weekly or 20 mg/m^2/day on days 1–5 and 22–26) to bolus cisplatin or to other chemoradiotherapy platforms have been conducted in nasopharyngeal cancer patients (Lee et al., 2016) or in the postoperative oral cavity setting (Tsan et al., 2012). However, multiple randomized studies that compared radiotherapy alone to concurrent chemoradiotherapy using nonbolus cisplatin schedules including daily cisplatin (6 mg/m^2/day) (Jeremic et al., 2000), weekly cisplatin (40 mg/m^2) (Sharma et al., 2010), or cisplatin (20 mg/m^2/day) given on days 1–5 repeated every 3 weeks (Huguenin et al., 2004) had comparable outcomes to bolus cisplatin. As previously mentioned, a recently reported study in patients with head and neck cancer (>90% with oral cavity cancer) receiving adjuvant or definitive concurrent chemoradiotherapy compared cisplatin delivered 30 mg/m^2 weekly versus 100 mg/m^2 every 3 weeks (Noronha et al.,

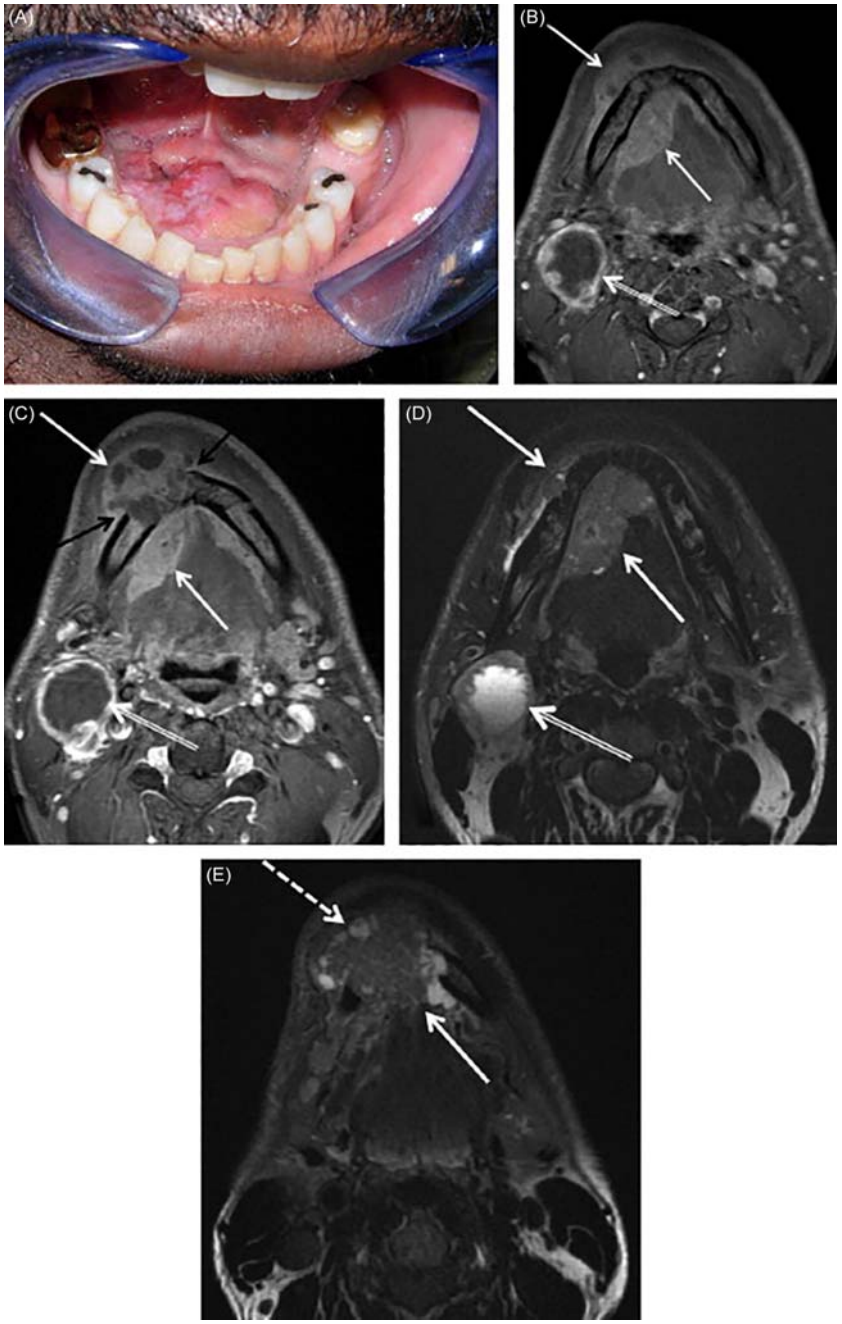

Fig. 21 T4a floor of mouth squamous cell carcinoma with bone invasion and necrotic right level II nodal metastasis. (A) Photograph shows a large exophytic and ulcerated mass in the right floor of mouth extending across the midline. (B, C) Axial postcontrast fat-saturated T1-weighted images from superior to inferior show a large heterogeneously enhancing mass with areas of necrosis in the right floor of mouth (*solid white arrows*) extending across the midline anteriorly. Gross tumor invasion of the mandible with erosion through the outer cortex is seen (*solid black arrows* in C). No evidence was seen on imaging of perineural invasion in the inferior alveolar canal. A large necrotic right level II node is seen posteriorly (*double-lined white arrows*). (D, E) T2-weighted fat-saturated images from superior to inferior similarly show a mass in the floor of mouth (*solid arrows*) extending across the midline, with anterior extension through the mandible into the submental region (*dashed white arrow* in E). Note the low T2 signal intensity of most of the mass, indicating hypercellularity. The necrotic right level II node (*double lined white arrow* in D) is also seen. From Hagiwara, M., Nusbaum, A., Schmidt, B. L. (2012). MR assessment of oral cavity carcinomas. *Magnetic Resonance Imaging Clinics of North America* **20**(3), 473–494.

2018). Bolus cisplatin (100 mg/m^2) was found to improve the primary endpoint of locoregional control; however, many consider the weekly cisplatin regimen of 30 mg/m^2 to be suboptimal. National Comprehensive Cancer Network (NCCN) guidelines recommend cisplatin 40 mg/m^2 if a weekly regimen is utilized, but high-dose cisplatin (100 mg/m^2 every 3 weeks for three cycles) remains the preferred regimen.

Concurrent chemotherapy and accelerated radiotherapy

Two recently reported randomized studies showed that there was no benefit to accelerated radiotherapy over conventionally fractionated radiotherapy when delivered with concurrent platinum-based chemotherapy. GORTEC 99-02 randomized locoregionally advanced head and neck cancer patients to either very accelerated radiotherapy 64.8 Gy (1.8 Gy twice daily); 70 Gy (2 Gy daily over 7 weeks) with concurrent carboplatin 70 mg/m^2 and 5-fluorouracil 600 mg/m^2/day on days 1–4, 22–25, and 43–46; or 70 Gy (2 Gy daily to 40 Gy, then 1.5 Gy twice daily) with carboplatin 70 mg/m^2 and 5-fluorouracil 600 mg/m^2/day on days 1–4 and 29–33. Outcomes in both chemoradiotherapy arms were similar, and both were superior to very accelerated radiotherapy with lower rates of acute toxicity and percutaneous gastrostomy tube placement during therapy and at 5 years (Bourhis et al., 2012).

Similarly, RTOG 0129 randomized patients to 72 Gy accelerated concomitant boost radiotherapy with two cycles of cisplatin 100 mg/m^2 or to 70 Gy daily radiotherapy with three cycles of cisplatin 100 mg/m^2. Again, there was no benefit to accelerated chemoradiotherapy seen in 8-year overall survival (accelerated 48% vs. conventional 48%), locoregional progression (37% vs. 39%) or worst grade 3–5 toxicity (38% vs. 37%) (Nguyen-Tan et al., 2014). Interestingly, on an unplanned post-hoc analysis, it appeared that standard fractionation patients who received one cycle of chemotherapy had worse outcomes than those who received the two or three cycles of chemotherapy. The value of acceleration via the use of a simultaneous integrated boost, a commonly used approach for IMRT delivery, must therefore be questioned when concurrent chemotherapy is being used as part of the treatment regimen.

Acute toxicities of chemoradiotherapy

The use of concurrent chemoradiotherapy in patients with oral cavity cancer is a life-changing event. Toxicities may include fatigue, nausea, emesis, thickened secretions, xerostomia, mucositis, dysphagia, odynophagia, alopecia, dermatitis, anemia, neutropenia, hoarseness, Lhermitte's syndrome, and infection.

Dysphagia is perhaps the most difficult acute and late complication. Prior to any treatment, oral cavity cancer patients are less likely to be affected by tumor-induced dysphagia than those with other cancers of the head and neck (Stenson et al., 2000). A retrospective review of prospectively collected data demonstrated that head and neck cancer patients with more advanced tumor stage (T3-T4) treated with chemoradiotherapy manifested an improvement in swallowing function that outweighed treatment-related toxicity, likely due to reduction in tumor volume (Salama et al., 2008). The study also noted a trend for worse post-chemoradiotherapy swallowing function in patients with increasing age, whereas patients with good performance status were less likely to have worse swallowing function.

Since dysphagia can significantly impact nutritional status, early therapeutic interventions with swallowing exercises to strengthen the pharyngeal musculature are recommended. Patients should be instructed to swallow as large a volume as possible during and after treatment, and perform exercises shown to improve swallowing ability (Rosenthal et al., 2006). Prospectively, dysphagia has been associated with exceeding specific dosimetric thresholds to the pharyngeal constrictors or laryngeal apparatus when treating other disease sites, which should be taken into consideration during radiotherapy planning, as discussed further below (Eisbruch et al., 2011).

Late toxicities of chemoradiotherapy

Late toxicities of chemoradiotherapy for patients with oral cavity cancer can include dysphagia, fibrosis, osteoradionecrosis, trismus, xerostomia, dental caries, feeding tube dependence, hearing loss, kidney damage, and neuropathy. The RTOG reported late toxicities following chemoradiotherapy based on a pooled analysis of 230 locally advanced head and neck cancer patients treated on three prospective chemoradiotherapy trials (Machtay et al., 2008). Patients with older age and increased tumor stage (T3-T4) were more likely to experience late toxicity, as well as those who underwent a posttreatment neck dissection. When late toxicity was analyzed by primary tumor site, patients with oropharyngeal and oral cavity primary tumors were statistically less likely to experience late toxicity; however, it should be noted that only 5% of patients had an oral cavity primary.

The incidence of late chemoradiotherapy toxicities are illustrated in single and multiinstitution experiences. For example, one multiinstitution retrospective analysis reported that only 7.8% of oral cavity cancer patients were dependent on gastric tube feedings for all caloric intake after a median follow up of 3.25 years post-chemoradiotherapy, while the remainder of patients were able to maintain their weight and nutrition by oral intake alone (Stenson et al., 2010). The investigators also reported that 18.4% of patients developed osteoradionecrosis requiring surgical intervention, with over half requiring only one procedure to achieve satisfactory results. These results were found to be similar in an updated analysis including patients treated up to 2014 with a median follow up of 5.7 years, with no difference in the rate of osteoradionecrosis across treatment decades (Melotek et al., 2016). In a separate analysis of patients with oral cavity cancer treated with chemoradiotherapy utilizing IMRT, it was noted that although a majority of patients required feeding tube placement at some point during the course of therapy, $<15\%$ had a feeding tube at the time of last follow up (Pederson et al., 2011). This study also showed an acceptable rate of osteoradionecrosis, 14%, after a median follow up of 60 months (**Table 3**).

Deintensification of therapy for HPV-positive oral cavity cancer patients

Given better outcomes of HPV-related oropharyngeal cancer patients, in combination with the known acute and late effects of surgery, chemotherapy, and radiotherapy, many are investigating strategies to maintain high rates of tumor control and survival while deintensifying curative intent treatment in locoregionally advanced patients. However, because of the weaker association between HPV and cancer of the oral cavity as discussed previously in the Epidemiology and Etiology section, deintensification

of therapy for oral cavity tumors is not an active area of research. Furthermore, in contrast to findings for oropharyngeal cancer, some studies suggest worse prognosis with HPV-positive oral cavity cancer compared to HPV-negative disease (Lee et al., 2012; Duray et al., 2012).

Systemic Therapy

The use of chemotherapy to treat head and neck cancer has evolved from its initial role only in the recurrent or metastatic setting to standard use in the definitive treatment setting. After nearly six decades of clinical research, a wealth of data demonstrate the benefit of concurrent chemotherapy administration in the definitive treatment of head and neck cancer with radiotherapy as summarized previously. For locoregionally advanced disease, the utility of neoadjuvant cytotoxic chemotherapy has been evaluated, as well as the safety and efficacy of targeted systemic agents and concomitant radiotherapy with or without chemotherapy.

Induction chemotherapy prior to definitive local therapy

The use of neoadjuvant chemotherapy prior to surgical resection or radiotherapy for oral cavity cancer patients has been tested in multiple randomized studies. In particular, one trial investigated the use of induction chemotherapy (cisplatin and 5-fluorouracil) followed by surgery with or without adjuvant radiation therapy (for high-risk patients only) in locally advanced resectable oral cavity squamous cell carcinoma and demonstrated no benefit in overall survival between the treatment arms at 5 years (Licitra et al., 2003). More recently, a randomized phase III trial evaluating the use of induction chemotherapy (docetaxel, cisplatin, and 5-fluorouracil) in locally advanced resectable oral cavity squamous cell carcinoma demonstrated no significant benefit in overall or disease-free survival from the addition of preoperative chemotherapy to surgery and adjuvant radiotherapy (Zhong et al., 2013). However, post-hoc analysis indicated that patients in the experimental arm who had a clinical response or $\leq$10% viable tumor cells on pathology demonstrated improved locoregional and distant control, as well as increased overall survival.

Whether induction chemotherapy prior to concurrent chemoradiotherapy improves survival when compared to chemoradiotherapy alone was an area of active study advocated by some given that distant metastases are frequently a site of first failure for patients with locoregionally advanced head and neck cancer (Brockstein et al., 2004). However, mature results from multiple randomized studies did not demonstrate improved survival with induction chemotherapy followed by concurrent chemoradiotherapy (Cohen et al., 2014; Haddad et al., 2013). It is unknown if the lack of demonstrated survival benefit was due to the therapy itself or the fact that these studies were initiated prior to robust knowledge of the behavior of HPV-associated oropharyngeal cancers. Therefore, inclusion of these patients with more favorable outcomes were not accounted for in the study design and may complicate interpretation of these studies.

Targeted agents and radiotherapy

Epidermal growth factor receptor (EGFR) is over-expressed in nearly 80%–90% of cases of head and neck squamous cell carcinoma and correlates with poor prognosis and radiation resistance. Preclinical evidence showed that blocking EGFR restores radiation sensitivity and enhances cytotoxicity, which led to clinical trials evaluating this class of agents. Cetuximab was approved in combination with radiation for the treatment of locally advanced head and neck squamous cell carcinoma based on a single randomized study comparing radiotherapy 70–76.8 Gy with or without weekly cetuximab (loading dose of 400 mg/m^2 followed by 250 mg/m^2). Combination therapy improved locoregional control, disease-free survival, and overall survival; however, this study did not include oral cavity cancer patients (Bonner et al., 2006; Bonner et al., 2010). Based upon lower-level evidence, there is expert consensus that cetuximab is appropriate in oral cavity cancer (category 2B recommendation). Updated analyses show that the addition of cetuximab for head and neck cancer remains beneficial regardless of p16 status (Rosenthal et al., 2016), and the presence of a prominent rash is a prognostic factor (Bonner et al., 2010). Consideration should be given to the use of altered radiation fractionation with cetuximab since improved overall survival was seen in patients who were treated with accelerated concomitant boost and hyperfractionated radiotherapy.

Cetuximab should be used with caution in specific geographic areas (particularly the southeastern United States) where severe anaphylactic reactions can occur. These are mediated by an immunoglobulin E response to the galactose-alpha-1,3-galactose oligosaccharide found on the Fab portion of the cetuximab heavy chain (Chung et al., 2008). The fully humanized monoclonal antibody to EGFR, panitumumab, has a much lower rate of severe allergic reactions, but no level-1 evidence exists to support equivalent efficacy to cetuximab for head and neck cancer. Other than geographic limitations, there is no consensus as to which patient populations are better served by concurrent chemotherapy versus concurrent cetuximab with radiation therapy. Certain patient factors, such as renal dysfunction or overall poor functional status, prompt physicians to utilize cetuximab preferentially over cisplatin with radiotherapy, but no level-1 evidence supports these as indications. Of note, those same medical conditions were exclusion criteria for the randomized trial that demonstrated cetuximab's benefit over radiation therapy alone (**Fig. 22**).

Targeted agents in combination with cytotoxins and radiotherapy

A meta-analysis of several phase II trials and retrospective studies comparing radiation therapy with concurrent cetuximab versus concurrent cisplatin found better survival and locoregional control in patients treated with radiation and cisplatin (Petrelli et al., 2014). RTOG 0522, which notably did not include oral cavity cancer patients, failed to show benefit of the combination of cetuximab with chemoradiotherapy over standard chemoradiotherapy, and the addition of cetuximab was associated with more grade

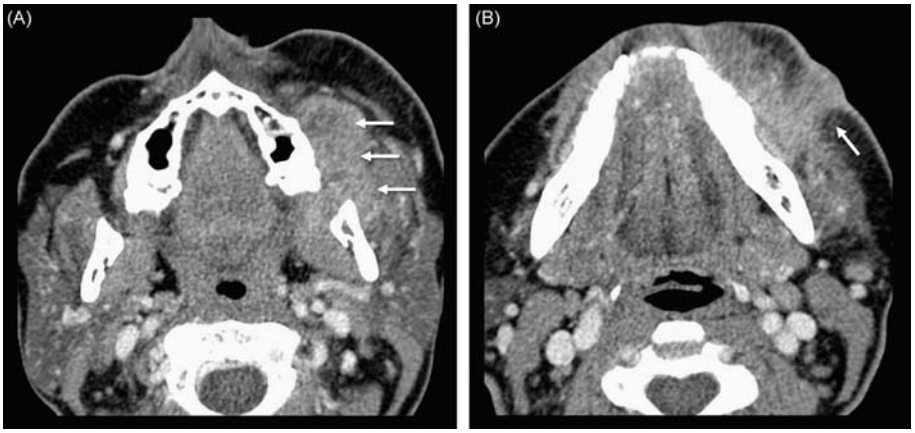

Fig. 22 Squamous cell carcinoma of the left buccal mucosa, T4a. (A) Axial contrast-enhanced CT shows large left buccal mass (*arrows*) extending to maxillary RMT. (B) Axial contrast-enhanced CT (inferior to A) shows inferior and lateral extension to involve the skin (*arrow*). Involvement of the skin is critical to note, because the tumor is upstaged to T4a. 3–4 toxicity (Ang et al., 2014). More recently, the published results of the GORTEC 2007-01 phase III randomized trial which included oral cavity cancer patients demonstrated that three cycles of concomitant carboplatin 70 mg/m^2/day and 5-fluoruracil 600 mg/m^2/day on days 1–4 with cetuximab-radiotherapy markedly improved progression-free survival and locoregional control with a nonsignificant gain in overall survival compared to cetuximab-radiotherapy without chemotherapy (Tao et al., 2018). To date the triple drug combination of cetuximab, carboplatin, and 5-fluouracil has not been compared to cisplatin alone. Therefore, single agent platinum-based chemoradiotherapy remains the standard of care for locally advanced squamous cell carcinoma of the head and neck.

Oral cavity cancer patients have also been included in studies evaluating the addition of bevacizumab to chemoradiotherapy. The addition of bevacizumab to 5-fluorouracil, hydroxyurea, and twice daily radiotherapy did not confer any benefit in a study of locoregionally advanced head and neck cancer patients, of which oral cavity was the most common primary site (31%) (Salama et al., 2011). Bevacizumab has also been integrated with erlotinib (synchronous dual inhibition of VEGF and EGFR) and cisplatin (33 mg/m^2 cisplatin on days 1–3 of weeks 1 and 5) together with 1.25 Gy twice-daily radiotherapy to 70 Gy. Fifteen percent of patients had oral cavity primary tumors. At a median follow-up of 46 months, 3-year locoregional control and overall survival were promising compared to historical series at 86% and 85%, respectively (Yoo et al., 2012). Soft tissue and osteoradionecrosis occurred in both series, and careful attention should be paid to the results of ongoing studies integrating bevacizumab to multiple chemoradiotherapy platforms for locoregionally advanced head and neck cancer patients including those with oral cavity tumors.

Posttreatment Management and Surveillance

Following definitive therapy for oral cavity cancer, patients should be seen regularly for clinical evaluation. Initial posttreatment follow up varies based on the duration and severity of acute treatment-related toxicities in order to provide appropriate supportive care and ensure adequate nutrition. Typically patients are seen every 1–3 months for the first year, then every 2–6 months for the second year, then every 4–8 months for years 3 through 5, and then every 12 months thereafter.

At each of these visits, a detailed history, thorough physical examination of the head and neck region, and direct fiberoptic laryngoscopy (if possible) should be performed. Periodic blood tests may be ordered to assess for adequate posttreatment organ function, such as the thyroid following neck irradiation or kidneys following cisplatin. Carotid ultrasounds may also be ordered to screen for accelerated carotid atherosclerosis causing hemodynamically significant stenosis following neck irradiation, although there is no consensus on the optimal timing. An annual low-dose CT scan should be performed for patients that meet lung cancer screening criteria based on smoking history. Additional imaging studies may be obtained if the clinical history or physical exam is concerning for any changes that may indicate tumor recurrence. Patients should also be encouraged to undergo regular dental evaluation, including dental cleaning and topical fluoride treatment. If dental extraction or other surgical intervention is planned within the irradiated field, then discussion with the radiation oncologist should be initiated for consideration of referral for hyperbaric oxygen treatment.

After definitive radiotherapy or chemoradiotherapy, follow-up imaging should be performed within the first three months of treatment completion in patients with node-positive presentations. In the neck, a radiographic complete response on CT is defined as nonenhancing, nonnecrotic nodal tissue <1.5 cm in size and is associated with 100% long-term disease control in the neck (Liauw et al., 2006). Surveillance CT imaging of the primary site does not add additional information to physical or fiberoptic examination and therefore should not be performed unless clinically indicated (Sullivan et al., 2011).

PET-CT is more often used as the sole imaging modality following the completion of radiotherapy to assess nodal response. A prospective analysis of over 100 node-positive head and neck cancer patients followed with PET-CT at around 12 weeks posttherapy and again 4 weeks later (if equivocal or greater residual activity was present on the 12 week scan) treated with neck dissection for metabolic persistence helped to clarify the role of PET-CT scan following chemoradiotherapy. Irrespective of residual CT abnormalities in the neck, a negative neck on the PET scan at 12 weeks, defined as the absence of metabolic activity, was associated with no isolated nodal progression (Porceddu et al., 2011). The negative predictive value of PET was 98.1% (95% CI 93.2–99.8) compared to 96.8% with CT (95% CI 88.8–99.6), and false positive readings were seen in only 1.8% of PET-CT scans compared to 38% of CT scans, yielding a positive predictive value of 77.8% for PET-CT and 14% for CT. Long-term follow-up of this patient cohort found that PET-CT-directed posttherapy neck management adequately spared >90% of patients from a neck dissection, with only one patient experiencing a neck recurrence after initial metabolic resolution (Sjovall et al., 2015). Of note, these patients also had a contrast enhanced CT scan performed 6 weeks after completion of treatment, and all patients with a negative contrast-enhanced CT scan were subsequently found to have a negative PET. Therefore, 12-week PET imaging may not be necessary for patients who have had a prior negative posttreatment contrast-enhanced CT scan.

More recently, a randomized study of 564 patients compared the utility of post-chemoradiotherapy PET-CT-based neck surveillance versus a planned neck dissection in patients with clinical AJCC 7th Edition N2 or N3 disease. Two-year overall survival was 84.9% (95% CI 80.7–89.1) for patients undergoing PET-CT-based neck surveillance compared to 81.5% (95% CI 76.9–86.3) in the group receiving a planned neck dissection. No differences were noted in the 2-year locoregional control rates between groups, with 91.9% (95% CI 88.5–95.3) control in the PET-CT surveillance group and 91.4% (95% CI 87.8–95.0) control in the planned neck dissection group. Additionally, PET-CT-based surveillance was more cost effective, saving an average of $2190 per patient. For these reasons, PET-CT-based surveillance of head and neck cancer patients should be considered standard post chemoradiotherapy (Mehanna et al., 2016).

Approximately 90% of tumor recurrences will occur within the first 18 months following treatment. Patients without evidence of disease two or more years after treatment are at greater risk of developing a secondary cancer than recurrence of their original disease. Patients who continue to use tobacco and alcohol are at the highest risk. Should a second primary head and neck cancer occur, identification at an early stage is paramount in order to achieve the best cure rate with the least invasive means of treatment. Therefore, close follow-up is essential in patients with cancers of the oral cavity (**Fig. 23**).

Treatment of Recurrent and Metastatic Oral Cavity Cancer

The appropriate management of metastatic or recurrent oral cavity cancer depends largely on the extent of disease, the prior therapy administered, and whether recurrence is local, regional, or both. If there is distant disease recurrence, systemic therapy approaches will likely assume primary importance. In the case of small recurrences at the primary site for patients treated with primary excision only, further excision with or without PORT is often recommended. For larger recurrences in patients who received radiation as part of their initial management, the rate of surgical salvage is quite low; however, in some cases, further resection may be considered for palliation or as an attempt at curative treatment, particularly in the setting of a clinical trial. Reirradiation is possible, but with the potential for increased toxicity. Systemic therapy and palliative care are also treatment options for this group of patients. The risks and benefits of each treatment should be discussed with the individual patient.

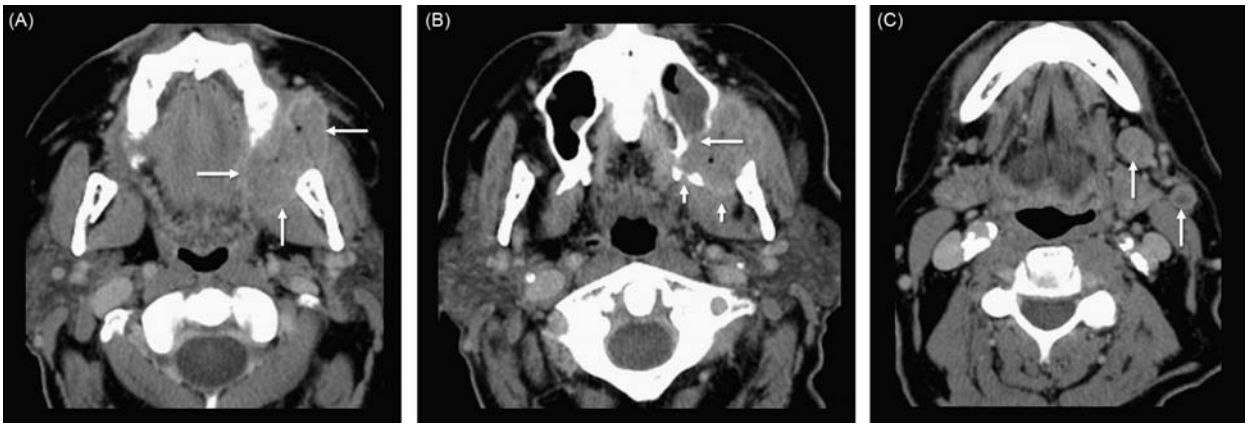

Fig. 23 Squamous cell carcinoma of the left retromolar trigone (RMT), T4b N2b. (A) Axial contrast-enhanced CT demonstrates large tumor centered in the left RMT (*arrows*). (B) Axial contrast-enhanced CT (cranial to A) shows obvious invasion of the posterior maxilla involving the maxillary sinus (*long arrow*) from tumor growing superiorly along the pterygomandibular raphe. Tumor is therefore upstaged to T4a. Also note tumor extension to medial pterygoid plate and masticator space (*short arrows*), resulting in overall T4b stage. (C) Axial contrast-enhanced CT shows metastatic level I and II nodes (*arrows*). Some have central low density, a very specific sign for metastasis. From Aiken, A. H. (2013). Pitfalls in the staging of cancer of oral cavity cancer. *Neuroimaging Clinics of North America* **23**(1), 27–45.

Systemic therapy for recurrent and metastatic oral cavity cancer

The standard of care for patients with recurrent or metastatic oral cavity or oropharyngeal cancer is systemic therapy with platinum-based chemotherapy. Phase III trials have investigated cisplatin (with or without 5-fluorouracil or methotrexate), 5-fluorouracil, single-agent methotrexate, and carboplatin with 5-flurouracil (Forastiere et al., 1992; Anon, 1990; Jacobs et al., 1992). Many drugs, in addition to platinum agents, 5-fluorouracil, and methotrexate, have been shown in phase II trials to exhibit single agent activity such as paclitaxel (Forastiere et al., 1998), docetaxel (Dreyfuss et al., 1996), gemcitabine (Catimel et al., 1994), ifosfamide (Sandler et al., 1998), vinorelbine (Saxman et al., 1998), pemetrexed (Pivot et al., 2001), capecitabine (Martinez-Trufero et al., 2010), and irinotecan (Murphy, 2005). Single agent cisplatin (100 mg/m^2) has been shown to improve overall survival compared to best-supportive care (Morton et al., 1985) and superior to single agent methotrexate in a phase III randomized trial (Anon, 1990). Many randomized trials have tried to improve survival with combination cisplatin-based regimens. Cisplatin (100 mg/m^2) with 5-fluorouracil (1000 mg/m^2/day) demonstrated improved response rates (32% vs. 17%, p = .035), but did not improve median survival (5.7 months) over cisplatin alone (Jacobs et al., 1992). Similar results were seen when cisplatin/5-fluorouracil, carboplatin/5-fluorouracil, and methotrexate alone were compared in a randomized phase III trial. Cisplatin/5-fluorouracil and carboplatin/5-fluorouracil demonstrated increased response rates (32% and 21%, respectively) compared to methotrexate alone (10%), but neither regimen improved median survival (6.6 and 5.6 months, respectively) compared to methotrexate alone (5.0 months) (Forastiere et al., 1992). Combination treatments were associated with worse toxicity. Similar response rates and survival have been seen with cisplatin/paclitaxel versus cisplatin/5-fluorouracil, providing a more easily administered treatment option for patients (Gibson et al., 2005).

Adding agents targeting EGFR to platinum-based systemic therapy has been shown to improve overall survival compared to platinum-based systemic therapy alone in a phase III study. The EXTREME study randomized recurrent and metastatic head and neck cancer patients to cisplatin 100 mg/m^2 on day 1 or carboplatin AUC = 5 on day 1 along with 5-fluorouracil 1000 mg/m^2/day on days 1–4 every 3 weeks, with or without cetuximab 250 mg/m^2 (following a loading dose of 400 mg/m^2) that was continued until disease progression or patient intolerance (Vermorken et al., 2008). The addition of cetuximab to chemotherapy resulted in an improvement in median overall survival from 7.4 to 10.1 months and an improvement in median progression-free survival from 3.3 to 5.6 months. Currently there are no phase III trials to suggest that addition of tyrosine kinase inhibitors (including gefitinib or erlotinib) to platinum-based therapy provides a survival benefit. Ongoing studies are investigating the role of bevacizumab and other targeted agents in combination with chemotherapy.

For patients with platinum-refractory recurrent and metastatic head and neck cancer, immune checkpoint inhibitors targeting the programmed cell death protein-1 (PD-1) pathway have significantly changed second-line therapy. The Checkmate 141 study randomized 361 patients (48.5% oral cavity cancers) to the anti-PD-1 antibody nivolumab 3 mg/kg every 2 weeks or investigator choice of 40–60 mg/m^2 methotrexate, 30–40 mg/m^2 docetaxel, or 250 mg/m^2 cetuximab (after a loading dose of 400 mg/m^2). Patients receiving nivolumab had longer median (7.5 vs. 5.1 months) and 1-year overall survival (36% vs. 16.6%, HR 0.70 [95% CI 0.51–0.96], p = .01) (Ferris et al., 2016). Similarly, the phase III KEYNOTE-040 trial randomized 495 patients to receive the anti-PD-1 antibody pembrolizumab 200 mg every 3 weeks or investigator choice of methotrexate, docetaxel or cetuximab. On intention to treat analysis, median overall survival was 8.4 months with pembrolizumab versus 7.1 months in the control arm (HR 0.81 [95% CI 0.66–0.99], one-sided p = .0204) (Cohen et al., 2017).

Reirradiation for locoregionally confined recurrent or second primary disease

For patients with locoregionally confined recurrent disease of the oral cavity, surgical resection is recommended, although it is only possible in a small percentage of patients (Taussky et al., 2005). In patients who are not surgical candidates (Choe et al., 2011) or following surgery in those with high-risk pathologic features (Janot et al., 2008), a second course of full dose radiotherapy with concurrent chemotherapy results in long-term survival in approximately 20% of patients. Patients able to undergo a surgical resection prior to reirradiation, as well as those not previously treated with chemotherapy and treated to higher doses, have been shown to have improved outcomes. Because of the high risk of toxicity (approximately 20% carotid rupture rate and 15% fatal toxicity), patients undergoing a second course of concurrent chemoradio therapy should be managed at experienced centers.

It remains unclear whether chemotherapy alone or chemotherapy and reirradiation is the optimal therapy for these patients, as a phase III comparison of these modalities failed to accrue patients. A nomogram (with concordance index of 0.68) exists to predict 2-year locoregional control following fractionated reirradiation for recurrent head and neck cancer using data from 257 patients treated at a single United States institution (Riaz et al., 2014). The criteria used included stage, site, organ dysfunction, surgical salvage, and radiotherapy dose. In this nomogram, the oral cavity subsite was associated with worse outcomes compared to reirradiation of other head and neck sites.

Recently, the use of hypofractionated image-guided radiation therapy (HIGRT), otherwise known as stereotactic body radiation therapy (SBRT) or stereotactic ablative radiotherapy (SABR), has been associated with high rates of treated tumor control in previously irradiated head and neck cancer patients with locoregionally-confined recurrences (Baliga et al., 2017). HIGRT is an attractive treatment option, as it is generally delivered over 1–2 weeks, as compared to 5–7 weeks of concurrent chemoradiation, and it has been safely combined with cetuximab (Vargo et al., 2015). However, similar to chemotherapy with conventionally fractionated reirradiation, high-grade late toxicities including carotid blowout have been reported, with patients with recurrent or second primary tumors arising in the larynx/hypopharynx being more likely to have high-grade late toxicity following reirradiation with HIGRT. The ability to offer HIGRT is limited by the size and location of the recurrent tumor. Furthermore, reirradiation with HIGRT should only be delivered by those with experience with this technique due to concerns for toxicity.

Prospective Vision

An area of active investigation for oral cavity cancer is identifying better systemic agents and determining appropriate timing of newer systemic therapies relative to surgery and radiotherapy. Several ongoing clinical trials are evaluating the safety and efficacy of immune checkpoint inhibitors in head and neck cancer. The use of immunotherapy will likely evolve from its current role in the recurrent and metastatic setting to earlier use in initial combined modality definitive treatment. Other clinical trials are evaluating the use of various combinatorial approaches of immune checkpoint inhibitors with immune modulators of regulatory T cells or natural killer cells (e.g., indoleamine-pyrrole 2,3-dioxygenase [IDO], glucocorticoid-induced tumor necrosis factor receptor-related protein [GITR], T-cell immunoreceptor with Ig and ITIM domains [TIGIT], killer-cell immunoglobulin-like receptor [KIR], etc.). IDO inhibitors in particular have demonstrated early promise in improving response rates to PD-1 inhibitors and are currently in ongoing clinical trials. Clinical studies inducing HPV-induced immunogenicity in HPV-positive disease are also being conducted through HPV vaccination trials. Additional clinical trials investigating radiosensitizers, proteasome inhibitors, and targeted therapies are also being conducted. Altered fractionation and adaptive radiation planning are two other areas of active investigation to identify methods of achieving better locoregional control and survival with reduced toxicity. Many prospective randomized trials are implementing various pharmaceutical interventions and oral care protocols to prevent or minimize mucositis and/or xerostomia. Additionally, chemoprevention to delay or prevent oral cavity cancer is an area of ongoing study. Many clinical questions remain to be answered, and significant advances in the coming years will likely translate into improved outcomes for patients with oral cavity cancer.

Definition

Ovarian neoplasms comprise several distinct histopathological entities. The most common of them is ovarian carcinoma, a malignant epithelial tumor originating from the ovaries (epithelial ovarian cancer, EOC), which accounts for approximately 90% of all ovarian cancer cases. This entry does not specifically cover other, less frequent, ovarian cancer types. However, the symptoms and the diagnostic considerations for most of them are similar to those of EOC.

Presentation and Diagnosis

Early ovarian cancer of any type is usually asymptomatic or associated with minimal nonspecific symptoms. Advanced epithelial ovarian carcinoma (EOC) manifests with a wide spectrum of vague nonspecific symptoms, such as abdominal discomfort and/or bloating, irregular menstruations or abnormal vaginal bleeding, difficulty eating and/or early satiety. Increased abdominal size and pelvic pain have been shown to be independently associated with the disease. Urinary symptoms (urinary urgency or increased frequency) may occur as a result of the pressure of the tumor mass on the bladder. A swollen leg due to venous thrombosis is also common. Gastrointestinal symptoms, like nausea and vomiting, constipation, and diarrhea, are usually associated with later stages of the disease, with tiredness and weight loss which follow. Ovarian or pelvic mass and/or ascites may be found at physical examination in patients with more advanced disease.

Given the nonspecific symptoms, ovarian cancer is usually detected at advanced stages. At the same time, several trials have shown that screening using the existing methods does not decrease mortality from ovarian cancer, while it may lead to overtreatment and complications associated with an unnecessary surgery. Therefore, many clinical guidelines and regulatory bodies (like the US Food and Drug Administration (FDA)) recommend against screening the general population for ovarian cancer, be it by transvaginal ultrasound examination, by measuring serum CA-125 levels, or by using any of the ovarian cancer tests currently available on the market. However, any pelvic mass in a woman over 1 year after menopause as well as the above-mentioned symptoms without any diagnosed source of malignancy in a woman of any age should be treated as a suspected ovarian cancer and warrant ultrasound examination and other studies as indicated.

Ultrasound is typically used for the initial evaluation of a pelvic mass and/or in case of symptoms suggesting a possible ovarian cancer. Abdominal/pelvic magnetic resonance imaging (MRI) may be useful to determine the malignant potential of lesions indeterminate by ultrasound. Otherwise, positron emission tomography with fluorodeoxyglucose (FDG-PET) combined with computed

tomography (CT) may be useful to this effect. Abdominal/pelvic CT is useful to assess for metastases but has less value than ultrasound or MRI for evaluating the ovarian mass. However, CT is useful for diagnosing cystic teratomas and cystadenomas. Both MRI and CT should be performed with contrast, for example gadolinium. Chest radiography or CT is often performed to exclude pleural effusions or pulmonary spread. In patients with gastrointestinal symptoms, a gastrointestinal tract workup may additionally be indicated.

Premenopausal women often present with benign cysts, many of which regress spontaneously. Masses that are smaller than 8 cm in premenopausal women and show cystic nature on ultrasound are likely to be benign lesions. They should regress after 2 months of oral contraceptives. For putative cysts which do not regress after 2 months as well as for all other lesions, a tissue-based diagnosis should be made.

The definitive diagnosis of most ovarian cancers is made based on a pathological analysis of a biopsy or a surgical specimen (pre-, intra-, or postoperatively). When a highly suspicious isolated adnexal or pelvic mass is present, surgical removal of an intact ovary is recommended to avoid tumor spillage and upstaging. Fine-needle aspiration (FNA) or percutaneous biopsy for diagnosing presumed early-stage ovarian cancer should be avoided if possible to prevent rupturing the cyst and spilling the malignant cells into the peritoneal cavity. However, FNA may be necessary in patients with diffuse carcinomatosis or in those with bulky tumors who are not candidates for surgery. Mucinous histology may indicate a metastasis of a gastrointestinal tumor and should prompt an evaluation of the gastrointestinal tract. A metastasis from the breast may be ruled out with the help of mammography.

Several serum markers have been suggested as potentially useful in the diagnostic workup for epithelial ovarian cancer, in particular CA-125, carcinoembryonic antigen (CEA), CA 19-9, and human epididymis 4 protein (HE-4). A very elevated CEA-to-CA-125 ratio should raise suspicion for a possible gastrointestinal malignancy. The use of serum CA-125 and HE-4 levels has been approved by FDA as part of the risk of ovarian malignancy algorithm (ROMA) which estimates the risk of finding a malignancy at surgery in women presenting with a pelvic mass. However, this test is rather an aid helping primary care physicians to identify patients who should be referred to a gynecologic oncologist than a real diagnostic tool and its use for diagnosing pelvic masses is not recommended by the expert panel of the US National Comprehensive Cancer Network (NCCN). Still, some serum markers, if initially elevated, may be useful to monitor the response to treatment in patients with epithelial ovarian tumors.

Management and Therapy

The most common primary treatment for presumed ovarian cancer is surgery, often followed by systemic chemotherapy. Primary Fallopian tube and peritoneal cancers are managed in the same way as epithelial ovarian cancers.

The surgery should consist of a surgical exploration and comprehensive surgical staging, and debulking (i.e., removing the primary tumor and as much of the metastatic disease as possible, also called cytoreductive surgery). The recommended surgical approach for all patients is total abdominal hysterectomy (TAH) with bilateral salpingo-oophorectomy (BSO). In selected patients with lowest-stage low-risk disease who wish to preserve fertility, a unilateral salpingo-oophorectomy (USO) which preserves the contralateral ovary and the uterus may be considered. However, in some cases, BSO may be necessary. If macroscopic disease is visible outside the ovary, all visible tumor should be removed. This may require extensive surgery, including bowel resection and/or appendectomy, partial gastrectomy, stripping of the diaphragm or other peritoneal surfaces, liver resection, distal pancreatectomy, omentectomy, splenectomy, cholecystectomy, partial cystectomy and/or ureteroneocystostomy. Suspicious and/or enlarged lymph nodes are also dissected whenever possible. It has been shown that systematic lymphadenectomy in patients with advanced ovarian cancer is associated with increased overall survival. Using minimally invasive techniques may be considered in patients with early-stage disease, while many surgeons tend to use open laparotomy in patients with more widespread disease. A comprehensive surgical staging including peritoneal cytology and multiple peritoneal biopsies is important in all cases to rule out the presence of occult higher-stage disease.

Surgery alone is sufficient in a small proportion of select ovarian cancer patients with low-stage and low-risk disease. A majority of patients, however, receive adjuvant chemotherapy following the primary surgery. Platinum (carboplatin or cisplatin) with paclitaxel is recommended for most patients, with intravenous or intraperitoneal administration. Dose-dense paclitaxel with carboplatin may also be considered. Patients with low-volume residual disease after surgical debulking are candidates for intraperitoneal therapy.

Patients who are not candidates for optimal frontline debulking understood as removing all visible disease (R0) may be considered for neoadjuvant chemotherapy followed by interval debulking and adjuvant chemotherapy. Even though in general the best outcomes are obtained with debulking performed as part of the primary treatment, neoadjuvant chemotherapy with interval debulking has been shown to be noninferior to upfront debulking in patients with bulky high-stage (IIIC–IV) disease. Therefore, it may be considered as an alternative in these patients, in particular in those with important comorbidities which may make them poor candidates for initial surgery. A prior histological confirmation of the ovarian cancer diagnosis (by FNA, core biopsy, or paracentesis) and a careful evaluation by a gynecologic oncologist are necessary. The optimal strategies to select patients best suited for primary cytoreduction versus neoadjuvant chemotherapy are still under investigation. In particular, scoring systems based on diagnostic laparoscopy and preoperative imaging are being evaluated to this effect.

Intravenous taxane/carboplatin and liposomal doxorubicin/carboplatin regimens are recommended for both neoadjuvant chemotherapy and adjuvant chemotherapy after interval debulking. The standard combined intraperitoneal/intravenous regimen of paclitaxel with cisplatin may also be used as adjuvant therapy following interval debulking. For nonsurgical patients with poor performance status, advanced disease (stage IV) and important comorbidities, as well as for elderly patients, single-agent platinum regimens may be more appropriate.

Radiotherapy (RT) is not recommended for the primary treatment of patients with EOC. Even though some studies have reported that it may provide a treatment benefit in patients with advanced cancer and/or small-volume residual disease present after primary surgery, it is usually not acceptable due to severe toxicities. However, localized RT is an option for palliative treatment to control symptoms in selected patients with advanced recurrent disease.

Ovarian cancer has a high response rate to the frontline treatment. However, advanced EOC recurs in over 75% of patients and has a very poor prognosis. Recurrence may be identified clinically, biochemically (rising serum CA-125 levels) and/or with imaging. The treatment options depend on the primary treatment and the length of the recurrence-free period after completing the primary therapy.

Patients with recurrent ovarian cancer are often retreated with multiple courses of chemotherapy. The disease which recurred after over 6 months without progression following a platinum-based chemotherapy (classified as platinum-sensitive disease) may be retreated with a platinum-containing regimen, with the probability of response increasing with the duration of the disease-free interval. A number of regimens combining carboplatin or cisplatin with paclitaxel, docetaxel, liposomal doxorubicin, gemcitabine and other chemotherapeutics are used. For patients who have isolated recurrent platinum-sensitive disease, a secondary cytoreductive surgery may be beneficial provided that the recurrence can be completely resected. This option is particularly viable for patients who have relapsed after a recurrence-free period of at least 24 months. In patients with platinum-resistant disease (i.e., disease relapsing within the first 6 months after completing platinum-based chemotherapy), response may be obtained with several nonplatinum treatments, like docetaxel, topotecan, oral etoposide, liposomal doxorubicin or gemcitabine, usually administered as sequential single-agent therapies rather than combined regimens. Treatment with capecitabine or other alkylating agents (like cyclophosphamide or melphalan) may be useful in patients with platinum- and taxanes-resistant disease. Hormonal therapy with tamoxifen or aromatase inhibitors may be considered for patients intolerant to chemotherapy but the response rates are rather low.

Given poor prognosis and high recurrence rates, much hope is put in novel therapies with targeted molecular and biologic agents for treatment of advanced epithelial ovarian cancer, and in particular recurrent platinum-resistant disease. Adding bevacizumab, a monoclonal antibody against vascular endothelial growth factor (VEGF), to the upfront carboplatin/paclitaxel chemotherapy followed by the maintenance bevacizumab has been shown to improve survival in a subset (but not all) of advanced ovarian cancer patients. Bevacizumab has been studied for use in combination with other chemotherapeutics or as a single-agent therapy. The experts disagree on the utility of this treatment, in particular for the maintenance therapy. So far, bevacizumab is approved by FDA for treatment of recurrent platinum-resistant disease, becoming the first antiangiogenic agent clinically available in the United States. A supplemental biologics license application for bevacizumab (Avastin, Genentech) for the first-line treatment of advanced ovarian cancer is currently being treated by FDA. Other antiangiogenic agents which may be beneficial in treatment of epithelial ovarian cancer, like pazopanib (an oral receptor tyrosine kinase inhibitor with an activity against VEGF receptor (VEGFR)), or suritinib and sorafenib (multiple tyrosine kinase inhibitors with anti-VEGFR activity), are currently being evaluated in clinical trials.

A very promising class of targeted molecular therapeutics are inhibitors of poly (ADP-ribose) polymerase (PARP). PARP inhibitors target DNA repair mechanisms and are particularly efficient in the treatment of *BRCA1*- and/or *BRCA2*-deficient tumors. The most widely used PARP inhibitor is olaparib (oral therapeutic) which was the first FDA-approved agent in this class. It is approved for treatment of advanced epithelial ovarian cancer in patients with germline *BRCA1/2* mutations who had been treated with three or more lines of chemotherapy. It is also recommended as a single-agent treatment for patients with recurrent platinum-resistant EOC. In addition to olaparib, two other PARP inhibitors: rucaparib and niraparib, are approved by FDA for treatment of EOC in a similar setting. The NCCN expert panel recommends rucaparib monotherapy in particular for recurrent platinum-resistant EOC, whereas niraparib for platinum-sensitive recurrent disease.

Inhibition of signaling pathways using MTOR and MAPK inhibitors has also been tested as a potential treatment modality of advanced EOC. However, early clinical trials (phase I) with these agents as monotherapies have shown no benefit and the trials have been stopped.

Multiagent regimens combining targeted therapies with known cytotoxic drugs or combinations of different classes of targeted therapeutics (like antiangiogenics with PARP inhibitors) seem to be the future of EOC treatment (in particular advanced disease), with a number of regimens being currently tested in clinical trials.

All EOC treatment regimens may be associated with serious complications and side effects. Therefore, providing supportive care throughout all stages of therapy is also very important. In particular, younger women will abruptly enter menopause following any non-fertility-sparing treatment and therefore require particular supportive care to this effect. Palliating symptoms, especially in patients with incurable advanced disease is also a serious concern. Palliative chemotherapy is the most common option. In patients who develop bowel obstruction and resistance to chemotherapy but have a reasonably good performance status, a palliative surgery may be considered. However, the mortality and complication rates are high and this decision should be thoroughly discussed with the patient, weighing the risks associated with the surgery against potential benefits in view of a short predicted life expectancy.

Glossary

Gamma-H2AX Double stranded breaks (DSBs) resulting from DNA damage are followed by the phosphorylation of the H2AX histone. H2AX is a variant of the H2A protein family, a component of the histone octomer in nucleosomes. This newly phosphorylated protein is the first step in recruiting and localizing DNA repair proteins.

Homologous recombination repair (HRR) A DNA repair process that includes the invasion of an undamaged DNA molecule by a damaged molecule of identical or very similar sequence. Re-synthesis of the damaged region is accomplished using the undamaged molecule as a template.

P53 signature Small foci of strongly p53-immunoreactive cells in largely histologically normal fallopian tube epithelium. Like serous tubal intraepithelial carcinoma (STIC), p53 signatures are comprised exclusively of secretory cells (at least 12 consecutive immunoreactive cells).

Serous tubal intraepithelial carcinoma (STIC) Intraepithelial high-grade serous carcinoma in the distal fimbriated end of the fallopian tube as the probable precursor of some advanced high-grade serous carcinomas.

SWI–SNF-A complex A nucleosome remodeling complex found in both eukaryotes and prokaryotes. It is a group of proteins that associate to remodel the way DNA is packaged.

Introduction

About two-thirds of ovarian tumors occur in women of reproductive age and 80%–90% of them between the ages of 20–65 years; less than 5% develop in children. Approximately 80% are benign tumors, and 60% of them are diagnosed in women under the age of 40 years. Conversely, 90% of ovarian epithelial cancers, including borderline tumors, are diagnosed after the age of 40 years, and 30%–40% of them after the age of 65 years. The odds that an ovarian epithelial tumor is borderline or carcinoma in a patient under 40 years is approximately 1:10, but beyond that age it increases to 1:3.

Ovarian cancer is the 5th most common cancer in females in the United States, with an annual incidence of 25,000 new cases and over 14,000 deaths; it accounts for 4% of the total cancers in women (ranked behind neoplasms of the lung, breast, intestine, and uterus) and 25% of the malignancies of the female genital tract. It has been estimated that 1 woman in 70 (1.4%) will develop ovarian cancer at some point during her lifetime. Its low cure rate (less than 40%) results in 6% of the total cancer deaths in women in the United States.

As with tumors of other organs, the most logical classification and system of terminology for ovarian tumors would be based upon histogenesis. However, implementation is difficult because: (a) gonadal embryology is unsettled; (b) several of these tumors may have a diverse or even unknown origin; and (c) many tumors have overlapping histologic features. Nevertheless, for the purpose of facilitating communication on epidemiologic features, biologic behavior, and therapy, a uniform terminology is strongly recommended. The classification system formulated in 1999 by the World Health Organization (WHO), and the International Society of Gynecological Pathologists, also adhered to by the authors of the last edition (1998) of the fascicle published by the Armed Forces Institute of Pathology, is based, if at all possible, on cell types and patterns of growth. The 2003 and 2014 WHO *blue books* follow essentially the same classification system with only minor changes. Tumors of the ovary ultimately arise from one of the three ovarian components: (1) the surface epithelium and the underlying stroma which embryologically give rise to the müllerian ducts; (2) the specialized ovarian stroma which includes the sex cords, precursors of the endocrine cells of the postnatal ovary; and (3) the germ cells, which migrate to the ovary from the yolk sac and are totipotential. As usual, there is a group of tumors that defy classification, and finally there are secondary or metastatic tumors, given that the ovary is a common site of metastases from various other cancers.

Epithelial Ovarian Tumors

Epithelial ovarian tumors account for approximately two-thirds of all ovarian tumors and for about 90% of all ovarian cancers in the Western World. They comprise a group of heterogeneous neoplasms which are primarily classified according to cell type into serous, mucinous, endometrioid, clear cell, transitional, and squamous cell tumors. Paradoxically, benign counterparts of these cells are not found in the normal ovary and their development during neoplasia has long been attributed to mullerian "neometaplasia" of the ovarian surface epithelium (mesothelium) which derives from the coelomic epithelium. Specifically, since the coelomic

epithelium gives rise to the müllerian ducts, it was proposed that, as the surface epithelium becomes malignant, it would acquire the morphologic features of the müllerian duct epithelium; that is, serous (fallopian tube-like), endometrioid (endometrium-like), and mucinous (endocervical-like). This aberrant differentiation constitutes the basis for ovarian tumor classification. Currently, tumors are thought to develop from embryonic stem cells of the ovarian surface epithelium. However, there is now evidence that a number of tumors thought to be primary ovarian cancers actually originate in other pelvic organs and involve the ovary secondarily. It has been recognized that high-grade serous carcinomas (the most common type of ovarian cancer) may sometimes arise from precursor epithelial lesions in the fimbriated end of the fallopian tube, whereas endometrioid and clear cell carcinomas result from ovarian endometriosis. The relative importance of the fallopian tube mucosa compared with the ovarian surface epithelium in the genesis of high-grade serous ovarian cancer is still a subject of debate. On the other hand, it can be argued that tumors arising in endometriosis are ultimately of endometrial origin. Thus, in some cases, the term ovarian cancer may not be accurate and it has been suggested that it should be replaced with the terms "pelvic" or "peritoneal" cancer. However, given the confusion that might follow in the literature, we think best keeping the term ovarian cancer until the various possible origins of these diseases are known better.

Borderline Tumors

Epithelial ovarian tumors are subdivided into benign, borderline and malignant (carcinomas) and this subdivision is most important since it correlates with behavior. Borderline ovarian tumors show epithelial proliferation greater than that seen in their benign counterparts and variable nuclear atypia; however, in contrast to carcinomas, there is no destructive stromal invasion, and their prognosis is much better than that of carcinomas. In spite of the lack of stromal invasion, serous borderline tumors, particularly those with exophytic growth, can implant on peritoneal surfaces and, rarely (about 10% of peritoneal implants), progress to low-grade serous carcinoma (LGSC) and invade the underlying tissues.

Although favorable in the great majority of cases, the biologic behavior of the borderline tumors differs from that of the obviously benign tumors of the same cell type(s) and, rarely ($<1\%$–3%), progression to invasive carcinoma occurs justifying the term "borderline tumor." Alternative terms such as *atypical proliferative* are not recommended since they are nonspecific; that is, all nonbenign epithelial tumors (borderline and carcinomas) are, by definition, proliferative neoplasms which exhibit nuclear atypia; also, this term is misleading as it does not take into account the malignant potential of a small but significant number of these tumors and discourage follow-up. Although the term "borderline" may suggest uncertainty, it accurately describes the ambiguous histologic and biologic features of these neoplasms and remains the most appropriate term. Accordingly, it has been recommended by the World Health Organization (WHO) for the last four decades. The majority of these tumors are associated with a favorable prognosis and the term "tumors of low malignant potential" is no longer recommended.

The distinction between borderline tumors and carcinomas is one of the most common problems in ovarian tumor pathology, yet the literature on borderline tumors is confusing, particularly with regard to their diagnostic features and treatment. With the exception of squamous cell tumors, the borderline concept applies to all types of ovarian epithelial tumors listed before; however, most data in the literature refer to the serous and mucinous intestinal categories which are the two most common types and show significant clinicopathological differences.

Serous and Mucinous Borderline Tumors

Serous borderline tumors (SBTs) account for from 5% to 10% of ovarian serous tumors and occur at an average of 42 years. Approximately 70% are confined to one or both ovaries (stage I) at the time of diagnosis; the remaining tumors have spread within the pelvis (stage II) or upper abdomen (stage III). One-third of stage I tumors are bilateral. Macroscopically, SBTs have one or more cysts that are lined by polypoid excrescences and closely packed papillae (endophytic growth) (**Fig. 1**). In almost half of SBTs the papillary growth covers the outer surface of the ovary (exophyytic growth). Microscopically, SBTs show stromal polyps, glands, and papillae lined by stratified cuboidal to columnar epithelial cells and ciliated cells resembling those of the fallopian tube (**Fig. 2**). The ramifying papillae form increasingly smaller branches ending in epithelial cells clusters apparently detached from the stroma (hierarchical branching); the tumor cells show varying degree of nuclear atypia; and there is absence of "destructive" stromal invasion or solid sheets of tumor with a cribriform pattern. Nuclear atypia varies from mild to moderate.

Mucinous borderline tumors (MBTs) have been subclassified into two different clinicopathologic forms: the most common form (85% to 90%) is composed of gastrointestinal-type epithelium and is designated MBT of gastrointestinal type. A second and less common variant of MBT contains endocervical-type epithelium and has been named MBT endocervical-like (**Fig. 3**).

Endocervical-like MBTs also designated as müllerian MBTs, account for 10%–15% of MBTs. About 140 cases have been reported. These tumors differ in many respects from intestinal MBTs. The average age of the patients with endocervical MBTs is 40 years and association with endometriosis is frequent (35%–50%). At the time of diagnosis, most tumors are confined to the ovary and approximately 20% have spread to the peritoneum or regional lymph nodes. The prognosis of endocervical-type MBT is excellent and approximates that of SBTs. Recent studies report that foci of intraepithelial carcinoma (IEC) or microinvasion do not influence the prognosis. No deaths from these tumors have been reported.

MBTs of intestinal type account for 10%–15% of ovarian mucinous tumors and are more common in the first two decades than their serous counterparts. About 80%–90% are stage I and only 5% are bilateral. Of note, metastatic mucinous tumors in the ovary often mimic primary ovarian mucinous neoplasms, particularly adenocarcinomas of the pancreas and large intestine. Nearly all

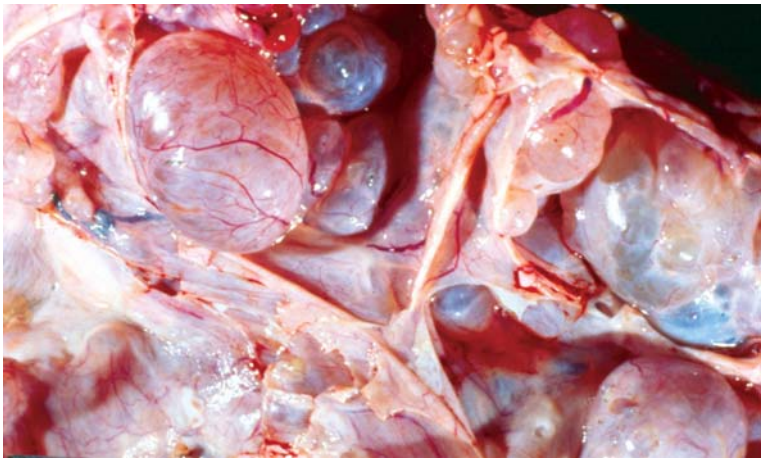

Fig. 4 Mucinous borderline tumor. Cystic and multilocular tumor with mucinous fluid. Lee, K. R., Tavassoli, F. A., Prat, J., et al. (2003). Surface epithelial-stromal tumours (Ch 2: tumours of the ovary and peritoneum). In: Tavassoli, F. A., Devilee, P. (eds.). *World Health Organization classification of tumours: pathology and genetics of tumours of the breast and female genital organs*, pp 117–145. Lyon: IARC Press.

stage II–III MBTs are associated with *pseudomyxoma peritonei* and, in these patients, the ovarian tumor is virtually always secondary (metastatic) from a primary low-grade mucinous appendiceal tumor.

On gross examination, MBTs of intestinal type average 19 cm in diameter, are usually cystic and multilocular, and contain mucinous fluid (Fig. 4). Microscopically, the tumor consists of cysts and glands lined by atypical epithelium of gastric pyloric-type. The cysts may contain papillae that are typically thin and branching The lining epithelium almost always contains goblet cells and may have argyrophil cells and occasional Paneth cells. The epithelial cells are usually stratified to two or three layers, nuclear atypia is mild to moderate, and mitotic figures vary from few to numerous. High grade nuclear features are absent and stromal invasion is not seen (Fig. 5).

MBTs of intestinal-type may exhibit areas of epithelial cell proliferation of four or more layers, scattered foci of cribriform or stroma-free papillary architecture, and moderate (grade 2) or severe atypical (grade 3) nuclei (Fig. 6). Numerous studies have shown that these tumors are almost always clinically benign, and we recommend classifying them as mucinous borderline tumors with intraepithelial carcinoma.

In contrast to serous tumors which are usually homogeneous, mucinous intestinal tumors often are heterogeneous. Benign-appearing, borderline, and invasive patterns may coexist within an individual neoplasm; this continuum suggests that progression occurs from cystadenoma and borderline tumor to noninvasive, microinvasive, and invasive carcinoma. This is supported by studies of *K-RAS* mutations, which represent an early event in mucinous ovarian tumorigenesis.

The overall outcome of SBTs is very favorable. The 5-year survival rates for patients with disease that is stages I to IIIb are between 88% and $>95\%$. For patients with stage I tumors, the risk of recurrence or the development of a second SBT has been estimated to be

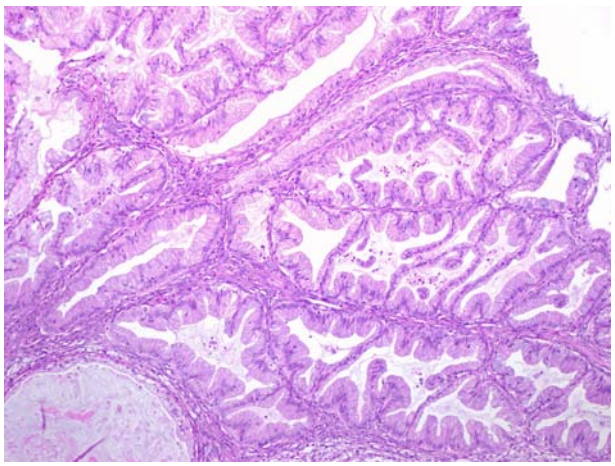

Fig. 5 Mucinous borderline tumor of intestinal-type. Packed intraglandular proliferation of mucinous epithelium with thin and branching papillae. There is no stromal invasion. Prat, J. (2017). Pathology of borderline and invasive cancers. *Best Practice & Research: Clinical Obstetrics and Gynaecology* ***41***, 15–30.

only 5%–10%. Risk factors for recurrence include conservative treatment, particularly cystectomy, bilaterality (stage IB), and incomplete staging. In SBTs, the presence of tumor at the resection margin of the cystectomy specimen and multifocality with removal of more than one cyst, are strong predictors of failure of cystectomy to control the disease. Transformation of SBT into low-grade serous carcinoma (LGSC) occurs in 6%–7% of patients late in the course of the disease. Other than the adverse effect of invasive implants (Fig. 7), there is no agreement in the literature as to which prognostic factors are important. Subdivision of SBTs into benign and malignant, based on the presence of a micropapillary architecture (Fig. 8), is artificial since SBTs with or without micropapillary pattern may rarely be associated with invasive peritoneal implants and poor outcome. The term "micropapillary" is flawed as all SBTs have micropapillae descriptively and their extension may range from a few papillae to a huge number of them. Bilaterality, ovarian surface growth, and advanced stage (mainly noninvasive peritoneal implants) are more common features of extensively micropapillary SBTs than of typical SBTs, but a strong association of the former tumors with invasive implants and poor outcome has been inconsistent. According to most investigators, SBTs with micropapillary pattern or SBTs with microinvasion have a prognosis similar to that of tumors lacking these features. Likewise, focal lymph node involvement has not demonstrated any effect on survival. The 5-year survival rate for patients with stage I MBT nears 100%. In a recent report, 6 of 144 patients (4.2%) had tumor recurrence. Risk factors for recurrence included FIGO stage IC, microinvasive carcinoma, age less than 45 years, and intraepithelial carcinoma.

In young patients who undergo fertility-sparing surgery, the nature of the recurrent tumor varies according to the histological type. In these patients, MBTs of intestinal type recur less frequently than SBTs, but when they do it is more often as an invasive carcinoma. Most SBTs maintain their microscopic features in the recurrences and usually do not progress to frankly invasive carcinoma. In contrast, MBTs of intestinal type represent intermediate stages of mucinous tumorigenesis and, even if a MBT per se is essentially a benign neoplasm, it may be accompanied by or may progress to intraepithelial and frankly invasive carcinoma. However, in

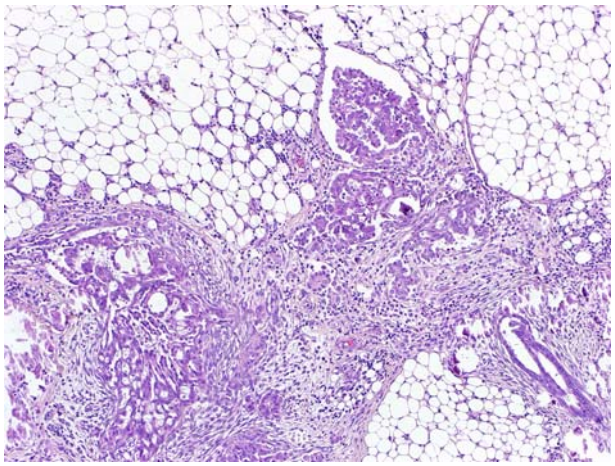

Fig. 7 Invasive implant of serous borderline tumor. The implant is composed predominantly of epithelial cells which disorderly infiltrate the adipose tissue.

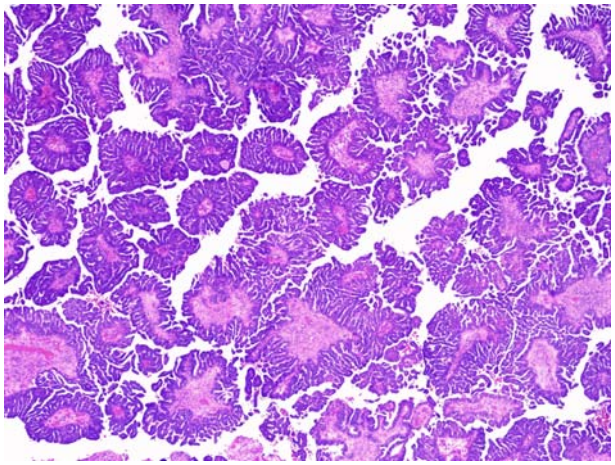

Fig. 8 Serous borderline tumor with micropapillary proliferation. Highly complex micropapillae growing in a nonhierarchical fashion from fibrovascular stalks ("Medusa head-like appearance").

patients with MBTs initially treated by unilateral salpingo-oophorectomy, recurrences that occur in the contralateral ovary most likely represent independent primary mucinous tumors, typically heterogeneous and containing benign-appearing, borderline, and carcinomatous elements. In other words, SBTs and MBTs of intestinal type are different diseases with different biologic behavior.

Endometrioid Borderline Tumors

Endometrioid borderline tumors are uncommon and constitute only 0.2% of all epithelial ovarian tumors and 2%–3% of borderline tumors. The average age of patients is 51 years. The majority of tumors are unilateral; bilateral disease is rare (4%). The average size is 9 cm. In one-half of cases an adenofibroma is present in the background. The glandular proliferation may consist of crowded, back-to-back endometrioid glands with mild or moderate cytological atypia, often with epithelial stratification. Squamous (morular) metaplasia is common (Fig. 9) and typically exhibits strong nuclear immunoreaction for beta-catenin indicating the occurrence of *CTNNB1* mutation. Prognosis is excellent.

Clear Cell Borderline Tumors

Clear cell borderline tumors comprise less than 1% of borderline tumors. Almost all the women are postmenopausal (mean age: 59–68 years). The majority of tumors are unilateral. Their size is variable with a mean of about 6 cm. These neoplasms are clear cell adenofibromatous tumors with atypia of the glandular epithelium without stromal invasion. The cyst and glands are lined by cuboidal, hobnail, or flattened cells with clear or eosinophilic cytoplasm (Fig. 10). All well documented cases have been benign.

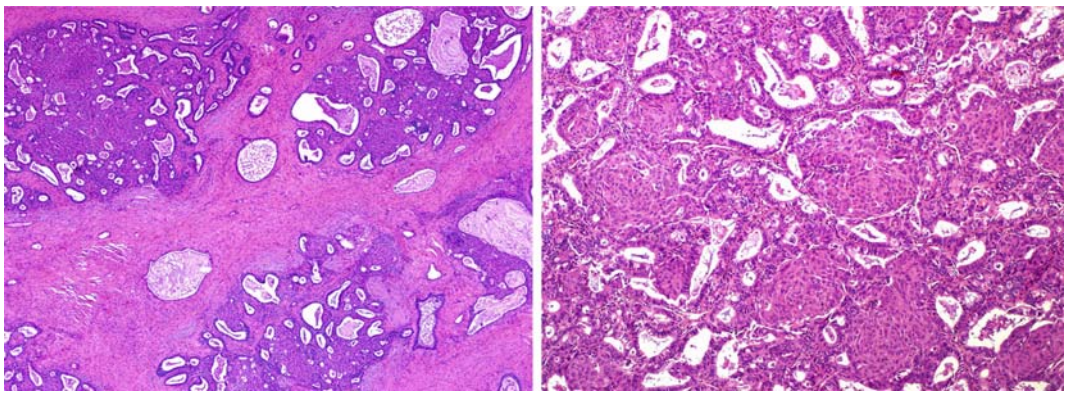

Fig. 9 Endometrioid borderline tumor. Left: endometrioid borderline adenofibroma. Right: endometrial glands are partly replaced by squamous morules.

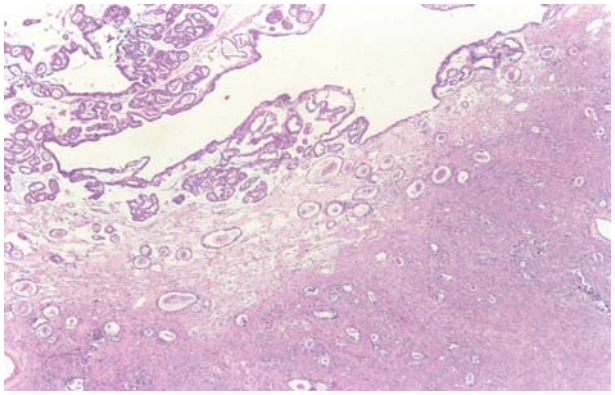

Fig. 10 Clear cell adenocarcinoma (upper left) with a borderline adenofibroma component (bottom right). Prat, J. (2004). Pathology of the ovary. Philadelphia: Saunders.

Borderline Brenner Tumors

Borderline Brenner tumors comprise less than 0.5% of borderline tumors. The mean patient age is 59 years. Tumors are unilateral. These are typically large, cystic tumors measuring, on average, 18 cm (range 10–28 cm) with papillary masses project into the cyst lumens. The papillary component closely resembles low-grade noninvasive papillary transitional cell (urothelial) tumors. Mucinous metaplasia is often present. A solid area of benign Brenner tumor is almost always present. The behavior is benign, although local recurrence may rarely occur (Fig. 11).

Ovarian Carcinomas

Ovarian carcinomas (malignant epithelial tumors) are the most common ovarian cancers and also the most lethal gynecological malignancies. Although traditionally referred to as a single entity, ovarian carcinoma is not a homogeneous disease but rather a group of diseases, each with different morphology and biologic behavior. Currently, based on histopathology, immunohistochemistry, and molecular genetic analysis, at least five main types of ovarian carcinomas are identified: high-grade serous carcinomas (70%), endometrioid carcinomas (10%), clear cell carcinomas (10%), mucinous carcinomas (3%), and low-grade serous carcinomas (<5%) (Table 1). These tumors account for over 95% of ovarian carcinomas, can be reproducibly diagnosed by light microscopy, and are inherently different diseases, as indicated by differences in epidemiological and genetic risk factors, precursor lesions, patterns of spread, molecular genetic alterations, response to chemotherapy, and prognosis. The fact that one tumor type (high-grade serous carcinomas) accounts for over two-thirds of cases, does not justify classifying ovarian carcinomas into only two

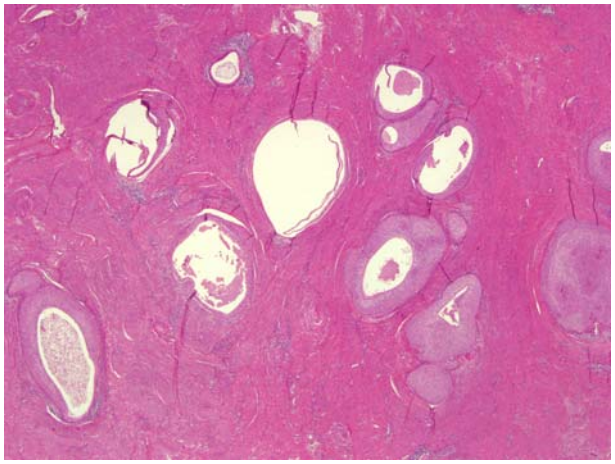

Fig. 11 Recurrent borderline Brenner tumor. Partly cavitated masses of transitional tumor cells invade the myometrium. Cuatrecasas, M., Catasus, L., Palacios, J. and Prat, J. (2009). Table 1 Main types of ovarian carcinoma

	High-grade serous	*Low-grade serous*	*Mucinous*	*Endometrioid*	*Clear cell*
Usual stage at diagnosis	Advanced	Early or advanced	Early	Early	Early
Presumed tissue of origin/precursor lesion	Fallopian tube or tubal metaplasia in inclusions of ovarian surface epithelium	Serous borderline tumor	Adenoma–borderline–carcinoma sequence; teratoma	Endometriosis, adenofibroma	Endometriosis, adenofibroma
Genetic risk	*BRCA1/2*	?	?	HNPCC	?
Significant molecular abnormalities	p53 and pRb pathways	*B-RAF* or *K-RAS*	*HER2*	*PTEN*, β-catenin, *ARID1A*, and *PIK3CA* *K-RAS* MI	HNF-1β, *ARID1A*, and *PIK3CA*
Proliferation	High	Low	Intermediate	Low	Low
Response to primary chemotherapy	80%	26%–28%	15%	?	15%
Prognosis	Poor	Favorable	Favorable	Favorable	Intermediate

Prat, J. (2017). Pathology of borderline and invasive cancers. *Best Practice & Research: Clinical Obstetrics & Gynaecology*. ***41,*** 15–30.

pathogenetic types, lumping together the other four (endometrioid, clear cell, mucinous, and low-grade serous carcinomas) as "type I carcinomas." The latter tumors are clinically, morphologically, and molecularly distinct diseases that individually bear resemblance neither to high-grade serous carcinomas nor to each other.

Serous Carcinomas

Low-grade serous carcinoma (LGSC) and high-grade serous carcinoma (HGSC) are fundamentally different tumor types and, consequently, different diseases. LGSCs are associated, in most cases, with a serous borderline component, carry *K-RAS* and *B-RAF* mutations, and are unrelated to *TP53* mutations and *BRCA* abnormalities. In contrast, HGSCs are not associated with SBTs and typically exhibit *TP53* mutations and *BRCA* abnormalities.

High-grade serous carcinoma (HGSC)

HGSCs are the most common ovarian carcinomas and most patients present with advanced stage disease (approximately 80%); tumors limited to the ovary at diagnosis are distinctly uncommon (< 10%) (Table 2).

Microscopically, HGSCs show papillary and solid growth with slit-like glandular lumens. The tumor cells are typically of intermediate size, with scattered bizarre mononuclear giant cells exhibiting prominent nucleoli (Fig. 12). In contrast to LGSCs, these tumors show more than threefold variation in nuclear size. In cases with equivocal degrees of nuclear pleomorphism, mitotic activity greater than 12/10 high-power microscopic fields (HPF) favors a diagnosis of HGSC. High grade and predominantly solid carcinomas showing serous differentiation, even in a minority of the tumor, should be classified as HGSC.

Most HGSC immunoreact for p53, BRCA1, WT1, and p16. They also exhibit a high proliferation index as indicated by an increased nuclear expression of Ki-67. Only strong and diffuse p53 and p16 reactions should be considered abnormal. Nuclear WT1 reaction occurs in approximately 80% of cases of HGSC and LGSC but in less than 5% of ovarian carcinomas of other types. Estrogen receptor (ER) is expressed in approximately two-thirds of cases of HGSC and is also expressed in LGSCs and ECs but is negative in almost all CCCs and MCs.

Women with germline mutations in *BRCA1* or *BRCA2* have a 30%–70% lifetime risk of developing ovarian cancer mainly HGSC. Carcinomas arising in patients with germline *BRCA1* or *BRCA2* mutations are almost invariably of high-grade serous type. Like *TP53* mutations, *BRCA* inactivation seems to be a consistent genetic alteration of HGSC. Besides germline mutation, inactivation of the BRCA pathway may result from somatic mutation in either *BRCA1* or *BRCA2*, or promoter hypermethylation in *BRCA1*.

The finding of serous tubal intraepithelial carcinoma (STIC) in risk-reducing salpingo-oophorectomy (RRSO) specimens from women with known *BRCA* mutations and/or a strong family history of ovarian cancer resulted in extensive research into the role of the fallopian tube in pelvic serous carcinogenesis. Early studies showed small foci of strongly p53-immunoreactive cells in histologically normal fallopian tube epithelium. These foci, which predominate in the distal portion of the fallopian tube, have been designated "p53 signatures." Like STIC, p53 signatures are comprised exclusively of secretory cells (at least 12 consecutive immunoreactive cells), and the majority exhibit evidence of DNA damage by immunoreaction for gamma-H2AX. They are more frequent and multifocal in tubes with STIC and, in some cases, can be identified in direct continuity with STIC. About 57% of p53 signatures contain *TP53* mutations; however, Ki-67 proliferation index is low (mean, 3%). p53 signatures probably represent early clonal expansion insufficient for neoplastic proliferation and, surprisingly, are found in both women with and without *BRCA1* or *BRCA2* mutations at the same frequency (10%–38% vs. 17%–33%, respectively). *TP53* mutation is an early event in the genesis of HGSC, occurring in p53 signature foci and leading to STIC in the distal fallopian tube. *BRCA1* mutation also occurs early in the development of STIC but after *TP53* mutation.

Table 2 Clinical staging of cancer of the ovary, fallopian tube, and peritoneum (International Federation of Gynecology and Obstetrics, FIGO, 2014)

I	Tumor confined to ovaries or fallopian tube(s)			
	IA	Tumor limited to one ovary (capsule intact) or fallopian tube, no tumor on ovarian or fallopian tube surface. No malignant cells in the ascites or peritoneal washings		
	IB	Tumor limited to both ovaries (capsules intact) or fallopian tubes. No tumor on ovarian or fallopian tube surface. No malignant cells in the ascites or peritoneal washings		
	IC	Tumor limited to one or both ovaries or fallopian tubes, with any of the following:		
		IC1	Surgical spill intraoperatively	
		IC2	Capsule ruptured before surgery or tumor on ovarian or fallopian tube surface	
		IC3	Malignant cells in the ascites or peritoneal washings	
II	Tumor involves one or both ovaries or fallopian tubes with pelvic extension (below pelvic brim)			
	IIA	Extension and/or implants on the uterus and/or fallopian tubes/and/or ovaries		
	IIB	Extension to other pelvic intraperitoneal tissues		
III	Tumor involves one or both ovaries, fallopian tubes, or primary peritoneal cancer, with microscopically confirmed spread to the peritoneum outside the pelvis or metastasis to the retroperitoneal lymph nodes			
	IIIA	Metastasis to the retroperitoneal lymph nodes with or without microscopic peritoneal involvement beyond the pelvis		
		IIIA1	Positive retroperitoneal lymph nodes only. Microscopically proven	
			IIIA1 (i)	Metastasis $\leq$10 mm in greatest dimension
			IIIA1 (ii)	Metastasis $>$10 mm in greatest dimension
		IIIA2	Microscopic extrapelvic (above pelvic brim) peritoneal involvement with or without positive peritoneal lymph nodes	
	IIIB	Macroscopic peritoneal metastasis beyond the pelvic brim 2 cm or less in greatest dimension, with or without metastasis to the retroperitoneal lymph nodes		
	IIIC	Macroscopic peritoneal metastasis beyond the pelvis more than 2 cm in greatest dimension, with or without metastasis to the retroperitoneal lymph nodes (Note 1)		
IV	Distant metastasis excluding peritoneal metastases			
	IVA	Pleural effusion with positive cytology		
	IVB	Metastases to extra-abdominal organs (including inguinal lymph nodes and lymph nodes outside the abdominal cavity)		

Note 1: Includes extension of tumor to capsule of liver and spleen without parenchymal involvement of either organ; *Note* 2: Parenchymal metastases are stage IVB.
OV: Primary tumor, ovary, Tov; FT: Primary tumor, fallopian tube, Tft; P: Primary tumor, peritoneum, Tp; X: Primary tumor cannot be assessed, Tx.
Modified from Prat, J. for the FIGO committee on gynecologic oncology: FIGO's staging classification for cancer of the ovary, fallopian tube, and peritoneum: Abridged republication. *Journal of Gynecologic Oncology* ***26*** (2), 87–89.

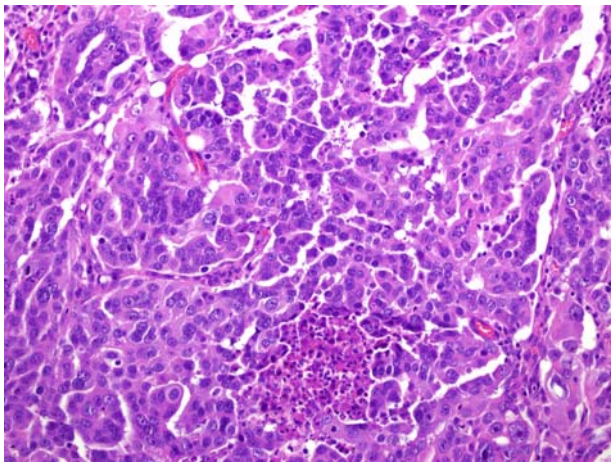

Fig. 12 High-grade serous carcinoma. Solid masses of cells with slit-like glandular lumens, high grade nuclear atypia, mitotic figures, and necrosis.

The sequence of epithelial changes taking place in the distal fallopian tube have been described as follows: normal fallopian tube epithelium, overexpression of p53, serous tubal intraepithelial carcinoma (STIC), and finally, invasive serous carcinoma. The secretory cells of the tubal epithelium have a limited ability to repair DNA DSB, as shown by the persistence of gamma-H2AX immunoreactive foci after DNA damage, which might explain why this tissue seems to be especially sensitive to inactivating *BRCA* mutations.

A pathogenetic model that includes the stages of initiation and progression of HGSC have been described (Fig. 13). It proposes as primary events early p53 loss followed by BRCA loss, leading to deficiency in homologous recombination repair (HRR) of DSB, which triggers chromosomal instability (genetic chaos) and widespread copy number changes. Once chromosomal instability is set up by mutation in *TP53* and *BRCA* inactivation, gene copy number is the major determinant of progression of HGSC.

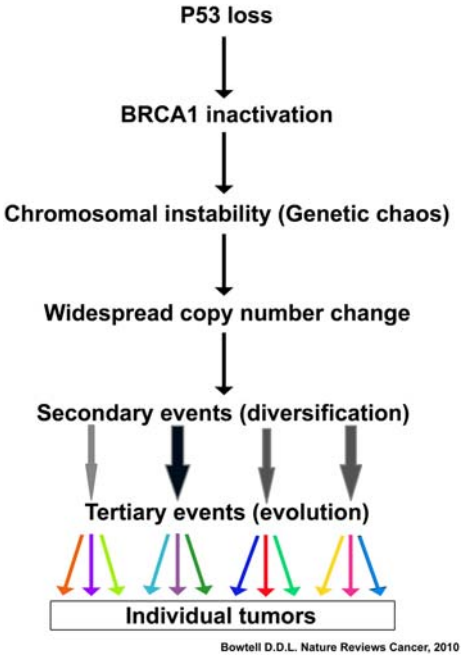

Fig. 13 Pathogenetic model that includes the stages of initiation and progression of HGSC. Modified from Bowtell, D. D. (2010). The genesis and evolution of high-grade serous ovarian cancer. *Nature Reviews Cancer* ***10,*** 803–808.

Approximately 5%–10% of *BRCA*-positive asymptomatic women have early HGSC, and 80% of them are associated with STIC. As a result, speculation that "all" HGSCs originated in the fallopian tube followed. However, the pathogenesis of HGSC appears to be more complex as indicated by the following: (a) only 40% of advanced HGSCs show STIC; (b) only 8% of HGSCs with SET (solid, pseudoendometrioid, transitional) morphology show STIC; and (c) high-grade serous carcinomas with SET morphology tend to be *BRCA*-positive, patients are younger, and outcome is better. Thus, it seems that HGSC (*BRCA* positive and *BRCA* negative) is not a homogeneous disease. Several variables, including age, histotype, STIC ±, and patient outcome, allow segregation of two tumor groups: (a) younger *BRCA*-positive patients, without STIC and with favorable outcome; and (b) older *BRCA*-negative patients, with STIC, and with unfavorable prognosis. Therefore, recent studies suggest that HGSCs may have at least two different origins; that is, ovarian surface epithelium and tubal epithelium.

Low-grade serous carcinoma (LGSC)

Low-grade serous carcinoma are uncommon and account for less than 5% of all cases of ovarian carcinoma. They frequently have a noninvasive SBT component (with or without micropapillary pattern) and most likely represent progression of SBTs. The presence of small foci of LGSC in an ovarian borderline tumor is associated with an excellent prognosis; however, patients with advanced stage disease fare less favorably even if the disease usually follows a relatively indolent course.

Microscopically, LGSCs show small papillae of tumor cells exhibiting uniform small nuclei within variable amounts of hyalinized stroma, which often contains psammoma bodies (Fig. 14). Uniformity of the nuclei is the principal criterion for distinguishing between LGSC and HGSC, with less than threefold variability. LGSC rarely progress to high-grade tumors.

The biomarker expression profile of LGSC is similar to that of their high-grade counterparts, but the median Ki-67 labelling index is of 2.5% in LGSC compared to 22.4% in HGSC. *BRAF* or *KRAS* mutations are present in LGSCs (30% and 35%, respectively, in one study and 5% and 40%, respectively, in another). LGSCs do not show chromosomal instability and lack the complex genetic abnormalities seen in HGSCs. LGSCs are not associated with *BRCA* germline mutations.

With regard to the distinction between LGSC and serous borderline tumor, micropapillarity, by itself, is not sufficient to warrant a diagnosis of carcinoma in the absence of invasion. If there are invasive foci measuring less than 10 mm^2, the tumor is considered to be borderline with microinvasion. Tumors with larger invasive components are classified as LGSC. Histopathologically, invasive peritoneal implants and LGSC are identical lesions which are only distinguished by the timing of the disease and the volume of the tumor. Whereas invasive implants are early superficial lesions of microscopic or small macroscopic size ($\leq$1–2 cm), LGSC frequently presents as bulky disease. Although the independent origin of the invasive peritoneal implants associated with ovarian SBT cannot be completely excluded, we have demonstrated identical *B-RAF* y *K-RAS* mutations as well as identical LOH in a series of ovarian SBT and peritoneal implants. Such findings support a monoclonal origin of these tumors and the secondary nature of the implants.

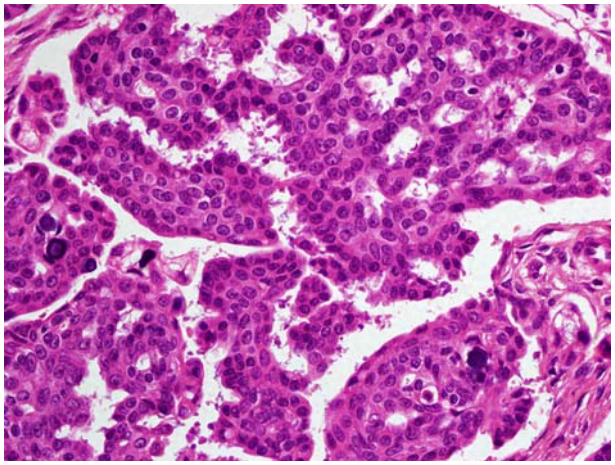

Fig. 14 Low-grade serous carcinoma. The papillary tumor shows epithelial cells with small and uniform nuclei (grade 1). The stroma contains psammoma bodies. Prat, J. (2017). Pathology of borderline and invasive cancers. *Best Practice and Research: Clinical Obstetrics and Gynaecology* ***41,*** 15–30.

Mucinous Carcinomas (MC)

Mucinous tumors account for 10%–15% of all primary ovarian tumors; however, approximately 80% are benign and most of the remainder are borderline tumors. If metastases to the ovary, particularly from the gastrointestinal tract, are carefully excluded, only 3%–4% of ovarian carcinomas are of mucinous type. The cells of MCs may resemble those of the gastric pylorus, intestine, or endocervix; nevertheless, the vast majority of these tumors show gastrointestinal differentiation. The origin of these tumors is unknown. Large size (>13 cm) and unilaterality are features suggestive of a primary MC, while metastases are typically smaller and bilateral. Primary MCs of the ovary are usually confined to the ovary, without ovarian surface involvement or pseudomyxoma peritonei.

As indicated before, malignant mucinous ovarian tumors are often heterogeneous. Benign-appearing, borderline, noninvasive carcinoma, and invasive components may coexist within an individual tumor and suggest tumor progression from benign to borderline and from borderline to carcinoma. Therefore, extensive sampling for histological examination is necessary. The category of MBT with intraepithelial carcinoma is used for those tumors that lack obvious stromal invasion but show areas, less than 10 mm^2, where the cytological features of the tumor cells are unequivocally malignant. MBTs with intraepithelial carcinoma have a very low risk of recurrence of less than 5%.

MCs have been divided into two categories: (a) an expansile type without obvious stromal invasion, but exhibiting back-to-back or complex malignant glands with minimal or no intervening stroma, and exceeding 10 mm^2 in area (>3 mm in each of two linear dimensions) (Fig. 15); and (b) an infiltrative type, showing evident stromal invasion in the form of glands, cell clusters, or individual cells, disorderly infiltrating the stroma and frequently associated with a desmoplastic stromal reaction. The expansile pattern of growth has also been referred to as the "noninvasive" pattern and is associated with a more favorable prognosis than the infiltrative pattern. A histopathological feature unique to mucinous tumors is the occasional finding of mural nodules of anaplastic carcinoma or high-grade sarcoma (Fig. 16). When such nodules are localized in the wall of an unruptured cyst, the prognosis may be favorable, but such tumors may recur and do so as the anaplastic component.

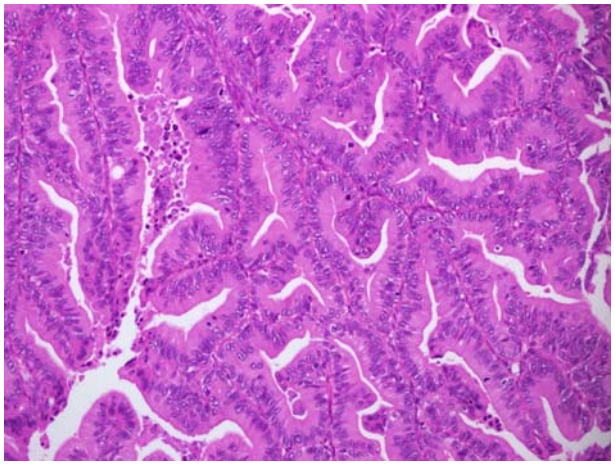

Fig. 15 Mucinous carcinoma with expansile invasion. Closely packed (back-to-back) malignant glands with no stromal response. Stromal invasion is not obvious.

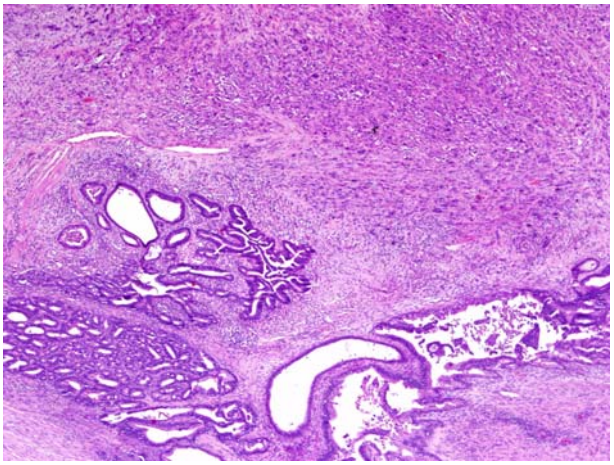

Fig. 16 Anaplastic carcinoma in a mucinous tumor. The epithelial lining appears to be of borderline malignancy (*bottom*). The undifferentiated component is composed of cells with pleomorphic (grade 3) nuclei (*top*). Longacre, T. A., Bell D. A., Malpica, A., et al. (2014). Mucinous tumours. In Kurman, R. J., Carcangiu, M. L., Herrington, C. S. and Young, R. H. eds. *World Health Organization Classification of tumours of female reproductive organs*. Lyon: IARC Press, pp. 25–28.

The gene expression profile of MCs differs from those of serous, endometrioid, and clear cell carcinomas. *KRAS* mutations, which are an early event in mucinous tumorigenesis, occur in 43.6% of MCs and 78.8% of MBTs. On the other hand, overexpression/amplification of *HER2* has been found in 18.8% of MCs and 6.2% of MBTs. Interestingly, *KRAS* mutations are near mutually exclusive of *HER2* amplification. Approximately 34% of MCs have neither *HER2* amplification nor *KRAS* mutation and these cases are associated with increased likelihood of disease recurrence or death when compared to tumors with either genetic alteration. Using highly-sensitive next-generation sequencing, *KRAS* mutations remain the most frequent alteration among MCs and MBTs (92.3%). *TP53* mutation occurred more frequently in carcinomas (68%) than borderline tumors (20%).

Primary ovarian mucinous tumors are almost always (up to 80%) immunoreactive for cytokeratin 7 (CK7) whereas metastatic colorectal adenocarcinomas are usually CK7 negative. Ovarian MCs are immunoreactive for CK20 in 65% of cases, but the reaction is typically weak and focal; staining for CDX-2 (nuclear immunoreaction) is similar. In contrast, colorectal adenocarcinomas are diffusely and strongly reactive for CK20 and CDX-2. Human papilloma virus (HPV) DNA assessment may be helpful for distinguishing mucinous adenocarcinoma of the cervix metastatic to the ovary from a primary ovarian MC. p16 expression is also a reliable surrogate marker for HPV. MCs are uniformly negative for estrogen receptor (ER) and WT1, in contrast to endometrioid (ER+) and serous (ER+ and WT1+) carcinomas.

FIGO stage is the single most important prognostic factor, and stage I MCs have an excellent prognosis. However, the prognosis in cases with extraovarian spread is poor.

Endometrioid Carcinomas (EC)

Endometrioid tumors of the ovary closely mimic their uterine counterparts. ECs account for 10% of all ovarian carcinomas, occur most frequently in women of perimenopausal age, and most are found at an early stage. The tumors are bilateral in 28% of cases and are associated in 15%–20% of cases with carcinoma of the endometrium. Most ECs are low-grade adenocarcinomas (**Fig. 17**) and seem to arise from endometriotic cysts. Up to 42% of cases have evidence of ipsilateral ovarian or pelvic endometriosis. Squamous differentiation occurs in 50% of cases. In contrast, high-grade ECs are morphologically indistinguishable from HGSCs (**Fig. 18**) and often express WT1. Gene expression profiling is also similar, suggesting that high-grade EC is not a distinct tumor type.

Atypical endometriosis is the precursor lesion of endometrioid and clear cell carcinomas of the ovary and a direct transition from ovarian atypical endometriosis to endometrioid or clear cell carcinomas has been described in 15%–32% of cases (**Fig. 19**). In these cases, common genetic alterations have been encountered in the adjacent endometriosis, atypical endometriosis, and adenocarcinoma. In mice harboring *K-RAS* mutations that result in the development of benign lesions reminiscent of endometriosis, deletion of *PTEN* leads to the induction of invasive EC. These results indicate that inactivation of tumor suppressor genes such as *PTEN* may represent early events in the malignant transformation of endometriosis.

ARID1A (AT-rich interactive domain 1A gene) mutations occur in both endometrioid (30%) and clear cell carcinomas (50%) and their finding in adjacent endometriosis has renewed interest in the molecular events that occur in precursor lesions. *ARID1A* is a component of the SWI–SNF-A complex, a large, multiprotein chromatin remodeling complex which is known to both enhance and repress transcription. It behaves as a tumor suppressor gene. BAF250 protein, encoded by *ARID1A*, plays a crucial role in chromatin remodeling. The question has been raised whether patients with endometriotic lesions that show loss of expression of BAF250 should be viewed as being at high risk for the development of CCC or endometrioid ovarian cancers.

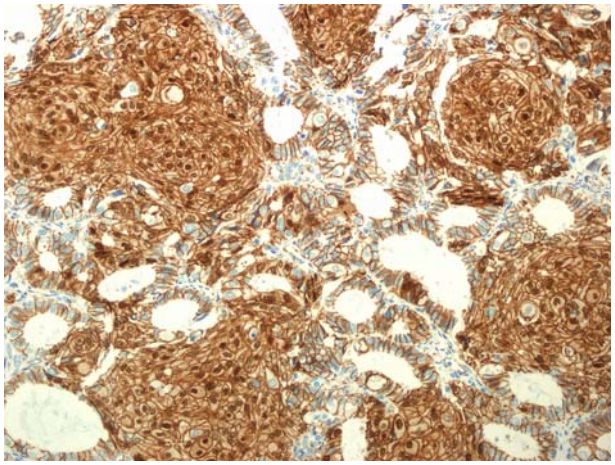

Fig. 20 Endometrioid borderline tumor. Nuclear immunoreactivity for beta-catenin in the squamous morules.

Somatic mutations of the beta-catenin (*CTNNB1*) and *PTEN* genes are the most common genetic abnormalities identified in ovarian ECs. Compared with uterine ECs, ovarian ECs have a similar frequency of beta-catenin abnormalities but lower rate of microsatellite instability (MI) and *PTEN* alterations. *CTNNB1* mutations, which occur in 38%–50% of cases, are associated with squamous differentiation, low tumor grade, and favorable outcome. Beta-catenin is immunohistochemically detectable in carcinoma cells in more than 80% of the cases (Fig. 20).

PTEN inactivation results in activation of the PI3K-AKT signaling pathway that inhibits apoptosis. *PTEN* is mutated in approximately 20% of ovarian ECs and in 46% of those with 10q23 LOH. An alternative mechanism for activation of the PI3K signaling in ECs is through activating mutations of *PIK3CA*, which encodes the p110 catalytic subunit of PI3K. *PIK3CA* mutations in exons 9 and 20 have been identified in 20% of ovarian ECs and CCCs but in only 2% of HGSC. *PIK3CA* mutations are associated with adverse prognostic parameters.

ECs are the types most commonly encountered in patients with hereditary nonpolyposis colon cancer syndrome. The reported frequency of MI in ovarian ECs ranges from 12.5% to 19%. Like endometrial carcinomas, ovarian ECs with MI follow the same process of *MLH-1* promoter methylation and frameshift mutations at coding mononucleotide repeat microsatellites. ECs are immunoreactive for vimentin, cytokeratins (CK7, 97%; CK20, 13%), epithelial membrane antigen (EMA), and estrogen and progesterone receptors. Immunoreaction for alpha-inhibin, WT-1, and calretinin are negative in most ECs. The median Ki-67 labelling index for endometrioid is 8.2%.

Simultaneous carcinomas of the uterine corpus and ovary, occur in 15%–20% of ovarian tumors and in approximately 5% of uterine tumors. Both tumors are of endometrioid type in the majority of cases. Besides prognostic implications, accurate diagnosis as independent primaries or metastases is necessary for appropriate staging and treatment. Assessment of conventional pathological features including tumor size, histological type and grade, pattern of tumor growth, vascular invasion, and coexisting atypical hyperplasia or endometriosis allows the distinction in most cases. Occasionally, however, the differential diagnosis can be difficult or impossible as the tumors may show overlapping features. In such cases, patient follow-up is the single most conclusive factor, but ancillary techniques may help to establish the correct diagnosis.

Clonality analysis using LOH and gene mutation have been used for distinguishing independent primary carcinomas from metastatic carcinomas. The frequency of molecular alterations in both independent and metastatic tumors, including MI and *PTEN* mutations, is higher than that observed in single sporadic tumors. Nuclear immunoreactivities for beta-catenin and *CTNNB1* mutations were restricted to independent uterine and ovarian tumors and were absent in metastatic tumors. These findings correlated with the clinical outcome. Recently, however, whole-exome massively parallel sequencing done in five patients with synchronous endometrioid endometrial and ovarian carcinomas revealed that the tumors of each case displayed strikingly similar repertoires of somatic mutations and gene copy number alterations. These results favor that sporadic synchronous EC of the endometrium and ovary are clonally related, and likely constitute dissemination from one site to the other. Nevertheless, the "independent" origin of the ovarian EC arising from endometrial stem cells that reached the ovary through menstrual reflux cannot be excluded.

EC is the type of ovarian carcinoma with the most favorable prognosis and this may be due to its lower grade and lower stage in most cases (Table 2).

Clear Cell Carcinomas (CCC)

Clear cell carcinomas account for approximately 10% of ovarian carcinomas and patients typically present with stage 1 or 2 disease (Table 2). Tumors are rarely bilateral. CCCs are associated with an unfavorable prognosis when they present at advanced stage. As with EC, there is a strong association with endometriosis, and CCCs associated with endometriosis have a favorable prognosis.

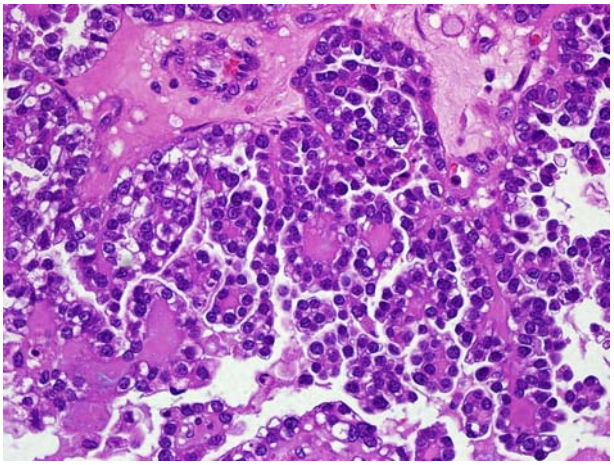

Fig. 21 Clear cell adenocarcinoma. The papillae are lined by clear cells and have hyalinized cores. Prat, J. (2017). Pathology of borderline and invasive cancers. *Best Practice & Research: Clinical Obstetrics & Gynaecology* ***41,*** 15–30.

The presence of clear cells alone is not sufficient for a diagnosis of CCC, as cells with clear cytoplasm can be seen in HGSC and EC. Besides the characteristic clear or hobnail cells with eccentric, rounded, and bulbous nuclei, the diagnosis is based on the following histological findings: (a) multiple complex papillae; (b) densely hyaline basement membrane material expanding the cores of the papillae (Fig. 21); and (c) hyaline bodies, which are present in approximately 25% of cases. Mitoses are less frequent than in other types of ovarian carcinomas (usually less than 5/10 HPFs).

Clear cell carcinomas lack the *BRCA* abnormalities, chromosomal instability, or complex karyotypes of HGSC. Also, mutations in *TP53*, which are common in HGSCs, are usually absent in CCCs. This suggests that other antiapoptotic mechanisms are likely to be involved in the development of CCC. Loss of PTEN expression has been found in 40% of early stage CCCs and inactivating mutations in 8% of cases. On the other hand, activating mutations in *PIK3CA* occur in 33% of cases. Recently, it has been found that nearly half the CCCs (46%–57%) carry *ARID1A* mutations and lack BAF250 protein. *ARID1A* mutations and loss of BAF250a expression have been found in the tumor and adjacent endometriosis, which suggests that *ARID1A* inactivation occurs early during malignant transformation of endometriosis. CCCs are usually positive for HNF1-beta (>90%) and are negative for ER and WT1 in more than 95% of cases. Mutations in *KRAS* are present in some CCCs but their frequency is very low. Microsatellite instability may be encountered in up to 15% of cases.

The genetic profiles of CCC are similar to those of renal and endometrial CCCs, which suggest that some molecular genetic alterations may be common to CCCs regardless of the organ of origin.

Hepatocyte nuclear factor-1beta (HNF-1beta) is upregulated in ovarian clear cell tumors, including benign, borderline tumors, and carcinomas (Fig. 22). This transcription factor facilitates glycogen synthesis and is expressed in mid-to-late secretory and gestational endometrium (Arias–Stella reaction), atypical and inflammatory endometriosis, and clear cell carcinoma. HNF-1beta regulates several specific genes of clear cell carcinoma, including dipeptidyl peptidase IV (glycogen synthesis), osteopontin (progesterone-regulated endometrial secretory protein), angiotensin converting enzyme 2 (ferritin induction, iron deposition,

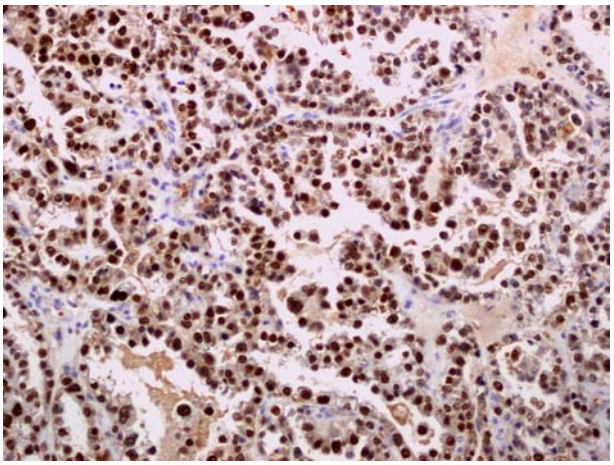

Fig. 22 Clear cell adenocarcinoma. HNF-1beta immunostaining.

antiapoptosis), annexin 4 (paclitaxel resistance), and *UGT1A1* (detoxification). Thus, HNF-1beta appears to play an important role in the pathogenesis and behavior of clear cell carcinoma.

Sex Cord-Stromal Tumors

Sex cord-stromal tumors account for only 8% of ovarian tumors and are the most common functioning ovarian neoplasms associated with endocrine symptoms. They may differentiate toward female (granulosa and theca cells) or male (Sertoli and Leydig cells) structures. Most of these tumors are benign and less frequently of low-grade malignancy. Rarely, malignant sarcomatoid forms occur.

Malignant Sex Cord-Stromal Tumors

Granulosa cell tumor

Granulosa cell tumors account for 12% of all sex cord-stromal tumors. Most granulosa cell tumors (95%) occur after the menopause (adult form) and are unusual before puberty. A juvenile form that develop in children and young women has distinct clinical and pathologic features (hyperestrinism and precocious puberty). Development of granulosa cell tumors is linked to loss of oocytes. Oocytes appear to regulate granulosa cells, and tumorigenesis occurs when follicles are disorganized or atretic. Adult-type granulosa cell tumors, are clinically palpable and, like most ovarian tumors, focally cystic and solid. The cut surface shows yellow areas, owing to lipid-rich luteinized granulosa cells, white zones of stroma, and focal hemorrhages (**Fig. 23**). Granulosa cell tumors show diverse growth patterns: (1) diffuse (sarcomatoid), (2) insular (islands of cells) or (3) trabecular (anastomotic bands of granulosa cells). Random nuclear arrangement about a central degenerative space (Call-Exner bodies) gives a characteristic follicular pattern (**Fig. 24**). Tumor cells are typically spindle shaped and have a cleaved, elongated nucleus (coffee bean appearance). They secrete inhibin, a protein that suppresses pituitary release of follicle-stimulating hormone (FSH). These tumors can also express calretinin, a primarily neuronal protein, which suggests possible neural differentiation or derivation for these neoplasms. Three fourths of granulosa cell tumors secrete estrogens; thus, endometrial hyperplasia is a common presenting sign. Endometrial hyperplasia or low-grade endometrioid carcinoma may develop if a functioning granulosa cell tumor remains undetected. At diagnosis, 90% of granulosa cell tumors are within the ovary (stage I). Over 90% of these patients survive 10 years. Tumors that have extended into the pelvis and lower abdomen have a poorer prognosis. Late recurrence, 5–10 years after surgical removal, is not uncommon and is usually fatal. The most common chromosomal abnormalities are trisomy 12, trisomy 14, monosomy 16, deletion of 16q, and monosomy 22. Missense somatic point mutations in the *FOXL2* gene (402 C to G) are found in over 90% of adult granulosa cell tumors.

Setoli–Leydig cell tumor

Sertoli–Leydig cell tumors (SLCT) are rare androgen-secreting mesenchymal neoplasms that resemble embryonic testis. They account for 0.5% of all sex-cord stromal tumors. Tumor cells typically secrete weak androgens (dehydroepiandrosterone), so tumors are usually quite large before patients complain of masculinization. Sertoli–Leydig cell tumors occur at all ages but are most common in young women of childbearing age. Sertoli–Leydig cell tumors are unilateral, usually 5–15 cm, and tend to be lobulated, solid, and brown to yellow. They vary from well to poorly differentiated and some contain heterologous elements (e.g., mucinous

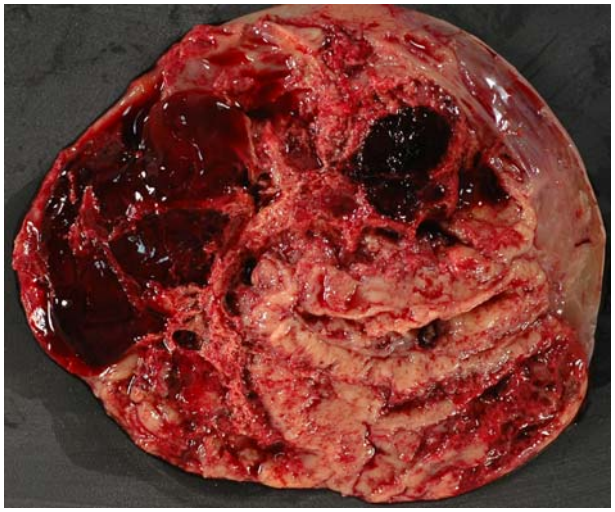

Fig. 23 Adult granulosa cell tumor. Cystic and solid tumor. The solid component is *yellow* and the cysts contain clotted blood.

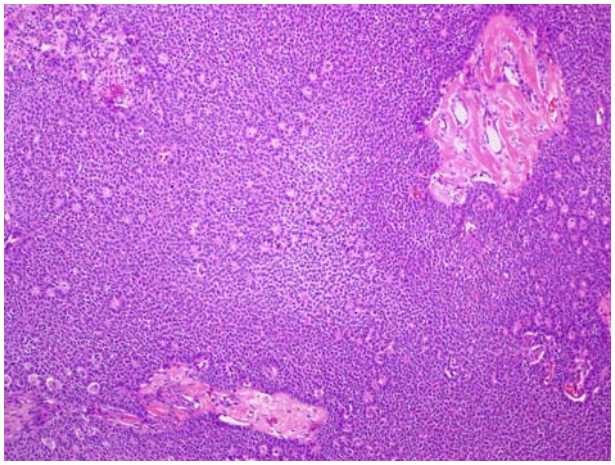

Fig. 24 Adult granulosa cell tumor. Microfollicular pattern (Call-Exner bodies).

glands and, rarely, even cartilage). Large Leydig cells have abundant eosinophilic cytoplasm and a central round to oval nucleus with a prominent nucleolus. The stroma in some areas often differentiates into immature solid tubules of embryonic Sertoli cells (Fig. 25). Nearly half of all patients with Sertoli–Leydig cell tumors exhibit signs of virilization: hirsutism, male escutcheon, enlarged clitoris, and deepened voice. Initial signs are often defeminization, manifested as breast atrophy, amenorrhea and loss of hip fat. Once the tumor is removed, these signs disappear or lessen. Well-differentiated tumors are benign and virtually always cured by surgical resection, but the rare cases of poorly differentiated (or sarcomatoid) SLCT may metastasize. Mutations in *DICER1*, a gene encoding an RNase III endoribonuclease, are found in 60% of Sertoli–Leydig cell tumors. Germline mutations in this gene are seen in familiar multinodular goiter with Sertoli–Leydig tumor, and tumor susceptibility includes pleuropulmonary blastoma in childhood. Sertoli–Leydig cell tumor has been reported in association with cervical embryonal rhabdomyosarcoma in four patients.

Malignant Germ Cell Tumors

Dysgerminoma

Dysgerminoma, the ovarian counterpart of testicular seminoma, is composed of primordial germ cells. It accounts for less than 2% of ovarian cancers but 10% of those occurring in women younger than 20 years. Dysgerminoma represents 45% of malignant germ cell tumors, Most patients are between 10 and 30. The tumors are bilateral in about 15% of cases, are often large and firm, and have a bosselated external surface. The cut surface is soft and fleshy (Fig. 26). They contain large nests of monotonously uniform tumor cells that have clear glycogen-filled cytoplasm and irregularly flattened central nuclei. Fibrous septa containing lymphocytes traverse the tumor (Fig. 27). The tumor cells show diffuse nuclear expression for the stem cell/primitive germ cell nuclear transcription factors OCT3/4, NANOG, and SALL4. Dysgerminomas are treated surgically; 5-year survival for patients with stage I tumor approaches 100%. Because the tumor is highly radiosensitive and also responsive to chemotherapy, even higher-stage tumors have 5-year survival rates exceeding 80%. The majority of dysgerminomas show isochromosome 12p. *c-Kit* mutations are seen in 25%–50% of tumors, most commonly in exon 17, not in the exon 11 location that confers susceptibility to imatinib therapy.

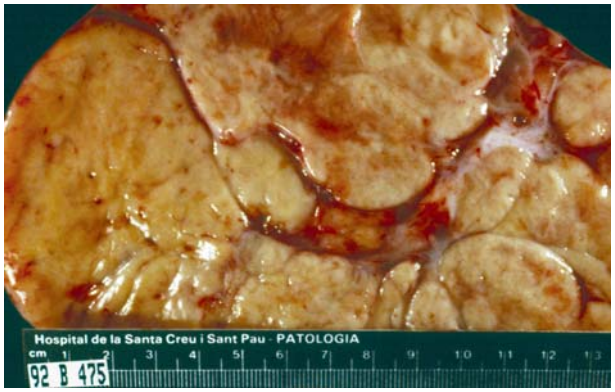

Fig. 26 Dysgerminoma. Solid, *yellowish–white*, and lobulated tumor.

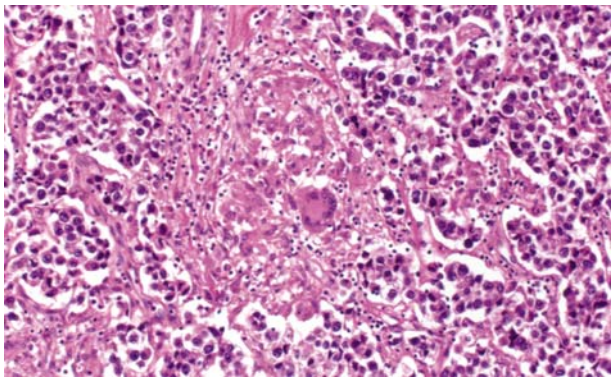

Fig. 27 Dysgerminoma. Nest of tumor cells separated by delicate fibrous septa. The stroma contains numerous lymphocytes and a sarcoid-like granuloma. Prat, J. (2004). Pathology of the ovary. Philadelphia: Saunders.

Yolk Sac Tumor

Yolk sac tumors are highly malignant tumors of women under the age of 30 that histologically resemble mesenchyme of the primitive yolk sac. They are the second most common malignant germ cell tumors (~20%) and are almost always unilateral. Yolk sac tumors are large, with extensive necrosis and hemorrhage. Several patterns are seen. The most common is a reticular, honeycombed structure of communicating spaces lined by primitive epithelial cells with glycogen-rich, clear cytoplasm and large hyperchromatic nuclei (primitive endoderm). Glomerular or Schiller–Duval bodies (Fig. 28) are found sparingly in a few tumors but are characteristic. They consist of papillae that protrude into a space lined by tumor cells, resembling the glomerular Bowman space. The papillae

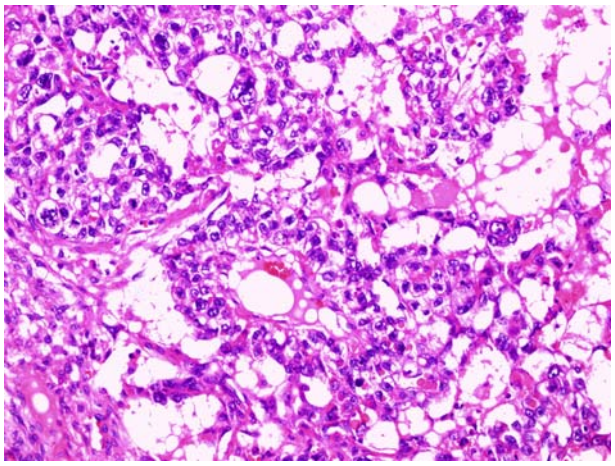

Fig. 28 Yolk sac tumor. Glomerular or Schiller–Duval body.

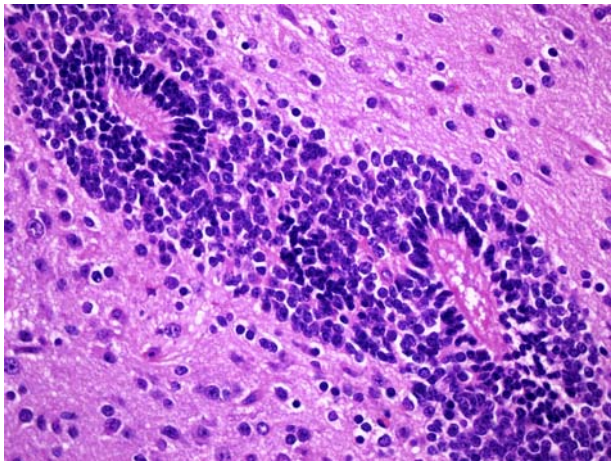

Fig. 29 Immature teratoma (grade 3). Immature neuroectodermal tissue with rosettes. Mutter, G.L. and Prat, J. eds. (2014). Pathology of the female reproductive tract. 3rd edn. Churchill Livingstone; Elsevier.

are covered by a mantle of embryonal cells and contain a fibrovascular core and a central blood vessel. Yolk sac tumor should not be confused with embryonal cell carcinoma, which is far more common in the testis. The former secretes α-fetoprotein, which can be demonstrated by immunohistochemistry. Detection of α-fetoprotein in the blood is useful for diagnosis and for monitoring the effectiveness of therapy. Although once uniformly fatal, 5-year survival with chemotherapy for stage I yolk sac tumors now exceeds 80%.

Immature Teratoma

Immature teratomas of the ovary contain elements derived from the three germ layers. However, unlike mature cystic teratomas, immature teratomas contain embryonal tissues. These tumors account for over 20% of malignant germ cell tumors. They occur predominantly in women under the age of 20 and become progressively less common in older women. Immature teratomas are predominantly solid and lobulated, with numerous small cysts. Solid areas may contain grossly recognizable immature bone and cartilage. Multiple tumor components are often seen, including those differentiating toward nerve (neuroepithelial rosettes and immature glia), glands and other structures found in mature cystic teratomas (Fig. 29). Grading is based on the amount of immature neural tissue present. Survival reflects tumor grade. Well-differentiated immature teratomas have a good prognosis, but high-grade tumors (mainly embryonal tissue) are often lethal.

Summary

Epithelial ovarian tumors are heterogeneous neoplasms primarily classified according to cell type and further subdivided into benign, borderline, and malignant (carcinoma). Borderline tumors show epithelial proliferation and nuclear atypia but, contrary to carcinomas, show no destructive stromal invasion and their prognosis is usually favorable. The term "borderline" accurately describes the ambiguous histologic and biologic features of these neoplasms. The five main types of ovarian carcinoma (HGSC, LGSC, CCC, EC, and MC) account for over 95% of ovarian carcinomas, can be reproducibly diagnosed, and are inherently different diseases. Correct histopathological diagnosis is critical for treating them successfully.

An undetermined number of cases of HGSCs originate in the tubal fimbria; however, an origin from embryonic stem cells of the ovarian surface epithelium cannot be excluded. HGSC is not a homogeneous disease and several variables, including age, histotype and association with STIC allow segregation of two tumor groups: (a) younger *BRCA*-positive patients, without STIC and with favorable outcome; and (b) older *BRCA*-negative patients, with STIC, and with unfavorable prognosis.

Endometrioid and clear cell carcinomas originate from ovarian endometriosis. Although endometriosis is essentially a benign disease, it exhibits some features reminiscent of malignancy such as metastatic potential and monoclonality. The incidence of malignant tumors arising from ovarian endometriosis is minimal, but the frequency of endometriosis in women with certain types of ovarian cancer (i.e., endometrioid and clear cell carcinomas) is more significant. Atypical endometriosis is the precursor lesion of EC and CCC of the ovary and a direct transition from ovarian atypical endometriosis to EC or CCC has been found.

Much less common are malignant germ cell tumors (dysgerminomas, yolk sac tumors, and immature teratomas) (3% of ovarian cancers) and potentially malignant sex cord-stromal tumors (1%–2%) (granulosa cell tumors).

Definition

The most common cancer of the pancreas is pancreatic ductal adenocarcinoma (PDAC; ICD-O code: 8500/3) which accounts for over 90% of all pancreatic malignancies. This entry is entirely devoted to this cancer type and does not cover the rare neuroendocrine and mesenchymal pancreatic cancers which are very different and require different clinical approaches.

Presentation and Diagnosis

Presentation

Early pancreatic cancer is usually asymptomatic and effective screening strategies do not exist. The initial presentations manifest with a range of nonspecific symptoms, which further delays the diagnosis. Therefore, most patients present with advanced symptomatic disease. Patients typically report a gradual onset of nonspecific symptoms, such as anorexia, malaise, nausea, fatigue or weakness, and mid-epigastric or back pain.

The most common presenting symptom is abdominal (mid-epigastric) pain (present in about 80% of patients), often unrelenting and/or during the night. The pain may be worse when the patient is lying flat. Some patients may experience increased discomfort after eating. Radiation of the pain to the back may occur due to retroperitoneal invasion of the splanchnic nerve plexus by the tumor. All patients experience pain at some point during the clinical course of the disease.

Significant unexplained weight loss occurs in about 60%–65% of patients as a result of cancer-associated anorexia and/or subclinical fat malabsorption due to pancreatic exocrine insufficiency caused by pancreatic duct obstruction by the tumor. Patients with malabsorption usually complain about diarrhea and malodorous, greasy stools. Nausea and early satiety may also occur and contribute to weight loss.

Diabetes mellitus is present in almost three quarters of pancreatic cancer patients and a new-onset diabetes may be the first PDAC symptom. Therefore, pancreatic cancer should be considered in patients with a sudden-onset diabetes, in particular if it occurs at older age and/or has uncommon manifestations, such as abdominal symptoms and continuous weight loss.

Depression which is disproportionate to the severity of the disease occurs in almost half of the patients and may be the most prominent presenting symptom. Sleeping problems may also occur.

The most characteristic sign of carcinoma of the pancreatic head is painless obstructive jaundice. Patients usually notice a darkening of their urine and lightening of their stools before noting the change in skin pigmentation. Pruritus may accompany or (often) precede clinical obstructive jaundice, and actually be the patient's most distressing symptom. Patients presenting with clinical jaundice may also have a palpable gallbladder at physical examination as well as skin excoriations from unrelenting pruritus.

Other, less common, signs and symptoms include xerostomia, dyspepsia, hoarseness, taste change, bloating or belching, hiccup, dysphagia as well as dyspnea, dizziness, or edema. Occasionally, patients may present with migratory thrombophlebitis or venous thrombosis, acute pancreatitis, hypoglycemia, and/or hypercalcemia. Marantic endocarditis may also develop in pancreatic cancer, occasionally being confused with subacute bacterial endocarditis.

In general, tumors of the pancreas body and tail cause symptoms later in the tumor development than those of the pancreatic head.

Workup and Diagnosis

The initial workup and staging of the disease are based on imaging techniques, and the definitive diagnosis is made upon a pathologic evaluation of a tissue sample. Noteworthy, tissue-based confirmation of pancreatic cancer diagnosis before surgery is not necessarily required. As surgery remains the only cure for PDAC, the priority is to resect all resectable disease rather than delay surgical procedures waiting for definitive diagnosis, and high-quality multiphase imaging can be sufficient to distinguish between patients eligible for a curative tumor resection and those with unresectable tumors. There is much debate on sensitivity and specificity of different imaging modalities for the diagnosis and staging of PDAC. No single modality is considered sufficiently sensitive and accurate to be used on its own during the initial workup. However, a combination of different imaging techniques performed and evaluated by experienced clinicians may achieve the accuracy exceeding 95%.

The mainstay of initial diagnostic modalities in case of a suspected pancreatic cancer or evidence of a dilated duct (stricture) is computed tomography (CT) scanning of the abdomen. The expert panel of the US National Comprehensive Cancer Network (NCCN) recommends multidetector CT (MDCT) angiography performed by acquiring thin (preferably submillimeter) axial sections using a dual-phase pancreatic protocol, with images obtained in the pancreatic and portal venous phase of contrast enhancement. The scan coverage may be extended to cover the chest and pelvis for complete staging. In up to 92% of patients, pancreatic adenocarcinomas appear as hypodense masses on CT scans. Early findings include abrupt cut-off and dilatation of the pancreatic duct. Dilatation of both biliary and pancreatic ducts indicates a cancer arising in the head of the pancreas where up to 70% of PDACs originate. Multiplanar reconstruction allows to precisely visualize the relationship of the primary tumor to the mesenteric vasculature and predict involvement of the superior mesenteric artery as well as to detect subcentimeter metastatic deposits. However, CT sensitivity for small hepatic and peritoneal metastases is limited. Moreover, small pancreatic tumors (below 2 cm) can be missed even with the most advanced CT-scanning techniques.

Endoscopic ultrasonography (EUS) may be complementary to CT, providing additional staging information in particular in patients with no lesions visible on initial scans and/or when vascular or lymph node involvement is questionable. Because of the proximity of the pancreas to the EUS transducer, high-frequency ultrasounds can be used to produce very high-resolution (submillimeter) images and detect pancreatic tumors smaller than 2 cm. An additional diagnostic advantage of EUS is the possibility to guide fine-needle aspiration (FNA), which allows for simultaneous cytological confirmation of PDAC diagnosis. However, introducing newer CT scanning techniques has significantly improved the sensitivity and specificity of abdominal CT-scan findings in patients with suspected pancreatic carcinoma and, in patients with visible lesions, also CT can be used to direct FNA. Expert opinions so as to which of these two techniques is superior in the initial workup of suspected PDAC vary and many guidelines actually consider them complementary. Overall, EUS appears to be equivalent to dual-phase spiral CT scanning for assessing tumor resectability. It is probably superior to CT scanning as a means of assessing the T stage of the tumor, especially when the clinician is looking for portal vein involvement in pancreatic head lesions, but it is probably inferior to CT scanning in assessing arterial involvement and distant metastases. Both EUS and CT scanning are poor at detecting occult nodal involvement.

Positron emission tomography (PET) combined with CT may be considered in selected high-risk patients following a CT scan. However, PET/CT does not substitute for high-quality contrast-enhanced CT.

Pancreas protocol magnetic resonance imaging (MRI) may have added value in the initial diagnostic workup and staging of PDAC, in particular when suspected pancreatic lesions are not visible on CT scans or if the patient is allergic to the contrast medium. It may also help characterize indeterminate liver lesions.

Endoscopic retrograde cholangiopancreatography (ERCP), which combines endoscopic and fluoroscopic procedures, is highly sensitive in detecting pancreatic and/or biliary ductal abnormalities. However, the findings are not specific to pancreatic cancer (it is particularly difficult to differentiate them from changes observed in patients with chronic pancreatitis). Moreover, ERCP is more invasive than the other available diagnostic imaging modalities and so associated with a higher risk of complications. Therefore, it is mostly used for specific therapeutic interventions, especially to relieve biliary obstruction by placing a stent. This may also be achieved using magnetic resonance cholangiopancreatography (MRCP) which is considered equivalent to ERCP in terms of sensitivity. Both modalities allow to obtain brushings for diagnostic cytological evaluation.

Laparoscopy can detect extrapancreatic involvement in approximately 40% of patients without visible lesions on CT. NCCN panel recommends considering laparoscopy for patients with resectable pancreatic cancer who are at increased risk for disseminated disease.

Laboratory findings in PDAC patients are usually nonspecific. They may include a mild normochromic anemia and thrombocytosis, as well as findings related to obstructive jaundice (elevated bilirubin, alkaline phosphatase, gamma-glutamyl transpeptidase, and—to a lesser extent—aspartate aminotransferase and alanine aminotransferase). Serum amylase and/or lipase levels are elevated in less than half of the patients with resectable pancreatic cancers and in only one quarter of those with unresectable tumors. However, about 5% of patients initially present with acute pancreatitis, in which case amylase and lipase would be

uniformly elevated. Liver metastases may result in relatively low-grade elevations of serum alkaline phosphatase and transaminase levels. Patients with advanced disease and weight loss may also have general laboratory evidence of malnutrition (e.g., low serum albumin or cholesterol levels).

No reliable and specific blood (serum) biomarker for PDAC screening and/or diagnosis has so far been identified. The most established of the existing biomarkers is cancer antigen 19-9 (CA 19-9), a sialylated oligosaccharide Lewis A blood antigen commonly found on circulating mucins in cancer patients. CA 19-9 levels are often increased in PDAC patients. However, this antigen is commonly expressed and shed in various pancreatic and hepatobiliary diseases as well as in many different malignancies, and so it is not specific to PDAC diagnosis. Moreover, up to 10% of PDAC patients do not produce this antigen because they lack the necessary enzyme. Still, in most patients, preoperative CA 19-9 levels correlate with the tumor stage and resectability, making it a useful prognostic marker. Moreover, variations in CA 19-9 levels may be of some diagnostic value helping to differentiate PDAC from pancreatitis. However, CA 19-9 is not an independent diagnostic PDAC marker.

Since a pathologic confirmation of PDAC diagnosis is not required before surgery, in patients with resectable tumors, the pathologic evaluation is made on surgical specimens. In patients who are not candidates for surgery, EUS- or CT-guided FNA biopsies are obtained. EUS-guided procedure is safer than CT-guided percutaneous approach because it limits the risk of internal bleeding and infections, and—more importantly—that of peritoneal seeding from the tumor. The NCCN panel recommends EUS-guided FNA as the preferred technique to obtain biopsy material in nonsurgical patients with a suspicion of PDAC. If performing neither EUS-, nor CT-guided FNA is possible, biopsy specimens can be obtained via endoscopic cholangioscopy (intraductal biopsies) or laparoscopy. Pancreatic ductal brushings or biopsies obtained at ERCP also often reveal cytological findings consistent with PDAC diagnosis. One negative biopsy does not exclude PDAC diagnosis and at least one repeat biopsy should be performed. It must be emphasized again, however, that the absence of histologically confirmed diagnosis (negative biopsy) should not delay surgery in patients with resectable disease in whom the clinical suspicion of a pancreatic malignancy is high.

Management and Therapy

The management of PDAC remains a considerable clinical challenge. This cancer type has a particularly bad prognosis and the existing therapeutic modalities, except for complete negative-margin surgical resection of localized tumors, provide only limited clinical benefits. The reported overall 5-year survival rates for treated PDAC patients range from 5% to 25%, while the life expectancy of untreated PDAC patients is no more than several months.

The fist-choice treatment of PDAC is surgery and surgical resection of the tumor remains the only potentially curative procedure. As patients usually present with advanced disease, defining resectability criteria is crucial to guide management decisions. These criteria may differ between centers. In general, extrapancreatic disease precludes surgery with a curative intent, while obtaining negative surgical margins is the most significant positive prognostic factor in patients with nonmetastatic disease. The NCCN panel recommends that patients be selected for surgery based on the probability of cure defined as the probability of obtaining negative resection margins ("R0 resection") as the only criterion, emphasizing that assessing this probability should involve a multidisciplinary expert team at a high-volume center with extensive expertise in managing PDAC.

Management of Resectable Disease

Curative resection options include pancreaticoduodenectomy, distal pancreatectomy, and total pancreatectomy.

Pancreaticoduodenectomy (Whipple procedure) involves removal of the pancreatic head, duodenum, gallbladder, and the antrum of the stomach, with surgical drainage of the distal pancreatic duct and biliary system, usually through an anastomosis to the jejunum. This procedure is most likely to be beneficial to patients who have a tumor located in the head of the pancreas or in the periampullary region. A pylorus-sparing variant of the standard Whipple procedure may also be used as an alternative to classic pancreaticoduodenectomy with antrectomy. Portal vein resection, even though practiced in some centers, as well as the extent of lymphadenectomy, remain controversial.

Distal (left-sided) pancreatectomy involves isolation and resection of the distal portion of the pancreas containing the tumor, with oversewing of the distal pancreatic duct. Preservation of the spleen is not recommended. This procedure may be effective for tumors located in the body and tail of the pancreas. However, as tumors at these locations give later symptoms, patients with these tumors have higher unresectability rates. Distal pancreatectomy may also be performed with a laparoscopic approach which gains increasing popularity over an open surgery approach due to lower complication rates.

Total pancreatectomy may be an option when the tumor involves the neck of the pancreas. However, this procedure is associated with the highest mortality rate and the most severe comorbidities (like exocrine insufficiency and diabetes mellitus), and is therefore the least commonly performed.

Preoperative biliary drainage may be considered before any of these procedures in order to alleviate symptoms of pruritus and cholangitis, and potentially decrease the probability of surgery-related morbidities by improving liver function. Biliary decompression is necessary in patients with jaundice who receive neoadjuvant induction therapy prior to pancreatic resection.

Postsurgical surveillance includes regular physical examinations (symptom assessment) and CT scans as well as serial measurements of serum CA 19-9 levels. Increasing CA 19-9 levels indicate disease progression or recurrence. However, some patients progress without an increase in this marker levels.

Postsurgical recurrence rates are generally high, even after R0 resection (complete tumor resection, with clear margins), with some patients relapsing as early as a few weeks after surgery. Therefore, all patients receive adjuvant therapy following surgery. Chemotherapy with gemcitabine is a widely accepted standard in this setting, either as monotherapy or with capecitabine. Another option is 5-fluorouracil (5-FU) with leucovirin. NCCN guidelines list all these options as equivalent in view of the current knowledge (**Table 1**). The usefulness of adjuvant FOLFIRINOX (leucovorin/5-FU/irinotecan/oxaliplatin) is currently being tested in clinical trials. Chemoradiation may also be administered in the adjuvant setting, either after or before chemotherapy. Chemotherapy with S-1, an oral antimetabolite manufactured by Taiho Pharmaceuticals, is used for postsurgical adjuvant therapy in some Asian countries but as of now it is not approved for treatment of PDAC in Western countries.

Management of Borderline Resectable and Nonresectable Disease

While immediate resection and postoperative adjuvant therapy is considered standard treatment for patients with resectable tumors, neoadjuvant chemotherapy may be beneficial to those with borderline resectable tumors, potentially downsizing the tumor and thus increasing the probability of a subsequent R0 resection. Neoadjuvant therapy is also sometimes used in high-risk resectable patients, however the benefits remain controversial. The most established neoadjuvant regimens include FOLFIRINOX, gemcitabine with albumin-bound paclitaxel, and gemcitabine with cisplatin (for patients with mutations in DNA repair genes, including *BRCA1* and *BRCA2*). Some studies suggest that neoadjuvant chemoradiation, followed by chemotherapy or without it, may be even more beneficial. Chemotherapy followed by stereotactic body radiation therapy (SBRT) may also be a safe and feasible neoadjuvant option. However, these remain to be validated. Of note, histological confirmation of PDAC diagnosis is necessary before administering neoadjuvant therapy in all cases.

The reported resectability rates vary between centers, yet they are consistently low. Overall, approximately 80%–95% of patients present with unresectable disease. A palliative surgery may be considered in these patients but the mainstay of the frontline treatment is chemotherapy and/or chemoradiation. In patients with metastatic or locally advanced disease and good performance status, FOLFIRINOX is currently the preferred first-line treatment. Before introduction of FOLFIRINOX, gemcitabine monotherapy had been the most widely used regimen in unresectable patients. As it has an advantage of relieving symptoms, it may be used regardless of the patient's performance status and may therefore still be the first choice for patients with metastatic disease and poor performance status. A number of gemcitabine-containing combination regimens have also been studied. Of these, only gemcitabine with albumin-bound paclitaxel and gemcitabine with erlotinib (an inhibitor of epidermal growth factor receptor) have been shown to significantly improve survival when used as frontline treatment in patients with unresectable disease. However, combining gemcitabine with some other targeted therapeutics have been shown to improve outcomes when used as maintenance therapy. Patients with mutations in DNA repair genes may benefit from a frontline combination of gemcitabine with cisplatin. Upfront SBRT may be used in patients who are not candidates for systemic treatment. Patients who maintain good performance status after the primary treatment may undergo second-line therapy. This may involve chemotherapy using a different regimen than that administered as a frontline treatment, or chemoradiation.

Different currently available PDAC treatment options and their therapeutic indications as recommended in the most recent NCCN guidelines are summarized in **Table 1**.

Other Considerations

Given poor outcomes of PDAC patients, best supportive care and palliation of symptoms are extremely important. Specific measures are needed in particular to relieve symptoms of biliary and/or gastric outlet obstruction, severe abdominal pain, thromboembolic disease, depression, and malnutrition. These may include surgical, radiotherapeutic and/or chemotherapeutic palliation. Local ablative techniques, such as radiofrequency ablation or irreversible electroporation may also be feasible options.

Prospective Vision

The detection and management of pancreatic cancer remains one of the biggest challenges of clinical oncology. While a multitude of putative or validated biomarkers combined with novel therapeutic approaches have significantly improved the outcomes of patients with many other cancer types, pancreatic cancer is usually diagnosed late and remains to be fatal in most cases. Therefore, identifying reliable early detection biomarkers as well as effective therapies is an extremely urgent need.

A large variety of candidate biomarkers for early detection of PDAC have been studied, including among others thrombospondin-2 (THBS-2), mucin-5 AC (MUC5AC), a panel of methylated gene markers to predict the grade of dysplasia in pancreatic cysts, exosome-derived DNA and RNA, genetic alterations found in cell-free DNA, and miRNA markers. Biomarkers measurable in pancreatic juice and cystic fluid seem to be the closest to large-scale validation studies. However, it becomes clear that no single biomarker will be sufficiently specific for PDAC diagnosis and that research should focus on identifying panels of molecular markers combined with modern imaging markers as a strategy for early detection of this cancer.

A search for novel therapeutic solutions for PDAC has also been the focus of extensive research. In particular, numerous potential molecular targets have been identified. Unfortunately, most of the tested targeted therapeutics, many of which have been successfully incorporated into treatment regimens for other cancer types, have failed to provide clinical benefit to PDAC patients. The

Pancreatic Cancer: Pathology and Genetics

Irene Esposito, Lena Haeberle, and Matthias Wirth, Heinrich Heine University, University Hospital, Duesseldorf, Germany

Glossary

Chromothripsis Single event in localized and confined genomic regions where up to thousands of chromosomal rearrangements occur.

Desmoplastic stroma Growth of dense connective tissue around a tumor.

Metaplasia Form of cell adaptation to an abnormal stimulus consisting of reversible transformation of a differentiated cell type into another differentiated cell type.

Precursor lesion (Usually local) change of a tissue occurring based on genetic aberrations and identifiable on a morphological level as a forerunner of a malignant tumor.

R1-resection Surgical resection with cancer cells present microscopically at the resection margin.

TNM-Classification A classification system to describe cancer stage. T: size of the primary tumor; N: involved lymph nodes; M: distant metastasis.

Introduction

Pancreatic cancers are traditionally classified according to their morphological and marker expression profile, which supposedly reflect their cell/tissue of origin. Accordingly, exocrine and endocrine cancers represent the main malignant epithelial pancreatic neoplasms. Exocrine cancers are further divided into ductal and acinar cell cancers. Pancreatic ductal adenocarcinoma (PDAC) represents the most common form of pancreatic cancer; therefore, the term pancreatic cancer is often used as synonym of PDAC in the scientific literature and in the social media as well.

Genetically engineered mouse models (GEMM) for PDAC have recently challenged the above outlined model of cancer origin, suggesting that a process of metaplasia of the acinar cell is involved in the origin of PDAC. Likewise, different cells of origin have been suggested for neuroendocrine neoplasms with different biological behavior. In addition, evidence coming from studies based on large-scale genomic and transcriptomic analyses has dramatically affected standard histology-based tumor classifications and is most likely going to affect pancreatic cancer classification as well.

In this article, the main morphological and genetic characteristics of pancreatic cancers are reviewed focusing on exocrine neoplasms; special attention will be set on new concepts concerning the origin and the molecular subtyping of PDAC.

Classification of Pancreatic Cancers and Their Precursor Lesions

Pancreatic neoplasms are currently classified according to standard criteria of tissue and supposed cell of origin and of biological behavior. Accordingly, epithelial and mesenchymal as well as benign and malignant tumors of the pancreas are recognized.

A classification of pancreatic epithelial neoplasms based on the current WHO systems for tumors of the exocrine and endocrine pancreas and incorporating the recent classification of precursor lesions of PDAC is shown in **Table 1**.

Pathology of Pancreatic Cancers

Exocrine Pancreas

Pancreatic ductal adenocarcinoma

Gross morphology

PDAC is most frequently (60%–70%) localized in the head of the organ, where it often causes obstruction of the main pancreatic duct and/or of the intrapancreatic bile duct. At diagnosis, most tumors have already grown beyond the organ's anatomical boundaries with infiltration of the peripancreatic fat tissue or of the duodenum and usually reach a size of about 3 cm (*pT2 UICC stage*). PDAC of the body and tail of the organ are usually larger and might infiltrate surrounding structures, such as the spleen, the mesocolon and the bowel wall, the stomach or the left adrenal gland. Tumors < 2 cm are rare and mostly associated with cystic precursors, such as intraductal pancreatic mucinous neoplasms (IPMN) and mucinous cystic neoplasms (MCN) (see below). Finally, an origin of PDAC in ectopic pancreatic tissue, for example in the stomach or in the small bowel, has been rarely reported. Grossly, PDAC appears as a mostly solid, whitish mass with firm consistency and irregular contours (**Fig. 1**A). Cystic changes as well as necrosis and hemorrhage rarely occur. The surrounding tissue often shows obstructive changes with fibrosis and acinar cell atrophy.

Table 1 Classification of epithelial pancreatic neoplasms

Exocrine neoplasms		
	Entity	*Subtype*
Benign	Acinar cell cystadenoma	
	Serous cystadenoma	
	Pyloric gland adenoma	
Premalignant	Pancreatic intraepithelial neoplasia, grade 3 (PanIN-3)	
	Intraductal papillary mucinous neoplasm	With low-grade dysplasia
		With high-grade dysplasia
	Intraductal tubulopapillary neoplasm	
	Mucinous cystic neoplasm	With low-grade dysplasia
		With high-grade dysplasia
Malignant	Acinar cell carcinoma	
	Acinar cell cystadenocarcinoma	
	Ductal adenocarcinoma	Adenosquamous carcinoma
		Colloid carcinoma
		Hepatoid carcinoma
		Medullary carcinoma
		Signet ring cell carcinoma
		Undifferentiated carcinoma
		Undifferentiated carcinoma with osteoclast-like giant cells
	Intraductal papillary mucinous neoplasm with associated invasive carcinoma	
	Intraductal tubulo-papillary neoplasm with associated invasive carcinoma	
	Mixed acinar/ductal/neuroendocrine carcinoma	
	Pancreatoblastoma	
	Serous cystadenocarcioma	
	Solid-pseudopapillary neoplasms	
Neuroendocrine neoplasms	Pancreatic neuroendocrine microadenoma	
	Neuroendocrine tumor	Nonfunctional pancreatic NET
		NET G1
		NET G2
		NET G3
	Neuroendocrine carcinoma (NEC)	Small cell NEC
		Large cell NEC
	EC-cell, serotonin producing NET (carcinoid)	
	Gastrinoma	
	Glucagonoma	
	Insulinoma	
	Somatostatinoma	
	VIPoma	

Regional invasion—Impact on resection status

Due to its retroperitoneal localization, the absence of a true capsule and its aggressive biology, infiltration of the retroperitoneal space accompanied by perineural and lymphovascular invasion and frequently by direct infiltration or metastasis in regional lymph nodes is commonly observed. All these aspects contribute to explain the high frequency of microscopically incomplete resections (*R1-resections*) that are encountered also in high-volume centers if pancreatic resection specimens are carefully analyzed according to standardized procedures. Particularly relevant is the microscopic analysis of the circumferential resection margins (CRM), which include the dorsal, the ventral and—in cases of a pancreatic head resection- the medial surface (vascular groove, superior mesenteric artery/superior mesenteric vein margin, uncinated margin) of the organ (**Fig. 1**A). According to the distance of the tumor cells from a resection margin observed microscopically, three different situations are encountered: R1, if tumor cells are present in the margin (**Fig. 1**B); R0 narrow, if tumor cells are encountered ≤ 1 mm from the margin (**Fig. 1**C); R0 wide, if tumor cells are encountered >1 mm from a given margin. This classification has been shown to be relevant for patient survival as well.

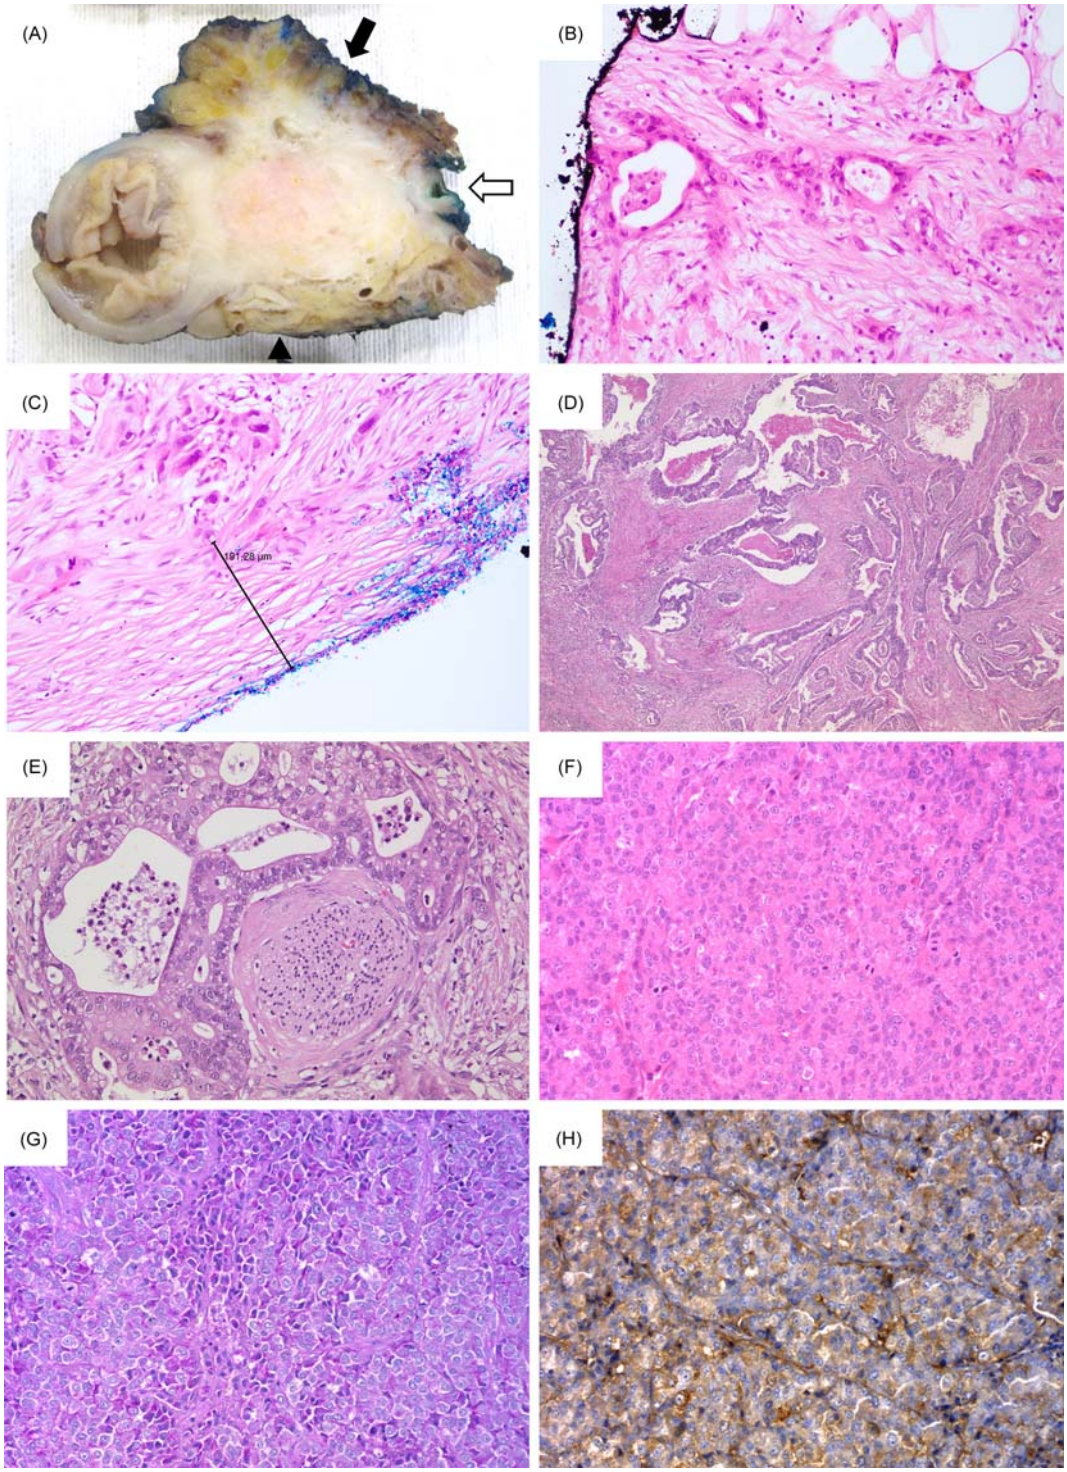

Fig. 1 *Morphology of exocrine pancreatic cancers*. (A) Gross morphology of pancreatic ductal adenocarcinoma: whitish mass with irregular contours infiltrating the duodenal wall. Margins are inked according to a defined color code. *Arrow*: ventral margin; *dotted arrow*: medial margin; *arrowhead*: dorsal margin. (B) R1-situation with tumor cells detected at the *black-inked* margin (HE, 20×). (C) R0 "narrow" situation with tumor cells within 1 mm from the margin (HE, 20×). (D) Histopathology of pancreatic ductal adenocarcinoma: neoplastic glands are surrounded by a desmoplastic stroma (HE, 4×). (E) Detail of a tumor gland infiltration a perineural space (HE, 20×). (F) Histopathology of acinar cell carcinoma displaying a typical acinar growth pattern and consisting of cylindrical cells with round nuclei and prominent nucleoli (HE, 20×). (G) PAS-positive zymogen granules in the cytoplasm of acinar cell carcinoma cells (PAS, 20×). (H) Trypsin expression in acinar cell carcinoma (20×).

Distant metastases and recurrence

Direct infiltration/metastasis of regional lymph nodes is observed in 75%–85% of the cases at diagnosis. The anterior and posterior pancreaticoduodenal nodes and the lymph nodes of the hepatoduodenal ligament are most commonly involved in cases of PDAC of the pancreatic head; lymph nodes on the upper pancreatic contour are most frequently positive in cases of PDAC of the body-tail. Depending on the number of affected lymph nodes a pN1 (1–3) or a pN2 (>3)-stage are distinguished according to the latest TNM classification (Brierley et al., 2016). This is based on studies showing a significant impact on prognosis of the number of affected lymph nodes. In addition to the presence of lymph node metastases and their number, the ratio between affected lymph nodes to the total number of retrieved lymph nodes (so-called lymph node ratio) has been shown to significantly impact on prognosis as well.

Distant metastases are commonly found in the liver (65%), lungs, and more rarely in bones or adrenals. About 50% of patients already have distant metastases at diagnosis.

Local tumor recurrences and/or distant metastases occur in the first 2 years after resection in about 70% of patients.

Histopathology

Classical PDAC consists of tubular structures reminding of pancreatic ducts and in most cases display a moderate degree of differentation (**Fig. 1**D–E). However, about half of the cases show heterogeneous differentiation with additional growth components (e.g., clear cell, micropapillary, cribriform). Well or poorly differentiated (G1 or G3) tumors are reported in 10%–30% of the cases. Tumor grading is performed according to the WHO criteria, which take into consideration the percentage of tubular structures (vs. solid areas), mucin production, nuclear abnormalities and the mitotic rate (**Table 2**). Well- and moderately differentiated PDAC display a characteristic *desmoplastic* stroma (**Fig. 1**D), consisting of whorls of connective tissue fibers with mesenchymal cells, including pancreatic stellate cells (PSC) and inflammatory cells. Histopathologic grade is a relevant prognostic factor for PDAC.

PDAC variants

Homogenous variants of PDAC, defined as a growth component making up at least 50% of the tumor mass, are found in about 10% of the patients. These include the *adenosquamous* carcinoma, characterized by solid-squamous differentiation, the *mucinous* (colloid) carcinoma, characterized by the presence of abundant extracellular mucin, the rare *signet-ring* cell carcinoma, the *large-duct* type adenocarcinoma, characterized by the presence of well-differentiated, large ductal structures, the *medullary* carcinoma, the *hepatoid* carcinoma, the *undifferentiated* (anaplastic) carcinoma and the undifferentiated carcinoma with osteoclastic-like giant cells. Some of these variants (e.g., mucinous, medullary, hepatoid) develop according to molecular pathways that differ from those of conventional PDAC (see below). An impact on survival depending on variant type has been described, with the adenosquamous and undifferentiated variants bearing the worst prognosis.

Immunohistochemistry

Usually immunohistochemistry is not necessary to make a diagnosis of PDAC. Classical PDAC express pancreatic ductal cyto keratins (CK), such as CK7, 8, 18, 19 and sometimes 20. Moreover, they show apical and cytoplasmic expression of MUC1 as well as a cytoplasmic expression of MUC4 and MUC5AC, whereas they are negative for MUC2. CEA also displays an apical and cytoplasmic pattern of expression; CA19–9 and CA125 are frequently expressed as well. Immunostains may be useful to distinguish PDAC from other primary cancers in case of metastasis and to distinguish well-differentiated tumor glands from reactive tubular structures, for example, when examining a pancreatic resection margin. Reactive tubules show no or only apical expression of CEA and MUC1; moreover, they usually do not display any stained cells when detecting proliferation-associated antigens, such as Ki-67.

Acinar cell carcinoma

Gross morphology

Acinar cell carcinoma (ACC) can occur anywhere in the pancreas and typically presents as a large, well-circumscribed, solid mass. Multinodular growth, as well as the presence of areas of necrosis and hemorrhage, have been described. A cystic variant, which may reach a very large size (>20 cm), and an intraductal variant with papillary growth have been reported.

Table 2 Grading of PDAC

Features	*G1*	*G2*	*G3*
Architecture	Tubular, middle-sized duct-like structures, papillary projections	Middle and small-sized duct-like structures, cribriform structures	Solid areas, budding, single cell infiltration
Cells	Cylindrical, retained mucin	Cubic, partial loss of mucin	Polygonal, pleomorphic, spindle Loss of mucin production
Nuclei	Slightly polymorphous	Moderately polymorphous	Very polymorphous
Mitoses	1–5/10 HPF	6–10/10 HP	>10/10 HPF

HPF = high-power field.

Adapted from Bosman, F. T., Carneiro, F., Hruban, R. H., Theise, N.D. (Eds.) (2010): WHO/IARC classification of tumours. WHO classification of tumours of the digestive system. IARC Press: Lyon.

Spread and metastases

ACC can invade adjacent structures (duodenum, spleen, large vessels) and spread to regional lymph nodes and distant sites, mostly to the liver.

Histopathology and immunohistochemistry

ACC display different growth patterns, including a classical acinar pattern, composed of acinar complexes with small lumina, a glandular pattern, composed of tubular structures with larger lumina, and a solid pattern. The tumor cells have round to oval nuclei, in some cases with a prominent central nucleolus (**Fig. 1**F). The cytoplasm is slightly eosinophilic, due to the presence of zymogen granules, which might be slightly PAS-positive (**Fig. 1**G). Immunostains for detection of pancreatic digestive enzymes (trypsin, lipase, amylase) are very useful to establish a diagnosis of ACC (**Fig. 1**H). A prominent stromal reaction is not a typical feature of ACC.

Others

Tubulo-papillary carcinomas

This is a rare form of pancreatic cancer, which has been described recently and occurs in association with an intraductal lesion known as intraductal tubulo-papillary neoplasm (ITPN), described below. Grossly, tubulo-papillary carcinomas form a solid whitish mass with pushing borders. Invasion of adjacent structures, as for example the duodenum, has been reported. Histologically, they consist of back-to-back tubules or glands as well as papillary structures without overt mucin production. Nuclear grade is usually high. Tubulo-papillary carcinomas are reminiscent of acinar cell or even neuroendocrine neoplasms, and immunohistochemistry may be useful to make the diagnosis.

Carcinomas with mixed differentiation

Carcinomas with mixed acinar-ductal, ductal-neuroendocrine, acinar-neuroendocrine and even acinar-ductal-neuroendocrine features have been reported. Each component should be detected in at least one-third of the tumor mass to warrant a diagnosis of mixed neoplasm.

Endocrine Pancreas

Neuroendocrine neoplasms (NEN) represent only 2%–5% of all pancreatic neoplasms. According to the latest WHO classification, NEN are classified into three groups: the well-differentiated neuroendocrine tumors (NET), further split into functioning and nonfunctioning tumors, the poorly-differentiated neuroendocrine carcinomas (NEC) and the mixed neuroendocrine-non-neuroendocrine neoplasms (MiNEN) (**Table 1**). These subtypes are distinguished on the basis of their growth pattern and proliferative activity, assessed by mitotic count or preferably by the Ki-67 index. The different morphology and biological behavior of PanNET and PanNEC argue against a direct evolutionary connection between these two entities and suggest that they might arise in different cells of origin. Conceivably, PanNET may originate in already differentiated neuroendocrine cells, which are capable of hormone synthesis and release and closely resemble normal neurendocrine cells of the islets of Langerhans. On the other hand, PanNEC, which have a less differentiated appearance and marker profile may originate from stem cells that are neuroendocrine committed, but not yet differentiated. The different key genetic events involved in these two entities support this concept.

PanNET

Nonfunctioning pancreatic NET (about 40%) most often (about two-thirds of cases) occur in the head of the pancreas and range in size 2–5 cm. PanNET smaller than 0.5 cm are called microadenomas; they are biologically benign and, if multiple, are often associated with Multiple Endocrine Neoplasia (MEN) type 1. PanNET are usually well-demarcated yellowish masses of soft consistency; a capsule may be present. Multinodular growth and a prominent stromal component may occur. Necrosis and hemorrhage are rare; a cystic variant has been described. Malignant PanNET may infiltrate adjacent organs and metastasize to regional lymph nodes. Distant metastases occur late and may affect different organs, such as liver, lung and bone. Histologically, several growth patterns (trabecular, nesting, gyriform, glandular, solid) are seen (**Fig. 2**A). The cells are monotonous and often display granular cytoplasm and granular chromatin, known as "salt and pepper" chromatin. Functioning PanNET, including insulinomas, glucagonomas, somatostatinomas, gastrinomas, VIPomas and others may become apparent due to clinical syndromes caused by hormone hypersecretion. PanNET are classified into three groups (G1–3) according to their Ki-67 or mitotic index (**Table 3**). Stage and grade have emerged as the most potent predictive factors in most studies. After surgical resection, the prognosis of PanNET is usually better than that of PDAC.

PanNEC

Pancreatic neuroendocrine carcinomas account for 2%–3% of PanNEN and are more frequently localized in the pancreatic head. They are usually large, whitish masses with ill-defined borders and areas of necrosis and hemorrhage. In the majority of cases distant metastases are present at diagnosis. Histologically, a small cell and a large cell variant of PanNEC exist. NEC are by definition G3 with a Ki-67 index of usually $>50\%$. Survival ranges from 1 month to a year, despite occasional initial favorable response to chemotherapy.

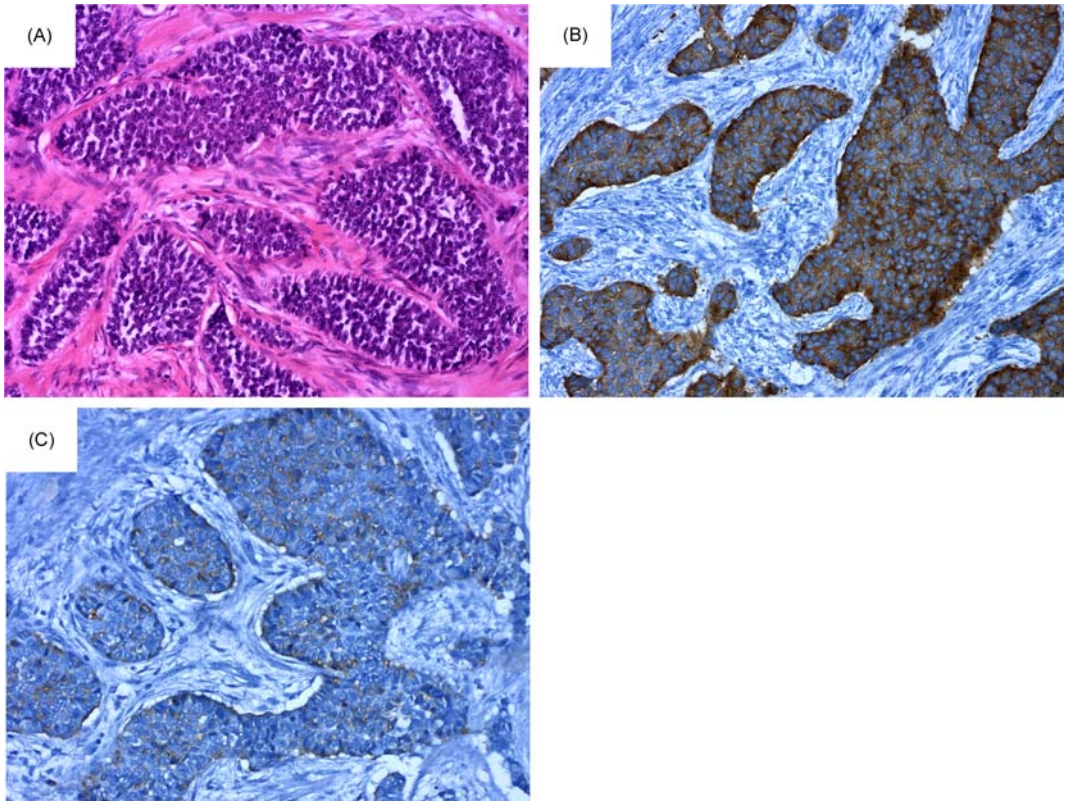

Fig. 2 *Morphology of pancreatic neuroendocrine neoplasms.* (A) Well-differentiated NET, G2, displaying an insular growth pattern and consisting of a monotonous cell population. Note the absence of nucleoli in the tumor cells (HE, 10×). (B) Immunostaining for synaptophysin (10×). (C) Immunostaining for chromogranin A (10×).

Table 3 Grading of PanNEN

	G1		*G2*		*G3*	
Entity	Ki67	Mitotic count	Ki67	Mitotic count	K67	Mitotic count
NET	<3%	0–2/10 HPF	3–20%	3–20/HPF	>20%[a]	>20/10 HPF
NEC	–		–		>20%[b]	>20/10 HPF

HPF = high power field.
[a]Usually max. 35%
[b]Usually >50%.

MiNEN

As stated above, mixed neoplasms composed of a ductal or acinar cell adenocarcinoma and a neuroendocrine neoplasm are defined by the presence of each component accounting for at least 30% of the tumors. Each component is graded separately.

Immunohistochemistry

Immunohistochemistry is essential for the diagnosis and further classification of PanNEN. Immunostains for chromogranin A and synaptophysin (Fig. 2B–C) define the neuroendocrine subtype; Ki-67 establishes the grade. Expression of chromogranin A is usually lost in NEC. Immunohistochemistry using antibodies specific for the different hormones assists in subtyping PanNET. The use of an epithelial marker (cytokeratin) is necessary to distinguish PanNET from other pancreatic tumors with similar morphology and at least partial synaptophysin expression (solid-pseudopapillary neoplasms, paragangliomas) and is very useful in poorly differentiated neoplasms. Immunostains are essential for the diagnosis of MiNEN as well. The transcription factor islet-1 can be used in the differential diagnosis of metastatic NEN, but it cannot usually be detected in PanNEC. PanNET usually expresses somatostatin receptors (SSTR2A and SSTR5), whereas this expression is lost in NEC.

Genetics of Pancreatic Cancers

Genetics of PDAC

During recent years, next generation sequencing (NGS), which enables large-scale whole-genome analysis, has become a standard tool also in pancreatic cancer research. Multiple genetic aberrations that occur during the development and progression of PDAC have been found in various whole genome screens. In 2008, one of the first global genomic screens in pancreatic cancer revealed an average of 63 genetic alterations (mostly point mutations), which result in an activation of multiple core pathways (e.g., KRAS-, TGF-β-, Wnt-signaling). However, alterations in four genes are found in most cases of PDAC: *KRAS*, *CDKN2A*, *TP53* and *SMAD4* (Table 4).

KRAS is part of the canonical RAS family (KRAS, NRAS and HRAS), which consists of small GTPases switching from an active state (GTP-bound) to an inactive state (GDP-bound) via guanine nucleotide exchange factors (GDP -> GTP exchange) and GTPase-activating proteins (GTP-hydrolysis). In PDAC, the frequency of *KRAS* mutation is about 95%, whereas *NRAS* and *HRAS* mutations are almost nonexistent. Most common *KRAS* mutations are located at codon 12 of exon 2 (e.g., $KRAS^{G12D}$, $KRAS^{G12V}$, $KRAS^{G12R}$) and result in constitutive activation of the protein. Via multiple signal transduction cascades, persistently active KRAS promotes activation of transcriptional programs (e.g., proliferation, metabolism, immune evasion, migration), which facilitate cancer development and progression. Evolution of PDAC may occur via gradual disease progression with stepwise accumulation of additional mutations of *CDKN2A*, *TP53* and *SMAD4* or by a sudden event via genomic instability/chromothripsis. CDKN2A/p16INK4 negatively regulates proliferation of normal cells through interaction with the cyclin dependent kinases CDK4 and CDK6. Epigenetic silencing or loss of *CDKN2A* is found in most PDAC patients. The "guardian of the genome" *TP53* initiates death of DNA damaged cells before they become cancerous. Loss of the tumor suppressor *SMAD4/DPC4* (deleted in pancreatic cancer, locus 4) results in disruption of TGF-β signaling, which generally suppresses growth of epithelial cells.

Molecular Subtyping of PDAC

In recent years, single marker-based subtyping of PDAC has been replaced by large scale genomic- and transcriptomic data-based studies and is now widely accepted for pancreatic cancer stratification. Four main molecular subtypes have been described, based on gene expression profiles or on the distribution of structural chromosomal rearrangements. One of the first studies in 2011 by Collisson et al., performed on microdissected specimens and human and murine cell lines, described three subtypes of pancreatic cancer: the classical, the quasi-mesenchymal and the exocrine-like subtype. This classification was based on differences in subtype-specific gene expression profiles. The classical subtype was characterized by the expression of adhesion-associated and epithelial genes; the quasi-mesenchymal subtypes was characterized by mesenchyme-associated genes, whereas digestive enzyme genes were strongly expressed in the exocrine-like subtype. Recently, Bailey et al. identified four subtypes of PDAC using whole exome sequencing and copy number variation (CNV) analysis. They identified a squamous subtype similar to the quasi-mesenchymal subtype of Collisson et al., and an aberrantly differentiated endocrine exocrine (ADEX) subtype, which recapitulates characteristics of the exocrine subtype of Collisson et al. In addition, Bailey et al. identified a pancreatic progenitor and an immunogenic subtype of PDAC. Genes like *PDX1*, which are involved in early pancreatic development, were characteristic for pancreatic progenitor PDAC subtype. In the immunogenic subtype, immune networks, such as acquired immune suppression pathways were found to be upregulated. Besides transcriptome profiling and gene set expression analysis, subtyping of PDAC has been performed also based only on copy number variations. Using this approach, Waddel et al. identified four subtypes of PDAC: stable (≤ 50 structural variation events), locally rearranged, scattered and unstable (>200 structural variation events). Inactivation of DNA maintenance genes (e.g., *BRCA1*, *BRCA2*, *PALB2*) and a high grade of genomic instability with defects in DNA damage repair were observed in the unstable subtype. Evaluation of these subtypes revealed possible targets for new therapeutic interventions. As an example, the unstable subtype described by Waddel et al. may be sensitive to DNA damaging agents such as PARP-inhibitors. For the classical and

Table 4 Top 10 mutated genes in PDAC

COSMIC (n = *5408*)		Bailey et al. (2016) (n = *384*)		*TCGA* (n = *150*)	
Gene ID	*(%)*	*Gene ID*	*(%)*	*Gene ID*	*(%)*
KRAS	70.0	*KRAS*	89.8	*KRAS*	90.7
TP53	44.0	*TP53*	66.1	*TP53*	69.3
SMAD4	15.0	*SMAD4*	22.5	*SMAD4*	24.7
CDKN2A	13.0	*CDKN2A*	18.5	*CDKN2A*	14.7

TGFBR2	3.0	*FLG*	5.0	*FAT3*	6.0

the quasi-mesenchymal subtype of PDAC, patients drug resistance markers, such as cytochrome P450 3A5 (CYP3A5), may be predictive for therapeutic efficacy.

Genetics of Special PDAC Subtypes

Hepatoid carcinoma

Hepatoid carcinoma is a rare subtype of PDAC, which is not associated with *KRAS* mutation. Amplicon sequencing of 600 cancer associated genes revealed mutations in *NOTCH1* and *BAP1*, a BRCA1-associated protein involved in DNA damage repair. In a pancreatic insertional mutagenesis screen in mice, based on a conditional *piggyBac* transposition system (*Pdx1-Cre; LSL-Kras^{G12D}; Rosa26^{LSL-PB}; ATP1*), the hepatoid variant of PDAC was significantly associated with *FIGN* insertions, which lead to its overexpression. *FIGN* insertions were observed in 11 of 15 hepatoid and 3 of 34 nonhepatoid tumors. Fign is part of the superfamily of AAA-ATPases, which are involved in various cellular processes, such as vesicle-mediated transport, microtubule regulation and proteasome function. These findings may help to identify this rare subtype of PDAC.

Medullary carcinoma

Medullary carcinoma has a low prevalence of somatic mutations. Most often observed aberrations are microsatellite instability and a loss of the expression of one of the DNA mismatch repair proteins, Mlh1 and Msh2. Alterations of the *KRAS* gene have been found in 31% of the analyzed cases. In principle, patients with medullary carcinoma are more likely to have a family history of cancer with deficiencies of DNA repair.

Hereditary Pancreatic Cancer

Through unbiased whole-exome sequencing of familial pancreatic cancer (FPC) patients ($n = 96$), *BRCA2* was found to be the most commonly and its binding partner *PALB2* the second most commonly mutated gene in hereditary pancreatic cancer. In addition to *BRCA2* and *PALB2*, both involved in double-strand break repair and homologous recombination, *ATM* gene mutations predispose some families to pancreatic cancer. ATM (serine/threonine kinase ataxia telangiectasia mutated) coordinates DNA double-strand break repair and is associated with an increased risk of cancer, particularly lymphoma and leukemia. Other known predisposition genes, such as *CDKN2A*, *TP53*, *STK11*, *MLH1*, *MSH2*, *MSH6 and PMS2* are also involved in DNA double strand or DNA mismatch repair.

Genetics of Other Cancers of the Exocrine Pancreas

Acinar cell carcinoma (ACC)

The most common gene alteration in ACC is found in the *APC* gene. *APC* is one of the most frequently mutated genes in colorectal cancer. By promoting degradation of the Wnt-key component β-catenin, APC negatively regulates the Wnt-signaling pathway. The most frequent alterations are gene loss (48%) or gene/promoter hyper-methylation (56%) while *APC* mutations are relatively uncommon (7%). In about 23% of ACC, rearrangements of *BRAF* and *RAF1* have been described, with, *SND1-BRAF* as most prevalent fusion, which results in activation of the MAPK pathway. Although contradictory results have been published, recent sequencing analysis revealed in 13% of 44 patients a mutation in the *TP53* gene. Whereas mutations of *KRAS*, *CDKN2A* are almost not present in this rare tumor type, *SMAD4/DPC4* mutations are found in ACC cases. In a recent study, whole exome sequencing of 73 ACC and 34 normal pancreatic tissue samples revealed that the four tumor suppressor genes *ID3*, *ARID1A*, *APC*, and *CDKN2A* are altered or downregulated in the vast majority of the analyzed ACC specimens. Alterations of the genes *CDKN2A*, *APC* and *ID3* are involved in cell cycle progression, for instance by interference with CDK4/6. Also, mutational signatures associated with defective DNA repair have been identified.

Pathology and Genetics of PDAC Precursors

Pancreatic Intraepithelial Neoplasms (PanIN)

Pancreatic intraepithelial neoplasms (PanIN), microscopic (<0.5 cm) ductal lesions, are probably the best-known precursors of PDAC. Natural history and step-wise progression to invasive carcinoma of PanIN, as well as underlying molecular alterations, have been studied extensively in transgenic mouse models. Like PDAC, PanIN lesions are more often located in the head than in the body-tail of the organ. While they are common findings in pancreas resection specimens both with and without invasive PDAC, the frequency of PanIN in the normal pancreas is lower than that in pancreas specimens with chronic pancreatitis and PDAC (16% vs. 60% vs. 82%, respectively). For high-grade PanIN, these numbers are 0%, 4% and 40%. PanIN lesions are especially common in patients with a strong family history of PDAC and then are often multifocal.

PanIN are characterized by a flat mucinous columnar or cuboidal epithelium in the earliest stage, but display an increasingly papillary architecture during the progression from low-grade to high-grade dysplasia (Fig. 3A–B). A two-tiered system in low- and high-grade PanIN (Table 1) has recently replaced the traditional three-tiered classification (PanIN 1–3). This new classification system is more in line with the clinical consequences: while the significance of PanIN with low-grade dysplasia for the development

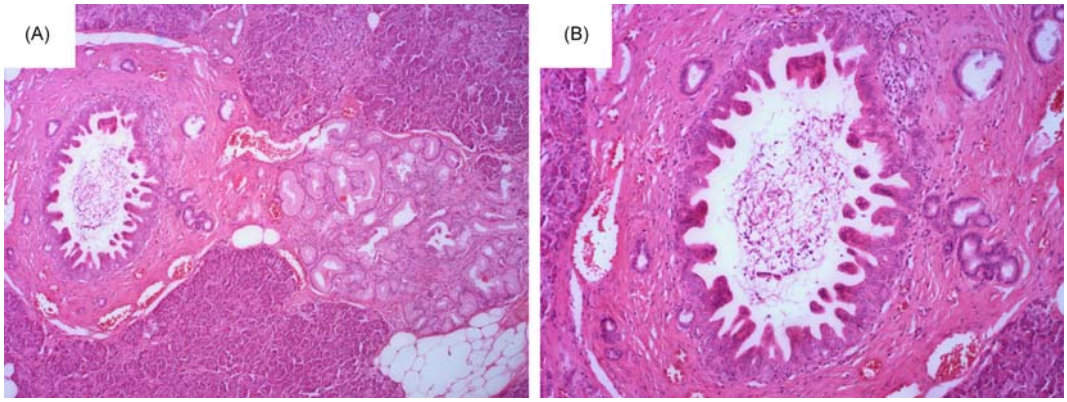

Fig. 3 *Morphology of PanIN.* (A) PanIN. Low (right) and high-grade (left) PanIN (HE, 10×). (B) Detail of high-grade PanIN with micropapillary architecture and nuclear atypia (HE 20×).

of PDAC is still controversial, PanIN with high-grade dysplasia is a direct precursor of PDAC and therefore warrants resection. Immunohistochemically, MUC5A is regularly expressed in both low-grade and high-grade PanIN lesions, while MUC1 is usually only expressed in high-grade PanIN.

A single *KRAS* mutation ($KRAS^{G12D}$) is sufficient for the development of PDAC via a precursor lesion in genetically engineered mice, which provides an argument in favor of the notion that mutant *KRAS* alone is sufficient to drive PDAC also in humans. Indeed, in more than 84% of microdissected human low-grade PanIN lesions, only a *KRAS*- mutation was identified. Sequencing data of 66 PanIN lesions in the COSMIC (catalogue of somatic mutations in cancer) database showed *KRAS* as the most frequently mutated gene, with most cases bearing only a *KRAS* mutation. In addition to *KRAS* mutations, alterations in *CDKN2A*, *GNAS* and *BRAF* have been observed in low grade PanIN. Alterations of *TP53* or *Smad4* are extremely rare in PanIN.

Intraductal Papillary Mucinous Neoplasm (IPMN)

Intraductal papillary mucinous neoplasms (IPMN) comprise a heterogeneous group of mucin-producing epithelial tumors with papillary architecture in the pancreatic duct system, which lead to cystic dilation of the involved duct segments (Fig. 4A). IPMN are most commonly located in the pancreatic head and are macroscopic lesions, by definition with a diameter of at least 1 cm. According to their site of origin, IPMN are distinguished in main duct-type IPMN, branch duct-type IPMN and combined-type (or mixed-type) IPMN.

In addition to these macroscopic subtypes, IPMN are classified by histomorphology and immunohistochemistry into four distinct histologic subtypes: gastric-type IPMN, intestinal-type IPMN, oncocytic-type IPMN and pancreatobiliary-type IPMN (Table 5). Main duct-type IPMN are usually intestinal-type or, less frequently, oncocytic-, pancreatobiliary- or gastric-type IPMN, while branch-duct type IPMN are most commonly gastric-type.

Gastric-type IPMN mimic gastric foveolar epithelium: they form short, wide papillae, which consist of columnar epithelial cells containing large amounts of mucin (Fig. 4B–D). By immunohistochemistry, gastric-type IPMN are characterized by expression of MUC5A; but not of MUC2 and MUC1 (Fig. 4C). Gastric-type IPMN have a similar, if not identical, phenotype as PanIN lesions, which complicates the differentiation between small gastric-type IPMN and large PanIN for lesions ranging between 0.5 and 1 cm. These lesions are reported descriptively, although the term "incipient IPMN" is used if molecular or morphologic features typical of IPMN but absent in PanIN are present, (e.g., *GNAS* mutation or villous, pancreatobiliary or oncocytic differentiation of the epithelium).

In contrast, intestinal-type IPMN are characterized by the formation of papillae similar to those of villous adenoma of the colon. The columnar epithelial cells have elongated basal nuclei and apical mucin and form villous structures protruding into the duct lumen (Fig. 4E). Intestinal-type IPMN express MUC5A, MUC2 and CDX2 (Fig. 4F–G), but show no expression of MUC1.

The papillae of pancreatobiliary-type IPMN are complex branch-like structures, consisting of cuboid cells with round nuclei, often displaying prominent nucleoli, and with considerably less mucin than gastric-type or intestinal-type IPMN epithelium (Fig. 4H). The pancreatobiliary-type IPMN epithelium stains positive for MUC5A and MUC1 (Fig. 4I), but is negative for MUC2 (Fig. 4G).

Oncocytic-type IPMN are similar to pancreatobiliary-type IPMN in morphology and marker profile. In analogy to pancreatobiliary-type IPMN, they consist of cuboid epithelial cells forming complex branched papillae. However, these cells show marked cytoplasmic eosinophilia and the round nuclei often have one single prominent eccentric nucleolus. Oncocytic-type IPMN focally express MUC1 and may show MUC2 expression in goblet cells as well as a diffuse expression of MUC5A and MUC6.

The degree of dysplasia in IPMN varies greatly, which calls for extensive sampling of these lesions. They are classified as IPMN with low-grade or high-grade dysplasia depending on the highest grade of dysplasia that can be found in the lesion. While all types

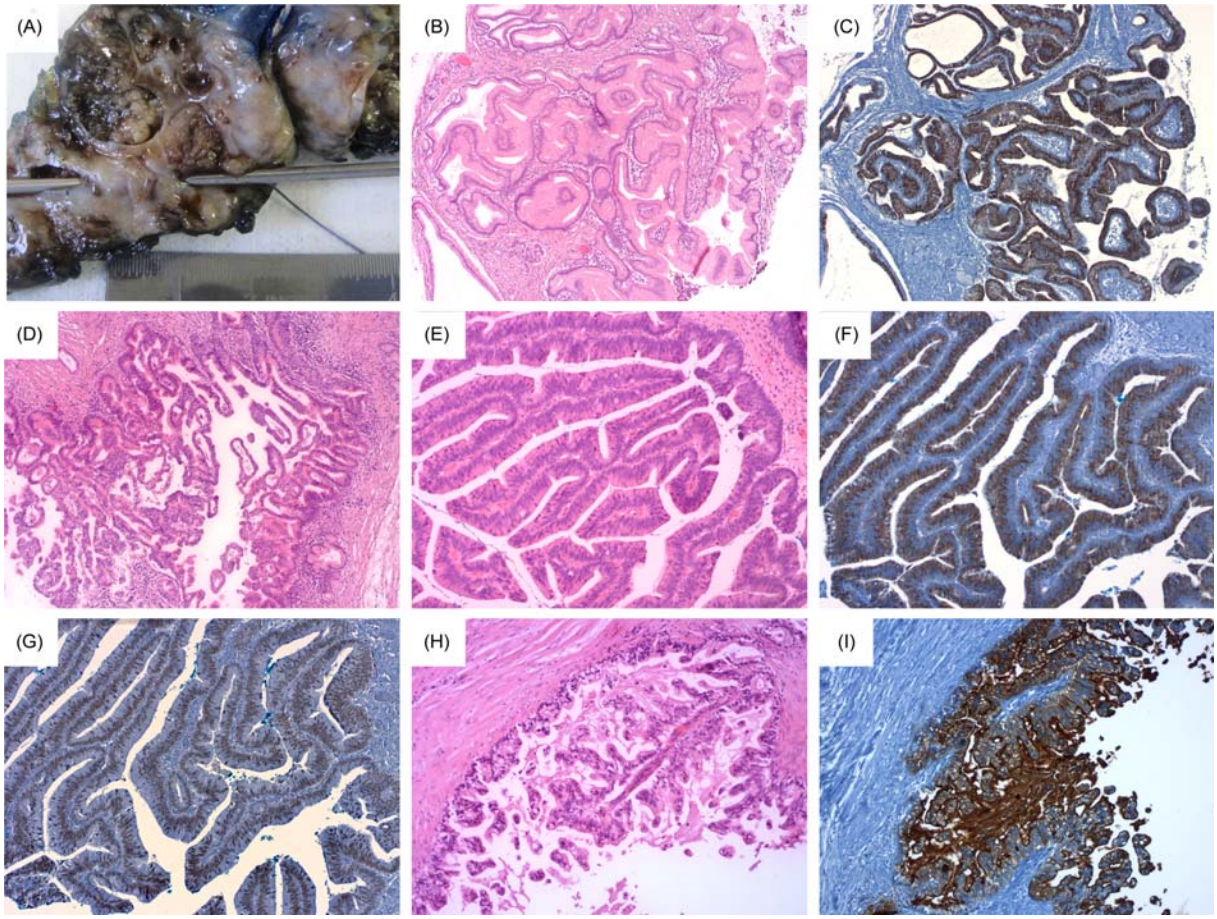

Fig. 4 *Morphology of IPMN.* (A) Gross aspect of an IPMN displaying cystic dilation of pancreatic ducts filled with papillary structures and mucus. (B) Gastric-type IPMN, low-grade, displaying a gastric-foveolar phenotype and basally located nuclei (HE, 4×). (C) MUC 5AC expression in gastric-type IPMN, low-grade (4×). (D) Gastric-type IPMN, high-grade, with irregular architecture and hyperchromatic nuclei (HE, 4×). (E) Intestinal-type IPMN, with moderate dysplasia (low-grade) with villous-like papillae (HE 10×). (F) MUC 2 expression in intestinal IPMN (10×). (G) Nuclear CDX-2 expression in intestinal IPMN (10×). (H) Pancreatobiliary IPMN, high-grade, with complex papillary and cribriform architecture (HE 10×). (I) MUC 1 expression in pancreatobiliary IPMN (10×).

Table 5 Morphology and immunohistochemical profile of intraductal neoplasms of the pancreas

Intraductal neoplasm	*Morphology*	*Dysplasia*	*MUC1*	*MUC2*	*MUC5A*	*MUC6*	*Others*
IPMN gastric	Predominantly papillary, mucinous	Low- to high-grade	−	−	+	−	−
IPMN intestinal	Predominantly papillary, mucinous	Low- to high-grade	−	+	+	−	CDX2+
IPMN pancreatobilliary	Predominantly papillary, mucinous	Low- to high-grade	+	−	+	(+)	−
IPMN oncocytic	Predominantly papillary, mucinous	Low- to high-grade	Focal	Focal (goblet cells)	+ (diffuse)	+ (diffuse)	−
ITPN	Predominantly tubular, nonmucinous	High-grade	+	−	−	+	CK7+ CK19+

of IPMN can progress to invasive PDAC, they differ both in their risk of progression and in the resulting type of carcinoma. It has been shown that gastric-type IPMN have the least malignant potential (invasive carcinoma in about 6% of cases), while oncocytic-type and intestinal-type IPMN have a moderate malignant potential (invasive carcinoma in about 25% or 34% of cases, respectively), and pancreatobiliary-type IPMN harbor the highest malignant potential with an invasive component in about 58% of cases. The subtype of the associated invasive carcinoma is dependent on the IPMN subtype. Thus, intestinal-type IPMN usually result in

colloid (mucinous) carcinomas, whereas pancreato-biliary and gastric type IPMN usually progress to classical tubular PDAC. Rare oncocytic carcinomas may arise from oncocytic IPMN.

These profound differences in morphology and immunohistochemical marker profile, together with the different molecular pathways involved into the pathogenesis of different IPMN, suggest that the four IPMN types represent different tumor entities more than a mere morphological spectrum. *GNAS* (Guanine nucleotide-binding protein G(s) subunit alpha isoforms short) mutations are found in PanIN lesions, but are more frequently present in IPMN. In approximately two thirds of IPMN cases, the hotspot mutation in codon 201 (mostly $GNAS^{R201C}$ or $GNAS^{R201H}$) has been identified. This mutation leads to constitutive activation of the *GNAS* encoded protein GS-alpha (adenylate cyclase stimulator), which induces cAMP (cyclic adenosine monophosphate) signaling to activate PKA (protein kinase A) and RAS stimulation via RAPGEF2 (Rap guanine nucleotide exchange factor 2). In pancreatic- and biliary-intraductal papillary neoplasms mutant *GNAS* and mutations in *RNF43* (ring finger protein 43), which are correlated with the downregulation of RNF43, occur together. The tumor suppressive ubiquitin E3 ligase RNF43 induces Frizzled ubiquitination, which leads to suppression of Wnt signaling. Hence, loss of RNF43 function promotes Wnt signaling, enhances cellular proliferation, and results in neoplastic transformation.

Accumulation of additional mutations in *TP53* and *SMAD4* (and *CDKN2A*), which can be found in high grade IPMNs, are responsible for progression to highly invasive carcinoma with a high metastatic propensity.

Gene alterations of the tumor suppressors *ARID1A*, *ARID1B*, *BRG1*, *PBRM1* and *SMARCA2*, which are all part of the SWI/SNF chromatin remodeling complex, have been identified as central players in PDAC. Especially loss of *BRG1* function seems to be associated with IPMN pathogenesis. A high incidence of IPMN has also been observed in patients with a somatic mutation of the *STK11* gene (responsible for Peutz-Jeghers syndrome). The Serine/threonine-protein kinase STK11 mediates *TP53* dependent cell death and controls the activity of AMPK (AMP-activated protein kinase). Certain mutations are associated with a particular IPMN subtype: *GNAS*-only mutations have a higher frequency in the intestinal type of IPMNs, whereas *KRAS*-only mutations are more frequent in the gastric and the pancreatobiliary IPMN subtypes. Of *GNAS* wild-type gastric-type IPMN, 43% were associated with PDAC, whereas in only 9% of cases with nongastric-type IPMN PDAC was found. Very rare *BRAF* mutations have been found in the oncocytic type IPMN.

Intraductal Tubular-Papillary Neoplasms (ITPN)

Similar to IPMN, intraductal tubular-papillary neoplasms (ITPN) are macroscopic (≥ 1 cm in diameter) epithelial neoplasms of the pancreatic duct system (Fig. 5A). However, in contrast to IPMN, their epithelium is not or only minimally mucin-producing, and as a result ITPN present much less commonly as a cystic lesion.

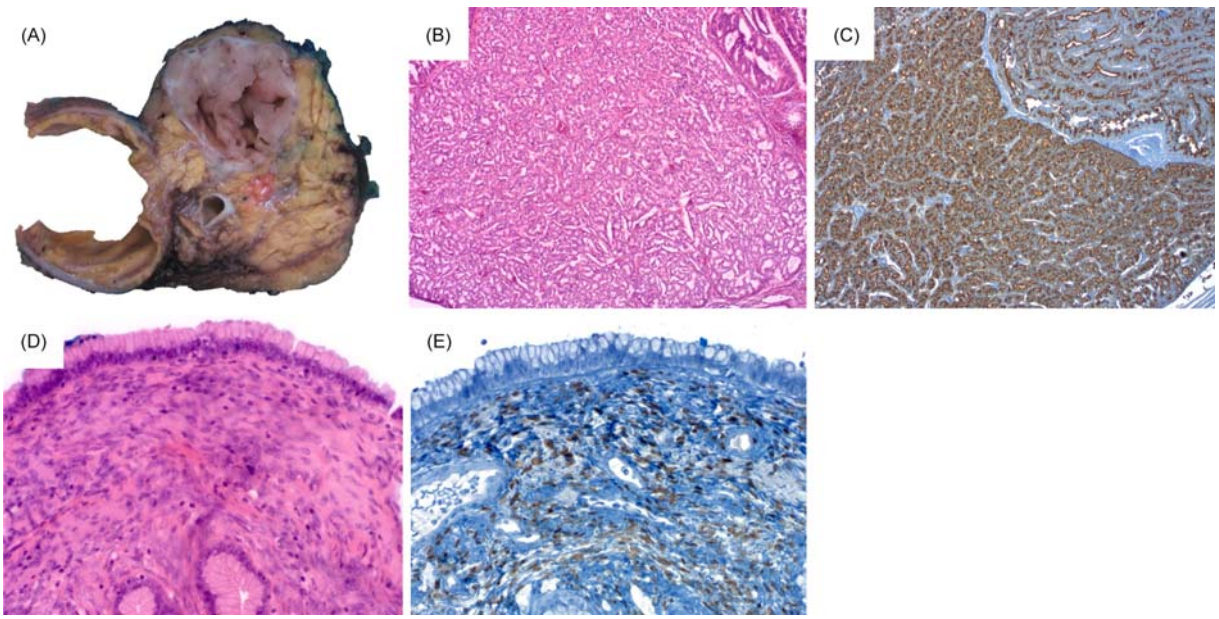

Fig. 5 Morphology ITPN and MCN. (A) Macroscopic aspect of ITPN without associated carcinoma. ITPN forms an intraductal soft, whitish and well-circumscribed mass. (B) Histology of ITPN showing back-to-back tubular structures and papillae (right) (HE, 4×). (C) Expression of MUC1 in ITPN with typical luminal pattern (4×). (D) Histopathology of MCN showing a cylindrical mucinous epithelium lying over a cellular stroma (HE, 20×). (E) Expression of the estrogen receptor in the stromal cells (20×).

Histomorphologically, the growth pattern of ITPN is predominantly tubular, although papillary components are also present. They form densely packed tubules, which can display a cribriform architecture and consist of cuboidal cells with round to oval nuclei, which usually show high-grade dysplasia and can contain comedo-like necrotic foci (Fig. 5B). By immunohistochemistry, ITPN express MUC1 and MUC6, similar to IPMN of the oncocytic subtype, but also show expression of CK7 and CK19 as well as absence of expression of MUC5A and MUC2 (Table 5). ITPN and IPMN are also different at the molecular level, for example, *KRAS* and *GNAS* mutations are distinctively less frequent to absent in ITPN compared to IPMN, which provides further support for the notion that ITPN and IPMN are indeed different entities.

More than half of the ITPN cases have been associated with an invasive carcinoma, larger tumor size and high Ki67 proliferation index being linked to invasiveness.

Mucinous Cystic Neoplasms (MCN)

Mucinous cystic neoplasms (MCN) are usually large uni- or multilocular thick-walled cysts, which are most often filled with mucinous fluid, but may also have a hemorrhagic or serous content. In high-grade MCN, the cysts may contain solid areas, mural nodules or papillary projections. MCN almost exclusively occur in the body or tail of the pancreas of women between 40 and 60 years, although rare cases in male patients have been reported.

The defining histomorphologic characteristics of MCN are mucinous columnar epithelium with an underlying dense *ovarian-like* stroma (Fig. 5D). The epithelial cells of MCN display various grades of dysplasia, even in one single lesion, warranting extensive sampling. Similar to the above-mentioned precursor lesions, MCN should be classified as MCN with low-grade or high-grade dysplasia according to the highest grade of dysplasia found in the lesion. As papillary epithelium may be present in MCN with high-grade dysplasia, the presence of *ovarian-like* stroma must be used to distinguish those lesions from IPMN. While the MCN epithelium expresses MUC5A and CEA, the spindle cells of the *ovarian-like* stroma express estrogen and progesterone receptors (Fig. 5E), smooth muscle markers like α-smooth muscle actin, desmin and vimentin, and can also undergo luteinization and show expression of α-inhibin, tyrosine hydroxylase and calretinin.

MCN can progress to invasive pancreatic cancer, usually invasive pancreatic adenocarcinoma of the classical (ductal) type. In a recent multicenter study, 12.6% of MCN cases were associated with invasive adenocarcinoma.

The most frequent alteration in mucinous cystic tumors is a mutation in *KRAS*. By whole-exome sequencing, mutations in the E3 ligase *RNF43* have been identified in mucinous cystic neoplasms. Hypermethylation of *CDKN2A*, which is commonly altered in PDAC, has been found in MCNs as well. *PIK3CA* mutations have been described in MCN lesions with very low frequency.

New Concepts Emerging From Genetically Engineered Mouse Models

PDAC has long been assumed to be of ductal origin due to its ductal phenotype and due to ductal differentiation of its precursor lesions. However, genetically engineered mouse models have challenged the ductal carcinogenesis model of pancreatic cancer. In these mouse models, activation of the *KRAS* oncogene induced PanIN lesions, faithfully resembling those in humans. While PanIN could be induced in adult acinar and other pancreatic cell types, they did not arise in ductal epithelial cells. Ductal epithelium therefore seems rather refractory to the induction of PanIN lesions, with the exception of early-stage PanIN-like lesions. Such findings have led to the emerging concept of pancreatic carcinogenesis through an acinar-ductal metaplasia-dysplasia sequence. According to this concept, cells of the centroacinar/acinar compartment undergo ductal metaplasia and then form PanIN, which then may progress to invasive pancreatic cancer. Newer data suggest that PDAC can even arise directly from centroacinar/acinar cells, without preceding PanIN lesions: in a $Kras^{G12D/+}$; $Ptf1a\text{-}Cre^{ex1/+}$ mouse model, atypical flat lesions (AFL) were identified as alternative precursor lesions of PDAC. Although they have a ductal phenotype, these lesions are found in the centroacinar/acinar compartment, which suggests that they are a result of acinar-ductal metaplasia. Adult acinar cells have recently been confirmed as cells of origin of AFL. Histomorphologically, AFL are small tubular lesions, which consist of flat to cuboidal cells with cytologic atypia, expressing CK19 and MUC1 by immunohistochemistry, and surrounded by reactive stroma (Fig. 6). Lesions resembling murine AFL have been reported in patients with familial pancreatic cancer, which is an umbrella term for patients with increased life-time risk for pancreatic cancer associated with various genetic syndromes. This confirms the clinical relevance of the ADM/AFL carcinogenesis model of pancreatic cancer.

Prospective Vision

Conventional morphological methods are essential for the diagnosis and classification of pancreatic cancers and deliver fundamental information for patient management. New knowledge coming from genetically engineered mouse models has revealed possible alternative pathways for pancreatic cancer development, which might be exploited for the identification of better biomarkers and, possibly, screening strategies. Additionally, high-throughput molecular methods have contributed significantly to the discovery of molecular signatures that define PDAC subtypes, which may in turn be associated with different therapeutic approaches. The next big challenge will be to integrate this large amount of information in feasible clinical, diagnostic and therapeutic algorithms for better patient care.

Papillomaviruses☆

Karl Munger, Tufts University School of Medicine, Boston, MA, United States

Glossary

Epigenetic modifications Posttranslational modifications of the DNA or DNA bound proteins, referred to as histones, that determine transcriptional competence of chromosomal loci.

Episome An extrachromosomal, autonomously replicating genetic element.

Pap-smear The Papanicolaou-smear is a procedure where cells derived from a cervical smear are microscopically evaluated for cytological abnormalities. This procedure has dramatically decreased the incidence and mortality of cervical cancer.

Posttranslational modifications In many proteins, certain amino acids are subject to modification by a number of chemical reactions including phosphorylation, acetylation, and ubiquitination. These reversible enzymatic reactions alter the biochemical and functional activities of a protein.

Papillomaviruses

Papillomaviruses are small nonenveloped viruses with circular double-stranded DNA genomes of approximately 8000 base pairs in size. They preferentially infect squamous epithelial cells and have been isolated from a wide range of animal species, from fish to birds to humans. Papillomaviruses are species-specific and there is little evidence for transmission from one species to another. A schematic outline of the HPV16 genome is represented in Fig. 1A. All the major open reading frames (ORFs) are located on one of the two DNA strands. They are overlapping and encoded in each of the three possible reading frames. Papillomaviruses contain less than 10 ORFs; early and late ORFs are identified by the letters, E and L, respectively, followed by a number. The lowest number designates the longest ORF. Early ORFs encode nonstructural, regulatory proteins, whereas the two late ORFs, L1 and L2, encode the major and minor viral capsid proteins, respectively. Viral gene expression involves extensive splicing, and some early viral mRNAs contain coding information derived from more than one ORF. In addition to the early and late coding sequence, there is an approximately 1000 bp portion of the genome that does not specify major ORFs. This region is referred to as the long control region (LCR) and contains regulatory DNA elements, including the origin of viral genome replication and binding sites for viral E2 transcription factors as well as cellular transcription factors (Fig. 1A).

Regulation of Papillomavirus Replication and Gene Expression

Like other viruses, papillomaviruses are obligate intracellular parasites that heavily rely on host cellular replication factors for synthesizing their genomes. Importantly, however, the papillomavirus viral life cycle is tightly coupled to the process of epithelial cell differentiation. Papillomaviruses initially infect undifferentiated, proliferative basal epithelial cells, which are located in the deepest, basal layer of the skin. Papillomaviruses gain access to these cells through microscopic abrasions or at squamo-columnar transformations zones, where basal-like epithelial cells are exposed and readily accessible for infection. The viral entry receptor remains unknown but upon reaching the nucleus, viral genomes replicate to a low copy number. Basal epithelial cells can remain persistently infected for years or decades. High-level synthesis of viral genomes, expression of viral capsid proteins, and formation of progeny virus, however, are confined to cells within the uppermost, differentiated layers of the skin. Infectious viral particles are shed together with the dead cells in the uppermost layers of the skin.

Differentiated epithelial cells no longer undergo DNA synthesis, and thus they do not express the cellular enzymes that are necessary to support viral genome replication. To complete their infectious life cycles, papillomaviruses have evolved to prevent cell cycle withdrawal during epithelial cell differentiation. The strategies that some papillomaviruses have evolved to accomplish this, form the basis for their oncogenic activities.

The E1 and E2 proteins are key to viral replication and genome maintenance. E1 is an origin binding protein with ATPase and DNA helicase activity. Papillomavirus origins of replication are flanked by E2 binding sites and E2 associates with E1 to allow for efficient E1 binding to the origin. E2 proteins are also major viral transcriptional regulators. E2 proteins bind to $ACCN_6GGT$ palindromic sequences in the viral genome to modulate viral gene expression. Like many transcription factors, E2 proteins are functional dimers. Each monomer consists of an amino terminal transcriptional activation domain, followed by a flexible hinge and carboxyl

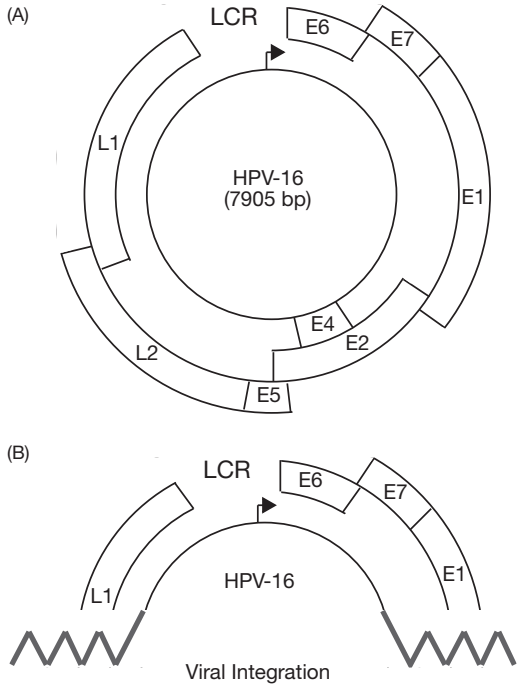

Fig. 1 (A) Schematic map of the genome of the high-risk alpha genus HPV16. LCR denotes the long control region, which harbors sequence elements important for the regulation of viral replication and transcription. Only one strand of the double stranded circular DNA genome is transcribed, open reading frames are encoded in all three different open reading frames. The early (E) genes each have functions relevant to the replication of the virus, the two late (L) genes encode the viral capsid proteins. The major early promoter that drives expression of early genes including E6/E7 is indicated by an *arrow*. (B) Integration of the viral genome into the host chromosome is a frequent hallmark of malignant progression. Integration retains expression of E6 and E7 and frequently disrupts expression of the E2 gene. Since E2 encodes a transcriptional repressor of E6/E7 expression, disruption of E2 as a consequence of viral genome integration causes dysregulated E6/E7 expression, which drives malignant progression.

terminal dimerization/DNA binding domains. E2 dimers associate with mitotic chromatin through amino terminal sequences, thereby enabling viral genome partitioning during cell division. Many papillomaviruses encode multiple E2 species with different transcriptional activities. The bovine papillomavirus type 1, BPV1, for example, encodes a full length E2 protein that can act as a transcriptional activator, as well as two smaller proteins. One is generated by initiation at an internal methionine residue and encodes a small part of the transactivation domain, the hinge, and the carboxyl terminal dimerization/DNA binding domains. The second shorter E2 protein is generated by a splicing event where a small segment of the E8 ORF is fused to the E2 hinge and dimerization/DNA binding domains. This protein functions as a potent transcriptional repressor. Other papillomaviruses also encode multiple, functionally distinct E2 transcription factors. In addition, viral transcription is also modulated by cellular factors. Of particular importance are differentiation specific proteins that may trigger the early to late switch of viral gene expression. In addition to transcription the early to late switch of the viral life cycle is also regulated at the level of RNA splicing and/or stability.

Cancer-Associated Human Papillomaviruses (HPVs)

More than 300 human papillomaviruses (HPVs) have been identified and new types are regularly added to this list. HPVs are classified as genotypes and can be phylogenetically classified into genera. The best studied HPVs fall within the alpha and beta genera. Most alpha HPVs infect mucosal epithelia, whereas beta HPVs are best known to infect cutaneous epithelia. HPV infections are very common. The majority of HPVs cause benign hyperplastic epithelial lesions or warts that have a negligible propensity for malignant progression, and these HPVs are referred to as "low-risk" HPVs. In contrast, "high-risk" HPVs cause lesions that have a certain potential for carcinogenic progression. High-risk alpha HPVs include HPV types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 66, with HPV16 being the most abundant high-risk HPV. Most high-risk HPV associated lesions spontaneously regress and malignant progression is quite rare and often occurs years or decades after the initial infection. Nonetheless, a high-risk HPV infection represents a greater risk factor for cervical cancer development than cigarette smoking for lung cancer formation. Overall, approximately 5% of all human cancer are caused by high-risk alpha HPV infections.

HPV-associated cervical cancers generally represent nonproductive HPV infections. This means that while HPV proteins are expressed, no infectious virus is produced. The best-studied mechanism that generates a nonproductive infection is integration of viral genomic sequences into a host cellular chromosome (Fig. 1B) although other mechanisms, including DNA methylation

of the viral genome, can affect viral gene transcription and also cause nonproductive infections. Hence, while cancer formation is not part of the normal life cycle of high-risk HPVs, it is caused by dysregulated expression of viral proteins that play important roles for the viral life cycle.

Alpha HPV Associated Anogenital Tract Lesions and Cancers

Low-risk alpha HPVs cause genital warts (condylomata acuminata) and more than 90% are low-risk HPV positive. Genital warts very rarely progress to malignancy although on occasion they can become locally invasive and form the giant condylomata described by Buschke and Löwenstein. The most abundant low-risk HPVs are HPV6 and HPV11.

In contrast, high-risk HPVs cause squamous intraepithelial lesions (SILs), which are at risk for malignant progression. The most prominent human cancer type associated with high-risk HPV infection is cervical carcinoma. More than 99% of cervical cancers are high-risk HPV positive, and cervical cancer is a leading cause of cancer death in women. Worldwide, there were an estimated 528,000 new cases of cervical cancer worldwide with approximately 266,000 deaths in 2012, and in United States there were 12,820 cases/4210 deaths estimated in 2017. The most abundant high-risk HPVs in the United States are HPV16 and HPV18; they are detected in approximately 70% of all cervical carcinomas. Cervical carcinoma is a venereal disease and early onset of sexual activity and multiple sexual partners have now been firmly established as the most prominent major risk factors for the development of SIL and cervical cancer.

High-risk HPV infections in males can cause penile intraepithelial neoplasia (PIN), which can progress to penile carcinoma. Although penile carcinoma is more rare than cervical cancer (2120 cases/360 deaths estimated in the United States in 2017), the incidence of cervical and penile carcinoma correlates in many parts of the world. In addition, a large percentage of other anogenital tract carcinomas, including vulvar, vaginal, and anal cancers are also caused by high-risk HPV infections. Anal cancer rates have increased in recent years. The incidence of high-risk HPV-associated cancers is higher in HIV positive patients; even in those patients with restored immune function due to antiretroviral therapy.

Most high-risk HPV infections resolve spontaneously and malignant progression often occurs years or decades after the initial infection. This extended period between HPV infection and cancer formation provides a window of opportunity to detect these potentially premalignant lesions before they progress to invasive carcinoma. The most commonly used technique is a cytological examination of cervical cells, the Papanicolaou-smear ("Pap-smear"), although this technology is gradually replaced by, or at least combined with HPV typing. Widespread implementation of the Pap-smear procedure has dramatically decreased the incidence rate of cervical cancer in many countries, and it is possibly the most impressive illustration of the value of early detection in cancer prevention. In countries where Pap-smears are not routinely performed, cervical cancer remains a leading cause of cancer death in women. An anal Pap-smear has been developed and is used in populations that are high risk for anal cancer development.

Alpha HPV-Associated Oral Lesions and Cancers

The oral mucosa is also readily infected with alpha HPVs. Oral infections with low-risk HPVs can give rise to recurrent respiratory papillomatosis (RRP), a rare disease with juvenile or adult onset. Juvenile onset RRP may be caused by vertical transmission, that is, infection during delivery, whereas adult onset RRP may be a venereal disease. HPV associated lesions in RRP patients grow very rapidly and frequent surgeries are required to keep the airways clear. On rare occasions, RRP lesions undergo malignant progression and can spread to the lungs. This is often associated with mutations and rearrangements in the viral genome particularly sequences in the viral LCR. Benign oral papillomas and oral focal epithelial hyperplasias have also been connected to with low-risk alpha HPV6 and HPV11 infections. Moreover, there is evidence for oral infections with beta and gamma genus HPVs, although it is unclear whether such infections are associated with any disease.

Approximately 20% of head and neck squamous cell carcinomas (HNSCCs) are HPV-positive. Of these, oropharyngeal squamous cell carcinomas (OPSCCs) are particularly highly associated with HPVs; approximately 65% are HPV positive. HPV16 is detected in more than 90% of the HPV associated OPSCCs. HPV positive OPSCCs frequently occur in patients that are younger and lack classical oral cancer risk factors such as poor oral hygiene and tobacco and alcohol abuse and are more common in males than in females. Transmission may be by oral sex practices and deep kissing. The incidence of HPV positive OPSCCs is rapidly increasing in many industrialized countries. There is no procedure for early detection of these cancers. Even though HPV positive OPSCCs appear more aggressive, they more readily respond to radiation and chemotherapy than HPV negative OPSCCs.

Beta HPV-Associated Nonmelanoma Skin Cancers

Studies with patients afflicted by a rare skin disease, epidermodysplasia verruciformis (EV), provided the first evidence that HPVs can contribute to human carcinogenesis. EV is a rare disease that is frequently linked to mutations in one of two genes on chromosome 17, *EVER1* (*TMC6*), and *EVER2* (*TMC8*). EV patients are not able to efficiently clear cutaneous, beta HPV infections, and they develop wart-like lesions that cover large parts of their bodies. Later in life, and particularly at sun-exposed areas of the body, these warts progress to malignant squamous cell carcinomas (SCCs), which contain beta HPVs, most prominently HPV5 and HPV8. These

results clearly implicate UV exposure as an important environmental cofactor for beta HPV associated skin cancer development in EV patients.

The HPV8 E6, E7, and E2 each are intrinsically oncogenic in that they can each contribute to skin cancer formation in transgenic mouse models. The molecular targets of the beta HPV oncoproteins are quite distinct from those of the corresponding high-risk alpha HPV proteins. Beta HPV E6 proteins inhibit NOTCH and TGF beta signaling and can inhibit apoptosis in response to UV irradiation potentially by inhibiting the proapoptotic BCL2 family member BAK1, and/or the ATR kinase and the acetyl transferases EP300/CREBBP that are involved in UV-induced DNA damage repair.

Beta HPV infections also contribute to cutaneous SCCs that frequently arise in organ transplant patients as a consequence of long term systemic immune suppression, but it has been more challenging to prove an etiologic role of these viruses in skin cancer formation in the general patient population because not every tumor cell is HPV positive and, more generally, beta as well as the rapidly expanding gamma genus HPVs appear to be part of the normal viral flora of the skin. This suggests that beta HPVs may contribute to skin cancer initiation, but that continuous HPV gene expression is not necessary for tumor maintenance and/or that noncell-autonomous mechanisms may be involved. Deep sequencing studies of skin cancer tissues have also detected some gamma HPVs in these cancers. Clearly, more work is required to clarify the roles that beta and, potentially gamma, HPVs may play in the genesis of human skin cancers in immunocompetent patients.

High-Risk Alpha HPV Oncogenes and Cancer Initiation

The transforming activities of the high-risk alpha HPV E6/E7 proteins are a consequence of the viral replication strategy that is to ensure long term persistent infection of rapidly dividing basal epithelial cells and viral genome replication and progeny synthesis in growth arrested, terminally differentiated epithelial cells. To accomplish this, HPVs encode proteins that subvert the normal programs of cell division, differentiation, senescence, and death (Fig. 2). During the productive viral life cycle, expression of these viral proteins is controlled by a complex interplay of viral and cellular regulatory factors. This causes only subtle disruptions of cellular functions, which can become clinically apparent as hyperplastic lesions. When the normal regulatory balance of viral gene expression is distorted, for example as a consequence of a nonproductive infection, the replication strategy of a high-risk HPV becomes a serious predicament for the cell that can lead to cancer and the eventual demise of the host.

Dysregulated HPV protein expression and a nonproductive infection can arise as a consequence of the accidental integration of parts of the HPV genome into a host cell chromosome, which terminates the viral life cycle (Fig. 1B). Viral genome integration is a frequent albeit not universal event during malignant progression, and HPV associated cancers frequently (also) contain extrachromosomal HPV genomes. HPV genome integration often involves common fragile sites in the human genome. There is a remarkable conservation of the pattern of integration with respect to the viral genome. The LCR as well as the E6 and E7 ORFs are consistently retained, while in contrast, expression of the E2 transcriptional repressor is frequently abrogated as a result of integration. Dysregulated E6/E7 expression caused by loss of E2 expression is a key step that drives malignant progression. Epigenetic alterations in HPV genomes may also contribute to abnormal E6/E7 expression and drive malignant progression even in cases where there is no viral genome integration.

Expression of high-risk alpha HPV E6 and E7 proteins is necessary for the induction and maintenance of the transformed state. High-risk but not low-risk HPV derived E6 and E7 proteins each have potent oncogenic activities. Expression of E6 and E7 in primary human genital epithelial cells causes cellular immortalization. While the resulting cell lines are initially nontumorigenic, they exhibit histopathological abnormalities that are reminiscent of high-grade precancerous SILs. Long-term continuous passaging of high-risk alpha HPV immortalized cell lines eventually yields fully transformed, tumorigenic lines. Transgenic mice with HPV16

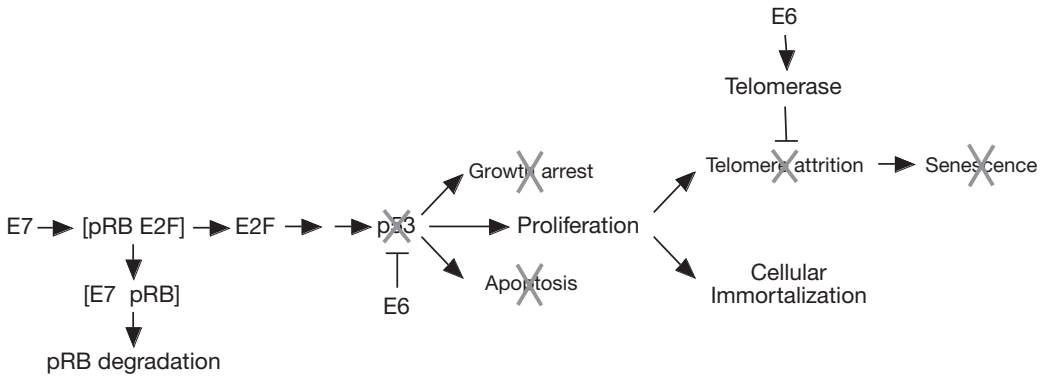

Fig. 2 Cellular targets of high-risk alpha HPV E6 and E7 proteins. Interfering with their activities is necessary for the ability of the high-risk HPVs to replicate their genomes in cells that would not normally support DNA synthesis, and for prolonged survival of HPVs within their infected host cells. In the context of nonproductive infection, when E6/E7 expression is dysregulated, inactivation of these cellular targets contributes to cellular transformation. See text for details.

E6/E7 expression targeted to basal epithelial cells develop cervical carcinomas when treated with low doses of estrogen. Similarly, oral and anal carcinoma formation can also be modeled in HPV16 E6/E7 expressing transgenic mice.

Persistent expression of the high-risk HPV E6/E7 is necessary for the maintenance of the transformed state. When endogenous high-risk HPV E6/E7 expression is inhibited by antisense, ribozyme, gene editing, or RNAi technologies or by re-expression of the E2 transcriptional repressor, cervical carcinoma cells undergo cell cycle arrest, replicative senescence or apoptosis. This demonstrates that cervical carcinoma cells remain "addicted" to HPV oncoprotein expression.

Even though HPV E5 is not consistently expressed in cervical cancers, it exhibits transforming activities in transgenic mice. Hence it is possible that E5 may contribute to tumor initiation, but given that it is not always expressed in cancer, it is likely dispensable for tumor maintenance.

Cellular Targets of High-Risk Alpha HPV E6 and E7 Proteins

E6 and E7 are small proteins of approximately 150 and 100 amino acid residues, respectively. There are no closely related cellular homologs, and E6 and E7 each contain related cysteine-rich zinc binding motives. The three-dimensional structures of E6 and E7 have been determined. E6 and E7 do not directly bind to specific DNA sequences, and they have no known intrinsic enzymatic activities, but function by binding to and functionally reprogramming host cellular protein/protein complexes. A large number of putative cellular partners of E6 and E7 have been reported and for the sake of simplicity only some of the main factors will be discussed here.

HPV E7 proteins share sequence similarity to oncoproteins encoded by other small DNA tumor viruses, including large tumor antigens (T Ag) of polyomaviruses and the adenovirus E1A proteins. A portion of the conserved sequence represents the interaction domain with the retinoblastoma tumor suppressor protein, RB1. Tumor suppressors are functional counterparts to cellular proto-oncogenes and drive cancer formation when they are inactivated. Mutational inactivation of RB1 is the rate limiting mutation that causes retinoblastoma, a rare childhood eye tumor. High-risk alpha HPV E7 proteins not only bind RB1, but target RB1 for degradation through the ubiquitin/proteasome system. Consequently, RB1-regulated cellular regulatory circuits, which include cell division, differentiation, senescence, apoptosis, and genome stability, are functionally compromised in high-risk HPV infected cells. The most studied biological activity of RB1 is the control of cell division. When a cell is in a resting state, referred to as G1, the intracellular RB1 pool is hypophosphorylated and tightly associated with E2F transcription factors. The RB1 protein contains a transcriptional repressor domain, and RB1/E2F complexes function as transcriptional repressors. When a cell receives a signal to undergo a round of cell division, a family of protein kinases, the cyclin dependent kinases (CDKs), are activated and drive progression through the cell division cycle. The very first CDK complex that is activated as a prelude to cell cycle entry (CDK4 or CDK6 in complex with a D-type cyclin) phosphorylates RB1. Phosphorylated RB1 species lose their transcriptional repressor activity and E2F family members activate expression of their target genes, thereby driving DNA synthesis and cell division. Since high-risk HPV E7 proteins bind to and destabilize growth suppressive, hypophosphorylated RB1, cells will be able to undergo aberrant DNA synthesis that is independent of CDK activity (Fig. 2).

However, a cellular failsafe mechanism exists that causes elimination of such aberrantly proliferating cells. In response to abnormal cell division in the absence of extrinsic growth factor availability, the TP53 tumor suppressor undergoes posttranslational modifications, is rendered more stable and accumulates in the nucleus. The TP53 protein functions as a DNA binding transcription factor and induces the expression of cellular target genes that signal either growth arrest or apoptosis (Fig. 2).

To counter elimination of HPV infected, E7 expressing cells by this mechanism, the high-risk HPV E6 proteins target the TP53 tumor suppressor for ubiquitination and proteasome-mediated degradation by forming a complex with the cellular UBE3A (E6AP) ubiquitin ligase (Fig. 2). Hence, high-risk HPV E6 proteins deflect the normal, abortive cellular response to RB1 inactivation. In combination, functional RB1 and TP53 tumor suppressor inactivation by high-risk alpha HPV E7 and E6 oncoproteins result in sustained, aberrant proliferation of infected cells.

Since the chromosomal termini, the telomeres, progressively shorten with every round of cell division, most normal cells can proliferate only for a limited time. Once telomeres have critically eroded, cells undergo replicative senescence, an irreversible withdrawal from proliferation. Some cell types, including stem cells maintain telomere length by expressing the telomerase enzyme.

To overcome the limitation of replicative senescence, high-risk HPV E6 proteins have evolved to enhance telomerase expression and activity (Fig. 2). Therefore, high-risk HPV E6/E7 expressing cells can divide for extended periods of time by inactivating the RB1 and TP53 tumor suppressors and overcome the normal limitation of replicative senescence by activating telomerase activity. Consistent with this model, ectopic expression of high-risk HPV E6/E7 extends the life span and facilitates immortalization of primary human epithelial cells (Fig. 2).

It is interesting to note that these cellular pathways targeted by the E6 and E7 oncoproteins are rendered dysfunctional by mutation in the majority of human solid tumors.

High-Risk Alpha HPV E6 and E7 and Malignant Progression

High-risk HPV immortalized cells are nontumorigenic, but tumorigenic clones will arise after long-term passaging in cell culture. This is reminiscent of high-risk HPV-induced lesions in patients that undergo carcinogenic progression relatively rarely and often

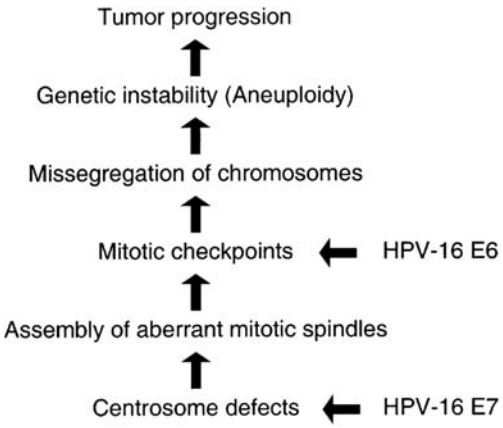

Fig. 3 High risk HPV E7 and E6 oncoproteins can induce and perpetuate genomic instability, respectively. See text for details.

only years or decades after the initial infection. This strongly suggests that additional cellular mutations are necessary to cause malignant progression. Consistent with this model, recurrent mutations affecting ERBB2, ERBB3, the phosphoinositide 3-kinase pathway, SHKBP1, CASP8, HLA-A and TGFBR2, and others have been identified in cervical cancers.

Normal cells effectively maintain the integrity of their genomes and accumulate mutations at an exceedingly low rate. Expression of E6 and E7 directly contributes to the loss of genomic integrity (Fig. 3). High-risk HPV E7 proteins increase the incidence of mitotic aberrations through several mechanisms. First, E7 expression triggers aberrant synthesis of centrosomes, which form the mitotic spindle poles (Fig. 3). In normal cells, centrosome synthesis is tightly coupled to cell division. It occurs once and only once per cell division to ensure the formation of two mitotic spindle poles and the symmetrical distribution of chromosomes during cell division. As a consequence of aberrant centrosome synthesis, the incidence of abnormal, asymmetrical mitoses generated by the presence of more than two mitotic spindle poles, is markedly increased in HPV16 E7 expressing. Such abnormalities have long been recognized as a hallmark of high-risk HPV-associated lesions and cancers. Daughter cells that arise after a cell undergoes aberrant, multipolar cell division contain abnormal chromosome numbers. Numerical chromosome abnormalities, referred to as aneuploidy, are the most frequent manifestation of genomic instability in solid tumors, and cervical cancers have been shown to be aneuploid. In addition, HPV E7 also increases the incidence of unrepaired double strand DNA breaks in cells, which can lead to chromosomal fusions and translocations. Other mitotic abnormalities, including defects in chromosome alignment during metaphase, have also been observed in E7 expressing cells. Lastly, HPV oncoprotein expression triggers activation of members of the APBEC3 family of cytidine deaminases, which cause G to A/C to T mutations and HPV associated cervical and oral cancer show APOBEC3 mutational signatures. APOBEC3 activation also causes extensive mutagenesis of the HPV genomes. Subversion of TP53 tumor suppressor activity by E6 compromises a critical surveillance mechanism that normally removes abnormal cells from the proliferative pool, which increases the possibility that abnormal cells with chromosomal abnormalities accumulate and malignant progression can ensue. Hence high-risk HPV E6 and E7 contribute directly and indirectly to accumulation of cellular mutations that drive malignant progression.

Clinical Intervention

Despite impressive advances in deciphering the molecular mechanisms of HPV-induced carcinogenesis, no HPV specific antivirals have been discovered. HPVs only encode a single enzyme, the E1 ATPase/DNA helicase, which would be an obvious target for the discovery of specific antiviral compounds. The oncogenic activities of E6 and E7 are mediated through cellular enzymes, and although these may be targeted for therapy, their functional inhibition may also have direct consequences for uninfected cells. Another possibility is to develop compounds that inhibit association of E6 and/or E7 with their cellular targets, but blocking protein–protein interactions with small molecule inhibitors remains challenging, despite the fact that three-dimensional structures of E6 and E7 are now available. Other approaches have focused on identifying cellular vulnerabilities that are caused by HPV E6 and/or E7 mediated rewiring of cellular control circuits. Such approaches have become feasible through RNAi based loss of function screens and a number of enzymes have been identified that are essential for proliferation/survival of HPV E6/E7 expressing cells but are largely dispensable for proliferation of normal cells. Last but not least, it may be possible to directly inactivate E6 and/or E7 by RNAi, gene editing or other approaches. Given the consistent "addiction" of HPV tumors to E6/E7 oncogene expression, such approaches, if technically feasible, appear particularly appealing.

A major breakthrough has been the commercial availability of extraordinarily efficacious prophylactic HPV vaccines, which essentially prevent infections with the most common high-risk HPVs as well as the low-risk HPV6 and HPV11. These vaccines consist of empty viral shells, "virus like particles," formed by the L1 major capsid protein that are produced in yeast or insect cells. Because these prophylactic vaccines only prevent new infections, they have to be administered, prior to the onset of sexual activity.

The incidence of premalignant cervical lesions has dramatically decreased in countries with national vaccination programs, however, in some countries including the United States, vaccination rates have been disappointingly low and in other countries these vaccines are not widely available due to high production costs and limited shelf life. In combination with the long latency period between the initial infection and cancer formation it will be years to decades before vaccination will have a measurable impact on the incidence and mortality of HPV associated lesions and cancer, worldwide.

Other strategies that are currently evaluated are immunological checkpoint inhibitors and postexposure, therapeutic vaccines. Such vaccines are directed against viral proteins expressed in tumors and they will have to be matched to the HPV type causing the lesion.

Large-scale deployment of the Pap-smear as a relatively inexpensive screening modality has decreased incidence and mortality of cervical cancer by approximately 70%. More sophisticated implementations of the basic Pap-smear technology that allow for more consistent sampling of the cells and automated processing of specimens are now widely used. Pap-smears, however, are increasingly complemented, and in many cases replaced by DNA typing and these innovations will further improve the vigilance of early detection to allow ablation of HPV associated lesions before they undergo malignant progression.

Parathyroid Cancer: Pathology and Genetics

Ying-Hsia Chu and Ricardo V Lloyd, The University of Wisconsin School of Medicine and Public Health, Madison, WI, United States

Glossary

Parathyroid carcinoma A malignant neoplasm derived from the parathyroid parenchymal cells.
Hungry bone syndrome Rapid profound and prolonged hypocalcemia associated with hypophosphatemia and hypomagnesemia that is exacerbated by suppressed parathyroid hormone levels after parathyroidectomy in patients with severe primary hyperparathyroidism such as with parathyroid carcinomas.
Hyperparathyoidism jaw-tumor syndrome Autosomal dominant inherited condition associated with parathyroid adenomas, parathyroid carcinomas and benign bone tumors of the mandible and maxilla.
Multiple endocrine neoplasia type 1 Autosomal dominant inherited condition associated with hyperplasia and tumors of the pituitary, parathyroid, pancreas and gastric acid hypersecretion.
Multiple endocrine neoplasia type 2 Autosomal dominant inherited condition associated with hyperplasia and tumors of the parathyroid, thyroid C-Cell, and adrenal medulla.
Nuclear pleomorphism A feature of parathyroid carcinoma in which there is variation in the size and shape of the nuclei in parathyroid carcinoma cells.
Oxyphilic/oncocytic cells Parathyroid carcinoma cells with granular pink cytoplasm after hematoxylin and eosin histochemical staining. The eosinophilia is caused by the abundant mitochondria in the cytoplasm of the tumor cells.

Nomenclature

Serum Calcium
Ionized calcium in serum 1–1.4 mmol/L (SI)
Total serum calcuim 2.2–2.6 mmol/L (SI)

Definition

A malignant neoplasm capable of metastasizing is derived from various types of parathyroid parenchymal cells. These can include chief cells, oncocytic or oxyphilic cells and clear cells.

Etiology

Most parathyroid carcinomas are sporadic while a small percentage of carcinomas are familial.

Sporadic Parathyroid Carcinoma

Some cases of parathyroid carcinoma may arise secondary to prior radiation to the head and neck region and secondarily involving the parathyroid glands. In this setting the latency period between radiation and parathyroid tumors is relatively long and may be more than 20–25 years. Post radiation parathyroid neoplasms are mainly adenomas, but rare cases of carcinomas have been reported. Rare cases of parathyroid carcinomas in patients with secondary and tertiary hyperparathyroidism following renal failure and chronic dialysis have been noted. In rare cases patients with celiac disease may also develop sporadic parathyroid carcinomas.

Genetic or Familial Parathyroid Carcinoma

Parathyroid carcinomas may develop in a familial setting in patients with hyperparathyroidism-jaw tumor syndrome (HPT-JT). This disorder is associated with mutations of the CDC73 gene and is autosomal dominant. The disorder was previously called HRPT2. In this condition patients have tumors of the parathyroid glands and about 10%–20% of these may be carcinomas. This syndrome is also associated with benign tumors of the jaw or osteomas. They may occur in the mandible or maxilla. Most tumors are unilocular, but they may occasionally be multifocal. Although the tumors are usually benign they may be infiltrative and recurrent. Female patients with this disorder may also develop uterine abnormalities including endometrial hyperplasia, uterine leiomyomas, adenofibromas and in a few cases adenosarcomas which are malignant uterine tumors. Rare cases of parathyroid carcinomas may also

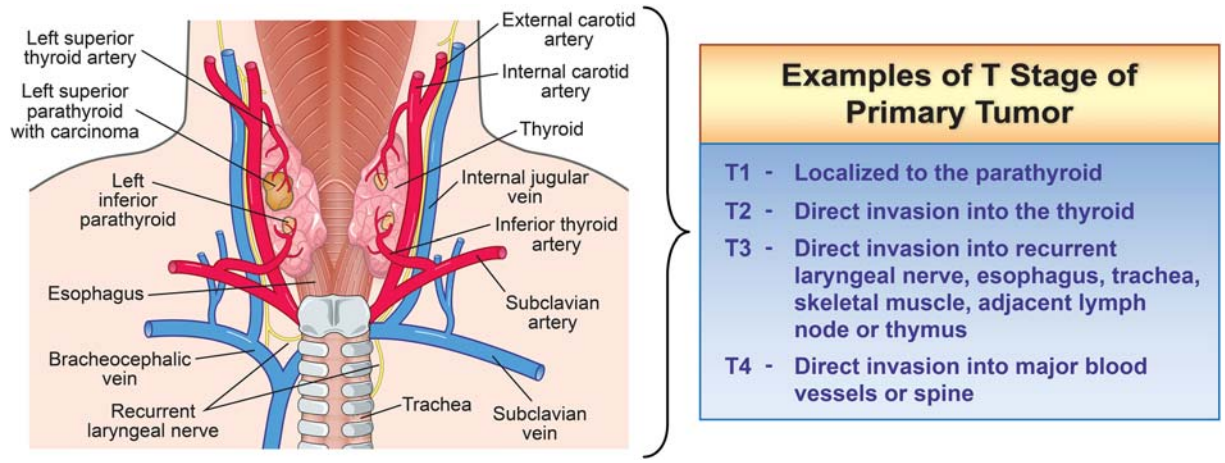

Fig. 1 Schematic diagram of the anatomy and pathology of the parathyroid glands including a parathyroid carcinoma from a posterior view. The carcinoma in the left upper parathyroid is markedly enlarged and is associated with the adjacent thyroid tissue. The right side shows examples of T stage classification of parathyroid carcinomas using the American Joint Commission on Cancer (AJCC) recommendation s. Most of the anatomic structures that could be invaded by the carcinoma and that are important in the T classification are shown in the diagram.

develop in patients with multiple endocrine neoplasia type 1 which usually affects the parathyroid glands, anterior pituitary gland and the pancreatic islets cells. Patients with multiple endocrine neoplasia type 2 or 2a may also develop parathyroid carcinomas rarely. These patients usually have familial tumors affecting the parathyroids as well as the C-cells of the thyroid and adrenal medullary cells.

Epideimiology

Parathyroid carcinomas are extremely uncommon. They are rarely encountered in a large surgical pathology laboratory (Fig. 1). In a large series of patients with primary hyperparathyroidism, which means that the disease originated in the parathyroid gland, less than 1% of these patients will have a parathyroid carcinoma that causes elevation of the serum calcium and parathyroid hormone level. Both sexes are equally affected by parathyroid carcinomas which are different from benign parathyroid tumors in which there is a female preponderance of cases. There has been an increase in the incidence of parathyroid carcinomas over the past few decades. One reason for this increase in both adenomas and carcinomas has been attributed to increased clinical screening that has enabled earlier detection of parathyroid tumors. Most patients with sporadic parathyroid carcinomas are in their 50s, but patients with familial disease are usually one or two decades younger.

Imaging of Parathyroid Carcinoma

Preoperative imaging for parathyroid carcinomas include ultrasonography (US), computed tomography (CT), magnetic resonance imaging and scintigraphy. The sensitivity of technetium-99 m sestamibi scanning is relatively high compared to ultrasound localization. A combination of sestamibi and ultrasound increases sensitivity for smaller lesions that are difficult to localize. Sestamibi scans can have a fairly high false positive rate, so newer methods such as single-photon emission CT (SPECT) and SPECT in combination with CT scanning (SPECT-CT) can improve the anatomic details and increase the rate of detection of smaller lesions. Recent studies have found that four-dimensional CT for parathyroid tumors that were previously considered nonlocalizable on US and single-photon emission CT with SPECT-CT increases sensitivity and specificity 4-D CT may be considered as first or second-line imaging for localizing parathyroid tumors. Fludeoxyglucose positron emission tomography may be used for detecting parathyroid carcinomas both in the primary site and for metastatic disease.

Clinical Features

Patients with parathyroid carcinomas usually have higher serum levels of parathyroid hormone and serum calcium than patients with parathyroid adenomas. Serum calcium is often greater than 3.5 mmol/L. Many patients may have renal disease at the time of presentation. The most common findings are renal stones or nephrolithiasis. The second most common fining would include bone diseases such as osteitis fibrosa cystica. Bone resorption, diffuse osteoporosis may be common in these patients. Some asymptomatic patients may present with spontaneous bone fractures. A combination of renal and bone diseases is not uncommon in patients

with parathyroid carcinomas. On physical examination patients often have a palpable neck mass, especially with larger parathyroid carcinomas. Some patients may present with hoarseness due to paralysis of the recurrent laryngeal nerves. Parathyroid adenomas are a lot more common than parathyroid carcinomas, but the possibility of carcinomas should be considered in patients with severe hyperparathyroidism, a palpable neck mass, hoarseness and evidence of local invasion at the time of surgery.

Gross Findings

Parathyroid carcinomas are quite variable in their gross appearance. They may be very small and weigh a little more than a gram or be extremely large and weigh up to 50 g or more. Many parathyroid carcinomas appear to have a thin capsule on gross examination. In very large tumor the capsule may appear extremely thin because of massive expansion by the tumor (Fig. 1). The cut surface of parathyroid carcinomas usually shows a firm tan to pink tumor mass that may look lobulated and hemorrhagic. Brown-tan firm fibrous bands may be appreciated on close gross examination. In large frank carcinomas with extensive invasion the tumor may be seen to permeate into the adjacent adipose tissue, skeletal muscle or into the nearby thyroid tissue that may have been excised with the parathyroid gland.

Microscopic Findings

Although the surgeon may suspect a parathyroid carcinoma at the time of surgery, it is usually the pathologist that makes the ultimate diagnosis of parathyroid carcinomas. A common reported finding by the surgeon is that the tumor is adherent to the adjacent thyroid. However some parathyroid adenomas are also adherent to the thyroid gland especially after fine needle aspiration biopsy in the vicinity of the parathyroid glands.

The most useful microscopic feature of malignancy is invasive growth of the tumor (Figs. 2–4). Invasion may involve the adjacent thyroid, adjacent skeletal muscle or fibroadipose tissue that may be appreciated on gross examination. More often the findings are more subtle such as vascular invasion or perineural invasion. Vascular invasion should involve vessels in the capsule or in the adjacent tissues. Invasion in the center of the parathyroid tumor does not qualify as true vascular invasion.

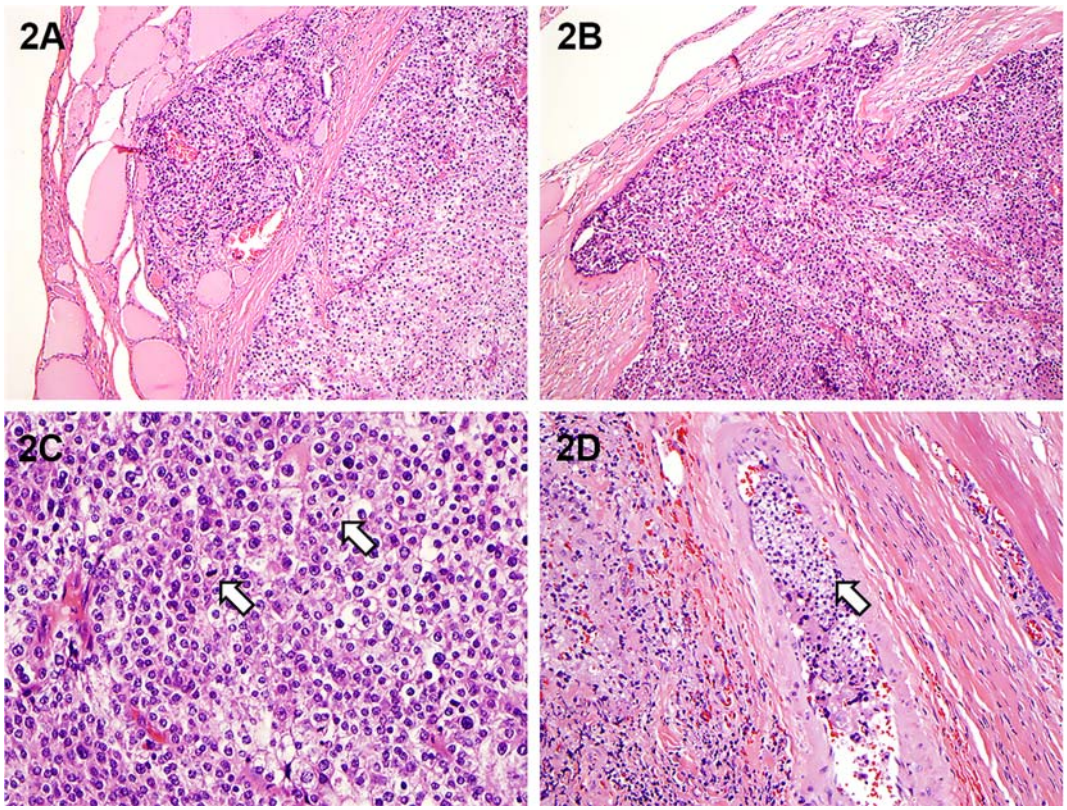

Fig. 2 Histopathological features of parathyroid carcinoma. (A) The parathyroid carcinoma shows invasion into the adjacent thyroid tissue. (B) The parathyroid carcinoma shows invasion into the thickened tumor capsule. (C) There is increased mitotic activity in the parathyroid carcinoma. Two mitotic figures are shown (*arrows*). (D) Vascular invasion in a parathyroid carcinoma. A vessel in the capsule (*arrow*) shows vascular invasion.

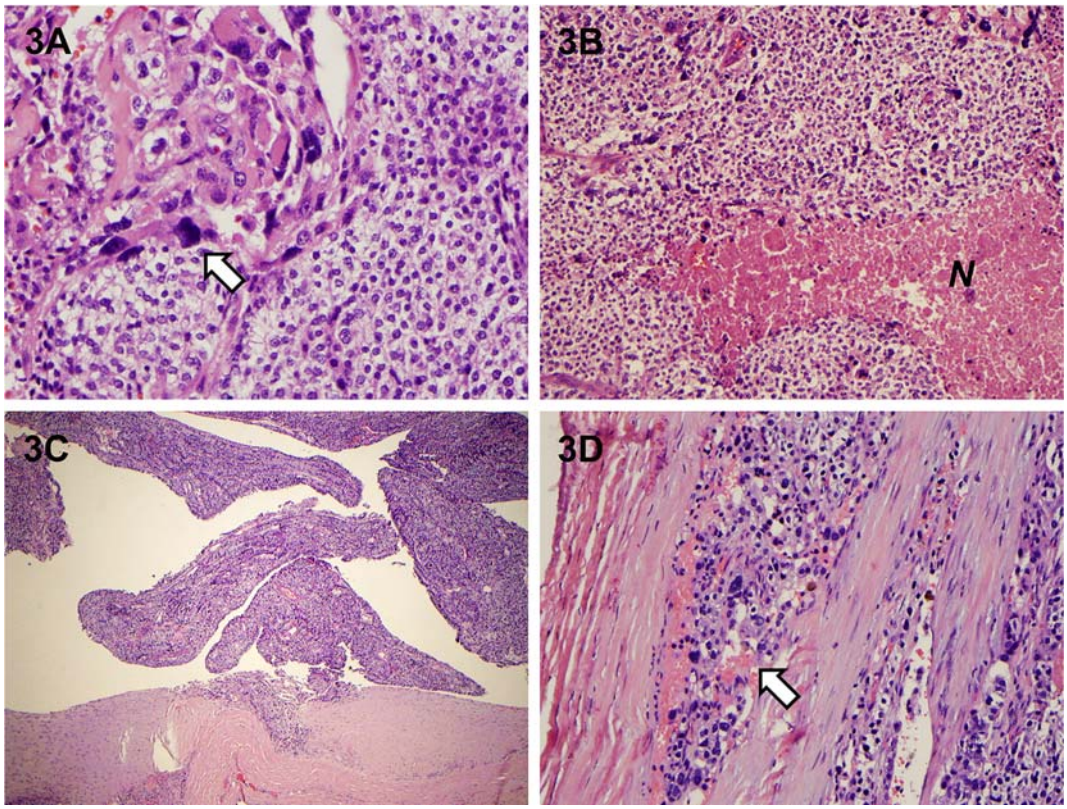

Fig. 3 Histopathological features of parathyroid carcinoma. (A) There is nuclear pleomorphism in the parathyroid carcinoma (*arrow*). (B) Extensive areas of necrosis (N) are present in this parathyroid carcinoma. (C) Hyperparathyroidism-jaw tumor (HPT-JT) syndrome in a 17 year old boy with parathyroid carcinoma. The cystic appearance of the parathyroid tumor is usually seen in about a third of patients with HPT-JT syndrome. (D) Another portion of the parathyroid carcinoma from the patient in C showing vascular invasion in the capsule (*arrow*).

A common finding seen in parathyroid carcinomas is the presence of broad fibrous bands. These bands consist of fibrous connective tissues which extend from the peritumoral capsule towards the center of the tumor. Although helpful in the diagnosis of parathyroid carcinomas, they are not specific for this disease, since they may also be seen in parathyroid adenomas and in atypical parathyroid adenomas. The type of cells in parathyroid carcinomas reflects the cell types seen in the normal parathyroid and in parathyroid adenomas. The chief cell is the most common constituent of parathyroid carcinomas. Oncocytic or oxyphilic parathyroid carcinomas were once thought to be nonfunctioning tumors, but studies in the literature have shown that most of these tumors are functional. There are only rare instances of nonfunctioning parathyroid carcinomas. Parathyroid carcinomas composed mostly of clear cells are very uncommon tumors. Nuclear pleomorphism is often seen in some areas of parathyroid carcinomas. Although some parathyroid carcinomas are composed of uniform population of tumor cells in many areas, nuclear pleomorphism is often seen focally. The pleomorphic nuclei may be quite large and have prominent nucleoli. The sizes of the pleomorphic cells may be two to three times larger than adjacent cells that are not pleomorphic. Ultrastructural examination of parathyroid adenomas shows similar features as seen in parathyroid adenomas. Cells usually have variable numbers of dense core secretory granules, moderate amounts of rough endoplasmic reticulum and Golgi complexes. The secretory granules vary in size from 100 to 600 nm. Oncocytic tumors usually contain abundant mitochondria on ultrastructural examination.

The proliferative index as evaluated by mitotic activity is another helpful diagnostic feature for parathyroid carcinomas. A minimum of 50 high power fields should be counted in the evaluation of parathyroid carcinomas. Most parathyroid adenomas may have 1 or 2 mitoses per 50 high power fields, but the number is usually much higher in parathyroid carcinomas. Mitotic figures may be found "in hot spots" which means that some areas may have abundant mitotic figures while many other areas may be devoid of mitotic figures. In recent years the proliferative index as assessed with Ki-67 or MIB1 may be helpful in the diagnosis of parathyroid carcinomas. The Ki-67 proliferative index is usually helpful in distinguishing adenomas from carcinomas, since the percentage is usually less than 4% in adenomas and greater than 6% in parathyroid carcinomas. Atypical mitoses are very helpful in the diagnosis of parathyroid carcinomas, since they are usually not seen in the normal parathyroid or in parathyroid adenomas. Immunohistochemical staining for Ki-67 may help in the detection of atypical mitoses.

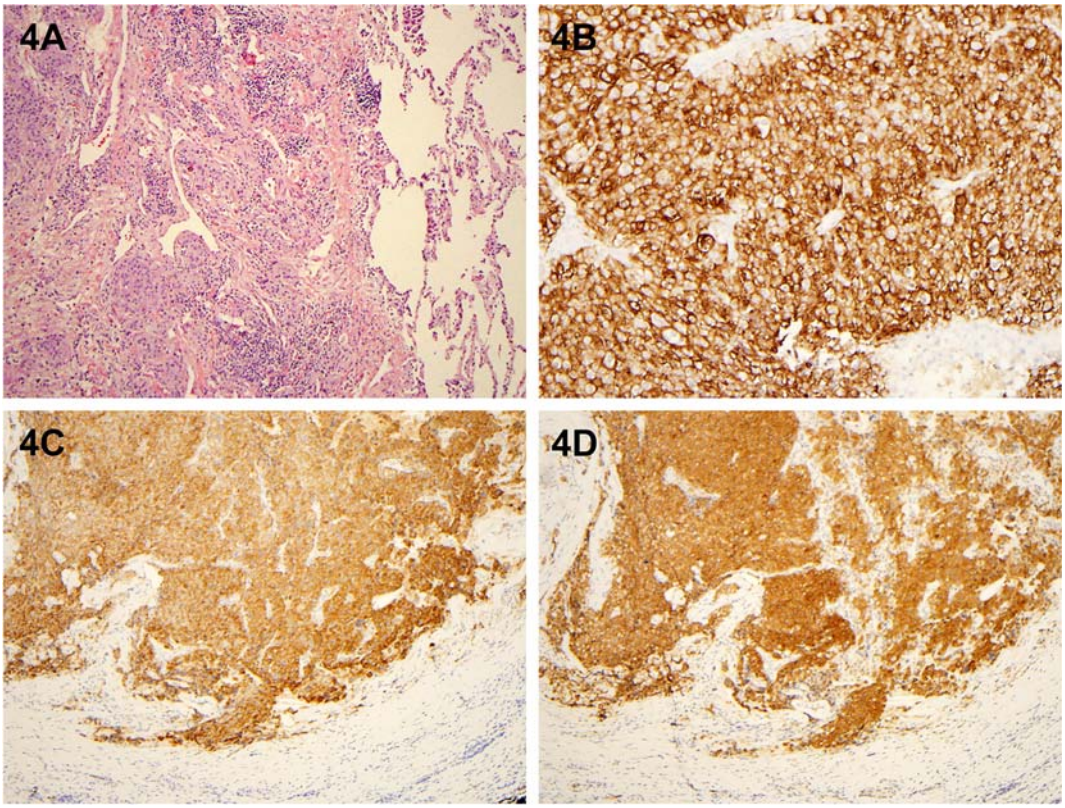

Fig. 4 Histological and immunohistochemical findings in parathyroid carcinomas. (A) Metastatic parathyroid carcinoma to the lung. Nest of malignant neuroendocrine cells are present in the left part of the field. (B) Immunohistochemical staining for parathyroid hormone is diffusely positive in this parathyroid carcinoma. (C) Immunohistochemical staining for chromogranin A is diffusely positive in the same parathyroid carcinoma as in B. (D) Immunohistochemical staining for synaptophysin is diffusely positive in the parathyroid carcinoma.

Immunohistochemical Staining

Immunohistochemical staing can be very helpful in the diagnosis of parathyroid carcinomas (Fig. 4). Immunohistochemical staining for Ki-67 has already been discussed under microscopic findings and its utility in the diagnosis of parathyroid carcinomas has already been emphasized. Immunohistochemical staining for parathyroid hormone can help to confirm the diagnosis of parathyroid carcinomas in more unusual cases. Immunopositivity for parathyroid hormone is typically weaker in parathyroid carcinomas compared to parathyroid adenomas or normal parathyroid gland tissues. General neuroendocrine markers such as chromogranin and synaptophysin can be useful in confirming the diagnosis of parathyroid carcinomas. Other broad spectrum neuroendocrine markers such as CD56 and neuron specific enolase are usually positive, but are not as specific as chromogranin and synaptophysin. Immunostaining for p27 (CDKN1B) has been studied in parathyroid carcinomas. Normal parathyroid tissues, parathyroid hyperplasia and parathyroid adenomas usually have higher levels of p27 than parathyroid carcinomas. Thus quantitation of p27 can be used as supplemental evidence in the diagnosis of parathyroid carcinomas, especially when used along with Ki-67 which shows the reverse relationship (highest in parathyroid carcinomas). Additional markers that are positive in parathyroid carcinomas include various keratins such as CAM5.2 and AE1/AE3. The mitochondrial keratin marker CK14 is surprisingly negative in most parathyroid carcinomas. RB protein which is a tumor suppressor gene is often negative in parathyroid carcinomas. The latter observation suggests that the RB gene may be important in the pathogenesis of parathyroid carcinomas. The transcription factor GATA3 is usually positive in parathyroid carcinomas. In addition, parathyroid carcinoma is usually positive for the regulatory gene that is important in the development of the parathyroid gland, GCM2.

Cyclin D1 is frequently overexpressed in parathyroid carcinomas. However like many markers some parathyroid adenomas and rare cases of normal parathyroid may express Cyclin D1, so this marker is not specific for parathyroid carcinomas. A molecule that is important for the pathogenesis of familial parathyroid carcinoma, parafibromin or CDC73 which was previously known as HPRT2 is often negative in a significant percentage of parathyroid carcinomas. However a significant percentage of parathyroid carcinomas may be positive for this marker, so it is not an absolute marker for parathyroid carcinomas. Some patients with parathyroid carcinomas and renal failure may retain expression of CDC73, so in this setting it is not a reliable marker. Another marker that is useful in the diagnosis of parathyroid carcinoma is the protein PGP9.5.

Some workers have shown that there is increased expression of PGP9.5 in parathyroid carcinomas, so combining the loss of parafibromin with increased expression of PGP9.5 would provide good immunohistochemical evidence supporting the diagnosis of parathyroid carcinoma.

Other markers that are frequently positive in parathyroid carcinomas include galectin 3, mTOR, COX1/2 and VEGFR-2. Markers that are frequently negative in parathyroid carcinoma include BCL2, CDKN1B, APC, RB protein and thyroglobulin.

Differential Diagnosis of Parathyroid Carcinoma

The differential diagnosis of parathyroid carcinomas includes parathyroid adenomas, atypical parathyroid adenomas, parathyromatosis and metastasis to the parathyroid. Parathyroid adenomas are the most common lesion that raises the possibility of parathyroid carcinomas in a few cases. Adenomas may be adherent to the thyroid gland, especially if the patient has a history of fine needle aspiration to the thyroid that is close to a parathyroid gland. Fibrous bands may occasionally be seen in parathyroid adenomas, but features such as increased mitotic activity, vascular invasion, perineural invasion, extension of parathyroid neoplasm into the thyroid or beyond the parathyroid gland to the fibroadipose or skeletal muscle tissue is usually not present. The mitotic activity and Ki-67 proliferative index are also helpful features that allow separation of parathyroid adenomas from parathyroid carcinomas.

Atypical parathyroid adenoma is an uncommonly used diagnosis that should be restricted for a specific entity. Atypical parathyroid adenomas usually have some of the features of parathyroid carcinoma, such as dense fibrous bands and capsular invasion. But the reliable diagnostic features of parathyroid carcinomas such as vascular and perineural invasion, invasion of the adjacent thyroid or invasion into the fibroadipose or skeletal muscle tissue is usually not present. Patients with atypical parathyroid adenomas should be followed closely with periodic measurement of serum calcium or parathyroid hormone levels to detect recurrent disease.

Parathyromatosis may be difficult to distinguish from parathyroid carcinomas, since there is often dispersement of nodules of neoplastic parathyroid gland tissue in the soft tissues of the neck. Primary parathyromatosis may result from persistent embryological remnants of parathyroid gland tissues in the soft tissues of the neck while secondary parathyromatosis is related to the surgical implantation of parathyroid gland tissues into the soft tissues of the neck during surgery for hyperparathyroidism. In this setting hyperplastic or neoplastic parathyroid tissues may be accidentally deposited in the soft tissues of the neck during surgery. The presence of a palpable neck mass is usually associated with a parathyroid carcinoma rather than primary or secondary parathyromatosis. Parathyromatosis may show increased mitotic activity on histological examination, but atypical mitosis is usually not seen. Other features diagnostic of carcinoma such as vascular invasion, perineural invasion, markedly elevated serum parathyroid hormone or calcium levels may help to make the distinction. Loss of parafibromin expression and increased expression of PGP9.5 may also be supportive evidence in favor of parathyroid carcinoma, although there have not been too many studies of parathyromatosis with respect to these biomarker expression.

Metastatic tumors to the parathyroid are very uncommon. It usually occurs in patients with a high tumor burden. Estimates in the literature have ranged from 0.2% to 12% of cases with disseminated malignancies. These are usually carcinomas from the most common organs that are likely to develop malignancies. The primaries sites of tumors reported as metastases to the parathyroid include breast, lungs, skin (melanoma), liver, kidney, and hematolymphoid malignancies such as chronic lymphocytic leukemia. Some of these metastases may be confused with a primary parathyroid carcinoma. An excellent example of this would be renal cell carcinoma because of the common finding of clear cells and the high vascularity as is seen in parathyroid carcinomas.

Treatment

Surgery

Surgery is the only potentially curative treatment for parathyroid carcinoma. According to the recently published guidelines by American Association of Endocrine Surgeons (AAES), complete resection of tumor with intact capsule should be attempted when there is clinical suspicion for carcinoma. It is often difficult to ascertain intraoperatively benign (adenoma) versus malignant (carcinoma) nature of the disease. Although an obviously invasive or metastatic tumor would indicate carcinoma, less specific signs such as enlarged size of the gland, fibrous capsule and adherence to the surrounding structures can occur in both adenomas and carcinomas. A piecemeal fashion of resection should therefore be avoided in parathyroid tumors with unknown pathology.

The optimal extent of resection for grossly confined tumors has been under debate. Traditionally, based on a large literature, extended en bloc resection including parathyroid tumor, ipsilateral thyroid lobe and other adherent structures has been believed to lead to better survival and reduced recurrence compared to simple parathyroidectomy. Nevertheless, more recent studies have found no outcome benefit in extensive resection over parathyroidectomy alone. The current AAES guidelines have no strong preference for either surgical approach.

Prophylactic cervical lymph node dissection in the absence of clinically suspicious nodes is controversial. The incidence of nodal metastasis is relatively low (up to 10%) in large series. Although nodal status was included in the current TNM staging system, multiple studies have found no association between survival and regional lymph node metastasis. Accordingly, the current AAES guidelines do not recommend prophylactic central or lateral neck dissection.

After tumor resection, patients should be monitored for development of hungry bone syndrome with acute, potentially life-threatening hypocalcemia, hypophosphatemia and hypomagnesemia due to abrupt drop of serum parathyroid hormone level

and reversal of bone resorption. Current AAES guidelines do not recommend adjuvant radiotherapy given that parathyroid carcinomas are typically radioresistant.

Nonsurgical Treatments

In patients with unresectable disease, treatment options are very limited. Radiotherapy and chemotherapy are both relatively ineffective. Patients with symptomatic hypercalcemia may be treated with generous hydration and calciuretic agents such as loop diuretics. Hypocalciuretic agents such as thiazides should be avoided. Sensipar (cinacalcet), a calcimimetic that acts on the calcium-sensing receptors on parathyroid chief cells to reduce parathyroid hormone secretion, was recently approved by the United States Food and Drug Administration for the treatment of hypercalcemia in patients with parathyroid carcinoma. The approval was based on a single-arm, open-label trial that included 29 patients. Calcitonin and bisphosphonates may also reduce bone resorption. Hemodialysis may be warranted in patients with renal failure.

Antiparathyroid hormone immunotherapy has been reported with promising results in three cases. These patients were immunized with human and bovine parathyroid hormone peptides with Freund's adjuvant and developed detectable anti-human parathyroid hormone antibodies within 4 weeks. All three patients experienced decreases in serum calcium; however, the sustainability of such improvement was heterogeneous. In one patient, the immunotherapy led to normalization of serum calcium and parathyroid hormone levels and 39.2%–71.4% shrinkage of pulmonary metastases for more than 2 years. In another patient, serum calcium decreased in the first week after injection but re-escalated in less than 3 weeks, with metastatic tumors continuing to develop. More research is needed to clarify the utility of immunotherapy. No molecular targeted therapy is currently available.

American Joint Commission on Cancer (AJCC) TNM Staging of Parathyroid Carcinomas

T Stage

Staging of parathyroid carcinomas is relatively new in risk assessment models, because of the rarity of these carcinomas (Fig. 1). There is no generally accepted staging system for parathyroid carcinomas at this time. A working TNM system has been proposed by the AJCC Cancer Staging Manuel and is summarized in this section. The staging of the primary tumor includes: TX or primary tumor cannot be assessed; T0 when the primary tumor cannot be localized; Tis refers to atypical parathyroid neoplasms or neoplasms of uncertain malignant potential. These are tumors that are histologically or clinically worrisome, but do not fulfill the exact criteria of malignancy for carcinomas such as invasion and metastasis. The atypical parathyroid adenoma would fall into this category. T1 refers to a carcinoma localized to the parathyroid gland with extension limited to adjacent soft tissues.T2 includes tumors with direct invasion of the adjacent thyroid gland. T3 includes carcinomas with direct invasion of the recurrent laryngeal nerve, esophagus, trachea, skeletal muscle, adjacent lymph nodes or the thymus gland. T4 stage involves parathyroid carcinomas with direct invasion into major blood vessels or spine.

N Stage

The N stage for parathyroid carcinoma ranges from no involvement of regional lymph nodes to extensive involvement of lymph nodes. NX indicates that lymph nodes cannot be assessed. N0 indicates that there are no lymph node metastases while N1 refers to lymph node metastases. The N1 category is divided into N1a in which there are metastases to level VI (Pretracheal, paratracheal and prelaryngeal/Delphian) lymph nodes. N1b refers to metastases to unilateral, bilateral or contralateral cervical (levels I, II, III, IV or V) or retropharyngeal or superior mediastinal lymph nodes (level VII).

M Stage (Distant Metastasis)

As with other tissues M0 refers to no distant metastasis, while M1 refers to cases with distant metastasis of parathyroid carcinoma.

Genetics/Molecular Biology

The major molecular driver for parathyroid carcinoma has been shown to be the *CDC73* gene which was previously known as *HPRT2* gene. This gene maps to 1q25-q31. The gene contains 17 exons spanning 18.5 kb of genomic distance and is predicted to express a 2.7 kb transcript. It encodes the 531 amino acid protein CDC73. CDC73 is ubiquitously expressed in many organs including lungs, brain, kidney, liver and pancreas. The gene is a tumor suppressor gene and is involved in the regulation of p53 and is a component of the PAF protein complex controlling RNA polymerase II-mediated general transcription. CDC73 protein has an important role in regulating gene expression and inhibiting cell parathyroid cell proliferation. Sporadic parathyroid carcinomas often have somatic inactivating mutations of the CDC73 gene. Germline mutation of the *CDC73* gene may be detected in some cases of patients who appear to have sporadic parathyroid carcinomas, which suggest that they may have a subtle manifestation of HPT-JT that may be more difficult to detect clinically without genetic testing. Other genetic abnormalities in

parathyroid carcinomas include loss of chromosome 13q. This may be associated with a genetic abnormality close to the RB1 gene. The MEN1 gene has also been associated with parathyroid carcinoma, but this is a very uncommon association, Next generation sequencing has uncovered other genes that may be important for the pathogenesis of parathyroid carcinomas including PIK3CA, ADCK1, KMT2D, PRUNE2, MTOR, UCHL1 which encodes the gene for PGP9.5 and CDH1. The general feeling of experts in this area is that parathyroid carcinomas do not usually develop by tumor progression from hyperplastic or adenomatous parathyroid disease.

Hyperparathyroidism-jaw tumor syndrome (HPT-JT) is an autosomal dominant tumor disorder. It has been linked to mutations in the *CDC73* gene. Patients usually develop parathyroid adenomas or carcinomas, ossifying fibromas of the mandible and maxilla, renal cysts, renal adenomas and carcinomas and females develop endometrial hyperplasia, uterine leiomyomas, adenofibromas. Patients with this condition are usually diagnosed by biochemical finding of primary hyperparathyoroidism, radiologic detection of ossifying fibromas, by family history and by molecular genetic analysis to uncover the CDC73 genetic mutations. Patients usually have solitary parathyroid lesions, but involvement of two or more glands may develop over time. About 80% of patients with HPT-JT present with hyperparathyroidism, but in some families the syndrome may be limited to the parathyroid abnormality without bone or renal lesions. Parathyroid disease usually becomes manifested in the second or third decade of life. The development of parathyroid carcinoma is much more common with HPT-JT syndrome compared to MEN1 and MEN2 diseases.

Prognosis

Parathyroid carcinomas tend to be indolent, persistent tumors. Postoperative recurrence is common, occurring in 30%–100% of cases. Distant metastasis occurs in up to 25% of cases, common metastatic sites include lung, bone, and liver. Recurrent and metastatic tumors are often treated by resection, embolization or chemical/heat ablation to reduce the metabolic effect of tumors, but these measures are rarely curative. Overall survival is estimated at 78%–85% at 5 years and 49%–70% at 10 years. The majority of mortalities are secondary to complications of hypercalcemia such as renal failure and cardiac arrhythmia (12). Adverse outcome predictors include older age, male gender, larger tumor size, incomplete resection, nonfunctional tumors and distant metastasis. It remains controversial whether regional lymph node metastasis has prognostic significance, and whether more radical surgery such as extended en bloc resection is more advantageous than simple parathyroidectomy.

Prospective Vision

The study of parathyroid carcinoma is rapidly advancing in several areas. Imaging studies will be developing newer and more sensitive methods to detect primary tumors that may be too small to detect with currently available techniques before surgery. Intraoperative techniques to try to distinguish between benign and malignant parathyroid tumors are being developed with mass spectrophotometric methods. New biomarkers including proteins, microRNAs and long noncoding RNAs are being examined as possible diagnostic and prognostic tools for parathyroid carcinomas. Finally whole genome sequencing and new molecular techniques are being used for gene discovery and for developing new methods to target recurrent and metastatic disease in patients with parathyroid carcinomas.

P-Glycoprotein-Mediated Multidrug Resistance☆

MM Gottesman, Laboratory of Cell Biology, National Cancer Institute, National Institutes of Health, Bethesda, MD, USA

Glossary

Apoptosis A process of programmed cell death stimulated by natural factors or anticancer drugs.

ATP binding cassette A protein sequence found in a related family of proteins that allows the cellular source of energy, ATP, to bind to these proteins and be utilized for various transport processes.

Extracellular space The space between cells in a tissue, or outside of a cell growing tissue culture, from which drugs are taken up by a cell.

Hydrophobic Of or relating to a property of molecules that prevents them from dissolving in water and enables their solution in cell membranes.

Induction A form of regulation of gene expression in which an environmental alteration (frequently the presence of a specific chemical) leads to the expression of a gene. In the case of drug resistance, the cytotoxic compound may turn on expression of a protective detoxifying mechanism. Induction is contrasted with mutations that are permanent, inherited changes in genes, which may result in drug resistance.

Lipid bilayer The collection of lipids that makes up the plasma (outer) membrane of cells. The phospholipids are arranged in two layers so that their polar, water-soluble heads are exposed either to the inner (cytoplasmic) or outer (extracellular) surface.

Multidrug resistance The development of cross-resistance to many different drugs as the result of a single biochemical change or a single genetic alteration. In its strictest sense, cross-resistance should refer to resistance to drugs with different structural features and different cytotoxic targets.

Multifactorial multidrug resistance Resistance that results from a change in many different resistance mechanisms, not a single mechanism as is the case in classical multidrug resistance.

Natural product A pharmacological agent that comes from the natural environment and is not synthesized *de novo* in the laboratory.

P-glycoprotein An energy-dependent plasma membrane pump responsible for multidrug resistance to many natural product drugs and their derivatives. In the human, P-glycoprotein is the 1280-amino acid product of the *MDR1* (*ABCB1*) gene.

Pharmacogenomics A term coined to indicate the study of those inherited changes in proteins and in the factors that regulate their expression and account for inherited differences in metabolism, uptake, distribution, and excretion of drugs.

Photoaffinity labeling The use of chemical compounds that can be activated by light so as to form chemical linkages with other macromolecules to which they are bound. When such photoaffinity labels are radioactive, they can be used to identify such binding macromolecules.

Plasma membrane The lipid bilayer and associated proteins and other molecules that make up the outer surface of cells.

Substrate A molecule that is acted upon by a macromolecule so as to change its chemical composition, or to transport it within, into, across, or out of cells.

Transgenic mice Mice whose genes have been altered in the laboratory to enable the study of the function of a specific gene or genes. Transgenic mice may carry new genes, or have altered genes, including alterations that totally knock out the expression of specific genes.

Transmembrane domains Those parts of proteins inserted into the lipid bilayer of cell membranes.

Xenobiotics Chemical materials, usually natural products, that are toxic to cells. Some of these are present in food and microorganisms and are ingested inadvertently, whereas others are used in the treatment of cancer and other diseases.

The Role of the Multidrug Efflux Pump, P-Glycoprotein, In Multidrug Resistance in Cancer Cells

Multidrug resistance is the phenomenon by which cancer cells display simultaneous resistance to many different anticancer drugs that are chemically dissimilar and that do not have the same cytotoxic target within the cancer cell. It is now known that multidrug resistance can have many different causes, including failure of cancer cells to accumulate drugs, to metabolize them to toxic products, to activate cell death pathways, and the ability of cancer cells to activate alternative growth-promoting pathways. For many years this

☆*Change History:* March, 2014. M. Gottesman introduced small edits and updates to the text. More references were added to the reference list. Figure 1 was re-done. Figures 2 and 3 were replaced with previously published figures that were slightly adapted for this article.
This article is an update of M.M. Gottesman,Multidrug Resistance I: P-Glycoprotein, In Encyclopedia of Cancer (Second Edition) edited by Joseph R. Bertino, Academic Press, 2002, Pages 247–254.

 https://doi.org/10.1016/B978-0-12-801238-3.98744-0

phenomenon of broad drug resistance was mysterious to investigators who studied resistance to anticancer drugs. The first major breakthrough in this field was made in 1985 when three groups published the sequence of an energy-dependent plasma membrane transporter, or P-glycoprotein, the product of the *MDR1* (*ABCB1*) gene. P-glycoprotein could detect many different lipid-soluble anticancer drugs and pump them out of the cell so as to prevent accumulation to toxic levels (see Figure 1). The relative lack of specificity of this transport pump, and the fact that many anticancer drugs are lipid-soluble natural products, accounted for its ability to confer multidrug resistance to cancer cells. Table 1 summarizes some of the known substrates for the P-glycoprotein pump, which include not only anticancer drugs, but also many other important pharmacologic agents in common use in the clinic. Subsequently, other energy-dependent multidrug efflux pumps were discovered, including the *MRP* family of transporters and ABCG2.

Once antibodies and molecular probes were available for detection of P-glycoprotein in cancer cells, it was possible to ask whether cancers from patients, with or without exposure to anticancer drugs, expressed this efflux pump. It was known by the late 1980s that many different kinds of cancers express P-glycoprotein at levels high enough to confer resistance to anticancer drugs, and that the presence of P-glycoprotein frequently correlated with resistance to drugs known to be substrates for transport by P-glycoprotein. For example, epithelial cancers of the colon, small intestine, pancreas, adrenal, and kidney, derived from tissues that normally express P-glycoprotein, usually express high levels of this transporter. Although P-glycoprotein pump activity is not the only reason for the multidrug resistance of these epithelial tumors, expression of P-glycoprotein does appear to be a barrier to effective therapy in these cancers with many different standard anticancer drugs.

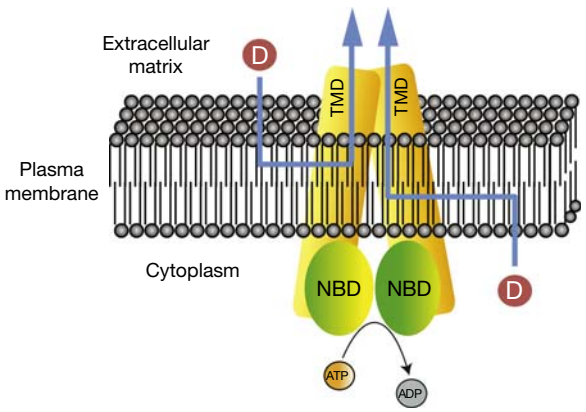

Figure 1 Diagram illustrating the potential mechanism of action of P-glycoprotein as it removes drugs (D) from the lipid bilayer, either as they are entering the cell, or once they have accumulated intracellularly. The solid lines represent likely pathways of drugs through the transporter. The molecule consists of two homologous halves each with a nucleotide-binding domain (NBD) which act together to hydrolyze ATP.

Table 1 Selected substrates of P-glycoprotein

Class	*Drug*
Anticancer drugs	Vinca alkaloids (vincristine, vinblastine)
	Anthracyclines (doxorubicin, daunorubicin, epirubicin)
	Epipodophyllotoxins (etoposide, teniposide)
	Paclitaxel (taxol)
	Actinomycin D
	Topotecan
	Mithramycin
	Mitomycin C
Other cytotoxic agents	Colchicine
	Emetine
	Ethidium bromide
	Puromycin
Cyclic and linear peptides	Gramicidin D
	Valinomycin
	N-Acetyl-leucyl-leucyl-norleucine
	Yeast **a**-factor pheromone
HIV protease inhibitors	Ritonavir
	Indinavir
	Saquinavir
Fluorescent compounds	Hoechst 33342
	Rhodamine 123
	Calcein-AM

Some cancers, which did not express high levels of P-glycoprotein initially, began to express high levels after many cycles of selection in anticancer drugs. Examples include leukemias, lymphomas, myelomas, and ovarian cancer. In these cases, it is presumed that the toxic drug kills most of the sensitive cells in the original population, and only those cells that express higher levels of P-glycoprotein, as a result of a mutation in the cancer cell affecting regulation of expression of this pump, are able to survive and multiply. Evidence suggests that, to some extent, cytotoxic drugs can directly turn on the expression of P-glycoprotein, and that this phenomenon might contribute to clinical multidrug resistance in some cases. However, in cultured cells, the survivors of drug selection appear to express P-glycoprotein in a stable manner, thereby arguing in favor of selection of a pre-existing mutant cancer cell, rather than an induction mechanism that would not result in stable, long-term expression of P-glycoprotein.

Finally, it appears that the malignant transformation process itself can result in turning on expression of the *MDR*1 gene. Examples include some leukemias (especially the blast transformation of cells, which occurs in chronic myelogenous leukemia), and neuroblastomas in children. It is not known why this occurs, but presumably the malignantly transformed state itself results in induction of the P-glycoprotein gene, and the resulting tumor cells are multidrug-resistant. Another possibility is that expression of P-glycoprotein enhances the malignant phenotype. There is preliminary evidence in some model systems that expression of P-glycoprotein has an antiapoptotic effect. These observations are consistent with the idea that P-glycoprotein may facilitate cell survival in tumors.

An important unanswered question is whether inhibiting the function of P-glycoprotein in tumor cells that express it will result in better responses to chemotherapy, i.e., is P-glycoprotein ever limiting in determining response to chemotherapy? Despite many clinical trials that have addressed this issue, the answer is not yet available. Until there are potent, specific inhibitors of P-glycoprotein available, and these are tested in cancers known to express P-glycoprotein, we will not have this answer. Preliminary studies for some leukemias and myelomas suggest that improved response is possible when P-glycoprotein is inhibited, but response in epithelial tumors seems minimal. Studies attempting to correlate resistance to chemotherapy in epithelial cancers with expression of a single multidrug resistance gene have so far suggested that in clinical cancers multidrug resistance is multifactorial, whereas resistance which occurs in cancers selected with anticancer drugs is more likely to be due to a single cause. However, despite the fact that inhibiting P-glycoprotein in epithelial cancers does not sensitize these cancers to natural product anticancer drugs, pharmaceutical companies have kept in mind the presence of this drug efflux pump, because drugs that do not accumulate in cells cannot kill them. Consequently, new anti-cancer drugs are now routinely screened to determine if they are P-glycoprotein substrates.

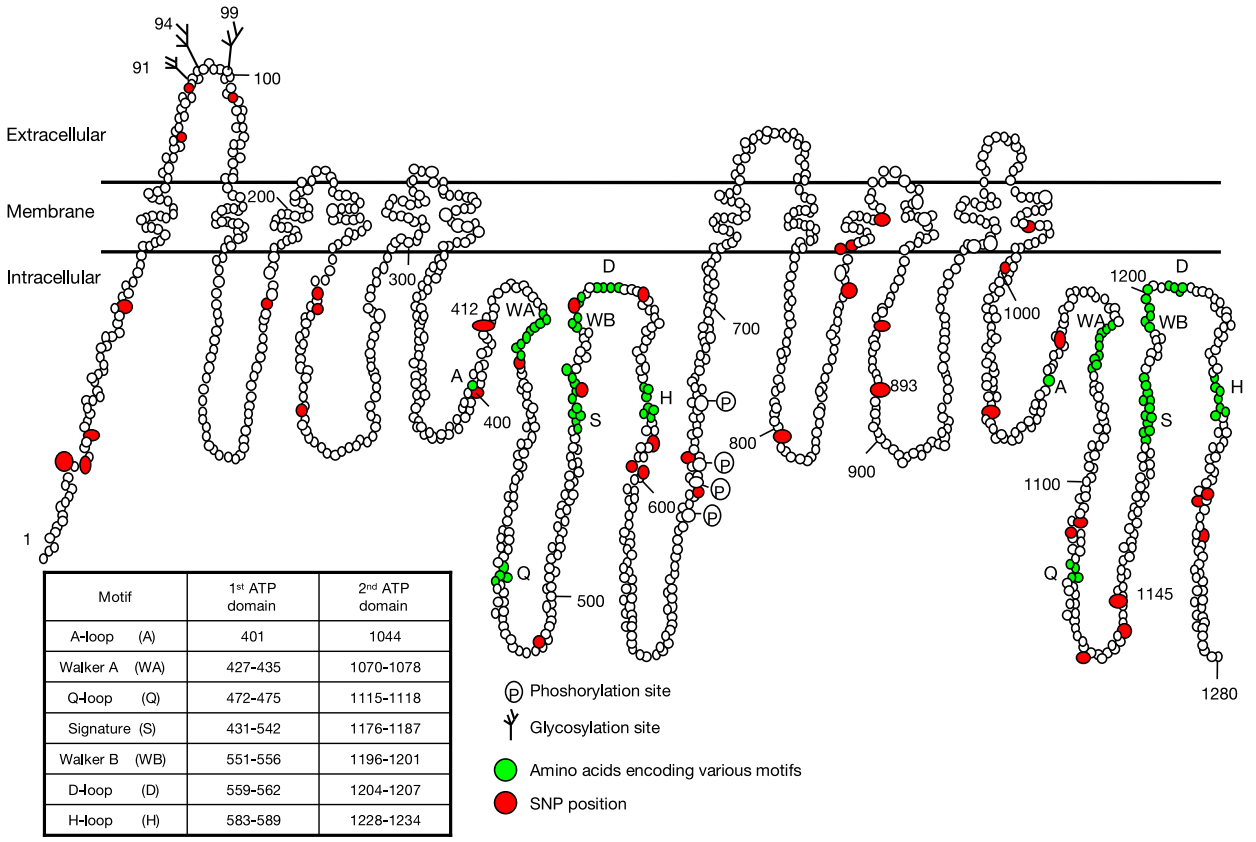
One new strategy to deal with P-glycoprotein-expressing tumors is to take advantage of the fact that expression of P-glycoprotein is an Achilles' heel that sensitizes cancers to other toxic small molecules. Efforts to develop such P-glycoprotein-targeted therapeutics are in progress.

Structure and Mechanism of Action of P-Glycoprotein

The discovery of a pump that can recognize and extrude many different anticancer drugs led naturally to the question of how so many different substrates could be recognized by one protein, and how the energy of ATP was harnessed to the pump process. The first step was to create a model of P-glycoprotein based on its known amino acid sequence. In the human, P-glycoprotein is encoded by 1280 amino acids. There are a total of 12 segments consisting mostly of water-insoluble amino acids that would be expected to cross the plasma membrane of the cell; 6 of these are in the amino-terminal half of the pump and 6 are in the carboxyl half. In addition, there are two regions that are very similar to ATP-binding regions of other proteins, and in particular appear to have some sequence characteristics seen in a large family of proteins (probably 80 are encoded in the human genome) involved in energy-dependent transport across cellular membranes. This family is known as the ATP-binding cassette (ABC) family of proteins. A hypothetical planar structure of P-glycoprotein based simply on the amino acid sequence and supported by data using specific antisera is shown in **Figure 2**.

Based on photoaffinity labeling studies using analogs of known substrates for P-glycoprotein, and on mutational analyses in which individual amino acids in the transmembrane domains of P-glycoprotein are mutated, it appears that the major drug interaction sites on P-glycoprotein are in the transmembrane segments. More recently, a low-resolution X-ray crystallographic structure of mouse P-glycoprotein with a drug bound has confirmed this prediction. This information, plus the knowledge that P-glycoprotein is able to decrease the rate of influx of drugs as well as increase their rate of efflux, and some studies showing a direct interaction of drugs dissolved in the plasma membrane with P-glycoprotein, has led to a model of P-glycoprotein as a 'hydrophobic vacuum cleaner.' In other words, P-glycoprotein detects and ejects drugs while they are still in the lipid bilayer (see **Figure 1**). The specific drug interaction sites on P-glycoprotein appear to be quite complex and consist of a series of overlapping hydrophobic sites within the parts of the protein that transit the plasma membrane. This model explains the rather broad substrate specificity of P-glycoprotein, as the important interactions are hydrophobic and not ionic. The general finding that recognition of drugs depends more on hydrophobicity and size and shape rather than specific chemistry is also consistent with this hypothesis.

The presence of two ATP-binding/utilization sites on P-glycoprotein has also been puzzling. Data suggest that ABC cassette proteins require hydrolysis of two molecules of ATP to transport a single molecule of substrate, and data based on transport of vinblastine by P-glycoprotein are consistent with this generalization. Why two molecules of ATP? Hydrolysis of one molecule of



Motif	1st ATP domain	2nd ATP domain
A-loop (A)	401	1044
Walker A (WA)	427-435	1070-1078
Q-loop (Q)	472-475	1115-1118
Signature (S)	431-542	1176-1187
Walker B (WB)	551-556	1196-1201
D-loop (D)	559-562	1204-1207
H-loop (H)	583-589	1228-1234

Figure 2 A hypothetical two-dimensional model of human P-glycoprotein based on hydropathy analysis of the amino acid sequence and its functional domains. In this schematic diagram, each circle represents an amino acid residue. Red circles represent the amino acids affected by known single nucleotide polymorphisms (SNPs) that alter the substrate specificity of P-gp. The regions that encode A-loops, D-loops, H-loops, Q-loops, signature motifs, Walker-A and Walker-B motifs are colored in green, and the amino acid positions of these motifs are summarized in the table. Phosphorylation sites and glycosylations are also shown. Adapted from Fung, KL and Gottesman MM (2009), A synonymous polymorphism in a common MDR1 (ABCB1) haplotype shapes protein function, *Biochimica et Biophysica Acta* **1794**, 860-71.

ATP appears to be sufficient to reduce the affinity of P-glycoprotein for its substrates, which probably corresponds to the change in shape that the pump undergoes as it extrudes drug from the lipid bilayer into the extracellular space. Evidence points to the need for hydrolysis of a second molecule of ATP so that the pump can return to its initial high affinity binding state and begin the pumping cycle all over again. Additional experimental evidence points to the need for two functional ATP sites (inactivation of one site results in loss of pump function), the asymmetry of the two sites, and the alternating action of these two sites so that ATP hydrolysis cannot occur at both sites at the same time.

Structural studies on other ATP-binding cassette (ABC) transporters indicate that the two ATPs each bind to sites formed from each half of the transporter. The binding of ATP brings the two ABCs together and activates the transport process.

Normal Cellular Function of P-Glycoprotein

The discovery of P-glycoprotein and its ability to recognize dozens, and perhaps hundreds of structurally dissimilar compounds, raised questions not only about its mechanism of action, but about how it had evolved and what its normal function might be. The finding that all living organisms so far studied, from bacteria to man, have pumps similar to P-glycoprotein, suggested that free living cells could not survive without a broad-spectrum pump for hydrophobic compounds. Whether this reflects the ubiquitous presence of toxic xenobiotics in the environment (most of which are themselves the products of life forms and may be part of the armaments of battle used as organisms strive to gain a selective advantage in their biological niches), or an intrinsic requirement for *MDR* genes to maintain cellular integrity, is still not known with certainty. However, genetically engineered organisms such as transgenic mice lacking *mdr*1 genes (in the mouse, there are two *mdr*1 genes, called *mdr*1a and *mdr*1b or *mdr*1 and *mdr*3), and other mammalian cells lacking *MDR*1 expression, survive with normal lifespans, suggesting that there is no absolute requirement for *MDR*1 expression in cells. Moreover, mice without functioning *mdr*1 genes are exquisitely sensitive to certain xenobiotics, but carry on other cellular functions with reasonable efficiency. Because many transport functions of P-glycoprotein in mammals are

redundant with other ABC transporters, especially the *MRP* system, it is still possible that every living cell needs one or another member of this class of transporters to survive.

What sort of evidence exists suggesting cellular functions for P-glycoprotein, other than to protect cells from toxic effects of xenobiotics? In general, overexpression of P-glycoprotein after gene transfer into various cell types or after selection in cytotoxic drugs, has been used to study the effect of P-glycoprotein on cellular processes. Under these conditions, it is possible to show a reduction in sensitivity to apoptosis in lymphoid cells, resistance to certain enveloped viruses, including HIV, and altered plasma membrane lipid composition. Early studies of P-glycoprotein-expressing cells suggested a correlation with metastatic potential of cancer cells. Use of inhibitors of P-glycoprotein results in altered cellular functions, but there are probably no totally specific P-glycoprotein inhibitors, which can give definitive results about the function of P-glycoprotein alone. Use of ribozymes and anti-sense technologies to eliminate P-glycoprotein expression have so far not totally eliminated expression of P-glycoprotein, although some reductions in P-glycoprotein levels have been possible using this approach.

Once again, the use of mice lacking functioning *mdr1* genes has proved useful in determining the normal function of P-glycoprotein. As noted above, *mdr1* knockout mice live normal lifespans and are sensitive to xenobiotics. More detailed studies of the function of individual tissues that normally express P-glycoprotein suggests subtle alterations in immune system function, not yet clearly defined, and relatively normal function of epithelial tissues of the gastrointestinal tract, liver, kidney and pancreas.

Role of P-Glycoprotein in Drug Pharmacokinetics

The use of inhibitors of P-glycoprotein and the study of *mdr*1 knockout mice has confirmed suspicions from the initial histochemical localization studies that *MDR*1 played a major role in uptake, distribution, and excretion of toxic xenobiotics in mice and men. Lack of expression of functional P-glycoprotein in the gastrointestinal tract dramatically enhances the absorption of several different drugs, including anticancer drugs such as taxol, the cardiac glycoside digoxin, and the antihistamine fexofenadine. This is manifested as much higher blood levels of these compounds after oral dosing. Furthermore, distribution of such drugs in the body is altered in the absence of functional P-glycoprotein, manifested as increased brain levels of compounds such as the anti-helminthic ivermectin, the anticancer drug vinblastine, and the anti-diarrheal narcotic analog loperamide. This is attributed to the abrogation of the blood-brain barrier for these compounds owing to the absence of P-glycoprotein in capillary endothelial cells in the brain. Similar effects of loss of P-glycoprotein at the placental barrier would be expected to result in increased teratogenicity of certain compounds that are P-glycoprotein substrates, as is seen in mice lacking P-glycoprotein, and perhaps toxic and/or mutagenic effects on germ cells in the testis and ovary.

Circulating cells, such as T cells and macrophages that normally express P-glycoprotein, might become sensitized to drugs and xenobiotics if their P-glycoprotein levels are altered. Because most of the HIV protease inhibitors are P-glycoprotein substrates, this phenomenon has led to the suggestion that cellular availability of drugs such as this could be manipulated by altering levels of functional P-glycoprotein. Conversely, resistance to certain drugs could occur at the cellular level because of variations in expression of P-glycoprotein that might be genetically determined (see below).

Finally, excretion by the liver (in bile) and kidney (in urine) of P-glycoprotein substrates is substantially reduced for many drugs in the mice lacking P-glycoprotein. This results in a decreased rate of clearance for drugs, and increased accumulation of drugs in the bloodstream and tissues. Thus, use of inhibitors of P-glycoprotein, or alterations in levels of functional P-glycoprotein that might be genetically determined, could have fairly profound effects on the blood and tissue levels of many different drugs, by increasing absorption, decreasing excretion, and altering distribution into tissues protected by P-glycoprotein barriers, or into cells expressing P-glycoprotein. These effects of P-glycoprotein are summarized in **Figure 3**.

Evidence is beginning to be published suggesting that levels of P-glycoprotein in the gastrointestinal tract may vary considerably from individual to individual, perhaps accounting for differences in absorption of drugs, which are primarily P-glycoprotein substrates. One study suggests genetic linkage with a single nucleotide polymorphism that does not change the sequence of P-glycoprotein. This polymorphism, though silent, changes the structure of P-glycoprotein mRNA, resulting in changes in the rate of mRNA translation and altered folding of P-glycoprotein, resulting in different substrate specificity. Several different coding polymorphisms of P-glycoprotein have also been described, and a few appear to alter the ability of P-glycoprotein to pump drugs. Much more work is needed in this important area of pharmacogenomics.

Implications of Studies on P-Glycoprotein for Treatment of Cancer

As we assemble a more complete picture of the biochemistry, pharmacology, and physiology of P-glycoprotein function, we can begin to make better guesses as to the role that manipulation of the *MDR1* gene is likely to have in future treatment of cancer. There are some conclusions that seem quite firm, and others that are still speculative. First, it seems clear from the correlative human studies and animal studies in which mouse cancers selected for drug resistance turn on expression of P-glycoprotein that P-glycoprotein is capable of conferring resistance to many anticancer drugs to cancer cells. Thus, as new drugs are developed, it will be necessary to determine whether cellular sensitivity to these drugs is affected by the presence of P-glycoprotein. As we continue to be dependent for the treatment of cancer on the existing hydrophobic natural products, and as new, more targeted

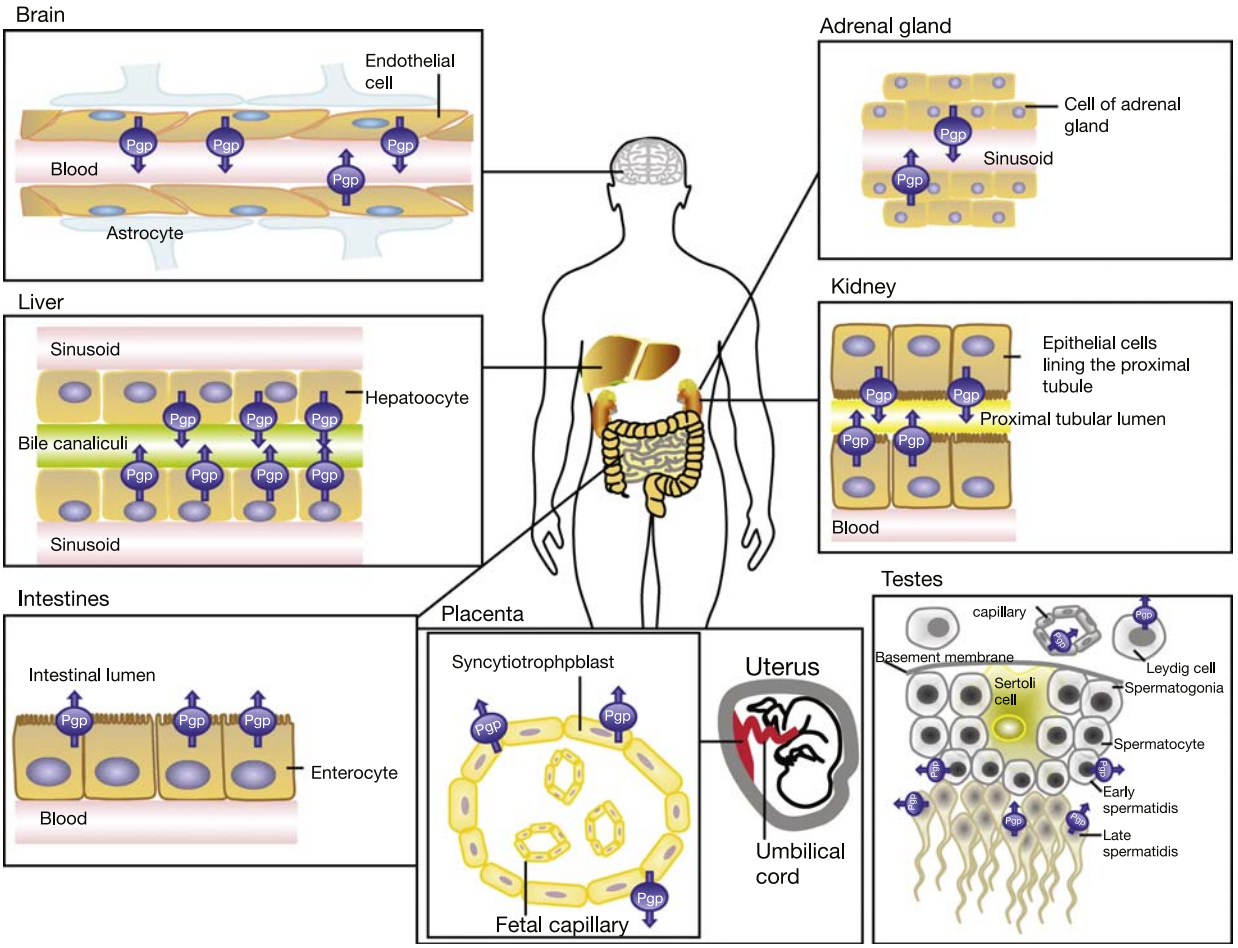


Figure 3 The effect of P-glycoprotein on pharmacokinetics and drug distribution is illustrated schematically. The multidrug transporter affects drug distribution throughout the body. Adapted from Wu CP, Ohnuma S and Ambudkar SV (2011) Discovering natural product modulators to overcome multidrug resistance in cancer chemotherapy. *Current Pharmaceutical Biotechnology* **12**, 609-620. Used by permission.

anti-cancer drugs are developed that may be P-glycoprotein substrates, then we will have to learn to inhibit P-glycoprotein, and its many molecular analogs, as we try to cure and palliate cancer.

Second, despite earlier concerns, it seems likely that more potent, more specific inhibitors of P-glycoprotein, or inhibitors of related ABC transporters, can be developed, and that their toxicity would be relatively limited and manageable. This conclusion comes from the studies with transgenic mice lacking P-glycoprotein, which have normal lifespans under controlled laboratory conditions. These inhibitors will play a role not only in sensitizing P-glycoprotein-expressing cancers to anticancer drugs, but also in altering uptake, excretion, and cellular distribution of many different drugs. Using P-glycoprotein inhibitors, it may be possible to give drugs orally that previously required intravenous administration, or to deliver drugs to the brain which previously were only active outside of the central nervous system.

Third, it appears that alterations in levels of expression of P-glycoprotein in different tissues, which may result from environmental exposures or from inherited alterations in pathways that regulate expression of the *MDR*1 gene, or inherited polymorphisms within the coding region of the *MDR*1 gene, could account for variations among individuals in the way they respond to drugs. Such changes could have substantial effects on drug uptake, distribution, and excretion. It will become necessary in the future to catalog these variations in the *MDR*1 gene and other genes, which affect metabolism, absorption, and excretion of drugs in order to predict individual responses to different drugs.

Finally, the cloning of the *MDR*1 cDNA encoding P-glycoprotein has made it possible to transfer this gene into drug-sensitive cells, thereby conferring multidrug resistance on all recipient cells. Because toxicity of anticancer drugs to sensitive tissues, such as epithelia and bone marrow, is a major dose-limiting problem in cancer chemotherapy, the ability to protect normal cells from this toxicity using transferred multidrug resistance genes has been the subject of much laboratory and clinical investigation. Although such gene transfer studies are limited by the low efficiency of existing vector systems and the safety of gene transfer of multidrug resistance genes is yet to be established, it is conceivable that multidrug resistance genes, such as *MDR1*, may prove useful in protecting normal tissues from cytotoxic effects of anticancer treatment.

Physical Inactivity and Cancer

Alpa V Patel, American Cancer Society, Atlanta, GA, United States
Erika Rees-Punia, University of Georgia, Athens, GA, United States

Introduction

It is well-documented that moderate- or vigorous-intensity physical activity (MVPA) provides vast health benefits including lowering risk of developing or dying from chronic diseases such as cardiovascular disease, type 2 diabetes mellitus, stroke, and some cancers (Leitzmann et al., 2007; Nocon et al., 2008; Paffenbarger Jr et al., 1986; Blair and Morris, 2009; Moore et al., 2016). Furthermore, an insufficient physical activity level (referred to as physical inactivity) has been estimated to account for 6%–10% of the world's burden of noncommunicable diseases (Lee et al., 2012), yet nearly half of all adults in the United States do not regularly engage in recommended levels of physical activity. Various public health guidelines (Haskell et al., 2007; Nelson et al., 2007; Kushi et al., 2012) state adults should engage in at least 150 min of moderate- (such as walking at a pace of 20 min/mile or 3 miles/h) or 75 min of vigorous-intensity (such as jogging or running) physical activity per week. For additional protection against cancer, the American Cancer Society further recommends approaching or exceeding twice the minimum recommended amount by engaging in 300 min of moderate- or 150 min of vigorous-intensity activity per week (Kushi et al., 2012).

To appropriately account for both amount and intensity of physical activities, many epidemiologic studies ask individuals to report the amount of time spent engaging in activities of different intensities (such as walking, jogging, cycling). Summary MVPA measures are then calculated by summing the frequency of each activity multiplied by the metabolic equivalent of task (MET) value for that activity (MET-hours) (Ainsworth et al., 1993, 2000). A MET is the ratio of energy expended during a specific activity compared to that while at rest. One MET is equal to the energy expenditure of an individual while seated at rest. Moderate-intensity activities are defined as those with MET values between 3 and 6, and vigorous intensity activities have MET values greater than 6. For reference, walking 1 h at an average pace of approximately 20 min/mile (or 2.8–3.2 miles/h) is equal to 3.3 MET-hours (Ainsworth et al., 2000). Thus, 7.5 MET-hours/week is equal to the minimum recommended amount of MVPA.

Studies have shown that engaging in even relatively small amounts of MVPA are associated with health benefits compared to inactivity. One recent pooled analysis demonstrated that engaging in MVPA well below recommended levels (0.1–3.74 MET-hours/week vs. no activity) was associated with approximately 20% lower risk of all-cause mortality (RR = 0.81, 95% CI 0.79–0.83) and 1.8 (95% CI 1.6–2.0) years of life gained compared to inactivity (Moore et al., 2012). While meeting the minimum recommended level of MVPA (7.5 to < 15.0 MET-hours/week) was further associated with 32% lower risk of overall mortality (95% CI 0.66–0.69) (Moore et al., 2012). Similarly, a more recent pooled study suggested that engaging in any level of physical activity less than the recommended amount was also associated with 13% lower risk of cancer mortality compared to engaging in no MVPA (95% CI 0.83–0.90), and meeting recommended levels was associated with 21% lower risk (95% CI 0.75–0.82) of cancer mortality (Arem et al., 2015). Increasing MPVA to approximately three times recommended levels (22.5+ MET-hours/week) was associated with 41% lower mortality risk (95% CI 0.57–0.61), and other studies suggest that the risk continues to decline up to 10 times recommended levels (75+ MET-hours/week) (RR = 0.69, 95% CI 0.55–0.87) (Arem et al., 2015; Matthews et al., 2012a).

Distinct from physical inactivity, the amount of time spent sitting has increased significantly over the past few decades. This increase in sedentary behavior, characterized by very low energy expenditure (≤1.5 METs) while in a sitting, reclining, or lying position (Tremblay et al., 2010), is largely attributed to technologic advancements (e.g., computers in the workplace), increased dependence on automobiles for transportation, and engagement in more sedentary activities during leisure time (e.g., watching television or playing video games). For example, in 1950, approximately 15% of jobs were classified as sedentary compared to 25% in 2000 (US Bureau of Labor Statistics), and the average amount of time spent watching television, the most common leisure-time sedentary activity, increased from 4.75 to 7.5 h/day (Nielsen Report, 2007). Recent evidence suggests that prolonged time spent sitting (such as while watching television or other screen-based entertainment) may have deleterious health effects independent of physical inactivity. In fact, there has been a growing body of evidence to support that prolonged time spent sitting is associated with total, cardiovascular disease, and cancer mortality (Matthews et al., 2012a; Ekelund et al., 2016; Chau et al., 2013; Patel et al., 2010), and a recent large meta-analysis (Chau et al., 2013) reported 34% higher mortality risk for adults sitting 10 h/day (vs. 0–3 h) after taking physical activity into account.

There is sufficient biologic rationale and mounting scientific evidence to support the role of physical inactivity and sedentary time in the development and progression of various types of cancer. This article will describe the associations observed between specific cancer types, physical inactivity, and sitting time, and provide an overview of the biologic plausibility for these associations. Finally, future directions for research will be discussed.

Biologic Mechanisms

Physical activity and sitting time may have indirect and direct effects on cancer risk. Indirectly, physical activity and reduced sitting time are important in weight management and may be associated with lower cancer risk due to obesity-mediated effects. The most recent International Agency for Research on Cancer (IARC) report on obesity and cancer concluded that obesity was causally

associated with 13 different cancer sites (Lauby-Secretan et al., 2016): esophageal adenocarcinoma, gastric cardia, colorectum, liver, gallbladder, pancreas, breast (postmenopausal), corpus uteri, ovary, kidney (renal cell), meningioma, thyroid, and multiple myeloma. Through lowering or maintaining body weight, it is plausible that physical activity and/or reduced sitting time could lower risk of these obesity-related cancers.

Observational and intervention studies have convincingly shown that physically active participants are less likely to gain weight compared to less active participants (World Cancer Research Fund/American Institute for Cancer Research Report, 2007). As reviewed in the World Cancer Research Fund/American Institute for Cancer Research Report (2007), randomized trials and prospective cohort studies have shown that physical activity is beneficial for both weight maintenance or change in adults. For example, one prospective study reported a 0.77% decrease in annual percentage change in weight (95% CI 0.53–1.01) per one MET-hour per day increase in MVPA (Macdonald et al., 2003). Another (randomized controlled trial) study examined a one-year aerobic exercise program where post-menopausal women exercised an average of 178 min/week and observed 1.8 kg loss for body weight and 2.0 kg loss for total body fat compared to the control group (Friedenreich, 2011).

Similarly, greater time spent sitting (especially while watching television) has been shown to be associated with the development of obesity. For example, in the Nurses Health Study, sitting between 2 and 5 hours per day while watching television was associated with 22% higher risk of becoming obese during the 6-year follow-up period compared to <2 hours per day of TV viewing (Hu et al., 2003). There was a strong dose–response relationship culminating with a nearly twofold higher risk among women who spent >40 hours per week sitting while watching television (RR = 1.94, 95% CI 1.51–2.49, trend $P < 0.001$). This association persisted, albeit was attenuated, even among physically active individuals (Hu et al., 2003).

Regardless of accompanying changes in weight or body composition, physical activity is directly associated with numerous benefits that may be related to cancer risk. In particular, aerobic exercise has been shown to improve lipid metabolism and facilitate glucose uptake (McTiernan, 2008; Kerr et al., 2017). Regular physical activity is also associated with a decrease in circulating sex hormones, including estrogens and androgens. More recent evidence has confirmed that exercise elicits a favorable immune response, including an increase in macrophage phagocytosis, and a decrease in systemic inflammation, as evidenced by a decrease in inflammatory biomarkers (for example, IL-6, TNF-alpha, and CRP) (Ashcraft et al., 2016).

Human mechanistic studies exploring the independent effect of sedentary time on cancer risk are sparse, however early bed rest studies provide insight on the biologic consequences of excess sitting (Bergouignan et al., 2011). The complete lack of skeletal muscle activation associated with sedentary behavior inhibits glucose uptake by the skeletal muscles, inducing an eventual decrease in insulin sensitivity (McTiernan, 2008; Bergouignan et al., 2011). Chronic excess sitting time has also been associated with various markers of chronic disease risk, such as high cholesterol, high fasting insulin levels, and other biomarkers of chronic disease (Fung et al., 2000; Healy et al., 2008a,b,c; Jakes et al., 2003). Emerging evidence suggests that even relatively short active "breaks" in sedentary time may be beneficial for metabolic function, particularly glucose regulation and triglyceride metabolism (Healy et al., 2008a; Owen et al., 2010).

Physical Activity and Cancer Prevention

Hundreds of studies have examined the association between physical activity and cancer prevention (World Cancer Research Fund/American Institute for Cancer Research Report, 2007; Kerr et al., 2017). The most recent consensus report published in 2007 evaluated the evidence for these associations (World Cancer Research Fund/American Institute for Cancer Research Report, 2007) and concluded that there is sufficient evidence suggesting that physical activity is associated with lower risk of colorectal, postmenopausal breast, and endometrial cancer. More recent studies have provided further evidence that physical activity may also be associated with lower risk of various additional cancers (Moore et al., 2016). In a recent large pooled analysis including 12 prospective cohorts with over 1.44 million participants and over 186,000 incident cancer cases, leisure-time physical activity (top 10th percentile vs. bottom 10th percentile) was inversely associated with 16 of 26 individual cancer sites. The expected associations with colon, postmenopausal breast, and endometrial cancer were confirmed, and associations with the following additional cancers were noted: esophageal adenocarcinoma, gallbladder, liver, lung, kidney, small intestine, gastric cardia, myeloid leukemia, myeloma, head and neck, rectum, bladder, and non-Hodgkin lymphoma.

The association between physical activity and colon cancer has been one of the most commonly studied and most consistently associated of all cancer sites in observational studies. Based on one meta-analysis that included over 50 observational studies, the most active people had a 24% reduced risk of developing colon cancer, compared with the least active persons (relative risk, RR = 0.76; 95% confidence interval, CI: 0.72, 0.81) (Wolin et al., 2009). The association between physical activity and rectal cancer is less clear. In a recent meta-analysis including 11 studies (Robsahm et al., 2013), the relative risk of developing rectal cancer was 0.98 (95% CI = 0.88, 1.08) for the most active compared with the least active participants. Conversely, in the large pooled analysis of 12 cohorts described above, leisure-time physical activity was inversely associated with risk of rectal cancer (RR = 0.87, 95% CI 0.80, 0.95) (Moore et al., 2016). Thus, evidence for an association between physical activity and rectal cancer risk remains inconsistent.

More than 75 observational studies worldwide have examined some measure of physical activity in relation to breast cancer risk (Friedenreich, 2011). The majority of these studies focused on recreational MVPA and provide consistent and strong evidence that physical activity is associated with lower breast cancer risk. Studies suggest that, on average, the most physically active women have 25% lower risk of developing breast cancer compared to the least active. Studies have even examined physical activity across various

age and time periods, and consistently support that physical activity is beneficial across the life course (Friedenreich and Cust, 2008). Recent studies have specifically examined walking, as it is the most common moderate-intensity activity, in relation to breast cancer risk. In one of the largest studies to date (Hildebrand et al., 2013), women who reported walking at an average pace (approximately 3 miles/h or 20 min/mile) for an hour per day as their only form of recreational activity had 14% lower breast cancer risk compared to inactive women; this finding is consistent with associations previously reported for other types of moderate-intensity activity. However, vigorous-intensity physical activity appears to be associated with a greater breast cancer risk reduction (approximately 20% lower risk) than moderate-intensity physical activity (approximately 15% lower risk) when examining the "highest" versus "lowest" level of each activity intensity.

A recent meta-analysis (Schmid et al., 2015) including more than 30 observational studies examined the association between physical activity and endometrial cancer risk and found a 20% lower risk in the "highest" compared to the "lowest" physical activity category (95% CI 0.75, 0.85). Few studies have examined associations separately for moderate- and vigorous-intensity activity, but 10 studies have previously examined walking in relation to endometrial cancer risk. Across these studies, regular walking was associated with 18% lower risk of endometrial cancer (RR = 0.82, 95% CI 0.69, 0.97) compared to inactivity (Schmid et al., 2015). Limited evidence also suggests that physical activity may be more strongly associated with endometrial cancer risk in overweight or obese women compared to normal weight women.

As previously described, the largest study to date on physical activity and cancer was published in 2016 and harmonized data from 12 prospective cohort studies to evaluate the associations between the top and bottom 10% activity levels (Moore et al., 2016). The strongest association between physical activity and cancer was observed for esophageal adenocarcinoma (RR = 0.58, 95% CI 0.37–0.89), a finding largely supported by a recent meta-analysis including 24 studies which reported an inverse association with lesser magnitude (RR = 0.79, 95% CI 0.66–0.94) when examining the "highest" versus the "lowest" activity level in each study (Behrens et al., 2014). In both the pooled analysis (RR = 0.80, 95% CI 0.61–1.06) and meta-analysis (RR = 0.94, 95% CI 0.41–2.16), there was no evidence of an association between physical activity and squamous esophageal cancer.

An inverse association was also observed in the pooled analysis between physical activity and cancer of the gastric cardia (RR = 0.78, 95% CI 0.64–0.95) which was very similar to a recent large meta-analysis including 22 studies examining the "highest" versus "lowest" physical activity level (RR = 0.84, 95% CI 0.73–0.96) (Psaltopoulou et al., 2016). Associations between physical activity and bladder cancer were also similar between the pooled analysis (RR = 0.87, 95% CI 0.82–0.92) and a recent meta-analysis of 15 observational studies (RR = 0.85, 95% CI 0.74–0.98) (Keimling et al., 2014). Conversely, a different meta-analysis including 22 observational studies reported a modest inverse association between "highest" versus "lowest" level of physical activity in relation to pancreatic cancer risk (RR0.93, 95% CI 0.88–0.98) (Behrens et al., 2015), conflicting with the large pooled analysis which concluded physical activity was not associated with pancreatic cancer risk (RR = 0.95, 95% CI 0.83–1.08).

Based on a recent meta-analysis of 15 observational studies which examined the association between physical activity and various types of hematopoietic malignancies, physical activity was modestly but nonstatistically significantly associated with non-Hodgkin lymphoma (RR = 0.91, 95% CI 0.82–1.00) (Jochem et al., 2014). This finding was nearly identical to that reported in the large pooled analysis (RR = 0.91, 95% CI 0.83–1.00). The hematopoietic malignancies meta-analysis also concluded that physical activity was not associated with myeloid leukemia (RR = 0.97, 95% CI 0.84–1.13) or myeloma (RR = 0.86, 95% CI 0.68–1.09). In contrast, the large pooled analysis found that physical activity was inversely associated with both myeloid leukemia (RR = 0.80, 95% CI 0.70–0.92) and myeloma (RR = 0.83, 95% CI 0.72–0.95).

The reported associations between physical activity and lung cancer are also contradictory, largely due to differences in adjustment for residual confounding by smoking. One meta-analysis of 28 studies found a strong inverse association between physical activity and lung cancer risk (Brenner et al., 2016) in which "highest" versus "lowest" level of physical activity was associated with 24% lower lung cancer risk (95% CI 0.69–0.85). A significant limitation of this and other previous studies is the lack of stratification by smoking status. Individuals who smoke cigarettes are far less likely to be physically active, and even when active, they are likely less active than nonsmokers. Thus, the association of physical activity and lung cancer risk is likely significantly confounded by smoking. It is further possible that heavy smokers have impaired lung function resulting in inactivity which would lead to reverse causality. When stratifying on smoking status, an inverse association between physical activity and lung cancer risk was only evident among current (RR 0.77, 95% CI 0.72–0.83) and former (RR 0.77, 95% CI 0.71–0.90) smokers, while no association was observed among never smokers (RR = 0.96, 95% CI 0.79–1.18). Similarly, while an inverse association between physical activity and lung cancer was observed in the overall large pooled study population (RR = 0.74, 95% CI 0.71–0.77), the association was null among never smokers. Thus, the current evidence does not support an association between physical activity and lung cancer when smoking is appropriately accounted for.

A recent meta-analysis of 19 studies (Liu et al., 2011) found a modest, yet statistically significant, 10% lower risk for prostate cancer among the most physically active compared to the least active men. Because physically active men are also more likely to be screened for prostate cancer, it is possible that the association with non-advanced and advanced prostate cancer may differ (Patel et al., 2005). A subset of studies included in the meta-analysis examined aggressive and nonaggressive prostate cancer separately and found a stronger association of physical activity with aggressive (RR = 0.89, 95% CI 0.71–1.12) compared to nonaggressive prostate cancer (RR = 0.98, 95% CI 0.79–1.21). In contrast to the meta-analysis, the large pooled analysis by Moore et al. (2016) found a modest positive association between physical activity and prostate cancer overall (RR = 1.05, 95% CI 1.03–1.08), and further found that the association was driven by non-advanced prostate cancer (RR = 1.08, 95% CI 1.03–1.12), as no association was observed for advanced prostate cancer (RR = 0.99, 95% CI 0.88–1.10). Thus, evidence to date supports that physical activity is unlikely to lower risk of non-advanced prostate cancer, but may offer some benefit to more advanced disease.

In summary, as demonstrated by previous meta-analyses and large pooled analyses, there is ample evidence to support associations of physical activity and lower cancer risk. Evidence is strong for the benefits of physical activity in the prevention of colon, postmenopausal breast, and endometrial cancer. Evidence is growing to support the broader benefit of engaging in physical activity in the prevention of many other types of cancer.

Sedentary Time and Cancer Risk

Numerous studies have shown that prolonged time spent sitting (total, television viewing, leisure-time) is associated with total mortality independent of physical inactivity (Matthews et al., 2012a; Ekelund et al., 2016; Chau et al., 2013; Patel et al., 2010). In one large meta-analysis that included 13 studies, most of which were prospective cohorts (Biswas et al., 2015), prolonged sitting was associated with 24% higher mortality risk after taking physical activity into account (95% CI 1.09–1.41). Included in this meta-analysis was a review of the seven studies to date that have specifically examined leisure-time sitting in relation to cancer mortality (Biswas et al., 2015). The summary risk estimate was not as strong as total mortality, but prolonged sitting was statistically significantly associated with cancer mortality (RR = 1.16, 95% CI 1.10–1.22). In the large prospective NIH-AARP Diet and Health Study, both men and women who spent 7 or more hours per day watching television had 22% higher risk of dying from cancer compared to those who watched <1 h of television/day (95% CI 1.06–1.40) suggesting that associations with sitting while watching television may be more strongly associated with health than measures of overall sitting time (Matthews et al., 2012a).

While extensive research supports the role of physical activity in cancer prevention, far fewer studies have examined associations between sitting time and site-specific cancer incidence. A 2013 meta-analysis including 43 observational studies examined the associations between total sedentary time and television viewing in relation to cancer risk across various sites (Schmid and Leitzmann, 2014). The "highest" versus "lowest" level of television viewing time was associated with higher risk of colon cancer (RR = 1.54, 95% CI 1.19–1.98) and endometrial cancer (RR = 1.66, 95% CI 1.21–2.28). Although TV viewing time is often used as a proxy for measuring sedentary behavior, outcomes appear to be more strongly associated with TV viewing than with total sedentary time in most studies. It is not yet clear whether television viewing time is simply measured with greater precision compared to overall sitting, or if this is due to effect modification by unhealthy behaviors which may be concurrent with or promoted by television watching, such as excess snacking. Accordingly, the 2013 meta-analysis found that total sitting time was associated with 24% increased risk of colon cancer (RR = 1.24, 95% CI 1.09–1.41) and 21% increased risk of endometrial cancer (RR = 1.21, 95% CI 1.03–1.43). The same study additionally found a positive association between occupational sitting time and colon cancer (RR = 1.24, 95% CI 1.03–1.50) but not endometrial cancer (RR = 1.11, 95% CI 0.88–1.39). While there is evidence to support an association between sedentary time and endometrial cancer risk, some previous studies have shown that the association is largely attenuated after adjusting for body mass index (BMI) (Friberg et al., 2006; Gierach et al., 2009; Patel et al., 2015) suggesting that the association between sitting time and endometrial cancer incidence might be confounded or mediated by BMI.

Following this meta-analysis, one study comprehensively examined leisure-time spent sitting in relation to total and site-specific cancer incidence and found marked sex-specific differences. Women who reported sitting for more than 6 versus fewer than 3 h/day during their leisure-time had a 10% higher risk of all cancers combined (Patel et al., 2015). However, authors found that the overall association in women was driven by site-specific associations with invasive breast cancer (RR = 1.10, 95% CI 1.00, 1.21), ovarian cancer (RR = 1.43, 95% CI 1.10, 1.87), and multiple myeloma (RR = 1.65, 95% CI 1.07–2.54). Other prospective studies have similarly reported a modest higher risk with total sitting time (George et al., 2010) in relation to invasive breast cancer. Additionally, one case-control study (Zhang et al., 2004) reported a higher risk between leisure-time sitting and ovarian cancer, although it is worth noting that other studies examining domain-specific sitting time (not including leisure-time) were null (Xiao et al., 2013; Dosemeci et al., 1993).

On the contrary, leisure-time sitting was not associated with overall cancer risk in men, although among obese men there was an 11% higher risk associated with high levels of sitting time. Two prospective cohort studies have also reported an inverse association with total prostate cancer; however, there was no dose–response and results were attenuated when restricted to advanced disease (Patel et al., 2015; Lynch et al., 2014). A statistically significant association with multiple myeloma and borderline associations with head and neck and gallbladder cancer in men and women, esophageal cancer in women, and pancreatic cancer in men have also been documented (Patel et al., 2015). In general, physical activities of a moderate- to vigorous-intensity, BMI, and age have not been shown to modify associations of sitting time with cancer risk, with the exception of endometrial cancer.

The previously described meta-analysis by Schmid and Leitzmann (2014) concluded that sedentary behavior was unrelated to all other cancers examined including: breast, rectum, ovary, prostate, stomach, esophagus, testes, renal cell, and non-Hodgkin lymphoma. However, the evidence was limited for most individual cancer sites, and aggregated studies often examined different domains of sitting time (e.g., occupational, total, leisure-time, television time). Thus, the evidence is still emerging and data are likely too sparse to draw strong conclusions for an association between sedentary behavior and most site-specific cancers.

Prospective Vision (Future Directions)

While there is substantial evidence to support that physical activity is beneficial in the prevention of various types of cancer, there are numerous gaps in the evidence that warrant further research. The dose–response relationship between moderate- and/or

vigorous-intensity physical activity or sitting time in relation to cancer risk is not well known. While the association between physical activity and overall longevity has been well-characterized (Arem et al., 2015), the early evidence suggests that the association between physical activity and cancer incidence may be linear (Moore et al., 2016). Furthermore, some studies suggest that a greater dose of physical activity may be necessary for cancer prevention (Hildebrand et al., 2013). Future studies should aim to better understand this dose–response relationship as the nature of that relationship will inform public health recommendations for cancer prevention.

As previously described, early evidence suggests that certain types of physical activity, such as walking, and certain sedentary behaviors, such as television viewing, may be individually associated with cancer incidence, but additional research is needed. Walking is free, does not require special training or equipment, and can be done almost anywhere making it the most common moderate-intensity physical activity (U.S. Department of Health and Human Services, 2015). Thus, better understanding the cancer prevention value of walking can have tremendous value in helping to increase population physical activity levels. Similarly, there is a paucity of research on light-intensity physical activities, such as shopping, housework, and gardening, in relation to cancer risk. As television viewing is the most common leisure-time activity, it is important to understand if there are specific greater harms associated with sitting while watching television versus other types of sitting. More broadly, improving our understanding of the underlying biologic mechanisms for both physical activity and sedentary time in relation to cancer risk are necessary.

Fewer studies have examined whether physical activity and cancer associations are modified by other factors such as race, BMI, or family history of cancer. For some cancer sites, understanding whether associations differ by molecular (e.g., by hormone receptor status in breast cancer) or histologic (e.g., different subtypes of non-Hodgkin lymphoma such as diffuse large B-cell or follicular lymphoma) subtypes or subsite of disease (such as distal versus proximal colon) is also necessary. As these subgroup findings have varied in some previous studies, but not others, an improved understanding of associations across population subgroups will shed light on biologic pathways and further enhance cancer prevention messaging.

There is also a need to improve physical activity measurement. Most observational studies rely on self-reported data captured by questionnaires, which are easy to administer and inexpensive, but are prone to a greater amount of misclassification than more objective measures. Over the past several years, automated methods of capturing physical activity behaviors, such as internet-based tools, have been implemented (Matthews et al., 2012b). These tools have proven to be more valid than questionnaires with regard to measuring sitting time, intensity of different activities, and the context and domains of physical activity (Matthews et al., 2013; Gomersall et al., 2011). Evaluating the feasibility of integrating research-grade accelerometers or commercial monitors (such as Fitbit or Garmin™) in large-scale epidemiologic studies is also of potential value. Certain commercial devices have been shown to be more valid than survey-based physical activity assessment and of similar validity to research-grade devices (Evenson et al., 2015), and given the wide-scale uptake of commercially available devices in the consumer market, they offer potential for improved physical activity data collection.

Pituitary Tumors: Pathology and Genetics

Stefano La Rosa, Institute of Pathology, Lausanne University Hospital, Lausanne, Switzerland
Silvia Uccella, University of Insubria, Varese, Italy

Abbreviations

ACTH Adrenocorticotropic hormone
CDX-2 Caudal type homeobox-2
CRH Corticotropin releasing hormone
FSH Follicle-stimulating hormone
GH Growth hormone
GHRH Growth hormone releasing hormone
GnRHR Gonadotropin-releasing hormone
LH Luteinizing hormone
MSH Melanocyte stimulating hormone
PRL Prolactin
SSRT2A Somatostatin receptor 2A
TRHR Thyrotropin releasing hormone
TSH Thyroid-stimulating hormone
TTF-1 Thyroid transcription factor-1

Epidemiology

Pituitary tumors account for up to 16% of all primary brain neoplasms and are the third most common intracranial tumor after gliomas and meningiomas, both in adults and in the pediatric age. The overall age-adjusted incidence rate of pituitary tumors has been reported by the Central Brain Tumor Registry of the United States (CBTRUS) as 2.94 cases per 100,000 persons between 2009 and 2013. In the last two decades the incidence has risen consistently, due to improvements in diagnostic technology that have increased sensitivity for detecting pituitary tumors. In addition, the greater use of imaging, particularly for indications such as sinusitis, trauma, and headache, has probably led to the increased detection of incidental pituitary tumors.

The risk of developing a pituitary tumor increases with age, with a peak incidence between 65 and 74 years, and is slightly higher in females, with a male/female ratio of 0.84. The male/female incidence rate ratio was 0.87, with incidence peaks in females at ages 30–34 and 70–74 years. In males, one large incidence peak at ages 75–79 years was found. The difference between sexes seems to be due to lactotroph adenoma, the most commonly diagnosed pituitary tumor, which occurs more frequently in women than in men and at earlier ages in women than in men. Lactotroph adenomas tend to present earlier in females because of an increased symptom burden from hyperprolactinemia, such as a galactorrhoea and disruption in the menstrual period. Among the various ethnicities, pituitary tumors are more frequent in black and Hispanic populations.

More than 90% of pituitary tumors have a benign behavior and are classified as pituitary adenomas. Pituitary carcinomas are very rare, accounting for only 0.12% of all pituitary tumors. Other rare tumors of the sellar region include craniopharyngioma, neuronal and paraneuronal tumors, tumors of the posterior pituitary, mesenchymal and stromal tumors, hematolymphoid tumors, germ cell tumors, and secondary neoplasms.

Classification

Pituitary tumors include a wide range of different neoplastic proliferations showing different morphological, immunohistochemical, molecular, clinical, and prognostic features. They can originate either in the anterior (adenohypophysis) or posterior (neurohypophysis) pituitary.

Most tumors arising in the *adenohypophysis* are adenomas; these show variable clinical behavior ranging from an incidentally detected small indolent clinically nonfunctioning tumor, to a biochemically active sellar mass giving rise to an endocrine syndrome, to rapidly growing large tumor invading adjacent structures with a high risk of local recurrence and causing visual disturbance and headache. Carcinomas are very rare neoplasms which can metastasize and have poor prognosis. Clinically, both adenomas and carcinomas can be either functioning (associated with specific symptoms related to hormone hypersecretion) or silent (lacking hormonal symptoms). Silent (or nonfunctioning) adenomas are usually larger and are more frequently associated with symptoms related to local growth, such as visual abnormalities and headache.

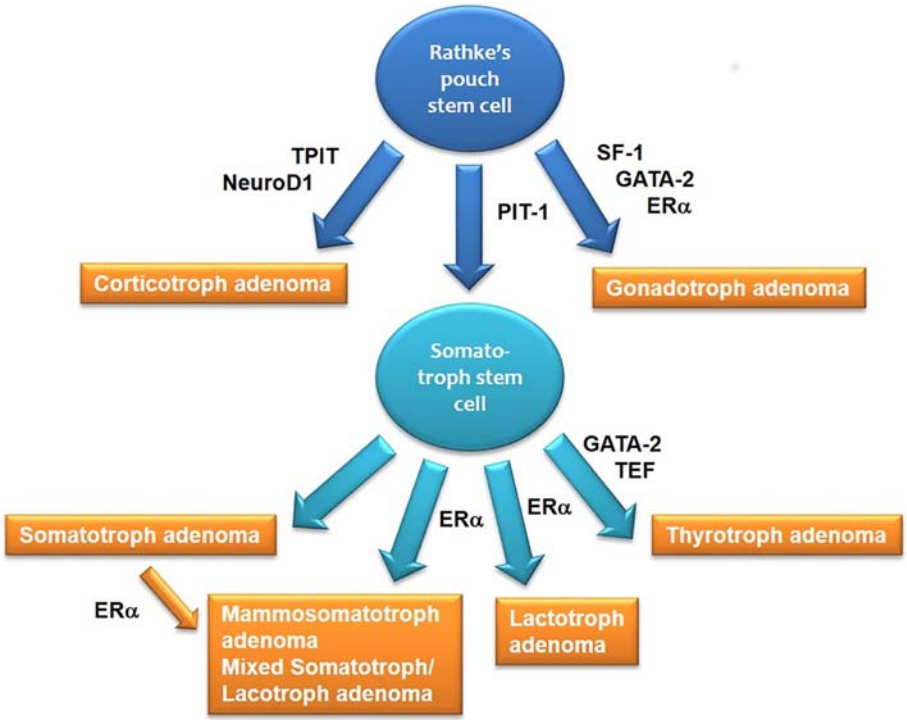

Fig. 1 Transcription factor-related pituitary cell differentiation and related pituitary adenomas.

The current classification of pituitary adenomas is mainly based on pituitary-cell lineage, which is characterized by expression of specific transcription factors involved in the differentiation of anterior pituitary cells (Fig. 1). Consequently, immunohistochemical staining to identify expression of such transcription factors, as well as of secreted hormones in tumor cells, is the basis of the current classification of pituitary tumors (Table 1). In addition, other immunohistochemical markers, including cytokeratins, are useful in identifying specific clinically relevant subtypes.

Tumors of the *neurohypophysis* are a heterogeneous group of low-grade neoplasms believed to derive from pituicytes and include pituicytoma and its variants: granular cell tumor of the sellar region, spindle cell oncocytoma, and sellar ependymoma.

In addition to tumors originating from pituitary cells, either of the anterior or posterior part of the gland, very rare neuronal, paraneuronal, and mesenchymal neoplasms can be observed in the pituitary glands.

Table 1 Classification of anterior pituitary adenomas

Cell type	*TS*	*Hormone*	*Tumor type(s)*
Corticotroph	TPIT Naro D1	ACTH, β-endorphin, MSH	DG corticotroph adenoma SG corticotroph adenoma Crooke cell adenoma
Somatotroph	PIT-1	GH	DG somatotroph adenoma SG somatotroph adenoma
Mammosomatotroph	PIT-1, ERα	GH, PRL	Mammosomatotroph adenoma Mixed somatotroph/lactotroph adenoma
Lactotroph	PIT-1, ERα	PRL	SG lactotroph adenoma DG lactotroph adenoma Acidophil stem cell adenoma
Thyrotroph	PIT-1, TEF, GATA-2	TSH	Thyrotroph adenoma Silent subtype 3 adenoma
Gonadotroph	SF-1, ERα, GATA-2	FSH, LH	Gonadotroph adenoma
Null cells	None	None	Null cell adenoma

TS, transcription factor; *DG*, densely granulated; *SG*, sparsely granulated.

Tumors of the Adenohypophysis

Pituitary Adenoma

Pathogenesis

Sporadic pituitary adenomas

Pituitary adenomas, regardless of cell type, are benign. Moreover, although they may invade parasellar structures, an overt malignant phenotype with documented extracranial metastases has never been reported. It is well established that pituitary adenomas are monoclonal proliferations which makes it unlikely that they are arisen in hyperplastic lesions as a consequence of hormonal signals, such as hypothalamic hormone excess or estrogen excess. This notion is supported by the absence of features of hyperplasia of the pituitary tissue surrounding the adenoma, and of activating mutations of hypothalamic hormone receptors in pituitary adenomas (GHRHR, CRHR, GnRHR, TRHR), as well as of inactivating mutations of hypothalamic inhibitory factor receptors (SSTR1–5; D2R).

Despite their benign phenotype, pituitary adenomas are remarkably aneuploid as a consequence of marked chromosomal instability, leading to both dysregulated hormone gene transcription and cell proliferative activity. On the other hand, mutational events implicated in pituitary tumorigenesis are few and apply to specific adenoma subtypes. The common mutations associated with neoplastic transformation, including activation of *RAS* or *BRAF* genes and loss of the tumor suppressor *TP53* or *RB1* genes, are not found in pituitary adenomas and have only been rarely reported in pituitary carcinomas. However, several growth factors, hormones and cell cycle genes have a pivotal role in the development of these neoplasms.

Cell cycle regulators

Heterozygote Rb+/− mutant mice develop pituitary adenomas with high penetrance, usually arising from the intermediate lobe. Although Rb is expressed (i.e., not mutated) in most nonfunctioning (silent) pituitary adenomas, approximately 25% of somatotroph adenomas show hypermethylation of the *RB* gene promoter with associated loss of expression. Rb activity is regulated by cyclin-dependent kinases (CDKs), which are, in turn, under the control of specific CDK inhibitors. In pituitary adenomas, inactivation of one or more of the members of two families of CDK inhibitors—the INK4a/ARF (p16, p15, p18) and cip/kip inhibitors (p21, p27, p57)—is involved in tumorigenesis. For example, the gene that encodes p16, which normally inhibits Rb phosphorylation and inactivation by CDK4, is hypermethylated and transcriptionally silent in some human pituitary tumors. In mice, deletion of p18 leads to gigantism, organomegaly, and pituitary intermediate lobe hyperplasia and adenomas; p18 protein levels are also attenuated in human adenomas. In a mouse model, disruption of the gene that encodes p27 results in mice with increased body weight, organ hyperplasia and intermediate pituitary lobe tumors. Furthermore, loss of p27 cooperates with overexpression of cyclin E to facilitate corticotroph tumorigenesis.

Another cell cycle regulator, encoded by the pituitary tumor transforming gene 1 (PTTG1), controls correct separation of sister chromatids. PTTG1 is a mammalian securin, and its overexpression causes cell transformation in vitro. Pituitary-directed PTTG1 overexpression in transgenic mice results in focal pituitary hyperplasia and adenoma development. Maintenance of chromosomal stability requires tight control of intracellular cell-cycle dependent PTTG1 levels, as either PTTG1 overexpression or disruption results in dysregulated G2 to M phase cell cycling, aneuploidy and chromosomal instability in vitro and in transgenic mouse models.

Defective signaling pathways

The G protein α (Gα) subunit, encoded by *GNAS* located on chromosome 20q13.2, is a key component of signal transduction pathways. The GTPase function of the Gα subunit is inactivated by *GNAS* mutation, commonly known as *gsp* mutation, which is present in about 30% of somatotroph adenomas, and results in elevated cAMP levels and hypersecretion of GH. Thus, constitutively induced somatotroph proliferation and GH secretion may occur independently of GH releasing hormone, and may also be associated with activation of downstream signaling factors. An endocrine hypersecretory syndrome (McCune–Albright syndrome), which includes pigmented skin lesions, precocious puberty, hyperthyroidism, acromegaly and/or Cushing syndrome with fibrous dysplasia of bone, is associated with a *gsp* mutation. The syndrome is not inherited as it is due to an early postzygotic *gsp* mutation, which results in mosaicism and constitutively active Gα subunit and cAMP activation in the affected cells. Patients with McCune–Albright syndrome usually exhibit selective pituitary hyperplasia, rather than focal adenomas. Furthermore, *gsp* mutation has also been described in the transition of an aggressive lactotroph adenoma to a somatotroph adenoma.

Several growth factors and their receptors, including selective members of the fibroblast growth factor, epidermal growth factor, nerve growth factor, bone morphogenetic protein and vascular endothelial growth factor families, and Akt signaling pathways, have been implicated in the pituitary tumorigenic cascade. Wnt pathway inhibitors are also differentially expressed in pituitary adenomas in comparison to normal pituitary tissue. Fibroblast growth factor receptor variants may underlie disrupted chromatin access and interfere with cell adhesion molecules in pituitary adenomas. Bone morphogenetic protein 4, which normally acts as a suppressor of corticotroph adenoma growth, is abundantly expressed in lactotroph adenomas. Disruption of other signaling molecules associated with pituitary tumorigenesis includes transforming growth factor β and gp130 cytokines. Studies in estrogen receptor β null mice have highlighted the requirement of estrogen receptor α for gonadotroph adenoma development. In fact, estrogen receptor α seems to be more abundantly expressed in large than small pituitary tumors.

Transcriptional regulators

In transgenic mice, overexpression of an HMGA2 protein results in both somatotroph and lactotroph pituitary adenoma formation, which appears to be mediated by enhanced E2F action. In humans, re-arrangement and amplification of *HMGA2* gene expression seems to occur predominantly in lactotroph adenomas, and HMGA2 mRNA abundance correlates with pituitary tumor size and proliferation markers. These tumor growth effects may result from *CCNB2* promoter induction, resulting in enhanced cyclin B2 levels and subsequent activation of the E2F transcription factor.

Expression of several putative pituitary-selective tumor suppressor genes have been shown to be lost or downregulated in adenomas in comparison to normal pituitary tissue. Several of these factors are inactivated by epigenetic mechanisms, which involve Runt-related transcription factor 1, which upregulates galectin-3, a pituitary tumor marker. Expression of the zinc finger protein PLAGL1, a transcriptional coregulator, appears to be lost in a subset of pituitary tumors and somatostatin analogs may in fact mediate anti-proliferative actions through PLAGL1. GADD45-γ and maternally imprinted MEG3 have been identified as pituitary-derived suppressor genes, and are silenced by methylation mechanisms especially in nonfunctioning pituitary tumors. A dominant negative isoform of the DNA-binding protein Ikaros is present in almost half of all pituitary adenomas and this molecule has been shown to regulate pituitary tumor cell chromatin remodeling and cell survival. Ikaros also activates the POMC promoter and may serve as a systemic integrator of hypothalamic–pituitary signaling.

Pituitary tumor microRNAs

The pathogenetic role of miRNAs and their target genes in the pathogenesis of pituitary adenomas remains largely unknown; however, the altered expression of some miRNAs has been associated with tumor diameter, invasiveness, and therapy efficacy. For example, miR-15a and miR-16-1, located in a region which is frequently deleted in pituitary tumors, were reported to have lower expression in somatotroph and lactotroph adenomas than in normal tissue. Moreover, each subtype of pituitary adenoma tends to be characterized by a specific miRNA profile. In corticotroph tumors miR21, miR15 and miR16 are downregulated, while miR122 and mi493 are upregulated in ACTH-expressing carcinomas. Suppression of let-7 miRNA family members, as well as of miR15a/miR16, is conserved across most pituitary tumor subtypes. In nonfunctioning and in somatotroph adenomas, Wee1-like protein kinase, which acts as a tumor suppressor protein, was shown to be regulated by miR128a, miR155 and miR516a-3p.93. MiR-126 and miR-381 have PTTG1 as a target and were shown to be downregulated in GH-secreting pituitary adenomas.

Familial pituitary adenomas

Multiple endocrine neoplasia type 1(MEN1) syndrome

MEN1 syndrome is an autosomal dominant disease with high penetrance characterized by the occurrence of multiple endocrine proliferations: pituitary adenomas, parathyroid hyperplasia, and pancreatic neuroendocrine tumors. It is caused by one of hundreds of inactivating mutations of the *MEN1* gene, which acts as a tumor suppressor gene. Pituitary tumors may include lactotroph, somatotroph, corticotroph and, very rarely, thyrotroph adenomas. MEN1 affects both sexes equally but the pituitary manifestations have a female preponderance.

Multiple endocrine neoplasia type 4 (MEN4) syndrome

Multiple endocrine neoplasia type 4 (MEN4) syndrome is the latest member to join the family of MEN syndromes. It has been defined as a *MEN1* mutations-negative MEN1-like syndrome, with a *CDKN1B* germline mutation. This syndrome may present with somatotroph or corticotroph adenomas. Evidence suggests that p27, encoded by *CDKN1B*, is a tissue-specific target for both the tumor suppressor menin and RET proto-oncogene-mediated cell proliferative signaling. As increasing numbers of *CDK* inhibitor mutations are being identified, it is conceivable that specific clinical phenotypes of these syndromes will become clearer in the future.

Carney syndrome

This autosomal dominant disorder is caused by activated protein kinase A activity, due largely to a *PRKAR1A* mutation on chromosome 17q22–24, and comprises spotty skin pigmentation, myxomas, testicular tumors, and adrenal and/or pituitary adenomas or hyperplasia.

Familial isolated pituitary adenoma (FIPA)

FIPA syndrome is defined as a familial presentation of any type of pituitary adenoma in the absence of clinical and genetic evidence for MEN1 and Carney complex. It represents about 2% of all pituitary adenomas. Genealogical information suggests that FIPA is inherited in an autosomal dominant pattern with variable penetrance. Based on the tumor phenotype in the individual families, FIPA can be divided into two almost equal subgroups: *homogeneous*, when all affected family members experience the same adenoma type, and *heterogeneous*, with different pituitary tumors within the family. Lactotroph and somatotroph adenomas comprise more than 70% of all cases, and although all types of tumors can be seen in heterogeneous FIPA, there is at least one prolactin- or growth hormone-secreting adenoma in almost all affected families. Females tend to be more frequently affected (62%). Gonadotroph, corticotroph, and thyrotroph adenomas are rare and account for 4%, 4%, and 1% of FIPA tumors, respectively. They are usually associated with other adenoma types in heterogeneous families, although individual families with a homogeneous presentation have been reported. Germline mutations in the aryl-hydrocarbon interacting protein gene are identified in

around 25% of familial isolated pituitary adenoma kindreds. Tumors associated with *AIP* mutations are large and generally diagnosed by the age of 25 years and hence patients present with gigantism.

McCune–Albright syndrome

McCune–Albright syndrome is a rare disorder associated with early embryonic postzygotic somatic activating mutations in the *GNAS1* gene. The disorder is characterized clinically by the classic triad of polyostotic fibrous dysplasia (POFD), cafe-au-lait skin pigmentation, and peripheral precocious puberty. However, the disorder is clinically heterogeneous and can include various other endocrinological anomalies such as thyrotoxicosis due to nodular or diffuse goiter, pituitary gigantism or hyperprolactinemia due to pituitary adenoma, and adrenal Cushing syndrome due to nodular adrenal hyperplasia.

Hereditary pheochromocytoma and paraganglioma syndrome

Individuals with this syndrome, associated with succinate dehydrogenase (*SDH*) genes, can also rarely be affected by pituitary adenomas in which the same SDHX mutation is detected.

X-linked acrogigantism (XLAG)

X-linked acrogigantism (XLAG) syndrome is a recently characterized genomic form of pediatric gigantism due to aggressive pituitary tumors, caused by submicroscopic chromosome Xq26.3 duplications that include the *GPR101* gene. Affected patients generally have a normal size at birth after unremarkable pregnancy, and develop mixed growth hormone (GH)- and prolactin-secreting pituitary hyperplasia and/or adenomas within the first 12–36 months of life.

Morphology and immunophenotype

Pituitary adenomas are neoplastic proliferations derived from adenohypophyseal cells. As such, they are composed of epithelial cells with neuroendocrine differentiation and must be distinguished from pituitary hyperplasia. For correct classification, the cell lineage population responsible for the proliferation must be established. Finally, a number of morphological, prognostic and predictive parameters have to be identified.

Hyperplasia may be clinically indistinguishable from adenoma, usually in patients with acromegaly or Cushing's disease, and radiological examination may also not be particularly informative. For microscopic evaluation, reticulin stain is very useful in distinguishing pituitary adenoma from pituitary hyperplasia or normal pituitary tissue. The normal adenohypophysis is composed of small acini of pituitary cells surrounded by a network of reticulin fibers. In hyperplasia, the acinar architecture is maintained and the reticulin network is preserved, but the acini are larger in size. In contrast, pituitary adenomas are characterized by complete disruption of the reticulin fiber network. Pituitary adenomas share morphological features with other well differentiated neuroendocrine proliferations: the cells show granular cytoplasm and round nuclei with finely dispersed chromatin. They generally express both general neuroendocrine markers (synaptophysin, chromogranin) and cytokeratins. However, they may present with a wide range of morphological features depending on their hormonal subtype or associated gene abnormalities, or as a result of a treatment effect. Although benign, pituitary adenomas can be locally invasive, with involvement of the adjacent vascular and bony structures.

The 2017 WHO classification of pituitary tumors is based on the recognition of the adenohypophyseal cell lineage composing the various adenomas, with subclassification of histological variants according to hormone content and specific histological and immunohistochemical features (see section "**Classification**"). Consequently, this new classification approach utilizes immunohistochemistry as the main ancillary tool for diagnosis, leaving the need for ultrastructural analysis only to very rare and unusual instances. Immunohistochemistry for the following general neuroendocrine markers and hormones is routinely performed: synaptophysin, chromogranin A, GH, PRL, ACTH, beta subunits of TSH, FSH and LH, and alpha subunit. In addition, immunohistochemistry for transcription factors, including PIT1, SF1 and TPIT is recommended even though the necessary antibodies are not generally available and their diagnostic value is still under investigation. Immunoreactivity for low molecular weight cytokeratin (CK 7/8 and/or CK 18) may be useful in evaluating specific types of adenomas. For example, it can help to discriminate between sparsely granulated and densely granulated somatotroph adenomas: dot like or globular staining corresponds to the fibrous bodies seen ultrastructurally in sparsely granulated somatotroph adenomas. MIB-1 antibody is used to establish Ki67-based proliferative index, which should always be reported, as it represents a relevant prognostic indicator in individual adenomas. The prognostic value of p53 expression is still under discussion, whereas useful predictive immunohistochemical markers are the somatostatin receptors 2 and 5 (SSTR2 and SSTR5), methyl-guanine methyl transferase (MGMT), and MSH6.

Somatotroph adenoma

Somatotroph adenoma is a pituitary adenoma, arising from PIT1-lineage cells, which expresses and secretes GH and clinically associated with gigantism and/or acromegaly. Somatotroph adenomas represent about 10%–15% of all pituitary adenomas, do not show sex predilection, and can occur at any age, with a mean age at diagnosis of 47 years. Most cases are endocrinologically symptomatic, even if rare silent (nonfunctioning) cases have been reported. Some tumors can co-secrete GH and PRL, resulting in acromegaly and/or gigantism associated with amenorrhoea and galactorrhoea. At radiological investigation, somatotroph adenomas are generally clearly visible and most of them are macroadenomas (1–4 cm).

All somatotroph adenomas show nuclear expression of PIT-1. On the basis of the density of GH-containing secretory granules and of their low-molecular-weight cytokeratin expression, pure GH-producing somatotroph adenomas are divided in two clinically

different subtypes: densely granulated (DG) somatotroph adenomas and sparsely granulated (SG) somatotroph adenomas. In addition, cases co-expressing PRL can be divided into three different categories: mammosomatotroph adenomas, mixed somatotroph and lactotroph adenomas, and plurihormonal adenomas. The distinction of these different subtypes is of clinical importance since they respond differently to available therapies.

- *DG somatotroph adenomas* are acidophilic tumors (Fig. 2A) with a trabecular, sinusoidal, or diffuse histological pattern. They show nuclear immunoreactivity for PIT-1, diffuse and strong cytoplasmic positivity for GH (Fig. 2B), and are also positive for α-subunit of glycoprotein hormones. Low-molecular-weight cytokeratin expression shows a perinuclear distribution.
- *SG somatotroph adenomas* are larger and more invasive tumors, showing a more aggressive behavior than the DG variant. These particular macroscopic and clinical features seem to be related to the delay of diagnosis due to the lower GH levels, with as a consequence a less conspicuous endocrine syndrome. Tumor cells grow in a solid fashion, are chromophobe (Fig. 2C) and show considerable nuclear and cellular pleomorphism. Although nuclear PIT-1 immunoreactivity is strong, GH expression is usually faint and focal. PRL and α-subunit are usually not expressed. The most characteristic feature of these tumors is juxtanuclear globular positivity for low-molecular-weight cytokeratins (fibrous bodies) (Fig. 2D).
- *Mammosomatotroph adenomas* are plurihormonal tumors in which the same neoplastic cells produce GH, PRL, and α-subunit (Fig. 3). They are usually strongly acidophilic tumors that resemble DG somatotroph adenomas with intense nuclear staining for PIT-1 and cytoplasmic positivity for estrogen receptors and GH, variable immunoreactivity for PRL, α-subunit, and a predominant perinuclear pattern of staining for low-molecular-weight cytokeratins. Occasionally they may also produce β-TSH and can be associated with hyperthyroidism and goiter.
- *Mixed somatotroph–lactotroph adenomas* are bihormonal tumors which, instead of being composed of a monomorphous population of GH and PRL producing cells, are composed of two distinct mature GH and PRL cells (Fig. 3). The most common association is DG somatotrophs and SG lactotrophs, but other combinations can be seen.

Most somatotroph adenomas are sporadic, but some cases are associated with a genetic predisposition, either as part of a syndromic disease or as an isolated pituitary disease. Somatotroph adenomas have been described in the context of MEN1, SDH-related familial paraganglioma syndromes, Carney complex, McCune–Albright syndrome, neurofibromatosis type 1, familial isolated pituitary adenoma, and X-linked acrogigantism syndrome.

Surgery is the first treatment choice, although it may not be curative in macroadenomas with extrasellar extension and invasion of the cavernous sinus. Risk stratification of patients is based on different parameters, including histologic subtype, Ki67 proliferative index and invasiveness. Somatostatin antagonists can be used, although they are less active on SG adenomas.

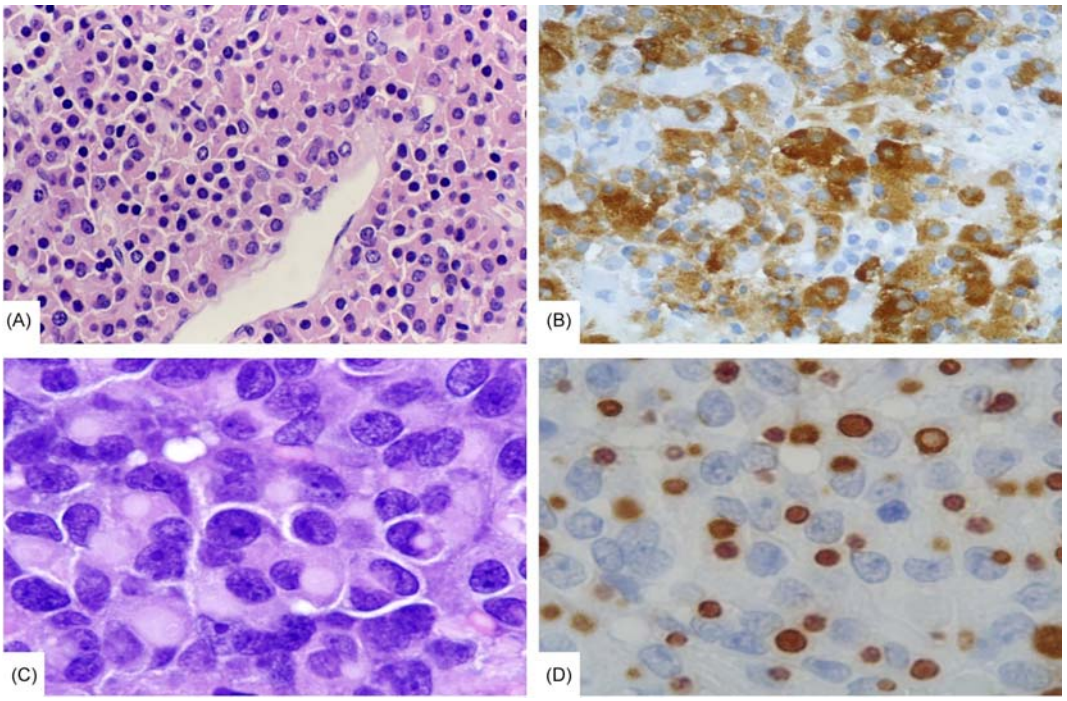

Fig. 2 Somatotroph adenomas: densely granulated somatotroph adenoma is composed of eosinophilic cells growing in a diffuse pattern (A), with intense expression of GH (B). Sparsely granulated somatotroph adenoma shows chromophobe cells with a juxta-nuclear pale cytoplasmic globules (C), which are intensely immunoreactive for low weight cytokeratin (D).

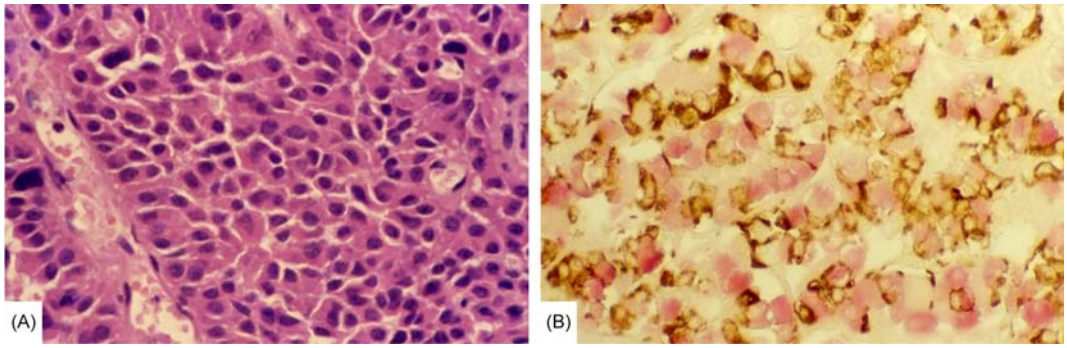

Fig. 3 Mixed somatotroph–lactotroph adenoma composed of a double population of acidophilic cells (A), with immunohistochemical expression of either GH (*brown*) or PRL (*red*) (B).

Lactotroph adenoma

Lactotroph adenomas are pituitary adenomas arising from PIT1-lineage cells, which express and secrete PRL. Lactotroph adenomas are the most common pituitary adenoma type, accounting for about 30%–50% of cases. They show a female predominance, and occur more frequently in young adults, with a peak incidence between 21 and 40 years. In most cases arising in women the adenoma is small, while in men they tend to be larger. Clinical manifestations of lactotroph adenomas include reproductive and sexual dysfunction, which is different between genders. In females, lactotroph adenomas are generally associated with galactorrhea, ovulatory disorders, and amenorrhea, while males present with decreased libido and impotence.

Most lactotroph microadenomas arise in the lateral and posterior part of the gland and are frequently discovered in females. In males they tend to be larger (macroadenomas) and widely invasive into adjacent structures.

Lactotroph adenomas can show prominent vascularity and some cases present abundant fibrous stroma and even occasional amyloid deposition (Fig. 4). On the basis of morphology and PRL immunoreactivity, they can be divided into three distinct histological subtypes.

- *SG lactotroph adenomas* are the most common type of pituitary adenoma. They are chromophobic tumors with variable architecture including trabecular, papillary, or solid patterns of growth. Cells are basophilic and show characteristic juxtanuclear globular positivity for PRL, depending on the abundance of hormone in the Golgi complex rather than in secretory granules,

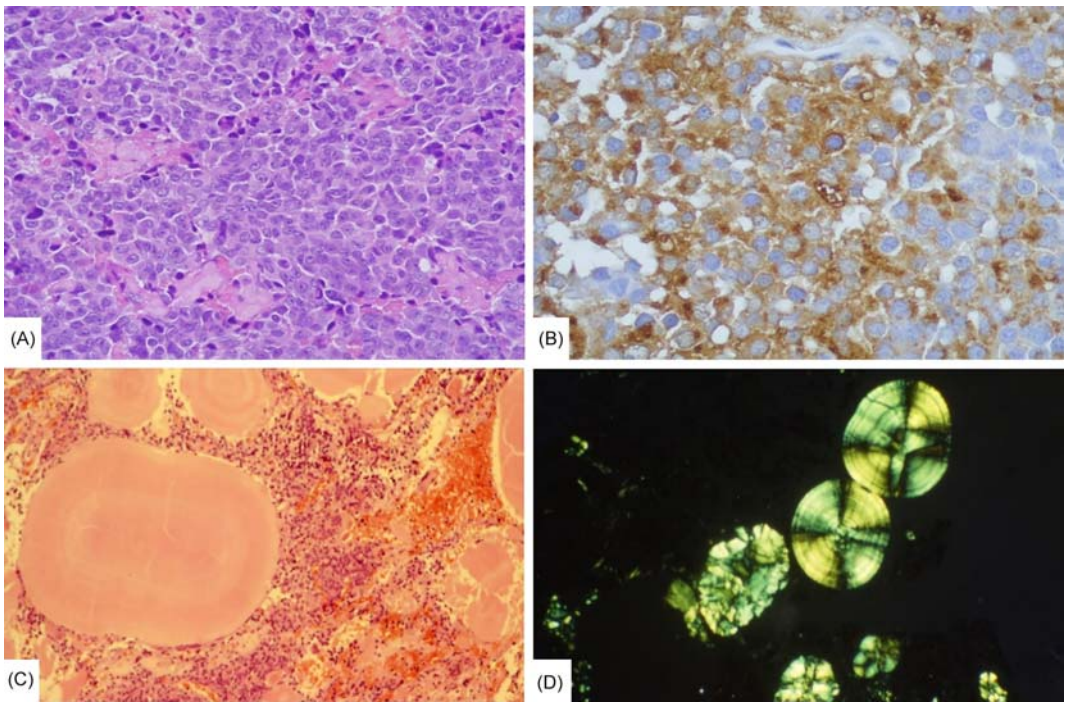

Fig. 4 Sparsely granulated lactotroph adenoma is composed of acidophilic cells (A) with diffuse cytoplasmic immunoreactivity for PRL (B). Stromal amyloid deposits which stain with Congo Red (C) and give an apple-green birefringence at polarized light (D) are observed in this case.

which are scarce. The tumor cells also express PIT-1 and estrogen receptors. They are generally negative for other pituitary hormones, although occasionally they can be positive for α-subunit.

- *DG lactotroph adenomas* are very rare and are composed of acidophilic cells with an abundant amount of PRL-storing secretory granules in the cytoplasm. These tumor cells strongly resemble resting non-neoplastic lactotrophs. The immunohistochemical profile is the same as that of the SG variant, with the exception of the pattern of PRL staining, which is diffuse throughout the cytoplasm.
- *Acidophil stem cell adenomas* are also rare PRL producing tumors, composed of oncocytic cells with abundant acidophilic granular cytoplasm, which may be punctuated by clear cytoplasmic vacuoles that represent giant dilated mitochondria. These adenomas show a diffuse histological architecture and are positive for PIT-1, estrogen receptors, PRL and occasionally for GH.

Only a minority of lactotroph adenomas are associated with familial predisposition and rare cases can be found in the context of MEN1, MEN4, SDH-related familial paraganglioma syndromes, Carney complex, McCune–Albright syndrome, familial isolated pituitary adenoma, and X-linked acrogigantism syndrome.

Pharmacotherapy with dopamine agonists is the first-line of treatment and morphological changes induced by preoperative dopamine agonists are dramatic and can create diagnostic pitfalls in the absence of appropriate clinical history. Most SG lactotroph adenomas undergo significant tumor mass reduction within weeks of initiating therapy and the tumors appear histologically more cellular because of shrinkage in cell size, due to the reduction of the cytoplasmic volume through involution of the rough endoplasmic reticulum and Golgi complexes. The nuclei can become irregular and heterochromatic and the number of secretory granules increases as a consequence of reduced PRL secretion. After prolonged therapy, perivascular, interstitial fibrosis, focal hemorrhage, and hemosiderin deposition are frequently observed. All these morphological changes are usually rapidly reversible on discontinuation of therapy.

Corticotroph adenoma

Corticotroph adenoma is a pituitary adenoma arising from TPIT-lineage cells which express and secrete ACTH (Fig. 5) and proopiomelanocortin-derived peptides. Corticotroph adenomas represent about 15% of all pituitary adenomas. All ages can be affected, but the peak incidence is between 30 and 50 years. In the pediatric population males predominate, while in adult patients corticotroph adenomas are more frequent in females. The majority of patients with corticotroph adenomas show high serum levels of ACTH and cortisol, and present symptoms of Cushing syndrome. However, about 20% of cases are clinically silent, lacking signs of ACTH and cortisol excess. These latter are called silent corticotroph adenomas and are an incidental finding in patients presenting visual or neurological symptoms related to tumor mass.

Corticotroph adenomas associated with Cushing syndrome are classified in three different subtypes: DG corticotroph adenoma, SG corticotroph adenoma, and Crooke cell adenoma.

- *DG corticotroph adenomas* are the most common tumor type in patients with Cushings disease. They have a sinusoidal architecture and are composed of basophilic cells, strongly positive with PAS stain. Tumor cells are immunoreactive for TPIT (nuclear staining), CAM5.2, cytokeratin 20, galectin-3, ACTH and other POMC derivatives including β-endorphin and MSH.
- *SG corticotroph adenomas* are less frequent than the DG counterpart, usually larger presenting as a macroadenoma with more subtle clinical features of Cushing syndrome. Tumor cells are faintly basophilic or chromophobic, with focal and weak PAS positivity and ACTH immunoreactivity. However, they retain a strong nuclear TPIT and cytoplasmic keratin and galectin-3 positivity.
- *Crooke cell adenomas* are rare variants in which tumor cells show Crooke hyaline changes, consisting of a homogeneous hyaline material composed of filaments occupying large areas of the cytoplasm and displacing organelles and secretory granules to the cell periphery. Tumor cells are large and have a homogeneous glassy, slightly acidophilic cytoplasm with granular basophilia limited to the cell periphery and juxtanuclear region. Nuclei may be highly atypical. Immunohistochemistry identifies nuclear

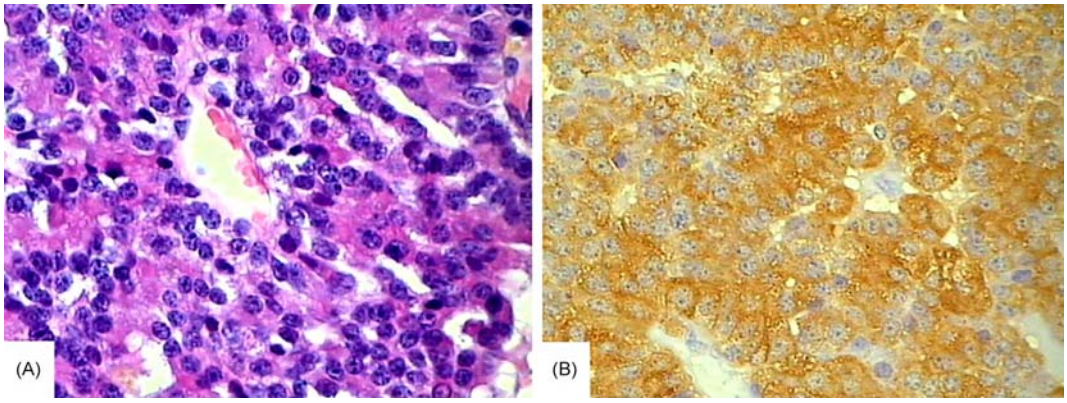

Fig. 5 Corticotroph adenoma showing a sinusoidal growth of basophilic cells (A) with intense immunostaining for ACTH (B).

TPIT positivity and ACTH reactivity limited to the cell periphery and juxtanuclear region, while low-molecular-weight cytokeratins exhibit intense ring-like cytoplasmic positivity. These tend to be more aggressive than the usual corticotroph adenomas.

In addition to corticotroph adenomas associated with Cushing syndrome there are some cases of clinically silent or nonfunctioning adenomas showing cytoplasmic immunoreactivity for ACTH and nuclear expression of TPIT. They are divided into two subtypes: *type 1* (densely granulated) and *type 2* (sparsely granulated).

Thyrotroph adenoma

Thyrotroph adenomas are rare pituitary tumors arising from PIT1-lineage cells, which express and secrete TSH. They account for $<2\%$ of all pituitary adenomas. In most cases the etiology is unknown, but rare cases have been described to arise in the context of MEN1 syndrome or in patients with long-standing untreated primary hypothyroidism. In general, thyrotroph adenomas are a rare cause of hyperthyroidism.

Thyrotroph adenomas are usually large and invasive lesions at the time of diagnosis. Microscopically, thyrotroph adenomas can be solid or may exhibit a sinusoidal or nesting pattern. Stromal fibrosis and calcification are common. Tumor cells are usually polygonal or elongated, with chromophobic cytoplasm and indistinct cell borders. Immunohistochemistry identifies uniform nuclear positivity for PIT-1 and variable cytoplasmic reactivity for α-subunit and β-TSH that highlights the angular morphology of the tumor cells. They frequently coexpress GH and PRL and are also positive for GATA2 and SSRT2A. Ki67 is generally $<3\%$.

Surgery is the first choice for therapy, but it is worth noting that thyrotroph adenomas are exceedingly sensitive to somatostatin analogs which reduce TSH secretion in more than 90% of cases.

Gonadotroph adenoma

Gonadotroph adenomas are derived from SF1-lineage cells of the adenohypophysis and produce β-FSH, β-LH and α-subunit. Functioning forms of these tumors are rare and present with elevated gonadotropins serum levels and signs or symptoms of gonadal dysfunction. More frequently, gonadotroph adenomas are diagnosed because of their mass effect, causing visual abnormalities, hypopituitarism or headaches. Functioning gonadotroph adenomas are frequently macroadenomas and have distinctive clinical manifestations, such as menstrual irregularities and ovarian hyperstimulation in premenopausal women, testicular enlargement in males, and isosexual precocious puberty in children. It is to be kept in mind that gonadotropin excess in children is almost never caused by a pituitary adenoma. True gonadotropin-dependent precocious puberty is usually caused by germ cell tumors, hypothalamic hamartomas, or other CNS tumors or tumor-like lesions that interfere with physiological suppression of the hypothalamic–pituitary–gonadotropic axis. In most men with gonadotroph adenoma, FSH is elevated; in some, both FSH and LH are high. Only in rare cases they produce LH only. In women, the elevation of one gonadotropin alone, or elevated gonadotropins in the presence of hypopituitarism, would suggest the diagnosis of a gonadotropin-producing adenoma.

Macroscopically, gonadotroph adenomas are usually large macroadenomas with significant suprasellar or parasellar invasion at the time of presentation. They are usually well-vascularized and may exhibit areas of hemorrhage or necrosis. Microscopically (Fig. 6), these tumors have a sinusoidal, trabecular, or papillary architecture and form prominent pseudorosettes around blood vessels. The cells are usually chromophobic, but oncocytic change is common and usually focal. Nuclear pleomorphism is not prominent. Tumor cells may contain a few PAS-positive cytoplasmic granules. Immunohistochemistry identifies strong nuclear SF-1 staining and focal, variable ERα. The cytoplasm contains variable positivity for α-subunit, β-FSH, and β-LH; FSH is usually more abundant than LH. It is worth noting that variation in fixation, signal amplification techniques and immunohistochemical methods may result in wide differences in immunostaining of gonadotropins. In addition, the immunostaining for α-subunit, β-FSH, and β-LH may be heterogeneous within the same tumor. For these reasons, many tumors diagnosed as null cell adenomas are in fact gonadotroph adenomas. Recently, it has been reported that SF1 may help to diagnose a gonadotroph adenoma in bona fide hormone-negative tumors.

The most reliable predictor of biological behavior in gonadotroph adenomas is the Ki67-based proliferative index. It is reported to be predictive for progression risk in tumor remnants, even if it may not be predictive for recurrence risk.

The first line therapy for these tumors is surgery, usually with a trans-sphenoidal approach. Gonadotroph adenomas express dopamine and somatostatin receptors. However, bromocriptine, as well as somatostatin analogs, suppress gonadotropin release

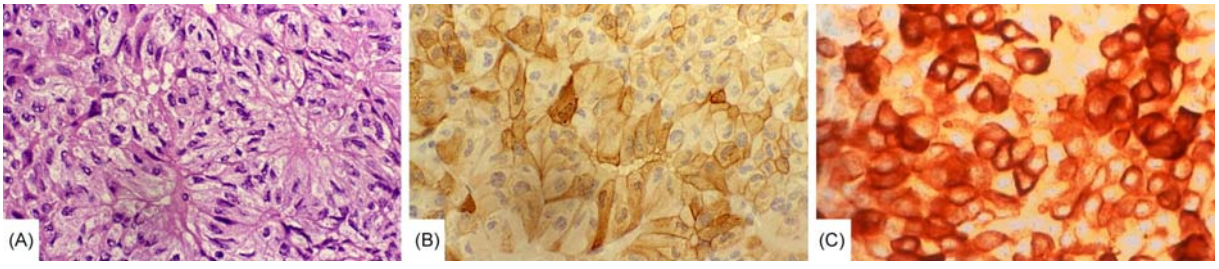

Fig. 6 Gonadotroph adenoma composed of eosinophilic elongated cells with pseudorosette formation (A). Immunostains show positivity for LH (B) and alpha-subunit (C).

in vitro and in vivo but have no effect on tumor size. Recurrence is common, occurring in up to 50% of patients at 10 years after surgery, but most patients are treated with repeat surgery and radiation therapy is reserved for those with rapid and aggressive tumor recurrence.

Null cell adenoma

Null cell adenomas are defined as pituitary adenomas with no evidence of specific cell lineage differentiation by immunohistochemistry for pituitary hormones and transcription factors. When restricted to these criteria, null cell adenomas are rare, representing $<5\%$ of clinically nonfunctioning adenomas. They are tumors that exhibit a somewhat more aggressive clinical behavior, consistent with their lack of differentiation.

The clinical presentation of null cell adenomas is that of a macroadenoma that causes symptoms of an intracranial mass lesion: headache, visual field defects, other cranial nerve deficits, or cavernous sinus syndrome. Some patients present with pituitary apoplexy or hypopituitarism, often with hyperprolactinemia due to pituitary stalk compression. Hypopituitarism may involve only GH or may also feature gonadotropin insufficiency. Reduced gonadotropin levels may be the result of hyperprolactinemia rather than tissue destruction. Hypothyroidism or adrenocortical insufficiencies are uncommon, but dynamic testing may elicit impaired corticotroph or thyrotroph responses.

Microscopically, null cell adenomas are composed of chromophobic cells, with a negative PAS reaction, that grow in chords or in solid sheets. Immunohistochemically, these adenomas lack all hormones and transcription factors of differentiated cells but are positive for cytokeratins.

The prognosis of null cell adenomas is still good after surgical resection, despite their somewhat more aggressive biological behavior than that of other nonfunctioning subtypes, as they are generally large, with extrasellar extensions and infiltration of adjacent vascular and bony structures. Radiotherapy may be of use in post-surgical residuals.

Plurihormonal and double adenomas

Plurihormonal adenomas are adenohypophyseal tumors producing two or more hormones. They represent $<1\%$ of all pituitary adenomas. The most common form of this adenoma derives from the PIT-1 lineage and produces various combinations of GH, PRL, and TSH. However, there are plurihormonal adenomas with unusual hormonal combinations, which cannot be related to a single cell lineage. Plurihormonal adenomas may be monomorphous, i.e. composed of a single cell type producing more than one hormone, such as mammosomatotroph adenomas, or they may be plurimorphous, i.e. composed of two or more different cell types, such as the mixed somatotroph–lactotroph adenomas. PIT-1 positive plurihormonal adenomas are frequently macroadenomas with extrasellar extensions and vascular and bony invasion. After surgical treatment, the persistence of residual tumor is common and the recurrence rate is around 30%. Medical treatment may include somatostatin analogs and temozolomide, as about 40% of these adenomas are reported to have MGMT promoter methylation and absent or low MGMT protein expression at immunohistochemistry.

Double adenomas are rare tumors (0.4%–1.3% of all adenomas in surgical series), composed of two different and separate neoplastic masses, possibly representing collision tumors. Multihormonal adenomas, with more than two tumor masses have rarely been described.

Pituitary Carcinoma

Pituitary carcinomas are malignant neoplasms composed of anterior pituitary cells showing cerebrospinal and/or distant metastasis, and this definition is independent of the morphological features. It is worth noting that the local growth and invasiveness is not sufficient to define an anterior pituitary tumor as a carcinoma. The presence of metastasis at the time of the first diagnosis is very rare, so most cases are first diagnosed as adenomas and the diagnosis is changed during follow-up when metastatic dissemination becomes evident, sometimes years after the original diagnosis.

Pituitary carcinomas account for about 0.12% of all anterior pituitary tumors; its annual incidence in Europe has been estimated to be <0.1 cases per 100.000 population. However, considering that metastases are frequently clinically occult, their incidence is probably underestimated. The median age at diagnosis is in the sixth decade and a slight female predominance has been reported. Pituitary carcinomas have been described to produce almost any type of pituitary hormone. Although pituitary carcinomas are usually a disease of adults, at least one pediatric case has been reported and clinically silent cases present at a younger age than their benign counterparts. The etiology of pituitary carcinomas is unknown.

Tumors generally present as invasive macroadenomas and the macroscopic appearance of a pituitary carcinoma is the same as that of a pituitary adenoma. There are no morphological features of a pituitary tumor that can predict the development of metastases. The tumors have the same morphological and immunohistochemical features of the various pituitary adenomas. Although pituitary carcinoma may exhibit nuclear pleomorphism, mitoses, and necrosis (Fig. 7) these parameters are not per se diagnostic of malignancy. Some parameters, including high microvascular density, high Ki-67 proliferative index, high p53 immunoreactivity, loss of p27 expression, and overproduction of HER2/Neu, have been proposed as markers of malignancy but none of them is specific.

Several molecular alterations have been documented in pituitary carcinomas, but there are no data supporting a specific pattern of molecular alterations. Point mutations of *HRAS* have been demonstrated in metastases, but not in the relative primaries, although the number of cases investigated is still not sufficient to demonstrate a role of this gene in pituitary carcinoma

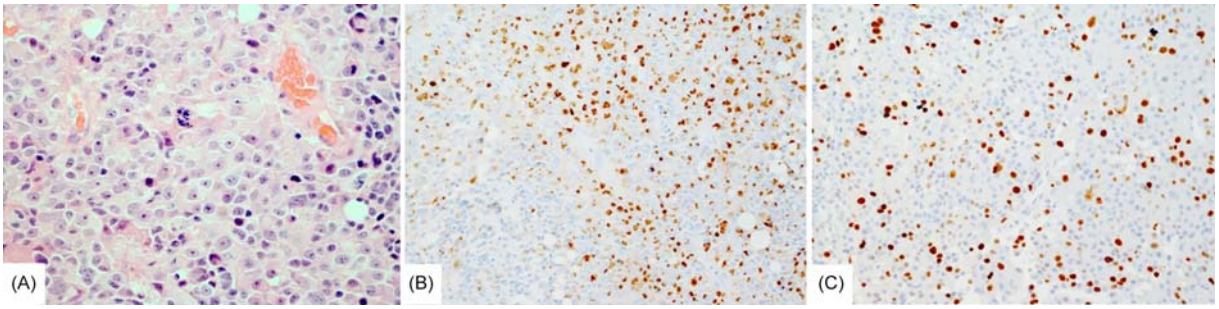

Fig. 7 Pituitary carcinoma composed of atypical cells with abundant eosinophilic cytoplasm and nuclei with prominent nucleoli. An atypical mitosis is visible at the center of the image (A). Tumor cells are positive for prolactin (B) and show high Ki67 proliferative index (C). tumorigenesis. Using CGH analysis several chromosomal alterations have been identified, including gains of chromosomes 5, 7p, 14q, 13q22. Loss of heterozygosity of 1p, 3p, 10q26, 11q13, and 22q12 has been described, while rearrangements of the *TP53* locus, as well as mutations of *TP53* have rarely been found. Finally, a pathogenetic role of microRNAs has recently been proposed, but these results need to be confirmed. Pituitary carcinomas have been described in the context of MEN1 syndrome but there are not sufficient data to support an association between carcinoma and MEN1 syndrome.

The survival of patients with pituitary carcinoma is poor: about 80% of patients die of metastatic disease. The survival rates at 1 year is 57%, and this decreases to 29% at 2 years but then remains stable. Surgical resection of metastatic deposits within the CNS is recommended, whereas radiation therapy and chemotherapy do not seem to be effective in improving patient survival.

Pituitary Blastoma

Pituitary blastoma is a rare primitive malignant neoplasm of the anterior pituitary gland, composed of cells resembling primordial Rathke epithelium, small folliculo-stellate cells, and partially differentiated adenohypophyseal cells. It occurs in children younger than 24 months of age (median 8 months), with a slight female predominance. In the majority of the cases, signs and symptoms of Cushing syndrome are present, followed by visual alterations. The overall prognosis is poor with 40% death in the first 2 years (median 8 months) after diagnosis.

Pituitary blastomas are consistently associated with mutation of the *DICER1* gene. Most of the cases are seen in the context of the DICER1 syndrome, or pleuropulmonary blastoma (PPB)-familial tumor and dysplasia syndrome, caused by heterozygous germline mutations in the *DICER1* gene. It is possible that some cases bear two somatic *DICER1* mutations, rather than one germline and one somatic mutation.

The tumors are histologically composed of three cell populations, variably admixed: (1) Rathke-type epithelial cells, arranged in glands with rosette-like formations, (2) small primitive appearing cells with a blastema-like appearance, and (3) larger secretory epithelial cells resembling adenohypophyseal cells. Most cases express ACTH, and a few pituitary blastomas were reported to express GH in a subset of cells. The Ki-67 based proliferative index varies from low to high, although a prognostic value for Ki-67 index has not been established.

Tumors of the Neurohypophysis

Tumors of the neurohypophysis are low grade neoplasms believed to derive from pituicytes, which are characterized by TTF1 immunoreactivity. Although different entities including pituicytoma, granular cell tumor of the sellar region, spindle cell oncocytoma, and sellar ependymoma have been described, they are currently thought to represent a morphological spectrum of a single nosologic entity. Pituicytomas are rare low-grade spindle cell tumors composed of pituicytes. Spindle cell oncocytomas, originally thought to derive from folliculo-stellate cells of the anterior pituitary, are now considered as oncocytic variants of pituicytomas. Granular cell tumors, also known as choristomas, granular cell myoblastomas, and granular cell schwannomas, are actually considered to be granular cell pituicytomas. Finally, a fourth variant of pituicytoma, reflecting the ependymal pituicyte, has also been reported.

Pituicytoma and Its Variants

These tumors are rare and their annual incidence is not known. Pituicytomas account for $< 0.1\%$ of sellar tumors, spindle cell oncocytomas for about 0.4%, and granular cell tumors for about 0.5%. Data on sellar ependymomas are lacking, as only seven cases have been described. Most cases occur in adults with a median age at diagnosis around 60 years. Pituicytomas and sellar ependymomas show a male predominance, while granular cell tumors are more common in females. The etiology of these neoplasms is unknown.

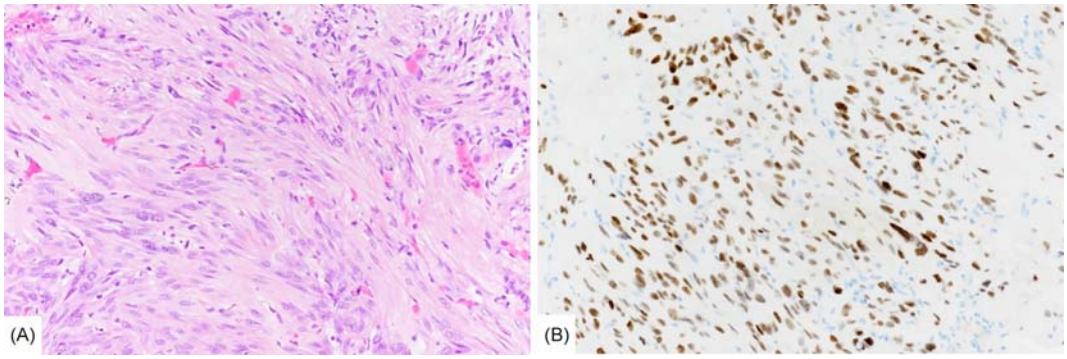

Fig. 8 Pituicytoma is composed of spindle cells that are arranged in interlacing fascicles with storiform pattern. Tumor cells have eosinophilic cytoplasm and nuclei showing minimal atypia (A) and strongly immunoreactivity for TTF1 (B). Courtesy from Dr. Jean-Philippe Brouland, Institut Universitaire de Pathologie, CHUV, Lausanne, Switzwerland.

Most are sellar and/or suprasellar neoplasms, although granular cell tumors show an exclusive suprasellar location. Clinically, they mimic a non-functioning pituitary macroadenoma often showing symptoms related to compression of the pituitary stalk with mild hyperprolactinemia. In addition, visual defects are quite frequent.

Macroscopically, pituicytomas and their variants are highly vascular proliferations with a propensity to bleed. Pituicytomas are composed of elongated spindle-shaped cells arranged in interlacing fascicles with a storiform pattern forming solid sheets (Fig. 8A). The tumor cell cytoplasm is eosinophilic with well-defined cell borders. Oncocytic and granular pituicytomas have more abundant granular cytoplasm, which may result in areas of polygonal or epithelioid morphology in the tumor cells. Spindle cell oncocytomas are characterized by a proliferation of cells forming poorly defined lobules. As a general rule, these tumors show minimal nuclear atypia and mitoses are inconspicuous. Immunohistochemistry is mandatory for a correct diagnosis. Indeed, these tumors are negative for pituitary hormones, cytokeratins, synaptophysin, chromogranin A, neurofilaments, CD34, BCL-2, smooth muscle actin, and desmin, but are positive for vimentin. However, the hallmark of these entities is nuclear reactivity for TTF-1 (Fig. 8B), which is produced in the developing and mature infundibulum, supporting their purported origin from infundibular pituicytes. Tumor cells also show positivity for galectin-3 although it does not seem to be of diagnostic utility, since other intracranial tumors including meningiomas, peripheral nerve sheath tumors and pituitary adenomas can also be galectin-3 positive. The granular variant has been found to be positive for CD68, α_1-antitrypsin, and cathepsin B suggesting histiocytic differentiation. The Ki-67 proliferative index is usually low. The differential diagnosis varies depending on tumor cell morphology and includes different entities. Pituicytomas mimic pilocytic astrocytomas while oncocytic and granular cell variants mimic pituitary adenomas. Immunohistochemistry is indispensable for the differential diagnosis. These low-grade tumors are associated with a favorable outcome when surgically resected.

Neuronal and Paraneuronal Tumors

Neuronal and paraneuronal tumors of the pituitary gland are extremely rare neoplasms including gangliocytoma, neurocytoma, paraganglioma, and neuroblastoma.

Gangliocytomas are well-differentiated, slowly growing intrasellar neoplasms composed of mature neurons resembling hypothalamic ganglion cells and producing hypothalamic peptides. These tumors may cause hypopituitarism alone or hypopituitarism with deafferentation hyperprolactinemia and visual field defects when they are large with suprasellar extension. Some of these tumors are hormonally active, producing hypothalamic regulatory peptides such as acromegaly due to GHRH secretion. They may also cause precocious puberty through GnRH production, or Cushing's disease with excess CRH. They may also be associated with pituitary adenomas (Fig. 9). Radiologically these tumors resemble pituitary adenomas and their gross appearance is non-specific. Morphologically they are composed of randomly oriented large mature ganglion cells of variable size and shape, with large nuclei and prominent nucleoli, sometimes binucleated or multinucleated. Mitoses are generally absent. Gangliogliomas are distinguished by the presence of glial stroma with Rosenthal fibers and eosinophilic granular bodies. Neurons and neuropil are intermingled with adenohypophyseal cells that may be normal, hyperplastic or adenomatous and may represent the dominant component of the tumor mass.

Pituitary neurocytomas are extraventricular neurocytomas (WHO grade II) involving the pituitary gland. These tumors are extremely rare. Pituitary neurocytomas are composed of small to medium-sized round monotonous cells forming solid nests and sheets within a reticulin-rich, fibrovascular stroma. There is abundant fibrillar neuropil, and rosettes may be present. The tumor cells have granular, pale eosinophilic or chromophobic cytoplasm with round to oval nuclei with finely granular chromatin, with or without prominent nucleoli. Tumor cells are positive for synaptophysin, chromogranin, neuron-specific enolase, and CD56 and lack expression of cytokeratins, EMA, glial markers (GFAP, OLIG2), and pituitary transcription factors and hormone expression. Vasopressin (ADH) expression has been reported. The therapy of choice is surgery and the prognosis depends on complete surgical

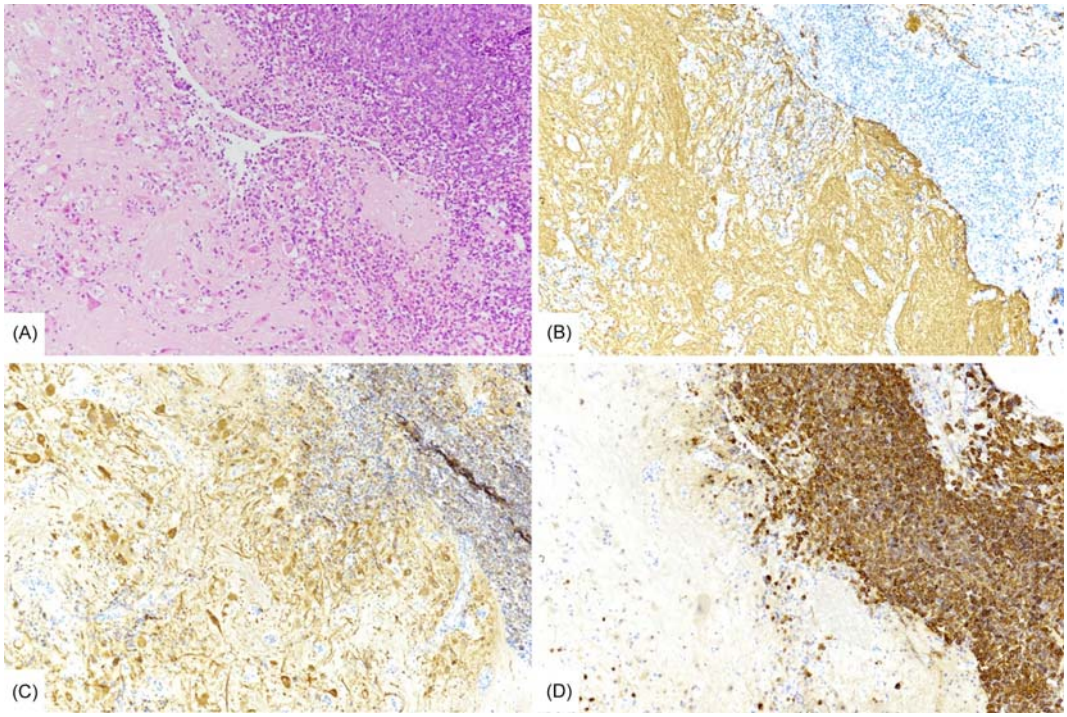

Fig. 9 Mixed pituitary gangliocytoma-adenoma. The tumor is composed of mature ganglionic cells distributed in abundant neuropil (A, left) and of a pituitary adenoma (A, right). The neuropil is positive for neurofilaments (B). Ganglion cells are strongly positive for microtubule-associated protein 2 (Map2) (C), while adenomatous cells are positive for GH (D).

resection and on histological features, as presence of necrosis, microvascular proliferation, increased mitotic activity ($\geq$3 mitoses $\times$ 10HPF) and a Ki67 index higher than 3% are associated with poorer prognosis. Radiation therapy has been reported to improve local control, but its impact on long-term survival is unknown.

Paragangliomas of the pituitary gland are extremely rare tumors arising from chief cells of the dispersed paraganglia of the sellar region. These tumors clinically resemble silent (nonfunctioning) pituitary adenomas, and are associated with headache, visual disturbances, hypopituitarism, and mild hyperprolactinemia due to stalk compression. Morphologically, they are very difficult to distinguish from hormone-negative pituitary adenomas. However, similar to paragangliomas of other sites, they are composed of large, irregular polyhedral or elongated cells with pale eosinophilic cytoplasm and bland nuclei with rare mitoses, which form solid nests called *zellballen* within a highly vascular stroma. Tumor cells are positive for synaptophysin, chromogranin A, and tyrosine hydroxylase, while sustentacular cells are positive for S100. The differential diagnosis with pituitary adenomas is based on immunohistochemistry for cytokeratins, particularly low-molecular-weight cytokeratins, since adenomas are positive, while paragangliomas are negative. Conversely, immunoreactivity for neurofilaments supports a diagnosis of paraganglioma. Most paragangliomas are benign and can be surgically resected. A diagnosis of paraganglioma strongly suggests to search for germline mutations of the *VHL* (the von Hippel–Lindau tumor suppressor), *SDHB*, *SDHC*, and *SDHD*, and *NF1*and *NF2* genes, which predispose patients to the disease.

Neuroblastomas of the pituitary gland or sellar region are neuroectodermal neoplasms similar to olfactory neuroblastoma (esthesioneuroblastoma). They are very rare, accounting for less than 20 cases reported in the literature, and are generally associated with symptoms of tumor mass, visual field loss, headache, and hormone deficiencies. Tumors show lobular architecture separated by fine fibrovascular septae that may contain stromal neurofibrillary material. Tumor cells are uniformly small and round with scant cytoplasm, positive for synaptophysin and chromogranin, but negative or only focally and weakly positive for cytokeratins. In addition, they are also negative for pituitary transcription factors and hormones. These lesions usually have a higher Ki67 proliferative index (10%–20%) than pituitary adenomas. S100-positive sustentacular cells are generally present at the periphery of tumor nests. Surgical resection is usually not curative and is usually followed by radiotherapy associated with chemotherapy in advanced cases.

Miscellaneous Tumors

Rare tumors of the pituitary gland include mesenchymal and stromal tumors, hematolymphoid tumors, germ cell tumors, secondary tumors, and mixed craniopharyngioma-pituitary adenoma (MiNEN).

Mesenchymal and stromal tumors developing in the pituitary region are mostly represented by meningiomas, however benign and malignant soft tissue tumors may occur in this site.

Meningiomas represent about 5% of sellar tumors and the most common meningioma types in this region are meningothelial, fibrous or fibroblastic, and transitional variants. They commonly occur in patients in their 5th and 6th decades of life and most frequently in females. The majority of meningiomas in this site are suprasellar, originating from the planum sphenoidale, the diaphragma sellae or the tuberculum sellae. Clinical signs and symptoms are that of a sellar mass, with visual alterations and headache. Meningiomas usually express EMA and vimentin, some are immunoreactive for S100 protein, and they are characteristically positive for estrogen and progesterone receptors, as well as for SSTR2A. Most are well-differentiated grade I lesions with rare mitoses and low a Ki-67 proliferative index (below 1%). Grade II tumors include those with ≥ 4 mitoses/10 high-power fields ($\times 40$) or three of the following features: increased cellularity, sheeting architecture, small cells with high nuclear/cytoplasmic ratio, macronucleoli, focal necrosis, or brain invasion. Chordoid and clear cell variants are also defined as grade II. The rare grade III or anaplastic meningiomas include rhabdoid and papillary subtypes, and meningiomas with a high proliferation index (>20 mitoses per 10 high power fields).

Sellar *schwannomas* are exceedingly rare and are derived from cranial nerves in and around the sella. They can be clinically misdiagnosed as non-functioning pituitary adenomas, causing hypopituitarism with or without hyperprolactinemia and other symptoms of a mass lesion. Macroscopically, they are well circumscribed, pseudoencapsulated and firmer than pituitary adenomas. Microscopically, schwannomas are composed of spindle-shaped cells, characteristically arranged in compact Antoni type A and loose Antoni type B patterns. The immunohistochemical profile includes strong S100 protein reactivity, with variable Leu-7, calretinin, and GFAP staining; they are usually negative for EMA, unlike meningiomas. Sellar schwannomas are usually benign and are amenable to surgical resection unless they involve critical structures in the parasellar region.

Chordomas are rare midline neoplasms that may rarely arise in the clivus and involve the sellar region. Clinically, they mimic nonfunctioning pituitary adenomas, presenting with signs and symptoms of a sellar mass, and usually arise in young patients (mean age 30 years). Macroscopically, they appear as a gelatinous mass, histologically composed of chords of physaliphorous cells surrounded by polysaccharide-rich matrix. Immunohistochemical markers of chordomas are S100, EMA, calretinin, cytokeratins and vimentin. Nuclear expression of the transcription factor brachyury proves derivation from the embryonic notochord. Chordomas are aggressive neoplasms, frequently invasive and with a high tendency to recur. The chondroid variant of chordoma shows focal cartilaginous differentiation, lacks EMA and cytokeratin reactivity, and may actually represent a well differentiated chondrosarcoma. This variant is less aggressive than the usual clival chordoma.

Hematological disorders, namely, *lymphoma*, *myeloma* and *leukemia*, may very rarely involve the sellar region and the pituitary as a consequence of a systemic dissemination. In immunocompromised patients, primary pituitary lymphomas have been anecdotally reported. Plasmacytoma or lymphoma involving the sellar region may clinically mimic nonfunctioning pituitary adenoma. Conversely, bromocriptine-treated prolactin-producing adenomas and lymphocytic hypophysitis, may be misdiagnosed as lymphoma. Immunohistochemical analysis is clearly pivotal in making a correct diagnosis in these cases. The majority of pituitary-involving lymphomas are diffuse large B-cell lymphomas (DLBCL), but also Burkitt lymphoma, marginal zone lymphomas, solitary plasmacytomas, and T-cell lymphomas have been described.

Among hematological disorders, Hand–Schüller–Christian disease belongs to the group of Langerhans' cell histiocytosis and its classical presentation involves the hypothalamus and, in some cases, the pituitary gland itself. Also non-Langerhans cell histiocytoses, including Rosai–Dorfman disease, Erdheim–Chester disease, hemophagocytic lymphohistiocytosis, and juvenile xanthogranuloma, as well as rare malignant histiocytic tumors, may involve the pituitary and the hypothalamus.

Germ cell tumors may be found outside the gonads along the midline, such as in the mediastinum and in the cranium, where they occur mainly in the pineal and suprasellar region. They represent $<1\%$ of intracranial neoplasms in adults, but are more common in children, where they constitute 6.5% of intracranial tumors. The most common germ cell tumors found in the sellar region are teratomas and mixed germ cell tumors, but all histotypes have been described. The prognosis of these neoplasms strictly depends on the histotype, germinomas having the best prognosis (5-year survival rates over 80%), compared to cases with a non-germinomatous component (5-year survival rates around 40%–50%).

Secondary tumors, i.e. metastasis to the pituitary gland, are uncommon but as they represent about 1% of pituitary tumors cannot be neglected (**Fig. 10**). The posterior pituitary is more frequently involved, whereas the anterior lobe seems to be protected by the portal nature of its vasculature. Pituitary metastases derive most commonly from primary carcinomas of the lung, breast, and colon. The presentation almost always includes diabetes insipidus, a feature that highlights the involvement of the hypothalamus and distinguishes even small lesions from pituitary adenoma. Large tumors cause headache, visual and oculomotor defects, along with anterior pituitary hormone deficiencies. Metastatic carcinoma to a pituitary adenoma has been reported and may cause a sudden increase of pituitary size with worsening of symptoms of a known tumor. Metastatic neuroendocrine carcinoma may represent a diagnostic challenge, because in the absence of immunoreactivity for pituitary hormones and transcription factors, and being immunoreactive for general neuroendocrine markers, it can be misdiagnosed as a null cell adenoma. Unusual features, such as high mitotic activity, high Ki-67 proliferative index, or any history of a primary neuroendocrine tumor elsewhere, are clues for a metastatic origin of the neuroendocrine proliferation. Additional immunostaining, including transcription factors (TTF-1 and CDX-2) and non-pituitary hormones may be helpful in the differential diagnosis with an adenoma and in finding an occult primary. The most complex examples have been reported in patients with acromegaly or Cushing's disease caused by ectopic expression of GHRH or ACTH and/or CRH, respectively. Aggressive neuroendocrine tumors of various sites commonly produce ACTH; a metastatic lesion in the pituitary producing ACTH could easily be mistaken for a primary pituitary adenoma. In this situation,

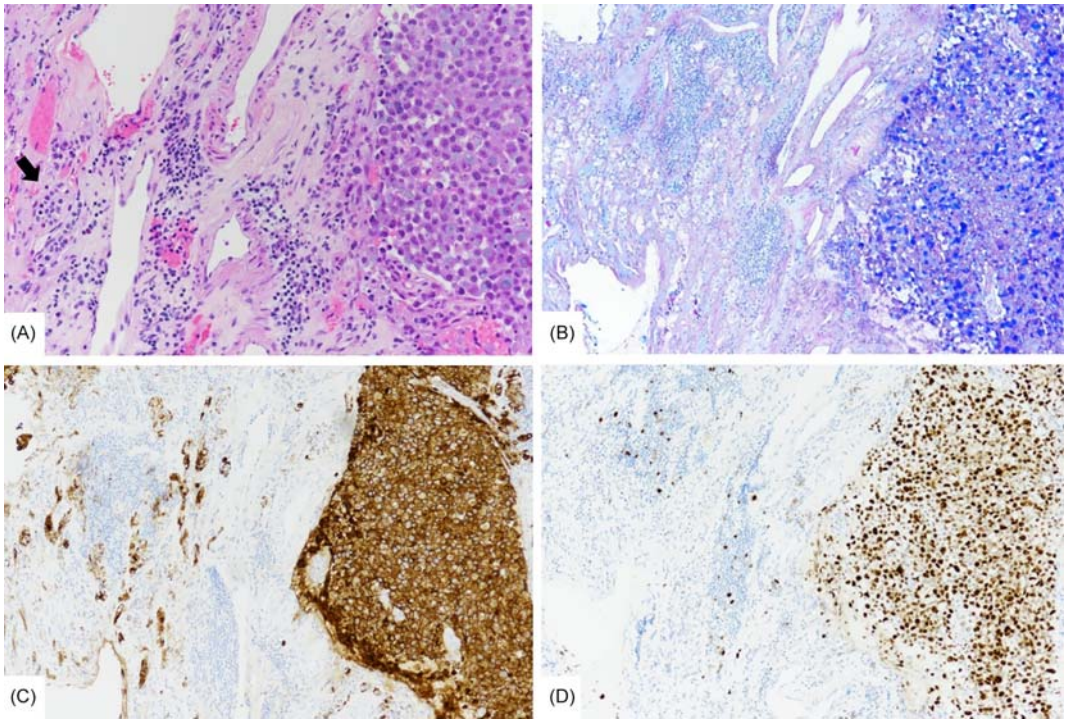

Fig. 10 Pituitary metastasis from a signet-ring cell carcinoma. Neoplastic tumor cells growth forming solid sheets (right side of the images), while residual pituitary tissue is found in the left side (A, *arrow*). Tumor cells show intracytoplasmic Alcian-Blue positive mucus (B), are strongly positive for cytokeratin (C), and show a high Ki67 proliferative index (D).

there is usually evidence of widespread disease; examination of TPIT may be helpful, since extrapituitary neuroendocrine tumors that produce ACTH do not express TPIT.

MiNENs arising in the sellar region are very rare and the cases described in the literature are composed of admixed craniopharyngioma and pituitary adenoma. Some of these cases represented concomitant or collision tumors in which separate pituitary adenomas and craniopharyngiomas were present in the gland. However, other reported cases were examples of true mixed neoplasms consisting of areas of pituitary adenoma strictly admixed with areas of craniopharyngioma. As a group, these tumors occurred more frequently in males with an average age of 48 years. The nonneuroendocrine component of sellar MiNENs was always represented by an adamantinomatous craniopharyngioma, whereas the neuroendocrine component consisted of different types of pituitary adenomas including gonadotroph, somatotroph, corticotroph and thyrotroph adenomas. The pathogenesis of mixed pituitary neoplasms composed of craniopharyngioma and pituitary adenoma is still not clear. Morphologically, they are characterized by an intimate admixture between the two components and hybrid cells, and features of both craniopharyngioma and pituitary adenoma have been demonstrated. This suggests that these tumors may originate from a common precursor, which undergoes divergent differentiation. However, molecular analyses confirming this hypothesis are lacking.

This entity needs to be recognized for clinical and prognostic reasons and should be considered among the potential differential diagnoses of neoplasms arising in the sellar region.

Glossary

Acromegaly A disease characterized by growth hormone (GH) excess in adults resulting in enlargement of the extremities.
Adenohypophysis The front (anterior) section of the pituitary gland that is composed of epithelial neuroendocrine cells.
Corticotroph Pituitary cell dedicated to the production of a pro-hormone pro-opiomelanocortin (POMC) from which the adrenal stimulating hormone, adrenocortictrophic hormone (ACTH), is cleaved.
Crooke cell A pituitary corticotroph cell characterized by accumulations of cytoplasmic filaments that reflect inhibition of that cell by adrenal steroid hormone excess.
Cushing disease A disease characterized by inappropriate hypersecretion of the adrenal stimulating hormone, adrenocorticotrophic hormone (ACTH).
Gigantism A disease characterized by growth hormone excess before puberty resulting in increased stature.
Gonadotroph A dedicated pituitary cell responsible for producing the gonad stimulating hormones: luteinizing hormone (LH) and follicle stimulating hormone (FSH).
Lactotroph A pituitary cell that is responsible for producing the breast milk-generating hormone prolactin.
Mammosomatotroph A pituitary cell with the capacity to produce both prolactin and growth hormone (GH).
Neurohypophysis The back (posterior) portion of the pituitary gland that is composed of the axons of hypothalamic neurons and their supporting stromal cells, modified glial cells known as pituicytes.
Pituitary A gland at the base of the brain, within the bony structure known as the sella turcica; the pituitary is responsible for sensing the body's hormones and responding by producing hormones that control the body's hormone-producing glands.
Somatotroph Dedicated pituitary cell responsible for producing growth hormone (GH).
Thyrotroph Dedicated pituitary cells responsible for producing thyroid stimulating hormone (TSH).

Nomenclature

αSU Alpha subunit of glycoprotein hormones
ACTH Adrenocorticotrophic hormone
FSH Follicle stimulating hormone
GH Growth hormone
LH Luteinizing hormone
MRI Magnetic resonance imaging
Pit-1 Pituitary transcription factor-1
PitNET Pituitary neuroendocrine tumor
POMC Pro-opiomelanocortin hormone
PRL Prolactin
SF-1 Steroidogenic factor-1
Tpit T-box pituitary transcription factor
TSH Thyroid stimulating hormone

Introduction

Pituitary tumors are common neoplasms that have been recognized with increasing frequency (Ezzat et al., 2004). The vast majority arise from the hormone-secreting cells of the anterior pituitary gland, the adenohypophysis, and are therefore epithelial neuroendocrine tumors. They are usually insidious in their initial presentation and have variable biological behaviors. Some are small incidental lesions that are of no major clinical significance, others are small tumors that produce hormones in excess but can be managed by medical therapy and do not progress. Those that come to surgery may be hormonally active, proliferative, and/or invasive, causing significant morbidity and ultimately can result in mortality due to tumor growth or invasion of critical brain structures. In this article, we provide an overview of their epidemiology and classification, as well as the fundamentals of the diagnosis and management of patients with these endocrine neoplasms.

Epidemiology of Pituitary Tumors

Epidemiologic data from prior to 1969 indicated that pituitary tumors were rare, with an annual incidence of 1.85 per 100,000 population (Gold, 1981). Surgical literature indicated that they represented 10%–25% of intracranial neoplasms (Scheithauer, 1984) however, this was considered to reflect a referral bias to publishing academics. Radiology and pathology data identified common incidental findings which were reviewed in a meta-analysis that resulted in a prediction of pituitary tumors in 17% of the population (Ezzat et al., 2004). Subsequent population studies identified that the prevalence of clinically diagnosed pituitary tumors ranges from approximately 78 to 116 cases per 100,000 people (Daly et al., 2006; Fernandez et al., 2010; Agustsson et al., 2015, Fontana and Gaillard, 2009) with only one study from Sweden finding a lower prevalence of 3.9/100,000 people (Tjornstrand et al., 2014).

These data indicate that pituitary tumors are much more common than previously thought and point to the importance of clinical awareness and education to ensure early diagnosis.

Clinico-Pathological Classifications of Pituitary Tumors

The classification of these tumors as "adenomas" belies the extreme variability of their clinical behaviors and the impact that they can have on patients. Relegation to the benign category has hampered collection of data on incidence, prevalence, and outcomes. Pituitary patients with significant morbidity are denied assistance that is available to cancer patients. For these reasons and more, and by analogy with other endocrine tumors that have variable biological outcomes, a change in terminology has been proposed by the International Pituitary Pathology Club to avoid the use of the term "adenoma" (Asa et al., 2017a). Instead, these tumors should be classified as "pituitary neuroendocrine tumors," or PitNETs, and when referring to specific subtypes, the cell type should be followed by "tumor" rather than "adenoma." In this review we will apply this new terminology.

The spectrum of PitNETs includes tumors that reflect the six cell types of the normal adenohypophysis (Asa, 2011). Each type can have several morphologic subtypes that have different clinical behaviors; each tumor type has a distinct clinical presentation, response to therapy, and prognosis (Mete and Asa, 2012, 2013; Gomez-Hernandez et al., 2015). **Table 1** outlines the various tumor types that arise from adenohypophysial cells, based on the cell lineages defined by transcription factors, the hormone(s) they

Table 1 Clinico-pathologic classification of pituitary tumors

Lineage	*Cell type*	*Tumor type*	*Hormone(s)*	*Typical presentation*	*Unusual presentation*
Tpit	Corticotroph	Densely granulated corticotroph tumor	ACTH; other POMC-derived peptides	Florid Cushing disease; small tumor	Clinically nonfunctioning
	Corticotroph	Sparsely granulated corticotroph tumor	ACTH; other POMC-derived peptides	Subtle Cushing disease, large tumor	Clinically nonfunctioning
	Crooke cell[a]	Crooke cell tumor	ACTH; other POMC-derived peptides	Cushing disease that may be cyclical or atypical	Clinically nonfunctioning
Pit-1	Somatotroph	Densely granulated somatotroph tumor	GH; αSU	Florid acromegaly	
	Somatotroph	Sparsely granulated somatotroph tumor	GH	Subtle acromegaly	Clinically nonfunctioning
	Mammosomatotroph	Mammosomatotroph tumor	GH; PRL; αSU	Florid acromegaly with hyperprolactinemia	
	Mammosomatotroph precursor	Acidophil stem cell tumor	PRL; GH; αSU	Hyperprolactinemia	Hyperprolactinemia with subtle acromegaly
	Lactotroph	Sparsely granulated lactotroph tumor	PRL	Hyperprolactinemia	
	Lactotroph	Densely granulated lactotroph tumor	PRL	Hyperprolactinemia	
	Thyrotroph	Thyrotroph tumor	TSH[b] (βTSH and αSU)	Hyperthyroid-ism	Clinically nonfunctioning
	Poorly differentiated Pit-1 lineage cell	Poorly differentiated Pit-1 lineage tumor	αSU; GH; PRL; βTSH	Clinically nonfunctioning	Acromegaly, hyperthyroidism, hyperprolactinemia or any combination
SF-1	Gonadotroph	Gonadotroph tumor	FSH;LH[b] (αSU; βFSH, βLH)	Clinically nonfunctioning	Gonadotropin excess
None	Null cell	Null cell tumor	None	Clinically nonfunctioning	
Multiple	Atypical	Unusual plurihormonal tumor	Multiple	Any or multiple hormone excess	Clinically nonfunctioning

[a]Crooke cells are suppressed corticotrophs that are usually found in the nontumorous gland of patients with cortisol excess from any etiology.
[b]The glycoprotein hormones TSH, FSH, and LH are composed of two subunits, the common αSU and a unique β subunit.

produce and their clinical features. Morphologic classification is based on immunoreactivity for transcription factors and hormones as well as other biomarkers, most importantly keratins (especially cytokeratin 18, usually identified using the Cam 5.2 antibody) that offer additional valuable information (Asa, 2011; Asa and Mete, 2016) (**Fig. 1**).

The clinical presentations of a pituitary tumor are classified based on the hormonal manifestations (Gomez-Hernandez and Ezzat, 2016). *Acromegaly* is a multisystem disorder with enlargement of the hands and feet due to a growth hormone (GH)-secreting tumor. Unfortunately, this clinical manifestation is usually only detected late in the course of the disease, by which time the prolonged excess of GH and its target, hepatic insulin-like growth factor 1 (IGF-1), have resulted in enlargement and dysfunction of most internal

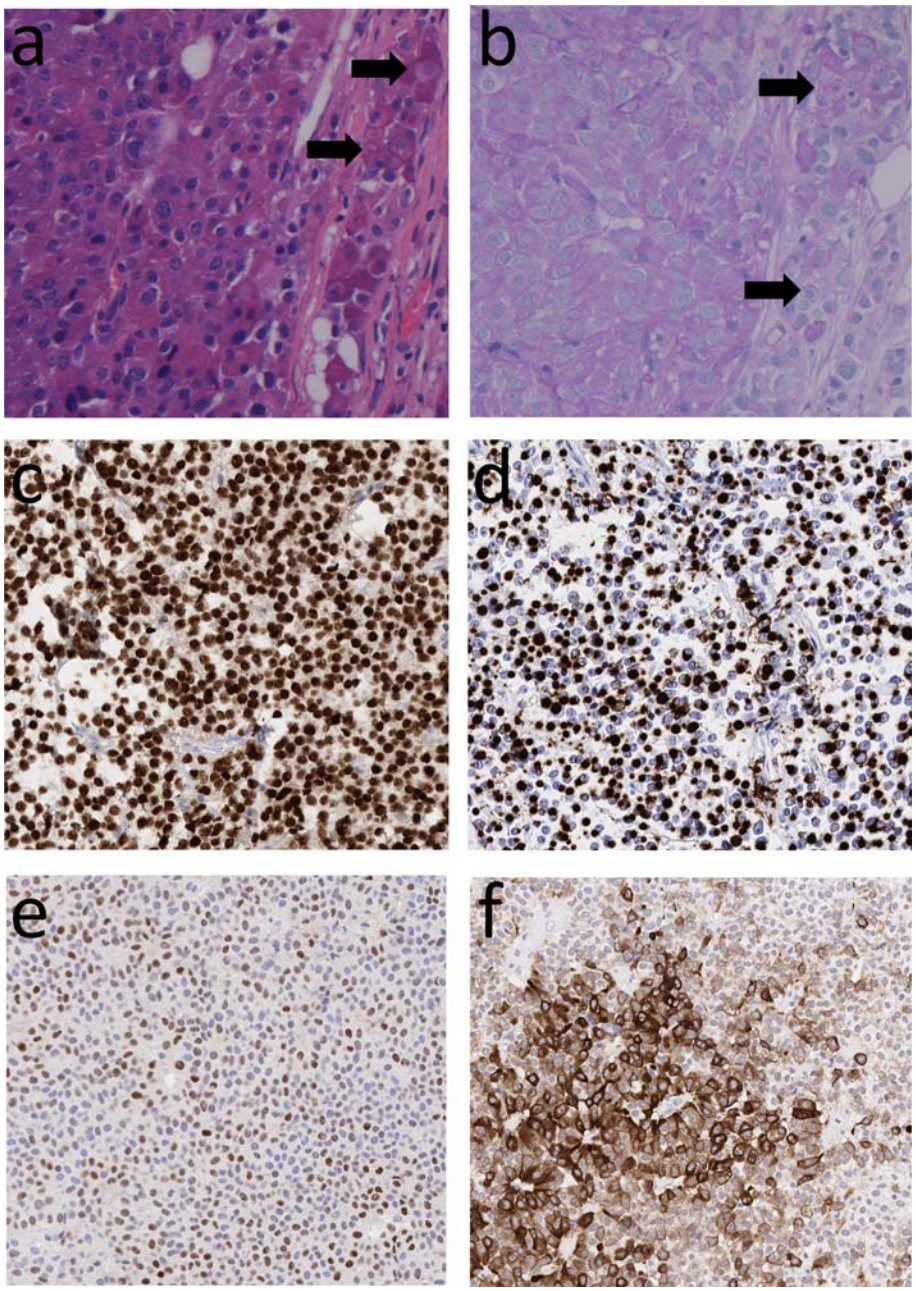

Fig. 1 Morphologic features of pituitary adenohypophysial tumors. (A and B) A densely granulated corticotroph tumor seen in the *left* of these photomicrophs with hematoxylin and eosin staining (A) and the periodic acid Schiff stain (B) has basophilic and PAS-positive cytoplasm that reflects ACTH content; the nontumorous tissue in the *right* of each photo contains corticotrophs with accumulation of pale glassy filaments induced by the negative feedback of excess cortisol (*arrows*), a feature known as Crooke's hyaline change. Crooke cells rarely comprise pituitary tumors. (C) Nuclear staining for the transcription factor Pit-1 identifies a tumor of this lineage that may produce GH, PRL, and/or TSH. (D) The tumor known as a sparsely granulated somatotroph tumor is characterized by juxtanuclear keratin aggresomes known as "fibrous bodies" identified with antibodies to cytokeratin 18. (E). Gonadotroph lineage is identified by nuclear staining for steroidogenic factor-1 (SF-1). (F) Some gonadotroph tumors have strong expression for gonadotropins, usually FSH as seen here, but they may also have faint, focal or no gonadotropin staining.

organs. The delay in diagnosis, typically nearly a decade, is associated with invasive tumors and incomplete surgical resection, necessitating long-term medical therapy. *Gigantism* is the result of early onset GH excess prior to epiphysial fusion; the young patients are tall but again, this diagnosis is often made only after many years of excessive growth and the disease progresses to acromegaly. *Cushing disease* presents with clinical features that result from cortisol excess; these range from weight gain, diabetes and hypertension to neurocognitive mood and behavioral changes. As with acromegaly, the slow, insidious and seemingly common manifestations often elude early diagnosis and patients eventually develop osteoporosis and immunosuppression. *Hyperprolactinemic disorders* present differently depending on the age at the time of presentation. In the young, failure to manifest pubertal features can be a warning sign. In middle aged men and women, sexual dysfunction is typical; women usually present earlier with menstrual irregularities. Infertilty in both genders often uncovers the underlying problem which significantly alters management. In the elderly, accelerated bone loss and/or muscle mass can be a sign of long-standing unrecognized prolactin-producing pituitary tumors. *Hyperthyroidism* presents with the typical hypermetabolic features of heat intolerance, palpitations, weight loss, and anxiety. Inappropriately "normal" levels of TSH can sometimes be overlooked, resulting in ablation of the thyroid gland without attention to the pituitary tumor as the true underlying cause. *Clinically nonfunctioning pituitary tumors* present with signs and symptoms attributable to the mass. These include headaches as well as visual field defects due to compression of the optic chiasm. Depending on the firmness and invasiveness of the pituitary tumor, loss of anterior pituitary hormones is another major presenting feature leading to the diagnosis.

The aggressiveness of a pituitary tumor is determined by the cellular differentiation, the proliferative rate of the tumor and its invasiveness. In general, tumors composed of well differentiated cells, including sparsely granulated lactotrophs, densely granulated somatotrophs, and mammosomatotroph, tend to be responsive to medical therapies that target their normal receptor regulation (Tindall et al., 1982; Bhayana et al., 2005; Asa and Ezzat, 2009). Proliferation rates, assessed by Ki67 labeling using the MIB-1 antibody, can give some indication of the rate of growth of a tumor; in general, tumors with low proliferative rates tend to regrow slower if incompletely resected than do those with higher proliferation indices (Asa and Ezzat, 2016; Mete et al., 2012). Tumors that grow upwards, pushing the diaphragma sellae up rather than infiltrating laterally into the cavernous sinuses or downwards into bone and paranasal sinuses, are more likely to be surgically resectable and therefore have a better prognosis (Micko et al., 2015; Knosp et al., 1993). The factors underlying invasive potential remain to be clarified (Mete et al., 2012, 2013) however it is interesting that among clinically nonfunctioning tumors, gonadotroph tumors tend to have low proliferation and upwards growth, whereas silent corticotroph, poorly differentiated Pit-1 lineage and undifferentiated null cell tumors are more likely to be locally invasive (Mete et al., 2013, 2016; Nishioka et al., 2015).

All three factors are important in determining the management and prognosis of a patient with a pituitary tumor. The application of proliferation alone or with p53 to define "atypical adenomas" (DeLellis et al., 2004) has been abandoned (Mete and Lopes, 2017). While some groups stratify pituitary tumors into three categories as "noninvasive," "invasive," and "aggressive-invasive" based principally on imaging features (Wierinckx et al., 2007), this categorization fails to include the likelihood of response to medical therapy. As examples, there are some giant lactotroph tumors that are widely invasive of many structures but respond well to dopamine agonist therapies with longterm shrinkage and normalization of hormone excess, and in contrast, some patients with corticotroph microadenomas that are not invasive of dura or bone and have low proliferation indices recur due to clinically and pathologically undetected local invasion of the adjacent adenohypophysis.

The classification of a pituitary tumor as a "carcinoma" requires the presence of discontinuous growth in the form of metastatic disease in other parts of the central nervous system or spread to lymph nodes, liver and other organs (DeLellis et al., 2004; Asa, 2011). This occurrence is exceptionally rare. There are no specific morphologic or other biomarkers that predict metastatic behavior and the vast majority of patients with pituitary carcinoma have had an initial diagnosis of a pituitary "adenoma," providing yet another rationale for changing the terminology to PitNET (Asa et al., 2017a).

Rarely, other types of tumor arise in the pituitary. These include *craniopharyngiomas* (**Fig. 2**) that arise from embryological remnants of the developing pituitary gland from the oral cavity, *neuronal and glial tumors* of the hypothalamus and neurohypophysis (the posterior neural portion of the pituitary gland), as well as *mesenchymal, hematologic, and germ cell tumors* that can arise in the region of the sella turcica (Asa, 2011). *Metastatic tumors* can involve the pituitary gland and there are also tumor-like lesions, including *cysts, inflammatory conditions*, and rare *hyperplasias* of adenohypophysial cells that can mimic a primary pituitary tumor.

Assessment of Patients With Pituitary Tumors

Biochemical Evaluation

Biochemical assessments are driven by the clinician's suspicions and rest on two major concerns. Hormone loss due to compromise of anterior pituitary function requires measures of serum pituitary trophic hormones and their targets. These include corticotroph secreted ACTH and its target cortisol, thyrotroph secreted TSH and its target thyroxine (T4), somatotroph secreted growth hormone (GH), and its target insulin like growth factor 1 (IGF-1), gonadotroph secreted luteinizing hormone (LH), and its target sex steroids, estradiol in women and testosterone in men. Follicle stimulating hormone can be measured directly but typically clinicians rely on the presence or absence or loss of LH from the same gonadotroph, or in the case of premenopausal women, the absence or presence of normal menstrual function. Finally, prolactin can be measured directly in the blood, where levels generally correlate with the size of the pituitary tumor if it is a lactotroph tumor; discrepancies between tumor size and prolactin values should raise the suspicion of a "stalk effect" where a nonlactotroph tumor grows to interrupt delivery of the hypothalamic prolactin inhibitor dopamine.

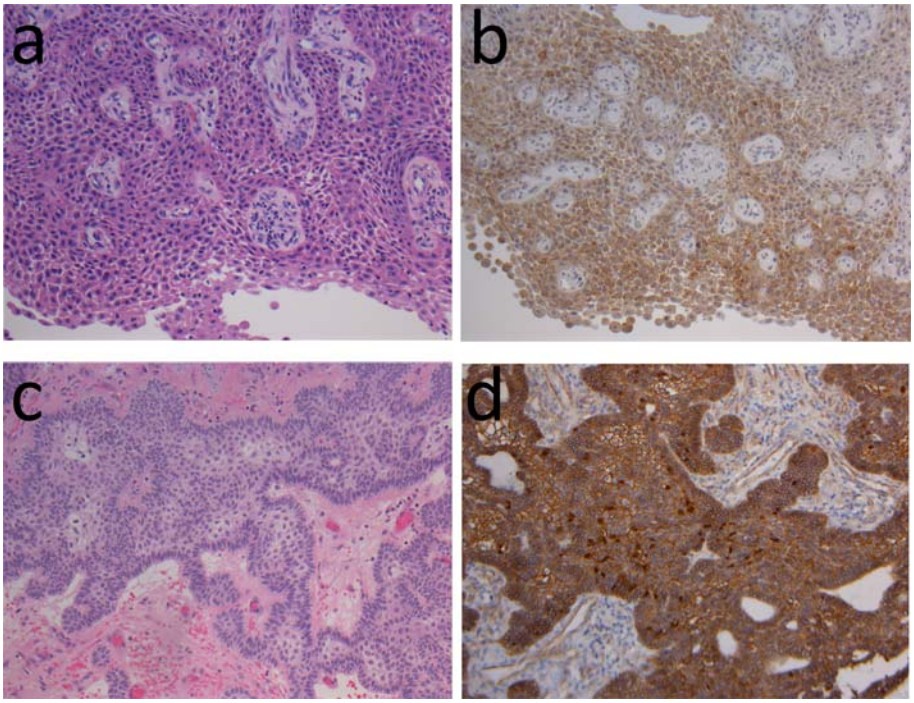

Fig. 2 Morphologic features of craniopharyngiomas. Craniopharyngioma is a tumor derived from the oral endoderm and the morphologic features reflect this squamoid origin. The papillary type (A and B) is composed of cords or islands of epithelial cells in a loose fibrous stroma; it may harbor the activating BRAFV600E mutation as identified by the VE1 antibody (B). The adamantinomatous type (C and D) has a morphology that resembles the ameloblastic organ; it may have mutation of beta-catenin that results in focal nuclear translocation (D).

Radiologic Imaging

As with biochemical studies, imaging is driven by clinical suspicion further supported by biochemical findings. The rationale behind this sequence of management helps avoid mis-diagnosis of incidental nonfunctional lesions, and to distinguish those of modest clinical relevance from small occult lesions of paramount importance. Magnetic resonance imaging (MRI) is the preferred method of examination (Bakir et al., 2016) (**Fig. 3**), as it affords detection of small lesions which require separation from the normal gland, as is typically required in patients with Cushing disease. It can also identify extension beyond the sella turcica and invasion into surrounding structures. This includes superior extension to involve the optic chiasm leading to visual field defects, lateral invasion into the cavernous sinuses where rapid growth can result in cranial nerve palsies leading to diplopia, and inferior growth into the sphenoid sinus leading to congestion and rarely cerebrospinal fluid leakage. More recently there has been a growing interest in how MR signals on T2-weighted images correlate with hormone granularity, in particular, hypointensity on T2 imaging appears to correlate with a densely granulated morphology which in the case of growth hormone tumors can be associated with favorable response to somatostatin analogue therapy (Asa et al., 2017b). While functional nuclear studies remain promising using isotopes that can detect pituitary tumor cell surface receptors (Opalinska et al., 2017), the limits of resolution remain problematic compared with current MRI 3T technology.

Genetic Testing

PitNETs are most often sporadic tumors (Asa and Ezzat, 2009); some are associated with somatic mutations such as *GNAS* in densely granulated somatotroph tumors and *USP8* mutations in densely granulated corticotroph tumors (Asa and Mete, 2018). The majority have no known genetic mutations and are thought to be due to epigenetic alterations (Ezzat et al., 2018).

There are, however, a number of familial syndromes that predispose to the development of PitNETs (Asa and Ezzat, 2009; Asa and Mete, 2018). These include Multiple Endocrine Neoplasia (MEN) Type 1 due to mutations in the *MEN1* gene, Carney complex due to *PRKAR1A* mutations, MEN Type 4 due to mutations in the genes encoding p27 or p18, familial isolated pituitary adenoma (FIPA) syndrome due to *AIP* mutations, and the 3PA syndrome (Pituitary Adenoma with Paraganglioma/Pheochromocytoma) due to SDH complex mutations. Other germline events associated with pituitary tumor development include McCune Albright syndrome due to mosaic germline *GNAS* mutation, X-linked acrogigantism (X-LAG) characterized by early childhood onset of gigantism due to Xq26 microduplications and *GPR101* mutation, and the very rare pituitary blastoma due to *DICER* mutations.

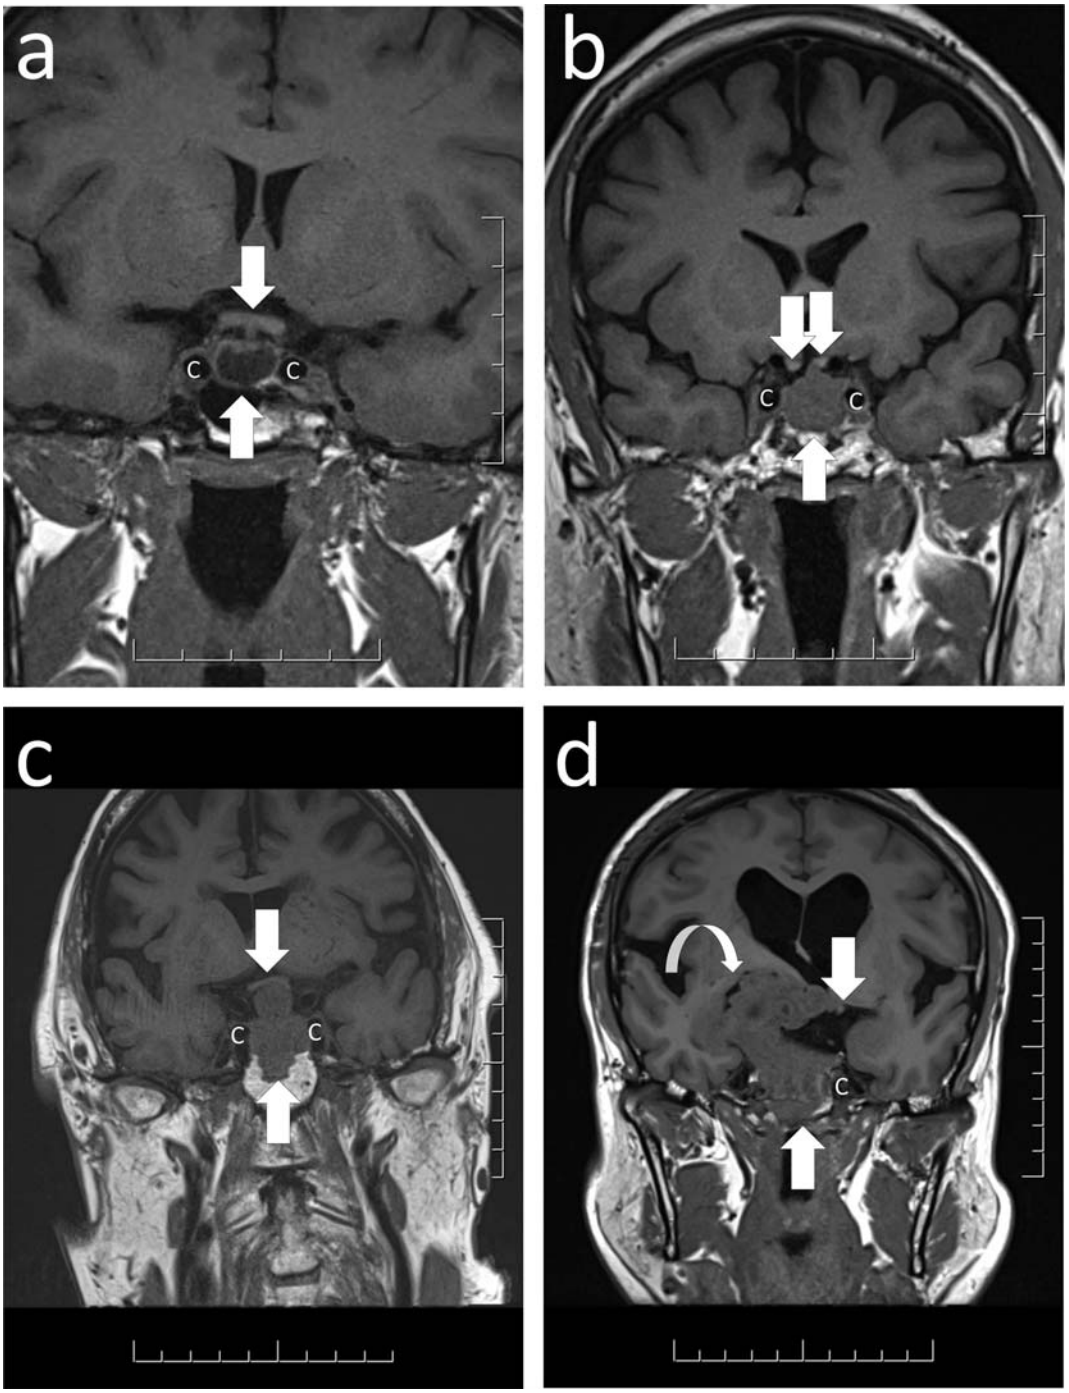

Fig. 3 Magnetic resonance imaging of pituitary tumors. The pituitary is located at the base of the brain in the bony structure of the sella turcica (bottom *arrows*) that lies between the cavernous sinuses (C) and below the optic chiasm (top *arrows*). Pituitary tumors can be (A) small, within the pituitary and cystic, (B) slightly invasive into the cavernous sinuses, (C) large and soft, ballooning upwards with a "snowman" shape due to compression by the diaphragm sellae, or (D) giant and aggressively invasive of the brain (curved *arrow*), obstructing cerebrospinal fluid flow and causing hydrocephalus, obliterating the lateral cavernous sinus, and infiltrating inferiorly though bone and into the paranasal sinuses.

Management of Patients With Pituitary Tumors

Medical Therapy

The purpose of medical therapy is to control if not reverse disease progression in terms of hormone excess, and where relevant, reduce tumor size, and invasiveness. Pharmacological agents have been developed based on recognition of endogenous pituitary

hormone inhibitors. These objectives have been met with varying degrees of success. Classically, dopamine agonists have proven their benefits in terms of reducing prolactin levels and diminishing the size of lactotroph tumors (Cuny et al., 2015), such that they are the mainstay of treatment for this tumor type. The same dopamine agonists have proven to be relatively less effective in GH-secreting tumors (Cuny et al., 2015) and even less in clinically nonfunctioning gonadotroph tumors (Greenman et al., 2005). First generation somatostatin analogues have proven to be effective in lowering GH levels and reducing the size of tumors causing acromegaly or gigantism (Cuny et al., 2015; Grasso et al., 2013; Iacovazzo et al., 2016). In some institutions, this medical therapy is used initially, to enhance the outcome of surgical resection, whereas in other institutions this medical therapy is only used for surgical failures. Response is usually better in patients with densely granulated somatotroph tumors than in those with sparsely granulated somatotroph tumors (Bhayana et al., 2005; Asa et al., 2017b), consistent with the presence of *GNAS* mutations that characterize the densely granulated tumors. More recently, second generation analogues, that bind with more somatostatin receptor subtypes, have also been used in managing inoperable Cushing disesase (Pivonello et al., 2014); again the response has been shown to be better in densely granulated tumors that may harbor *USP8* mutations (Hayashi et al., 2015). Analogues of the GnRH hypothalamic peptides have not shown to be of benefit in shrinking gonadotroph tumors (Cuny et al., 2015) and, therefore, are rarely used in managing patients with pituitary tumors.

Aggressive PitNETs and pituitary carcinomas can be quite challenging to treat. Use of the DNA methylation inhibitor temozolomide has gained momentum, given its utility in primary CNS tumors (Vieira et al., 2013; Annamalai et al., 2012; Raverot et al., 2010, 2012; Bush et al., 2010; Fadul et al., 2006). Unfortunately, such therapy continues to be associated with the emergence of resistance (Batisse et al., 2013), highlighting the need for more effective agents in restraining rapidly proliferative and metastatic pituitary neoplasms.

Whether cured of their pituitary tumor or not, patients may require ongoing medical follow up to ensure appropriate hormone replacement and to deal with visual field loss, cardiac dysfunction, bone loss, sleep apnea, and obesity that can be complications of the hormone excess or from hormonal loss due to anterior pituitary failure.

Surgery

As with medical approaches, the aim of surgical intervention is to reduce, if not normalize hormone levels, and eliminate the responsible tumor. Naturally, the obvious advantage would be the more definitive nature of a surgical procedure. To a great extent, these objectives are met when the tumor is detected early and its limits are confined within the sella turcica. Surgical success rates, however, decline sharply as tumor invasiveness extends into surrounding structures (Micko et al., 2015). Despite improvements in current surgical techniques, frank invasion into the lateral walls of the carvenous sinuses precludes complete endoscopic pituitary microsurgery. With these limitations in mind, there continues to be debate on the optimal approach to the integration of medical and surgical management of pituitary tumors. It is anticipated that prospective controlled studies will assist in the selection and design of optimal management approaches to difficult pituitary tumors.

Radiation Therapy

The role of external beam radiation has evolved over the last decades (Lillehei et al., 1998; Tsang et al., 1994). In general, with improvement in medical and surgical approaches, the role of radiation has declined. In most centres, radiation is reserved for those cases where other therapeutic options have failed. In contrast, the role of more focused, gamma-knife radiotherapy has emerged as a suitable option where the tumor target is confined to a limited region within or outside the sella turcica (Jagannathan et al., 2008; Oyesiku, 2007). Long-term outcomes of gamma knife radiation continue to emerge, helping provide better evidence for integration of this therapeutic modality in the growing armamentarium of management options.

Psychosocial Assistance

Patients with pituitary tumors are known to have emotional disturbances that result from hormone excess, hormone deficiency or the effects of the tumor on adjacent brain structures (Sobrinho, 1998; Flitsch et al., 2000; Starkman et al., 2007; Sievers et al., 2009; Tiemensma et al., 2010a,b). It is also possible that there are common predisposing factors to endocrine and emotional dysfunction (Kiehl et al., 2008). The psychosocial alterations including depression, anxiety, loneliness, anger, and other reactions to changes in body image and sexuality require supportive management to enhance the quality of life of patients with pituitary disorders.

Prospective Vision

Pituitary tumors represent one of the more common endocrine neoplasms. They vary widely in terms of endocrine manifestations and structural impact. A successful management approach rests fundamentally on heightened clinical suspicion and early detection. Delayed diagnosis is associated with the potential for significant endocrine, neurologic, and multisystem dysfunctions. Fortunately, advances in biochemical, radiographic, and histomorphologic examinations are leading to refinements in risk stratification and management approaches.

Polyomaviruses in Human Cancer

Masahiro Shuda, University of Pittsburgh Medical Center (UPMC) Hillman Cancer Center, Pittsburgh, PA, United States; and University of Pittsburgh, Pittsburgh, PA, United States

Glossary

Large T (LT) LT is a polyomavirus replicase that possesses DNA helicase activity, but also acts as viral oncoprotein by inhibiting multiple tumor suppressors such as the retinoblastoma protein and p53 protein.

Merkel cell polyomavirus (MCV) A first human oncogenic polyomavirus discovered in 2008 that is strongly linked to human Merkel cell carcinoma.

Polyomavirus (Greek: poly many, multiple; oma: tumors) A small circular double-stranded DNA virus originally identified in animals as an infectious agent that induces tumors in nonpermissive hosts.

Small T (sT) sT is another oncoprotein encoded by T antigen gene that commonly inhibits the host protein phosphatase 2A tumor suppressor.

Tumor (T) antigen A polyomavirus gene required for viral genome replication. This is a major polyomavirus oncogene that produces multiple oncogenic proteins such as large T and small T antigen proteins by the alternative splicing.

Polyomavirus research has been central to cancer research. Animal polyomaviruses, in particular, murine polyomavirus (MPyV) and simian vacuolating virus 40 (SV40), are well-studied tumor viruses that have been used to model cellular transformation and carcinogenesis in rodents. Research on the SV40 T antigen led to the discovery of p53 and uncovered the functions of a retinoblastoma tumor suppressor protein (pRb) in cell cycle regulation. On the other hand, molecular analysis of the MPyV oncogene identified the importance of tyrosine phosphorylation and phosphoinositide 3-kinase signaling in cell transformation.

Because of their strong tumorigenicity, polyomaviruses have been suspected to play a role in human cancer. However, for a long time until 2006, the JC polyomavirus (JCV) and BK polyomavirus (BKV) were the only known human polyomaviruses, and neither of these viruses had been strongly linked to human cancer. In this century since 2007, the developments in all fields of genetics and genetic technology facilitated the discovery of human polyomaviruses. As a result, 12 new polyomaviruses joined the human polyomavirus family. Notably, the discovery of the Merkel cell polyomavirus (MCV or MCPyV) from human Merkel cell carcinoma (MCC), as well as the identification of the rare BKV integration event in urological cancers, proved our assumptions of polyomavirus involvement in human tumorigenesis to be true.

This article provides an overview of basic polyomavirus virology, revisits hallmarks of polyomavirus-induced malignancy, and describes common molecular mechanisms of the T antigen-mediated oncogenic transformation. With an updated list of 14 new human polyomaviruses, their discoveries and potential roles in human carcinogenesis are discussed. Finally, the first human oncogenic polyomavirus MCV is described with a particular focus on its transformation mechanisms.

Genome Structure and Basic Virology of Polyomaviruses

Polyomaviruses are unenveloped, double-stranded DNA viruses with a closed-circular genome of approximately 5000 base pairs (bp), which can be divided into the viral regulatory region and the early and late coding sequences (Fig. 1A). The regulatory region, or noncoding control region (NCCR), contains the DNA replication origin and two bidirectional promoters that drive early and late gene expression. The early gene is transcribed prior to viral DNA replication and expresses the Tumor (T) antigen, also known as a viral oncogene. The T antigen gene expresses at minimum the large tumor antigen (LT) and small tumor antigen (sT) proteins from a single multiply spliced mRNA, which are common across the polyomavirus family. In addition to LT and sT, each polyomavirus expresses unique isoforms of the T antigen such as the middle T (MT) antigen from murine polyomavirus (MPyV) and the multiply spliced 17kT from simian vacuolating virus 40 (SV40). While the oncogenic function of T antigens is better described, these two viral antigens play important roles in polyomavirus replication. LT is the viral replicase protein with an origin-binding domain (OBD) and DNA helicase domain, which directly binds to the replication origin (Fig. 1B). In fact, the cell-free SV40 replication system has served as a model for understanding mammalian DNA replication, because SV40 DNA replication exploits the host eukaryotic cellular replication machinery except for the MCM helicase, whose function is fulfilled by the LT. Recent studies demonstrated that the architecture, dimensions, and assembly of LT and MCM2–7 double hexamers on their cognate origin DNAs are closely related, and the host protein machinery at viral and host replication forks is remarkably similar. The LT helicase directly binds to the pentanucleotide sequences (GAGGC) in the replication origin through OBD and assembles into two

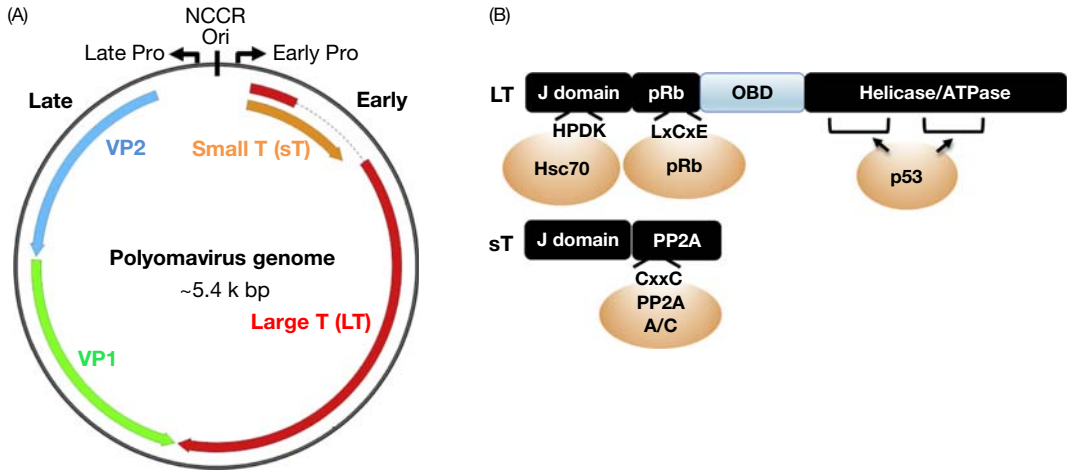

Fig.1 (A) The genome structure of polyomavirus. (B) LT and sT antigen proteins. Host proteins and their interacting domains on T antigen proteins are indicated.

ring-shaped hexamers. Upon binding to ATP, the LT double hexamers separate from each other, and the individual hexamers move in opposite directions on single-stranded DNA in a 3′-to-5′ direction to initiate bidirectional DNA replication. Thus, LT is the protein to orchestrate the replication of the viral mini-chromosome in infected cells.

The sT protein is also important for virus replication. However, in contrast to LT, the effect of sT is indirect, because the sT protein does not enhance the LT-mediated viral replication in vitro. In SV40, the sT deletion mutant is infectious, but virus production is significantly reduced. It has been shown that the exogenous expression of SV40 sT in cells infected with a sT-defective mutant virus stimulates viral DNA replication. Because sT promotes cell cycle progression from G0/G1 to S phase, which coincides with viral replication enhancement, sT is suggested to create an optimal environment for viral DNA replication. Similar to the SV40 sT, human JC polyomavirus (JCV) sT also activates viral replication through its protein phosphatase 2A (PP2A) and Rb binding domains, which are critical for cell cycle progression. In contrast, human Merkel cell polyomavirus (MCV) sT activates virus replication in a PP2A-independent mechanism. MCV sT harbors a functional domain that stabilizes MCV LT, which is described later in this article.

In addition to the LT and sT proteins, the T antigen gene also expresses other isoforms that are unique to each polyomavirus. These T antigen isoforms are produced by the unique alternative splicing of T antigen transcripts or by the alternative translation initiation that occurs on the LT transcript. The early gene region is expressed in polyomavirus-induced cancers and has been shown to be the polyomavirus oncogene. The oncogenic roles of LT and sT oncoproteins will be described in the following section.

The late gene transcription occurs after DNA replication to produce VP proteins—components of the viral capsid. The polyomavirus capsid is an icosahedral shell with a diameter of approximately 40–50 nm and consists of pentameric capsomeres, which are composed of the major capsid protein VP1. The viral capsid also contains minor capsid proteins VP2 and VP3 that are not always required for the self-assembling process of the capsid, but rather for infectivity, egress, and for viral genome transport into the nucleus.

Hallmarks of Polyomavirus-Induced Malignant Transformation

MPyV, the founder of the polyomavirus family, was discovered in 1953 as a filterable infectious agent from mouse leukemia tissue extracts. Extracts of the tumor contained a virus that induced the formation of a variety of solid tumors in newborn mice. It was thus termed polyomavirus for its ability to induce multiple tumors in mice. SV40, which naturally infects rhesus macaque, was the second member of this family isolated in 1959. It was identified as a contaminant of Salk poliovirus vaccines prepared using Macacus monkey renal cell cultures. SV40 infection in nonpermissive rodents developed tumors, while infection in permissive monkey cells produced progeny viruses instead of inducing transformation. Because of the strong tumorigenic activities in nonpermissive hosts and in cultured cells, SV40 provided a new model for cell transformation and tumorigenesis.

Polyomavirus is a direct carcinogen, delivering its T antigen oncogene into cells to induce malignant transformation, and each transformed tumor cell contains a clonally integrated viral genome. Importantly, although the T antigen is required for viral replication, the loss of viral replication activity in a nonpermissive host is associated with increased transformation activity of animal polyomaviruses. The functional domain of LT for viral replication can be separated from the domain responsible for cell transformation. Replication-defective MPyV, for instance, shows better transformation efficiency in vitro and induces more tumors in vivo than wild type MPyV. Similarly, SV40, with mutations disrupting viral replication and helicase activity, shows enhanced transforming activity. Loss of LT helicase expression is also observed when examining MPyV-induced tumors in hamsters, while sT and MT expression is maintained. Furthermore, in transformed tumor cells, these animal polyomaviruses produce neither late capsid proteins nor progeny viruses. Taken together, the loss of viral replication capacity in transformed host cells resulting from LT

helicase mutation, viral genome integration, and the loss of capsid protein expression are the hallmarks of polyomavirus-induced tumors. Consequently, tumor cells become the terminal host for the oncogenic polyomaviruses.

The Molecular Mechanism of Polyomavirus Transformation

T Antigen: The Polyomavirus Oncogene

The strategy of polyomaviruses for inducing cellular proliferation and transformation is generally the direct inhibition of tumor suppressors and the activation of oncogenic pathways. T antigen is the primary polyomavirus oncogene that mediates these processes and plays essential roles in cell transformation and tumorigenesis. Mutational analysis of the T antigen uncovered independent domains that contribute to transformation. The reverse genetic studies on SV40 T antigen molecules revealed three cellular tumor suppressors: retinoblastoma protein (pRb), p53 protein, and protein phosphatase 2A (PP2A). Inhibition of these tumor suppressors by T antigen results in aberrant cell cycle progression, leading to oncogenic transformation. While each polyomavirus targets unique oncogenes and tumor suppressors, this section focuses on three tumor suppressors pRb, p53, and PP2A that are commonly targeted by oncogenic polyomaviruses and required for human cell transformation by SV40.

Retinoblastoma family

Most polyomavirus LTs have a well-conserved pRb-binding motif LxCxE (Leu-X-Cys-X-Glu), which is responsible for cell transformation and tumorigenesis. pRb, originally described in a rare childhood eye tumor—retinoblastoma—in which this protein is defective, regulates cell cycle progression from G1 to S phase. The pRb is a member of retinoblastoma protein family that also includes p107 (pRb1) and p130 (pRb2). pRb is hypophosphorylated in resting G0 cells, increasingly phosphorylated during cell cycle progression through G1 by cyclin-dependent kinases cyclinD1/cdk4 and cyclin E/cdk2, and maintained in a hyperphosphorylated state until mitosis. Furthermore, Rb family proteins control S phase progression by modulating E2F-response genes. E2F is a family of transcription factors that consist of eight members. E2F1, E2F2, and E2F3 (E2F3a and E2F3b) are potent transcriptional activators that interact exclusively with pRb and are periodically expressed throughout the cell cycle. On the other hand, E2F4, E2F5, E2F6, E2F7 (E2F7a and E2F7b), and E2F8 are transcriptional repressors. Unlike activator E2Fs, E2F4 interacts with all three Rb family proteins, while E2F5 associates predominantly with p130, and these suppressor complexes exert their influence in the large multiprotein complex called DREAM (*d*imerization partner (DP), *R*b-like, *E*2F *a*nd *M*uvB) during G0 phase quiescence. The DREAM complex directly binds to the E2F-regulated gene promoter through the suppressor E2Fs and p130 or p107. This transcriptional suppression is suggested to play important roles in the maintenance of cellular quiescence, senescence, and tumor suppression. Other suppressor E2Fs, including E2F6, E2F7, and E2F8, do not interact with Rb family members and are thought to function independently. E2Fs regulate transcription of the genes required for cell cycle progression and DNA replication such as cyclin A, cyclin D1, cyclin E, dihydrofolate reductase, cdk2, survivin, thymidine kinase, c-myc, c-myb, cdk1, cdc6, and DNA polymerase α. Other targets also include gene products involved in DNA repair, cellular differentiation, and apoptosis. To regulate E2F activities, hypophosphorylated pRb suppresses the activities of E2F transcription factors by recruiting chromatin remodeling factors, histone deacetylases (HDAC), and histone methyltransferases. Moreover, pRb binds within the transactivation domains of E2F1-E2F3 and prevents the assembly of the transcription initiation complex. Phosphorylation of pRb results in the disassembly of the Rb-E2F complex, leading to the activation of E2F1-E2F3, while the phosphorylation of p130 and p107 also results in the dissociation of the DREAM repressor complex. Thus, the inactivation of Rb family proteins is critical for natural cell cycle progression.

Shortly after the pRb protein was discovered, SV40 LT was identified as a direct binding partner to pRb and later to p107 and p130 as well. This interaction is mediated by the LT LxCxE motif that is conserved in most polyomaviruses (**Fig. 1**B). For pRb inhibition, the LxCxE domain cooperates with the N-terminal J domain (His-Pro-Asp-Lys (HPDK) motif) of LT that binds Hsc70, a chaperone with weak ATPase activity. The J domain is conserved in the DnaJ protein chaperone family and activates the ATPase activity of Hsc70 upon its binding. The energy produced from the ATP hydrolysis is exploited by LT to dissociate the pRb/E2F complex and to liberate E2F from the pRb regulation. Another mechanism for LT to target the Rb-E2F pathway is by affecting the expression levels of the Rb family proteins. SV40 LT decreases p130 protein levels by promoting proteasomal degradation of p130, but not pRb. While LT interaction with Rb family proteins is a highly conserved phenotype among polyomaviruses, the binding affinity to each Rb family protein varies across different polyomavirus LTs. Nevertheless, human polyomavirus LTs from JCV, BK polyomavirus (BKV), and MCV have been shown to interact with Rb family proteins and promote E2F-target gene transcription. BKV LT downregulates the protein expression and phosphorylation of all Rb family proteins. JCV LT also reduces p130 protein expression, and re-expression of p130 protein is shown to overcome JCV LT-mediated tumorigenesis both in vitro and in vivo. Thus, the inhibition of Rb family proteins by LT is likely to play critical roles in polyomavirus-associated human cancers.

p53 protein

In 1979, several groups independently stumbled upon p53. When sera from animals with SV40-induced tumors were used to immunoprecipitate SV40 LT, a host cellular protein with an apparent molecular weight around 53 kDa was identified as a binding partner. p53 is a transcription factor that suppresses tumor growth through regulation of dozens of target genes involved in antiproliferative and apoptotic responses, and its mutation is associated with $>50\%$ of all human cancers. p53 is a transcription factor whose activity is controlled at the protein level by MDM2. MDM2 is a ubiquitin E3 ligase that inhibits p53-mediated gene expression through direct binding to p53 and ubiquitin-mediated degradation via its E3 ligase activity. The protein kinases ATM and ATR,

which signal DNA damage, phosphorylate the N-terminal of p53 protein to dissociate p53 from MDM2 and stabilize the p53 protein. On the other hand, to prevent oncogene-induced transformation, ARF protein ($p14^{ARF}$ in mouse and $p19^{ARF}$ in human) induced in response to oncogene activation promotes MDM2 degradation and stabilizes the p53 protein. As a tumor suppressor, p53 plays a central role in cell cycle checkpoints that limit cell division or that induce cell suicide in response to DNA damage or oncogene activation. In particular, p53 is involved in cell cycle arrest in the G1/S and G2 phases. G1/S phase arrest is achieved by the cyclin-dependent kinase inhibitor $p21^{Waf1/Cip1}$ (CDKN1A), a negative regulator of cyclinD1/cdk4 and cyclin E/cdk2 that phosphorylate and inactivate pRb as mentioned in the previous section. Part of the mechanism by which p53 blocks cells at the G2 checkpoint involves inhibition of cdk1, the cyclin-dependent kinase required to enter mitosis. Cdk1 is simultaneously inhibited by three p53 transcriptional targets: Gadd45, p21, and 14-3-3 sigma.

Polyomaviruses including SV40, JCV, and BKV contain the p53-binding domain that overlaps with the C-terminal helicase/ATPase domain (Fig. 1B). The binding of SV40 LT to p53 blocks the ability of p53 to bind to its consensus sequence and inhibits transcription of its targets such as $p21^{Waf1/Cip1}$. This drives cell cycle progression even in the presence of oncogene activation and DNA damage and contributes to transformation.

Moreover, oncogenic polyomavirus T antigens also inhibit p53 function independently from their direct interaction with this protein. For instance, none of the T antigen proteins encoded by oncogenic MPyV associate with p53, nor do they inhibit p53 DNA binding. MPyV LT, however, blocks p53-mediated growth suppression. Even a SV40 T antigen defective in p53 binding suppresses p53-mediated gene transcription. Several reports suggest that the J domain and Rb-binding motif of LT are also required, or even essential, to override p53-induced growth inhibition. MPyV sT also inhibits p53 function by preventing $p14^{ARF}$-mediated activation of p53. Thus, even if LT lacks p53-binding activities, oncogenic polyomaviruses exploit different components of their viral machinery to escape from the antiproliferative activity of p53. Similar to MPyV LT, human MCV LTs expressed in MCC tumors do not associate with p53 nor inhibit p53 activities, and the intact p53 protein is generally expressed in MCV-positive MCC tumors. MCV T antigen may yet have unknown mechanisms to counteract p53-mediated tumor suppressor activities.

Protein phosphatase 2A

Protein phosphatase 2A (PP2A) serves as a tumor suppressor by its phosphatase activity. This protein phosphatase contains an active core dimer composed of a catalytic C subunit (PP2A C) and a scaffolding A subunit (PP2A A). The scaffolding subunit PP2A A mediates the formation of heterotrimeric holoenzymes by interacting with regulatory B subunits that determine substrate specificity, localization, and function. Specific PP2A holoenzymes containing B56γ and B56α regulatory subunits control the dephosphorylation of oncoproteins Akt and c-Myc to negatively regulate their activities. The B56 holoenzyme complex also downregulates Wnt/β-catenin signaling by destabilizing the β-catenin protein; however, the molecular mechanism for this still remains unclear.

PP2A was identified to be one of the binding partners of SV40 sT and MPyV MT. To inhibit PP2A activity, SV40 sT binds to PP2A A and PP2A C subunits by displacing the regulatory B subunit. Structural studies have demonstrated that the conserved C-terminal zinc-binding motifs CxxC (Cys-X-X-Cys) and the N-terminal J domain of the sT protein are critical for interaction with the PP2A A subunit (Fig. 1B). The PP2A interaction domain is well-conserved in the sT protein of most polyomaviruses. sT proteins from human polyomaviruses JCV, MCV, HPyV6 and MWPyV have also been shown to interact with PP2A.

Studies on SV40 sT mutants demonstrated that the sT interaction and inhibition of PP2A activity are essential for its transforming activity in human cells. Human cells are generally more resistant to malignant transformation. While the coexpression of SV40 LT with oncogenic H-Ras is sufficient to transform several types of rodent cells, human cell transformation requires additional expression of human telomerase reverse transcriptase (hTERT), oncogenic H-Ras, and SV40 sT. This model has served as a system to study the transformation activities of the SV40 sT antigen. SV40 sT has been shown to displace the aforementioned B56γ and B56α subunits from the PP2A A-C core dimer, leading to the increased phosphorylation of Akt and c-Myc oncoproteins as a result of the phosphatase inhibition. Increased Akt phosphorylation persistently activates downstream Akt-mTOR pathway signaling, while the phosphorylation on c-Myc inhibits its turnover and activates its function. SV40 sT also activates Wnt/β-catenin signaling, consistent with its inhibition of PP2A isoforms containing B56γ and B56α subunits. Activation of these oncogenic pathways is strongly implicated in SV40 sT-induced human cell transformation. The inhibition of Akt, β-catenin, or c-Myc expression by shRNA significantly reduces the transformation-associated soft agar colony formation in SV40 sT-transformed human cells, and the expression of gain-of-function Akt or c-Myc mutants substitutes for SV40 sT in human cell transformation.

The Rapidly Expanding Family of Human Polyomaviruses and Their Potential Roles in Human Malignancy

As of 2017, 14 human polyomaviruses have been identified (Table 1). For nearly 35 years, however, BKV and JCV had been the only known human polyomaviruses until 2006, presumably due to the lack of techniques needed to sensitively detect low copy polyomavirus infection in healthy and diseased tissues. New genetic technologies such as next generation sequencing and rolling circle amplification developed in this century broke this barrier and discovered 12 more human polyomaviruses (Table 1). Because of the expanding number of new polyomaviruses, the International Committee on Taxonomy of Viruses (ICTV) updated the taxonomy of the *polyomaviridae* family in 2016 and divided it into four genera (alpha-, beta-, gamma-, and delta-polyomaviruses) based on the observed phylogenetic distances between large T antigen amino acid sequences (Fig. 2). Human polyomaviruses are a diverse family of small DNA viruses that usually cause asymptomatic, lifelong infections in healthy individuals. This is consistent with relatively high seroprevalence of human polyomaviruses (Table 1). Some of the human polyomavirus infections have been associated with

Table 1 Human polyomaviruses

Name (ICTV designation)	*Abbreviation*	*Year of discovery (reference)*	*Ref. seq. accession*	*Methods of discovery*	*Source of isolation*	*Disease association*	*% seroprevalence*[a]

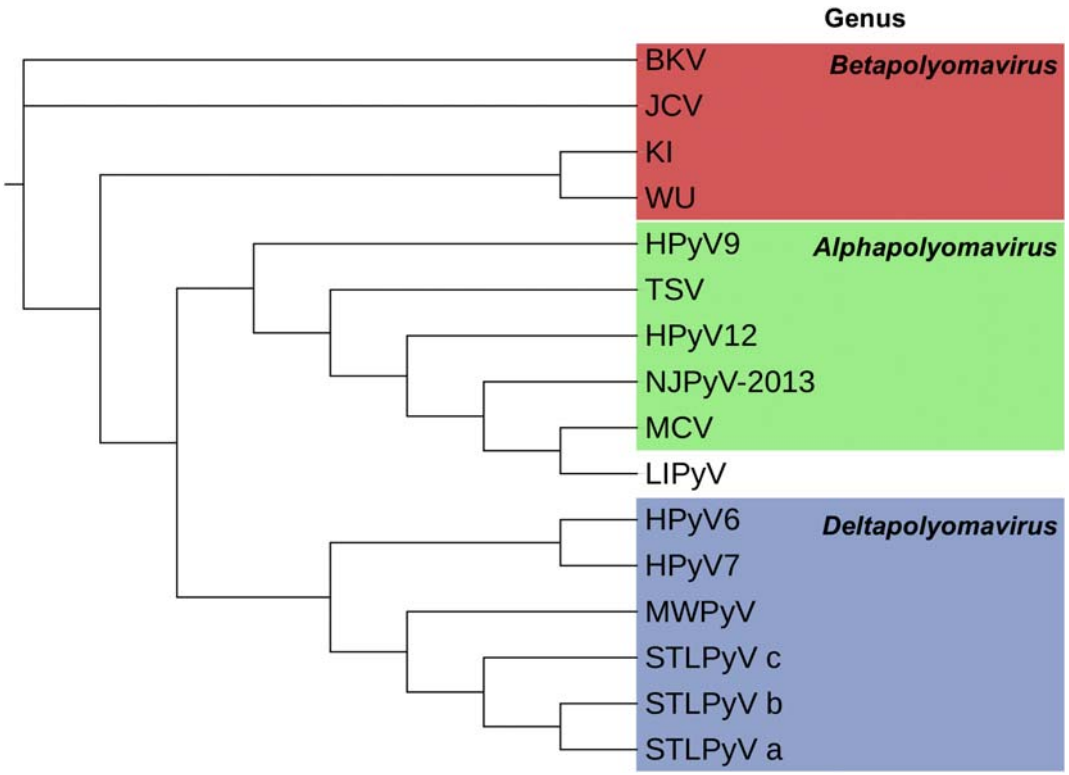

Fig. 2 Bayesian chronogram deduced from the alignment of human polyomavirus 14 large T protein sequences. Due to the reported variations, STLPyV are divided into three substrains.

human disease, including cancers. An important commonality is that all polyomavirus-mediated pathogenesis reported so far is associated with immune suppression. This section focuses on the discovery of human polyomaviruses, disease associations, and their potential roles in human cancer.

BK Polyomavirus (BKV/BKPyV/HPyV1) and JC Polyomavirus (JCV/JCPyV/HPyV2)

In 1971, two independent groups discovered the first human polyomaviruses, BK polyomavirus (BKV or BKPyV) and JC polyomavirus (JCV or JCPyV) in specimens from immunocompromised patients. BKV was identified from the urine of a renal transplant patient and JCV from the brain of a patient with a history of Hodgkin's lymphoma and progressive multifocal leukoencephalopathy. Both diseases show strong association with immune suppression. Subclinical infection with BKV and JCV occurs in early childhood, and these viruses coexist within the human population, as approximately 82%–95% and 39%–54% of adults in United States exhibit BKV and JCV seroreactivity, respectively. Despite their close association with acute diseases in the immunocompromised population, BKV and JCV have been suspected as human tumor viruses because of their strong oncogenic potential. Based on their well-documented transforming potential in experimental models, BKV and JCV are categorized as "possible carcinogens (group 2b)" by the International Agency for Research in Cancer.

BKV in human cancer

BKV is highly tumorigenic in newborn hamsters and mice, inducing several different types of tumors. When injected into hamsters intracerebrally or intravenously, BKV efficiently induces tumors in 82% of the inoculated animals. The most frequent tumors are cerebral ependymomas (72%), followed by pancreatic islet tumors (12%), and osteosarcoma (10%). BKV is frequently integrated into the tumor cell genome and expresses T antigen in tumors. Generation of transgenic mice expressing the BKV early region revealed that BKV T antigen expression induces renal tumors in line with viral tissue tropism. In addition, hepatocellular carcinoma and thymoproliferative disorder (ranging from extreme hyperplasia to thymomas and lymphomas) were also observed in the transgenic mice. BKV T antigen expression also transforms normal cells such as embryonic fibroblasts and cells cultured from the brain and kidneys of hamsters, mice, rats, rabbits, and monkeys consistent with its tumorigenic effect in vivo. In human cells, however, BKV T antigen is insufficient to induce transformation. Although BKV-infected or transfected normal human cells show increased lifespan, they do not display complete transformed phenotypes such as anchorage-independent cell proliferation and tumorigenicity in nude mice. BKV T antigen expression contributes partially to human cell transformation, and additional oncogene expression such as adenovirus E1A is required for full transformation.

Because BKV shows oncogenic tropism for the ependymal tissue, pancreas, and bones in rodents, BKV DNA was initially explored in human ependymomas, other brain tumors, and insulinomas. The search was extended to Kaposi's sarcoma, bone tumors, urinary tract tumors, genital tumors, neuroblastomas, Hodgkin's disease, acute lymphoblastic leukemia, and neuroblastomas. Through southern hybridization and PCR techniques, multiple groups detected BKV DNA in human brain tumors, neuroblastomas, insulinomas, Kaposi's sarcoma, urinary tract tumors, and genital tumors, as summarized in a review article. However, in most studies, BKV DNA in tumors has been detected at a low copy number, less than a single copy per cell, and the results from different groups are not consistent within the same types of tumors.

On the other hand, a rare clonal integration event of BKV DNA is reported. Monini et al. identified two cases of bladder carcinoma, which contain 1–50 copies of viral DNA per cell. Southern blot hybridization combined with two-dimensional gel electrophoresis identified that the first tumor case harbors clonally integrated BKV genome, while the second case contains both integrated BKV and episomal viral genomes. In both cases, the late region was disrupted. This was recently confirmed by two groups. Tang et al. detected predominant expression BKV LT-host fusion transcript in 1 out of 96 bladder carcinoma cases from The Cancer Genome Atlas Research Network (TCGA) transcriptome database. Kenan et al. reported a case of urothelial carcinoma arising in a renal allograft that expresses BKV LT expression. Genomic DNA sequencing of this tumor identified that BKV is clonally inserted into the *MYBPC1* gene with a breakpoint in the VP1 gene. Recently, Kenan et al. also identified a high-grade renal cell carcinoma that harbors clonally integrated BKV in the *BRE* gene from chromosome 2. Similar to the first case, viral breakpoints were found at the integration site, disrupting the late gene encoding VP1 and VP2/3. Despite its rare occurrence, BKV is clonally integrated in bladder carcinoma, urothelial carcinoma, and renal cell carcinoma, losing the viral replication capability due to clonal integration and late gene ablation. These BKV-associated tumors are terminal hosts for BKV infection, reflecting the hallmarks of polyomavirus-induced cancers established in the animal models. These results strongly indicate that BKV plays etiological roles in rare cases of bladder, urothelial, and renal cell carcinomas.

JCV in human cancer

Similar to BKV, JCV also induces tumors in newborn hamsters, particularly in the tissues of neural origin, including medulloblastomas, undifferentiated neuroectodermal tumors, glioblastomas, pineocystomas, neuroblastomas, and meningiomas. Productive infection of JCV has not been observed in JCV-induced tumors. However, the tumors retain T antigen gene expression. Furthermore, in owl and squirrel monkeys, astrocytoma, glioblastoma and neuroblastoma are also developed after intracerebral JCV inoculation. In accordance with the observations in hamster models, neither the expression of VP1 protein nor viral replication is detected in tumor tissues, which only express the JCV T antigen proteins. These results are consistent with the fact that the JCV-induced tumor cells are nonpermissive for JCV replication. JCV transgenic mice, generated to express JCV early T antigen by its own promoter, also develop neural tumors including adrenal neuroblastoma, pituitary adenoma, malignant peripheral nerve sheath tumor, and medulloblastoma. Above all, JCV-infected animals or mice expressing JCV T antigen are predisposed to develop tumors of neural origin. JCV-mediated transformation can also be seen in cell culture. JCV has the ability to infect and transform primary cells of neural origin, including human cells such as fetal glial cells and vacuolar endothelial cells as well as rodent cells such as baby hamster kidney cells and rat fibroblasts.

Because JCV is a neurotropic virus and induces tumors of neural origin in these animal models, viral DNA and T antigen protein expression were intensively searched for in various central nervous system tumors by PCR-based techniques and T antigen immunohistochemistry. After JCV was identified as the etiologic agent of progressive multifocal leukoencephalopathy (PML), investigations were focused on CNS tumors that concomitantly developed in PML patients. The studies covered a wide variety of CNS tumors: gangliocytomas, choroid plexus papillomas, pilocytic astrocytomas, subependymomas, pleomorphic xanthoastrocytomas, oligodendrogliomas, all subtypes of astrocytomas, ependymomas, oligoastrocytomas, glioblastomas, medulloblastomas, pineoblastomas, gliosarcomas, and primitive neuroectodermal tumors, as summarized in the recent review article. Despite the accumulating evidence of an association between JCV infection and CNS tumors, there is a lack of consistency between studies. Several reports also demonstrated that JCV DNA or even a fragment of JCV is present without gene expression in brains from healthy immunocompetent individuals, with neither PML nor CNS tumors. The nature of ubiquitous, latent JCV infection also makes it difficult to affirm whether JCV is the etiological factor or a simple bystander in human CNS tumorigenesis. Until now, no clear case that displays clonal JCV integration into the tumor cell genome, like BKV integration in bladder tumors, has been identified in human malignancies. Taken together, a causative role of JCV in human cancers is still to be evidenced while, based on its strong tumorigenicity in animal models and the presence of JCV in multiple human tissues, it is reasonable to hypothesize that JCV could play a role as a possible cofactor during human tumorigenesis.

Karolinska Institute Polyomavirus (KI/KIPyV/HPyV3) and Washington University Polyomavirus (WU/WUPyV/HPyV4)

In 2007, groups from Karolinska Institute (KI) and from Washington University (WU) independently discovered KI polyomavirus and WU polyomavirus from human respiratory tract samples by exploiting random PCR and by shotgun sequencing, respectively. Phylogenetic analysis in the LT sequence revealed that these two viruses coincidentally fall into the same clade, belonging to *betapolyomavirus* (**Fig. 2**). High seroprevalence suggest that KI and WU are common human infections (**Table 1**). Since their initial discovery, both of these viruses have been detected in respiratory specimens worldwide. One interesting feature of LI and WU infections is their high rate of coinfection with other respiratory viruses. A coinfection rate of 74% has been detected for KI and rates ranging from 68% to 79% for WU. While the clinical significance of WU and KI infection remains unclear, clinical presentation

in individuals with specimens positive for WU or KI appears to be similar to that of other respiratory viruses, including fever, cough, and other upper and lower respiratory symptoms. To find their involvement in human cancer, presence of KI and WU has been investigated in multiple malignant tissues, including tumors of the CNS including neuroblastoma, non-UV-associated melanoma, kidney/urinary bladder tumors, and various types of lung cancers by PCR-based methodology and serological analysis to detect KI and WU infection. However, none of the studies shows direct involvement of KI and WU in human cancers.

Merkel Cell Polyomavirus (MCV/MCPyV/HPyV5)

In 2008, a group at the University of Pittsburgh discovered a novel member of the human polyomavirus family, named Merkel cell polyomavirus (MCV or MCPyV) by next generation sequencing in the genome of Merkel cell carcinoma (MCC), a rare skin cancer associated with immunosuppression. Their initial report and several studies from different geographic regions confirmed that ~80% of MCCs are associated with MCV, while ~20% are virus-negative MCCs linked to an ultraviolet (UV)-damage pathway associated with a high mutation rate with a signature of UV mutagenesis and inactivation of RB1 and p53. As seen in animal polyomavirus-induced rodent tumors, MCV is clonally integrated into the tumor genome and loses replication capacity in tumor tissues as a result of a tumor-specific mutation that ablates C-terminal viral helicase activity. In addition, the expression of late gene has never been detected in MCC tumors and virus-positive MCC cell lines, consistent with tumor cells being a terminal host for MCV infection. Despite being a rare cancer, MCC is associated with the virus that naturally exists as a component of the human skin microbiome. Showalter et al. demonstrated that MCV virions are chronically shed from the surface of healthy human skin. Seroepidemiological analysis using the seroreactivity to the MCV VP1 protein as a marker of past MCV infection indicates that seropositivity for MCV is 60%–65% (**Table 1**). These results are consistent with MCV being a virus commonly present in the human population. MCV has also been investigated in other cancers to identify secondary MCV-associated cancers. Non-small cell lung cancer (NSCLC) is one of cancers in which MCV DNA is frequently detected by several groups, while contradictory results are also reported. Hashida et al. reported MCV genome integration into the host genome and the LT truncation mutation in several NSCLC cases as seen with MCC. These results suggest the possibility of MCV contribution to a subset of NSCLC tumors. However, a more detailed characterization of MCV-positive tumors is necessary, such as Southern blotting for clonality and histopathological characterization with reliable biomarkers for NSCLC.

While evidence in humans and animal models is still limited, based on the strong mechanistic evidence in humans, IARC classified MCV as "probable carcinogen to human (group 2A)" in 2012. The details of MCV-mediated MCC carcinogenesis will be described later in a following section.

Human Polyomavirus 6 and Human Polyomavirus 7 (HPyV6 and HPyV7)

Rolling cycle amplification (RCA) is a robust molecular technique for new virus discovery that does not require prior viral genetic information. If a sample contains small circular DNA viruses, such as polyomaviruses and papillomaviruses, the bacteriophage phi29 DNA polymerase and random primer efficiently amplify long, concatenated linear DNA, exploiting its unique 5′-to-3′ strand-displacement properties and 3′-to-5′ proofreading exonuclease activity. Cleavage of the amplified DNA with a single-cut restriction enzyme results in the generation of a single genome unit of the circular DNA. A group from National Cancer Institute applied RCA to identify circular viruses in skin swabs from healthy adults and discovered two polyomaviruses human polyomavirus 6 (HPyV6) and human polyomavirus 7 (HPyV7), along with MCV. ICTV classified these viruses as *deltapolyomavirus*. Phylogenic study classified these viruses into the same clade (**Fig. 2**). The same study also demonstrated that MCV, HPyV6, and HPyV7 are shed from healthy, normal skin and suggested that these viruses are a part of the normal human virome in the skin. Recently, however, two groups demonstrated that HPyV6 and HPyV7 are closely associated with pruritic dermatoses in immunosuppressed individuals. Selective B-RAF inhibitor therapy is associated with the development of malignant and benign cell growths. Schrama et al. has reported that HPyV6 is frequently present in the proliferative epithelial cells from the skin of the cancer patients treated with mutation-specific B-RAF inhibitor. HPyV6 may play a role in inducing pathological skin proliferations in combination with specific chemotherapeutic drugs.

Trichodysplasia Spinulosa Polyomavirus (TSV/TSPyV/HPyV8)

A polyomavirus from trichodysplasia spinulosa (TS) was also discovered by RCA, and the virus was named trichodysplasia spinulosa-associated polyomavirus (TSV or TSPyV). TS is a rare skin disease characterized by the development of follicular papules and keratin spines, which are strongly associated with immune suppression. Since 1999, viral etiology has been suspected since affected hair follicle cells contain icosahedral virus-like particles. TS is likely to be associated with the lytic TSV replication, because affected lesions express both viral VP1 capsid protein and T antigen proteins. While the TSPyV T antigen gene is characterized and known to express five different T antigen isoforms in the skin of TS patients, the role of T antigen in cell transformation remains unknown. Because of its skin tropism, TSV was searched for in uncommon skin cancers, including mycosis fungoides, Sezary syndrome, primary cutaneous T-cell lymphoma, primary cutaneous B-cell lymphoma, and non-UV-associated mucosal melanoma, as well as benign skin cancers including spitz nevi and keratoacanthoma. One study also examined benign nonmalignant tonsillar tissues and tonsillar carcinoma for TSV detection. By and large, the results from these studies do not support an etiological role of TSV in the examined human cancers.

Human Polyomavirus 9 (HPyV9)

Serological studies have suggested the presence of cross-reactive antibodies in human sera that recognize the viral capsid protein VP1 of the African green monkey polyomavirus, also known as monkey B-lymphotropic papovavirus or LPV. LPV by itself could explain the reactivity because the LPV DNA sequence could be detected in peripheral blood mononuclear cells (PBMCs) from the human immunodeficiency virus-positive (HIV+) patients with different leukoencephalopathies. On the other hand, in 2011, Scuda et al. identified human polyomavirus 9 (HPyV9) from the sera and urine of kidney transplant patients under immunosuppressive treatment. HPyV9 is a novel polyomavirus that resembles LPV, showing 76% of pairwise nucleic acid identity. In the same year, by using next generation sequencing, Sauvage et al. also identified HPyV9 from the skin surface of a MCC patient together with MCPyV, HPyV6, and HPyV7. While discovered from the skin surface of the MCC patient, HPyV9 was rarely detectable in skin swab specimens from healthy individuals or non-MCC patients, suggesting that HPyV9 is not a component of normal skin virome unlike HPyV6, HPyV7, and MCV. On the other hand, HPyV9 viremia was reported in sera from kidney transplant patients, consistent with its discovery from a kidney transplant patient. In this report, 21% of kidney transplant patients showed increased HPyV9 viral DNA load and seroprevalence after transplantation, suggesting that HPyV9 infection is more common in kidney transplant patients. However, the question of the nature of HPyV9 infection and its pathogenic potential remains unanswered.

Malawi Polyomavirus (MWPyV/HPyV10/MXPyV)

In 2012 Siebrasse et al. identified a new polyomavirus in the stool from a healthy 15-month-old child from Malawi and named it Malawi polyomavirus (MWPyV). To discover a new virus in feces, they used virus-like particles (VLP) recovered from a fecal sample, amplified the circular VLP-derived DNA by RCA, and applied it to next generation shotgun sequencing. A nearly identical virus was actually reported by two additional groups in the same year. Buck et al. discovered a polyomavirus, termed human polyomavirus 10 (HPyV10) by RCA from anal warts derived from a rare genetic disorder called warts, hypogammaglobulinemia, infection, and myelokathexis (WHIM) syndrome. This syndrome is a congenital immunodeficiency disease in which HPV infections cannot be controlled. Thus, WHIM patients may not be able to control human polyomavirus as well as HPV infections. In addition, a third group from Mexico also identified the new polyomavirus from stool samples of a Mexican child presenting with diarrhea and named it Mexico PyV (MXPyV). An analysis on nucleotide sequences of MWPyV, HPyV10, and MXPyV demonstrated 95%–99% nucleotide sequence similarities, indicating that these viruses are variants of the same virus. In 2015, ICTV classified these viruses as *deltapolyomavirus* (Fig. 2). While the presence of MWPyV DNA was searched for in several human cancers including mucosal melanoma, lung, and tonsillar cancers, no significant correlation has been observed. The oncogenic activity of MWPyV T antigen has been also studied in vitro. While MWPyV T antigens interact with known human tumor suppressors such as p53 and pRb proteins, its effect on cell proliferation was minimal due to the faster turnover of MWPyV LT than that of SV40 or MCV LT, suggesting that MWPyV T antigen has lower transforming potential.

STL Polyomavirus (STLPyV/HPyV11)

In 2013, a group from Washington University further identified a new 11th polyomavirus from the stool of a healthy 15-month child in Malawi and named it STL polyomavirus (STLPyV). STLPyV was also detected in clinical stool specimens from the United States and The Gambia at ~1% frequency. STLPyV shares ~64.2% nucleotide sequence similarity to MWPyV, appears to share an ancestral recombination origin with MWPyV, and is classified as *deltapolyomavirus* (Fig. 2B). The comparison of two full-length virus isolates demonstrates significant divergence (~5%) in their nucleotide sequence. The prevalence of STLPyV infection was tested on samples collected in US cities by measuring seroreactivity to STLPyV VP1 capsid protein. So far, no human diseases including cancers have been convincingly linked to STLPyV infection, although its DNA has been detected in both cancerous and noncancerous tonsillar and lung tissues.

Human Polyomavirus 12 (HPyV12)

The 12th human polyomavirus, HPyV12, was discovered in 2013 from liver specimens by degenerate PCR targeting the VP3 gene. In the initial study, while polyomaviruses were searched for in various gastrointestinal samples including liver, gall bladder, esophagus, stomach, colon, rectum as well as spleen and lymph node samples, HPyV12 was found only in 4 out of 124 liver specimens, but not in other samples. These results suggest HPyV12 is a liver tropic polyomavirus, although the presence of this virus has not been investigated in non-gasterointestinal samples. Viral sequence analysis revealed that HPyV12 belongs to a group of primate polyomavirus or genus *Alphapolyomavirus* in the updated ICTV taxonomy in 2015 (Fig. 2). Seroprevalence of HPyV12 was also examined by the VP1 capsomer-based ELISA assay, and the prevalence was determined at 23% and 17% in sera from healthy adults and a pediatric group of children, respectively. This data indicates that HPyV12 naturally infects humans and that the primary infection of HPyV12 occurs during childhood.

As of 2017, the role of HPyV12 infection in human cancers and diseases has not yet been elucidated. HPyV12, however, is the first human polyomavirus that lacks the Rb-binding LxCxE motif in the LT protein. Since Rb-targeting is a critical step for polyomavirus-induced transformation, HPyV12 is likely to exhibit a weaker transforming potential.

New Jersey Polyomavirus (NJPyV-2013/HPyV13)

In 2014, a novel polyomavirus was identified from the muscle tissue of the pancreatic transplant patient in New Jersey who developed weakness, retinal blindness, and necrotic plaques on face, scalp, and hands. The new polyomavirus, named New Jersey polyomavirus (NJPyV-2013), was identified by next generation sequencing, and shares 80.7% overall nucleotide homology to chimpanzee polyomaviruses. In 2015, ICTV classified NJPyV-2013 as a member of the genus *Alphapolyomavirus* (Fig. 2). In situ hybridization studies demonstrated that NJPyV-2013 is present in endothelial cells located in endomysium and in the superficial dermis. The high copy viral infections in both muscle and skin lesions were also confirmed by qPCR analysis. Thus, an initial study revealed that NJPyV-2013 is the human polyomavirus that infects endothelial cells in muscle and skin, and its viral replication is closely associated with immunosuppression. However, the recently found NJPyV-2013 requires further investigation, and whether or not NJPyV-2013 plays a role in malignant transformation and human cancers remains unclear.

Lyon IARC PyV (LIPyV/HPyV14)

Lyon IARC PyV (LIPyV) is the newest human polyomavirus discovered by a group at the International Agency for Research on Cancer (IARC), World Health Organization at Lyon. A DNA fragment of LIPyV was discovered by next generation sequencing performed on crude PCR products amplified from cutaneous skin swabs by degenerate primers targeting the conserved LT antigen sequence. Analysis of the complete genome sequence revealed the typical 5269 bp polyomavirus genome that encodes early LT, sT, and ALTO open reading frames (ORFs) and late VP1, VP2, and VP3 ORFs. While not yet classified by ICTV, LIPyV falls into the same clade as MCV according the large T protein sequence similarities among 14 human polyomaviruses (Fig. 2). Extended search for LIPyV using skin swabs, eyebrow hair samples, and oral gargles demonstrated that approximately 2% of skin and oral gargles are positive for LIPyV DNA. Nonetheless, no information is available to predict the role of LIPyV in human cancer. However, an analysis of viral sequences demonstrated that most of the previously defined transforming domains, including the p53 binding motif, LFCDE Rb-binding motif, and J domain on LT as well as the PP2A binding motif on sT, remain intact in LIPyV T antigen. Seroprevalence has not been determined yet, but an evaluation of a multiplex immunoassay to measure serum IgG reactivity to 13 polyomavirus VP1 proteins suggests that seroreactivity to LIPyV is low. Further molecular epidemiological studies and cell biological evaluation of LIPyV T antigen oncogenic activities may reveal its potential involvement in human cancers.

Merkel Cell Polyomavirus-Mediated Merkel Cell Carcinogenesis

Cells Targeted by MCV for MCC Genesis

The discovery of MCV revealed that ~80% of MCC is linked to MCV. MCC, a small neuroendocrine skin cancer described by Toker in 1972, is an uncommon skin cancer associated with immunosuppression. Despite the similarities between MCC and Merkel cells, MCV infection in normal Merkel cells in the skin has not been evidenced. Recent reports suggest that MCV preferentially infects dermal fibroblasts in human skin. In addition, cells of origin for MCC are still debated. Several groups suggest that MCCs do not arise from Merkel cells, but instead arise from epidermal stem cells, dermal stem cells, or pre-/pro-B cells. Although MCV is a common virus present in the human skin virome, the origin of MCC tumor cells that were transformed by MCV as a result of viral clonal integration has not yet been identified.

MCC Tumor Cells Are the Dead-End Host for MCV Infection

Among the 14 known human polyomavirus, MCV is the only human polyomavirus clearly linked to human cancer. Similar to the animal polyomavirus-induced tumors described in the previous section, approximately ~80% of MCC tumors harbor clonally integrated MCV and express the early T antigen gene. In contrast, expression of the late gene has never been detected in MCC tumors and MCV-positive cell lines, consistent with MCC tumors being nonpermissive to MCV infection. Viral sequence analysis revealed that tumor-derived viral LT antigens always harbor mutations that prematurely truncate the C-terminal helicase domain of LT, while the N-terminal tumor suppressor targeting Rb-binding and Hsc70-binding J domains remain intact. The tumor-specific viral mutations render MCV replication-defective in MCC tumors, ablating helicase function of LT. This is consistent with the hallmarks of polyomavirus-induced cancers.

MCC Is Addicted to Viral T Antigen Expression

The integrated MCV early gene expresses truncated LT and sT antigens in MCC tumors. The expression of these antigens is essential for MCC tumors. Several studies have shown that the knockdown of viral T antigen transcripts in MCV-positive MCC cancer cell lines ablates cell proliferation, indicating that MCC tumors require viral T antigen oncogene expression. Targeting of individual T antigen isoforms further demonstrated that both MCV LT and sT play important roles in promoting MCC cell proliferation whereas one group suggests that LT targeting of pRb is solely responsible for promoting MCC cell proliferation.

Mechanism of MCV-Induced Carcinogenesis

Similar to other polyomaviruses, the MCV T antigen locus encodes two major overlapping transcripts for the large T (LT) and small T (sT) antigen oncoproteins. In contrast to other oncogenic polyomaviruses, MCV sT is highly oncogenic, and the expression of sT alone is sufficient to transform immortalized rodent fibroblast cell lines such as NIH3T3 and Rat-1, indicating that MCV sT possesses unique oncogenic properties. Surprisingly, MCV sT-mediated rodent cell transformation is not mediated by its PP2A-binding activity unlike SV40 sT. This has been supported by a report showing that the displacement of the PP2A B regulatory subunit by MCV sT is more restricted than that of SV40 sT. This suggests that PP2A inhibition of MCV sT is not as potent as that of SV40 sT. If PP2A inhibition is not the major oncogenic mechanism, what is the host signaling pathway involved in MCV sT transformation? As aforementioned, SV40 sT activates the Akt-mTOR pathway by preventing PP2A dephosphorylation of Akt, and this activity is essential for human cell transformation. MCV sT, however, has a minimal effect at this node of the Akt-mTOR signaling pathway and instead, acts downstream of mTOR to increase levels of hyper-phosphorylated 4E-BP1, a negative regulator of cap-dependent mRNA translation. Activation of cap-dependent translation by eIF4E plays important roles in tumorigenesis, and 4E-BP1 is a tumor suppressor that negatively regulates eIF4E. Phosphorylation of 4E-BP1 by upstream Akt-mTOR signaling disables its tumor suppressor function, leading to active cap-dependent translation, cell proliferation, and tumorigenesis. Expression of a constitutively active, phosphorylation-defective 4E-BP1 mutant prevents sT-mediated rodent cell transformation, and thus, 4E-BP1 phosphorylation is critical for MCV sT transformation.

As discussed in the section "**The Molecular Mechanism of Polyomavirus Transformation**", polyomavirus T antigens promote cell transformation by directly interacting with host tumor suppressor proteins. MCV sT also binds to host proteins including PP2A, Fbw7, Cdc20, PP4C, NF-κB essential modulator (NEMO), and L-Myc. A structural prediction suggests that the MCV sT protein possesses two molecular surfaces that allow the interaction of sT with host cell molecules. One molecular surface binds to PP2A and shares significant structural similarity to that of SV40 sT. In contrast, the second surface is quite unique to MCV and contains a disordered loop, which is predicted to bind host proteins. The second surface of MCV sT contains a unique functional domain that stabilizes LT and enhances MCV replication. The large T stabilization domain (LSD) is also responsible for cell transformation; mutation of this domain not only ablates sT-mediated LT stabilization but also transformation. This LSD domain interacts with Fbw7 and inhibits the SCF^{Fbw7} E3 ubiquitin ligase that targets MCV LT for proteasomal degradation. Actually, SCF^{Fbw7} is known as a tumor suppressor E3 ligase that degrades multiple oncogenes, such as c-Myc, c-Jun, cyclin E, and mTOR proteins. Interestingly, MCV sT binds to multiple ring finger ubiquitin ligases, including the anaphase promoting complex/Cdc20 (APC/C^{Cdc20}), APC/C^{cdh1}, and β-TrCP. The promiscuous targeting of these E3 ligases has been shown to induce mitotic 4E-BP1 phosphorylation and chromosomal instability. Thus, MCV sT activates oncogenic pathways and promotes transformation primarily by hijacking host oncoprotein degradation machinery. A recent study further revealed that the second surface of MCV sT molecule also binds to L-Myc, Max, and EP400 histone acetyltransferase complexes. L-Myc is one of the Myc isoforms predominantly expressed in MCV-positive MCC, and the EP400 histone acetyltransferase complex is involved in multiple biological events including transcription, stem cell maintenance, and DNA damage response. Cheng et al. have shown that MCV sT recruits L-Myc/Max to the EP400 complex to activate specific gene expression, promote cellular transformation, and contribute to its oncogenic potential.

Although MCV LT alone does not show strong transforming activity in a rodent fibroblast transformation model, MCV LT is a strong growth promoter, and the conserved N-terminal J domain and Rb targeting domain mostly mediate the oncogenic property of MCV LT. In MCV-positive MCC cells, MCV LT maintains expression of the genes downstream of the E2F transcription factor by inhibiting the function of pRb protein. While SV40 LT inhibits p53 by the C-terminal p53-binding domain, truncated MCV LT proteins expressed from MCC lose the corresponding p53 binding domain and do not interact with p53. Instead, MCV LT uniquely binds to the host vesicle trafficking factor Vamp6p, and this interaction has been shown to inhibit MCV virus production. The functional significance on transformation, however, has been unclear.

Some studies suggest that host molecules targeted by MCV LT could be druggable targets for MCC. One of them is Survivin (BIRC5), an E2F downstream factor activated by LT. The inhibition of Survivin by shRNA and its transcriptional inhibitor YM155 has been shown to inhibit MCV-positive MCC cell proliferation in mouse xenografts. Furthermore, the Hsp70 ATPase inhibitor MAL3-101, which is required for SV40 LT-mediated Rb-E2F disassembly, efficiently prevents xenograft MCC growth and induces apoptosis. Now that MCV has been shown to be a causal agent of most MCCs, rational targeting of cellular pathways perturbed by MCV may lead to the identification of additional treatments that may be more effective than current therapies.

Conclusions and Outlook

By virtue of the new genetic techniques for sensitive virus detection, 12 new human polyomaviruses were identified during the last 13 years. In particular, the discovery of MCV and BKV clonal integrations in human Merkel cell carcinoma and urological cancers have renewed the interest in the roles of human polyomaviruses in human cancer. The available information for cancer association with human polyomaviruses is predominantly from old JCV and BKV studies, while the knowledge on the recently discovered human polyomaviruses and their association with human cancer remains limited.

The fast pace of new polyomavirus discoveries suggest that a plethora of undiscovered human polyomavirus exist. It would not be surprising if these previously unknown human polyomaviruses play roles in other human cancers.

Glossary

Adipocytes Fat cells that compose adipose tissue, or body fat mass.

Adipose tissue The body's fat-storing tissue, made up of adipocytes that have further paracrine roles for example, through adipokines and steroid hormone synthesis; generally measured as a percentage (%) of total body mass

Alpha-linolenic acid (ALA) An *n*-3 polyunsaturated fatty acid (18:3); essential fatty acid; precursor to *n*-3 very long-chain polyunsaturated fatty acids docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA); generally measured in milligrams (mg) or grams (g).

Arachidonic acid (ARA) An *n*-6 very long-chain polyunsaturated fatty acid (20:4); synthesized in the body from dietary linoleic acid (18:2); and is a precursor in the biosynthesis of eicosanoids, including prostaglandins, thromboxanes, and leukotrienes that have major roles as tissue hormones, that is, on inflammation and immune function; generally measured in grams (g).

Body fat The total mass of fat/adipose tissue in the body; generally measured as a percentage (%) of total body weight.

Body mass index (BMI) A commonly used calculated measure of height-proportionate weight, reported as kg m^{-2}. A healthy range is 18.5–25 kg m^{-2}, while 30 kg m^{-2}, and above represents obesity.

Cancer mortality shift The epidemiological turning point whereby cancer mortality surpassed that from heart disease.

Complex carbohydrate Polymeric carbohydrate molecule composed of long chains of monosaccharide units bound together by a variety of glycosidic linkages, and include starch, glycogen, and soluble and insoluble fiber; generally measured in grams (g).

Dietary energy density The amount of energy (or calories) per gram of food.

Eicosapentaenoic acid ((EPA) 20:5 *n*-3) and docosahexaenoic acid ((DHA) 22:6 *n*-3) *n*-3 very long-chain polyunsaturated fatty acids; mostly attained from marine sources; slightly synthesized in the body, especially during pregnancy and breast feeding, from dietary alpha-linoleic acid (18:3)—DHA can also be synthesized from dietary EPA—and are precursors in the biosynthesis of *n*-3 eicosanoids, competing with *n*-6 very-long polyunsaturated fatty acids for same desaturase enzyme and having opposing effects, including with antiinflammation, anticoagulation, and anticarcinogenesis; generally measured in milligrams (mg).

Gender gap The difference between men's and women's parameters, for example, life expectancy and mortality.

Gender-specific nutrition The dichotomy between men's and women's requirements for nutrients and dietary composition, physiological responses, and associated socio-cultural factors.

High-density lipoprotein (HDL) cholesterol Cholesterol carried within small lipoprotein particles distinguished by a high proportion of proteins to lipids; generally measured in mmol L or mg dL

Linoleic Acid (LA) An *n*-6 polyunsaturated essential fatty acid (18:2), a source of very long *n*-6 polyunsaturated fatty acids, attained from fatty plants (nuts, seeds) and animals fed high *n*-6 feed; essential for immune, inflammation, blood coagulation and skin health; generally measured in grams (g).

Lipoprotein Complex lipid-protein particles transporting fat molecule micelles in the blood/extracellular fluid; include high-density lipoprotein (HDL), low-density lipoprotein (LDL), and very low-density lipoprotein (VLDL); generally measured in mmol L or mg dL.

Long-chain polyunsaturated fatty acid (LCPUFA) A polyunsaturated fatty acid with 20 or more carbons; generally measured in grams (g) or milligrams (mg).

Low-density lipoprotein (LDL) cholesterol Cholesterol carried within large lipoprotein particles distinguished by a low proportion of proteins to lipids; generally measured in mmol L or mg dL

Monounsaturated fatty acid (MUFA) A fatty acid with one double bond between carbon atoms at a specific location in the molecule, with the rest of the carbon atoms being linked with single bonds; generally measured in grams (g) or milligrams (mg).

Obeso-carcinogenic Tending to cause obesity-related cancer.

Obesogenic Tending to cause obesity, for example, nutritional and environmental factors.

Polyunsaturated fatty acids (PUFA) A fatty acid with double bonds between carbon atoms in multiple locations in the molecule, with the rest of the carbon atoms being linked with single bonds; generally measured in grams (g) or milligrams (mg).

Saturated fatty acid (SFA) A fatty acid with single bonds between all carbon atoms in the molecule; generally measured in grams (g).

Simple carbohydrate The most basic units of carbohydrates; in the context of diet, this can refer to monosaccharides or disaccharides, and are usually present as purified/refined sugars with little-to-no fiber; generally measured in grams (g).

 https://doi.org/10.1016/B978-0-12-801238-3.65115-2

Trans-fat A type of fat produced either naturally by biological process, for example, in cow rumen, or industrially from unsaturated vegetable fats through hydrogenation or heating; generally measured in grams (g).
Waist circumference The girth measured at a level midway between the lowest rib and the iliac crest, generally measured in centimeters (cm) or inches (in); it is a principle criterion of the metabolic syndrome.

Introduction

"Cancer Mortality Shift" Over Heart Disease Risk

This term was coined in Israel in 1999 to describe the epidemiological turning point, led by women, whereby cancer mortality surpassed that from heart disease. This trend became global, with risk of death declining more steeply for heart disease than cancer. If current trends continue, cancer will become the leading cause of death by 2020.

This shift is especially prominent among females, given their innate tendency toward fat accumulation, especially in obesogenic environments and due to nutrient-exhausting menstruation, pregnancy and lactation, and resultant deficiencies. Gender-differential effects of the obesogenic environment on women can also explain the recent decline in the gender gap in life expectancy (LE) and in healthy LE (HLE), gradually narrowing the gender gap.

According to the American Cancer Society (ACS), the rising global cancer epidemic causes more than 8 million cancer deaths worldwide annually; in 2012 there were 6.1 million new cancer cases in developed countries compared to 8 million new cancer cases in developing countries and predicted to rise to 13.1 million by 2030. Many of these occurrences are considered avoidable through lifestyle modifications.

It was predicted that from 1969 through 2020, the number of heart disease deaths would decrease 21.3% and 13.4% among men and women while cancer deaths would increase 91.1% and 101.1% respectively, suggesting that cancer would become the leading cause of death.

The Global Obesity Epidemic

Worldwide obesity has nearly tripled since 1975. The World Health Organization (WHO) reported that In 2016, 39% of adults aged 18 years and older were overweight (BMI ≥ 25 kg m^{-2}), translating to 1.9 billion in absolute numbers, with approximately 13% categorized as obese (BMI ≥ 30), over 650 million; among children under the age of 5, 41 million were overweight or obese, and for older children and adolescents aged 5–19, the number was over 340 million.

The obesity epidemic has become the leading lifelong risk factor for disability and mortality, and a high level of obesity is contributing to reduced LE. It is increasingly recognized as a potentially modifiable factor associated with poor prognosis in several cancers, such as those of the breast, colon, and endometrium.

Obeso-Carcinogenic Environmental Pressure

Conditions of early human evolution included food scarcity, which drove the need for efficient transformation of available nutrition to daily living activities, metabolic energy, tissue-building, reproduction, building energy reserve and health of ensuing generations. However, the enabling physiology that was once advantageous may now be a liability in the modern obesogenic environment that is increasingly shown to be carcinogenic.

The increase in dietary energy intake over the past several decades is due to increased availability/accessibility, portion size, dietary energy density (DED) and eating opportunities—with reduced nutrient density in processed foods and associated metabolic implications—linking obesity to cancer.

The "obeso-carcinogenic" diet, most common in modernized cultures, is characterized by excessive energy intake, high intake of saturated fatty acids (SFA) and *n*-6 polyunsaturated fatty acids (PUFA), reduced *n*-3 PUFA and fiber intake, overuse of salt and refined sugar, and inadequate exposure to beneficial microorganisms, a combination believed to contribute to obesity, as well as to the type of immune dysfunction that enable cancer development and progression.

Obesity and Cancer Relationships

One-fourth of all cancer cases related to excess BMI in 2012 could be attributed to the rising BMI since 1982, especially in women. Overweight and obesity are clearly associated with increased risk for developing many cancers, including breast cancer in postmenopausal women, endometrium, adenocarcinoma of the esophagus, and kidney. Evidence is highly suggestive that obesity also increases risk for cancers of the pancreas, gallbladder, thyroid, ovary, and cervix, and for multiple myeloma, Hodgkin lymphoma, and aggressive prostate cancer. Hepatocellular carcinoma, the fifth most common cancer in the world and the second leading cause of cancer-related mortality, has been linked obesity both directly and indirectly through nonalcoholic fatty liver disease (NAFLD) or steatosis, particularly prevalent in obesity.

Obesity has also been associated with a higher risk of cancer recurrence, progression, and poorer prognosis. Increased risk of progression was shown in patients who gained weight from the time they finished chemotherapy, and possibly in ovarian cancer.

The longer the duration and the higher the degree of overweight/obesity, the greater the risk of developing several forms of cancer, especially endometrial cancer. Therefore, preventing overweight/obesity or meliorating it from early onset may be important to reducing cancer risk. In women, however, managing excess body weight was shown to be more critical regardless of age.

Obesity-Related Cancer Mechanisms

Overweight and obesity have been shown to affect risk of cancers through a variety of mechanisms, some of which are specific to particular cancer types. These mechanisms include insulin resistance (hyperinsulinemia and dysglycemia); inflammation; oxidative stress; immune dysfunction; fat (adipose and lipid/lipoprotein) and sugar (including carbohydrate) metabolism; microbial balance; altered adipose-derived cytokines (adipokines, e.g., higher leptin and lower adiponectin), sex hormones (estrogens, androgens, and testosterone); factors that regulate cell proliferation and growth, such as insulin-like growth factor-1 (IGF-1); and carrier proteins that make hormones more or less available to tissues, such as sex hormone-binding globulin (SHBG) (Fig. 1). These alterations impact biological processes implicated in tumor development, progression and invasion, and are affected by nutrition-related factors, providing potential routes for preventive dietary actions.

Insulin Resistance and Metabolic Syndrome

Elevated insulin or C-peptide (cleaved from proinsulin) is associated with increased risk of numerous cancers, including those of the breast and colon. In the context of obesity-associated hyperinsulinemia, the insulin receptor and its associated signaling pathways can activate numerous growth-promoting and proliferative intracellular signaling pathways, potentially driving the adverse effects of obesity in cancers. This is particularly evident in breast: more than 90% of breast cancer tumor specimens in two different patient cohorts were found to express the insulin receptor; and insulin receptor expression and activation in tumors have been linked to poor survival in patients with breast cancer.

Insulin resistance and hyperinsulinemia are features of the metabolic syndrome, defined by at least three of five metabolic factors: high plasma levels of glucose (>110 mg/100 mL), high levels of triglycerides (>150 mg/100 mL), low levels of high-density lipoprotein (HDL) cholesterol (<50 mg/100 mL), large waist circumference (>88 cm), and hypertension (systolic blood pressure >130 mmHg or diastolic blood pressure >85 mmHg). A systematic review and meta-analysis (97,277 adult females)

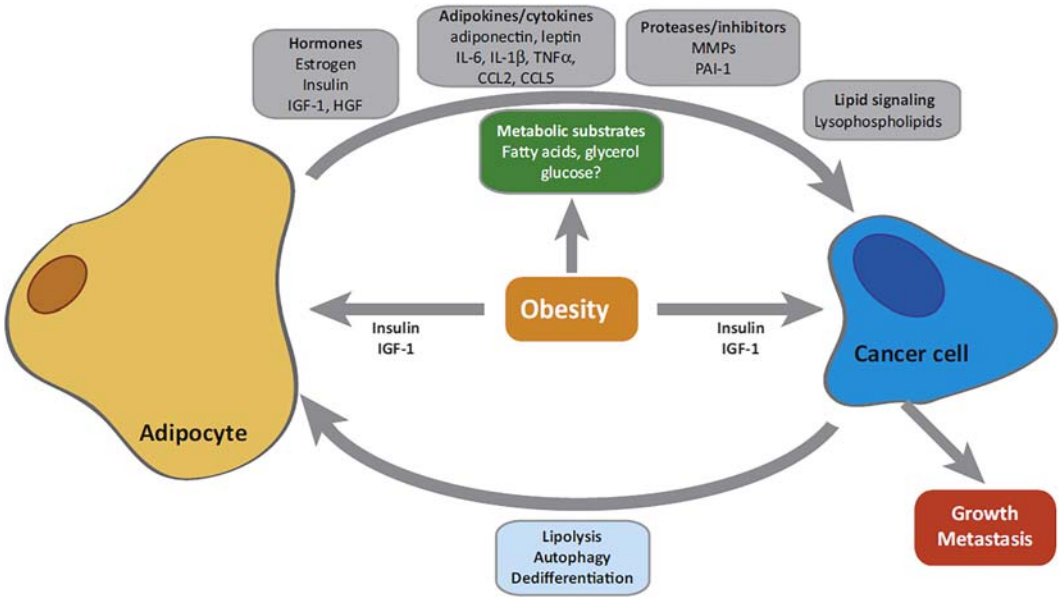

Fig. 1 Within the cancer microenvironment, tumor cells and adipocytes are in close proximity and can exert a variety of reciprocal effects on each other. Cancer cells induce the production of endocrine and paracrine signaling mediators, proteolytic enzymes, and bioactive lipids, along with metabolic substrates by adipocytes. These in turn drive increased growth and invasion of tumor cells along with therapeutic resistance. Obesity leads to the increased production of some signaling factors, such as hormones and adipokines and/or cytokines, and increased availability of metabolic substrates, accentuating in turn, cancer cell growth and metastasis. *CCL2*, C-C motif chemokine ligand 2; *CCL5*, C-C motif chemokine ligand 5; *HGF*, hepatocyte growth factor; *IGF-1*, insulin-like growth factor 1; *IL-1β*, interleukin 1β; *IL-6*, interleukin 6; *MMP*, matrix metalloproteinases; *PAI-1*, plasminogen activator inhibitor-1; *TNFα*, tumor necrosis factor α. From Hoy, A. J., Balaban, S., Saunders, D. N. (2017). Adipocyte-tumor cell metabolic crosstalk in breast cancer. *Trends in Molecular Medicine* **23** (5), 381–392. https://doi.org/10.1016/j.molmed.2017.02.009, with permission.

showed a modest positive association between the metabolic syndrome and breast cancer risk (RR = 1.47), confirmed for postmenopausal women (HR = 1.80). Cholesterol's connection was recently emphasized, through the observed agonist effect of its metabolite 27-hydroxycholesterol on estrogen receptors and postmenopausal breast cancer pathogenesis. Moreover, breast cancer patients with the metabolic syndrome have shown worse prognoses, especially if associated with increased androgenic activity; together suggesting that beyond individual factor associations with breast cancer, their combination may elevate the risk by activating molecular pathways through endocrine, metabolic, and immune functions, which influence breast tumorigenesis.

High serum insulin and insulin resistance associated with obesity are also risk factors for developing prostate cancer. Along with hyperinsulinemia, insulin growth factor (IGF) elevation is also observed in obese men. Insulin stimulates the expression of growth hormone receptors and inhibits liver production of insulin-like growth factor binding protein (IGFBP)-1 and 2, thus further increasing the bioavailability of insulin-like growth factor (IGF)-1.

In type 2 diabetics and obesity, insulin treatment in a dose-dependent and time-varying manner has demonstrated a significant association with increased risk of the most prevalent malignancies in men and women with hemoglobin A_{1c} (HbA_{1c}) $\geq 8.5\%$—colorectal cancer (16.3%) and breast cancer (20.7%), respectively—while metformin use was associated with lower risk. This suggests that in an outpatient setting, the obese patients with poorly controlled insulin-treated type 2 diabetes mellitus should be rigorously assessed toward malignancies, particularly breast cancer in women and colorectal cancer in men.

Adipokines and Obesity-Related Cancers

Alterations in adipokines, particularly leptin and adiponectin, are commonly observed in obesity, and may influence tumorigenesis in obese individuals. Adiponectin and leptin are produced by adipose tissue, but their biosynthesis and secretion are affected differently in the context of obesity—where leptin levels are elevated in the obese state, adiponectin secretion is reduced, resulting in disruptions in a variety of critical processes implicated in affecting whole body homeostasis, as well as cancer.

Correspondingly, binding of adiponectin negatively regulates proliferation, and inhibition of factors that stimulate cell division and growth, while leptin receptor causes activation of these same cellular networks. Thus, the imbalance in circulating levels of adiponectin and leptin observed in the obese state may lead to signaling networks favoring cancer cell proliferation and growth, with implications for incidence and outcome of numerous obesity-related cancers.

Reproductive Hormones and Obesity-Related Cancer

Beyond adipose tissue playing a role of energy storage, it also acts as an endocrine organ. Multiple hormones secreted by the fat tissue can activate alternative pathways that effect physiological function of the body system or promote pathological procedure. Abnormal metabolism of sex hormones, including estrogens and androgens, has been associated with both BMI and the risk of breast cancer. Large increases in endogenous estrogen levels (estrone [E1] and estradiol [E2]) caused by excess body fat among postmenopausal women have been linked to higher risks of postmenopausal breast and endometrial cancer. A significant increase in penetrance of breast cancer-related genetic mutations over the years is thought to reflect increased western lifestyle risk factors, including overfatness, smoking, and low physical activity.

Postmenopausal overweight is associated with increased peripheral conversion of androgens into estrogens, decreased SHBG, and increased insulin levels. Insulin in turn stimulates the synthesis of androgens in the ovary and inhibits liver production of SHBG, thus increasing the bioavailability of sex hormones.

Increased levels of serum estradiol in men with obesity lead to an inhibition feedback of pituitary–hypothalamic axis, resulting in low levels of serum free and bioavailable testosterone, which have been significantly associated with higher prostate cancer risk, though some studies have suggested an opposite association with high grade and advanced tumors.

Obesity-Related Oxidative Stress

Oxidative stress is a physiological state of imbalance between the body's inherent antioxidant defenses and high pro-oxidant load from reactive oxygen species ([ROS], also referred to as "free radicals"). Oxidative stress is known to damage DNA, alter signaling pathways, and regulate progression of various cancers, including those of the breast, lung, liver, colon, prostate, ovary, and brain. Cancer initiation from diet-related oxidative stress has been attributed to alterations in epigenetic events and induction of genomic instability, which alter gene expression, increase the risk of mutagenesis, cause resistance to apoptosis, and induce tumor invasion and metastasis.

Intracellular ROS production in adipocytes can increase with substrate overload from dietary overconsumption. As visceral fat stores expand due to nutrient overconsumption, adipocytes generate increasing levels of ROS and thus oxidative stress that incites increased expression and secretion of inflammatory adipokines and leads to insulin resistance.

Cancer progression is aided by ROS, either by their activity as signaling elements or stimulation of alterations or damage to DNA. ROS also incapacitates tumor suppressors, due to the existence of the redox-sensitive cysteine residues that exist in their catalytic sites. Like those for normal stem cells, cancer stem cell renewal and differentiation are controlled by ROS levels. Liver and breast cancer stem cells tend to have low ROS levels. Since cancer stem cell growth is vital for tumor initiation, retaining low ROS levels may be essential for their proliferation in these organs.

The presence of high levels of oxidized low-density lipoprotein (LDL) cholesterol (ox-LDL), as well as increased LDL receptor expression in macrophages, may serve as a chemotaxis signal that recruits or stimulates the macrophages, and further supports tumor cell growth, as has been demonstrated in colon cancer cells. Accordingly, NAFLD has demonstrated a high association to colorectal, as well as breast cancers.

Obesity-Related Inflammation

Low-grade chronic inflammation and dysregulated adipose tissue inflammatory mediator/adipokine secretion are well-established in obesity, and these factors increase the risk of developing inflammation-associated cancer.

A growing body of evidence demonstrates links between visceral obesity in particular—the type associated with insulin resistance and the metabolic syndrome—and a related secretion pattern of adipokines and cytokines contributing to carcinogenic processes, including adiponectin, leptin and resistin, are able to cyclically increase the pro-inflammatory and insulin resistant state and thus promote tumorigenesis and cancer cell progression through the NFκB pathway, which controls transcription of DNA and cytokine production. NFκB is activated by toll-like receptors, essential components of the innate immune responses. Increased toll-like receptor levels in visceral adipose tissue have been shown to link obesity with inflammation and extracellular matrix remodeling, the latter being a key factor in cancer.

Breast cancer is a key example of how toll-like receptors drive pathogenesis and recurrence through NFκB, as increased inflammation within the subcutaneous mammary adipose tissue depot can alter the local tissue inflammatory microenvironment such that it resembles that of obese visceral adipose tissue. Therefore, in obese women with breast cancer, increased inflammatory mediators both locally and systemically can perpetuate inflammation-associated pro-carcinogenic signaling pathways, thereby increasing disease severity.

Visceral fat-induced inflammation has also been identified as an independent risk factor for esophageal adenocarcinoma, colorectal adenocarcinoma, and colorectal adenomas.

Obesity-Related Immune Response

Dietary factors that result in overweight and obesity influence inflammation, and in turn, immunological reactions. Hyperplastic and hypertrophic adipose tissue from obese individuals exhibits significant irregularities in production of hormones, adipokines, and cytokines contributing to altered immune cell infiltration. Among the immune cells in fat depots, macrophages are especially common, and their properties are altered by obesity. Adipose tissue macrophages in healthy fat depots are skewed toward the M2 antiinflammatory phenotype, but during obesity, pro-inflammatory M1 macrophages become more abundant. Pro-inflammatory adipose tissue macrophages produce tumor-promoting cytokines, including tumor necrosis factor (TNF) α, interleukin (IL)-6, and IL-1b, as well as monocyte chemo-attractants such as monocyte chemotactic protein (MCP-1 or CCL-2), and macrophage migration inhibitory factor (MIF)—orchestrated by the IκB kinase/NF-κB and c-Jun N-terminal kinase/activator protein-1 pathways involved in malignant transformation.

Effect of Local Adiposity on Cancer Risk

A mechanism making breast cancer more aggressive was elucidated in a recent study, and the lipogenic enzyme acetyl-CoA carboxylase (ACC) 1 is now suggested to be a key player in breast cancer metastasis. ACC1 is a key component of fatty acid synthesis, the first and speed-determining step in fatty acid synthesis. ACC1 function is impaired by the cytokines leptin and TGF-β, particularly in the blood of severely overweight subjects. *Thus, fatty acid precursors promote metastases* due to the described inhibition of ACC1 that leads to the accumulation of the fatty acid precursor acetyl-CoA. This precursor is transferred to certain gene "switches" that in turn increase the metastatic capacity of cancer cells by activating a specific gene program.

Effect of Blood Lipids on Cancer Risk

Lipid profile, including triglycerides and total, HDL, and LDL cholesterol, are modifiable factors sensitive to obesity. Recent studies suggest risk of prostate cancer may increase with obesity-related dyslipidemia, including a low HDL, high LDL and total cholesterol, and high triglycerides. Dyslipidemia may also be related to increased tumor grade, as evidenced by abnormal HDL level being a strong predictor of developing high-risk disease.

The association between cancer and lipid metabolic dysfunction in obesity is especially high in liver cancer, where 80% of cancer occurs in patients with underlying steatosis. Steatosis is accompanied by infiltration of macrophages, resulting in enhanced expression of wingless-type mammary tumor (Wnt) signaling and the activation of Wnt/β-catenin signaling, which in turn leads to the accumulation of tumor-initiating cells and tumorigenesis. Wnt signature genes were observed to predict 90% of tumors in a cohort of 558 patient samples.

Epithelial cells of normal prostate have higher cholesterol content compared with other normal cells of organs across the whole body and during the progression of prostate cancer, the cholesterol content gets even higher, indicating that the accumulation of cholesterol may contribute to the malignant conversion of prostate. HDL cholesterol can transport cholesterol from cells to the liver and other steroidogenic organs, and has antiinflammatory and antioxidant functions, and may reduce growth and progression

activity of prostate cancer. High level of triglycerides has also been demonstrated to be responsible for prostate cancer development by elevating oxidative stress and insulin resistance.

Effects of Hyperglycemia on Cancer Risk

Blood sugar metabolism results in highly reactive compounds called advanced glycation end-products (AGE). Excessive production from dietary sugar overconsumption and/or impaired glucose metabolism, with failure to remove them from the system can lead to protein damage, aberrant cell signaling, increased stress responses, and decreased genetic fidelity. AGEs offer a potential mechanistic link between excess sugar-derived metabolites and cancer, which may provide a molecular consequence of lifestyle choices.

Diabetics experience a roughly 20%–25% higher cancer incidence compared to nondiabetics, as well as increased early and late mortality compared to cancer patients without diabetes. Prediabetes is also related to an increased risk of developing and dying from cancer. In addition to hyperglycemia and related AGE generation, possible mechanisms include hyperinsulinemia, alterations of the insulin-like growth factor system, chronic subclinical inflammation, abnormalities in sex hormone metabolism, and adipokines.

Effects of the Microbiome on Cancer Risk

The most important aspect of host-microbiome interactions is host exposure to components of intestinal bacteria that stimulate inflammatory reactions. In particular, high-fat and high-energy diets have been shown to facilitate absorption of bacterial lipopolysaccharide (LPS) from intestinal bacteria.

The microbiome can be affected by changes in carcinogenic or tumor-suppressive metabolites and microbe-associated molecular patterns generated in the gut; endocrine factors, such as insulin, insulin-like growth factor, leptins and adiponectins; and inflammatory and immunological parameters, which are interrelated because the same leukocyte populations contribute to both inflammation and immune responses.

Obesity-induced alterations of gut microbiota have been observed to increase the levels of deoxycholic acid, a gut bacterial metabolite known to cause DNA damage. The enterohepatic circulation of deoxycholic acid provokes senescence-associated secretory phenotype in hepatic stellate cells, which in turn secrete various inflammatory and tumor-promoting factors in the liver, potentially facilitating hepatocellular carcinoma development, including in individuals with nonalcoholic steatohepatitis (NASH).

Carcinogenic Cell Initiation, Proliferation, and Growth

Dietary effects on stem cell mutations

Obesity has been shown to promote stem cell expansion during cancer initiation, and to enhance the conversion of adipose-derived stem cells into carcinoma-associated fibroblasts, leading to cancer cell proliferation and progression to an invasive form.

It was recently assessed that the majority of carcinogenic genetic mutations—66%—are caused by simple random errors occurring when self-renewing cells divide, accumulating damage over time, may be exacerbated by key extraneous inputs such as diet. However, increased stem cell divisions have been observed to correlate with feeding-induced growth of cancer cells.

Poor diet high in "empty calories" tends to be low in essential vitamins—particularly B6, folate, and choline—involved in the methylation pathways critical to DNA repair during cell division. As a result, abnormal cells proliferate unchecked, ultimately contributing to cancer cell growth. Further, choline insufficiency has been independently linked to fatty liver, adding a compounding mechanism.

Adiposity effect on cancer cell progression and invasiveness

Adipose tissue within the tumor microenvironment actively contributes to tumor growth and metastasis by functioning as an endocrine organ, through secretion of signaling molecules such as adipokines, pro-inflammatory cytokines, pro-angiogenic factors and extracellular matrix constituents, and acting as an energy reservoir for embedded cancer cells. Thus, the importance of adipose tissue as an integral contributor to cancer progression and recurrence is increasingly appreciated.

Hypertrophic expansion of adipose tissue in the context of obesity shares many features with solid tumor growth. For example, tumor hypoxia is a hallmark of cancer that is associated with poor patient outcomes and resistance to chemotherapy. The rapid cellular proliferation and expansion of adipose tissue also induces hypoxia, which triggers compensatory angiogenesis, so that limitations in nutrient and oxygen supply can be overcome. Similar to that seen in tumor growth, the hypoxia in adipose tissue that occurs in the context of obesity induces expression of the transcription factor HIF-1α, which upregulates a profibrotic pathway involving extracellular matrix proteins (such as collagens, matrix metalloproteinases and tissue inhibitors of metalloproteinases) and pro-inflammatory cytokines (such as IL-6, TNFα, and C–C motif chemokine (CCL) 2 (also known as monocyte chemo tactic protein-1)). The microenvironment within local adipose deposits clearly provides a tumor-permissive niche for transformed, infiltrating cells. Importantly, fibrotic and pro-inflammatory cytokines that are characteristic of adipose tissue in individuals with obesity, such as endotrophin (a C-terminal cleavage fragment of collagen 3α(VI) chain), IL-6, IL-8, and plasminogen activator inhibitor-1, have also been directly implicated in tumor growth and metastasis.

Excessive expansion of white adipose tissue in obesity is linked to increased aggressiveness of certain cancers. Adipose stromal cells can become mobilized from white adipose tissue, recruited by tumors and promote cancer progression. It was recently shown

that adipocytes from periprostatic adipose tissue support the directed migration of prostate cancer cells and that this event is strongly promoted by obesity. This process is dependent on the secretion of the chemokine CCL7 by adipocytes. In human prostate cancer tumors, expression of the CCR3 receptor is associated with the occurrence of aggressive disease with extended local dissemination and a higher risk of biochemical recurrence.

Gender Differential in Obesity

Obesity rates are higher in women, though varying widely by country. For example, an estimated 18% of women in France are obese, in Greece 26%, in Mexico 35%, and in Saudi Arabia 44%; in contrast, the percentage in both Japan and China is 3%.

In the United States, with overall prevalence of 68.3% overweight and 33.9% obesity, women show higher rates than men of severe obesity (BMI $\geq$35), 17.8% versus 10.7%, and morbid obesity (BMI $\geq$40) 7.2% versus 4.2%, differences of 78% and 71.4%, respectively. Between 1975 and 2014, obesity increased from 6.4% to 14.9% in women and from 3.2% to 10.8% in men. A representative sample of 13,066 men and non-pregnant women from the United States National Health and Nutrition Examination Survey (NHANES) found fat mass percentage—a clinically more relevant marker—in men was 28.1% ($n = 6559$) and 40.0% in nonpregnant women ($n = 6507$), both well above the recommended levels of 25% and 32%, respectively ($p < 0.001$ for sex differences). As several of the obesity-related cancer types only affect women, the growing number of people of both sexes who are severely overweight is likely to have a greater effect on incidence of the disease among women, according to a recent analysis by Cancer Research United Kingdom. Cases of ovarian, cervical and oral cancers are predicted to rise the most, approximately 0.5% for men and 3% for women.

Critical Periods

Rapid length, weight, and BMI growth from birth is associated with higher insulin levels in childhood. The health of young people, and that of the adults they will later become, is critically linked to the establishment of healthy behaviors in childhood, which are more likely to continue throughout life. About half of people who are overweight as children will remain overweight in adulthood; 70% of overweight adolescents will remain overweight as adults.

In adolescent girls, when adiposity shifts to higher metabolic risk—coupled with the increased eating opportunities noted as contributory to obesity—it may create precarcinogenic potential. High birth weight, early menarche, fast growth during adolescence, age at first full-term pregnancy, breast feeding, and menopause all are factors associated with critical periods in which hormonal and metabolic factors are mutually related to obesity and cancer risks.

Where overweight predicted an increased risk of colon cancer, the association of BMI $\geq$85th percentile was even more pronounced in analyses that were restricted to men followed until at least 40 years of age; this suggests that adolescent overweight may be significantly associated with colon cancer incidence in young to middle-aged adults, emphasizing the need for approaching adolescent obesity with its attendant increasing population impact.

Epidemiological studies show that the inclusion of vegetables, legumes, fruits, and whole grains in diets are associated with reduced cancer risk, with diet during early life (age $<$8 years) having the strongest apparent association with cancer incidence. For these reasons, efforts to establish healthy weight and eating patterns should begin in childhood.

Dietary Risk Factors

Dietary factors considered contributory to obesity are increasingly being studied for their associations with cancer. Overeating, an imbalance between consumption and need, is a principal driver. However, specific dietary components and metabolic characteristics can differentially affect each side of the equation.

Animal-Based Foods

Data from the adventist health study showed BMI to increase commensurately with the amount of animal foods in the diet. United States national cross-sectional data also show positive associations between meat consumption and risk for general and central obesity, due to higher energy and fat content (especially SFA), correlation to higher overall daily total energy intake, and displacement of less energy-dense, high-fiber, nutrient-rich plant foods associated with a superior health profile. Studies in Italian, Swedish, and Taiwanese populations revealed similar observations.

Higher total red meat, fresh red meat, and processed meat intake have also been found to be risk factors for several types of cancer, including breast and colorectal, for similar and additional reasons. Chymotrypsin levels are increased in individuals eating a high-meat diet, which could deplete innate tumor suppressors from cells of the gastrointestinal tract and immune cells in contact with it, as well as in other tissues. Heme iron in red meat may generate free radicals that damage DNA, and substances used to process meat (nitrates/nitrites) contribute to the formation of nitrosamines that can also damage DNA, possibly exacerbated by increases in secondary bile acids and other promoters of carcinogenic activity triggered by the fat content in meat. Further, cooking of meat can yield mutagens and carcinogens, including heterocyclic amines and polycyclic aromatic hydrocarbons.

Overeating

It is well-known that overnutrition may generate free radicals and subsequently elevate oxidative stress and ROS-mediated modulation of various molecular pathways. Additionally, overeating increases secretion of the serine protease chymotrypsin, which can induce carcinogenic mechanisms such as increased cell migration and decreased innate tumor suppressors, thereby contributing to obesity-related cancer.

Postprandial Risk Factors

The modern nutritional environment is replete with eating opportunities, resulting not only in increased obesity risk, but also increased likelihood of constantly being in a postprandial state most of the day—an estimated 18 h daily. Among the main postprandial risks of modern meal practices are hyperlipemia, hyperglycemia, and oxidative stress, as well as paradoxical lack of satiety, which can drive additional overconsumption.

Oxidative stress after carbohydrate, protein, and lipid intake results in a series of metabolic alterations in various tissues, including the liver, adipose tissue, pancreatic β-cells, and skeletal muscle. Such active but metabolically distressed tissues further augment oxidative stress, eventually resulting in an infinite vicious cycle. Obese individuals experience more pernicious and acute oxidative stress after a meal, compared to non-obese individuals.

Excessive caloric intake further abnormally increases concentrations of blood glucose, free fatty acids, and triglycerides circulating in the blood, outpacing the capacity of mitochondria for oxidative phosphorylation, the transfer from single electrons to molecular oxygen; consequently, ROS enter the circulation. ROS production by leukocytes is also induced by caloric overload, and conversely caloric restriction can lead to a reduction in ROS production from lipid peroxidation and protein carboxylation.

In obese individuals, hyperglycemia may impact tumor growth by providing cancer cells with an abundance of fuel and enabling them to maintain their rapid proliferative rates. Cancer cells are known to exhibit alterations in glucose metabolism, particularly their reliance on glycolysis even in the presence of oxygen, known as the Warburg effect. Although glycolysis is a less efficient form of energy production compared with mitochondrial oxidative phosphorylation, cancer cells surmount this shortcoming by upregulating glucose transporters, thus increasing their glucose uptake and potentially increasing their sensitivity to the elevated systemic glucose levels found in obesity.

Dietary Energy Density (DED)

High DED is considered to be a notable contributor to overconsumption leading to overweight and obesity. It has also been associated with a 10% increased risk of any obesity-related cancer compared to individuals of normal weight. High DED, increasing portion sizes, and increased eating opportunities—that multiply the incidences of postprandial oxidative and inflammatory stress—can complicate associated overconsumption and obesity, making the individual more susceptible to carcinogenic mechanisms.

Higher DED may be a contributing factor to obesity-related cancers. DED has been associated with statistically significantly greater risk of pancreatic, postmenopausal breast, endometrial, ovarian, and colorectal cancers among women, largely through its contribution to obesity. High DED is potentially modifiable through dietary interventions, suggesting a significant route of reducing obesity-associated cancer risk.

Dietary Fat

As fat is the highest-ED source of calories, it has been correlated with high DED and low satiety, and therefore with risk of "passive" overconsumption that may contribute to overweight and obesity. Excess weight has itself been associated with at least 11 types of cancer, suggesting an indirect effect of dietary fat. Early research on diet and cancer risk also suggested a direct link, since countries with low fat intake, such as Japan, had lower rates of cancer than countries with higher-fat diets, such as the United States.

Relative proportions of energy from dietary fat and carbohydrates have also been suspected to affect excess body fat storage and cancer, which in turn is related to refining of carbohydrate and ratios between major fat categories, for example, high SFA versus unsaturated fatty acids (UFA), and among unsaturated, high *n*-6 PUFA versus *n*-3 PUFA or *n*-9 monounsaturated fatty acids (MUFA).

The Western diet is characterized by excessive intake of energy, SFA and *n*-6 PUFA, sodium, and refined carbohydrates (including sugar), with low intake of *n*-3 PUFA that likely contribute to immune dysfunction, oxidative stress, augmented inflammatory and oncogenic cellular reactions, and altered tissue metabolism. Under unfavorable conditions, in which dietary factors act as inflammatory and pro-oxidant factors, oxygen derivatives can damage nucleic acids, lipids, and proteins, and most significantly, alter cell viability.

As low-fat dietary interventions can influence body weight and decrease breast cancer recurrence, a differential effect of diet on hormone-receptor-positive and -negative disease suggest that metabolic mechanisms involving insulin and insulin-like growth factor-1 may be involved in tumorigenesis indirectly through fat intake.

Saturated fat (SFA)

Some long-term research adjusting for other dietary and lifestyle choices ruled out total fat, and narrowed the *focus to fat from red meat, of which a significant percentage is saturated*. The mechanistic link between SFA and cancer in obese individuals was recently suggested to be through increasing lipopolysaccharides.

Gastric cancer has demonstrated a positive association with intakes of total fat and saturated fat, with an inverse association for PUFA and no effect of MUFA. High total, saturated, and trans-fats increase ovarian cancer risk, and different histological subtypes have different susceptibility to dietary fat. For example, trans-fats have been shown to increase risk of epithelial ovarian cancer overall and endometrioid tumors in particular, while *n*-3 PUFA was found to be protective.

Polyunsaturated fatty acids (PUFA)

PUFA have consistently demonstrated advantages in supporting weight loss and metabolic improvements when substituting for SFA in the diet. Though the *n*-6 PUFA linoleic acid ([LA] 18:2) is essential in the diet, high intake of *n*-6 PUFA has been associated with increased risk of various cancers, including in a cross-generational manner. The incorporation of fatty acids in cell membranes has been considered a pivotal event in modulating inflammatory processes.

n-6 long-chain PUFA (LCPUFA) arachidonic acid ([ARA] 20:4), a product of LA and precursor to inflammatory eicosanoids, induces DNA methylation with profiles similar to those described for palmitic acid and linked to atherosclerosis, diabetes, obesity, and autism, but relatively dissimilar from *n*-9 MUFA oleic acid (OA)-induced profiles. Human atherosclerosis grade-associated DNA methylation profiles were significantly enriched in ARA-induced profiles, with biochemical evidence pointing to β-oxidation, PPAR-α, and sirtuin 1 as important mediators of the changes.

In contrast, dietary *n*-3 PUFA—particularly LCPUFA such as eicosapentaenoic acid [(EPA] 20:5) and docosahexaenoic acid ([DHA] 22:6), synthesized from essential alpha-linolenic acid ([ALA] 18:3)—may have utility in mitigating the severity of obesity-associated inflammation and cancer. *n*-3 PUFA modulate inflammation and specifically the production of adipokines by increasing levels of antiinflammatory adiponectin, while decreasing levels of inflammatory mediators such as leptin and cytokines including TNFα, IL-6, and CCL2. Moreover, dietary *n*-3 PUFA have been found to reverse and/or improve obesity-associated hepatic steatosis and impairments in glucose metabolism and insulin sensitivity. Collectively, these antiinflammatory effects of *n*-3 PUFA alter the obesity-associated inflammatory environment and may meliorate related cancer risk.

The chemoprotective effects of *n*-3 LCPUFA decrease cell proliferation and increased apoptosis, ultimately resulting in reduced cancer tumor incidence, growth, multiplicity, and metastasis, as observed in rodent models. Similar *n*-3 PUFA-mediated antitumorigenic effects have been reported in overweight humans wherein *n*-3 PUFA supplementation upregulated the expression of several genes involved in cell cycle regulation. In rodents, a beneficial effect of *n*-3 PUFA shown on the breast cancer phenotype was related to their potential for reducing obesity-associated inflammation and consequent tumorigenic risk. In an obese postmenopausal model of breast cancer, *n*-3 PUFA supplementation reduced mammary adipose tissue inflammation and markers of inflammatory M1 macrophage infiltration, reflecting the inflammatory microenvironment promoting tumorigenesis. These studies clearly demonstrate that *n*-3 PUFA can independently modulate responsiveness to cell proliferative and/or apoptotic signaling.

Monounsaturated fatty acids (MUFA)

As with PUFA, MUFA substitution for SFA in the diet has been shown to reduce postprandial inflammatory responses and improve insulin sensitivity in obese individuals. This benefit was shown to be enhanced with co-consumption of dietary fibers, with a decrease in *E*-selectin, TNFα, interferon (IFN)γ, IL10, and IL17, compared to an increase in IFNγ and I6 with saturated fat intake. Weight maintenance with a MUFA-rich diet was shown to improve HOMA-IR and fasting proinsulin levels, while the latter effects have been more consistent and superior with PUFA, MUFA has demonstrated an advantage overall inflammatory responses linked to carcinogenic metabolic processes. In a large-scale European case-control analysis investigating colorectal cancer incidence, risk reduction was observed with the MUFAs OA (*n*-9, 18:1) and palmitoleic acid (*n*-7, 16:1), in contrast to pro-inflammatory PUFAs LA and ARA, as well as the SFA stearic acid.

OA has been observed to suppress over-expression of HER2 (erbB-2), and to react to invasive progression and metastasis in several human cancers; intracellular calcium signaling pathways have been observed to induce apoptosis in carcinoma cells, where its antiinflammatory effects could support the activation of various pathways of immune-competent cells.

Dietary Carbohydrates and Fiber

Dietary carbohydrate effects on glycemic and insulin metabolism have long been suspected to contribute to overweight and obesity, and have been linked to cancers as well.

While total carbohydrate intake itself has been associated with breast cancer risk in some population-based studies, many have found associations with dietary glycemic index (GI) and glycemic load (GL), which more directly reflect how foods impact metabolism. High intakes of staples, especially refined white rice, were positively associated with endometrial cancer, with the link to GI being more evident among lean and normal weight women, suggesting that intake of high GL or GI foods may be more relevant as a risk factor. A Mediterranean population characterized by traditionally high and varied carbohydrate intake demonstrated that a diet high in GL played a role in the development of breast cancer, colon cancer, and esophageal cancer risk. Caucasian American adults (1991–2013) demonstrated associations between carbohydrate intake and cancer that varied by cancer site, and healthier low-GI carbohydrate foods lowered the risk of adiposity-related cancers among women, for example, lower breast cancer risk (HR 0.51).

Fructose

Fructose was previously considered a beneficial or at least relatively innocuous dietary sugar, as it does not stimulate insulin secretion and demonstrates a low GI. However, it has more recently been closely linked to NAFLD and the related NASH, which is considered a precancerous condition. A very recent Australian study showed that even one portion daily of a beverage sweetened with fructose syrup significantly increased 13 types of cancer, and the greater the amounts and the longer the intake the higher the cancer risk.

Dietary Protein

A recent study evaluating links between protein intake and mortality found that in individuals aged 50–65 years, high protein intake was associated with a 75% increase in overall mortality and a fourfold increase in cancer death risk during the ensuing 18 years, though plant-based protein abolished or attenuated the effect, and reduced cancer and overall mortality. Studies in murine models confirmed the effect of high protein intake and GHR-IGF-1 signaling on the incidence and progression of breast and melanoma tumors. High-protein diets are often used to manage weight in obesity, including during middle age, when it may counteract the health benefits of losing weight, while a low-protein diet was found to be detrimental in individuals over 65 years of age.

A protein-restricted diet is thought to improve metabolism and attenuate cancer progression by modulating levels of associated adipokines and other endocrine signals, for example, elevated FGF21 and adiponectin and reduced leptin concentrations. Long-term consumption of a low-calorie, low-protein diet has been associated with reductions in the plasma growth factors, such as IGF-1, and hormones linked to increased risk of cancer, including independent of body fat mass.

Animal-based protein sources

In contrast to red meat, fish and poultry proteins were shown to be suitable to obesity- and cancer-preventive diets. Two 100-g portions of fatty fish per week provide 3.5 g of *n*-3 PUFA, that potentially reduce obesity and cancer, with suggested calculated potential of each additional 0.7 g of marine omega-3 polyunsaturated fat per week reduces risk by 5% of breast cancer.

Pescetarian diets, such as the Mediterranean and Okinawa diets that are high in fish and other seafoods as well as low-medium-fat dairy products—often fermented and containing "friendly" bacteria—have been shown to be among the best obesity- and cancer-protective diets.

Though dairy foods contain the potentially cancer promoting hormones estrogen and IGF-1, concerns are not supported by epidemiological evidence. This may be because these hormones are present in minute amounts (even with daily intake), and are counteracted by protective compounds in the same foods, including short-chain fatty acids (SCFA) and branched-chain fatty acids (BCFA), conjugated fatty acids (CFA), cysteine-rich whey proteins, calcium, and vitamin D. Fermented dairy products in particular have demonstrated protective contributions against obesity and cancer through supporting a healthy microbiome and producing intermediate products of fermentation.

Plant-based protein sources

Cancer risk has been found to decrease with intakes of soy food, other legumes, nuts, poultry, skim milk, and fish, leading some researchers to advocate vegetarian diets for prevention.

The EPIC-Oxford study, as well as many other studies, showed a more plant-based diet to be protective against weight gain, and that older adults and men were more likely to lose weight in response to a plant-based diet. Such a diet is also highly recommended against cancer risk due to its low DED and high nutritional density, including high amounts of vitamins, minerals, fiber, and phytonutrients such as carotenoids, polyphenols, protease-inhibitors, sulforaphanes, and more, which having demonstrated preventive potential against various aspects of cancer development.

Vegetarians have a 22% lower risk of colorectal cancer—in the colon by 19% and rectum by 29%—compared to nonvegetarians. In Japan, age-adjusted prostatic cancer mortality rose during the 50-year period from 1948 to 1998, concurrently with an increase in intake of eggs (sevenfold) and meat (ninefold). Legumes constitute a nonmeat, "plant-based" protein source that also yields nutrients shown to protect against cancer, for example, fiber, as well as micronutrients whose insufficiency is linked to increased cancer risk. They are especially rich in isoflavones, nutrients that may protect against cancer, including incidence of endometrial and gastrointestinal cancers, and mortality and recurrence of breast cancer.

A plant-based diet does not necessarily mean vegetarian or vegan, but can also be one that quantitatively emphasizes plant sources of nutrition with potentially protective qualities against obesity and cancer, complemented by animal-based proteins, which have high nutritional and biological value—being rich in micronutrients, especially iron, zinc, copper, and B12 and additional B vitamins—and are effective in enhancing satiety and building lean body mass.

Fiber

Fiber content is protective through mechanisms that are key in healthy weight management. In the gut, fibers promote the decomposition and excretion of inflammatory and carcinogenic substances, growth of beneficial and inhibition of pathogenic bacteria, phagocytosis of macrophages, inhibition of nitrosamine synthesis, reduction of estrogen levels, modulation of IGF-1 activity and inflammation, and production of short-chain fatty acids (SCFAs) by bacteria in the colon, all of which are associated with attenuation of tumor development. Balancing of the microbiome in particular is gaining attention for its important role in metabolic

regulation affecting carcinogenesis and body weight and composition. Further, fiber's contribution to satiety through retention of liquids from food and drinks and resultant gastric distension, and to improved glucose and insulin metabolism through slowed digestion, has been linked to lower risk for obesity and related hormonal and inflammatory processes linked to cancer. Both colon and breast cancers have been linked to both high BMI and their risks attenuated by weight management and high-fiber intake. A dose-response analysis showed that for every 10 g d^{-1} increase in dietary fiber intake, there was a 4% reduction in breast cancer risk, particularly in postmenopausal women.

Nutrient Deficiencies

The malnutrition that often accompanies obesity is attributed to poor diet high in "empty calories" and low in essential micronutrients, that is, those involved in the methylation pathways critical to DNA repair during cell division. As a result, damaged DNA leads to cell mutations that proliferate unchecked and ultimately contribute to cancer.

High prevalence of micronutrient deficiencies has been repeatedly observed in obese individuals, despite overconsumption of energy that often means low intake of micronutrient-rich foods such as fruits and vegetables, whole grains, nuts, legumes, dairy products, and fish that are major sources of most vitamins, minerals, and essential fatty acids. The nutrients most commonly affected include vitamins A (as well as precursor beta-carotene), B1, B12, and D, folate, and the essential minerals magnesium, selenium, zinc, and iron, with notable presence of nutritional anemia.

B-vitamins such as folate and choline, as well as betaine and other reactants may influence the methyl donor pool and ultimately, levels of DNA and histone methylation. Calorie restriction and excess have opposite effects on DNA methylation, where calorie excess and high BMI are risk factors for several types of cancer via multiple DNA methylation alterations.

Deficiencies of these nutrients can cause significant damage to DNA via single and double-strand breaks, oxidative lesions, or both, or limit the body's repair mechanisms for these processes. They may be a contributing factor to the twofold greater risk of most types of cancer (lung, larynx, oral cavity, esophagus, stomach, colon and rectum, bladder, pancreas, cervix) among individuals with the lowest consumption of fruits and vegetables compared to those with the highest. More than 200 studies showed an association between low consumption of fruits and vegetables and the incidence of cancer; unfortunately, $\geq$68% of Americans of all ages do not meet the intake recommendations of the National Cancer Institute and National Research Council.

However, the majority of supplementation studies indicate no effect on general mortality or cancer incidence, either positive or negative. The antioxidant supplements tested thus far seem to offer no improvement over a well-balanced diet, possibly because of the choice of the substances tested, inadequate or excessive dosage, or lack of synergistic variables present in foods. Despite the protective effects observed for dietary micronutrients—vitamins, minerals, and phytonutrients, for example, polyphenols, carotenoids, sulforaphanes—when they come in a whole food source, isolated and concentrated active compounds are still believed to potentially hold greater promise in some cases.

Nutritional Recommendations

Diet, physical activity, and body weight have been shown to play important roles in reduction of cancer risk, as well as recurrence and mortality. Optimal strategies to reduce pro-inflammatory and oxidative exposures linking obesity with cancer differ in each individual. Most research on energy imbalance and cancer focuses on increased risks associated with overweight and obesity, showing that losing weight may reduce the risk of cancer (**Table 1**). Even bariatric surgery to treat morbid obesity and short-term intentional weight loss has been shown to improve insulin sensitivity and biochemical measures of hormone metabolism, and to contribute to reduced obesity-related cancers. Efforts to reduce weight—and specifically fat weight, and primarily abdominal fat—are considered paramount in prevention of related cancers.

Table 1 2007 World Cancer Research Fund (WCRF) conclusions on diet and cancer

Food group/other	*Risk effect*	*Cancer types*	*Evidence strength*	*Recommendation*
Obesity (linked to energy-dense foods high in fat/sugar)	Increase	Breast Bowel Esophagus	Convincing	Maintain healthy bodyweight, avoid energy-dense foods (>250 kcal/100 g)
Physical activity	Decrease	Bowel	Convincing	30 min day^{-1} of moderate exercise
Alcohol	Increase	Bowel Breast Liver	Convincing	Limit drinks to 2 day^{-1} (men) or 1 day^{-1} (women)
Red meat	Increase	Bowel	Convincing	<500 g $week^{-1}$
Processed meat	Increase	Bowel	Convincing	Avoid
Fiber	Decrease	Bowel	Probable	More whole grains
Fruit and vegetables	Decrease	Digestive tract prostate	Probable	Five portions day^{-1}

Reducing Energy Density

Reducing caloric intake through favoring low DED foods can provide a trifecta of benefits by managing body weight and fat, dyslipidemia and dysglycemia, and inflammatory and oxidative processes linking excess weight to cancer. DED is lowered by adding water and fiber and reducing intake of added sugars (particularly refined sugars), saturated and trans-fats, and alcohol, which all provide substantial calories but few or no essential nutrients, and yield low satiating potential because of lack of gut distension. Caloric intake can also be reduced by decreasing the size of food portions and frequency of eating opportunities.

High-DED foods and beverages high in refined ingredients are consistently recommended to be replaced with low-DED, nutrient-rich choices like vegetables and fruits, whole grains, beans, soups, and water or unsweetened beverages.

Increasing Nutrient and Phytonutrient Density

Meliorating micronutrient deficiencies through improved nutrition—such as greater consumption of vegetables, fruits and other whole foods—is a viable means of greatly reducing obesity and cancer risk. A major part of the protective effect of fruits and vegetables may be due to their micronutrient content, including plant phytoestrogens, fiber, and especially antioxidants such as vitamin C, phenolic acids, and carotenoids. This is emphasized the strong recommendation to consuming whole rather than processed/ultra-processed foods.

Recent large-scale studies have confirmed effectiveness of evidence-based recommendations for reducing cancer risk, which are the same corroborated as being effective against obesity and pathometabolic sequelae, promoted by health authorities around the world, as well as cancer-specific organizations such as the ACS and National Cancer Institute (NCI).

Optimizing Dietary Fatty Acid Profile

n-*6 PUFA*

High dietary intake of *n*-6 PUFA has been found to be associated with an increased risk of various cancer development. The incorporation of fatty acids in cell membranes has been considered a pivotal event in modulating inflammatory processes. Excessive *n*-6 PUFA can harm DNA, that is, by creating ethenoadducts, depurination, and mutations. Cross-generational effects shown by the total number of reproductive system tumors, pituitary tumors and metastases was increased in the offspring of dams exposed to a high dietary level of *n*-6 PUFA. The differential impact of ARA and OA on the DNA methylome, with ARA contributing to the epigenome of important metabolic diseases, supports and expands current diet-based therapeutic and preventive efforts to limit its overconsumption and excessive endogenous production.

n-*3 PUFA*

Marine-derived *n*-3 PUFA have well-established antitumorigenic effects in chemically induced, transgenic and xenograft rodent models of breast cancer. The traditional diets of populations with historically superior obesity and cancer profiles, that is, that of Japan, features 1%–2% of daily energy as *n*-3 LCPUFA, and Greenland Inuit typically consume 2.4%–6.3%, demonstrating influence against both inflammation and obesity.

n-*6*:n-*3 PUFA ratio*

A high dietary *n*-6:*n*-3 PUFA ratio has been shown to cause an increase in pro-inflammatory cascades contributing to both obesity and cancer. By decreasing *n*-6 and increasing *n*-3 in the diet, the proadipogenic and procarcinogenic pathways may be inhibited. Therefore, it has been recommended to return to the balanced dietary *n*-6:*n*-3 ratio of 1–2:1 based on data from evolutionary studies, observational studies of populations, and large-scale clinical studies, while diets of modern populations known to be relatively free from obesity and cancer, that is, Japan, tend to be in the range of 4–5:1.

n-*9 MUFA*

OA has been found to specifically regulate cancer-related oncogenes, and to exert antiinflammatory effects opposing those of *n*-6 LCPUFA ARA and SFA palmitic acid. It is the primary MUFA in olive oil, and a principle component of the traditional Mediterranean diet, a pattern linked to protection against obesity sequelae and cancer. To achieve these benefits, it has been recommended to use OA to replace a similar amount of SFA and *n*-6 PUFA, especially when *n*-6 PUFA intake exceeds daily needs.

Maximizing Plant Food Potential

Whole grains are considered to be an important part of an overall healthful diet for people without contraindications. Whole grain foods, which are those made from the entire grain seed, are relatively low in caloric density and can contribute to maintaining energy balance, are higher in fiber, polyphenols, vitamins and minerals than highly processed (refined) flour products, and have been associated with lower risk of cancer and other metabolic sequelae of obesity and dysglycemia.

Polyphenols have been reported to be efficacious in the prevention of cancer and the reversal of cancer progression. Polyphenols may affect epithelial-to-mesenchymal transition pathways, which are involved in cancer metastasis, including by increasing levels of epithelial markers while downregulating mesenchymal markers.

For example, the olive oil polyphenol hydroxytyrosol inhibits cell proliferation in colon cancer cells and enhances targeted chemotherapy, an effect presumably related to its antiinflammatory activity; epigallocatechin gallate, found in high amounts in green tea and touted for thermogenic benefits in weight management, has been found to inhibit the type of oncoprotein-induced angiogenesis that contributes to tumor growth and metastasis.

High intake of fruit, vegetables, and legumes has been associated with reduced risk of various cancers. They are complex foods, each containing numerous potentially beneficial vitamins, minerals, fiber, carotenoids, and other bioactive substances, such as flavonoids, terpenes, sterols, indoles, and phenols, which increase the efficacy of epigenetic mechanisms that help decrease the risk of obesity and its comorbidities and prevent cancer. Inhibition of serine proteases by compounds in fruit and vegetables could also account for some of the protective effects of a plant-rich diet. Greater consumption of produce is associated with decreased risk of lung, esophageal, stomach, and colorectal cancer in particular.

For other cancers, fruits and vegetables provide benefit by reducing DED, total energy intake, and weight gain and thus risk of developing obesity over time. Using produce to replace more calorically dense foods is a frequently recommended strategy for maintaining a healthy weight, but only when not deep-fat fried (e.g., French fries) or consumed with calorically dense dressings and sauces high in saturated fat and/or overly processed ingredients.

There is ongoing research on the potential benefits of particular plant foods or groups, including dark green and orange vegetables, cruciferous vegetables (e.g., cabbage, broccoli, cauliflower, Brussels sprouts), soy products, legumes, *Allium* vegetables (onions and garlic), and tomato products.

Attempts to isolate specific nutrients and administer them as supplements, sometimes in very high doses, have been mostly unsuccessful in preventing cancer or its precursor lesions, and in some cases, have had adverse effects. Notable examples were four randomized trials of beta carotene for prevention of lung cancer, based on epidemiological indications against lung cancer; in two of these trials, the smoking individuals taking high-dose beta carotene supplements developed lung cancer at higher rates than those taking a placebo, supporting the concept of whole foods being more protective than the isolated active compounds.

Despite recommendations for increasing intake of fruit and vegetables, it remains low among both adults and children. This may be partially due to lack of access to affordable options, preparation time, and taste preferences. For cancer risk reduction, the recommendation is to consume at least five servings of a variety of vegetables and fruits each day; however, for overall health, the ACS supports the recommendation to consume higher levels, depending on calorie needs, as stated in the US Department of Health and Human Services' Dietary Guidelines for Americans.

Advantageous Dietary Patterns

Better understanding of dietary interrelationships with cancer—as applied to food selection, combination, and preparation, and potential for recommended patterns—have increased public motivation and authoritative support for early, timely, and ultimately lifelong prevention and management of both obesity and cancer.

Traditional dietary patterns such as the Mediterranean and Okinawa have been associated with healthy weight and low cancer rates in observational studies, and improved metabolic health in interventional studies. Increasing rates of disease in those regions, concurrent with abandonment of original principles in favor of modern western obeso-carcinogenic dietary characteristics, have served to confirm the formers' advantage and encourage a return in order to regain health and extreme longevity. Several medical diets have been established based on key factors that traditional diets have in common, and have yielded outcomes corroborating the value of these factors and their relationships to specific risk factors.

- *Mediterranean diet*: A pescetarian diet, low in red meat and highly based on local plants—legumes, beans, whole grains, almonds, fresh and lightly-cooked vegetables, fruits, herbs and spices, olives and extra-virgin olive oil—plus eggs, light and fermented dairy, and moderate red wine with meals; incorporates social eating with family and friends.
- *Okinawan diet*: A pescetarian diet, with great variety of whole, fresh and/or lightly cooked or fermented local foods, high in plants and algae/seaweed, very low in meat, most carbohydrates from whole tubers, rice, and buckwheat, without highly processed foods; traditionally yields the longest longevity with lowest noncommunicable disease risk.

Both the Mediterranean and Okinawan diets are low in DED, GL, and fat—particularly SFA and artificial trans-fats—with much of the fat content consisting of *n*-9 MUFA and *n*-3 PUFA, yielding an *n*-6:*n*-3 PUFA ratio of 5:1 or lower. They are high in whole plant foods such as unrefined grains, fresh fruits, and fresh or lightly cooked vegetables, rich in fiber, micronutrients, and phytochemicals, many of which have antioxidant properties. Protein sources are largely lean, and include fish, eggs, dairy, legumes, nuts, seeds, and probiotic-rich fermented dairy, while red meat is greatly limited. Refined sugar and industrially processed foods are rarely—if at all—used. Many of the local traditional foods, herbs, and spices consumed on a regular basis are considered "functional foods," exerting protective benefits beyond basic nutrition.

In addition, traditional cultures with low rates of obesity and cancer were known to complement their dietary advantage with an active lifestyle that involved very little sedentariness.

Leading health authorities, such as the WHO, United States National Cancer Institute, ACS, and dietetics associations around the world, have adopted these principles in their formal recommendations for prevention and management of obesity and cancer. The following are shared recommendations for prevention of cancer through prevention and management of obesity:

- Achieve and maintain a healthy weight throughout life, as lean as possible without being underweight. Body weight should be maintained in the body mass index range of 18.5–25 kg m^{-2}.
- Engage in regular physical activity and limit consumption of high-calorie foods and beverages as key strategies for maintaining a healthy weight.

- For those who are currently overweight or obese, losing even a small amount of weight has health benefits and is a good place to start.
- Adults should engage in at least 150 min of moderate intensity or 75 min of vigorous intensity activity weekly, or an equivalent combination, preferably spread throughout the week.
- Children and adolescents should engage in at least 1 h of moderate or vigorous intensity activity each day, with vigorous intensity activity occurring at least 3 days each week.
- Limit sedentary behavior such as sitting, watching television, or other forms of screen-based entertainment.
- Reduce dietary energy density (DED) to increase specific satiety per calorie and thus limit risk of overconsumption linked to obesity and cancer.
- Consume a healthy diet, with an emphasis on whole foods and variety of plant foods.
- Limit consumption of red meat, choose light/slow cooking and avoid ultra-processed meat.
- Cook foods by steaming, sautéing, baking, or boiling, rather than deep-fat frying or charbroiling/grilling.
- Eat at least 2.5 cups (500 mL) or five servings of vegetables and fruits each day.
- Choose whole grains instead of refined/processed/ultra-processed grain products.
- If you drink alcoholic beverages, limit consumption—no more than 1 drink per day for women or 2 per day for men.

Prospective Vision

Appreciation of chronic, cumulative events linking obesity and cancer is leading researchers and practitioners toward comprehension of the cumulative effects of acute postprandial responses to characteristics of each meal, for example, size and composition, and ultimately to recommendations for early and lifelong optimization of diet and fitness, from birth through critical periods in the life cycle, as a preventive strategy against obesity and cancer. Measures include harnessing whole, fresh, minimally processed, home-cooked foods as a simple means of reducing DED and obesogenic and carcinogenic factors, which is attainable by wide-ranging populations.

Beyond population-based approaches, rapidly accumulating research is demonstrating how interactions between gender, genes and environmental factors such as dietary intake impact both obesity and cancer, including through mutual pathways that could ultimately lead to synergistic interventions. This is important to better understand obesity by individuals' genetic predisposition and to create a concept of "personalized nutrition" for the effective prevention and treatment of obesity.

Definition and Classification

Prostate cancer (PCa) is a malignant tumor of the prostate gland. The most frequent PCa type is acinar adenocarcinoma (ICD-O code: 8140/3) which is an invasive carcinoma of the prostate consisting of neoplastic epithelial cells with secretory differentiation arranged in a variety of histomorphological patterns, including glands, cords, single cells and sheets. Basal cells are typically absent.

In addition to "usual" acinar prostate adenocarcinoma, there are eight histological prostate adenocarcinoma variants: atrophic, pseudohyperplastic, microcystic, foamy gland, mucinous (colloid; ICD-O code: 8480/3), signet ring-like cell (ICD-O code: 8490/3), pleomorphic giant cell, and sarcomatoid variant (ICD-O code: 8572/3).

The recommended grading system is the Gleason score ($2-10$) which takes into account the inherent morphological heterogeneity of prostate cancer and is of clear prognostic value.

Presentation and Diagnosis

Most prostatic adenocarcinomas are multifocal, with an average of two to three separate tumors per gland and are macroscopically variable.

Prostate cancer is usually suspected based on a digital rectal examination (DRE) and/or prostate-specific antigen (PSA) levels. DRE, however, is not specific for prostate cancer and misses 25%–50% of cases detected by serum PSA, especially smaller size and lower-stage carcinomas. Hence, PSA serum levels have become a largely accepted parameter in evaluating the risk of prostate cancer, with higher levels indicating a higher PCa risk. Still, some men may harbor preclinical PCa despite having low PSA levels. Several PSA derivatives, like PSA density, doubling time, and velocity, have been used to improve the specificity of PSA testing, although with a rather modest efficiency.

Transrectal prostate ultrasound is the first technique of choice to use in a diagnostic setting when a prostate cancer is suspected based on an abnormal DRE and/or elevated or rising serum PSA levels. Magnetic resonance imaging (MRI) is used for localizing prostate tumors and determining their size and invasiveness. Definitive PCa diagnosis is based on a histopathological verification of prostate biopsy cores, or specimens from transurethral resection of the prostate or prostatectomy for benign prostatic enlargement.

In countries where PSA measurements are standard clinical practice, most prostate cancers are detected at an asymptomatic stage. Clinical symptoms are usually a manifestation of locally advanced or metastatic disease. For locally advanced disease, these include urinary frequency and difficulty urinating which can stimulate benign hyperplasia, acute urinary retention and hematuria, whereas rectal invasion, priapism and uremia are late findings characteristic of highly advanced tumors.

Epidemiology and Risk Factors

Prostate Cancer Burden

Prostate cancer is the second most commonly diagnosed cancer in men. With an estimated 1.1 million diagnoses worldwide in 2012, it accounted for 15% of all cancers diagnosed. The frequency of autopsy-detected PCa is roughly the same worldwide. However, there are remarkable differences in the PCa incidence between different geographical areas, with 70% of cases diagnosed in more developed regions. The highest incidence rates were reported in Australia/New Zealand and Northern America (2012 age-standardized incidence rates (ASR) of 111.6 and 97.2 per 100,000, respectively), and in Western and Northern Europe. This is largely due to the use of prostate-specific antigen (PSA) testing in standard clinical practice and due to the aging population. Incidence rates are also relatively high in certain less developed regions, such as the Caribbean (79.8), Southern Africa (61.8), and South America (60.1), but remain low in Asian populations (10.5) as well as in Eastern and South-Central Asia (4.5; Fig. 1).

With an estimated 307,000 deaths in 2012, prostate cancer is the fifth leading cause of death from cancer in men (6.6% of all male deaths). As PSA testing has a lower effect on mortality than on incidence, there is relatively less variation in mortality rates worldwide (10-fold from approximately 3 to 30 per 100,000). Mortality rates are generally high in predominantly black populations (Caribbeans: ASR of 29 per 100,000 and sub-Saharan Africa: 19–24 per 100,000), very low in Asia and intermediate in the Americas and Oceania (Fig. 1).

Both PCa incidence and mortality rates are predicted to rise, with 1,853,391 new cases and 544,209 PCa-related deaths predicted for the year 2030.

Etiology and Risk Factors

Family history and racial/ethnic background are associated with an increased PCa incidence suggesting a genetic predisposition. Genome-wide association studies have identified 100 common susceptibility loci contributing to the PCa risk, explaining nearly 40% of the familial risk for this disease. Proposed sites of prostate cancer susceptibility loci include hereditary prostate cancer (HPC) 1 (1q24–q25, candidate gene: *RNASEL*), HPC2 (17p, candidate gene: *ELAC2*), PCAP (1q42.2–q43), HPCX (Xq27–q28), CAPB (1p36), HPC20 (20q13), and 8p21–q23 (candidate gene: *MSR1*). An increased prevalence of germline mutations in genes mediating DNA repair processes was found among patients with metastatic PCa. Moreover, male *BRCA1* and *BRCA2* mutation carriers have also been found to be at an increased risk of prostate cancer. However, only a small subpopulation of men with PCa (about 9%) have a true hereditary disease.

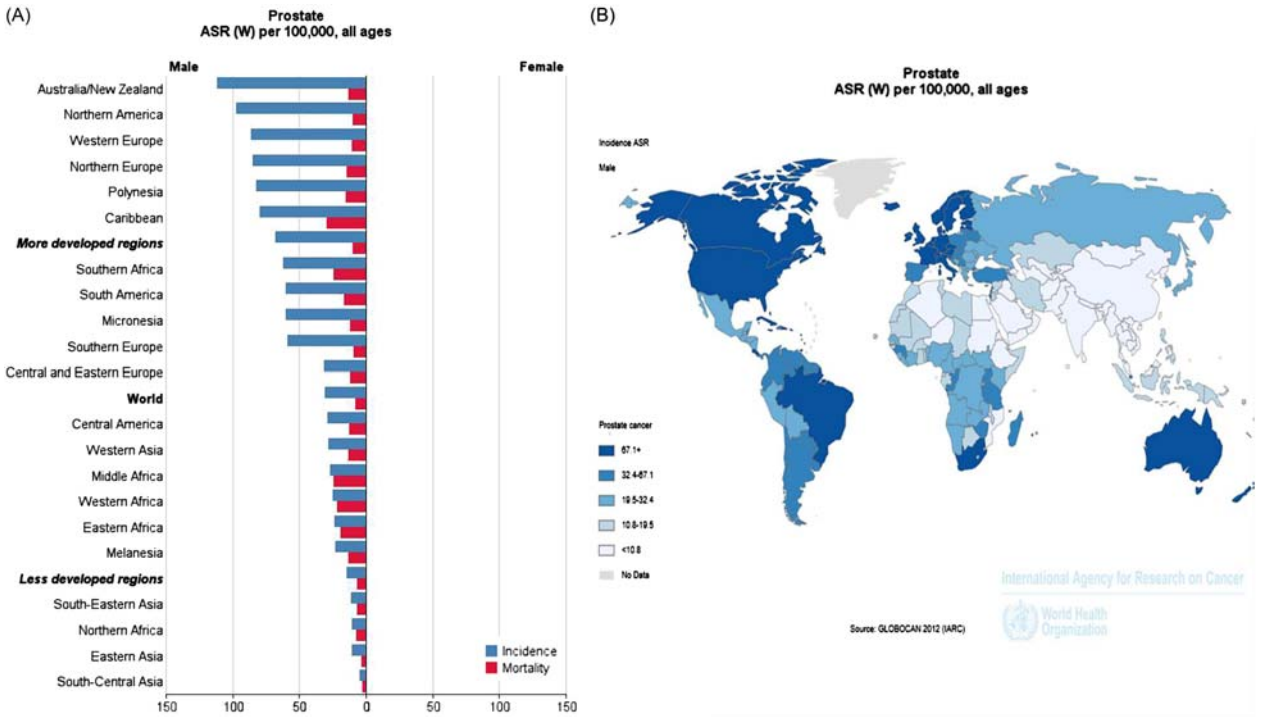

Fig. 1 Incidence and mortality of prostate cancer worldwide. (A) Age-standardized incidence and mortality rates (ASR) by gender and geographical area. (B) Incidence distribution worldwide. From Ferlay, J., Soerjomataram, I., Ervik, M., Dikshit, R., Eser, S., Mathers, C., Rebelo, M., Parkin, D. M., Forman, D. and Bray, F. (2013). *GLOBOCAN 2012 v1.0, cancer incidence and mortality worldwide: IARC CancerBase No. 11 [Internet].* Lyon, France: International Agency for Research on Cancer. Available from http://globocan.iarc.fr (accessed on February 20, 2018).

Table 1 Risk factors for prostate carcinoma

Carcinogenic agents classified by IARC Monographs on the Evaluation of Carcinogenic Risks to Humans (volumes 1–120)
Agents of limited[a] evidence for prostate carcinogenicity in humans
Androgenic (anabolic) steroids
Arsenic and inorganic arsenic compounds
Cadmium and cadmium compounds
Malathion
Rubber production industry
Thorium-232 and its decay products
X-radiation, gamma-radiation
Red meat consumption
Other carcinogenic agents and lifestyle risk factors
Obesity
Animal fat consumption
Prostate inflammation due to sexually transmitted infections

[a]No agents with sufficient carcinogenicity evidence have been identified.

The risk of developing PCa increases with age. A number of lifestyle and environmental factors have been linked to an increased risk of prostate carcinoma. In particular, growing evidence points to dietary habits, such as consumption of animal fat and red meet, especially if cooked at high temperature or charbroiled, as risk factors. Obesity has been shown to be associated with an increased risk of high-grade PCa. Sexually transmitted infections (e.g. trichomoniasis, chlamydia) have been cited as potential initiators of predisposing prostate inflammation. However, pinpointing exact environmental carcinogens associated with an increased prostate cancer risk has proven to be difficult (**Table 1**).

Pathology and Genetics

Prostate tumors show considerable molecular heterogeneity. The most common genetic alteration are recurrent fusions involving *ETS* transcription factors, typically fusing the 5′ untranslated region of an androgen-regulated gene to an almost entire coding sequence of an *ETS* family member, which are found in approximately half of PSA-detected prostate cancers. *ETS* fusions have been shown to be associated with poor prognosis in population-based studies of watchful waiting cohorts. However, studies in radical prostatectomy patients have reported conflicting results. *ERG*, an *ETS* family member, has been identified as a potential therapeutic target in tumors with *ETS* fusions ("*ETS*-positive"). Inhibiting poly ADP-ribose polymerase I (PARPI), a protein which is critical for the ERG function, results in a decreased growth of *ETS*-positive prostate cancer xenografts.

The prostate cancer genome displays relatively few focal chromosomal gains or losses (most commonly focal loss at *PTEN*) and an overall low mutation rate compared with cancers at other sites. In localized cancers, the genes most frequently harboring point mutations are *SPOP*, *TP53*, and *PTEN*, whereas more advanced and metastatic tumors treated with androgen-targeting regimes show amplifications and point mutations of the *AR* gene, which may suggest that AR is not involved in PCa pathogenesis but appears with resistance to AR treatment. However, proteins regulating the AR function have been shown to be affected by mutations or otherwise dysregulated in prostate tumors, for example, the product of the *FOX1A* gene which is hyperactivated by point mutations in about 5% of prostate cancers.

SPOP mutations are mutually exclusive with the *TMPRSS-ERG* fusion and other *ETS* rearrangements as well as with *TP53* alterations. Moreover, *SPOP* mutations are usually associated with lack of abnormalities in the *PI3K/PTEN/Akt* pathway and a higher prevalence of *CHD1* deletions. Dysregulation of *PTEN* is the most common way of inactivating the *PI3K/PTEN/Akt* and is consistently associated with a poor prognosis (**Table 2**).

A model of progressive accumulation of genetic alterations in the prostate carcinogenesis is shown in **Fig. 2**.

Biomarkers

Prostate-Specific Antigen (PSA) Serum Levels

PSA is a glycoprotein secreted by prostatic epithelial cells. Its protease activity lyses clotted ejaculate to increase sperm motility. PSA enters the circulation through unknown mechanisms and anti-PSA antibodies can be measured in blood serum using commercially available assays. As there is no single standard for comparing the results of these tests, repeat testing to monitor changes in serum PSA levels is recommended. PSA testing is a widely accepted method of population screening for prostate cancer (see section "**Presentation and Diagnosis**") A number of assays that combine PSA testing with measurements of other biomarkers are

Table 2 Gene loci that are most frequently altered in prostate carcinoma

Pathway	*Gene (locus)*	*Alteration type*	*Estimate*
MAPK/ERK signaling	Members of the *ETS* family	Recurrent gene fusions (most common: *TMMPRSS2-ERG* fusion)	Approximately 50% of tumors detected by PSA screening
P13K/PTEN/Akt signaling (control of cell metabolism)	*PTEN* (10q23)	Deletions and inactivating point mutations	40% and 45%–50% of prostate cancers, respectively; more common in advanced tumors
	PIK3CA (3q26)	Amplifications and point mutations	25% and 5%, respectively
Androgen signaling/*MAPK/ERK* signaling	*AR* (Xq12)	Amplifications and point mutations	40% and 50% of treated metastatic tumors respectively; alterations absent in localized disease
p53 signaling	*TP53* (17p13.1)	Deletions and point mutations	Deletions in 25%–40% and point mutations in 5%–40% of tumors; more common in metastatic disease but 25%–30% localized tumors harbor some *TP53* alterations
Hedgehog signaling	*SPOP* (17q21.33)	Point mutations	6% to 15% of primary prostate cancers
Chromatin remodeling and transcription control	*CHD1* (5q15–q21)	Deletions, rearrangements and point mutations	Deletions in 10%–25% of prostate tumors (both primary and metastatic); restricted to *ETS*-negative tumors

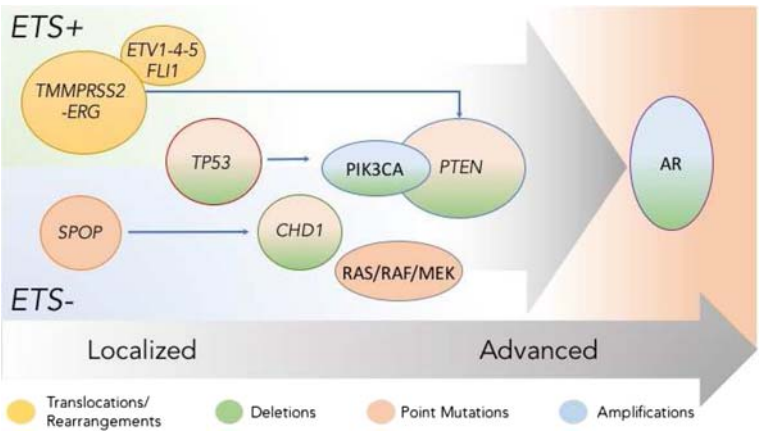

Fig. 2 Temporal sequence of genetic events in the progression of prostate cancer (PCa). Genes with frequent somatic alterations are shown. Progression is represented by a *gray arrow*. Conversion to androgen resistance in advanced lesions is shown by a change in the background color. This model distinguishes tumors with rearrangements in *ETS* gene family (*ETS*+) and without such rearrangements (*ETS*−). Somatic inactivations of *TP53* and/or *PTEN* are common events in both pathways. Modified from Barbieri et al. (2015). *Urologic Oncology: Seminars and Original Investigations* **33**, 95–102.

commercially available (Table 3). Serum PSA measurement is also used for monitoring PCa patients for recurrence following primary treatment as well as to evaluate response to treatment and the probability of distant metastases.

PCA3 Levels and the *ERG* Gene Rearrangements

Prostate cancer gene 3 (PCA3) is a prostate-specific, non-coding mRNA biomarker which is detectable in urine sediments obtained during DRE and can be measured by real-time PCR. It is highly overexpressed in prostatic adenocarcinoma as compared to normal prostate and benign prostatic hyperplasia. However, due to difficulties in determining the cut-off values, and to the complexity and cost of the test, it cannot replace PSA testing as an initial screening or a diagnostic test. As PCA3 score increases with PCa volume, it has been suggested it could be used as a monitoring marker but there are conflicting data on whether it independently predicts Gleason score and so its usefulness for active disease surveillance has not yet been confirmed.

ERG is a member of the family of the ETS transcription factors and is affected by gene rearrangements in about a half of prostate cancers. Currently, two commercially available assays (ExoDx Prostate and Mi-Prostate Score) aim to improve prostate cancer detection and risk stratification based on measuring the expression of the *ERG* gene in combination with that of PCA3.

Table 3 Biomarkers and tissue-based tests for the detection and management of prostate carcinoma

Biomarker	*Characteristics and clinical utility*
Early detection (screening) biomarkers	
Prostate-specific antigen (PSA) serum levels	Changes in serum PSA levels upon repeated testing, in particular in conjunction with abnormal digital rectal examination, indicate a suspicion of prostate cancer (FDA-approved)
PCA3 in urine	Useful in determining the need for a repeat biopsy (FDA-approved); clinical usefulness of commercial kits measuring the PCA3 expression in combination with testing for *ERG* rearrangements [ExoDx *Prostate(IntelliScore)* (EPI) and *Mi-Prostate Score* (MiPS)] is still under study
Prostate Health Index (PHI)	A combination of tPSA, fPSA, and proPSA tests; discriminates between high-grade and low-grade tumors/negative biopsies; predicts aggressive cancers (FDA-approved)
ConfirmMDx (MDxHealth, USA)	A multiplex epigenetic assay measuring hypermethylation of *GSTP1*, *APC*, and *RASSF1* promoter regions in core biopsy tissue samples; aims to improve stratification of men considered for repeat prostate biopsy
DLX1 and *HOXC6* expression in urine	The *SelectMDx* commercial kit (MDxHealth) used to perform this measurement on post-DRE urine; aims to identify men with clinically significant (more aggressive) prostate cancer prior to biopsy; still at an investigational stage
Prognostic biomarkers: tissue-based prognostic tests	
OncotypeDX genomic prostate score (Genomic Health, USA)	Testing the expression of 12 prostate cancer-related genes and 5 housekeeping genes; a potential tool for predicting recurrence and time-to-recurrence following a biopsy in very low and low risk PCa patients considered for active surveillance versus definitive therapy
Prolaris (Myriad Genetics Inc., USA)	Measures the expression of 31 genes related to cell-cycle and 15 housekeeping genes; a potential tool for predicting mortality, recurrence, and metastasis following a biopsy in very low and low risk PCa patients considered for active surveillance versus definitive therapy
Promark® (Metamark, USA)	Quantitates the expression of eight protein biomarkers correlated with disease aggressiveness; a potential tool for predicting mortality, recurrence, and metastasis following a biopsy in very low and low risk PCa patients considered for active surveillance versus definitive therapy
Decipher (GenomeDX, Canada)	Measures the expression of 22 genes involved in multiple biological pathways and associated with aggressive prostate cancer; predicts metastasis following radical prostatectomy

DRE, digital rectal examination; *FDA*, US Food and Drug Administration.

Germline Mutations in *BRCA1* and *BRCA2*, and in Other DNA Repair Genes

Recent reports suggest that men suffering from inherited syndromes associated with germline mutations in DNA repair genes are at an increased risk of prostate cancer. In particular, carriers of *BRCA1* and *BRCA2* germline mutations have a higher risk of earlier-onset prostate cancer and cancers in these patients have a more aggressive phenotype associated with reduced survival.

Gene Expression Profiles as Prognostic Biomarkers

The progression from benign prostate lesions to aggressive prostate cancers involves alterations in the expression of multiple genes involved in different cellular pathways. A number of commercial assays aiming to predict recurrence-free survival, the probability of recurrence and metastases, the aggressiveness of the tumor, and/or disease-related mortality based on cancer gene signatures are available (Table 3).

Predictive Biomarkers

Given a plethora of evidence-based therapeutic sequences for treatment of prostate cancer, the precision medicine approach seems to be the choice of the future. However, no effective predictive biomarkers have been validated up to date. Current search for these biomarkers turns to the detection of circulating tumor cells and cell-free DNA in the blood stream ("liquid biopsies") rather than tissue-based assays.

Management and Therapy

The management of all stages of prostate cancer is controversial. Given that the disease occurs in older men, deferred treatment is often recommended, in particular for lower stages localized carcinoma. A life expectancy of at least 10 years is considered mandatory for any benefit of local treatment. For elderly patients with limited life expectancy, watchful waiting with symptom-guided treatments to maintain life quality despite progressing disease is usually considered the most appropriate, regardless of the disease stage. For younger patients with longer life expectancy and low-risk localized disease, active surveillance (sometimes also called expectant management) is the first-choice treatment. In contrast to watchful waiting which aims to delay palliative treatments, active surveillance has a curative intent: it aims to achieve correct timing for curative treatment considering individual life expectancy of each patient. However, precise risk assessment for patients with longer life expectancy (and so potentially candidates for active surveillance) remains a challenge. A number of biomarkers exist (see section "**Biomarkers**") and numerous models, including nomograms which take into account different patient and tumor parameters, have been used in clinical practice but none of them has been clearly shown to be optimal or superior to others.

The decision to switch to active treatment is taken based on changes in biopsy results or T stage progression, or at the patient's request. Surgery and radiotherapy (RT) are usually the first treatment choices under consideration.

Radical prostatectomy is a common choice for primary treatment. It is appropriate for any patient whose cancer clinically appears as localized to the prostate. The goal of radical prostatectomy is to eradicate the disease, while preserving continence and potency whenever possible. Open prostatectomy can be performed with retropubic or perineal approach. The two approaches seem to be equivalent in terms of long-term cancer control outcomes. Laparoscopic and robot-assisted radical prostatectomy (RARP) are commonly used alternatives to open prostatectomy. If performed by experiences surgeons, they are usually considered to be comparable, even though some recent data suggest that the robot-assisted approach may be associated with perioperative benefits and a quicker recovery after surgery. Return of urinary continence after radical prostatectomy may be improved by preserving the urethra beyond the prostatic apex and by avoiding damage to the distal sphincter mechanism, while preserving bladder neck may allow quicker recovery of urinary control. Pelvic lymph node dissection is simultaneously performed in case of high-risk disease and/or advanced disease with nodal involvement.

External beam RT (EBRT) as primary treatment is an alternative to surgery, giving the same oncological outcomes at 10 years follow-up as radical prostatectomy. Intensity-modulated radiation therapy (IMRT), the second-generation 3D radiotherapy technique, is increasingly used in clinical practice because of reduced risk of gastrointestinal toxicities. Brachytherapy, that is placing sources of radioactivity in the prostate tissue, is traditionally used in patients with low-risk disease. Some earlier studies found it less effective than EBRT for high-risk disease. However, increasing evidence suggests that technical advancements in the contemporary brachytherapy may make it appropriate also for treatment of high-risk PCa patients. Brachytherapy can also be considered in men with biochemical recurrence (i.e. increasing PSA levels but no clinical evidence of recurrence; sometimes also called PSA recurrence) after EBRT.

Other options for primary treatment of localized PCa include cryosurgery, high-intensity focused ultrasound (HIFU) and focal therapy (brachytherapy or CyberKnife Robotic Radiosurgery). Cryosurgery (also called cryotherapy or cryoablation) is a minimally invasive treatment that damages tumor tissue through local freezing. Focal therapy of any sort appears promising but remains investigational. Therefore, the European Association of Urology recommends to offer focal therapy, as well as cryotherapy and HIFU only in clinical trial settings.

In advanced disease, androgen deprivation therapy (ADT) is administered as primary systemic treatment. It remains the gold standard for initial treatment of patients presenting with metastatic disease. ADT is also used as neoadjuvant or adjuvant treatment combined with radiation in localized or locally advanced PCa.

Androgen deprivation can be achieved either by suppressing the secretion of testicular androgens or by inhibiting the action of circulating androgens at the level of their receptors. Suppressing androgen secretion can be obtained by surgical castration (bilateral orchiectomy) or by using agonists of the luteinizing hormone-releasing hormone (LHRH; also called gonadotropin-releasing hormone; "medical castration"). The two methods are equally effective, however some recent data suggest that surgical castration may be safer. These two methods can also be combined to achieve complete androgen blockade (also called combined androgen blockade, CAB). The use of LHRH antagonists (e.g. degarelix) has the advantage of avoiding the phenomenon of testosterone surge ("flare-up", the initial release of LH and FSH) which is associated with the use of LHRH agonists. Blocking androgen receptors can be obtained by using synthetic antiandrogens. These can be either steroidal (e.g. cyproterone acetate, CPA) or nonsteroidal compounds (e.g. flutamide or bicalutamide).

ADT is associated with substantial side effects, like decreased bone mineral density and increased risk of cardiovascular disease, which usually increase with the duration of the treatment. Moreover, developing castration resistance renders the treatment ineffective with time. Actually most patients with advanced disease eventually become castration-resistant (also called castration-recurrent), that is they stop responding to ADT. One of the approaches suggested to partially overcome this problem is intermittent ADT, that is administering cycles of androgen deprivation followed by reexposure to androgens, with the assumption that this may delay "androgen independence" and also reduce treatment-related morbidity. Furthermore, a number of novel hormonal therapeutics have also been developed with the aim to replace ADT in treatment of advanced and/or metastatic castration-resistant PCa. Out of those, the following two agents have been approved by the US Food and Drug Administration: abiraterone acetate (abiraterone; Zytiga®) and enzalutamide (Xtandi®). Abiraterone blocks androgen synthesis by inhibiting CYP17 and has been approved for treatment of metastatic castration-resistant PCa in combination with low-dose prednisone in patients who had received chemotherapy

with docetaxel. Enzalutamide is a novel antiandrogen with a higher affinity for the androgen receptor than bicalutamide. While nonsteroidal antiandrogens still allow transfer of androgens to the nucleus, enzalutamide also blocks androgen transfer and therefore suppresses any possible agonist-like activity. Enzalutamide has been approved for treatment of metastatic castration-resistant PCa in patients who had received chemotherapy with docetaxel and also for treatment of hormone-sensitive PCa in combination with ADT. Moreover, recent studies suggest that it may be a reasonable treatment option also in pre-docetaxel setting or in patients who are not candidates for chemotherapy.

Chemotherapy is also one of the treatment options in the management of PCa. Patients with progressive androgen-stimulated PCa and distant metastases are usually treated with docetaxel. Moreover, the guidelines of the US National Comprehensive Cancer Network (NCCN) recommend using docetaxel in combination with ADT and EBRT in fit patients with high-risk localized disease. Cabazitaxel, a semi-synthetic taxane derivative is approved by FDA for treatment of metastatic castration-resistant PCa in patients who had undergone a docetaxel-based therapy. The results of recent trials suggest that it may also be an alternative for patients who are not candidates for docetaxel treatment, in particular those who are intolerant of docetaxel or who have a preexisting mild peripheral neuropathy (cabazitaxel treatment is associated with lower rates of peripheral neuropathy than docetaxel regimens).

With the advent of new, targeted therapies, immunotherapy may also have a role in the treatment of PCa. Autologous dendritic cell vaccine sipuleucel-T (PROVENGE®) has been shown to extend overall survival in asymptomatic or minimally symptomatic metastatic castrate-resistant (hormone refractory) PCa patients and is approved by FDA for treatment of the disease meeting these criteria. Using checkpoint inhibitors for treatment of advanced PCa is currently being tested. Also some targeted molecular therapies currently tested in clinical trials seem promising. In particular, PARP1 inhibitors (like olaparib) have given encouraging results for treatment of metastatic castration-resistant PCa in patients with *BRCA1* and/or *BRCA2* mutations in phase II trials.

The Prostate Gland

Introduction

The goal of this article is to provide the current state of knowledge of the pathology of prostate cancer and of the genetic features of prostate cancer, primary and metastatic, and of the men who have prostate cancer. Starting with the anatomy of the prostate gland, we will provide basic information on the histology, immunophenotype, and molecular features of different cell types in the prostate and of prostate carcinoma cells. We will briefly discuss clinical implications, while focusing on the current standard of practice in diagnosing and pathologically characterizing prostate cancer. We will also present our thoughts on limitations of what is known currently and we will speculate on future directions. Recognizing the importance of standardizing terms across disciplines we will use Human Gene Ontology (HUGO) terms for specific molecules, acknowledging that some terms are not intuitive. For example, the HUGO term for "Prostate Specific Antigen" is KLK3.

Anatomy of the Prostate Gland

The prostate gland, which is positioned between the urinary bladder and penis, is a truncated, cone-shaped organ through which the urethra and the ejaculatory ducts pass. The prostate produces, stores, and, upon demand, secretes proteins which, combined with the proteins expressed in the seminal vesicle, forms the ejaculate. Enzymes in the ejaculate, including kallikreins, such as KLK3 (prostate specific antigen or "PSA"), liquefy the ejaculate to enable sperm motility. Histologically, the prostate is composed of three zones—peripheral, transition, and central zones. These are based on the branching pattern of the ducts and subtle histological differences of both the glands and the stroma of the zones. The zones differ in the frequency of being the site of prostate cancer or of benign prostatic hyperplasia (BPH), and in the frequency of histological variants of prostate carcinoma. BPH consists of non-neoplastic, hyperplastic nodules of parenchyma which enlarge the transition and central zones of the prostate. As a consequence, the increased mass of prostate parenchyma (termed BPH) can compress the urethra and bladder neck, leading to lower urinary tract syndrome (LUTS), or obstructive uropathy. Conversely, the peripheral zone, which is juxtaposed to the outer wall of the rectum and is the region of the prostate most accessible to biopsy, is the most frequent site of prostate carcinoma. Finally, the foamy gland histological variant of prostate cancer is found more frequently in the transition zone than in the peripheral zone.

Cell Types

The glands (aka acini and ducts) of the prostate are embedded in a fibromuscular stroma which is innervated by alpha adrenergic neurons. Two predominant cell types comprise the pseudostratified epithelium of the glands—luminal cells, which synthesize and secrete kallikreins and other proteins, and basal cells, the apparent precursor cells to luminal epithelial cells. Within the basal epithelium is a third cell type—the neuroendocrine cell. These cells comprise less than 1% of the epithelial cells of the prostate. The stromal cell population is composed predominantly of admixed fibroblasts, myofibroblasts, and smooth muscle cells. Less frequent are functionally specialized cells—nerve sheath cells, perineural cells, vessels (endothelial and smooth muscle cells), and cells of the hematopoietic/lymphoreticular system.

Genome of Normal Prostate

Cell phenotype

Cells of the prostate have distinct protein profiles, which are readily characterized immunohistochemically. By cell type the proteins are:

- *Luminal epithelial cells*: Intermediate filaments, low molecular keratins weight KRT 8, 18; enzymes KLK3 (aka PSA), ACPP (aka prostatic acid phosphatase); cell membrane proteins CD24, MME (aka CD10), B3GAT1 (aka CD57); transcription factors AR (androgen receptor), NKX 3.1.
- *Basal epithelial cells*: Intermediate filaments, high molecular weight keratins KRT 5/6, 7, 10, 20; cell membrane proteins CD44, 49b, 49c, 104; transcription factor TP63. Note that basal cells, which do not express contractile proteins smooth muscle actin, desmin or myosin, are not categorized as myoepithelial cells.
- *Neuroendocrine cells*: Membrane-bound organelles CHGA (chromogranin A) of endocrine granules and SYP (synaptophysin) of neuron vesicles; cell membrane protein NCAM1 (aka CD56), which is also expressed by prostate fibromuscular stromal cells, thus not being specific for neuroendocrine cells.
- *Smooth muscle stromal cells*: Intermediate filaments Des (desmin), VIM (vimentin), and DES (desmin); myogenic filaments ACTA2 (smooth muscle actin); cell membrane proteins ITGA5 (aka CD49e), NCAM1 (aka CD56), ITGB3 (aka CD61).
- *Fibroblasts*: Intermediate filament VIM (vimentin). Since vimentin is expressed by many cells types it is not a fibroblastic-specific marker.
- *Cells of the hematopoietic system*: Cell membrane proteins (primarily cluster of differentiation/CD biomarkers) CD45 (all lineages), CD's specific to basic hematopoietic cell types: granulocytes CD15, B lymphocytes CD19, T lymphocytes CD3 (including PD-1 of activated T cells), monocytes CD14 (including PDL1 of antigen presenting cells) and natural killer cells CD56, thrombocytes CD61. Of note the number and distribution of hematopoietic cell types in disease-free prostate tissue has not been determined. Thus, the number of any hematopoietic cell type that is regarded as abnormal and associated with disease is not known. Accordingly the term "chronic prostatitis" is not strictly defined as a tissue-based abnormality.

The protein phenotype of cells provides a basis for diagnosing prostate lesions using immunohistochemistry. For example, absence of gland-based cells expressing basal cell proteins KRT 5/6 or TP63 is evidence that the glands are carcinoma. Other proteins are ubiquitous, including cell cycle gene products (cyclin D1, E, MKI67), and DNA repair gene products, including mismatch repair gene proteins (MSH2, MSH6, MLH1, PMS1), and homologous recombination helicases and exonucleases. Of note, many markers are not specific for these nonneoplastic prostate cell types. For example, NCAM1 (CD56) is expressed by neuroendocrine, natural killer cells, and fibromuscular stromal cells.

Investigators have identified additional epithelial cells based on distinct keratin profiles, that is, intermediate epithelial cells—KRT 15, 17, 19; and transit amplifying cells—KRT 8, 19. No role for these subtypes of epithelial cells has been reported in prostate carcinoma.

Several potential considerations confound using immunohistochemical stains to identify cell types. Preanalytical variables include loss of analyte and consequent false negativity if fixation is inadequate to stop protein degradation. Conversely overfixation may impair immunoreactivity, that is, prolonged (weeks) fixation in formalin decreases keratin immunoreactivity. Incomplete characterization of the range of expression of a given analyte can result in inaccurate interpretations of immunostains. Likewise incomplete characterization of the range of immunoreactivity of a given antibody can also lead to false positivity. Use of monoclonal antibodies addresses some questions of specificity.

The Host (A Man With Prostate Carcinoma)

Demography

Prostate carcinoma is primarily a disease of old age, rarely diagnosed below the age of 40. Incidence and mortality are higher in African-Americans and lower in Japanese. Incidence is higher among family members—both of men who have prostate cancer and of women who have breast or ovarian cancer.

Environmental Factors

Numerous factors have been associated with patients who have prostate carcinoma, such as obesity, a diet that is high in carbohydrates, in total and saturated fat, and/or includes overcooked meat. In addition, the frequency of prostate carcinoma is increased in family members who immigrate to the United States from Japan. Whether this change in incidence is a consequence of exposure to a non-Japanese diet, to a change in lifestyle, or to use of more sensitive detection methods is unknown. Associating possible external sources of tumorigenesis is confounded by the high prevalence of undiagnosed prostate carcinoma in men, which makes unraveling of prostate cancer etiology a real challenge. Based on several autopsy studies, the proportion of males affected by prostate carcinoma is equal to their age. Another challenge in these studies is controlling for diet and environment in a disease which has such a long natural history.

Host Genomics

There is clinical evidence that a notable number of patients have heritable prostate carcinoma, evidenced by male family members having prostate carcinoma and female family members having breast and/or ovarian carcinoma.

- Linkage studies of family members have been undertaken to identify germ-line gene features. Genes that have been identified as possible prostate carcinoma susceptibility genes include HPC1, PCAP, HPCX, 17q21-22 (HOXB13). Case control-based studies identified other genes including androgen receptor gene variants, AMACR, CHEK2, EMSY, as susceptibility genes. However, results have been mixed. For example, the length of the polymorphic trinucleotide CAG and GGN microsatellite repeats in exon 1 of the AR gene, which is located on the X chromosome, have been associated with the risk of developing prostate carcinoma in some, but not other, studies. Based on genome wide association studies (GWAS) in population-based cohorts, more common low-penetrance genetic polymorphisms have been identified, including 3q26.2, 6q25.3, 8q24.21, 10q11.23, 11q13.3, and 17q12. Of note, SNP rs138042437 ($P = 1.7e\ (-8)$) at 8q24.21 achieved a large estimated effect size in this cohort (odds ratio = 13.3).
- Recent sequencing studies provide evidence that mutations in some DNA repair genes correlate with prostate carcinoma that carries a high risk of progression. More than 12% of patients with metastatic androgen deprivation resistant prostate carcinoma (also termed castration resistant prostate carcinoma or CRPC) have mutation(s) in a mismatch repair gene, that is, BRCA2, ATM, CHEK2, BRCA1, RAD51D or PALB2, or in a mismatch repair gene, that is, MSH2. The combined BRCA1/2 and ATM mutation carrier rate was significantly higher in patients who died of CRPC (6%) than in patients with localized prostate carcinoma (1.4%). Clinics to screen for carriers of DNA repair gene mutations have opened. The goal is to treat these patients earlier in the course of a possibly high risk prostate adenocarcinoma. In addition, patients with CRPC who have germ-line pathogenic variants in BRCA2 and other DNA repair genes have higher response rates to PARP inhibitors and platinum compounds than to taxanes.

Prostate Carcinoma

Primary Prostate Carcinoma

Clinical presentation

In 2014, the number of men presenting with newly diagnosed prostate carcinoma in North America was 230,000, of which 95% of cancers were localized to the prostate. At initial diagnosis 5% were already metastatic; 20,000 men died of prostate carcinoma. The number of patients presenting with clinically localized disease was equal to the number of patients with metastatic disease at presentation.

Screening

Historically, the primary modality used to screen for prostate carcinoma was a digital rectal examination. Firm prostate nodules were biopsied. However, most nodules were benign—firm regions of nodular hyperplasia of the prostate in BPH. There is no evidence that these nodules of BPH have malignant potential. Prostate carcinoma in many patients manifested clinically as painful metastases to bones. Approximately three decades ago clinicians began using levels of serum KLK3 (PSA) to screen for prostate carcinoma. A serum value of 4 ng/mL of PSA best distinguished populations of men with clinically manifest prostate carcinoma from men without clinical evidence of prostate carcinoma. Widespread use serum PSA to screen men resulted in increased discovery of predominantly clinically occult prostate carcinomas and a decrease in the proportion of men with metastatic prostate carcinoma. Modifications of the serum PSA assay, such as PSA velocity (rate of change of serum PSA over months), PSA density (PSA concentration normalized to the size of the prostate), free:bound PSA ratios and the 4-kallikrein panel have not significantly improved the precision of detecting high-risk prostate carcinoma. Based on a series of 1200 patients treated by radical prostatectomy, serum PSA was a better measurement of the size of the prostate than it is a detector of high risk prostate carcinoma. Recognition that many prostate carcinomas were small, of low Gleason grade, and were limited to the prostate and, thus, of low-risk of progression, has led to ever more widespread implementation of active surveillance programs. The goal of these programs is to minimize complications of treating men whose cancer would not progress if not treated and optimize treatment of men whose cancer would progress if not treated. The typical design of an active surveillance program is to examine the patient on a regular schedule, during which biopsies are taken and serum PSA is assayed. Intent-to-cure treatment is considered if the number of biopsies with cancer or the grade of the cancer is greater than that of the study entry biopsy.

The current state of PSA screening is summarized in two reports—in the Cochrane Database of Systematic Reviews and by the US Preventive Services Task Force. The latter organization estimates that "of 1000 men (55–69 years old) offered PSA-based screening, no more than two will avoid death from prostate cancer" if they receive intent-to-cure therapy. We expect a consequent decline in per capita incidences of PSA testing, prostate biopsy, and definitive therapy (radical prostatectomy and radiation therapy). It should not be surprising that the majority of prostate carcinomas do not lead to death, since the prevalence of prostate carcinoma in a large forensic study is equal to the age of the man (e.g., 80% of 80 years old men has prostate cancer). And most men die of cardiovascular disease.

Biopsy

An elevated serum PSA level, abnormal DRE exam and/or family history of prostate or of breast cancer are the most common indications for a prostate biopsy. The current procedure is to obtain 12 needle core biopsies (2.2 cm long, 0.9 mm diameter) which systematically sample the prostate gland using a probe with a built-in ultrasound imaging camera to help the urologist position the biopsy instrument. Since the biopsy is directed transrectally, the anterior region (which is predominantly transition zone) is undersampled. Consequently the volume and grade of some anterior cancers are underestimated. More thorough sampling of the prostate by needle biopsy can be done by saturation biopsies, that is, more than 50 symmetrically distributed biopsies, done under general anesthesia in patients from whom multiple previous biopsies failed to detect carcinoma and the clinical suspicion that there is carcinoma is high.

Recently multiparametric proton-based magnetic resonance imaging (mpMRI) in conjunction with ultrasound imaging (MRI/US fusion) has been used to target biopsies to hypothetically cancer enriched areas of the prostate and potentially increase the rate of detection of clinically significant, high risk of progression cancer. The rationale that proton MRI will detect cancer is based on the observation that tumor cell lines have a higher water content than normal tissues. The performance of this expensive imaging modality in distinguishing carcinoma, particularly high grade carcinoma, from benign prostate parenchyma has not been rigorously tested. One limitation of mpMRI is that spatial resolution is no greater than 3 mm, whereas individual cancer cells have a maximum dimension of 0.03 mm. Consequently a cancer consisting only of Gleason pattern 5 cells (the highest risk cancer) may not be detected. Furthermore, histologically distinguishing some benign entities, such as adenosis, from low-grade cancer can be virtually impossible without immunohistochemically determining whether the glands have a basal cell population.

Needle biopsies are the most common way tissue for diagnosing prostate cancer is obtained. Transurethral resections of prostate tissue, typically done to alleviate the clinical symptoms of lower urinary tract obstruction, can also reveal prostate cancer. These cancers are generally of low grade, of transition zone origin and are incidental, without clinical significance.

Histological architecture

The large majority ($>95\%$) of carcinomas of the prostate are acinar adenocarcinomas. Subtypes of prostate carcinomas are neuroendocrine carcinoma, ductal adenocarcinoma, and the sarcomatoid component of some acinar adenocarcinomas. Less frequent are other cancers which involve the prostate–urothelial carcinoma, which originates in the urothelium of prostatic urethra or of the urinary bladder, sarcomas (most common are leiomyosarcoma in adults and rhabdomyosarcoma in infants), and lymphoma (virtually all originate in lymph nodes and secondarily involve the prostate). We shall focus on primary carcinomas of the prostate-acinar adenocarcinoma, ductal adenocarcinoma, and neuroendocrine carcinoma.

Acinar Adenocarcinoma

The histological architecture of prostate acinar adenocarcinoma is variable. Adenocarcinoma is histologically distinguished from benign prostate glands by histological features viewed at low ($20\times$–$100\times$) and high ($200\times$) magnification. At low magnification, the architecture is disrupted, with loss of the normal lobular distribution of profiles of prostate glands and an infiltrative growth pattern between and around benign glands. At high magnification, large nuclei, prominent nucleoli, and a more basophilic cytoplasm characterize carcinoma. Other histologic features help make the diagnosis—intraluminal corpora amylacea (round aggregates of proteins, predominantly lactoferrin from neutrophils), characterizes benign glands; conversely, intraluminal crystalloids (of unknown chemical composition) and mucin are often seen in the lumens of cancer glands. The pathognomonic feature of prostate adenocarcinoma is absence of a basal cell population, which is a specific component of benign glands. Since identifying basal cells by light microscopy is sometimes problematic, immunohistochemical staining of tissue sections for basal cell markers KRT 5/6 or TP63 can improve diagnostic precision. Two other useful immunohistochemical markers are the enzyme AMACR (alpha-methylacyl-coA-racemase) and the transcription factor erg (overexpressed, consequent to the translocation of the TMPRSS2 gene promoter to the erg gene). These proteins are expressed by more than 90% and 45% of primary and metastatic prostate carcinomas, respectively. Notable is nonspecificity of these markers. Some benign glands express AMACR at a level of staining intensity similar to that of prostate carcinoma cells. And erg is expressed by endothelial cells and by some sarcomas.

Additional architectural features of adenocarcinoma provide the basis for grading. The current system for grading, formulated in the 1980s, is the Gleason system. The system is based solely on the architecture of prostate carcinoma in prostates which have not been subjected to systemic or radiation therapy. Cytologic features of carcinoma cells, that is, nuclear size, nuclear pleomorphism, nucleolar size, are not relevant for grading. By convention small cell/neuroendocrine carcinoma is not graded. The cells of prostate carcinoma can form many different histological patterns. These have been categorized into five patterns, termed Gleason patterns 1–5. The grade (or "score") of a carcinoma is the sum of the most frequent pattern and second most frequent pattern. Though the patterns are numbered, they are not continuous variables. Thus, there is no such entity as an average Gleason score. And analyses of a population of carcinomas of different Gleason scores are most appropriately done using a nonparametric statistical test. As currently defined, patterns 1–3 are "well-formed" glands consisting of a cluster of cells. Pattern 3 carcinoma infiltrates between benign glands; this architecture contrasts with patterns 1 and 2 glands, which form circumscribed aggregates of glands (pattern 1) from which foci of glands extend (pattern 2). There are different histologic forms of both patterns 4 and 5. Included in pattern 4 are four forms—poorly formed ("ill-formed") glands, fused glands, cribriform glands, and glomeruloid structures. Pattern 5 can appear as three forms—single cells, sheets of cells without histological evidence of gland formation and comedocarcinoma (**Figs. 1 and 2**).

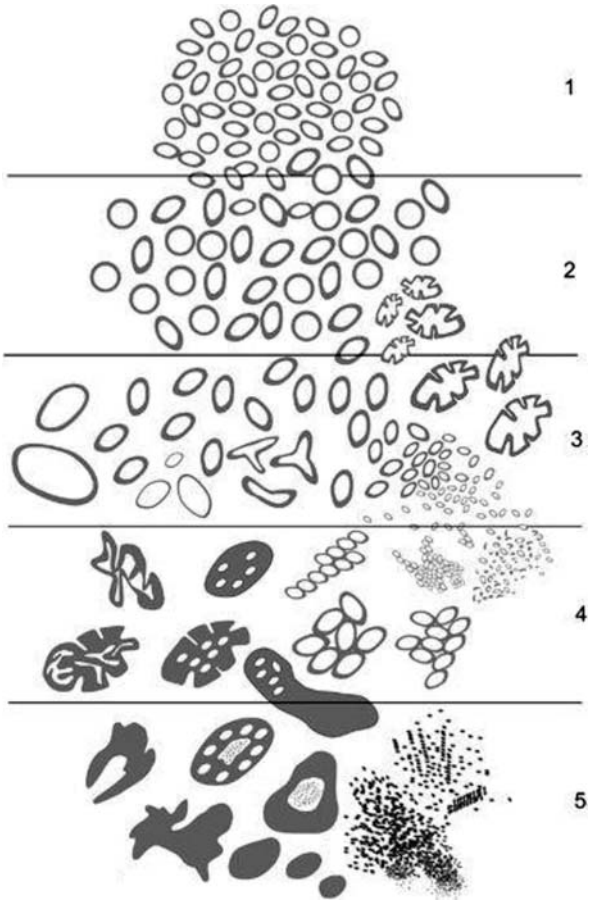

Fig. 1 Current modified schematic Gleason diagram (courtesy of David Grignon, Indiana University Medical Center). Schematic of grade patterns of prostate adenocarcinoma, modified from the original Gleason schematic of grade patterns. From Epstein, J. I. (2018). Prostate cancer grading: A decade after the 2005 modified system. *Modern Pathology* **31**, S47–S63, with permission.

At consensus meetings sponsored by the International Society of Urological Pathology (ISUP), the grading system has been refined. One refinement that had a potentially profound effect on both population studies and on the clinical management of individual patients is virtual exclusion of patterns 1 and 2 from the Gleason score of carcinoma in needle biopsies. The rationale is that extension of carcinoma glands between benign glands excludes categorizing a carcinoma as pattern 1 or 2 since the diameter of the current needle biopsy (less than 0.1 cm in diameter) is less than most clusters of prostate carcinoma glands. Furthermore, many cancers graded as pattern 1 or 2 were probably "adenosis" (a benign proliferation of prostate glands) since immunohistochemical stains, used to more accurately distinguish prostate carcinoma from its mimics, were not used when the Gleason system was developed. Adoption of this principle has resulted in grade shifting (colloquially termed the Will Rogers phenomenon).

A rule of thumb for investigators studying a population of men with prostate carcinoma is to consider upgrading to pattern 3 all carcinomas which have been assigned patterns 1 or 2. An exception to this rule would be specimens of a size sufficient for the pathologist to assess the periphery of a cluster of carcinoma glands. Such specimens are typically the tissue ("chips") of transurethral resections and carcinoma within the transition zone of prostatectomy specimens. Another refinement is changing the definition of the secondary pattern in a biopsy sample from the second most frequent pattern to the pattern that has the highest numerical value. Thus a cancer which is a Gleason $3 + 4$ carcinoma with a minor (or, tertiary) pattern 5 is graded as a Gleason $3 + 5 = 8$ carcinoma. A refinement which has less effect on population studies, though equivalent effect on the care of individual patients, is categorizing all carcinoma glands with a cribriform architecture as Gleason pattern 4. In a previous iteration of the Gleason system uniformly round or ellipsoidal cribriform glands were regarded as pattern 3.

Ductal Adenocarcinoma

The cells of ductal adenocarcinoma, a variant of prostate carcinoma, have a defined histology—ellipsoidal cells with nuclear atypia form a pseudostratified. Ductal adenocarcinoma glands can have different architecture. Most common are papillary and cribriform. Less common are solid and gland-like patterns. While this histological variant of prostate carcinoma is rare, occurring in up to 3% of cancers, it is most frequently a component of an acinar adenocarcinoma. Pure ductal adenocarcinoma represents no more than

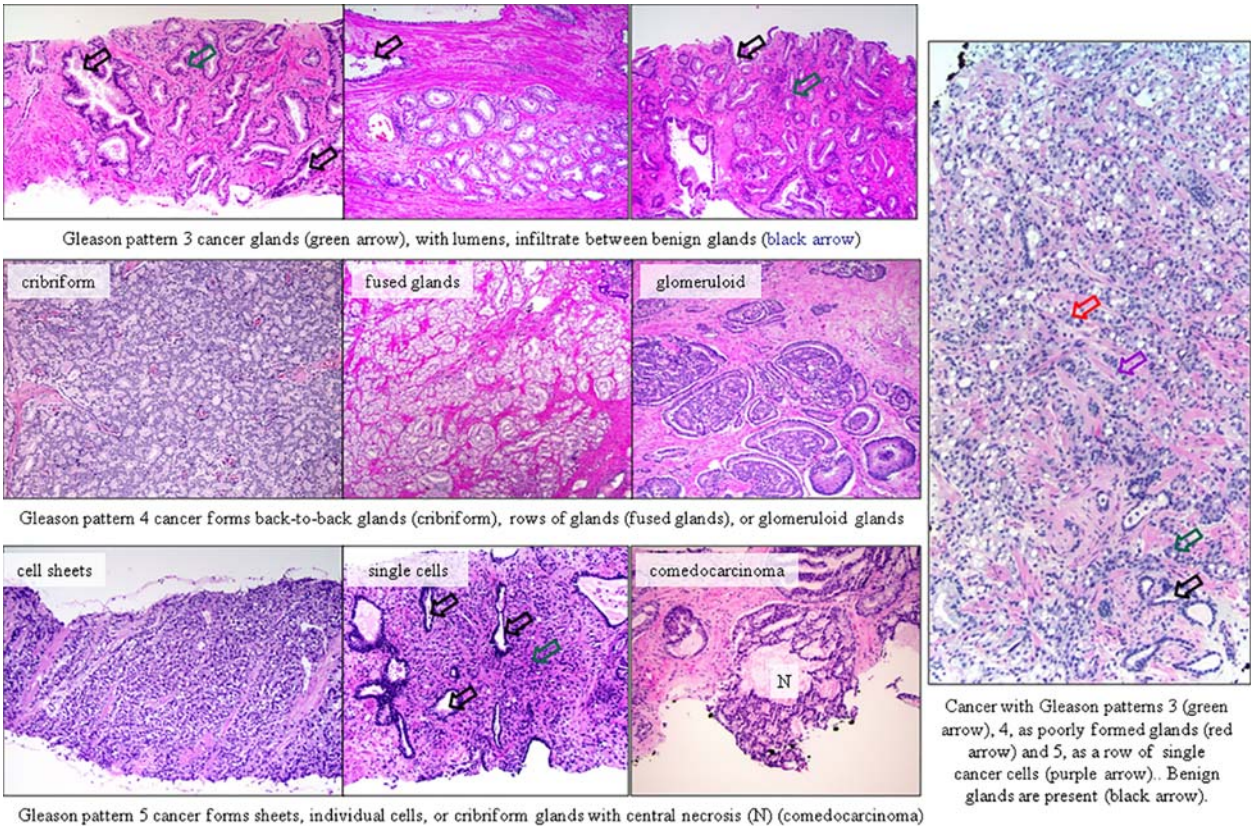

Fig. 2 Gleason patterns. Montage of photographs of different histological architectures of prostate adenocarcinoma, categorized by grade pattern.

0.2% of prostate cancers. Since the molecular phenotype of ductal adenocarcinoma extensively overlaps with acinar adenocarcinoma, we might question whether it should be categorized as a separate histological entity.

Neuroendocrine Carcinoma

Based on a consensus meeting sponsored by the Prostate Cancer Foundation, and subsequently accepted by the ISUP, neuroendocrine (NE) carcinoma has five histological phenotypes—mixed neuroendocrine-acinar adenocarcinoma, small cell carcinoma, and three very rare phenotypes—carcinoid, large cell NE carcinoma, and adenocarcinoma with Paneth cell-like NE differentiation. Tumor cells with a NE phenotype have a distinct protein profile—expressing immunoreactive SYP and/or CHGA and lacking androgen pathway gene products AR, NKX3.1, PSA, and ACPP. Most clinically distinctive is pure small cell carcinoma. Since this highly proliferative tumor (the MKI67 positive tumor cell fraction is at least 80%) does not express androgen pathway gene biomarkers, the organ of origin of metastases of pure small cell carcinoma of prostate cannot be pathologically distinguished from small cell NE carcinoma of more common sites of origin, such as the lung. One exception to this observation is those NE carcinomas which have the TMPRSS2-erg rearrangement. Expression of erg immunoreactivity, by immunohistochemistry or by FISH, is strong evidence that a neuroendocrine carcinoma is of prostate origin, once erg-expressing tumors, such as some sarcomas, have been ruled out. A clinically significant consequence of AR deficiency is that these tumors are not sensitive to androgen deprivation therapy (ADT).

Intraductal Carcinoma

Intraductal carcinoma (IDC) is a proliferation of cells that have the cytological features of acinar adenocarcinoma but which are confined to an acinus. Typically IDC expands the acinus. The most common architecture of IDC is cribriform. The presence of IDC correlates with adenocarcinoma that is high volume and high grade. Mechanistically, IDC is thought to be extension of invasive adenocarcinoma into an acinus of a benign gland. IDC is a microscopic lesion—a truly minor component of adenocarcinoma. IDC is histologically distinctive, to be distinguishable from both PIN and ductal adenocarcinoma.

Prostate Intraepithelial Neoplasia (PIN)

PIN is thought to be the preinvasive state of acinar adenocarcinoma due to similar molecular and cytological features. PIN is characterized by a proliferation of cells that have the cytological of acinar adenocarcinoma but that are confined to an acinus. PIN cells form a pseudostratified epithelium that usually has a papillary architecture. The presence of PIN in a prostate biopsy is evidence that there is a prostate adenocarcinoma, of any grade or volume, within the prostate.

Histological Mimics

Knowing the histological mimics of prostate carcinoma is important so that a patient is treated appropriately. We briefly summarize the histological mimics, to make the reader aware of the challenge a pathologist has in correctly classifying a histological lesion of the prostate parenchyma.

Differential diagnosis

A wide range of cell and tissue entities histologically mimic prostate carcinoma. Correct identification of these mimics relies upon knowledge of these entities and, often, use of appropriate immunohistochemical stains.

Small glands

- Simple atrophy versus acinar adenocarcinoma (Gleason pattern 3) or acinar adenocarcinoma (poorly formed gland variant of Gleason pattern 4)
- Adenosis versus acinar adenocarcinoma (Gleason pattern 3)

Large glands

- Cribriform hyperplasia versus acinar adenocarcinoma (cribriform variant of Gleason pattern 4)
- Hyperplasia versus PIN or pseudohyperplastic acinar adenocarcinoma (Gleason pattern 3)
- Seminal vesicle and ejaculatory duct versus acinar adenocarcinoma (Gleason pattern 3)

Diffuse cell infiltrates

- Acinar adenocarcinoma, Gleason pattern 5 versus hematopoietic cell infiltrate (lymphocytic inflammation, granulomatous prostatitis or lymphoma)
- Acinar adenocarcinoma, Gleason pattern 5 versus small cell and large cell neuroendocrine carcinoma

Spindle cell infiltrate

- Sarcomatoid component of prostate adenocarcinoma or of urothelial carcinoma versus benign stromal cell nodule, inflammatory myofibroblastic pseudotumor, leiomyoma or malignant sarcoma

Nuclear structure

The typical microscopic image of nuclei of prostate cancer cells is that of enlarged, round nuclei with prominent, round nucleoli. This iconic image, which is neither specific for carcinoma nor associated with all prostate carcinomas, contributes to the basis of the microscopic diagnosis of prostate cancer. Confounding the specificity of large nucleoli for carcinoma are histological variants of prostate carcinoma, including the foamy gland variant of primary prostate carcinoma and androgen deprived prostate carcinoma, both of which have small nuclei and nucleoli, and the large nucleoli of some benign hyperplastic basal cells.

Genomics of Primary Prostate Carcinoma

- *Acinar adenocarcinoma*. Prostate adenocarcinoma cells have a phenotype which, in general, recapitulates that of the nonneoplastic luminal epithelial cells: Intermediate filaments, low molecular keratins weight KRT 8, 18; enzymes KLK3 (aka PSA), ACPP (aka prostatic acid phosphatase), cell membrane proteins CD24, MME (aka CD10), B3GAT1 (aka CD57), transcription factors AR (androgen receptor), NKX 3.1. Of note, the protein of some genes is expressed at higher levels in carcinoma, that is, AMACR (alpha-methylacyl-coA-racemase), CD24, and HPN (hepsin). Of these, a subset are expressed at higher levels in higher grade carcinoma than in lower grade carcinoma, that is, MAOA (aka monoamine oxidase a) and DAD1. In addition to transcript features, there are DNA abnormalities in many prostate carcinomas. Changes in DNA involve smaller regions of the genome than can be detected by flow cytometry. Most primary prostate carcinomas are DNA diploid. A small number of carcinomas are DNA tetraploid. DNA aneuploidy is rare. There is hemizygous loss or mutation of PTEN in approximately 40% of acinar adenocarcinomas. Androgen receptor amplification and selection of AR variants, that is, ARv7 and ARv567, increase in frequency in androgen deprivation. The NCI Cancer Genome Anatomy Project (TCGA) characterized the molecular features of more than

300 primary prostate acinar adenocarcinomas. The majority of tumors could be categorized into seven molecular subtypes. Approximately half involved fusion of a promoter to an ets family gene (erg, etv1, or etv4). The other categories were fusion to fli1 and mutations of SPOP, FOXA1, and IDH1. Twenty-five percentage of these carcinomas had a potentially actionable abnormality in the PI3K and/or MAP kinase signaling pathway. DNA repair genes were mutated in 20% of cases. In contrast to metastatic CRPC, there is little evidence of AR variants in primary prostate adenocarcinoma. A subsequent small study reported mutations in DNA repair genes—mismatch repair and homologous recombination genes—in ductal adenocarcinomas of the prostate. Confirmation of this latter study awaits a larger study.

- *Neuroendocrine carcinoma*. The genotype is, in large part, distinctive. Neuroendocrine carcinomas are characterized by loss of RB and of TP53 and virtually all genes and gene products in the androgen pathway—AR, PSA, NKX3.1, hepsin, APCC—and increase expression of AURKA and myc. One exception is that the TMPRSS2-erg rearrangement, which characterizes 45% of acinar adenocarcinomas. This rearrangement is also present in a large number of NE carcinomas.

Prognosis and Prediction

There are two categories of tissue biomarkers—predictive and prognostic. Predictive biomarkers predict response to a given therapy. Prognostic predict clinical outcome, that is, time to biochemical failure (evidenced by posttreatment rising serum PSA), time to metastasis, time to death.

Prognostic parameters

Histological grade

Assigning a grade to a primary acinar (gland forming) adenocarcinoma of the prostate is one of the most clinically important activities of pathologists. The three basic parameters—tumor grade, clinical stage, and serum PSA—stratify patients for prognosis, clinical outcome, and treatment. To generalize, patients with Grade Group 1 carcinoma are candidates for active surveillance. Patients with Grade Group 2 or 3 carcinoma are candidates for intent-to-cure therapy (radical prostatectomy, external beam radiotherapy, or implantation of radiation-emitting "seeds"/brachytherapy). Patients with Grade Group 4 or 5 carcinoma may be offered neoadjuvant therapy prior to intent-to-cure therapy, or may be treated with androgen deprivation. Nomograms of the three basic parameters, supplemented with additional parameters, such as patient age, location of needle biopsies with cancer, amount of cancer in each biopsy, have been developed by different groups, that is, Kattan nomogram, Partin tables, UCSF-Capra score. These prognostic tables are applicable to both biopsies and to prostatectomies.

Grade groups

A recent development is reporting the Gleason score as a Grade Group, of which there are five. Grade Groups correlate as well with clinical outcome as do Gleason scores. The rationale for reporting a carcinoma as a Grade Group is a simpler value and clearer communication of pathologic grade. For example, Grade Group 4 includes Gleason score 4 + 4, score 3 + 5, and score 5 + 3 carcinomas. The consequences of using grade groups are, in general, beneficial. The Grade Group of the carcinoma which has the lowest frequency of progression is 1. These carcinoma are Gleason score 6 carcinomas. Telling a patient with a prostate carcinoma that his carcinoma is Grade Group 1 instead of Gleason score 6 conveys a more "benign" message.

Composite grade

A standard practice of many pathologists has been to grade each core. The clinician then has used the highest grade of a core as the basis for managing the patient. An alternative is for the pathologist to report a single composite grade, which is based on the relative amount of cancer of each grade in each biopsy, in addition to reporting the grade of cancer in each core. The composite grade correlates better with the grade of carcinoma in the whole prostate at prostatectomy than does the highest grade of a core. The composite grade seems more intuitive since, with few exceptions, the cores sample different parts of the same cancer in a prostate.

Pathologic staging

As one of the prognostic parameters, pathologic staging provides information about the extent of the disease—whether the tumor is confined to the prostate or it extends into periprostatic fibrofatty tissue, seminal vesicles, or lymph nodes. This information, also known as TNM staging, is reflected in the American Joint Committee on Cancer staging system, which was updated in 2016. As an example, a prostatic adenocarcinoma in a prostatectomy specimen which invades the seminal vesicle but has not metastasized to lymph nodes or distant sites is classified as pT3bN0M0. The stage predicts outcome after radical prostatectomy.

Predictive models and nomograms incorporate clinical stage, grade, and PSA to stratify patients into risk groups—low-risk or high-risk of progression. Risk categories are based on the grade and volume of cancer in the biopsies. Clinical stage is based on the findings in the biopsies, physical examination, and imaging studies, including pelvic CT, MRI, and bone scans. Although clinical stage is used to aid the clinician in the treatment modality she/he recommends to the patient, pathologic stage, assessed only after prostatectomy, provides more accurate information about the extent of the disease. A carcinoma that is localized to the prostate at prostatectomy but that extends into extraprostatic fibroadipose tissue or into the seminal vesicle, or that involves the radial surgical margin, predicts a shorter time to PSA recurrence. These findings provide a basis for treating a patient with adjuvant radiation therapy.

Tumor volume

The goal of assessing tumor volume in biopsies and in prostatectomies differs. The total volume of tumor in all biopsies in a biopsy procedure is a parameter for recommending active surveillance to a patient. A typical volume threshold value for active surveillance is carcinoma in fewer than four biopsies. The volume of carcinoma in a prostatectomy correlates in some studies with tumor progression and response to neoadjuvant therapy. However, there are discrepant studies. A major source of discrepancy in these studies is the lack of a standard approach to determining tumor volume and of a reference volume. That said, the two most frequent methods used to assess volume are based on visual assessment of the fraction of cells in a region of parenchyma that contains cancer. One method reports volume as a percentage of prostate cells that are carcinoma cells. The second reports volume as the volume of cancer containing parenchyma.

Shortcomings of current grading

The current grading system has shortcomings. One is that variants of different patterns are assumed to have an identical biology. This assumption has been contravened by recent studies which provide evidence that carcinomas with any component of the cribriform variant of pattern 4 have a clinical outcome similar to that of Gleason pattern 5 carcinoma. A future development might be categorizing the cribriform variant as pattern 5 instead of pattern 4. A second shortcoming is inter- and intrapathologist variance in grading carcinomas. For example, pathologists are challenged when distinguishing tangential sections of well-formed carcinoma glands (pattern 3) from poorly formed glands (pattern 4). A possible solution to this problem is substituting transcript profiles of cancer cells for grading. However, basing prognosis on transcript profiles as presently practiced seems unlikely to succeed since the profiles of Gleason grades reported by different investigators differ. Explanations for these differences include inadequate sampling (typically only a few thousand cells are analyzed from a tumor composed of 10^9 cells), contamination (most studies have not isolated tumor cells from stromal cells and inflammatory cells), and different molecular technologies.

Candidate tissue-based prognostic biomarkers

Numerous biomarkers of different categories of analytes (protein, RNA's, DNA) have been assessed in tissue, urine, cells in blood, and cell free samples of blood. We will limit our discussion to tissue-based analytes, of which hundreds have been reported. In univariate analyses many have prognostic value, that is, the fraction of carcinoma cells in cell cycle (the MKI67 fraction), increased expression of MME (CD10), increased fraction of SPINK1 expressing cells, decreased fraction of AZGP1 expressing cells, loss of tumor suppressor gene PTEN and methylation of tumor promoters of CD01, GST-pi, RASSF1, PITX2. Another type of biomarker is a transcript panel from homogenates of tumor containing tissue. Several have been commercialized—ConfirmMDx, Prolaris gene panel, OncotypeDX Genomic Prostate score, and Decipher classifier. However, to date, no biomarker has been shown to improve prognosis stratification in a multivariate analysis which includes carcinoma grade, stage, and diagnostic level of serum PSA. The reasons are multifold. There are shortcomings with preanalytical and analytical study designs and with statistical analyses. A general explanation for the failure of these biomarkers may be that the investigators who discover the biomarkers have not allied the clinical laboratorians who have the tools and experience to validate clinical use.

Predictive biomarker

Currently, there are two predictive tissue-based biomarkers—one histological, the second molecular. Prostate carcinoma that has an exclusively neuroendocrine histological phenotype is predictive to be insensitive to androgen deprivation. Metastatic small cell neuroendocrine carcinoma of the prostate is responsive, somewhat, to cytotoxic chemotherapy. Acinar adenocarcinomas which have a neuroendocrine component are not predictably responsive to chemotherapy. These carcinomas are initially treated with androgen deprivation therapy (ADT). Many patients with metastatic CRPC that expresses AR variant 7 do not respond to even the latest generation of androgen deprivation therapy, that is, enzalutamide and abiraterone. Nonresponse to ADT of ARv7 carcinomas is attributed to absence of the C terminal AR ligand binding domain. Accordingly, these CRPC cancers are treated, forthwith, with cytotoxic chemotherapy. A second histological phenotype which hypothetically predicts response to therapy is ductal adenocarcinoma of the prostate. This type of carcinoma is predicted to not respond to ADT. Extending the possible predictive power of tumor histology further, we have evidence that the cribriform pattern of ductal adenocarcinoma, which tends to have mutations in homologous recombination genes, responds to PARP inhibitors or cytotoxic platinum therapy. Conversely, the papillary pattern of ductal adenocarcinoma, which tends to have mismatch DNA repair gene defects, responds to immune checkpoint blockade therapy.

Metastatic Prostate Carcinoma

Clinical presentation

Most frequently metastatic prostate carcinoma presents in bone, causing pain, and producing fractures and resulting in an often markedly elevated serum PSA. Obtaining biopsies of bone, which can be challenging due to the typically osteoblastic nature of bone metastases, is important, both to confirm the clinical diagnosis and to obtain tissue for sequencing.

Histological architecture

Metastatic prostate carcinoma can be categorized as either subjected, or not, to systemic therapy.

- Metastatic prostate carcinoma not subjected to systemic therapy. The histology of carcinoma not subjected to androgen deprivation therapy is similar to that of the primary carcinoma. However, since neither architecture nor tumor cell cytology is specific for prostate adenocarcinoma, immunohistochemical stains for androgen regulated genes, that is, AR, KLK3, NKX3.1, can often, though not always, be confirmatory. One exception is neuroendocrine carcinoma, as discussed previously.
- Metastatic prostate carcinoma subjected to systemic therapy. The nonsurgical treatment modalities of prostate carcinoma, that is, hormonal ablation and radiation therapy, alter the histology of both the carcinoma and of the nonneoplastic glandular tissue. Both therapies result in decrease of tumor cell and nuclear size and cytoplasmic vacuolization. In general, tumor cells become inconspicuous and appear to be of higher grade. Changes in benign glands are also distinctive. Radiated benign glands are atrophic with a multilayered epithelium enriched in basal cells, including a subset of large, pleomorphic basal cells. In contrast, androgen-deprived benign gland are small and round with a prominent rim of hyperplastic basal cells. Both treatment modalities result in two potentially misleading types of histological features. Since there is a decrease in the number of tumor cells in a region of cancer containing parenchyma, the volume of actual cancer cell mass may be overestimated. And since cancer cells shrink, many appearing as single cells, tumor may be over-graded. General practice is to not grade cancer which has been radiated or androgen deprived, unless there is no histological evidence of treatment effect in either the benign or malignant glands. Of note, the neuroendocrine variant of prostate carcinoma is more frequent in patients with CRPC than in patients with androgen deprivation sensitive metastatic prostate adenocarcinoma. A subcategory of CRPC is prostate carcinoma which has neither an acinar nor neuroendocrine phenotype. Whether this phenotype has a unique immunophenotype or whether it is expresses biologically significant, but immunohistochemically undetectable, levels of either a neuroendocrine or acinar phenotype awaits further studies.

Genomics of metastatic prostate carcinoma

The only detailed studies of large numbers of patients with multiple metastases have been studies of CRPC in patients treated with androgen deprivation. Compared with primary untreated acinar adenocarcinoma, molecular changes in DNA repair genes BRCA2, BRCA1, and ATM were more frequent, occurring in 19% of cases. The large majority of patients had a potentially actionable molecular change. Most frequent were changes of AR (63% of cases). AR changes included single base pair changes, amplification, and an increase in AR variants, most frequently ARv7. Changes in PTEN and in TP53 were also more frequent than in primary prostate carcinoma. The question of heterogeneity of metastases has been addressed in a study of 176 metastases from 63 men in a rapid autopsy program. Interpatient heterogeneity of the molecular phenotype of metastases was great, based on whole exome sequencing, array comparative genomic hybridization, and RNA transcript profiles. In contrast, the molecular profiles of cell cycle and AR activity genes in separate metastases in an individual were similar. Consequently a biopsy of any one metastasis is likely to represent the molecular phenotype of all metastasis.

Prospective Vision

More accurate grading

Although grade is of proven prognostic value in populations of patients and of clinical value in categorizing patients for treatment, there is multiinstitutional evidence that individual patients are often not accurately graded. Interpathologist, and intrapathologist, variance is high. Kappa values (a metric of observer variance where kappa < 0 is no agreement and kappa $= 1$ is perfect agreement) range between 0.3 and 0.8. The following approaches may improve the accuracy of grading:

- Regarding any carcinoma that has a cribriform component as being of highest grade, or as a Grade Group 5 carcinoma. At present carcinomas with a cribriform component can have a Grade Group score from 2 (Gleason score $3 + 4 = 7$) to 5 (Gleason score $5 + 4 = 9$). More than six studies have correlated the presence of any cribriform component with worse outcome, which, in one study, is comparable to the outcome of Grade Group 5 cancer.
- Providing a web-based set of reference images vetted unanimously by a large group of internationally recognized experts in grading prostate adenocarcinoma. Given the present state of interobserver variance, this goal seems to be more aspirational than achievable.
- Histologically assessing prostate carcinomas in 3-D instead of basing grading on 2 dimensional sections of 5 μm thick sections on glass slides. Hypothetically many or all sections of the poorly formed gland variant of Gleason pattern 4 carcinoma are tangential sections of well-formed Gleason pattern 3 carcinomas. An open table top light sheet microscope can assess the architecture of tissue measuring up to 10×10 cm in the x, y axes and at least 0.3 cm in the z axis at a resolution sufficient to distinguish carcinoma from benign glands. The goal of more accurately grading cancer by the Gleason system may be succeeded by a novel system based on 3-D architecture. Confirmation that grading by 3-D microscopy improves prognostic accuracy and decreases pathologist variance would likely involve analyzing thousands of primary prostate carcinomas for which the 10 year outcome is known.
- Replacement of histological grading by a molecular assay. Investigators have reported transcript profiles which distinguish carcinomas of different Gleason grade. To date, transcript profiling has not led to more accurate prognosis by multivariate analysis. And transcript profiles differ by investigator, which raises questions about the accuracy of any profile. Reasons for these differences include the effect of preanalytical variables, that is, warm and cold ischemia time, hypoxia, and pH, degree of

contamination of the tissues by such noncarcinoma cells as stromal and hematopoietic cells and by benign prostate glands, and the molecular heterogeneity of a given tumor. Samples which are profiled typically represent a small component of a tumor. For example, a laser microdissected sample contains only hundreds of cells from a tumor composed of a million tumor cells as well as stromal and inflammatory cells. Analyzing larger samples may not detect minor biologically important subclones, despite use of such a PCR artifact correcting methods as duplex sequencing. Genomic profiling of each tumor can be done more accurately by controlling for preanalytical and analytical variables and by obtaining additional, sequential samples until the marginal data from the next sequential sample leads to no significant change in the data.

- Spatial-based molecular sequencing. As the ability to obtain accurate transcript profiles of single cells improves, the prospect of locating the most malignant subclones in a population of tumor cells increases. Using a combination of 3-D based localization of cells with "driver" genes and in vivo imaging techniques to guide the biopsy hand of the urologist would be a laudable goal, and a formidable challenge.

New histological variants

Different histological variants of carcinoma which cannot be categorized by the system developed for neuroendocrine differentiation have been identified.

- Novel forms of NE-type carcinomas include amphicrine (or, adenoneuroendocrine) carcinoma and metastases of pure NE carcinoma. The tumor cells of amphicrine carcinoma coexpress biomarkers of both neuroendocrine differentiation and of acinar differentiation. The response of this mixed phenotype tumor has not been characterized. A second histological phenotype is pure NE carcinoma. This carcinoma lacks features of both small cell carcinoma (sheets of mitotically active small cells with crush artifact, overlapping nuclei, and frequent apoptotic bodies) and of large cell NE carcinoma (large, pleomorphic cells forming a pseudostratified epithelium around areas of necrosis). Since these tumor cells have more abundant cytoplasm than the cells of small cell carcinoma and are less cytologically atypical than large cell NE cells, we can consider naming them "Intermediate cell neuroendocrine carcinoma."
- A clinically distinctive and pathologically nondistinct form of metastatic CRPC has been termed "anaplastic" carcinoma. What is distinctive about these carcinomas is a serum PSA which is disproportionately low for the mass of tumor metastases, a higher ratio of visceral to bone metastases than is seen in a typical metastatic CRPC, absence of tissue markers of acinar and neuroendocrine differentiation, and insensitivity to ADT. Since the term anaplastic is conventionally used for cytologically pleomorphic cells, a better term might be "null" prostate carcinoma, in lieu of naming it for a specific marker(s). Another curious phenomenon is the variability in expression of the two biomarkers of neuroendocrine differentiation—CHGA and SYP. What is curious is that these proteins, associated with neurosecretory granules of endocrine cells and with synaptic vesicles of neurons, respectively, are expressed by the same tumor cells. This observation raises a question—Is the biology of CHGA-expressing NE tumor cells different than the biology of SYP-expressing NE tumor cells?

More accurate staging

More accurate prognosis may be provided for individual patients if we include in the margin-positive stage pT2 cancers (cancer limited to the prostate), those cancers which are within 0.1 mm of, but not at, the surgical margin. Conventionally such tumors are classified as margin-negative. At least two studies report that the hazard ratio of tumor progression in these patients is the same as that of patients with positive margins.

Nuclear structure

The iconic prostate cancer nucleus is large, round, with a prominent, round nucleolus. This phenomenon, which is clinically so important, raises the question—Why are prostate cancer nuclei histologically different from the nuclei of nonmalignant prostate epithelial cells? Understanding genome organization might provide a basis for both understanding why translocations are characteristic of specific cancers and how genome structure can be diagnostically useful. There is pilot data that nuclear matrix protein SP100, which inhibits expression of some matrix metalloproteinases, is underexpressed in prostate cancer nuclei compared with paired benign nuclei, and that the gene is repositioned in cancer cell nuclei. Hypothetically, carcinomas expressing SP100 are less likely to progress than carcinomas which do not express SP100.

Imaging sciences

We anticipate that spatial resolution of both conventional ex vivo imaging modalities (mpMRI and CT) and of functional modalities (PET scans) will improve in both resolution and in the range of molecules that can be imaged so that cancer can be detected and, perhaps, even graded. Staging, thus prognosis, will become more accurate as the sensitivity and specificity of imaging modalities increases. In about one third of patients whose prostate carcinoma is clinically and pathologically confined to the prostate at radical prostatectomy the carcinoma will recur as metastases. Better imaging promises to detect many of these carcinomas prior to radical prostatectomy. The question then will be how to treat patients with clinically occult, minimal volume metastatic carcinoma. A second possibility is that all prostate carcinoma is metastatic at time of radical prostatectomy, and the cancer remains dormant for many years, even until the individual dies of a nonprostate carcinoma-associated disease. It is also conceivable that a prognosis and

predictive grading system, that is not based on the structure of cancer cells but on functional features which can be imaged, might be developed.

Communication with patients

The vocabulary of pathology reports grows in complexity as new methods of analysis of tissue evolve and are used in clinical practice. Consequently, clearly and successfully communicating pathology and genetic findings to patients, and, even, to clinicians, is a challenge. Without clear communication, patients and their families do not fully comprehend the consequences and risks of treatments. And they risk feeling dis-empowered. Several multidisciplinary teams are developing patient-centered pathology reports. Using graphics and written in a manner that is understandable by patients of common literacy level, these reports promise to improve communication between pathologists, other health care providers, and patients.

Pyruvate Kinase

Gopinath Prakasam and Rameshwar NK Bamezai, National Centre of Applied Human Genetics, School of Life Sciences, Jawaharlal Nehru University, New Delhi, India

Glossary

Aerobic glycolysis (Warburg effect) A phenomenon where unlike normal cells, cancer cells take-up large amounts of glucose and break it primarily into lactate regardless of the presence of molecular oxygen (O_2), a tendency exploited in clinical detection of cancer by fluorodeoxyglucose positron emission tomography (FDG-PET) scan.

Protein moonlighting A phenomenon that elucidates the ability of a protein to perform more than one function. In common the primary function of these proteins are catalysis of a biochemical reaction, but through their secondary moonlighting property they can involve in signal transduction, transcriptional regulation, replication, translation, scaffolding, motility, and apoptosis. Researchers believe that proteins would have acquired their moonlighting function through evolution, further they believe that the ancestral protein would have possessed only single function.

Substrate-level phosphorylation An enzyme-catalyzed biochemical reaction that yields a molecule of ATP or GTP by directly transferring a phosphate group to ADP or GDP (energy) from high-energy rich phosphate containing metabolic intermediates, for example, phosphoenol pyruvic acid. Unlike mitochondrial oxidative phosphorylation, the energy (ATP) produced through substrate-level phosphorylation is independent of oxygen.

Introduction

Characterization of PK Isoforms

Enzyme pyruvate kinase (PK; ATP-pyruvate 2-O-phosphotransferase, EC 2.7.1.40) catalyzes an irreversible, decisive step of the glycolytic pathway. PK catalyzes a transphosphorylation reaction between phosphoenolpyruvate (PEP) and adenosine diphosphate (ADP) to yield a molecule of pyruvate and ATP. Energy (ATP) generated from the above biochemical reaction is through substrate-level phosphorylation which is oxygen independent, substantially contributing to the net glycolytic ATP. PK is ubiquitously expressed across all living beings, originating from simple unicellular organism to complex multicellular organism, where the presence of at least one isoform of PK is essential to drive glycolysis. Mammals possess four isoforms of pyruvate kinase, named as PKR, PKL, PKM1 and PKM2; and these PK isoforms primarily differ from one another by their differential kinetic properties. The expression of PK isoforms is strictly regulated to demonstrate tissue specificity, which is essential to meet the different metabolic demands of diverse cell types. For instance, the expression of PKL is predominant in hepatocytes, to support gluconeogenesis. Similarly, expression of PKM2 is ideal for cells with high anabolic biosynthesis rate, such as embryonic cells. Among four isoforms of PK, M2-PK has gained enormous interest; and has been extensively studied. Since PKM2 has been shown to preferentially express in cancer cells, it is considered as one of the metabolic hallmark features of such cells. Cancer cells in addition to expressing PKM2, alter its quatnery state into an enzymatically less active dimeric form. This in-active form of PKM2 is indispensable for cancer cells to rewire its metabolism to exhibit aerobic glycolysis, a mechanism through which cancer enhances glycolysis and replenishes its biosynthetic and energetic demand to sustain rapid growth and proliferation. Moreover, PKM2 aids cancer cells with manifold nonmetabolic benefits, such as protein kinase activity, cotranscriptional activation of gene expression, maintaining redox balance, chromosomal segregation and regulation of apoptosis.

Allosteric Regulation of PK Isoforms

Although, the biochemical reaction (pyruvate kinase activity) catalyzed by PK isoforms are identical in nature, however, they markedly vary among one another for their kinetic properties, in relation to varied affinity to its substrate PEP and allosteric regulation by metabolic intermediates. Moreover, PK isoforms show almost similar affinity for its substrate ADP. PKM1, a nonallosteric, constitutively more active form, in comparison to the other PK isoforms has the highest affinity to PEP. Likewise, PKR and PKL have the least affinity to their substrate PEP and both isoforms can be allosterically activated by fructose 1, 6-bisphosphate (FBP) and -inhibited by the concentration of ATP. Intriguingly, PKM2 affinity for its substrate PEP varies based on its quaternary structure (dimer or tetramer). The kinetic characterization of two oligomeric forms of PKM2 has revealed that the tetramer of PKM2 has high affinity to its substrate PEP and it is enzymatically active; whereas, the dimeric form of PKM2 has a relatively very weak affinity for PEP and is enzymatically inactive at physiological conditions.

PK Isoforms and Tissue Distribution

The genome of *Homo sapiens* comprises of two distinct PK genes, termed as *PKLR* and *PKM* located on chromosome 1q22 and 15q23, which encode for four PK isoforms, PKR, PKL, PKM1 and PKM2. *PKLR* gene codes for PKR exclusively in erythrocytes

(red blood cells, RBCs), and expresses PKL predominantly in liver and sparsely in kidney, and intestine. The expression of PKL and PKR in the selective tissue types is achieved by the activation of two alternate promoters located in *PKLR* gene by the tissue-specific transcription factors. The upstream promoter present in the *PKLR* gene drives the expression of a full-length PKR transcript, exclusively in RBC, possessing an extra exon in its 5′ terminal end, in comparison to a shorter variant PKL (**Fig. 1**), thus coding for a polypeptide chain of 574 amino acids. Whereas, the PKL transcript codes for 543 amino acids (58.4 kDa) containing polypeptide chain.

The *PKM* gene, located on chromosome 15q23, is 32 kb long with 12 exons and 11 introns; and codes for two alternative splice variants, PKM1 and PKM2. Out of 12 exons' that *PKM* gene codes for, the mature PKM mRNA that acquires exon 9 and omits exon 10 is termed as PKM1 (**Fig. 1**). On the other hand, the transcript that includes exon 10 and excludes exon 9 is designated as PKM2. The mature mRNAs of PKM1 and PKM2, harbor coding sequences with identical length (1593 base pairs), however, they differ by 160 nucleotide sequences from 1143 to 1303 bases, due to their alternative selection between exon 9 and 10. The polypeptide chain of 531 amino acids (aa) translated from theses mature mRNAs of PKM1 and PKM2 are of identical size. The amino acid sequence of PKM2, based on its characteristic biochemical properties, is categorized into three functional domains (A-, B- and C). The interlinking region between the A-domain (aa 44–116 to aa 219–389) and B-domain (aa 117–218) forms the catalytic active site, which binds to the enzyme substrates PEP and ADP. The C-domain (aa 390–531) situated at the C-terminal end of PKM2 harbors the binding site for allosteric activator—fructose 1, 6 bisphosphate (FBP), nuclear localization signal sequence and an intersubunit contact domain (ISCD) (**Fig. 2**A). The ISCD sequence is unique to PKM2 and provides it with some exclusive privilege over other PK isoforms to exist in two distinct oligomeric states with different enzyme kinetic properties that is, enzymatically more active tetramer and an enzymatically inactive dimer. All other PK isoforms (M1, -L and -R) exist only in a tetrameric quaternary state to act as active enzymes. Two monomers of PKM2 interact at their A-domain to give rise to a dimer; further two dimers associate at their C-domain-ISCD-interface in a dimer-of-dimers arrangement to form an enzymatically active tetrameric oligomeric state. Unlike PKM2, PKM1 is a constitutively active form and lacks ISCD, as it differs from PKM2 due to alternative splicing. The amino acid sequences coded by exon 9 and exon 10, corresponding to amino acids sequence between 378 and 434 in the C-terminal of PKM isoforms, differs by 23- out of 56-amino acids. Hence, PKM1 exists only in tetrameric form and its enzyme activity cannot be activated by allosteric activators, such as FBP.

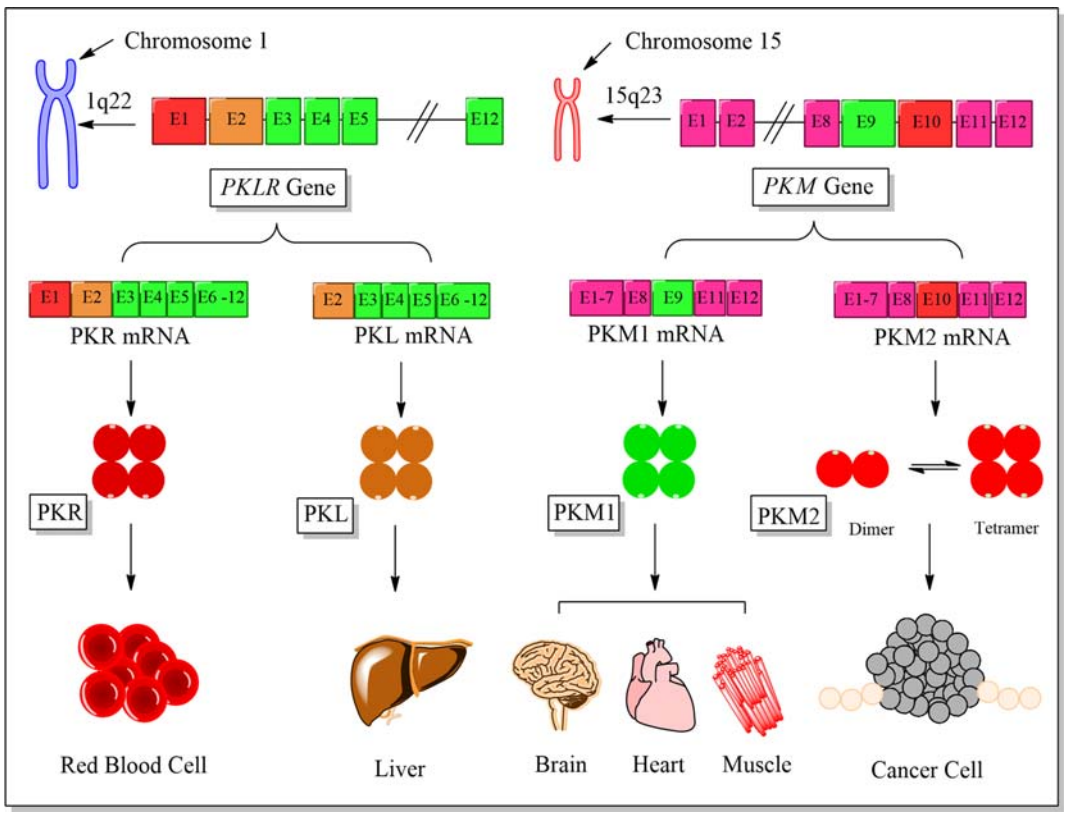

Fig. 1 Pyruvate kinase isoforms and tissue distribution. *PKLR* gene located on chromosome 1q22 region codes for PKR and PKL isoforms by activating tissue-specific promoters and restricts their expression to particular tissues, such as PKR in RBC and PKL in Liver. Likewise, *PKM* gene on chromosome 15q23 encodes for two more isoforms, termed PKM1 and PKM2, through alternative splicing of mutually exclusive exon 9 and 10. The expression of PKM1 is confined to differentiated cells, such as skeletal muscle, brain and heart. On the contrary, the expression of PKM2 is restricted to proliferating cells, for example, malignant cancer cells.

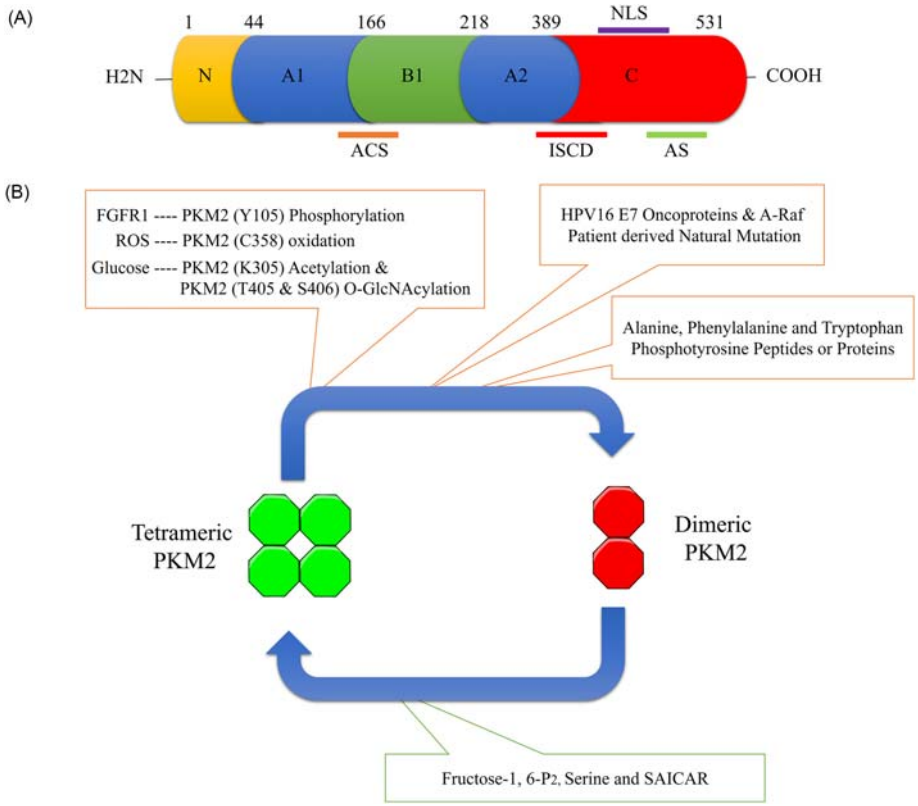

Fig. 2 A schematic diagram portraying the domain structures of PKM2 and the cellular molecular cues that influence PKM2 enzyme activity. (A) The adjoining region between the PKM2 A1 and B-domain forms a catalytic active site (ACS) and the interface between A2 and C-domain forms an intersubunit contact domain (ISCD), the latter enables the two dimers of PKM2 to interact and form tetrameric oligomer. Further, C-domain harbors a nuclear localization signal sequence (NLS) and an allosteric activator (FBP) binding site. (B) Illustration depicts the metabolic intermediates, oncogenes and posttranslational modification that activates and inhibits PKM2 enzyme activity and its oligomeric state. PKM2 exists as an enzymatically active tetramer and relatively inactive dimer and the allosteric activation of PKM2 involves stabilization of its enzymatically active tetrameric state. PKM2 is allosterically activated by glycolytic intermediate FBP, amino acid serine and SAICAR, a metabolic intermediate from purine biosynthesis pathway. Likewise, PKM2 activity is inhibited (i.e., dissociation of PKM2 into dimers) by metabolites (alanine, phenylalanine and tryptophan), binding of oncoproteins (HPV16 E7 oncoprotein and A-Raf), natural mutations, phospho-tyrosine-mediated release of FBP and PTMs, such as phosphorylation, acetylation, oxidation and O-GlcNAcylation.

Tissues that comprise of highly differentiated cells with high basal metabolism rate (i.e., catabolism) and high-energy (ATP) turnover to support normal physiology, such as skeletal muscle, heart and brain, ideally express the constitutively active M1 isoform of PK (PKM1). PKM2 expression is abundant in cells that undergo rapid growth and frequent cell division, such as embryonic cells and the transformed neoplastic cells (Fig. 1). Embryonic cells during their differentiation, gradually replace the expression of prototype PKM2 isoform with other tissue-specific isoforms. However, malignant transformation of adult differentiated cells results in reexpression of PKM2. For instance, PKL to PKM2 shift was reported in the cases of hepatocellular carcinoma and PK-M1 to -M2 in a variety of cancer types, such as glioblastoma, lungs and so on. Studies have cited the expression of PKM2 in normal differentiated cells, such as intestinal epithelium, pancreatic islets, lung, retina, distal renal tubules and brown adipose tissue; and the exclusive presence of PKM2 in cancer cells has also been questioned. Interestingly, the coexpression of PKM2 and PKM1 isoforms has been noticed; and reported in sporadic breast cancer tissue as well as in multiple cancer cell lines from different tissue origin. The latter suggests that besides PKM2 supporting cancer cell growth and division, there is a unique role played by PKM1 in cancer cells as well. Besides occurring as homo-tetramers, PKM2 can exist as hetero-oligomers. Hybrids between PKM2 and PKL have been reported in liver, colon and rectum. Similarly, PKM1 and PKM2 hetero-tetramer hybrids have been described in stomach, esophagus and recently in lung cancer cell lines.

Regulation of PK-Isoform Expression and Enzyme Activity

Expression Regulation of PKL/R Isoforms

PKL expression is linked with the tissue (Hepatocytes) that principally supports gluconeogenesis, an adaptive metabolism during fasting or nutrient starvation. Intriguingly nutritional status is one of the essential features that impact the expression of PKL in the

liver. Carbohydrate-rich diet stimulates the activation of carbohydrate-response element-binding protein (ChREBP) to induce the expression of PKL. On the other hand, nutrient starvation suppresses the PKL expression. Hormone, glucagon, phosphorylates- and inhibits-PKL enzyme activity through a mechanism apparently involving cyclin-AMP activated protein kinase. Similarly, hormone epinephrine blocks the activity of PKL to promote gluconeogenesis. However, hormone insulin reverses the effects of glucagon and epinephrine on PKL activity, thus promoting glycolysis and inhibiting gluconeogenesis. There are insufficient reports to elucidate the expression regulation of PKR.

Expression Regulation of PKM Isoforms

The molecular mechanism behind the alternative splicing of PKM isoforms, as well as the mechanistic link by which cancer cells reexpress PKM2 has been elucidated recently. In this article, authors propose an apparent role of c-Myc (frequently deregulated oncogene) driven activation of heterogeneous nuclear ribonucleoproteins (hnRNPs; hnRNPA1, hnRNPA2 and polypyrimidine tract binding protein (PTB)), in dictating alternative splicing of PKM isoforms. The hnRNPs directly bind the sequences flanking exon 9 of the PKM precursor RNA and repress its inclusion into the mature PKM transcript, thus indirectly facilitating the inclusion of exon 10 and resulting in increased copy number of PKM2 transcripts in cancer cells. Moreover, serine/arginine-rich splicing factor 3 (SRF3) binds- and facilitates-exon 10 inclusion to mature PKM mRNA; thus, increasing the proportion of PKM2 mRNA in the cancer cells through one another distinct mechanism. Since numerous splice factors exist to check (repress) the inclusion of exon 9 and prevent the expression of PKM1, one can assume that PKM1 could be the default protein to express in mammalian cells, however, more studies are required to conclude anything further.

The expression of PKM2 in normal proliferating as well as in malignant tumor cells is broadly influenced by diverse signaling pathways, stimulated by growth factors, hormones, aberrantly mutated oncoproteins and the elements from tumor microenvironment (hypoxia and nutrient status). These molecular cues facilitate the expression of PKM2, by stimulating the expression of numerous transcription factors that bind their consensus DNA binding site in *PKM* gene (promoter or enhancers). Hypoxia-inducible factor 1α (HIF-1α), peroxisome proliferator-activated receptor gamma (PPARγ), nuclear factor kappa (NFκB), specificity protein (Sp1 and Sp3) are few of the transcription factors known to directly regulate PKM2 expression. HIF-1 transcription factor, which is canonically stabilized under hypoxic conditions, induces the expression of PKM2 isoform by binding hypoxic response element (HRE; HIF-1α consensus DNA binding sequence) located at the first intron of *PKM* gene. The PKM2 that is overexpressed under hypoxic stress, localizes into the nucleus and interacts with HIF-1 transcription complex to coregulate the transcription of glycolytic enzymes including PKM2, through a positive feedback loop. The resultant changes in expression of glycolytic enzymes, including PKM2 is necessary to support aerobic glycolysis (an adaptive metabolic reprogramming) in cancer cells, which is essential to support tumor progression and to survive the recurrent hypoxic stress that ascends from tumor microenvironment. In addition to hypoxia, insulin and aberrant oncogenic signaling networks, such as receptor tyrosine kinase, PI3K and AKT, which are frequently mutated and deregulated in cancer, constitutively trigger the downstream effector mammalian target of rapamycin (mTOR) and facilitate the normoxic stabilization of HIF-1 and induce the expression of c-Myc transcription factor. HIF-1 and c-Myc transcription factors together activate the expression of PKM2 and other essential glycolytic enzymes to rewire cancer-metabolism. Sp1 transcription factor stimulates the transcription of PKM2 by binding GC-boxes (Sp1 consensus DNA binding site) located in *PKM* gene promoter. Sp3 transcription factor has been shown to synergize this Sp1 function by enhancing the expression of PKM2. In addition, under hyperglycemic conditions protein phosphatase 1 has been shown to dephosphorylate- and stimulate-Sp1 to bind PKM gene at GC-box to facilitate the expression of PKM2. Hyperactivated AKT2 in PTEN null mouse liver cells has been shown to induce the expression of the transcription factor peroxisome proliferator-activated receptor gamma (PPARγ), also a nuclear hormone receptor. PPARγ by specifically binding PKM and HK (Hexokinase) gene promoters was shown to induce the expression of PKM2 and HK2, resulting in liver metabolism rewiring, which paves the way for liver pathophysiology. EGFR stimulated NFκB (p65) recruits HIF-1α transcription factor to PKM gene promoter to coregulate the expression of PKM2 and rewire the metabolism of cancer cells. Hormones, including, glucocorticoid, triiodothyronine-T3 and insulin have been shown to regulate the transcription of PKM2. Collectively, the above evidences suggest that cancer cells exploit the flexibility in the expression regulation of PKM2 and reap the benefit of reprogramming metabolism to meet the demands of biomass and energy to support their persistent growth and proliferation.

PKM2 at Crossroads of the Metabolic Rewiring of Cancer Cells

Cancer cells are facilitated by the concomitant expression of PKM2 and the alteration of its quaternary state by promoting subunit dissociation into an enzymatically less active dimeric form. The accumulation of dimeric PKM2 obstructs the terminal step of glycolysis. This, as a result stockpiles the high energy-rich glycolytic metabolites above the pyruvate kinase reaction, which is then channeled into anabolic metabolism to support the biosynthesis of amino acid, nucleotides and lipids, offering a metabolic advantage for cancer cell growth and proliferation. The tetramer:dimer ratio of PKM2 and its enzyme activity, in normal proliferating cells and notably in cancer cells, is controlled by multiple cellular intrinsic parameters, such as binding metabolic intermediates (that act as an allosteric regulators), physically interacting oncoproteins, dominant negative natural mutations, competitively binding phosphotyrosine peptides and most importantly posttranslation modifications (PTMs). Glycolytic intermediate, fructose 1, 6-P2 (FBP), and amino acid serine, bind- and enhances-PKM2 activity by stimulating the subunit association of dimeric PKM2. However,

a reduction in the concentration of FBP results in reversible disassociation and inactivation of PKM2 activity. Likewise, succinylaminoimidazolecarboxamide ribose-50-phosphate (SAICAR), a metabolic intermediate from the purine biosynthetic pathway, which accumulates under nutrient-deprived conditions, specifically binds M2-PK to enhance its activity. Whereas, amino acids alanine, phenylalanine and tryptophan serve as an allosteric inhibitors of PKM2.

Apart from the metabolic intermediates, numerous oncogenic protein interacting partners of PKM2 have been shown to modulate its oligomeric state and enzyme activity. Remarkably, human papillomavirus 16 (HPV16; high-risk type papillomavirus) encoded E7 oncoprotein, physically interacts with tetrameric PKM2 to stimulate its subunit disassociation into enzymatically inactive dimers. FBP fails to reverse the above PKM2 oligomeric shift mediated by HPV16 E7 oncoprotein. Through a similar mode of mechanism, A-Raf promotes the dimerization and inactivation of PKM2 in A-Raf transformed NIH3T3 cells. Besides, enzyme activity of PKM2 has been shown to affect its interaction with EGF stimulated Jumonji C-domain containing dioxygenase (JMJD5), cytosolic promyelocytic leukemia (cPML) or Tyr-46 phosphorylated MUC1-C (Mucin 1). JMJD5 reduces PKM2 activity by obstructing the association of PKM2 dimers to form enzymatically active tetrameric form. cPML decreases PKM2 activity by selectively binding tetrameric form of PKM2, without altering its quatnery state. In case of EGF stimulated Tyr-46 phosphorylated MUC1-C, the molecular mechanism by which it impedes the activity of PKM2 is not known. Moreover, recently the interaction between PKM2 and a serine/threonine kinase, death-associated protein kinase (DAPK), has been shown to increase PKM2 activity. Differing from the above molecular mechanism, PARP-14 has been shown to suppress PKM2 activity by inhibiting JNK-1 (proapoptotic factor) mediated Thr365 phosphorylation- and activation of -PKM2 enzyme, and therefore PARP-14 indirectly supports aerobic glycolysis. Further, natural mutations in PKM2, especially within the sequence that codes for inter-subunit-contact-domain located at the C-terminus of PKM2 were shown to decrease its enzyme activity by manifold. The reason being, mutations in ISCD obstruct the association of two dimers to form an enzymatically active PKM2 tetramer, accumulating more dimers, which has been validated using both computational and experimental techniques.

The amino acid sequence of PKM2 retains many conserved PTM sites, frequently modified by phosphorylation, acetylation, oxidation, hydroxylation, ubiquitination, glycosylation, methylation and so on. These wide variety of PTMs can be categorized into two types based upon their impact on PKM2 and resultant metabolic and nonmetabolic sustenance to cancer cells. The modifications that specifically affect PKM2 structural and functional features and provide metabolic advantage to cancer cells include, PKM2 tyrosine (Y) 105 phosphorylation, lysine (K) 305 acetylation, cysteine (C) 358 oxidation, threonine (T) 405/serine (S) 406 O-GlcNAcylation and Arginine (A) 445/447/455 methylation of PKM2. PKM2 Y105 phosphorylation (mediated by the deregulated Fibroblast growth factor receptor 1 (FGFR1), BCR-ABL and JAK2) decreases PK enzyme activity by stimulating the enzymatically active tetramer form of PKM2 to release the bound FBP (allosteric activator), and to undergo subunit disassociation. The above metabolic alteration channels the precursors within the glycolytic pathway toward the biosynthesis of macromolecules, supporting the metabolic necessity of cancer cells. Similar to the above mechanism, in response to high glucose, acetyltransferase P300/CBP-associated factor (PCAF), acetylates K305 residue of PKM2 and reduces its enzyme activity; and also directs acetylated PKM2 for lysosomal degradation. The relative poor stability of PKM2 and resultant reduced activity eventually contributes to the proproliferative metabolic phenotype of cancer cells. An upsurge of reactive oxygen species (ROS) has been shown to oxidize PKM2 at C358 residue, prompting PKM2 dissociation into a less active dimeric form. The accumulated glycolytic intermediates due to less PKM2 activity are directed toward PPP shunt for the production of reducing potential ($NADPH + H^+$) to detoxify ROS in cancer cells. Multiple factors have been shown to trigger ROS production in cancer cells such as growth factors, hormone (insulin), aberrant growth factor signaling as well as defective mitochondria that harbor mutant subunits of oxidative phosphorylation complexes, for example, ND5, ND3 and COI. Nutrient status of cancer cells has been shown to dynamically regulate O-GlcNAc transferase (OGT) to interact and O-GlcNAcylate PKM2 at T405 and S406 residues. O-GlcNAcylation reduces PKM2 activity by destabilizing the PKM2 tetramer into less active dimer, remodeling the metabolism of cancer cells to acquire aerobic glycolysis. In addition, O-GlcNAcylated PKM2 localizes inside the nucleus, for which it requires additional S37 phosphorylation, mediated by EGF stimulated ERK1/2 protein kinase. Nuclear PKM2 (i.e., T405 and S406 O-GlcNAcylated and S37 phosphorylated PKM2) coregulates the transcription of c-Myc target genes GLUT1 and LDHA and enhances procancerous metabolism and tumor progression, a unique and pioneering study to emphasize the crosstalk between the PTMs of PKM2, where it turns out both PKM2 O-GlcNAcylation and phosphorylation are mutually exclusive and essential to translocate PKM2 in nucleus and to exhibit nonglycolytic nuclear function in cancer cells. Methylation of PKM2 at Arg445/447/455 residues, by the coactivator associated arginine methyltransferase 1 (CARM1), promotes aerobic glycolysis to support tumor cells proliferation, invasion and metastasis. This study is unique to elucidate a novel molecular mechanism through which PKM2 methylation influences the aerobic glycolysis without altering its activity and the quaternary state. The methylated PKM2 is translocated into mitochondrial associated—endoplasmic reticulum membrane to interact—and reduce the stability of—$InsP_3Rs$ (inositol 1,4,5-trisphosphate receptors), which significantly decreases the calcium influx from endoplasmic reticulum to mitochondria, thus decreasing the mitochondrial membrane potential and paving the way for a shift from aerobic glycolysis to oxidative phosphorylation. Knockdown of PKM2 or the introduction of methylation ablative PKM2 mutant ectopically or by delivering nanoparticles harboring competitive nonmethylated PKM2 peptide in cancer cells have been shown to abrogate tumor favoring features of PKM2.

Concomitantly, a few PTMs of PKM2, varying marginally from the above defined molecular mechanism, can direct nuclear translocation of PKM2 to execute several nonglycolytic moonlighting functions. These collectively orchestrates metabolic rewiring in cancer cells to acquire procancerous aerobic glycolytic metabolic trait. EGF stimulated ERK1/2, mediates PKM2 S37 phosphorylation in cancer cell and offers PKM2 an advantage to selectively bind PIN and importin α5 (Nuclear exporter) and localize inside the nucleus. Nuclear PKM2 act as a transcriptional coactivator of β-catenin to promote the expression of its target gene, c-Myc. The

transcriptional activation of c-Myc influences the expression of glycolytic enzymes, GLUT1, LDHA and remarkably PKM2, through a positive feedback loop, to enhance the metabolic capabilities of cancer cells. Similarly, a secretory glycoprotein, extracellular matrix protein 1 (ECM1), also shown to stimulate PKM2 S37 phosphorylation, directs nuclear localization and transcription activation of glycolytic enzymes in tumor cells. Besides posttranslational modification, PKM2 stands unique in comparison to all other PK isoforms, by its atypical characteristic of binding the tyrosine-phosphorylated peptides or proteins. The latter prompts PKM2 to release its allosteric activator FBP, resulting in the inhibition of PKM2 activity and its subunit disassociation, which in turn supports the procancerous anabolic metabolism. The report of PKM2 profound affinity for phosphotyrosine protein is further substantiated by a recent study, which has revealed that PKM2 interacts specifically with Y333 phosphorylated β-catenin, in EGF stimulated cells. PKM2- β-catenin complex in nucleus interacts with T-cell factor (TCF) and then binds to the CCDN1 gene promoter for the transcription activation of cyclin D1 expression to promote brain tumor cell division. To sum up, PKM2 acts as a metabolic tuner, which decides the fate of glycolytic intermediates (used for anabolic biosynthesis or energy generation) by modulation of its activity and structural configuration by above-stated mechanisms.

The Nonmetabolic Attributes of PKM2 and the Hallmark Features of Cancer

Malignant cancer cells markedly differ from nontransformed normal cells by six cardinal hallmark features, such as self-sufficiency in proliferating signal, resisting growth inhibitory signals, immortality, infinite replicative competence, angiogenesis and metastasis. In addition, aerobic glycolysis, one of the key biochemical hallmark feature of the cancer cells, has been added to the above list in the recent past. A large body of evidence has corroborated the indispensable role of PKM2 in aerobic glycolysis. Moreover, emerging studies have elucidated a wide range of remarkable nonglycolytic functions of PKM2 that collectively support the stated hallmark features of cancer cells, such as growth, proliferation, evasion of cell death and spreading. The diverse nonglycolytic attributes of PKM2 associated with tumor progression are primarily by virtue of its moonlighting-protein kinase, transcriptional coactivator or co-repressor-functions. In this section of the article, we bring in all the new developments and landmark discoveries that highlight the nonmetabolic attributes of PKM2 and their link with other cardinal-hallmark features of malignant tumors (Fig. 3).

Self-Sufficiency in Growth Factor Signaling

Unlike normal cells, tumor cells are least dependent on the extracellular mitogenic cues for their proliferation. Rather, they acquire the ability to proliferate with the sustenance of oncogenes. Cancer cells harbor a variety of such aberrant oncogenes, which are key

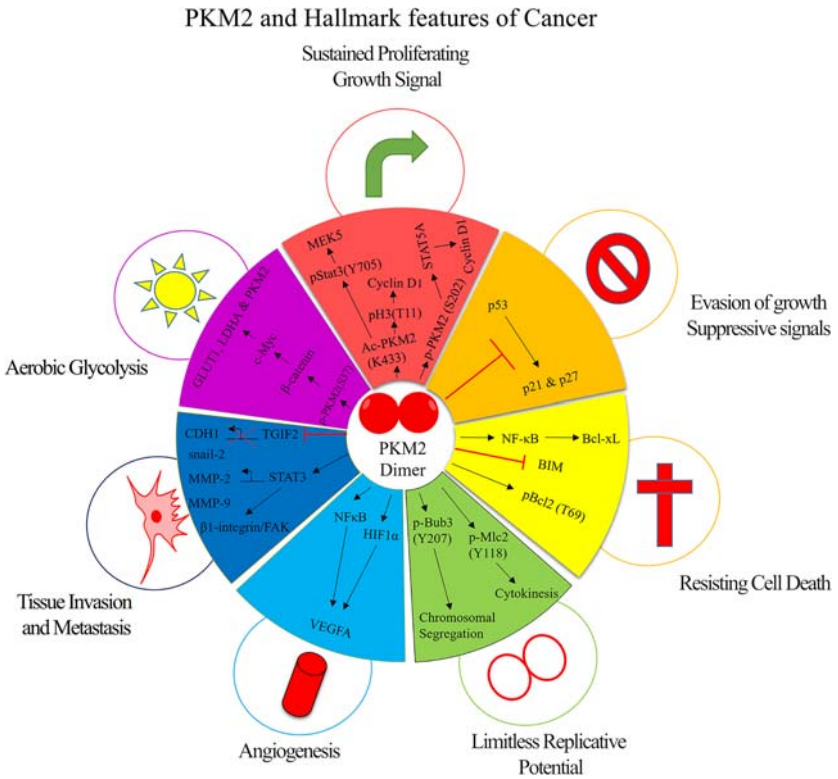

Fig. 3 PKM2 and the hallmark feature of cancer. Illustration highlights the association of PKM2 with established key hallmark features of cancer, suggesting an apparent role of PKM2 in cancer progression.

components of constitutively active growth factor signal transduction pathway due to gain of function mutations or aberrant post-translational modifications. Emerging studies have emphasized prooncogenic properties of PKM2 through its nonglycolytic virtues, such as protein kinase and transcription coactivator functions. Growing body of evidence suggests that the tetramer of PKM2 is an active enzyme, pyruvate kinase; and the dimeric form of PKM2 is relatively an inactive enzyme and a protein kinase. In difference to a typical protein kinase, the dimeric PKM2 utilizes PEP (phosphoenolpyruvate) as the phosphate donor for its protein kinase activity. It has been suggested that the dimeric PKM2 is a dual-specificity protein kinase (i.e., it can act as both tyrosine kinase and serine/threonine kinase), which is highly specific in binding and phosphorylating its protein substrates. However, there has not been characterization of any specific consensus binding site of PKM2 protein kinase on its protein substrates.

In a recent study, PKM2 has been shown to phosphorylate Y705 residue of Stat3 transcription factor (mechanism which is independent of the canonical Janus kinase (JAK)) and enhance its transcriptional activity to express its target gene MEK5, which in turn promotes the cell growth and proliferation. EGF stimulated cancer cells have been shown to facilitate PKM2 dimerization and its nuclear localization to phosphorylate histone (H3) at T11 residue, the latter stimulates the expression of two master transcription factors, c-Myc and cyclin D1, which transactivates the expression of genes that directly dictate cell proliferation. SAICAR, a metabolic intermediate from purine biosynthesis pathway that accumulates vastly in the proliferating cells, has been shown to specifically bind dimeric PKM2 and enhance its protein kinase activity. The PKM2–SAICAR complex has been shown to phosphorylate several novel protein substrates (typically protein kinase) including Erk1/2 which in turn sustains the mitogen-induced cell proliferation. Acetyltransferase-p300 stimulated by the spectrum of mitogenic signals and oncogenes were shown to acetylate K433 residue of PKM2. K433 acetylation enables PKM2 to localize into the nucleus and act as a protein kinase to phosphorylate Stat3 at Y705 and H3 at T11 residues, which in turn transcriptionally activate the expression of key factors that promote cell proliferation and tumorogenesis. Marginally differing from the above molecular mechanisms, insulin-like growth factor (IGF-1) stimulated cancer cells trigger AKT to interact and phosphorylate PKM2 at S202 residue to facilitate its nuclear entry and to transcriptionally activate the Stat5A target gene—cyclin D1 expression. PKM2 mediated cyclin D1 expression allows the cells to enter into cell division. This unique observation highlights how downstream to IGF/PI3K/AKT axis PKM2 functions as a transcriptional coactivator of Stat5A, which promotes tumor growth (**Fig. 3**). PKM2 can also serve as a transcriptional coactivator of transcription factors such as β-catenin and signal transducer and activator of transcription (Stat-3) and regulate the expression of their target genes that directly regulate cell proliferation or reprogramming of the metabolism of cancer cells.

Insensitivity to Growth Inhibitory Signals and the Evasion of Cell Death

In addition to the role of PKM2 in stimulating progrowth signaling in cancer cells, emerging evidences support the immense significance of PKM2 in stimulating antiapoptotic factors and in repressing proapoptotic factors (i.e., regulating apoptosis). The studies that have corroborated with this line of thought are: silencing of PKM2 expression in multiple cancer cells by introducing small interference RNA, resulting in the proliferation inhibition and apoptosis. Likewise, knockdown of PKM2 in non-small cell lung carcinoma (NSCLC), both in vitro and in vivo has demonstrated an increased sensitivity for radiation therapy; and also resulted in apoptosis. The molecular mechanism to elucidate the significance of PKM2 in apoptosis regulation continued with some uncertainty until recently, where emerging studies proposed multiple molecular mechanisms through which PKM2 could regulate programmed cell death. The expression of PKM2 in gastric cancer (GC) cells was shown to enhance the protein stability of NFκB (p65) transcription factor and in doing so, PKM2 promoted the transcription of NFκB target gene Bcl-xL (an antiapoptotic protein). PKM2 silencing in GC cells was shown to disrupt the stability of NFκB and thus decreasing the expression of Bcl-xL, resulting in apoptotic cell death. Thus, the axis of PKM2/NFκB/Bcl-xL was proposed as a potential survival signaling in gastric cancer cells. This correlation between the expression of PKM2 and Bcl-xL was also recognized in hepatocellular carcinoma. On the contrary, the high level of PKM2 expression in HCC tissue samples was inversely correlated with the expression of a proapoptotic factor, Bcl-2-like protein 11 (BIM). PKM2 knockdown in HCC cell line stabilized BIM expression and the latter stimulated apoptotic cell death, which could be prevented by prior silencing of BIM. In this article, it was proposed that the negative correlation with the expression of BIM and PKM2 could be exploited for its therapeutic benefits. More recently, PKM2 was shown to localize in the mitochondria in response to the oxidative stress (induced by treating the cells with H_2O_2) to stabilize the antiapoptotic factor Bcl2. Mitochondria localized PKM2 phosphorylated Bcl2 at T69 residue to prevent its interaction with Cul3-based E3 ubiquitin ligase and its subsequent proteasomal degradation, suggesting that PKM2 prevented oxidative stress-induced apoptosis in glioblastoma cells. PKM2 mediated T69 phosphorylation and stabilization of Bcl2 protein have been suggested to provide endurance in tumor cells against oxidative stress and promote gliomagenesis. The study sheds light on the mechanistic link between PKM2 regulation and apoptosis, resulting in the tolerance in cancer cells against oxidative stress (**Fig. 3**). A novel transcription corepressor role of PKM2 has also been shown to provide the cancer cells with tolerance against DNA damaging agents. PKM2 selectively interacts- and represses-p53 to activate the transcript of cell-cycle inhibitors (p21 and p27) in cancer cells that are treated with DNA damaging agents, providing a unique molecular mechanism in cancer cells to acquire resistance against DNA damaging agents involving PKM2 (**Fig. 3**).

Limitless Replicative Competency

The primary objective of the dividing cell is to inherit genetic material equally in the daughter cells with high fidelity. In addition to the availability of enough nutrient supply and exogenous growth factor signals to support cell division, a proliferating cell should gain license to advance further through multiple cell-cycle checkpoints. Cancer cells surpass these well-orchestrated cell-cycle

checkpoints with the help of aberrant oncogenic signal pathways. A few emerging studies have emphasized the crucial role of PKM2 in cell division. Apart from controlling the G1-S transition by regulating the expression of cyclin D1, PKM2 also regulates mitosis. In particular, the protein kinase activity of PKM2 is considered instrumental to achieve transition across mitotic checkpoints, such as chromosomal segregation and cytokinesis, eventually to establish cancerous state with unlimited replicative competency. For instance, PKM2 physically interacts- and phosphorylates-Bub3 (a spindle checkpoint protein) at Y207 residue. Phosphorylated Bub3 interacts with Bub1 and resultant Bub3-1 complex is recruited to kinetochores, where it interacts with Blinkin to enable a proper kinetochore-microtubule attachment and to advance through spindle-assembly checkpoint for proper chromosome segregation and eventually cell division of cancer cells (brain tumorogenesis) (Fig. 3). Subsequent to this observation, an independent investigation carried out by the same group has revealed the significance of PKM2 in cytokinesis. Where, PKM2 phosphorylated at T45 residue by Aurora B kinase has been shown to localize near the contractile ring of dividing cells to interact and phosphorylate myosin light chain 2 (MLC2) at Y118 residue. The phosphorylated Y118 residue of MLC2 (mediated by PKM2) serves as a priming site for ROCK2 protein kinase binding, which in addition to PKM2, phosphorylates MLC2 at S15 residue to commence cytokinesis (Fig. 3). Together, this study highlights the pivotal role of PKM2-guided MLC2 phosphorylation in cytokinesis, cell proliferation and brain tumor development. Moreover, the above role of PKM2 could also be enhanced by EGF stimulation or ectopic expression of EGFRvIII, K-Ras G12 V and B-Raf V600E mutants.

PKM2 and Tumor Angiogenesis

PKM2 contributes to tumor angiogenesis by regulating the expression of proangiogenesis factor, vascular endothelial growth factor (VEGF); and by promoting endothelial cell division. PKM2 through its nonglycolytic function of cotranscriptional activation regulates the expression of VEGF. For instance, studies carried out using endothelial cells infected with Kaposi's sarcoma-associated herpesvirus to examine pathological angiogenesis have revealed the mechanistic link involving PKM2 dependent transcriptional coactivation of HIF-1α to express proangiogenic factor, VEGF. Similarly, human cytomegalovirus-encoded US28-chemokine binding receptor has been shown to promote angiogenesis in glioblastoma cells, by stimulating the HIF1-PKM2 axis to express VEGF. Moreover, in solid tumors under hypoxic condition, enzyme prolyl hydroxylase 3 (PHD3) hydroxylates PKM2 at proline (P)-403 and -408 residues, which is essential for PKM2 to localize inside nucleus to interact with HIF1 transcription factor and eventually to express HIF1 target genes. This includes most of the glycolytic pathway enzymes, including PKM2, through a positive feedback loop that reprograms the glycolytic metabolism to resist hypoxic condition. However, the role of PKM2 in facilitating the transcriptional activation of HIF1 to express proangiogenic factor, VEGF, under hypoxic condition is still elusive. In addition to HIF-1α, PKM2 can act as a transcriptional co-activator of NFκB and governs the expression of VEGF. A recent investigation using pancreatic adenocarcinoma cells have revealed that PKM2 activates both NFκB/p65 and HIF-1α to enhance the transcription of VEGF-A, the latter triggers tumor angiogenesis and alleviates tumor from recurrent hypoxic stress. Immuno-histological studies using sporadic breast tumor specimens with their matched adjacent tissue controls has revealed an overexpression of PKM2 and VEGF-C in breast cancer, associated with poor prognosis (Fig. 3).

It has long been known that patients with gastrointestinal-, colorectal-, pancreatic-, lung- and ovarian-cancer were shown to release dimeric PKM2 in plasma and stool. This was exploited as a diagnostic and prognostic marker to identify early-stage cancer development, and in the follow-up studies, respectively, to examine the treatment response of antineoplastic drugs. However, the mechanism through which cancer cells secrete (or release) PKM2 in blood circulation and the potential benefits that cancer cells harness by releasing PKM2 in circulation remains ambiguous. Investigations of the objectives have shed light on this long-standing puzzle and revealed the direct involvement of dimeric PKM2 (i.e., released by the cancer cells in blood circulation) in tumor angiogenesis. This study revealed the vital role played by the circulating dimeric PKM2 in triggering angiogenic endothelial cell proliferation, migration and extracellular matrix (ECM) adhesion. In addition, PKM2 isotype expressed preferentially in ontogeny, poses a provocative objective of examining the involvement of PKM2 in governing angiogenesis during fetal organ development and maturation.

PKM2 in Cancer Cell Invasion, Migration and Metastasis

For a cancer cell to invade and metastasize to distant organs, it requires to undergo morphological changes, such as cell–cell junction dissolution, loss of cell polarity (apical and basolateral) and expression of mesenchymal markers, a phenomenon collectively termed as epithelial–mesenchymal transition (EMT). Growing body of evidence has revealed an association between deregulated PKM2 expression and EMT in cancer cells. Evidence from a recent study have suggested a novel role for PKM2 in colorectal cancer (CRC) migration, where the study used both in vitro cell culture system and immuno-histological study to validate the association between the deregulated expression of PKM2 and the advanced stage lymph metastasis of tumors cells. However, the study failed to characterize the molecular mechanism. Following this preliminary observation, several studies have attempted to examine the molecular mechanism through which PKM2 regulates the tumor cell- EMT and metastasis. Recently, Hamabe et al. revealed that CRC cells that are cultured with EMT stimulating factors, facilitated PKM2 to localize inside the nucleus to interact with TGF-beta induced factor homeobox 2 (TGIF2) and repress the expression of the TGIF2 target gene CDH1 (E-cadherin).

PKM2 impedes the TGIF2 dependent transactivation of E-cadherin by recruiting HDAC (histone deacetylase) to CDH1 gene and deacetylate its promoter, eventually repressing epithelial phenotype, and facilitating the expression of the mesenchymal trait. In a similar kind of study, EMT stimulation in colorectal cancer cells was shown to enhance the nuclear translocation of dimeric

PKM2 to activate STAT3 transcription activation. Activated STAT3 is known to enhance the transcription of snail-2, matrix metallopeptidase-2 (MMP-2), matrix metallopeptidase-9 (MMP-9) and also induce the β1-integrin/FAK signaling. Furthermore, snail-2 activation has been shown to modulate the expression of N-cadherin and repress E-cadherin to demonstrate epithelial to mesenchymal transition (Fig. 3). The molecular mechanism involving PKM2, thus, has been shown to regulate EMT in hepatocellular carcinoma cells (HCC). EGF stimulated HCC in an ERK1/2 dependent manner influences PKM2 to localize inside the nucleus and transactivate β-catenin-TCF/LEF-1 transcription complex to code for EMT markers to exhibit mesenchymal phenotype. In breast cancer cells that are stimulated with leptin (an adipokine), it has been shown to activate PI3K/AKT pathway to stimulate EMT in a PKM2 dependent manner. Either abolishment of PI3K/AKT activation using LY294002 or silencing of PKM2 expression attenuated the leptin-induced expression of EMT markers in breast cancer cells, inhibiting the invasion and migration of cancer. An aberrant high level of PKM2 expression was reported in cases of hilar cholangiocarcinoma (HC). Notably, the expression of PKM2 was shown to directly correlate with the expression of syndecan 2 (SDC2), the latter involved in the neuronal invasion. Silencing of PKM2 expression in HC downregulated SDC2 expression and attenuated the neural invasion of HC in vitro and in vivo.

PK Isoforms in Noncancer Human Pathologies and in Cell Physiology

Pyruvate Kinase Deficiency (PKD)

Inherent reasons, such as aberrant mutations in *PKLR* gene that affect the expression of PKR isoform and its biochemical function are referred to as pyruvate kinase deficiency (PKD). PKD is inherited as an autosomal recessive trait and until recent 195 distinct mutations have been identified in *PKLR* gene. Such aberrant mutation in PKR gene directly affect the glycolytic metabolism of RBCs and alter these in unhealthy cells that fail to meet the demand for the oxygen supply of body tissues, causing a severe pathological condition, chronic nonspherocytic hemolytic anemia. The unhealthy RBCs with hemolytic anemia differ from the normal cells with respect to their lifespan, which is lesser than 120 days. The severity of disease differs from case to case, where PKD results in a mild chronic neonatal anemia that may turn worse in childhood and in rare cases results in neonatal death. Until now, the practice of bone-marrow transplantation is one of the prominent ways to cure PKD, but with huge limitations. Moreover, advancement in the practices of gene therapy is providing new hopes and in future may cure PKD.

PKM2 and Nonmalignant Pathologies

Evidences accumulated in the past decade have substantiated the indispensable role of PKM2 in the pathophysiology of cancer, keeping in view the glycolytic and nonglycolytic attributes of PKM2. In addition to cancer, the aberrant PKM2-expression, -enzyme activity and consequential metabolic rewiring (i.e., aerobic glycolysis) is now well-recognized to be associated with numerous human pathologies, such as myotonic dystrophy, coronary artery disease (CAD), Bloom syndrome (cases with natural mutations in PKM2), severe aplastic anemia (SAA), preclampsia (PE), Crohn's disease and rheumatoid arthritis.

Nonmetabolic Role of PKM2 in Cell Physiology

Besides, what is now known about PKM2 expressing in adult progenitor and differentiated cells, only a few studies in the recent past have revealed the multifunctional role of PKM2 in governing physiology at cellular and whole-body level, such as regulation of inflammatory response against invading pathogens and in the processes of wound healing. Macrophages that were stimulated with LPS or *S. typhimurium* both in vitro and in vivo, promoted the accumulation of the dimeric form of PKM2 and its nuclear localization to form complex with HIF1α. PKM2-HIF1α complex enhanced the transcription of a proinflammatory cytokine IL-1β (a HIF1 target gene). Notably, either knockdown of PKM2 expression or stimulation of PKM2 tetramerization in LPS-induced macrophages abrogated PKM2 and HIF1 interaction; as well as IL-1β expression and secretion. The study proposed a unique and novel nonglycolytic physiological role for PKM2 in inflammatory responses. In addition, a recent study has revealed, that in activated macrophages, PKM2 complex with HIF1α and regulated the expression of HIF target gene, high mobility group box-1 (HMGB1; a secretory proinflammatory cytokine). Likewise, PKM2 in LPS-induced colorectal cancer cells stimulated Stat3 transactivation to express its target genes, IL-1β and TNF- α. A recent study has demonstrated the role of PKM2 in the early inflammatory response and wound healing, where activated neutrophils infiltrate the site of injury and secrete PKM2, the latter promoting angiogenesis at the wound site; and as a consequence, healing the wound. Parkin, an E3 ubiquitin ligase (an autosomal recessive mutation in Parkinson disease) has been shown to monoubiquitinate PKM2 and PKM1 at lysine (K) -186 and 206 residues and reduce its enzyme activity, however without altering protein stability, depicting the apparent role of Parkin in energy metabolism and offering a novel understanding of Parkinson's disease with possible novel therapeutic strategies.

Potential of PKM2 in Onco-Therapy

Considering the quantum of metabolic and nonmetabolic functions of PKM2 that support the cancer cell growth, proliferation, and spreading, PKM2 has emerged as a potential target with immense anticancer therapeutic opportunities. Several studies have proposed a variety of therapeutic strategies to target PKM2 expression and thus curtail cancer cell progression. This includes

RNA interference, natural compounds (phytochemicals), small molecule inhibitors and -activators. In brief, knockdown of PKM2, using small interfering RNA (siRNA), has been shown to significantly affect the growth and proliferation of tumor cells, both in vitro and in vivo, the latter corroborated with the observation of increased caspase-dependent apoptosis. It is also reported that the cancer cells silenced for PKM2 are highly sensitive to radiation therapy as well as for anticancer drugs that are potential DNA damaging agents, suggesting the synergetic effect of PKM2 siRNA with other approaches of oncotherapy to formulate a tailored therapeutic strategy with more efficacy. Further, natural compounds that are derived from the phytochemicals, such as shikonin, resveratrol and gemcitabine have also been shown to inhibit tumor growth by perturbing the expression of PKM2. High throughput chemical screen has revealed several novel small molecule inhibitors of PKM2. Compounds, such as Arava and *N*-(3-carboxy-4-hydroxy) phenyl 1-2, 5,-dimethylpyrole were shown to specifically bind PKM2 and inhibit its enzyme activity. In addition to these drugs or therapeutic strategies, recently cell permeable structural analogs of the allosteric activator FBP, such as TEPP-46 (ML265; thieno-[3,2-*b*]pyrrole[3,2-*d*]pyridazinone) and DASA-58 (ML203; substituted *N*,*N*′-diarylsulfonamide) have been shown to promote PKM2-tetramerization and -enzyme activity. Lung cancer cells treated with TEPP-46 and DASA enhanced PKM2 enzyme activity and eventually inhibited lung cancer cell progression in in vitro conditions and in xenograft mouse models. The plausible molecular mechanism through which compounds that stimulated the tetramerization of PKM2 and inhibited cancer cell proliferation is by limiting the biosynthesis of macromolecules, which was actually supported by dimeric form of PKM2. Collectively, results from a multitude of studies have emphasized that PKM2 could be a potential target to design anticancer therapy with improved efficacy. However, one of our recent publication has shed light on the molecular mechanism involving cell survival signaling pathways that could develop resistance and may diminish the efficacy of therapeutic strategy, involving inhibition or silencing of PKM2, proposing a potential therapeutic strategy that may improve the efficacy of PKM2 silencing to curtail tumor propagation. The multifaceted nonglycolytic role of PKM2 in cancer and in a few physiological processes is due to its PTMs, however, more studies are required to identify that the PTMs of PKM2 that are unique to cancer cells and not shared by the other adult differentiated cells, may open up new therapeutic opportunities with fewer side effects.

Concluding Remarks

PKM2 is evolutionarily conserved prototypic glycolytic enzyme. Its expression, the quaternary structure and a physiological role are controlled by a variety of extrinsic and intrinsic cellular signals. Considering the key position that PKM2 occupies in the glycolytic pathway, it senses a variety of signals and integrates these with the metabolic status to modulate the glucose metabolism to meet the bioenergetic and biosynthetic expenses of cells that either grow, proliferate, differentiate, rest or resist the stresses from the microenvironment (i.e., hypoxia and hypoglycemia). For instance, differentiated cells that are under quiescent state retain an enzymatically active tetrameric form of PKM2, which primarily supports energy synthesis with limited biosynthesis of macromolecules. On the contrary, embryonic cells or malignant cancer cells that often divide, necessitate a hefty demand for macromolecules with balanced energy supply, thus preferring to overexpress PKM2 and simultaneously alter it into enzymatically inactive dimeric form.

A variety of growth factors and survival signals regulate PKM2 expression and function (i.e., glycolytic and nonglycolytic attributes) to achieve vital physiological functions and to preserve cellular and whole-body level homeostasis. Aberration in these signaling pathways (e.g., oncogenes that constitutively stimulate signaling) result in deregulated PKM2-expression and -enzyme activity, leading to malignancy and numerous pathologies, such as myotonic dystrophy, coronary artery disease, inflammatory bowel disease and neuronal disorders. Thus, the therapeutic strategies that would target PKM2 to curtail tumor growth, may hold a promise to treat other pathologies as well. However, more studies are desired to understand the respective roles of the two isoforms of pyruvate kinase (PKM1 and PKM2) under aberrant and normal cellular genetic backgrounds.

Glossary

Image-guided radiotherapy (IGRT) General term describing the process of integrating various imaging modalities into the treatment workflow of radiotherapy to improve precision and accuracy of radiotherapy. IGRT is used to support and verify patient positioning and alignment, to compensate for motion of the patient or target (mainly used for respiratory motion) and to monitor anatomical changes during the course of radiotherapy that potentially influence the treatment application and therapy outcome.

Intensity-modulated radiotherapy (IMRT) Advanced technique of external beam radiotherapy applying irradiation fields with specifically inhomogeneous dose distributions mostly using high energy photons.

Linear energy transfer (LET) Term used in dosimetry describing the energy transfer of ionizing radiation to the tissue traversed per unit distance. A distinction can be made between sparsely ionizing radiation such as photons, electrons and protons exhibiting a low LET, and densely ionizing radiation such as alpha particles and ions exhibiting a high LET.

Oxygen enhancement factor (OER) Term used in radiobiology describing the ratio of absorbed dose between hypoxic and oxic conditions within a specific biological system resulting in the same defined effect or experimental endpoint.

Particle therapy Type of external beam radiotherapy using high energy particle beams such as protons or ions (e.g., C-12, O-15) generated by dedicated medical circular accelerators.

Photon therapy Type of external beam radiotherapy using high energy photon beams generated by medical linear accelerators.

Relative biological effectiveness (RBE) Term used in radiobiology describing the ratio of absorbed dose between different fields of ionizing radiation (i.e., type, energy) resulting in the same defined effect or experimental endpoint within a specific biological system. Thereby, an investigated radiation field is typically compared to a reference radiation field, which is traditionally 200 kV X-rays or Co-60 and today often megavoltage photons from medical linear accelerator.

Introduction

Radiotherapy together with surgery, chemotherapy, and emerging, immunotherapy is one of the four main treatment modalities for cancer patients. The value of radiotherapy for cancer treatment was established more than 100 years ago and up today the role of this therapeutic option is continuously gaining importance. At present, more than 50% of all cancer patients receive radiotherapy during their course of disease. Rapid advances in the field of radiation oncology with respect to biology (e.g., tumor environment, normal tissue reactions, and radiation effects) and treatment technology lead to a more personalized cancer treatment. For this purpose, individual biological and tumor-specific factors are considered for the therapy decision besides anatomical and clinical information.

The main aim of radiotherapy is to achieve local or locoregional control of tumor disease without major damage to the surrounding normal tissue. Radiotherapy can also decrease distant metastases by preventing metastatic spread from locally uncontrolled tumors. Radiotherapy is often applied in combination with systemic treatments. Today, mostly classical chemotherapeutics like Cisplatin are used, but in recent years the combination with small molecules and immunotherapy has gained increasing importance. For many tumor entities, radiotherapy is also combined in a pre- or postoperative setting with surgery. Radiotherapy can be applied with curative intention but also plays an important role in palliative care of patients with very locally advanced tumors or distant metastases. In this situation, radiotherapy can efficiently reduce pain, for example by bone metastasis, prevent paraplegia caused by metastases to the vertebral column and dissolve life-threatening symptoms of vena-cava-superior syndrome. For this palliative intention, reduction of symptoms and preservation of quality of life are primary therapy goals, which usually can be achieved rapidly and with relatively low doses. A special situation is so called oligometastasis, in which radiotherapy can be applied with curative intention to a limited number of distant metastases.

Radiobiology

Radiobiology describes the biological effects of irradiation on molecules, cells, tissues, organs, and organisms. The interactions of ionizing radiation with tissues are in clinical practice broadly divided into effects on tumors and early- or late-responding normal tissues.

The main interactions of radiation with target molecules are ionization and excitation. The intensity of these processes and the resulting biological effect are beam-quality-dependent. To characterize a beam and its effects, two parameters are used namely the linear energy transfer (LET) and the relative biological effectiveness (RBE). The LET describes the energy transfer of ionizing radiation to the tissue dE traversed per unit distance dx, which represents the ionization density along the beam (Eq. 1). A distinction is made between sparsely (low LET, e.g., photons, electrons, protons) and densely (high LET, e.g., ions) ionizing radiation. The spatial density of damage caused by high-LET radiation is high, meaning that damage to target molecules is clustered and often difficult or even impossible to repair. Therefore, LET correlates with the biological effect (high LET leads to a large effect) and is dependent from the radiation energy.

$$LET = {dE}/{dx} \tag{1}$$

Beside of the physical characteristics, the biological effect of ionizing radiation is dependent on many other factors, for example the irradiated tissue, the evaluated effect and dose fractionation scheme. The relative biological effectiveness (RBE) describes the biological effect of a specific beam and dose on a specific biological system using a specific endpoint (Eq. 2). A RBE above 1 means, the biological effect of the investigated beam is greater than the reference beam (traditionally usually 200 kV X-rays or Co-60, today often megavoltage photons), and vice versa for a value lower than 1.

$$RBE = \frac{\text{Dose reference beam}}{\text{Dose investigated beam}} | \text{isoeffect} \tag{2}$$

When radiation travels through matter, secondary electrons are produced through interactions. These secondary electrons deposit the energy to the matter and thereby are the mediator of biological radiation effects. Interactions between secondary electrons and target molecules can be direct or indirect. Direct interaction leads to ionization or excitation and as a consequence to damage of the target molecule. Indirect effects of radiation generate radicals, which then interact with target molecules thereby causing damage. Most important in this context is radiolysis of water, which constitutes the largest component of molecules within cells, leading to hydrogen and hydroxyl radicals as well as hydrogen and hydrogen peroxide. These radicals are highly reactive, interact with the target molecules and damage them. Whether a beam leads to indirect, direct or both interactions, is dependent on the radiation quality and energy, and correlates with LET. With increasing LET, the impact of direct interactions increases and of indirect interaction decreases.

The most important radiation target determining the fate of irradiated cells is the deoxyribonucleic acid (DNA), which contains the genetic information of the individual cell. Important radiation-induced types of DNA damages include single- and double-strand breaks, as well as clusters of these damages. Only a small proportion of the DNA damage leads to cell death, because cells during evolution have developed very efficient DNA repair mechanisms. Important examples include base excision repair, homologous recombination, and nonhomologous end joining. Only incorrectly repaired or unrepaired DNA damage, most prominently unrepaired DNA double-strand breaks, lead to cell death. Radiation-induced cell death can occur by several mechanisms including apoptosis, senescence and, most importantly and quite distinct from other anticancer agents, mitotic catastrophe.

Beside of DNA repair capacity, additional factors, most importantly reassortment, reoxygenation, intrinsic radiosensitivity and repopulation, have an influence on cell survival and tissue damage after irradiation. These factors are usually referred to as the five R's of fractionated radiotherapy.

Cycling cells run through the cell cycle, from which mitosis is the most sensitive and the late S phase the most radioresistant. After irradiation of a cell population, the most sensitive cells are killed while the more resistant cells have a higher chance to survive. In addition, cells build dose-dependently a G2 phase arrest allowing improved DNA repair of radiation damage before entering mitosis. All these mechanisms lead to a partial and temporary phase synchronization of surviving cells after irradiation, with selection of more resistant cells. With increasing time after irradiation, the cells distribute again over the cell cycle, which is called reassortment or redistribution. This phenomenon is associated with increasing radiosensitivity of cell populations. Cells can also temporarily leave the cell cycle and enter the dormant G0 phase. Particularly stem cells are preferentially dormant, which allows better protecting their DNA from damage. Dormant stem cells in tumors may therefore be the cause of radioresistance. Recruitment of stem cells into the cell cycle may occur as a consequence of sensing depletion of more differentiated cells during radiotherapy, which would be expected to be associated with an increasing radiosensitivity on a cellular level. However, at the same time the radiosensitivity of cells with stem cell characteristic may increase. The effect of high-LET radiation is less dependent on the cell differences and different radiosensitivity of the cell cycle phases. This is maybe one of the reasons why high-LET radiation is on average more efficient in very slowly proliferating tumors.

Cellular radiation sensitivity importantly depends on the oxygen concentration during irradiation. Comparing the dose leading to the same cell surviving fraction under anoxic and oxic conditions (photon irradiation), an oxygen enhancement ratio (OER) of about 2–3 has been derived in many cell lines and tissues:

$$OER = \frac{\text{Dose hypoxic conditions}}{\text{Dose oxic conditions}} | \text{isoeffect} \tag{3}$$

Oxygen plays an important role for the fixation of the DNA damage caused by free radicals. The indirect interaction of radiation in tissue builds unstable radicals, which interact with the DNA. In the presence of oxygen, changes in the DNA are stabilized and thereby the damage is fixed. In contrast, radiation with high LET produces more direct damage resulting in a lower OER. Thus, high-LET radiation is expected to be particularly effective in hypoxic tumors. After irradiation with low-LET radiation, preferentially

radioresistant hypoxic cells survive in tumors. Over time following irradiation, these cells may reoxygenate, for example (1) by reperfusion of vessels, which were not perfused at the time of treatment, (2) by shrinkage of the tumor, which may lead to a higher ratio of vessels over tumor cells, (3) by renormalization of the vasculature or (4) by decreased oxygen consumption of surrounding tumor cells with radiation damage.

Intrinsic radiosensitivity describes the genetically determined sensitivity of cells to radiation. Intrinsic radiosensitivity may differ significantly between different cell lines. On average radioresistant tumor entities and normal tissues are also characterized by low cellular radiosensitivity.

Repopulation refers to an increase in the number of stem cells in tumors or normal tissues during the course of radiation. Repopulation can be caused either by proliferation during treatment or by decreased cell loss. In any case, repopulation leads to increasing radioresistance with increasing overall time of treatment. This has also been coined as time factor of fractionated radiotherapy. For example, it is well recognized from preclinical experiments and clinical studies that, because of repopulation, many tumors, most prominently squamous cell carcinomas, have a lesser chance to be controlled after long compared to short treatments when applying comparable doses. This accounts on average for 0.5–1.0 Gy for each day of treatment prolongation, which is highly relevant for clinical practice.

In clinical practice, effects on tumors have to be differentiated from effects on so called early- and late-responding normal tissues. The tumors are not simply a bag of homogenous tumor cells, but a complex tissue of many different cell populations interacting with each other. Description of these interactions is beyond this article. However, for radiobiological considerations it is important to differentiate between stroma, containing a large number of nonmalignant cell populations, on the one side and tumor cells on the other side. Tumor cells again can be divided into cancer stem cells (CSCs), which usually constitute a minority of the tumor cells, and noncancer stem cells, which usually constitute the majority of the tumor burden. CSCs and non-CSCs are not exclusive to each other, as CSCs can lose their stemness while non-CSCs can gain stemness in the course of disease or during treatment. However, only CSCs can cause recurrence of the primary tumor after radiotherapy or metastases. If not eliminated by the host using other mechanisms including immune responses, a single surviving CSC can lead to a recurrence. Therefore, the aim of the curative radiotherapy is to kill all CSCs. The probability of local tumor control increases with increasing dose according to an S-shaped curve, with a steep dose response relationship after a threshold dose. In principle, all tumors could be eradicated by radiotherapy if high enough doses can be applied. However, this is limited by the tolerance of the tumor surrounding normal tissues. Thus, the clinical challenge is to prescribe and deliver the dose leading to the optimum of uncomplicated local control, resulting in a high chance for local tumor control at an acceptable risk of serious normal tissue damage (**Fig. 1**). This concept was first described by Holthusen in 1936.

Side effects of radiation are classified into stochastic and deterministic according their dose-effect relationship. The probability of stochastic radiation damage, for example mutations and secondary cancer induction, increases with dose without a threshold value. In contrast, deterministic radiation damage occurs only above a threshold dose, the likelihood and severity are dose-dependent. Deterministic radiation damage is further subdivided by the time point of occurrence, with regard to treatment, into early and late side effects. Early (acute) side effects occur during radiotherapy up to 90 days after start of treatment and usually recover. The duration and severity of early side effects are dose-dependent. Mucositis and dermatitis are typical examples. These tissues are hierarchically structured and have a high turnover. Irradiation leads to death of stem and precursor cells with subsequent reduced cell replacement, which leads to tissue depletion. The mechanism of repopulation allows the tissue to recover. In contrast,

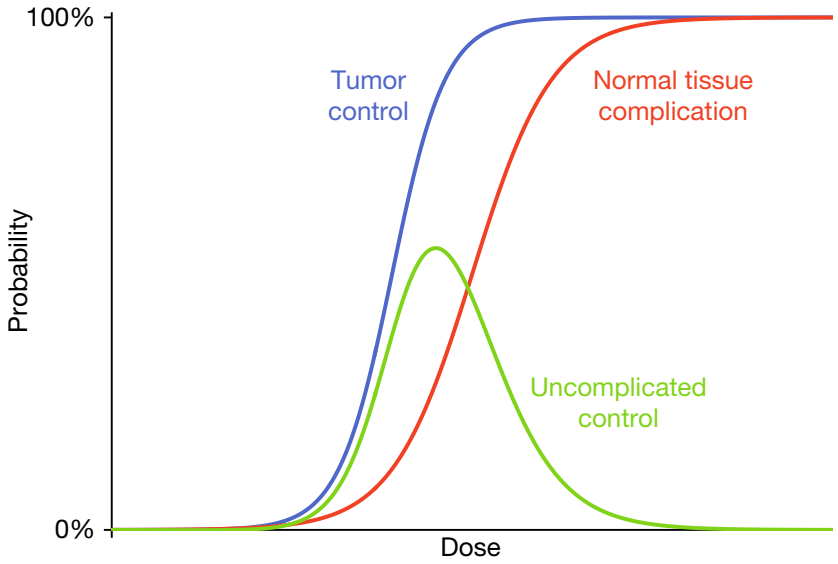

Fig. 1 Dose response relationship for tumor control and normal tissue complications. The closer the dose response curves for tumor and normal tissues are located to each other, the smaller is the therapeutic window for uncomplicated local control and vice versa.

late effects do generally not recover, latency is inversely dose-dependent and effects can occur from day 90 after start of treatment up to months or even many years. Fibrosis of the lung, bladder, subcutaneous tissues or neurons of the central nervous system are typical examples. The radiobiological mechanism is more complex than for early side effects and depends on the interplay of different cell types and tissues, including the immune system. Subclinical damage induced by irradiation may lead to late damage over time, which is often progressive. Early and late side effects usually occur independent of each other, with the exception of consequential late effects. These occur as a result of a particularly severe acute reaction with underlying radiobiological mechanisms combining early and late reactions. Early side effects increase with total dose and shortened overall treatment times. Late effects are mainly dependent on total dose, high dose per fraction and short intervals between fractions.

Radiotherapy is usually applied over several weeks with daily fractions of 1.8–2 Gy. This so called conventionally fractionated schedule has been developed empirically over decades and exploits the radiobiological mechanism underlined by the R's of fractionated radiotherapy. Several modified fractionation schedules have been developed on a radiobiological basis. Accelerated radiotherapy means shortening the overall treatment time by increasing the weekly dose above 10 Gy. It has been shown that shortening the overall treatment time counteracts the repopulation of CSCs during radiotherapy and increases local tumor control, but also increases early side effects. In contrast, a prolongation of the planned treatment time results in worsening tumor control and should therefore be avoided or compensated using radiobiological isoeffect calculations. Another concept is hyperfractionated radiotherapy, for which the total dose is divided into a larger number of fractions with smaller dose per fraction (< 1.8 Gy) maintaining the overall treatment time. Because of the dependence of late normal tissue damage on dose per fraction, hyperfractionation can be used to decrease late normal tissue toxicity or, at an isotoxic level, to increase the dose to the tumor. In clinical practice, hyperfractionation is typically used in combination with slight acceleration, which potentially allows a reduction of late side effects and improved local tumor control. Treatments with doses higher than 2 Gy per fraction are called hypofractionated radiotherapy. Doses up to approximately 3 Gy per fraction are often called moderate hypofractionation. Hypofractionation is frequently applied for palliative treatments. In this case, limited total doses are given, for example 10×3 Gy, 5×4 Gy or 1×8 Gy. In recent years, the application of moderate hypofractionated radiotherapy with only slightly reduced total dose has gained in importance also for curative treatments, for example for breast and prostate cancer. Usually tumor treatments are also moderately accelerated. Compared to conventional fractionated radiotherapy moderately hypofractionated and accelerated radiotherapy to lower total dose may achieve a comparable rate of tumor control and late normal tissue damage. As less fractions need to be given, the treatments may be more convenient for patients and may allow treatment of more patients at a given number of machines. The fact that, despite higher doses per fraction, late normal tissue damage was not increased in a number of clinical trials testing this approach can be explained by reduced total doses and high precision treatments of small volumes with modern technologies. This is also the reason for successful application of very high doses per fraction using stereotactic radiotherapy approaches, which allow precisely treating small target volumes with a very steep dose gradient. For example, stereotactic radiotherapy is applied with so called ablative doses (e.g., 3×18 Gy) to small lung tumors or metastases in bone, lung, liver and brain. Hypofractionation appears also to be a promising option for curative treatments with particle therapy and should be tested in clinical trials.

The linear-quadratic (LQ) model describes the biological effect of irradiation to tumor and normal tissues and allows the comparison of different fractionation protocols. The LQ model is based on the observation that a typical cell survival curve after irradiation, when plotted in the usual semilogarithmic way, can be described by a linear component proportional to dose and a quadratic component proportional to dose squared. The constants α and β characterize the slopes of these components and vary between different tumors and normal tissues. The α/β ratio can be used to evaluate normal tissue reactions and convert between fractionation protocols. Thereby, a high α/β ratio goes along with a low fractionation sensitivity, which is typical for most tumors and early-responding normal tissues. Inversely, a low α/β ratio indicates high fractionation sensitivity and is typical for late-responding normal tissues but also for some tumors (e.g., breast cancer, prostate cancer melanoma, chondrosarcoma).

Beside the reported radiotherapy parameters (e.g., dose per fraction, total dose) the irradiated volume of normal tissues has significant influence on damage and associated function loss. For example, a large part of the liver can be damaged by irradiation without severe function deficits of the whole organ if a sufficient proportion of liver can be spared. In contrast, radiation damage of just a small volume of the spinal cord may lead to paralysis. These different volume effects depend on the respective organ architecture. The organs at risk (OAR) can be classified broadly according to their functional tissue organization as serial and parallel. Serially organized organs consist of a continuous chain of functional units (FUs) and damage to only one unit causes complete organ failure, which applies, for example, for the spinal cord and esophagus. In contrast, parallelly organized organs consist of individual-acting functional units and damage is compensated to a certain extend. Typical examples are the lung and liver, where organ function is maintained until an organ-specific threshold of damaged FUs is exceeded. The volume effects in different tissues are taken into account during the radiotherapy treatment planning by dose-volume constraints for the individual OARs. However, the recommended constraints are empirical data without considering additional influencing factors for organ damage requiring individual evaluation for every patient (e.g., simultaneous or previous systemic therapy). For parallelly organized organs, function preservation is essentially determined by the remaining FUs. Is the function already impaired before radiotherapy, for example due to exogenous noxae, illness or age, the remaining FUs and therewith the dose-volume tolerance are different compared to healthy individuals. Therefore, additional diagnostics like lung or kidney function tests are crucial before radiotherapy.

Tumor response and normal tissue complications vary greatly between patients with, according to clinical and histopathological parameters, apparently similar disease. With clinical and pathological parameters it is not possible to define, for example, the number of CSCs or their radiosensitivity, which importantly influences the treatment result. Therefore their predictive power for treatment outcome is limited. Genetic variations and a host of other radiobiologically important factors influence the reaction

of tumors and normal tissues to radiotherapy. It is therefore necessary to develop clinically suitable radiotherapy specific biomarkers to predict treatment response regarding tumor and normal tissues. Such biomarkers can be assessed using medical imaging, tissue samples or liquid biopsies. A predictive biomarker is usually evaluated before treatment and indicates a different outcome for a specific treatment in biomarker-positive versus-negative patients. An example is the methylation status of O^6-methylguanine-DNA methyltransferase (MGMT) in glioblastoma. Patients with MGMT-methylated tumors exhibit a better response to radiochemotherapy with Temozolomide compared to MGMT-unmethylated tumors. A prognostic biomarker can be evaluated before or during treatment and indicates the likely course of the disease without providing information on advantages or disadvantages of specific treatments. In clinical practice, it is sometimes difficult to distinguish between predictive and prognostic biomarkers. Additionally, the treatment itself may have an influence on the prognostic or predictive power, such that the value of a given biomarker has always to be referred to a specific clinical situation. The predictive and prognostic value of biomarkers may also change during treatment necessitating repeated evaluation of the biomarker's dynamic. A typical example for a prognostic marker is the human papillomavirus (HPV) status of oropharyngeal carcinoma, of which HPV-positive tumors are more radiosensitive compared to HPV-negative ones. Note that, if future interventional studies should show that HPV-positive tumors can be treated equally effective with reduced doses or without chemotherapy, HPV status would change from a prognostic to a predictive biomarker. Radiomics, that is, the evaluation of profiles derived from quantitative texture analysis of imaging data, is an emerging approach to generate spatially resolved biomarkers switches for radiotherapy treatment planning and monitoring. A great advantage of this approach lies in the fact, that imaging data are available for all radiotherapy patients from treatment planning and increasingly from monitoring tests during treatment. So far, radiomics in mostly retrospective clinical studies has shown similar potential for prognostic stratification as tissue-based markers.

Further investigations and identifications of biomarkers are needed to classify patients and their disease not only according to anatomical and histological information but also to biomarker status to decide for the optimal therapy and avoid under- or over-treatment. The biomarkers for tumor and patient characteristics as well as the radiomics approach support the development toward a personalized radiotherapy.

Hardware and Technique

Due to the enormous development in radiotherapy, a variety of modern equipment and techniques are currently available for treatment. Application in patients requires modern information technology consisting of (1) high performance computers for fast device control, calculations and visualization, (2) high capacity servers for data storage and management using large databases (e.g., for images, backup in case of crash, long term storage), (3) fast network connection between the devices including import/export options, and (4) dedicated software with clear and intuitive graphical user interfaces facilitating simple operation and assistance of all processes.

Four main categories of radiotherapy can be distinguished: external beam therapy, brachytherapy, intraoperative radiotherapy (IORT) and systemic radioisotope therapy. Differences of these categories result from the position of the radiation source and therewith the distance between source and target. With external beam radiotherapy, irradiation is delivered from outside the patient's body without direct contact between source and target. To obtain adequate penetration of the tissue, typically high energy electrons, photons or particles, produced by clinical accelerators, are used but also high energy gamma rays from Co-60 are still of relevance. For brachytherapy, sealed radioactive sources are temporarily or permanently placed in direct vicinity of the target area. Irradiation is applied using low and medium energy beta and gamma rays from radioisotopes such as Ir-192 or I-125. IORT is a special type of radiotherapy applied during surgery. Dedicated applicators are brought in direct contact with the tumor bed after tumor resection and irradiation is delivered using low or medium energy photons or high energy electrons. Systemic radioisotope therapy is a category of targeted therapy usually applied by a nuclear medicine specialist. Targeting is achieved due to the chemical properties of the radioisotope (e.g., iodine absorption of thyroid gland) or attaching the radioisotopes to a transporting molecule (e.g., a hormone) or antibody specifically binding to the target tissue. The resulting therapeutic agent is then delivered to the patient through infusion or ingestion.

Selection of therapy options for cancer treatment is mainly determined by evidence summarized in guidelines according to tumor characteristics (e.g., stage, volume, spread, and position), patient condition and wishes, treatment intention and expertise and infrastructures of the treatment center. The central goal of physical planning and application of radiotherapy is to maximize the dose to the target volume while minimizing the exposure to normal tissues. Hence, delivered dose distribution should be as conformal as possible, which is attained by using design features of the treatment devices as well as physical radiation properties differing between the types of radiotherapy.

External Beam Therapy Using High Energy Photons and Electrons

External beam therapy using high energy photons and electrons is the current standard of radiotherapy. Radiation is usually produced by a clinical linear accelerator (LINAC), which consists of three main components: (1) a static structure holding (2) an isocentric gantry that can vertically rotate 360 degree around (3) a patient couch. High-frequency electromagnetic waves are used to accelerate electrons to high energies through a linear tube of approximately 1 m length inside the gantry. The generated pulsed electron pencil beam is bent toward the patient by means of magnets inside the gantry head. For photon irradiation, the

beam hits a target to produce bremsstrahlung as well as a flattening filter to homogenize the beam intensity. For electron irradiation, the beam passes a scattering foil to widen it. Following these, ionization chambers are used to monitor dose, dose rate and beam characteristics (e.g., flatness, symmetry) and therewith to control the machine output. At the beam exit at the gantry head, several steps of collimators are integrated for field formation and radiation protection purpose. The LINAC thus provides electron and photon cone beams of typically 5–25 MeV energy with a focus-isocenter-distance of normally 1 m, a maximum field length of approximately 40 cm and a dose rate of 3–6 Gy min^{-1}.

Beam shaping of photon beams today is mainly achieved by a multileaf collimator (MLC). MLCs consist of opposing sets of tungsten alloy leaves with a height of about 7–12 cm and, projected to the plane of isocenter, a width of about mostly 3–10 mm. Resulting transmission through the leafs is few percent of the open field dose rate. Each individual leaf is moveable by a computer-controlled motor allowing for stepped beam shaping. MLCs are mostly supported by preceding or succeeding motor-driven jaws, which are used for field shaping and reduction of scattered or leakage radiation. These collimation features have a typical distance of about 40 cm to the isocenter. Due to an increased scattering in air, beam shaping of electron beams is achieved by additional applicators comprising metal scrapers to absorb leakage radiation as well as an insert to hold apertures casted from Rose's metal. Alternatively, an electron MLC (eMLC) is available as add-on component exhibiting similar characteristics as integrated MLC. These applicators or eMLC can be mounted to the gantry and patients are typically positioned with a small air gap of few centimeters to it.

Fig. 2 exemplarily shows lateral and depth dose profile distributions of photon and electron beams. Lateral dose profiles are characterized by a flat, homogenous plateau and a penumbra of several millimeters. Depth dose profiles differ between electrons and photons, both showing dose built-up when entering tissue. Electron beams are stopped at a certain range defined by their energy (within several centimeter depth) and are therefore suitable for superficial targets whereby tissue in greater depth is protected. In contrast, photon beams exhibit an energy-dependent, exponential dose fall-off in the depth. Sparing of normal tissue is attained by delivering photon beams from different directions and with field shapes adapted to the target shape resulting in a superposition of applied dose distributions.

Irradiation with electrons is usually applied to the patient by a single fixed beam from a defined gantry angle. For each beam, an individual aperture has to be casted according the target shape before and needs to be inserted to the applicator, or a specific eMLC needs to be utilized. Irradiation with photons can be delivered by fixed beams from various gantry angles. For simple cases (e.g., with palliative intent), single or opposing beams are used but typically multiple beams are applied to achieve higher dose conformity. Each photon beam is shaped by the MLC resulting in a homogeneous dose distribution but also inhomogeneity can be useful, for example to compensate for varying materials (i.e., density, thickness, atomic composition) traversed by the beams. In addition, some advanced high precision techniques explicitly require areas of higher dose inside the target volume (i.e., simultaneous integrated boost) to increase treatment intensity in these areas while keeping limited doses in other areas of the target volume and in healthy tissues. Such intended dose inhomogeneity's can be generated by leaf motion and are therewith an important characteristic of an advanced technique called intensity-modulated radiotherapy (IMRT). Two delivery modes of IMRT are distinguished (Fig. 3). For step-and-shoot IMRT, radiation and leaf motion are executed sequentially (leaves cannot be moved when the beam is on). For sliding-window IMRT, radiation and leaf motion are executed simultaneously (leaves can be moved when the beam is on). Beside fixed beams, another way of delivering photons to the patient is arc therapy. Thereby, the gantry rotates during irradiation in combination with either static MLC shape or leaf motion (e.g., dynamic conformal arc therapy, intensity-modulated arc therapy). Arc therapy is provided by LINACs equipped with gantry and MLC generating a cone beam, but also by TomoTherapy® devices. These devices consist of a LINAC that is mounted on a CT ring gantry for continuous 360 degree rotation around a patient couch. A pneumatic MLC is used for field shaping to produce a 6 MeV photon fan beam, which is applied to the patient as a helical arc through continuous couch translation.

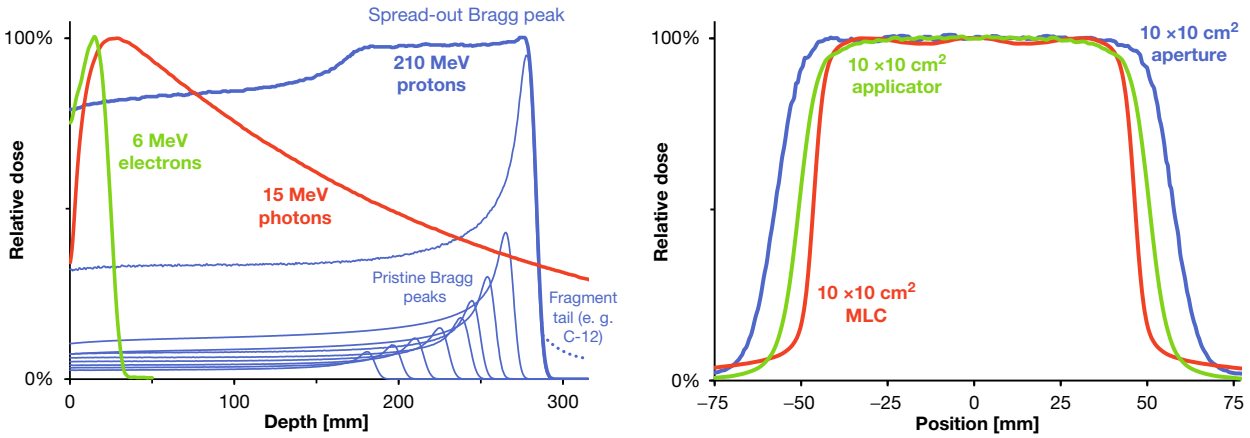

Fig. 2 Schematic depth dose (*left*) and lateral dose profiles (*right*) of 6 MeV electrons, 15 MeV photons, and 210 MeV protons (passive scattering) used for external beam radiotherapy.

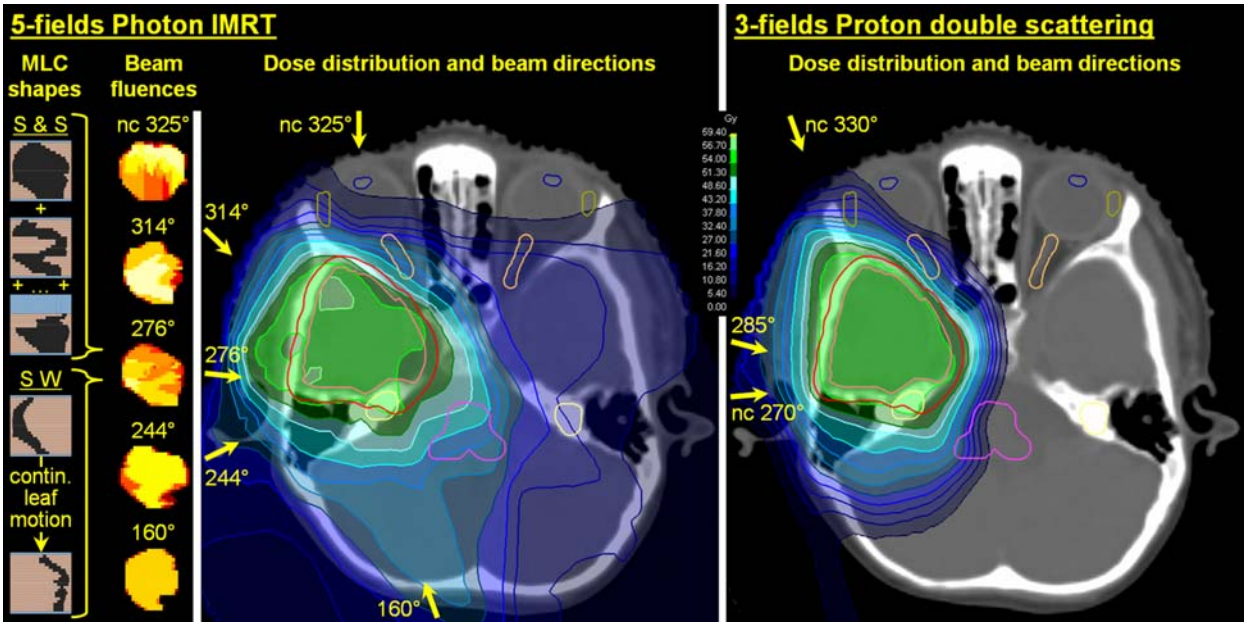

Fig. 3 Comparison of dose distributions for external beam radiotherapy using 5-fields photon IMRT (left) and 3-field proton double scattering irradiation (right). For IMRT, beam fluences as well as exemplary MLC shapes for one of these fluences using the two different IMRT delivery modes (*S&S*, step-and-shoot; *SW*, sliding-window) are included. Beam directions are indicated as gantry rotation angles, in some cases with additional patient couch rotation marked as noncoplanar (nc).

A specific type of external beam radiotherapy with photons is the stereotactic radiotherapy (SRT). The particularity of SRT is the high accuracy and precision of beam application resulting in high dose conformity as well as steep dose fall-off outside the treatment volume. This allows application of very high doses to a small target volume (<3 cm diameter) in a single treatment or a limited number of fractions. For that, multiple fixed beams or several arcs with largest possible spatial separation are needed to focus the high dose to the target volume while minimizing exposure of surrounding tissues by widely distributing entrance and exit doses. SRT can be performed with a LINAC equipped with an MLC with particular thin leaves or cylindrical cone collimators for beam shaping. To shorten the irradiation time for the patient and therefore increase the dose rate (up to factor four), the flattening filter inside gantry head of dedicated LINACs was removed. This leads to a nonuniform, radially decreasing lateral dose distribution and a reduction of the scattered radiation. Another device for intracranial SRT is the Gamma Knife®, which consists of about 200 Co-60 sources arranged in a hemispherical or cylindrical configuration as well as a helmet or a ring array collimator focusing circular field shapes (4–18 mm diameter) to the isocenter. During the treatment with both LINAC and Gamma Knife®, the patient position needs to be very stable and motion needs to be controlled. For extracranial targets, patients are ideally positioned inside a vacuum cushion, whereas for intracranial targets, rigid fixation of the head is feasible, especially used at the Gamma Knife®. The CyberKnife® allows for SRT without fixation. This system consists of a LINAC and a patient table both mounted on computer-controlled robots enabling near-complete freedom to position source and target. Beam shaping is alternatively achieved by exchangeable fixed cone collimators, a motorized Iris™ variable aperture collimator or an MLC. An integrated stereoscopic radiography system continuously evaluates the target position by means of anatomical structures (e.g., bones) or fiducial markers during the treatment enabling online adaption of beam and target position.

External Beam Radiotherapy Using Particles

Particle therapy with protons or heavier ions like C-12 is an emerging development in radiotherapy with various options for treatment optimization. Particles are accelerated by means of high-frequency electromagnetic waves using circular accelerators. The large mass of particles necessitates a much larger therapy devices compared to LINACs, resulting in higher costs and efforts for operation. The particle devices consist of four main components: (1) circular accelerator, (2) energy selection system, (3) beam line, and (4) patient application system (nozzle). For protons, a cyclotron of 2–5 m diameter and about 100–200 t weight and, for ions, a synchrotron of 20–40 m diameter with upstream LINACs for preacceleration are used to generate a mono-energetic beam. The following energy selection system is comprised of a degrader in form of a graphite wedge or wheel. The beam line is an evacuated tube of several 10 m length, surrounded by magnetic quadrupole lenses for beam focusing and dipole magnets for bending in case of curves or junctions. The patient application device differs between protons and ions. Protons are usually delivered by an isocentric 360 degree rotating gantry with about 10 m diameter and about 100 t weight. For ions, the worldwide only one 360 degree gantry is installed in the Heidelberg Ion-Beam Therapy Center with 13 m diameter, 25 m length and about 600 t rotating weight.

Other institutes using ions operate static beam lines guided into the treatment room, which is equipped with a respective couch or chair system for patient positioning.

For particle therapy, two different kinds of field shaping can be differentiated namely passive scattering and active beam scanning (also termed as pencil-beam or spot scanning). Beam shaping with passive scattering is achieved by guiding the mono-energetic pencil beam through a first scatterer to widen the beam. A range modulator or ridge filter forms the spread-out Bragg peak (SOBP) by partially decelerating particles to adapt the energies to the required ranges in tissue according to the tumor width in the beam direction. Afterwards, a second scatterer for further beam widening can be necessary. The lateral shaping of the homogenous beam is performed with a collimator milled from brass or poured from Rose's metal. Distal beam shaping is achieved by a compensator from acrylic or wax of varying thickness. These hardware devices have to be manufactured for each patient and irradiation field, and are mounted close to the patient at the beam nozzle before irradiation. Due to the fact that the proximal target contour cannot be fully shaped with passive scattering, normal tissue is to some extend unnecessarily exposed to higher doses. This can be overcome by active beam scanning, which allows also shaping of the proximal contour of the target without patient-specific hardware. By varying the beam energy through the degrader, a change from one range to another within the target is possible. The spatial deflection of the pencil beam is ensured by two vertical and horizontal magnet couples, such that single spots can be irradiated one after another scanning over the treatment area. Active beam scanning can be used to apply homogenous dose distributions, but also a highly complex dose distribution can be achieved by modulating the number of particles and thus the applied dose at each spot. Analogues to IMRT using photons, the latter is termed as intensity-modulated particle therapy (IMPT).

Treatment with particles has several advantages compared to photons and electrons. While passing through matter particles are continuously stopped mainly by collisional but also radiative processes having the highest energy transfer at the end of their track. Therefore, the depth dose profile exhibits a plateau region with a sharp increase of dose in a well-defined, energy-dependent depth (Bragg peak) and steep dose fall-off beyond the maximum (**Fig. 2**). For ions, additional nuclear fragmentation processes lead to a fragment tail in the depth dose profile. Lateral and range straggling decreases with particle mass such that both the width of the Bragg peak and the penumbra of the lateral dose profile are larger for the light protons as compared with the heavier ions like C-12. The physical characteristics of particle beams allow sparing of normal tissue by reducing the irradiated volume, which, based on radiobiological principals and clinical evidence gained from photon therapy, is expected to lead to a reduction of risk and severity of side effects as well as secondary cancer. However, on the other hand, the accurate and precise dose deposition of particles makes the treatment very sensitive to anatomical changes (e.g., changed body weight, edema) as well as organ motion and filling. Already minor changes can cause underdosage of the target and overdosage of the surrounding normal tissue. To prevent this, continuous dose and patient monitoring as well as knowledge of organ motion are even more important for particles than for photons. Beside the physical benefits, the increased RBE of particles may also be advantageous in some clinical situations. Differences between RBE of particles and photons are less pronounced for protons (RBE 1.1) than for ions (e.g., RBE 2–3 for C-12). The benefit of particle therapy using either protons or ions is still under investigation for each tumor entity and not generally accepted as a clinical standard. At present, the treatment of chondrosarcoma near the spinal cord or skull base, chordoma, ocular melanoma, pediatric tumors of the central nervous system, brain tumors with long life expectancy in adults as well as curative treatments in preirradiated tissues are among the accepted indications for particle therapy. To obtain a better database for evidence-based treatment allocation guidelines, it is necessary to perform comparative treatment planning with best practice photon therapy and treatment of patients in prospective trials.

Brachytherapy

Brachytherapy (BT) is a form of radiotherapy to treat cancer by placing sealed radioactive sources within the tumor volume. Through the direct contact, high dose can be locally applied whereas the dose to distant tissues decreases rapidly following the inverse square law. Therefore, BT is a highly efficient and conformal treatment, but with a limited applicability for several tumor entities and therapy schemes due to the required accessibility to the target area and its maximum size. BT can be used as monotherapy but it is typically delivered as additional local dose (boost) in combination with external beam radiotherapy.

Different types of BT can be defined according to the placement and dose rate of the radioactive sources as well as the way and duration of treatment delivery. The placement of sources can be interstitial using hollow needles or plastic catheters that are brought directly into the tissue by an invasive procedure. Another possibility is contact BT using the space adjacent to the target area for source placement, which might be the patient external, body cavities, lumens or vessels. Interstitial BT can be used for breast and prostate cancer, contact BT can be applied for gynecological, lung, esophageal and skin cancer. Regarding the dose rate of sources, BT is clinically applied with high dose rate (HDR) and low dose rate (LDR). Using HDR sources, irradiation time is in the range of several minutes and usually several fractions are applied to allow for repair of DNA damage in normal tissues thereby reducing morbidity. Conversely using LDR sources, the irradiation time is in the range of days to weeks. As repair in normal tissues takes place during treatment, fractionation is not necessary. To combine the radiobiological advantages of LDR BT with regard to repair of DNA damage and the physical advantages of HDR BT (e.g., flexibility in treatment planning, adaption and optimization), a third option termed as pulsed dose rate (PDR) BT was developed. Fractions of HDR BT with 0.4–1.2 Gy are given in 1–2 h interval over several days up to the prescribed dose (mostly boost).

Two main techniques of treatment delivery for BT can be distinguished: afterloading and seed implantation. Afterloading refers to a technique of first preparing the target area for irradiation by positioning nonradioactive applicators, needles or catheters that are subsequently connected to a remote-controlled afterloader for temporary placement of a radioactive source. Such afterloader

contains a shielded HDR point source (e.g., Ir-192 or Co-60) attached to a flexible wire enabling fast, motor-driven placement inside connected applicators. Treatment is applied according to calculated dwell times and positions taking into account exponential decay of the source activity. Seed implantation refers to a technique of implanting LDR point sources (so called "seeds," e.g., I-125 or Pd-103) in a planned pattern into the target volume by interstitial BT. This implantation is mostly permanent, for example, to treat prostate and brain tumors, but also temporary implantation with removal after few weeks has been performed. Radionuclides like I-125 and Pd-103 emit photons with lower than 30 keV energy, for which an increased RBE (I-125: 1.3–1.5; Pd-103: 1.9) has been reported. Radioactive seeds are also used for the treatment of ocular tumors. For this, dedicated ophthalmic applicators are sutured to the sclera for local irradiation over several days. These applicators can alternatively be equipped with seeds or a foil coated with a beta emitter (Ru-106) both enclosed by a thin gold or silver shielding for sterilization.

Intraoperative Radiotherapy (IORT)

Intraoperative radiotherapy (IORT) is usually applied after surgical resection directly in the operating room. A suitable applicator is placed in direct contact with the tumor bed or residual tumor and aligned for connection to the irradiation device. Deeper normal tissue can thereby be protected from exposure by inserting additional shielding material. IORT is typically given in a single fraction with doses of 10–20 Gy. In this ranges, lower doses are applied when IORT is followed by external beam radiotherapy whereas higher doses are prescribed when IORT is applied alone. IORT has been found effective for different tumor entities that are treated by surgery, for example breast, skin, pancreas, rectum, soft tissue sarcoma. The advantages include application of high local doses with direct visualization of the target area and very good preservation of normal tissues and OARs from irradiation.

There are two main types of irradiation devices for delivering IORT. Electron-beam IORT is applied by compact LINACs generating 3–12 MeV electron beams that are guided to the target area through circular applicators. The LINACs are mounted to a motorized stand or C-arm structure enabling flexible positioning for delivering beams directed from above onto the surgical table. For radiation protection purposes, a beamstop opposite the electron beam is integrated. To improve beam uniformity and flatness, scattering foils can be incorporated, however, requiring additional shielding to reduce stray radiation. The source-surface distance ranges from 50 to 100 cm such that electron beam IORT is subsumed under external beam radiotherapy. In contrast, IORT using low energy photons is also referred as electronic brachytherapy. Respective devices are equipped with low kilovoltage X-ray sources (≤ 50 keV), either point sources or collimated tubes, which are connected to applicators for intraoperative treatment with 1–4 cm focus-surface distance. For flexible applicator positioning, the X-ray source is carried by an articulated arm or, in case of the point source, a connecting tube. Due to the low energy of the X-ray source, radiation protection is comparatively simple. The radiant units of the described IORT devices are mobile due to integrated transportation systems and are therefore very flexible.

Systemic Radioisotope Therapy

Radionuclides, usually beta or alpha emitters, can be used for therapeutic purposes. This approach gains importance in the context of developing targeted molecules including antibodies that specifically bind to the surface of cancer cells. If these are labeled with therapeutic radioisotopes, the radiation can be guided directly to the tumor. As the range of the emitted electrons is in the order of several cell layers, also neighboring cells are irradiated besides the actual target cells to which the antibody is bound. An example is radioimmunotherapy of CD20-positive non-Hodgkin lymphoma with the antibody Ibritumomab-Tiuxetan labeled with Y-90. Particularly promising seems to be the combination of internal irradiation using targeted radionuclides and external beam radiotherapy. Preclinical studies using radionuclide-labeled Cetuximab in with combination external beam radiotherapy showed a significant improvement of local tumor control for some squamous cell carcinoma. Theranostic approaches refer to the use of targeted drugs, which can be labeled with radionuclides suitable for imaging (e.g., PET) and, if accumulating in the tumor, can be applied with therapeutic radionuclides for treatment. Such approaches promise personalized application of systemic radioisotope therapy.

Radiotherapy Workflow

Clinical Decision Making

Today, radiation oncologists are increasingly working as member of a multidisciplinary and multiprofessional team. They cooperate closely with medical oncologists, radiologists, surgeons, pathologists, additional disciplines depending on the tumor entity (e.g., dermatologists in case of melanoma) as well as other health professionals including psycho-oncologists, dieticians and physical therapists. This team discusses the overall disease situation of the patient based on relevant information, such as general condition, tumor staging, histology and images, and recommends the treatment according to guidelines or, increasingly, personalized treatment concepts. Before starting radiotherapy, the patient has to be informed in detail about the treatment intention (curative or palliative) and chances of success, treatment planning and application, possible early and late side effects, alternative treatment options, and wherever possible on potential use of data for clinical cancer research and quality control of treatment. After the patient consent, radiotherapy planning starts with treatment prescription including detailed information for treatment planning and application (e.g., required imaging, target volume, total dose, fractionation, beam quality and technique).

Imaging for Treatment Planning

Radiotherapy requires a defined, reproducible, stable and as convenient as possible patient position with free access to target area as basis for treatment planning. Therefore, imaging for radiotherapy, outside of the context of basic staging, has specific requirements. Patient position is determined during imaging using different aids, such as thermoplastic masks for head and neck region, skin marking stain or tattoo and immobilization devices such as vacuum cushion, knee rolls and arm rests. In recent years, additional procedures for increased reproducibility of organ fillings and for movement reduction have been developed. For example, for prostate cancer patients, bladder filling can be reproduced by a daily drinking protocol and ultrasound monitoring, and the rectum can be stabilized by a special rectal balloon. A spacer can be implanted between prostate and rectum, thereby reducing dose to the anterior rectum wall. For brachytherapy planning, CT imaging of the treated area has to include applicators or catheters to determine source positions and dwell times. For seed implantation, an ultrasound examination and, if necessary, an MRI is performed to determine the target volume (e.g., postage volume) in order to plan probable seed numbers and positions.

A CT scan of the target region typically builds the basis for treatment planning. Scans are usually performed by a modern multislice scanner with high spatial resolution in the range of submillimeters and a short acquisition time due to fast rotation. These CT scanners also have a large field-of-view due to the built-in detector array and options for low dose imaging by modulating the X-ray tube current during rotation. CT reconstruction is performed using filtered backprojection algorithm or additional iterative reconstruction algorithms for low dose protocols and artifact reduction. To enhance visibility and differentiation between anatomical and tumor structures, contrast agent may be applied or fiducial marker may be implanted. For periodically moving targets, which can typically be found in the thoracic or abdominal region due to heartbeat and breathing, 4D CT imaging is advantageous. The breathing cycle can be monitored, for example, by a pressure sensor, surface monitoring or spirometry. The respective signals are synchronized with the CT image acquisition such that defined phases of the 4D CT dataset can be reconstructed (e.g., inspiration) or further image processing using algebraic algorithms (e.g., average CT, maximum or minimum intensity projection) can be carried out. Dual energy CT, which describes the acquisition of two CT scans with different X-ray tube potential, has a growing importance in clinical practice for diagnostics and treatment planning. These scans can be performed with a single source scanner allowing subsequent acquisition or also synchronous acquisition using a fast alternation between the tube voltages. With this technique, artifacts by implants and also application of contrast agent can be reduced. Furthermore, assessment of physical tissue properties (e.g., density) is more precise, which improves precision of dose calculation for radiotherapy using photons, electrons and even more particles. Finally, acquired images are transferred to the treatment planning system (TPS) to start the process of contouring and thereafter treatment planning.

For dose calculation, in particular for external beam radiotherapy, the Hounsfield unit of each voxel from the CT dataset is converted by the TPS to the physical quantity relevant for radiation interaction (e.g., electron density, stopping power). This requires calibration for defined CT scanners and imaging protocols to determine respective relation. Since the turn of the millennium and the progress in the availability of MRI scanners, the usage of MRI in radiotherapy is of growing interest. Due to its superior soft-tissue contrast and radiation-free acquisition compared with CT, MRI has become increasingly relevant for contouring, treatment planning and verification besides the traditional immense importance for diagnostics, However, many challenges have to be overcome regarding the compatibility to radiotherapy equipment (e.g., for patient positioning, treatment delivery, and dosimetry), the geometrical accuracy (e.g., system- and patient-related distortions, patient, and organ motion) and the conversion of MRI signal to physical quantities for dose calculation. Continuous progress in research and development has provided innovative solutions and enables versatile clinical application by now.

Contouring

In the reports of the International Commissions on Radiation Units and Measurements (ICRU), recommendations for target volume definition for radiotherapy are given. Extent and location of the malignant growth including primary tumor as well as lymph node and other targets, such as (distant) metastasis, needs to be delineated as the gross tumor volume (GTV). This target volume is determined by clinical information (e.g., inspection, palpation) and various imaging modalities (e.g., MRI, PET-CT, and endoscopy). As the GTV does not include the subclinical microscopic extension, it needs to be enlarged by empirical margins in three dimensions to generate the clinical target volume (CTV). For this, tumor characteristics like local invasion capacity, potential spread to different regions and results from recurrences patterns need to be considered. To compensate for expected physiologic movement as well as variation in size, shape and position of the CTV, a so called internal margin is added to the CTV resulting in the internal target volume (ITV). These variations arise from respiration, heartbeat, swallowing, different fillings and movement of hollow organs (stomach, intestine, and bladder) and extent of margin can be assessed, for example, by time-resolved imaging (4D, consecutive). A further margin is added to account for uncertainties in patient positioning and beam alignment resulting in the planning target volume (PTV). This setup margin may differ substantially depending on factors like variations of patient position, influenced by helping aids and image-guidance techniques, mechanical uncertainties of the equipment as well as dosimetry-based uncertainties. The latter applies in particular for external beam therapy using particles since the beam characteristics necessitates consideration of range uncertainties because the location of the Bragg peak in depth depends importantly on the amount of tissue in the entrance channel (vide supra).

In the proximity to target volumes, normal tissues may significantly influence the treatment planning and prescribed dose due to their radiation sensitivity. For serial-like organs, the dose at or close to the maximum is the best predictor of loss of function. In

contrast, for parallel-like organs the mean dose or excess of dose given to a defined volume have been used as the best predictors of loss of function. Actually, tissue organization of many organs is a mixture of both with more or less pronounced characteristics. Analogous to the margins between CTV and PTV, uncertainties and variations of the OAR must be considered to avoid complications generating the planning organ at risk volumes (PRV).

For delineating target volumes and organs at risk (OAR), TPS provide versatile tools for manual contouring, for example freehand, polygon and brush tools as well as options for local deformations of the resulting region of interest (ROI). Simplification tools, inter- and extrapolation as well as the possibility of 3D contouring ease the completion of manually drawn ROIs and Boolean algebra for margining and combining ROIs (e.g., union, difference, and intersection) can be used. In addition, TPS include sophisticated (semi-)automatic tools for contouring such as thresholding (global, local), edge detection and region-growing methods. Model-based segmentation makes use of statistical models of shape and appearance, for example, of organs that is combined with image information (gray value, gradients) for delineating ROIs. In atlas-based segmentation, segmented structures from multiple image sets in a clinical database are taken to find the best matching for contouring the current image set. The given methods can also be found in combination, which additionally can be supported by machine-learning approaches. Especially automatic tools enable simultaneous contouring of multiple ROIs and even patients increasing efficiency and throughput. Furthermore, accuracy and reproducibility may be improved since manual contouring may vary with experience and training of the observer as well as image modality (and quality) and treatment protocol. To reduce this variability and increase the reproducibility, guidelines for contouring of tumor entities according to stage and situation as well as OARs are available.

Frequently, different CT datasets complemented by other image modalities are required for comprehensive contouring. This applies for time-resolved imaging to examine target or organ movement or monitor the course of treatment for possible adaptions. Another reason might be the low soft-tissue contrast of CT impeding differentiation of normal and abnormal tissue as well as organ boundaries. Furthermore, functional imaging modalities such as PET or functional MRI add physiological information such as metabolism, oxygenation (e.g., hypoxia), perfusion, diffusion and substance distribution (e.g., proteins) to already existing anatomical information. TPS typically provide import and export functionality for various image modalities based on the DICOM format (Digital Imaging and Communications in Medicine). For image registration, rigid image transformations are integrated using manual operations (e.g., translation, rotation, scaling) as well as (semi)-automatic algorithms based on comparison of landmarks or gray values (e.g., mutual information). Moreover, several TPS enable nonrigid, deformable registration, which is particularly important for therapy adaption due to volume changes of the patient (e.g., edema, swelling) or treatment planning within a previously irradiated area (e.g., in case of recurrence, metastasis, and secondary tumor), possibly even with long time interval.

In addition to target volumes and OARs, contouring of helping aids as well as applicators and catheters for brachytherapy is relevant for consideration during treatment planning, for example to avoid collision with the irradiation device or to calculate radiation interaction or source dwell times. For inverse treatment planning used for IMRT, help contours are typically required to control the optimization mostly drawn by the physicists by means of manual contouring tools and Boolean algebra. An important feature of TPS is the density override of a ROI needed, for example, to cope with image artifacts caused by metal implants or to correct the Hounsfield unit of tissue modified by contrast agent. Without this function, dose calculation might be wrong due to incorrect gray values. In this context, generation of a so-called bolus at the patient surface to compensate for the dose built-up of high energy photons and electrons is also a necessary feature. Such bolus can usually be drawn with desired thickness based on the external contour using a semi-automatic routine. For treatment application, this bolus is placed onto the patient at the intended area. Besides delineation of ROIs, TPS also enable definition of points of interest facilitating patient alignment, plan modeling and evaluation as well as dose verification and quality assurance.

Treatment Planning

TPS provide models for treatment devices and sources used for the different types of radiotherapy. On the one hand, these models comprise all design features (e.g., gantry) and beam shaping components (e.g., MLC, electron applicators) relevant for treatment application as well as their characteristics regarding material, motion and geometry. On the other hand, dosimetric properties of radiation source and field are included. For modeling, extensive measurements of absolute dose as well as relative depth and lateral dose profiles are required using appropriate detectors (e.g., ionization chamber, diode detector, radiochromic film) and phantoms (e.g., motorized water phantom, slab phantom) conforming to national standards. These measurements are mostly performed during the commissioning phase of a treatment device and, for monitoring purpose, during the regular quality assurance procedures.

The aim of designing a treatment plan is to achieve an optimal dose distribution complying with prescribed dose objectives for the target volume and the tolerance doses of surrounding normal tissues. The traditional way is termed as forward planning, which is an iterative trial-and-error approach of the planner by manually specifying and modifying a set of plan parameters to accomplish this goal. The result depends largely on the experience, effort and decisions of the planner. During the last decades, computing power has strongly improved allowing for an alternative way of plan design termed as inverse planning. Here, the planner defines dose constraints for target volume and OARs as well as some framework conditions (e.g., beam directions, number of MLC shapes). Then, an optimization algorithm determines the plan parameters that best satisfy the constraints using an objective function. The planner may influence the optimization by modifying the penalty weight of each constraint to indicate relative importance. In a powerful IT environment, inverse planning can potentially be very time-efficient because much of the trial-and-error time is removed. Furthermore, plan quality with regard to dose conformity or OAR sparing can be superior to those resulting from forward planning.

Many TPS provide both ways of plan design for the individual types of radiotherapy. The resulting treatment plan consists of a set of parameters differing between the respective treatment devices. For external beam radiotherapy, these parameters comprise beam positions, energies, directions, shapes, and weights (i.e., monitor unit). Inverse planning is mostly associated with IMRT using photons for external beam radiotherapy as the optimization algorithm results in inhomogeneous dose distributions for each fixed beam or arc, which is realized by the two IMRT delivery modes (i.e., step-and-shoot or sliding-window). IMRT is also feasible with electrons using the eMLC and with particles using IMPT. In addition, there are applications for inverse planning in connection with brachytherapy to spare an OAR by optimized dwell times. Two interesting approaches of inverse planning have recently been developed possessing a great potential for future treatment planning of external beam radiotherapy but requiring high computing power to be performed with reasonable time requirement (i.e., within several minutes). The first one is termed as automated planning and describes the automatic generation of numerous treatment plans for defined clinical goals and combinations of treatment techniques (e.g., IMRT with varying beam number, types of arc therapy) and devices (e.g., different LINACs, TomoTherapy®). The decision for a certain plan might be taken based on criteria fulfillment and treatment efficiency considerations. A variant of automated planning is the so called fallback planning, which can be very valuable in contingency situation (e.g., device breakdown), is the so called fallback planning. Here, additional plans are automatically created, possibly with a different treatment technique and/or device, by replicating the dose distribution of a given plan. The second one is termed as multicriteria optimization and describes an alternative workflow for the optimization. Instead of the iterative process of modifying dose constraints and penalty weights by the planner, TPS automatically generates Pareto optimal plans, meaning that all constraints are respected and no criterion can be improved without impairing another one. The planner may select a certain plan through continuous interpolation between these precalculated alternatives.

An important step of plan design is the dose calculation based on the treatment device model and patient anatomy. Several algorithms have proven suitable for calculating high accurate and realistic dose distributions. For external beam radiotherapy and brachytherapy using photons, dose calculation is typically performed by a collapsed cone convolution superposition algorithm or an approach based on solving the linear Boltzmann transport equation. Alternatively, a Monte-Carlo simulation is implemented in TPS, which is furthermore suitable for dose computation from electron beams. In contrast, the formerly widespread pencil-beam algorithm is hardly used as it does not accurately account for inclined beam directions as well as disturbed secondary electron equilibrium and lateral photon scattering from patient heterogeneities. For particles therapy, two central aspects have to be considered for dose calculation. Physical dose distribution can be computed by a pencil-beam algorithm for protons as well as analytical algorithms or Monte-Carlo simulation for ions. In addition, the increased relative biological effectiveness requires a conversion of physical absorbed dose to RBE-weighted dose. For protons, today usually a RBE of 1.1 is assumed although radiobiological data indicate some variability. RBE dependencies for ions are more complex involving parameters such as ion type, energy, depth, LET and cell type, conversion of physical absorbed dose is carried out using a fixed (HIMAC approach) or variable (local effect model) RBE scheme.

Plan Evaluation

Plan evaluation is an important step to finally select a treatment plan for application. This decision is usually taken by the radiooncologist, optimally as a team effort together with medical physicists. For plan evaluation, criteria for both target volumes and OARs are recommended in reports and guidelines of professional organizations (e.g., ICRU, RTOG, and EORTC) for the different types of radiotherapy. For example, for external beam radiotherapy the ICRU report 50 specifies that in the best technical and clinical conditions the dose heterogeneity in the PTV should be kept within 95%–107% of the prescribed dose. As these minimum and maximum criteria are difficult to be maintained for IMRT plans, ICRU report 83 recommends replacement of these values by a near-minimum $D_{98\%}$ and near-maximum $D_{2\%}$ (D_V means dose D [% or Gy] received by volume V [% or mL] of a target volume or OAR). Criteria for radiation tolerance of OARs can also be found from various literature expressed as maximum doses or dose-volume-parameters (e.g., D_V or analogous V_D). These criteria are typically related to relevant side effects of the OARs (i.e., toxicity endpoint and rate, severity grade, and time of occurrence) allowing the radiooncologist a risk-benefit assessment taking into account the patient situation. In addition to physical dose, also biological dose, that is dose taking into account the dose per fraction, overall treatment time and time interval between fractions, needs to be considered during treatment plan evaluation, for example by converting accepted tolerance doses according to the LQ model.

The gold standard of plan evaluation is a dose-based assessment combining qualitative and quantitative methods. The calculated 3D dose distribution is superimposed on the treatment planning image dataset by means of isodose contours or color wash using absolute or percentage dose scaling. This allows a direct, qualitative slice-by-slice review of dose in relation to target volumes and OARs. However, the amount of information is huge and the visual evaluation of target volume dose coverage as well as OAR tolerance dose compliance is difficult. Therefore, various quantitative surrogates serve for simplification of the 3D dose information within a specific ROI. Dose statistics such as minimum, maximum or mean and median values are easy to calculate. A dose-volume histogram (DVH) is a 2D graph showing the frequency distribution of dose values within a certain ROI ignoring spatial information. There are two variants of DVH, namely the differential and the commonly used cumulative (integral) DVH. Dose statistics and DVH are important tools for plan evaluation as both facilitate comparison to recommended criteria. These features should always be used in conjunction with each other and the visual analysis of the 3D dose distribution. For example, separate DVH interpretation can cause serious mistakes as the DVH is only calculated for delineated ROIs, it is insensitive to small spots of low or high doses and the graph shape can be misleading (e.g., in case of ROIs containing high density differences).

An additional aspect of plan evaluation is the comparison of different treatment plans with each other to find an optimum for the current patient situation with the best possible clinical outcome. Plan scoring can be based solely on dose information (i.e., 3D distribution, statistics, and DVHs). For this, various indices can be calculated as a measure of, for example, dose homogeneity inside the target volume or conformity of the dose distribution with respect to the target volume and prescription also considering the extent of sparing relevant OARs. However, these indices mostly lack clinical relevance. Therefore parameters such as the tumor control probability (TCP), the normal tissue complication probability (NTCP) or the equivalent uniform dose (EUD) can be incorporated for plan scoring. These parameters are interesting for research purpose and future clinical practice, however for current clinical decisions, these tools should be used with caution as the validity of underlying models and their input parameters are often yet uncertain.

The practicalities of treatment delivery pose further important issues for plan evaluation, in particular for external beam radiotherapy using intensity-modulated beams. Complexity of a treatment plan can be assessed considering the limits of the irradiation devices, the treatment time for the patient as well as clinical aspects such as the patient's general condition and treatment intention. Safety of delivery can be evaluated in terms of sensitivity of a treatment plan to patient positioning errors or anatomical changes (e.g., due to breathing or differing organ fillings) by recalculating the dose distribution in spatially-shifted CT datasets or different phases of a 4D CT. In this context, patient-specific quality assurance is often conducted. Thereby, dosimetric measurements are performed for the comparison with the planned dose distribution typically using a gamma-index analysis. In addition, the treatment plan can be checked for collisions (e.g., between irradiation device and patient, positioning aids or couch) and necessary patient-specific equipment can be tested prior to the treatment delivery.

Fig. 3 provides an example for dose plan assessment, comparing a proton dose distribution in comparison with photons in the same patient suffering from brain tumor. Very significant differences occur with regard to the dose in normal tissue. While large portions of normal brain receive low to intermediate doses when the photon plan is applied ("dose bath"), the portion of irradiated normal brain is much less for proton treatment. Differences between the plans are much less for target volume coverage, target volume conformity and high dose regions in healthy tissues. Overall, the proton plan is from a physical and radiobiological perspective superior for this patient and was selected for clinical treatment. However, it needs to be noted that clinical benefit cannot be directly be determined from treatment plan comparison at present time and requires further data to be validated in predictive models.

Treatment Application and Verification

The course of radiotherapy often lasts several weeks, during which inter- and intra-fractional changes can occur due to shifts in patient positioning as well as target- and patient-related alterations or motion. Nevertheless, precise and accurate application of the irradiation according to the treatment plan needs to be ensured over the entire radiotherapy period. Therefore, integration of various imaging techniques into the workflow for treatment verification is advisable for three main purposes. Correct positioning of patient, target volume and OARs can be supported by suitable imaging, which is typically carried out for all fractions before irradiation delivery, but also position verification by imaging should be performed in regular intervals. Moreover, anatomical changes such as swelling, tumor shrinkage or patient weight loss should be monitored with the help of imaging, for example on a weekly basis or on demand of the radiooncologist, possibly leading to a necessary treatment adaption. The third purpose is the management of patient motion during the irradiation, mainly used for respiratory motion. Two methods for compensating the detected motion have been established. Gating refers to restricted irradiation delivery to a defined breathing phase (e.g., inspiration). Tracking refers to a nonrestricted irradiation delivery during the breathing cycle while continuously adjusting the patient or beam position. Both methods require a correlation between motion signal and target position as well as an approved connection between the motion sensing device and the irradiation device, which is sometimes problematic due to medical products regulations. All the above mentioned utilization of proper imaging techniques for treatment verification and application are subsumed under the term image-guided radiotherapy (IGRT).

Several imaging modalities are used for IGRT, of which X-ray imaging is currently still of highest importance. Modern devices for external beam radiotherapy are equipped with on-board imaging systems. LINACs include an electronic portal imaging device (EPID) opposite the gantry head using the megavoltage photon beam for imaging. As the tissue contrast for such high energy is low and the exposure can be high compared with kilovoltage X-ray imaging, an additional X-ray tube and corresponding flat-panel detector are integrated into several LINACs arranged parallel or perpendicular to the therapy beam. Both EPID and X-ray imaging systems allow for radiography and, with additional gantry rotation, for cone-beam CT (CBCT). For particle therapy, even a pair of orthogonal X-ray imaging systems can be installed within the gantry enabling radiography. Alternatively, a ceiling-mounted robotic C-arm X-ray imager or a table-mounted X-ray imaging ring allows for radiography and CBCT. Beside these on-board systems, additional in-room X-ray imaging systems are used. Such systems are, for example, permanently-installed X-ray systems for (stereoscopic) radiography, mobile C-arms mostly used for brachytherapy or in-room CT scanners. The latter can also allow for CT imaging with a fixed position of the patient couch, as is the typical case for external beam radiotherapy, when a CT sliding gantry is mounted on rails. The acquired helical CT scans are of diagnostic image quality, which is advantageous over CBCT scans, however a patient relocation from the treatment position through couch rotation is required.

As radiation-based imaging always involves additional dose exposure of the patient, various nonradiation-based methods for IGRT are available. Different systems enable monitoring of the patient's surface and are valuable for superficial target (e.g., breast) and respiratory motion detection. These systems are ceiling-mounted and use methods like infrared-light reflection of respective

markers, speckled-light projection or laser triangulation. Ultrasound is a simple, fast method primarily applied to treatment sites like prostate, lung or breast. However, ultrasound requires comprehensive user experience as well as a direct patient contact associated with an inherent sensitivity to conduction and pressure of the probe to the tissue. Electromagnetic tracking is another method using seed-like transponders that are implanted subcutaneously or into the target area (e.g., prostate), or placed on the patient's skin. During recent years, MRI has been increasingly used for IGRT. Due to the special requirements with regard to the magnetic fields and the lack of compatibility to irradiation devices, off-room MRI scanners in combination with a dedicated patient couch transfer system have been implemented. In addition, research and development was pursued to directly integrate MRI into external beam radiotherapy devices and tackle the resulting technological challenges such as attaining material compatibility and considering magnetic fields for dosimetry and dose calculation (charged primary and secondary particles are affected by Lorentz force). A solution has been found by equipping an MRI scanner with a rotating-ring gantry, which holds three highly radioactive Co-60 sources and corresponding MLCs mounted with 120 degree separation. The newest, most innovative solution is the hybrid MR-LINAC, which combines complete functionalities of latest MRI scanners and LINACs. Furthermore, there is on-going effort of integrating MRI into particle therapy, for example using open MRI systems.

Different image modalities are differently suited for the variable purposes of IGRT and need to be assessed accordingly by the radiooncologist for each patient. Factors like additional dose exposure, image quality as well as requirements of time, effort and costs have to be individually balanced. All image modalities are suitable to support and verify patient positioning with varying effort and resulting precision and accuracy. Volumetric imaging like (CB)CT or MRI is usually needed for monitoring anatomical changes, however these modalities are inappropriate for motion management due to low temporal resolution. For this purpose, fast IGRT methods such as (stereoscopic) planar imaging (e.g., X-ray, MRI), surface monitoring, ultrasound, electromagnetic tracking are used. The acquired images are subjected to manual or (semi-)automatic evaluation, which is normally a comparison to former images acquired for treatment planning or during previous fractions. For example, radiographs from on-board or in-room X-ray devices are compared to digitally reconstructed radiographs (DRR) calculated from the treatment planning CT. Similarly, surface monitoring systems can make use of the delineated patient external contour for comparison whereas (CB)CT and MRI scans can be directly co-registered to the treatment planning dataset. Image evaluation is thereby performed by means of anatomical structures (e.g., bones) or fiducial markers, which have been placed on the surface or implanted into body of the patient.

An additional issue is the verification of dosimetric properties of the irradiation field during treatment application using external systems. A method named portal dosimetry has been specifically developed for monitoring IMRT delivery of a LINAC using the EPID for dose measurement. Alternatively, an independent transmission ionization chamber array is available, which is attached to the gantry head allowing online monitoring. For brachytherapy, in vivo dose measurement can be performed during irradiation using small-size dosimeters (e.g., thermoluminescent dosimeters, ionization chambers) that are placed in the vicinity of the target volume. For particle therapy, range verification is of particular interest due to the sensitivity to changes of the anatomical conditions in relation to the treatment plan. PET has been extensively used to measure the induced activity distribution of positron-emitting target (and projectile) residuals and subsequently compare them with Monte-Carlo simulations. Three options namely in-beam, in-room, and off-line PET have been implemented associated with different advantages and disadvantages. For example, the benefit of in-beam PET is the short, synchronous data acquisition and treatment application at the highest nuclide activity level, but implementation is complex, expensive and technically demanding. In contrast, off-line PET uses commercial PET scanners outside the treatment room, however necessitating a patient transport system to reduce repositioning uncertainties and longer acquisition times due to the rapid decay and biological washout of radionuclides, the latter is additionally impairing the image quality. In recent years, approaches for detecting prompt gammas, emitted as a result of nuclear reactions, have been explored. The underlying interactions happen within nanoseconds and are therefore a more direct indicator for the delivered particle distribution compared with the activity of positron emitters. Furthermore, prompt gamma emission exhibits a broad energy spectrum in wide range of 1–20 MeV including characteristic lines from specific elements of irradiated tissues. Different systems comprising a slit or Compton camera have been investigated and first clinical application for proton range verification has been demonstrated. Further promising systems are under development using time- and energy-resolved prompt gamma measurements instead.

Follow-Up

After the end of radiotherapy, long term follow-up is necessary to evaluate the treatment result and normal tissue toxicity. In this context, quality of life and patient-reported outcome should be evaluated possibly through standardized questionnaires. According to the tumor entity, the follow-up is usually combined with diagnostic imaging (e.g., CT, MRI), laboratory tests as well as medical examination by the radiooncologist and responsible medical specialists (e.g., gynecologist, surgeons). The treatment and follow-up data are required for early detection of potentially treatable recurrence, side effects and secondary tumors as well as for scientific evaluation and quality assurance.

Combination of Radiotherapy and Systemic Therapy

Radiotherapy in combination with chemotherapy is currently the standard treatment for a number of different tumor entities (e.g., head and neck, lung, rectal, and cervical cancer). By adding systemic agents to local irradiation, two potential effects namely increased local tumor control and/or elimination of occult metastasis can be expected. Chemotherapy can be applied

neoadjuvantly, simultaneously or adjuvantly to radiotherapy and also mixed forms are possible. The schedule depends on the aim (i.e., simultaneous to increase local control, (neo-)adjuvant to reduce distant metastasis) and evidence of treatment for the tumor entity. The main mechanisms for increased therapeutic efficacy are independent tumor cell killing (reducing CSC population) or superadded local effects by interaction with radiation-induced damages (e.g., inhibition of DNA repair, synchronization of cells in sensitive cell cycle phases). Combined therapy is also associated with additional and more severe toxicity due to a relatively unspecific cell killing by cytostatic drugs. With increasing knowledge of tumor biology and behavior, it has become possible to develop substances, antibodies and small molecules that specifically intervene in signal transduction pathways and modulate the reaction of the tumor cell to radiation. A well-known example is the epidermal growth factor receptor (EGFR) antibody Cetuximab. Studies showed an improved overall survival of the combination of Cetuximab and radiotherapy when compared with radiotherapy alone, but also uncommon side effects such as acne-like skin reaction. Conversely, other substances interacting in the EGFR pathway like tyrosine kinase inhibitors did not show the same effects in combination with radiotherapy. It is assumed that, in contrast to the small molecules, antibodies trigger an additional immune effect.

Another interesting approach is the combination of DNA-repair inhibitors with radiotherapy. Irradiation induces approximately 30–40 double-strand breaks per cell per Gy, of which almost all can be repaired by the tumor cells. The inhibition of this DNA-repair mechanism, for double-strand breaks especially nonhomologous end joining (NHEJ) and homologous recombination, leads to a strongly increased radiosensitivity and may furthermore improve the clinical outcome. Currently, a number of inhibitors of the DNA-dependent protein kinase, which is the key enzyme for NHEJ, are under investigations and the first are in clinical phase I testing. Beside the promising improvement of clinical outcome and tumor control, the side effects on normal tissue have to be considered and the therapeutic ratio for new combination treatments have to be evaluated.

A further quite new approach is the combination of radiotherapy with immunotherapy. The immune system has a complex structure with a plethora of parallel and consecutive, cellular and humoral processes to protect living beings against foreign substances, microorganisms or diseased tissues including malignant cells. The immune system is usually able to distinguish between own and foreign structures. Unfortunately, cancer cells develop mechanisms to escape from immune surveillance. The aim of immunotherapy is to stimulate the immune system to attack cancer cells. The currently most prominent example is the use of checkpoint inhibitors for CTLA-4 (e.g., Ipilimumab) or PD-1/PD-L1 (e.g., Pembrolizumab), which lead to a significant benefit in overall survival for patients with metastases in a number of tumor entities. Case reports and increasingly also clinical studies show that radiotherapy may lead to effects on metastases located outside the target area after or during Ipilimumab treatment. These so called abscopal effects are in line with data showing that radiotherapy can enhance the immune system by increasing vulnerability for T-cell-depending cell death, recruitment of T-cells to the treated tumor and induction of immunogenic cell death. To translate combinations of radio- and immunotherapy to clinical practice, a number of issues including dose fractionation, treatment sequence and the impact of irradiating adjacent lymphatic tissues on the immune response need to be clarified. To utilize the abscopal effects of radiotherapy in metastasized disease, another important question is how many and which lesions need to be irradiated. Beside of or in addition to combinations of radiotherapy with checkpoint inhibitors, other approaches such as addition of IL-2, usage of chimeric antigen receptor (CAR) cells and peptide or ribonucleic acid (RNA) vaccination, as well as the development of biomarkers are of current research interest.

Future

The advances in radiotherapy over the last years have led to an anatomical personalized and tumor-entity-specific treatment (e.g., fractionation, total dose, and chemotherapy). Further investigations are necessary according predictive and prognostic biomarkers for personalized treatment decisions and applications. These developments will lead to increased treatment efficiency and will avoid over- or undertreatment. Another important research field/aim is the identification and development of new selective and tumor-specific drugs for combination with radiotherapy to improve treatment outcome and reduce severe side effects and late tissue complications. Especially immunotherapy provides a range of potential combinations but also selective intervention in the DNA-repair and survival pathways seems promising. The focus of technical developments will be on clinical studies using particle therapy and on the establishment of fully image-guided particle therapy. Furthermore, individualized concepts for regular adaption during radiotherapy in a quick and uncomplicated way will gain in importance to cope with patient- and target-specific alterations using the entire range of technical possibilities of modern radiation oncology.

Introduction

Radiation therapy (RT) is a popular treatment modality for many cancer patients. Recent advances in RT technology, along with surgical procedures and chemotherapy, have significantly increased the lifespan of cancer patients (DeSantis et al., 2014). However, many patients suffer adverse effects from RT, one of them being the development of secondary malignant neoplasms, or SMNs (Suit et al., 2007). This is especially apparent in survivors of prostate, breast, and pediatric cancers (Sountoulides et al., 2010; Ning et al., 2011; Choi et al., 2014). It is estimated that 1 in 12 cancer survivors develop a secondary malignancy and greater than half will succumb to the occurrence of secondary cancer (Donin et al., 2016). Additionally, time from exposure plays a major role, as the relative risk (RR) of survivors of childhood cancers for developing any SMN after RT was 2.7, and RT was the highest independent risk factor for SMN development (Choi et al., 2014). However, it should be noted that the incidence of RT-induced SMN is difficult to calculate, as many patients will develop SMNs due to other genetic abnormalities and lifestyle choices (e.g., tobacco and alcohol use) (Vaughan et al., 1995). Whether SMNs arise from metastatic cohorts of the primary tumor or develop as completely new tumors that are unrelated to the primary is a controversial subject. This review will specifically discuss how radiation-induced metastasis contributes to the development of SMN (**Fig. 1**), the mechanisms by which this occurs, and future perspectives to overcome metastatic-induced SMN development.

Radiobiology

The main goal of radiation therapy is to damage as many tumor cells as possible while not impacting normal cells. Radiation can target tumor cells both directly and indirectly. Direct damage by RT occurs when energy is directly absorbed by nuclear DNA and induces DNA damage that is hard to repair, especially in tumor cells that lack specific DNA repair mechanisms (Altmeyer and Lukas, 2013; Thompson, 2012; Hunt et al., 2013; Lavelle and Foray, 2014). Indirect DNA damage occurs when molecules within the tumor microenvironment, such as oxygen, absorb energy emitted from RT and become molecules that are highly reactive (ROS, reactive oxygen species) and damaging to DNA (Widel et al., 2014; Cadet and Wagner, 2013; Alan Mitteer et al., 2015). Hence, tumor cells are more susceptible to damage by RT than normal cells as they continuously copy their DNA in order to proliferate. When tumor cells are unable to repair genomic DNA, they initiate apoptosis or cellular suicide (Alan Mitteer et al., 2015). On the other hand, normal cells have appropriate DNA repair mechanisms in place and are able to survive fractionated RT. However, some cancerous cells survive RT because of their microenvironment or mutation status, primarily loss-of-function mutations in the DNA damage response pathway or gain-of-function mutations in DNA repair pathways. It is quite likely that RT-induced DNA damage results in faulty repair, which introduces further mutations in tumor cell DNA and may confer selective advantage to those cells or emergence of RT-resistant cells (Van Houten et al., 2018; Weeden and Asselin-Labat, 2018; Chang et al., 2015; Cao et al., 2002). These RT-resistant cancer cells are highly aggressive and confer metastatic behavior leading to the progression of disease.

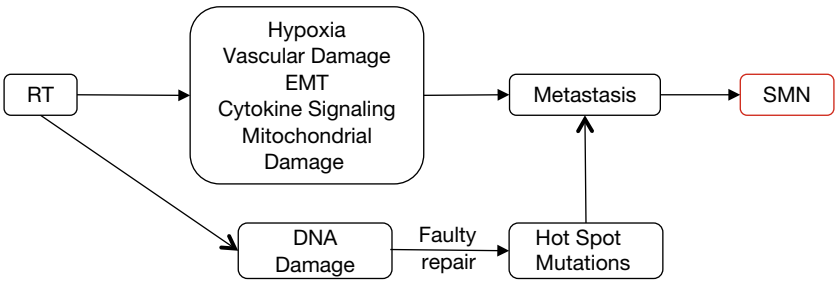

Fig. 1 RT induces metastasis to facilitate SMN development. A graphical representation depicting the mechanisms by which RT potentiates metastasis, ultimately leading to SMN development.

Mechanisms of Radiation-Induced Metastasis

Epithelial-Mesenchymal Transition

Epithelial cells are round in shape and typically resemble a cobblestone phenotype (Gonzalez and Medici, 2014). They express markers such as E-cadherin and maintain cell polarity with distinct apical and basal membranes (Wodarz and Nathke, 2007). Epithelial cells form adherent and tight junctions with other neighboring cells and prefer to stay in one place. Meanwhile, mesenchymal cells express markers such as vimentin, are more elongated than epithelial cells and display spindle-like profusions and lose polarity with respect to their apical and basal membranes (Gonzalez and Medici, 2014). Because of their genetic characteristics and phenotype, mesenchymal cells readily migrate. Although migratory potential plays a critical role in tumor cell dissemination, cells must also be able to invade the surrounding tumor microenvironment (TME) (Quail and Joyce, 2013). Mesenchymal cells typically express and secrete proteins such as matrix metalloproteinases (MMPs) that degrade TME (Gilkes et al., 2013). Thus, epithelial-mesenchymal transition (EMT) is the first step in tumor cell dissemination, as epithelial tumor cells must acquire migratory and invasive characteristics before they can disseminate from the primary tumor.

Several studies have already investigated the link between RT and EMT. In an orthotopic model of hepatocellular carcinoma, RT induces greater dissemination of primary tumor cells and development of distant metastatic lesions compared to the non-irradiated tumor cells (Li et al., 2011). Tumors receiving RT show increased protein expression of mesenchymal markers such as N-cadherin and vimentin along with concomitant loss of E-cadherin (Li et al., 2011). Interestingly, the transmembrane protease, serine 4 (TMPRSS4) seems to control RT-induced EMT in vivo (Li et al., 2011). This is an important observation because TMPRSS4 is overexpressed or mutated in various cancers and is associated with malignant phenotypes, most notably invasion and remodeling of the extracellular matrix, which are considered a pre-requisite for metastasis (de Aberasturi and Calvo, 2015). A similar study was performed using rat glioma cells, whereby irradiation of tumor cells induced EMT, invasion, and development of metastatic lesions in an in vivo model (Park et al., 2012). Human specimens have also been tested for the role of RT in metastasis. In this regard, a recent study profiled human prostate cancer samples for EMT markers pre- and post-RT (Stark et al., 2017). Indeed, EMT occurred after RT in those prostate cancer patients as evidenced by an increase in vimentin, a decrease in E-cadherin and a decrease in the cytoskeleton remodeling protein cofilin (Stark et al., 2017). As mentioned previously, cytoskeleton remodeling is an essential step in EMT, as cells must become de-polarized in order to migrate. Cytoskeleton remodeling changes the biomechanical makeup of single cells as observed via atomic force microscopy in tongue squamous cell carcinoma (TSCC) cells after X-ray irradiation (Zheng et al., 2015). Specifically, TSCC cells decreased in height, became more elongated, and actin fibers were disorganized after X-ray radiation, which allows the cells to de-polarize and for migration to occur (Zheng et al., 2015).

Vascular Damage

RT damages the TME in several ways, including demolishing vasculature of TME (Juntermanns et al., 2014; Sabatasso et al., 2011; Grabham et al., 2012; Zywietz, 1990; Kinoshita et al., 2014). Tumors require vasculature for oxygen and nutrient supply. If the primary tumor becomes too large, tumor cells will have no access to oxygenated blood vessels and become hypoxic and nutrient-deprived. In this scenario, many tumors will create their own blood vessels to connect to the main vasculature system, a process known as angiogenesis. High dose RT has been shown to severely damage tumor vasculature, which also leads to hypoxic conditions in tumors post-RT (Juntermanns et al., 2014; Sabatasso et al., 2011; Grabham et al., 2012; Zywietz, 1990; Kinoshita et al., 2014). High dose RT-induces activation of HIFs (hypoxia-inducible factors), most importantly HIF-1α and 2α leading to the activation of several signaling cascades including stress response pathways and secretion of various pro-survival cytokines and chemokines, which are discussed later in this article. However, low dose RT activates several pathways involved in angiogenesis and metastasis (He et al., 2013; Sofia Vala et al., 2010). One such study demonstrated that in hepatoma cells, low dose RT induces vascular endothelial growth factor (VEGF) secretion and MMP2 activation, both of which seem to rely on p53 activation by low dose RT (He et al., 2013). VEGF is a family of cytokines that initiate angiogenesis after binding to their receptor, VEGFR, on endothelial cells and as previously mentioned, MMP's degrade the TME to allow for cell dissemination (Vempati et al., 2014). In another study, low dose RT initiated endothelial cell migration and angiogenesis in the zebrafish fin regeneration model, as well as increased invasion in a murine matrigel plug assay—all of which seem to rely on VEGF activation (Sofia Vala et al., 2010). In addition, RT has been reported to alter the expression of cell adhesion proteins like ICAM-1, VCAM-1 and selectins on tumor-associated endothelial cells, thus further contributing towards alteration of the TME (Gaugler et al., 1997; Hallahan and Virudachalam, 1999).

Hypoxia

It has long been established that low oxygen levels within the tumor microenvironment, or hypoxia, promote the development of aggressive cancer phenotypes including metastatic potential (Gilkes et al., 2014). Hypoxia is also a contributing factor of resistance to RT. As previously mentioned, molecular oxygen is one of the main molecules that absorb energy from radiation to transform into damaging reactive oxygen species (ROS). Therefore, low oxygen levels inhibit DNA damage produced by indirect RT damage. Chronic hypoxia potentiates the development of a dysfunctional TME, so there are underlying mechanisms that tumor cells activate in order to escape the harsh environment (Hemmerlein et al., 2001; Ji, 2014; Mimeault and Batra, 2013). Low oxygen levels activate the transcription factor hypoxia inducible factor 1 (HIF-1α). HIF-1α is responsible for inducing transcription of genes involved with metastasis, such as VEGF, MMP-2, TGF-A, vimentin, and c-Met (Krishnamachary et al., 2003; Pennacchietti et al., 2003; Semenza,

2003). Activation of these genes promotes migration and invasion of tumor cells and in this way allow tumor cells to escape the hypoxic conditions. HIF-1α not only promotes the activation of migratory genes, but also induces angiogenic genes. For example, a recent study demonstrated that HIF-1α levels increase in response to RT, but also modulate VEGF expression levels (Fu et al., 2015). Interestingly, HIF-1α can be activated by RT under both normoxic and hypoxic conditions in glioma cells (Kim et al., 2014). Thus, HIF-1α and the hypoxic tumor microenvironment promote both radio resistance and metastasis.

Mitochondrial Damage

Mitochondria contain their own DNA, referred to as mitochondrial DNA or mtDNA. Unlike nuclear DNA, mtDNA is not wrapped around protective histones and lacks DNA repair proteins and is therefore more susceptible to damage than nuclear DNA (Croteau and Bohr, 1997). Thus, mtDNA is more sensitive to DNA-damaging agents including RT and RT-induced ROS. The mitochondrial proteome consists of a delicate balance between nuclear- and mitochondrial-encoded genes. Specifically, the mitochondrial genome contains 13 structural genes that encode subunits of the electron transport chain. The stoichiometry between nuclear- and mitochondrial-encoded genes must be kept constant or a "mitochondrial (mito)-nuclear imbalance" will occur (Karpac and Jasper, 2013; Houtkooper et al., 2013). A mito-nuclear imbalance can occur whenever mtDNA is damaged, mutated, amplified or depleted (Karpac and Jasper, 2013; Houtkooper et al., 2013). Mito-nuclear imbalances lead to defective oxidative phosphorylation, the generation of ROS and ultimately cell death in normal cells if the proper repair mechanisms are not set in place (Karpac and Jasper, 2013; Houtkooper et al., 2013). However, tumor cells have adapted the ability to hijack and prolong the mitochondrial unfolded protein response (mt^{UPR}), a stress response system that alleviates mitochondrial damage through activation of mitochondrial-specific proteases, chaperones and antioxidants (Kalen et al., 2017; Fiorese et al., 2016; Jovaisaite et al., 2014; Shpilka and Haynes, 2017; Pellegrino et al., 2013; Mouchiroud et al., 2013). In this way, the mt^{UPR} increases the apoptotic threshold and promotes cell survival even in the presence of mitochondrial stressors. Importantly, the mt^{UPR} was shown to be activated in response to RT in *Caenorhabditis elegans* (Li et al., 2017). Additionally, irradiation was shown to change mtDNA copy number, damage mtDNA and alter mtDNA structure, all of which are known activators of mt^{UPR} (Zhang and Okunieff, 2014; Zhou et al., 2011, 2012). Other studies have demonstrated that mtDNA-depleted cells increase cell survival in response to RT and employ different mtDNA replication modalities in response to low dose RT, which ultimately preserves mitochondrial maintenance (Torregrosa-Munumer et al., 2015; Nieri et al., 2013). Thus, cancer cell mitochondria can be preserved, despite being damaged by RT, due to mt^{UPR} activation (**Fig. 2**).

Several studies have explored the relationship between mitochondrial dysfunction and metastatic potential, thus establishing a concrete link between mitochondria and metastasis. For example, mtDNA-depleted cells are reported to have elevated metastatic potential (Moro et al., 2008, 2009). Additionally, mutated mtDNA associates with increased migration and invasion of cancer cells (Arnold et al., 2015; Imanishi et al., 2011; Ishikawa et al., 2008). One of the best methods to study the influence of mutant mtDNA on metastasis is through cybrid technology, whereby mtDNA is transferred from one cell to another (Ishikawa et al., 2008). In this way, the direct effect of mtDNA mutations on different phenotypes can be assessed. Indeed, when mutated mtDNA was transferred into a non-invasive cell line, the non-invasive cell line became highly invasive (Ishikawa et al., 2008). On the contrary, the replacement of mtDNA from a highly metastatic cell line, MDA-MB-231, with mtDNA derived from normal human cells suppressed metastatic potential (Imanishi et al., 2011). Overall, it is clear that RT induces mitochondrial damage, and damaged mitochondria contribute to an invasive phenotype.

Cytokine/Chemokine Signaling

Tumor cells develop within a TME where they communicate with stromal cells to sustain their growth and survival (Quail and Joyce, 2013). This communication between these cells may be through either direct cell-to-cell interaction or via cytokines and chemokines. Similar to RT, disruption of this TME can produce both beneficial and undesirable outcomes. Although RT is known to be directly cytotoxic towards tumor cells, radiation can also cause the release of various pro-inflammatory cytokines and growth factors like FGF (fibroblast growth factors), EGF (epidermal growth factors) and TGF (transforming growth factors) within the TME to promote cell migration, invasion, and metastatic progression.

For example, in response to RT, non-small cell lung cancer (NSCLC) cells experience an increase in the stability of β-catenin, subsequent activation of the PI3K/Akt pathway, followed by release of granulocyte-colony-stimulating factor (G-CSF) (Cui et al., 2015). Acting in an autocrine manner, G-CSF triggers the G-CSFR/JAK1/STAT3 signaling pathway to induce EMT of NSCLC cells (Cui et al., 2015). In addition, RT promotes HIF-1α signaling in NSCLC to enhance CXCR4 expression. CXCR4 expression increases sensitivity to CXCL12 and this CXCL12/CXCR4 interaction activates the Akt and ERK1/2 pathways to enhance MMP-2 and MMP-9

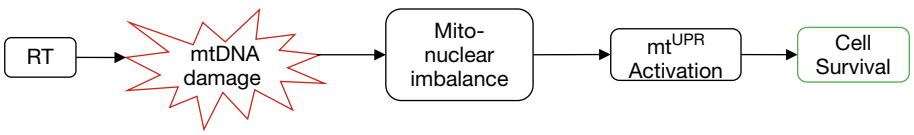

Fig. 2 Mt^{UPR} is activated by RT and potentiates cell survival. A graphical representation that describes how RT induces mitochondrial damage and promotes cell survival via the unfolded protein response.

expression, which in turn increase the invasiveness of NSCLC cells (Gu et al., 2015). RT also stimulates the release of IL-6, which acts in an autocrine manner to enhance CCL2 and CCL5 secretions and attracts macrophages to the tumor site (Wang et al., 2017) (Fig. 3A).

Similarly, RT of breast cancer cells causes the release of granulocyte-macrophage colony-stimulating factor (GM-CSF), which promotes tumor cell invasion as well as recruitment of circulating tumor cells at distant metastatic sites (Vilalta et al., 2014) (Fig. 3B). Additionally, both breast cancer and renal cell carcinoma cells release macrophage migration inhibitory factor (MIF) due to RT (Gupta et al., 2016) (Fig. 3C), a factor known to promote metastasis (Simpson et al., 2012; Lv et al., 2016). Notably, during breast cancer RT the lung experiences radiation as well. This causes the release of CXCL12 by lung epithelial cells, which enhances the migratory activity of breast cancer cells and promotes lung-specific metastasis (Feys et al., 2015) (Fig. 3B).

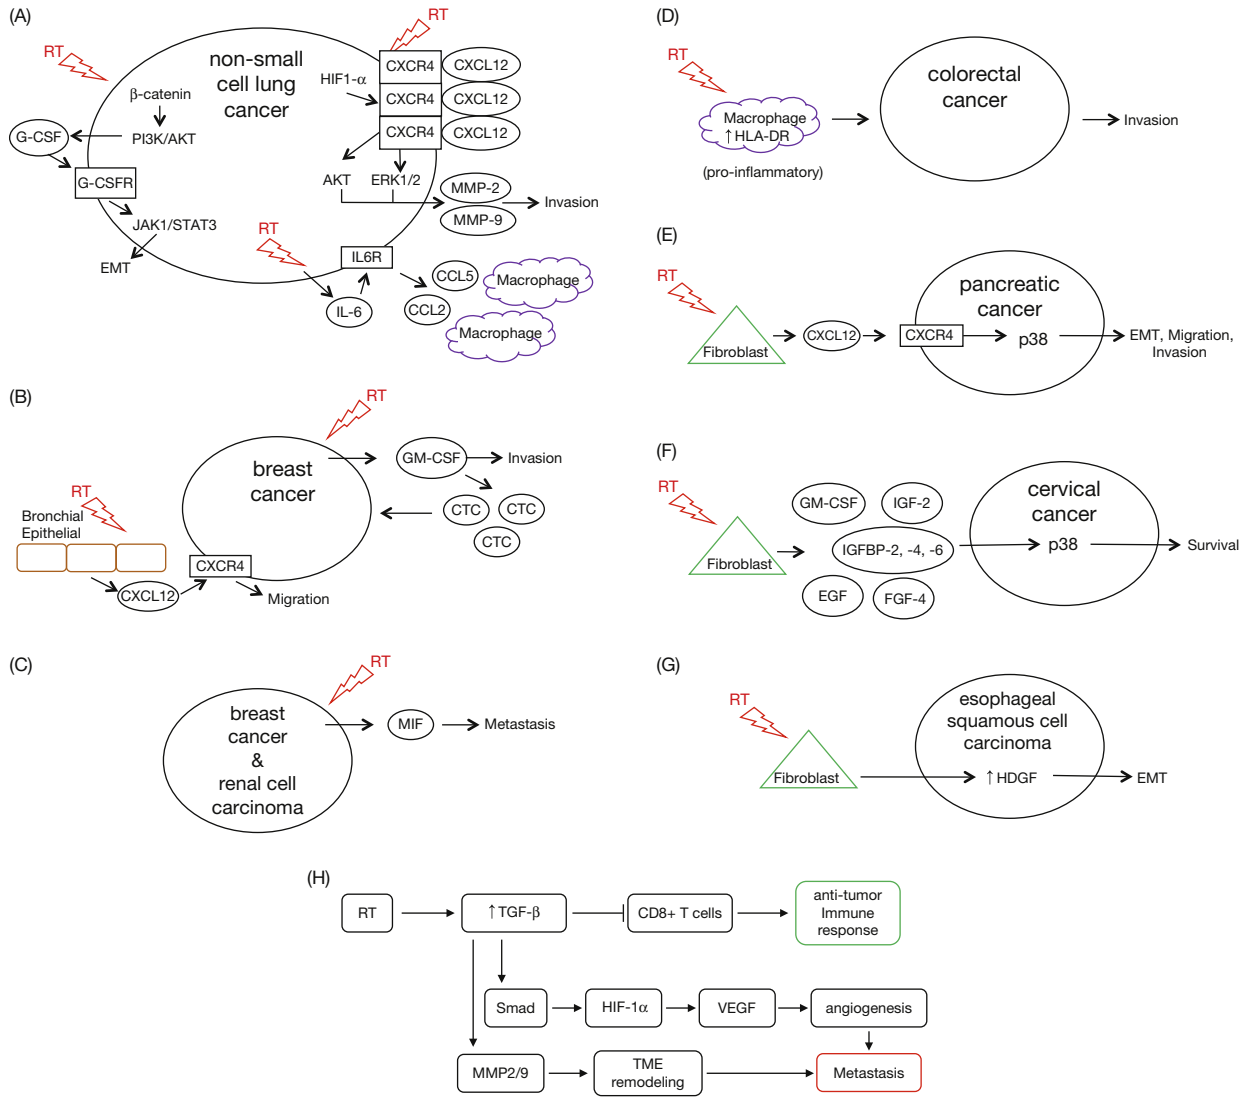

Fig. 3 RT induces the release of cytokines, chemokines, and growth factors within the tumor microenvironment to promote metastasis. (A) In non-small cell lung cancer, RT causes the release of G-CSF that acts in an autocrine manner to induce EMT. RT upregulates CXCR4 expression to enhance MMP-2 and MMP-9 secretion and promote invasion. RT induces the release of IL-6, which acts through autocrine signaling to promote the release of CCL2 and CCL5 which attract macrophages. (B) In breast cancer, RT causes the release of GM-CSF, which promotes invasion and attracts circulating tumor cells (CTCs) at metastatic sites. Also, RT induces the release of CXCL12 by bronchial epithelial cells of the lung, which in turn enhances the migration of breast cancer cells. (C) RT causes the release of MIF by breast cancer and renal cell carcinoma cells to promote metastasis. (D) RT induces macrophages towards a pro-inflammatory phenotype that act upon colorectal cancer cells to promote invasion. (E) RT induces the release of CXCL12 by fibroblasts that acts upon pancreatic cancer cells to promote EMT, migration, and invasion. (F) RT prompts the secretion of GM-CSF, IGF2, IGFBP-2, -4, -6, EGF, and FGF-4 by fibroblasts to enhance survival of cervical cancer cells. (G) During RT, fibroblasts act on esophageal squamous cell carcinoma cells to upregulate HDGF and promote EMT. (H) RT induces expression of TGF-β, which inhibits the anti-tumor immune response and promotes metastasis.

Stromal cells such as macrophages and fibroblasts influence the metastatic potential of tumor cells. Although RT inhibits the invasive ability of colorectal cancer cells, RT-treated macrophages are able to restore and even enhance their invasive properties due to a shift towards a pro-inflammatory phenotype, which includes increased expression of HLA-DR (Teresa Pinto et al., 2016) (**Fig. 3**D). Fibroblasts from pancreatic tumors secrete CXCL12 in response to RT, and in turn this CXCL12 acts through CXCR4 to activate the p38 MAPK pathway and promote epithelial-mesenchymal transition (EMT), migration, and invasion of pancreatic cancer cells (**Fig. 3**E). In vivo, this RT-induced CXCL12/CXCR4 interaction accelerates the growth of lung metastases (Li et al., 2016). Similarly, cervical cancer-associated fibroblasts activate p38 in HeLa cells to increase their survival after RT. The release of granulocyte-macrophage colony-stimulating factor (GM-CSF), insulin-like growth factor 2 (IGF2), insulin-like growth factor binding proteins (IGFBP)- 2, -4, -6, epidermal growth factor (EGF), and fibroblast growth factor 4 (FGF-4), by fibroblasts may contribute to cancer cell survival (Chu et al., 2014) (**Fig. 3**F). RT-treated fibroblasts from esophageal squamous cell carcinoma (ESCC) tissue enhance the migratory and invasive properties of ESCC cells by induction of epithelial-mesenchymal transition (EMT). These effects are initiated by the upregulation of hepatoma-derived growth factor (HDGF) in ESCC due to interactions with RT-treated fibroblasts (Bao et al., 2015) (**Fig. 3**G).

RT also modulates anti-tumor immunity and promotes the elusion of tumor cells against anti-tumor immune responses (**Fig. 3**H). The major factor modulating anti-tumor immune response is TGF-β, which acts by inhibiting the differentiation of $CD8^+$ cytotoxic T cells, as well as inhibiting the expression of cytolytic proteins in these cells, which include granzymes, perforin, fas ligand, IFN-γ, etc. Without these factors, cytotoxic T cells fail to impart its cell death-inducing function on its target tumor cells (Thomas and Massague, 2005). In addition, TGF-β also modulates the function of other immune cells in the TME like dendritic cells, a subtype of antigen presenting cells, which lose their ability to activate T cells (Geissmann et al., 1999). Furthermore, TGF-β induces angiogenesis, TME remodeling, EMT, and therefore, promotes metastasis in solid tumors (Padua and Massague, 2009). The pro-metastatic ability of TGF-β has been attributed to its ability to activate HIF-1α and Smad signaling pathways, which in turn induce the expression of VEGF and MMPs (MMP2 and MMP9). TGF-β is known to promote EMT by suppressing the expression of E-cadherin and other junction proteins by activation of Snail and Slug transcription factors and MAPK pathway molecules (Oft et al., 1996). Taken together, enhanced expression of TGF-β expression in TME post-RT has been a significant problem and may be one of the main reasons behind emergence of SMNs.

Therapeutic Approaches to Overcome RT-Induced Metastasis

Several studies have investigated how to surmount this negative side effect of RT (**Fig. 4**). For example, HIF-1α is a frontrunner for therapeutic development since it is activated both by hypoxia and RT, regulates EMT and angiogenesis and participates in cross-talk with the TME (Hu et al., 2013). Several HIF-1α inhibitors have shown promising results and may have potential for clinical use, such as silibinin and everolimus, each of which work by blocking mTOR and thus inhibit HIF-1α translation (Garcia-Maceira and Mateo, 2009; Cejka et al., 2008). The FDA-approved HDAC inhibitor SAHA (vorinostat) also inhibits HIF-1α transcription and activity and was shown to decrease metastatic spread in several cancer types (Zhang et al., 2017; Shankar et al., 2009). Furthermore, there are many HIF-1α inhibitors being tested in a preclinical setting.

The angiogenic factor VEGF has been targeted as well, but with mixed outcomes (Heist et al., 2015; Papadimitriou et al., 2015; Rahbari et al., 2016; Das et al., 2014). For example, bevacizumab is an FDA approved monoclonal antibody that targets VEGF and inhibits angiogenesis (Panoilia et al., 2015). However, the success of this agent is short-lived and the cancer typically recurs in a few months (Carmeliet and Jain, 2011). Recently, Rahbari et al. have demonstrated that bevacizumab alters the extracellular matrix and induces stiffness via hyaluronic acid aggregation of liver metastatic sites in metastatic colorectal mouse models, and that targeting hyaluronic acid build-up sensitizes these models to treatment with bevacizumab (Rahbari et al., 2016). Thus, anti-VEGF therapy may still be beneficial as long as the proper agents are targeted in combination.

Recently, radio immunotherapy (RIT) (Behr et al., 2002) also gained much consideration as targeted therapy against tumor cells. Tumor-specific antibodies conjugated with chemotherapeutic agents or radioisotopes have been shown as a targeted

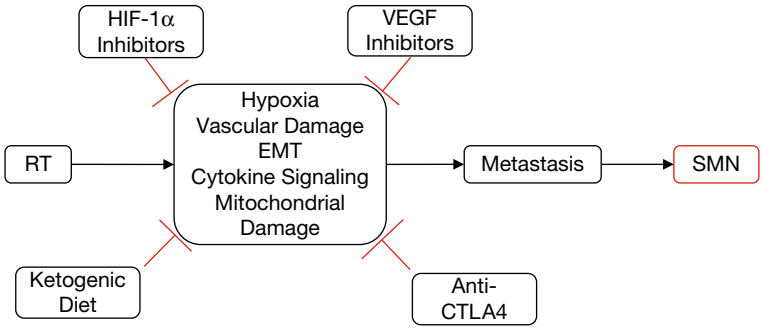

Fig. 4 Potential therapeutic approaches to overcome RT-induced SMN. A flowchart describing advances in therapeutic approaches to inhibit metastatic-induced SMN development.

delivery method to tumor cells with minimal exposure to adjacent normal cells. In this regard, CD20 targeting antibodies ibritumomab tiuxetan (Zevalin) conjugated with yttrium-90 (Y-90) and tositumomab (Bexxar) conjugated with iodine-131 (I-131) were used for treatment of non-Hodgkin's lymphoma (Ghobrial and Witzig, 2004). RIT has also shown promise for treatment of metastatic cancers such as colorectal (Behr et al., 2002) and prostate (O'Donnell et al., 2001). More research needs to be done to analyze the effect of radioisotope-conjugated antibodies on tumor stroma and other immune cells in the TME.

Lifestyle choices can also impact response to RT. Most notably, a calorie restricted or ketogenic diet (KD) has shown promising results. Specifically, KD combined with RT was demonstrated to have a greater anti-tumor affect than RT alone (Abdelwahab et al., 2012; Allen et al., 2013). Since KDs are low in carbohydrates, and tumor cells require carbohydrates for glycolysis, KDs selectively starve out the cancer cells (Lv et al., 2014). Additionally, the lack of carbohydrates pushes the cancer cell to use oxidative phosphorylation over glycolysis, which promotes the generation of mitochondrial ROS and induces damage.

Ironically, RT itself has been implicated to act as a type of anti-cancer vaccine by activating tumor-specific T-cells, and is reviewed extensively in (Demaria et al., 2016). To summarize, the common problem in immunotherapy is the concept of sensitizing tumor cells to immunotherapy, or turning "cold" tumors into "hot" ones (Gajewski, 2015). The basic premise is that dendritic cells must activate T-cells, and these activated T-cells must be able to successfully infiltrate the tumor microenvironment in order for immunotherapy to be effective. However, refractive tumor microenvironments have poor T-cell infiltration. Several approaches have been put forth to overcome this barrier. An interesting approach, the combination of RT with the anti-Cytotoxic T-lymphocyte-Associated Protein 4 (CTLA-4, an immunosuppressive protein receptor), has shown to decrease growth of the primary tumor and metastatic spread in several mouse models of breast cancer (Demaria et al., 2005; Dewan et al., 2009). The combination of RT with anti-CTLA-4 has also demonstrated clinical benefit, as metastatic lesions and tumor burden were both decreased in patients with metastatic non-small cell lung cancer and metastatic melanoma after the combination therapy (Golden et al., 2013; Hiniker et al., 2012). These results are both promising and surprising, as RT was previously thought to be strictly immunosuppressive. However, these results demonstrate that the immunogenicity of RT may be circumstantial with regards to cancer biology. In addition, TGF-β also causes anti-tumor immune suppression in the TME by inhibiting $CD8^+$ cytotoxic T cells as well as promotes metastasis by inducing HIFs and Smad signaling. Therefore, TGF-β inhibitors in the form of small molecules and neutralizing antibodies have been extensively studied and it is safe to assume that in combination with RT, TGF-β inhibition will be helpful in inhibiting SMN development post-RT by activating the immune response and inhibiting metastasis.

Concluding Remarks

RT is a useful anti-cancer tool. Its long-term use in the clinical setting is evidence of its efficacy. The risk of developing SMNs after RT is well described but it is seen as a necessary risk to cancer patients that have no other options. In this modern era, we have made impressive advances in understanding how SMNs develop with respect to RT-induced metastasis. Because of these recent advances, new therapeutic targets are currently being characterized and validated in order to prevent RT-induced metastasis. Nonetheless, all of these advances have helped to better our understanding of tumor biology and will pave the way for new therapeutic ideas and approaches to combat RT-induced metastases with the ultimate goal of eliminating the risk of SMN development in cancer survivors.

Renal Cell Cancer: Pathology and Genetics

Sean R Williamson, Henry Ford Cancer Institute, Henry Ford Health System, Detroit, MI, United States; and Wayne State University School of Medicine, Detroit, MI, United States

Glossary

Cytogenetics The study of chromosomal structure and function.
Histology Microscopic study of tissues.
Immunohistochemistry Detection of proteins in tissue samples using antibody-based staining techniques.
Nephron The microscopic functional and structural unit of the kidney, composed of the glomerulus and renal tubule.
Renal cell carcinoma Cancer of the kidney that is thought to recapitulate the phenotype of the renal tubules.
Renal tubules Structures that carry urine and modify its salt and water composition after filtration by the kidney.

Introduction

In adults, most cancers of the kidney are renal cell carcinomas, tumors that are largely thought to recapitulate the phenotype of cells of the tubules of the nephron. A smaller subset of kidney cancers are urothelial carcinomas originating from the urothelial lining of the renal pelvis or ureter, and rarer are sarcomas and mesenchymal tumors of the kidney. This article summarizes the pathology and genetics of the most common form of adult kidney cancer, renal cell carcinoma. This cancer type is somewhat unique compared to those of many other organs, in that tumors often form predominantly spherical masses, a growth pattern that is prototypically associated with benign tumors, and they do not necessarily exhibit the characteristic pattern of infiltrative, crab-like growth for which cancer is named. Nonetheless, renal cancer is known for sometimes surprising behavior, including metastasis decades after the first diagnosis, and sometimes unusual sites of metastases, such as to the pancreas or visceral organs. With increasing sophistication of radiologic imaging and more widespread use of imaging, however, there is also a shift toward detecting renal cancers at an earlier stage, in which case the treatment paradigm has begun to shift toward less aggressive and nonsurgical management of early-stage tumors.

Epidemiology

Kidney cancer is approximately the eighth most common site of cancer diagnosis, with 60,000 cases estimated to be diagnosed in the United States in 2017. Renal cell carcinoma is more common in men, in countries with higher levels of socioeconomic development, particularly northern and eastern Europe, North America, and Australia, and in particular the Czech Republic has the highest incidence, for incompletely understood reasons. Risk factors include obesity, smoking, hypertension, acquired cystic kidney disease (cystic changes of the kidney from long-term renal failure, usually associated with dialysis), and occupational exposure to certain chemicals. A subset of renal cancers is found in the setting of hereditary susceptibility, estimated to make up about 2%–4%, with each syndrome tending to associate with a specific tumor histology. These are discussed in more detail with each type of renal cancer in this article.

Clinical Management

Usual clinical management for localized (non-metastatic) renal cancer includes local treatment of the primary tumor, most typically in the form of radical nephrectomy (removal of the entire kidney) or partial nephrectomy (surgical removal of only the tumor with a small rim of normal kidney tissue). For the most part, adjuvant therapy is not employed in addition to surgical resection in the setting of localized kidney cancer; however, this remains an area of exploration with ongoing clinical trials evaluating possible roles for adjuvant therapies in high-risk patients. Alternate therapies to surgery are also increasingly considered, especially in patients whose health status would make surgery riskier, such as cryoablation or radiofrequency ablation of the tumor. Metastatic kidney cancer, in contrast, is typically managed with one or more chemotherapeutic treatment pathways, including interleukin-2 (IL-2) or interferon therapy, molecularly-targeted agents, and more recently, anti-PD-1/PD-L1 therapies that modulate immune response. Nonetheless, metastatic kidney cancer is typically a progressive disease that is rarely, if ever, completely cured.

Renal Mass Biopsy

Renal cell cancer also differs somewhat from other cancers in that a diagnostic tissue sample or biopsy is not as a rule undertaken prior to proceeding with definitive surgery, since a solid and/or vascular renal mass identified by radiographic imaging is usually

considered presumptive malignancy until proven otherwise. A relatively small number of renal masses are proven benign, predominantly angiomyolipomas (which can often be diagnosed by the presence of fat on imaging studies and therefore biopsy or surgery avoided) and oncocytomas (approximately 5% or less of renal masses), which remains difficult to distinguish from renal cell carcinoma by imaging. This, combined with historical fears of "seeding," or causing tumor cells to implant into the soft tissue of the biopsy site, among other factors, had resulted in limited use of renal mass biopsies in the past.

However, more recently, the paradigm for kidney cancer management has begun to shift, with historical fears of safety and efficacy and renal mass biopsy largely mitigated. Now, renal mass biopsies are increasingly used, especially in patients for whom a small renal mass is identified, especially in the setting of other medical comorbidities, such that surgery or other treatment may be risky. In this context, various strategies, such as surveillance, ablation, and surgery are now more widely tailored to the patient, based on biopsy information and patient factors. Likewise, in the setting of metastatic renal cancer, a biopsy may be the only confirmation of tumor histology, used to select tumor-specific treatment options or to employ molecular studies in search of targetable treatment.

Clear Cell Renal Cell Carcinoma

Clear cell renal cell carcinoma is by far the most common subtype of renal cell cancer, making up at least 60%–75% of adult tumors, although novel entities continue to be extracted from this category based on refined understanding of genetics and subtle differences in histology. Clinical presentation has become more variable for these tumors in current practice, as many are now recognized incidentally when radiographic imaging is done for other reasons, in contrast to historically larger tumors that presented with clinical symptoms, such as hematuria or flank pain or mass. However, generally, clear cell renal cell carcinomas form spherical masses that can be endophytic, entirely within the kidney, or can bulge well beyond the normal contour of the kidney and substantially distort its shape. This often-spherical configuration differs from many other cancers that prototypically have an infiltrative growth pattern with stromal reaction, or desmoplasia. In contrast, invasion by renal cell carcinoma often manifests as subtler, tongue-like, rounded protrusions into veins or soft tissue.

The characteristic gross pathologic appearance of clear cell renal cell carcinoma includes a bright, golden-yellow cut surface, although this may vary with the presence of hemorrhage or cystic areas, imparting red-brown areas or fluid-filled spaces (Fig. 1). Microscopically, clear cell renal cell carcinoma prototypically is composed, as its name suggests, of cells with empty-appearing (clear cytoplasm), resulting from cytoplasmic lipid and glycogen (Fig. 2). However, the histologic appearance can also be quite variable, especially in tumors of higher grade, which can have eosinophilic cytoplasm (historically often known as "granular cell renal cell carcinoma") and a variety of unusual patterns.

Immunohistochemistry

Due to alterations in the von Hippel-Lindau gene (*VHL*) pathway, these tumors characteristically demonstrate upregulation of multiple downstream targets of the *VHL* gene, which has led to several targeted therapies against these pathway components. In pathologic practice, diagnostic immunohistochemical staining can demonstrate diffuse membrane positivity for carbonic anhydrase IX (Fig. 3), a downstream element of the hypoxia pathway, which has been found to be helpful for diagnosis of clear cell renal cell carcinoma and debatably in some settings possibly a prognostic marker. Radiographic imaging techniques directed against carbonic anhydrase IX have also been tested in some centers as a possible mechanism to support the diagnosis prior to tissue sampling. In contrast to adenocarcinomas of many other organs, clear cell renal cell carcinomas are usually negative for cytokeratin 7, and therefore they are usually among the group of adenocarcinomas that are positive for neither cytokeratin 7 nor 20, two

Fig. 1 The characteristic gross appearance of clear cell renal cell carcinoma is often *bright yellow*. This tumor includes a mixture of *yellow* and *red-brown* areas, as well as cystic spaces.

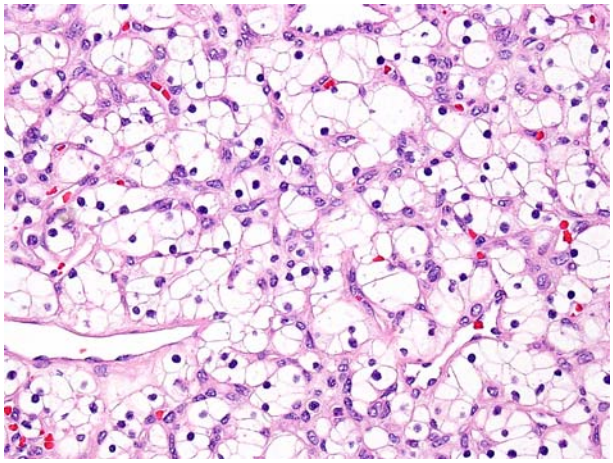

Fig. 2 The classic microscopic appearance of clear cell renal cell carcinoma includes a nested arrangement of cells with empty-appearing (clear) cytoplasm, although a wide variety of patterns can occur, especially in higher grade tumors.

markers which are often used in assessment of metastatic carcinoma from an unknown origin. Immunohistochemistry for paired box gene 8 (PAX8) has emerged in pathologic practice as a lineage-specific marker for renal cell tumors (among other tumors, such as gynecologic and thyroid tumors). Although not specific for clear cell renal cell carcinoma, labeling for this antigen can be used to support an origin from renal cancer in the appropriate context. Additionally, many renal cell carcinomas, including clear cell renal cell carcinoma, share the feature of reactivity for both epithelial markers and vimentin. Although the latter is nonspecific, it is generally considered a marker of mesenchymal lineage and dual reactivity for both epithelial markers and vimentin is somewhat more restricted to specific cancer types, especially renal cell and endometrial cancer. Interestingly, renal oncocytoma, a benign renal cell neoplasm, and chromophobe renal cell carcinoma, discussed additionally later, essentially always lack reactivity for vimentin. In general, it is thought that the cells of clear cell renal cell carcinoma, and most renal cancers, have a phenotype or "cell of origin" resembling the proximal tubules of the nephron.

Genetics

Clear cell renal cell carcinoma, as the most common form of adult kidney cancer, has paved the road for understanding of renal cancer genetics, based on work identifying the *VHL* gene and chromosome 3p25 (the region where the *VHL* gene is located) as critical in the development of these tumors. Patients with the syndrome VHL disease have germline mutations of the *VHL* gene and develop multiple tumors, including clear cell renal cell carcinoma of the kidney, pheochromocytomas of the adrenal gland, neuroendocrine tumors of the pancreas, pancreatic cysts, renal cysts, and hemangioblastomas of the central nervous system and retina, among others. Knowledge of the *VHL* gene can also be extrapolated to the sporadic setting (patients without germline mutation), in which patients likely progress through a two-hit mechanism to tumor development, whereas in VHL patients already harbor one

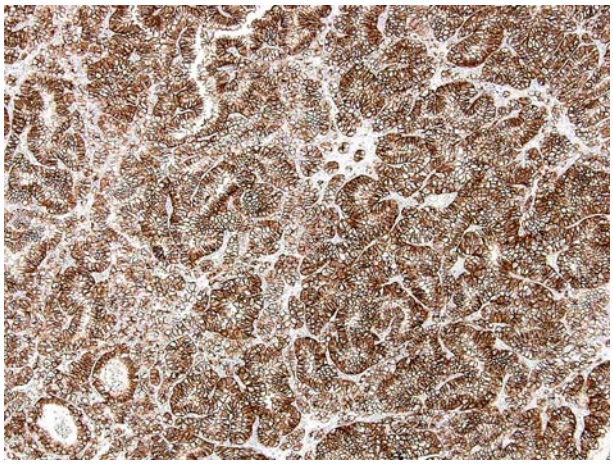

Fig. 3 Carbonic anhydrase IX, a component of the hypoxia-inducible pathway, is typically markedly upregulated in clear cell renal cell carcinoma and can be detected by immunohistochemistry with diffuse membranous labeling (*brown*).

VHL gene alteration from birth, accelerating this process. *VHL* is a tumor suppressor gene, and usually one copy is inactivated via mutation and the other is lost via sizable deletion of large regions of chromosome 3p or the entire 3p arm. Therefore, fluorescence in situ hybridization (FISH) or other molecular techniques have been used as one approach to support a diagnosis of clear cell renal cell carcinoma via detection of chromosome 3p deletion. More recent work as part of large-scale sequencing studies has revealed that several other key genes, many of which are also located on chromosome 3p, are also frequently altered in clear cell renal cell carcinoma, especially *PBRM1* (and other members of the switching defective/sucrose nonfermenting or SWI/SNF family), as well as *SETD2*, and *BAP1*. Deregulation of the mammalian target of rapamycin complex 1 (mTORC1) pathway is also found in a subset of tumors, resulting from mutations in *MTOR*, *TSC1*, *PIK3CA*, and *PTEN*. From this knowledge of clear cell renal cancer genetics, recent decades have yielded multiple additional treatment options targeting these pathways, especially the vascular endothelial growth factor (VEGF) pathway and the MTOR pathway.

Multilocular Cystic Renal Cell Neoplasm of Low Malignant Potential

Multilocular cystic renal cell carcinoma was considered a distinct tumor subtype in the 2004 World Health Organization (WHO) Classification of Tumors, strictly defined as an entirely cystic renal cell neoplasm with thin fibrovascular septa containing only aggregates of cells, resembling clear cell renal cell carcinoma cells, but not forming a gross mass (Fig. 4). When defined according to these criteria, no example has been published that exhibited aggressive behavior, resulting in the 2016 WHO recategorization of this entity as multilocular cystic renal cell neoplasm of low malignant potential. Despite the highly favorable prognosis of this entity, there is nonetheless some evidence for genetic overlap with clear cell renal cell carcinoma, including chromosome 3p25 loss and a subset with mutation of *VHL* (although the rate of these alterations may be lower than those of usual clear cell renal cell carcinoma). Though the WHO definition of this entity requires an entirely cystic tumor with no solid growth, other studies have also argued that a cystic component in clear cell renal cell carcinoma may impart a good prognosis, even for tumors that are not entirely cystic, and sometimes with even a relatively minor cystic component.

Papillary Renal Cell Carcinoma

Papillary renal cell carcinoma is the second most common form of adult renal cancer but considerably less common, at approximately 15% of renal cell carcinoma. Presentation of papillary renal cell carcinoma can be highly variable, ranging from small renal nodules (single or multiple) to large masses that bulge beyond the normal shape of the kidney. Patients with end-stage renal disease tend to develop papillary renal cell carcinoma, among other tumor histologies, sometimes multifocally; however, multifocal papillary renal cell carcinoma can also occur in non-end-stage kidneys for unknown reasons, and as part of hereditary syndromes, especially the hereditary papillary renal cell carcinoma syndrome, characterized by germline mutation of *MET*.

The gross appearance of papillary renal cell carcinoma can also be highly variable, depending on factors such as intratumoral hemorrhage, which can impart a red-brown appearance, or abundant foamy macrophages, which can impart a yellow appearance like clear cell renal cell carcinoma. Histologically, papillary tumors have been subdivided into type I and type II tumors. Type I tumors are more common, composed of cuboidal cells (Fig. 5) with a generally basophilic appearance. In contrast, type II tumors have eosinophilic cytoplasm, more elongated and pseudostratified nuclei. Prognosis is generally considered to be better for type I tumors; however, some authors have found distinguishing these two tumor types difficult in practice due to overlapping or mixed patterns. This classification may also be confounded by the fact that certain aggressive tumor types, especially hereditary

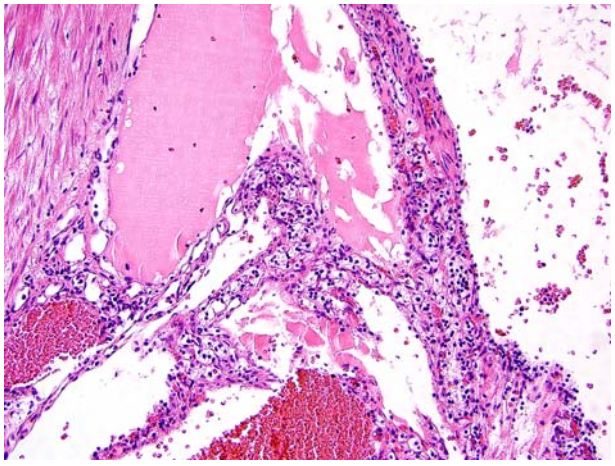

Fig. 4 Multilocular cystic renal neoplasms of low malignant potential are composed of cells that are similar to those of clear cell renal cell carcinoma; however, by definition these tumors are entirely cystic and associated with an excellent prognosis.

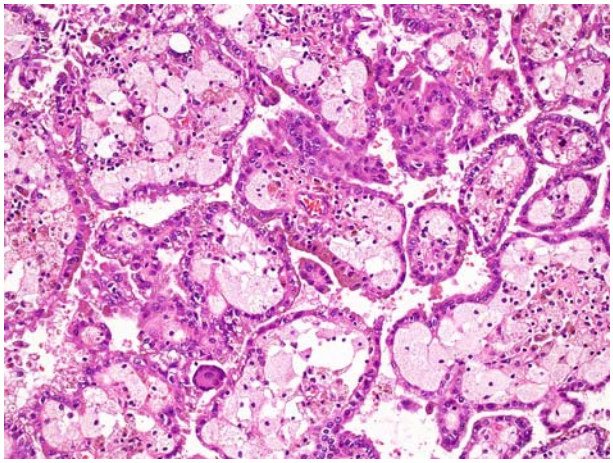

Fig. 5 Papillary renal cell carcinoma is characteristically composed of cuboidal-shaped cells lining papillary structures. Foamy macrophages within the papillae are a common feature, as present in this example.

leiomyomatosis and renal cell carcinoma syndrome (HLRCC)-associated tumors, have been historically considered type II papillary renal cell carcinoma, but are currently thought better classified as a distinct tumor type.

Immunohistochemistry

Using immunohistochemistry, papillary renal cell carcinoma is generally considered to be cytokeratin 7-positive, in contrast to clear cell renal cell carcinoma; however, this holds true primarily for classic type I tumors with basophilic cells. Staining for cytokeratin 7, in contrast, is often negative or limited in examples with eosinophilic cytoplasm. Alpha-methylacyl-CoA racemase (AMACR) reliably demonstrates strong, diffuse reactivity independent of cytology in almost all papillary tumors, and like clear cell renal cell carcinoma, labeling of epithelial cells for the mesenchymal marker vimentin is common. Carbonic anhydrase IX labeling is usually limited compared to clear cell renal cell carcinoma, although as a marker of the hypoxia pathway, carbonic anhydrase IX labeling can be present in other tumors or non-tumor tissues, especially in areas of tissue ischemia or necrosis.

Genetics

In the setting of the hereditary papillary renal cell carcinoma syndrome, patients have germline mutations of *MET* and develop numerous bilateral, multifocal papillary renal cell carcinomas (type I). In contrast to the *VHL* gene, however, this association is not as clearly translated to the sporadic setting, in which only a relatively small subset of papillary tumors is *MET* mutant. Characteristic chromosomal alterations in papillary renal cell carcinoma include trisomy of chromosome 7 and/or 17 and loss of the Y chromosome in male patients. Detection of these changes by conventional karyotype, FISH, or other techniques has been used as supportive of papillary renal cell carcinoma classification; however, the specificity of these alterations is debatable, as copy number changes for these chromosomes can also be found in other renal tumors and diseases of other organs. Multiple other chromosomal copy changes have also been recognized, including amplification of 8q with overexpression of *MYC*. Recent large-scale genomic characterization studies have also supported the interpretation of type I and type II tumors as different entities, with distinct genomic alterations in each category; however, this classification undoubtedly remains to be further refined. For example, *TFE3* gene fusions have been reported as one pattern of molecular alteration in type II tumors, a finding which likely in reality should justify classification as not papillary renal cell carcinoma but translocation-associated renal cell carcinoma, discussed additionally later. Some papillary renal cell carcinomas also harbor alterations in chromatin-modifying genes such as *SETD2*, *BAP1*, and *PBRM1*, which as noted previously are also now recognized to have important roles in clear cell renal cell carcinoma. *CDKN2A* silencing has also been recognized in some papillary renal cell carcinomas.

Chromophobe Renal Cell Carcinoma

Chromophobe renal cell carcinoma is typically considered the third most common subtype of renal cell carcinoma, usually making up approximately 5% of tumors. Overall, chromophobe renal cell carcinoma is usually regarded as a nonaggressive or less aggressive renal cancer type; however, there are some notable exceptions this rule, especially in the case of sarcomatoid dedifferentiation. The gross appearance of chromophobe renal cell carcinoma can resemble that of renal oncocytoma (a benign renal cell tumor), often demonstrating a tan or brown cut surface, either similar in color to normal renal parenchyma or paler in color. Although central fibrosis or "central scar" is considered a characteristic feature of oncocytoma, this can also be found in chromophobe renal cell carcinoma and other tumors, making it not entirely specific.

The prototypical histologic appearance of chromophobe renal cell carcinoma includes cells with variable amounts of pale-staining cytoplasm (hence the name "chromo" meaning color and "phobe" meaning fearing, or color-fearing, Fig. 6). Tumor cells are sometimes described as resembling plant cells or vegetable cells, since their histologic appearance includes very prominent cell borders, mimicking the cell walls that are found in plant cells. Cell volume is characteristically highly variable, with preservation of the nuclear-cytoplasmic ratio, so that some cells are very large and may appear to have no nucleus due to histologic sectioning through the large cell that entirely misses the nucleus. In contrast, other cells are much smaller and more crowded, yet still with a similar nuclear-cytoplasmic ratio.

Although this tumor type is named for its characteristic pale cytoplasm, it was not long after its recognition that the eosinophilic variant of chromophobe renal cell carcinoma was recognized, which has dense eosinophilic cytoplasm (making the chromophobe designation a misnomer in this setting). This appearance can lead to considerable overlap with the benign renal neoplasm oncocytoma, such that discriminating these two entities continues to be a challenge in diagnostic practice even today. As such, it is also a topic of debate whether oncocytoma and chromophobe renal cell carcinoma represent a spectrum of disease, with the benign counterpart (oncocytoma) at one end and classic (pale-staining) chromophobe renal cell carcinoma at the other end, separated by a gray zone of borderline tumors. A progressive model in which tumors evolve from oncocytoma to chromophobe renal cell carcinoma is not entirely intuitive, however, as many chromophobe renal cell carcinomas have a pure pale cell morphology, leading to no significant overlap with oncocytoma. Therefore, an alternative hypothesis is that chromophobe renal cell carcinoma and oncocytoma are unrelated entities, for which the former may occasionally mimic the latter.

Both oncocytoma and chromophobe renal cell carcinoma have been subject to study at the electron microscopic level (ultrastructural examination), in which oncocytoma exhibits numerous, densely-packed mitochondria, and chromophobe renal cell carcinoma contains numerous cytoplasmic microvesicles, structures usually 140–300 nm in size that may be related to defective mitochondrial development. Colloidal iron histochemical staining (historically known as Hale colloidal iron, or in modern practice modified Mowry or Muller–Mowry colloidal iron staining) has been exploited as a technique to highlight the differences in cytoplasmic constituents between oncocytoma and chromophobe carcinoma, which is thought to reflect disrupted microvesicles (positive staining in chromophobe and negative staining in oncocytoma). However, like many other diagnostic parameters, there remains overlap in both the presence of microvesicles ultrastructurally and staining for colloidal iron histochemically, especially in tumors that are equivocal for diagnosis of oncocytoma and chromophobe renal cell carcinoma. Therefore, due to lack of availability in many diagnostic pathology laboratories and challenges and subjectivity in interpretation, electron microscopy and colloidal iron staining are often not employed in current practice. Nonetheless, the balance of features at the morphologic, immunohistochemical, and ultrastructural level has led to the theory that oncocytoma and chromophobe renal cell carcinoma are tumors that arise from, or recapitulate the phenotype of, intercalated cells of the collecting ducts.

Although chromophobe renal cell carcinoma is generally considered a less aggressive renal cancer type, aggressive behavior sometimes occurs, particularly in tumors with sarcomatoid dedifferentiation, tumor necrosis, and vascular invasion. Interestingly, although clear cell renal cell carcinoma is the most common renal cell carcinoma subtype and likely is the origin for the largest *number* of sarcomatoid renal cancers, chromophobe carcinoma has been found in some studies to have a paradoxically high rate of sarcomatoid change, despite its much lower incidence and usual nonaggressive behavior, perhaps related to its tendency for *TP53* mutation, which is discussed later.

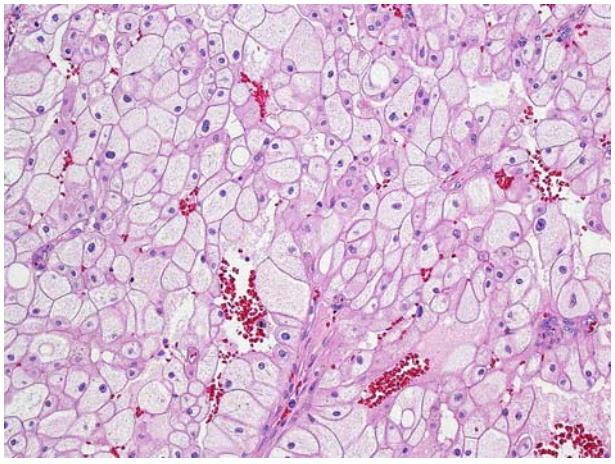

Fig. 6 Chromophobe renal cell carcinoma is composed of cells with pale-staining cytoplasm and prominent cell borders, resembling the cell wall of plant tissue as observed microscopically. In this example, some cells are so voluminous that they appear to have no nucleus, due to the plane of tissue sectioning entirely missing the nucleus.

Immunohistochemistry

Using immunohistochemistry, chromophobe renal cell carcinoma characteristically differs from clear cell and papillary renal cell carcinoma, in that it uniformly does not label for mesenchymal marker vimentin. Staining for KIT (CD117) often reveals a membranous pattern of labeling, which can be used to distinguish chromophobe from clear cell renal cell carcinoma (although this feature is shared with oncocytoma and therefore not helpful in discriminating these two entities). Classic chromophobe renal cell carcinoma (with pale cells) usually exhibits diffuse staining for cytokeratin 7, which differs from clear cell renal cell carcinoma and oncocytoma; however, this becomes less helpful in tumors with eosinophilic cells and the eosinophilic variant of chromophobe carcinoma, in which staining for cytokeratin 7 can be quite limited and minimally different from that of oncocytoma, if at all. A precise threshold of amount of cytokeratin 7 staining that precludes a diagnosis of oncocytoma remains to be fully agreed upon, although in general oncocytomas exhibit only rare single cells and clusters of cells that label for cytokeratin 7, making up typically 5% of cells or less. Other immunohistochemical markers that are used by some pathologists and researchers to discriminate chromophobe carcinoma from oncocytoma include S100A1, kidney-specific cadherin, among a wide variety of others that have been investigated in many studies; however, usage in diagnostic practice remains limited for most of these.

Genetics

At the chromosomal level, chromophobe renal cell carcinoma typically exhibits abnormal copy numbers for multiple chromosomes, often loss, particularly for chromosomes Y, 1, 2, 6, 10, 13, 17, and 21. However, there are conflicting data as to whether the eosinophilic variant exhibits a similar chromosomal profile. Some studies using FISH have found similar chromosomal losses in the eosinophilic variant when defined according to strict criteria; however, others, such as the Cancer Genome Atlas cohort, have found that the eosinophilic variant may have a diploid (normal) number of chromosomes, further blurring the distinction from oncocytoma. For the most part, oncocytomas exhibit a normal karyotype, loss of chromosome 1, loss of chromosome Y, or rearrangement of 11q13. The latter likely represents *CCND1* (cyclin D1) gene rearrangement, which has recently emerged as a molecular finding in some oncocytomas, which some authors suggest may define a molecular subtype of oncocytoma.

Regarding chromophobe renal cell carcinoma in general, other studies have also found that some tumors have chromosomal gains as well as losses. Other genetic alterations that have been recognized in chromophobe renal cell carcinoma include somatic mutations in mitochondrial DNA, such as NADH dehydrogenase, and alterations of *TP53*, *PTEN*, and rearrangements involving the *TERT* promoter. Although mutations of *TP53* are not entirely specific and can be found in clear cell renal cell carcinoma, these mutations appear to be enriched in chromophobe renal cell carcinoma, which might account for its predilection for sarcomatoid dedifferentiation, as *TP53* mutations are associated with a wide variety of cancers, including sarcomas.

"Hybrid" Oncocytic Tumors

An incompletely defined term in the renal cancer literature is the so-called "hybrid" oncocytoma-chromophobe tumor (HOCT or hybrid oncoytic tumor/HOT), which generally has some features of oncocytoma and some features of chromophobe renal cell carcinoma (Fig. 7). The context in which this term is used can be somewhat variable, with some authors using it for any oncocytic tumor with borderline diagnostic features, others using it only when the tumor has a mosaic morphology (some areas identical to oncocytoma and others to chromophobe carcinoma), and others using it particularly for tumors that occur in the context of an apparent

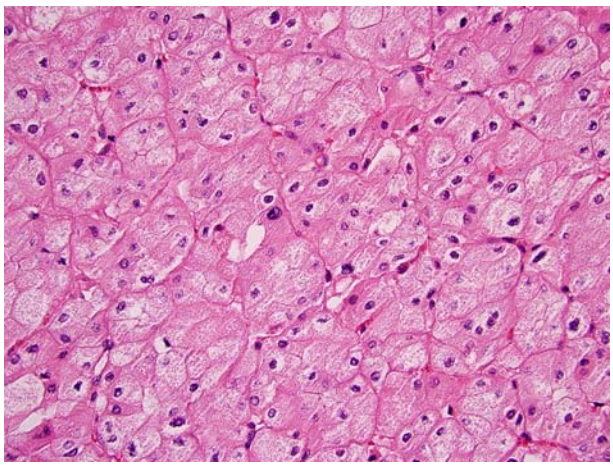

Fig. 7 The term hybrid tumor is used in some contexts for tumors that have mixed features of oncocytoma and chromophobe renal cell carcinoma. This tumor contained a mixture of morphology and exhibited multiple chromosomal gains using fluorescence in situ hybridization, making it somewhat atypical for either oncocytoma or chromophobe renal cell carcinoma.

syndrome (multiple oncocytic renal tumors). One context in which patients have multiple oncocytic renal tumors is Birt–Hogg–Dubé syndrome (germline mutation of the folliculin gene, *FLCN*), in which patients develop multiple skin tumors, fibrofolliculomas, as well as lung cysts. In this context, tumors have been reported as oncocytomas, chromophobe renal cell carcinomas, and hybrid tumors; however, it remains to be better understood whether these are the same entities as their sporadic counterparts or whether Birt–Hogg–Dubé-associated tumors are a distinct tumor type. In the absence of this syndrome, the constellation of multiple oncocytic renal tumors is otherwise known as renal oncocytosis, and again, it is debated whether these tumors are true oncocytomas or a distinct tumor type. For now, the WHO Classification has designated "hybrid" tumors as a subcategory of chromophobe renal cell carcinoma, principally due to a lack of consensus on this topic.

Clear Cell Papillary Renal Cell Carcinoma

Clear cell papillary renal cell carcinoma has only been recognized as a type of renal neoplasm since approximately 2006, first distinguished from conventional clear cell renal cell carcinoma in patients with end-stage renal disease. Since this recognition, however, it is now known that most cases occur in non-end-stage kidneys, and this tumor may make up as much as 4% of renal cell carcinoma, making it probably the fourth most common renal cell carcinoma subtype, close in incidence to that of chromophobe renal cell carcinoma. Due to close resemblance in many cases to clear cell renal cell carcinoma, it is not surprising that this entity eluded recognition for decades; however, several of its features are distinctive, including aligned nuclei in branched glandular structures (Fig. 8) and small papillae protruding into cysts. Grossly, these tumors are usually white or tan, and often not golden-yellow as seen in clear cell renal cell carcinoma. A cystic component is common. Microscopically, areas of solid growth are not unusual, and may be morphologically indistinguishable from clear cell renal cell carcinoma; however, histologic clues to this diagnosis include prominent alignment of the nuclei at the same height within the cytoplasm, a branched configuration of the glandular structures (rather than solid, round nests), and variable papillae protruding into cystic spaces (ranging from small stubby papillae to more complex branching).

Although this tumor is currently classified as a subtype of renal cell carcinoma, mostly based on the relatively recent discrimination from clear cell renal cell carcinoma and close resemblance, there is no convincing example with metastasis to date, suggesting that these may be reclassified as benign neoplasms or low malignant potential neoplasms in the future, as this entity accumulates more widespread recognition and longer-term follow-up. Interestingly, the morphology and immunohistochemistry of these tumors is quite similar to several other tumor entities, including clear cell papillary cystadenoma of the epididymis and broad ligament and serous cystadenoma of the pancreas, which curiously are both VHL disease-associated tumors, yet as discussed later, clear cell papillary renal cell carcinoma of the kidney is characteristically not *VHL*-mutant or associated with VHL disease, for unknown reasons.

Immunohistochemistry

One piece of the puzzle that has led to recognition of clear cell papillary renal cell carcinoma as a distinct entity is its overlapping but different immunohistochemical staining pattern. They share with clear cell renal cell carcinoma the finding of diffuse labeling for carbonic anhydrase IX; however, in contrast to the usual findings of clear cell renal cell carcinoma, these tumors are consistently diffusely positive for cytokeratin 7 and have only focal labeling for CD10, if any. In contrast to papillary renal cell

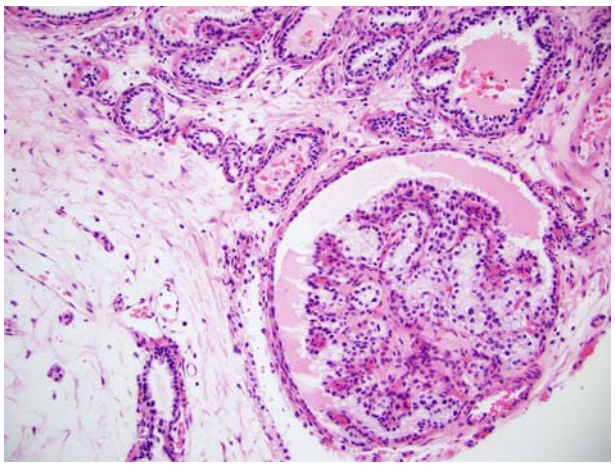

Fig. 8 Clear cell papillary renal cell carcinoma has been recently recognized to be the fourth most common renal cell carcinoma, often having substantial overlap in appearance with clear cell renal cell carcinoma. However, subtle diagnostic clues include alignment of nuclei at the same height within the cells and branched shape of the glandular structures.

carcinoma, these tumors have minimal to no labeling for AMACR. Recent studies have found these tumors to often label for GATA3 and high molecular weight cytokeratin, suggesting that the originate from, or recapitulate the phenotype of, the distal nephron.

Genetics

After the recognition of this entity based on unique morphology, studies using immunohistochemistry and genetic techniques have supported its consideration as distinct from clear cell and papillary renal cell carcinomas, the two most common entities and its two closest mimics. In general, almost all have been found to lack *VHL* mutations and chromosome 3p25 loss, in contrast to clear cell renal cell carcinoma, with perhaps rare exception. However, the VHL pathway likely appears to be upregulated nonetheless, as evidenced by their consistent labeling for markers such as hypoxia-inducible factor (HIF) and carbonic anhydrase IX. Although these tumors are typically not *VHL* mutant, some clear cell renal cell carcinomas in patients with VHL disease have been noted to have a morphology closely mimicking this entity, for unknown reasons. In this setting, however, the immunohistochemical phenotype generally does not match that of sporadic clear cell papillary renal cell carcinoma. In contrast to papillary renal cell carcinoma, the clear majority of clear cell papillary tumors have been lacking chromosome 7 or 17 gains, although this has been reported in a minority of cases and may not be entirely specific for papillary renal tumors. Otherwise, a distinctive genetic profile has yet to be recognized for this entity, largely with absence of recurrent copy number changes reported to date.

Translocation Renal Cell Carcinoma

Renal cell carcinomas with translocations involving the microphthalmia transcription factor (MITF) family of genes, including *TFE3* and *TFEB*, and recently perhaps *MITF* itself, are now well recognized as a distinct category of renal neoplasia. These tumors were first recognized in children and young adults, and if a renal cell carcinoma occurs in a child or young adult, the likelihood of translocation renal cell carcinoma is substantially increased. However, since renal cell carcinoma is rare in children, there is likely an overall greater *number* of translocation-associated renal cancer cases in older adults, and indeed these tumors can be found in patients of all ages. Interestingly, the gene fusion between *ASPSCR1* and *TFE3* involves the same two genes as in alveolar soft part sarcoma, a rare soft tissue tumor that shares epithelioid cytologic features with renal cell carcinoma but differs in several other ways.

Morphologically, translocation-associated renal cancers typically exhibit a mixture of morphologic features that may make them difficult to classify as a single specific subtype of renal cell carcinoma, such as mixed solid and papillary architecture, or mixed clear and eosinophilic cytologic features (Fig. 9). In general, these tumors often most closely resemble clear cell renal cell carcinoma, although the spectrum of morphology continues to widen with increasing awareness of these entities and more accessible molecular testing, and therefore tumors mimicking a wide spectrum of neoplasms have been reported. Specific morphologic associations are also known, such as more voluminous cytoplasm, papillary architecture, and psammomatous calcifications in tumors with *ASPSCR1-TFE3* fusion, compared to more compact architecture and less calcifications in tumors with *PRCC-TFE3* fusions. Tumors with *NONO-TFE3* fusion as well as those with *SFPQ* fusion may have a pattern of clear cell-like morphology with nuclear alignment, resembling that pattern of clear cell papillary renal cell carcinoma.

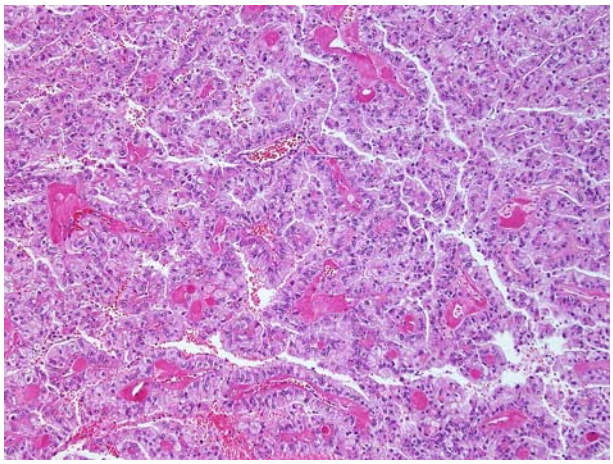

Fig. 9 Translocation-associated renal cell carcinomas often have a mixture of features of clear cell and papillary renal cell carcinoma and sometimes occur in younger patients. This tumor, occurring in a child, demonstrates papillary architecture with cells that have clear to eosinophilic cytoplasm.

Immunohistochemistry

Translocation-associated renal cell carcinomas have some unique immunohistochemical features compared to conventional renal cell carcinomas, including positivity for markers of melanocytic differentiation (HMB45, melan-A), and decreased labeling for epithelial markers (cytokeratins and epithelial membrane antigen). TFE3 and TFEB proteins can often be detected with immunohistochemical antibodies against them, and if there is strong positivity, this generally correlates well with gene fusion. However, molecular techniques are usually regarded as more sensitive and specific for confirmation of the gene fusions, particularly FISH, which is one of the most common diagnostic techniques in current practice. Cathepsin K, a papain-like cysteine protease, has also been recognized to have positive immunohistochemical labeling in many translocation-associated renal cell carcinoma (*TFE3* rearrangement tumors, depending on the fusion partner, and most *TFEB* rearrangement tumors).

Genetics

The *TFE3* gene is located at Xp11.2, and therefore translocation renal cell carcinomas are variably also referred to as Xp11 translocation-associated tumors; however, gene fusions involving the related family member *TFEB* (located at chromosome 6p21) also occur. The typical fusion partner for *TFEB* is *MALAT1* (also known as Alpha), resulting in a *MALAT1-TFEB* gene fusion, or t(6;11). In contrast to alveolar soft part sarcoma, multiple other fusion combinations in renal cell carcinoma have been found, including *PRCC-TFE3*, *SFPQ-TFE3*, *NONO-TFE3*, *CLTC-TFE3*, and unknown partners.

Very recently, an additional group of tumors with amplification of the *TFEB* and *VEGFA* gene region located at 6p21 has also been reported (usually without rearrangement). These tumors have some features overlapping with those of translocation carcinoma, including positivity for melanocytic markers (especially melan-A) and cathepsin K. Morphologically, these have been noted to have a tendency for an eosinophilic tubulopapillary appearance, although like translocation carcinomas, they have heterogeneous morphology with other areas resembling clear cell or chromophobe renal cell carcinoma and some showing collecting duct carcinoma-like features. Although data on these tumors so far are limited, they appear to have aggressive behavior.

Sarcomatoid Renal Cell Carcinoma

Sarcomatoid renal cell carcinoma is not per se a distinct entity, but a form of aggressive transformation or dedifferentiation that can occur in multiple renal cancer types. In most cases, conventional morphology of one of the other described renal cell carcinoma types can be appreciated in some areas, and therefore current recommendations are that these be diagnosed as sarcomatoid carcinomas arising from a specific renal cell carcinoma subtype, if possible. However, examples in which the sarcomatoid pattern is predominant and no definite low-grade component can be appreciated do occur, which may be diagnosed as pure sarcomatoid renal cell carcinomas or unclassified sarcomatoid renal cell carcinoma. The principle diagnostic feature for sarcomatoid dedifferentiation is that areas of the tumor lack apparent epithelial differentiation and could be mistaken for a mesenchymal neoplasm (sarcoma) if viewed in isolation (**Fig. 10**). However, occasional cases of clear cell renal cell carcinoma occur in which the cells take on a spindle-shaped appearance but are still largely recognizable as epithelial. In this context, it remains debatable whether this should be considered an early form of sarcomatoid change or a transitional pattern, not yet reaching sarcomatoid features. Rhabdoid cytologic features, formed by large cells with voluminous cytoplasm containing a globule of eosinophilic material, are so named for their resemblance to rhabdomyoblastic cells of rhabdomyosarcoma, yet without true muscle differentiation as

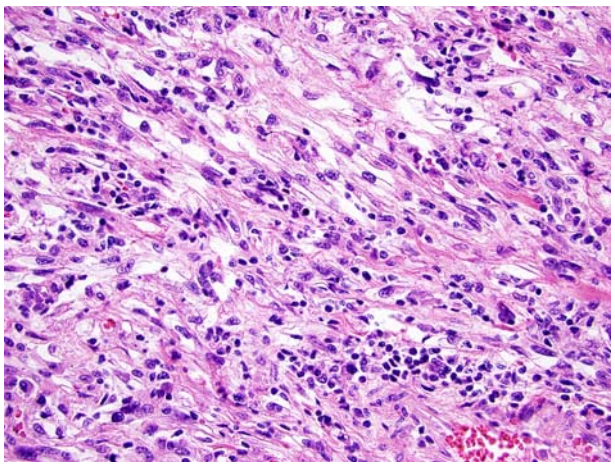

Fig. 10 Sarcomatoid renal cell carcinoma is defined as a transition of renal cell carcinoma to areas resembling sarcoma (cancer of mesenchymal or connective tissue). In this example, the tumor cells take on a spindle-shaped rather than rounded appearance.

detectable immunohistochemically. In current thinking, this is largely considered a pattern of sarcomatoid dedifferentiation, although there are conflicting data on whether this feature carries an equally adverse prognosis to that of sarcomatoid carcinoma formed by sarcoma-like morphology.

Immunohistochemistry

Sarcomatoid renal cancers may be difficult to recognize as of renal cell origin, if the sarcomatoid component is predominant. In general, these tumors have much more limited evidence of epithelial origin, and therefore immunohistochemistry for multiple markers of epithelial origin, such as cytokeratin, epithelial membrane antigen, and PAX8 (a transcription factor involved in renal organogenesis), may be used in combination to garner some support of epithelial origin, combined with careful search for areas with epithelial morphology. Carbonic anhydrase IX typically exhibits diffuse labeling in clear cell renal cell carcinoma; however, this may be decreased in sarcomatoid tumors.

Genetics

There is some evidence that sarcomatoid renal cell carcinomas share major molecular events with the conventional renal cancers from which they originated, such as *VHL* mutation and 3p25 deletion when originating from clear cell renal cell carcinoma. Alterations in other clear cell renal cell carcinoma-associated genes, such as the chromatin remodeling genes discussed previously, have also been documented, and there is also some evidence that additional distinct genetic alterations may be enriched in sarcomatoid renal cancers, including alterations of *NF2*, *TP53*, *CDKN2A*, among others. Other data suggest that some sarcomatoid renal cell carcinomas may progress to the sarcomatoid phenotype through different molecular pathways that may bypass some of the presumed early steps in carcinogenesis.

Other Renal Cell Carcinoma Subtypes

Collecting Duct Carcinoma

Renal collecting duct carcinoma is a rare, aggressive subtype of renal cancer that is more like a prototypical cancer, differing from the previously discussed, more common renal cell carcinoma types. In contrast to usual renal cell carcinoma, which usually forms a spherical, circumscribed mass, collecting duct carcinoma typically manifests as a diffusely infiltrative cancer with desmoplastic reaction, composed of tubular structures. This diagnosis is largely one of exclusion, requiring the pathologist to discern these tumors from urothelial carcinoma arising from the renal pelvis invading the kidney, renal medullary carcinoma (a largely similar histology that occurs characteristically in patients with sickle cell trait), and metastatic cancer from another origin. A medullary location is also considered one of the diagnostic features for this entity. In general, this diagnosis can be supported by immunohistochemical labeling for renal-specific markers such as PAX8 and usually negative labeling for markers of urothelial carcinoma, such as p63 and GATA3 (although these patterns may overlap in some cases, likely due to overlapping phenotypes of distal renal tubules and urothelium), and negative markers of other cancer origins. Genetically, recent studies have found alterations of *NF2*, *SETD2*, *SMARCB1*, and *CDKN2A* in collecting duct carcinomas, although a defining set of molecular alterations is not currently recognized. The *SMARCB1* gene (also known as INI1) has gained recent recognition as a key molecular alteration in renal medullary carcinoma, a tumor almost by definition occurring in patients with sickle cell trait. A novel terminology of "renal cell carcinoma unclassified with medullary phenotype" has been proposed for tumors with this morphology, combined with loss of INI1 protein labeling by immunohistochemistry or *SMARCB1* alteration, yet with absence of known sickle cell trait. Therefore, the cases of collecting duct carcinoma with *SMARCB1* alteration may now fall into this category, which has only recently been proposed.

Renal Medullary Carcinoma

As discussed in relation to collecting duct carcinoma, renal medullary carcinoma has substantial overlap in morphologic features with collecting duct carcinoma, requiring evaluation of a similar differential diagnosis; however, unique features of this diagnostic entity include occurrence at a relatively young age (often 2nd or 3rd decade of life) in patients with sickle cell trait and related hemoglobinopathies. As noted previously, loss of *SMARCB1* via translocation and deletion appears to be a key molecular feature of all or almost all tumors, which can be detected with abnormal absence of immunohistochemical staining (for INI1/SMARCB1 protein). Behavior of these tumors is highly aggressive, with survival in months rather than years.

Mucinous Tubular and Spindle Cell Carcinoma

Mucinous tubular and spindle cell carcinoma is considered a separate entity in the WHO Classification of renal tumors; however, it has debatably several features that overlap with papillary renal cell carcinoma, leading some authors to speculate whether it might be a morphologic variant of papillary renal cell carcinoma. These tumors characteristically contain tubular elements, like those of type I papillary renal cell carcinoma, with similar immunohistochemical staining characteristics, including labeling for AMACR and cytokeratin 7. However, these elements are admixed with other areas of spindle-shaped cell morphology and areas of stromal mucin

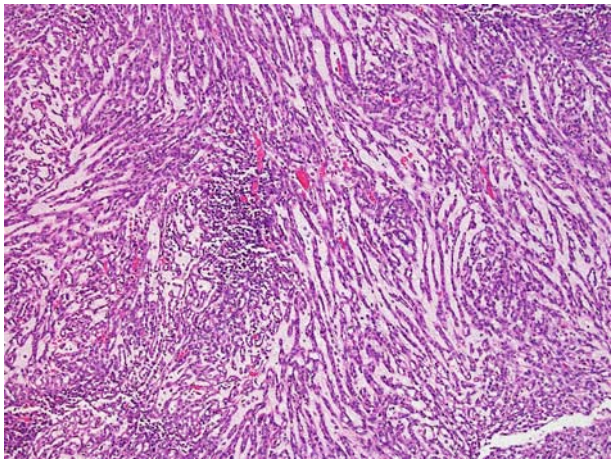

Fig. 11 Mucinous tubular and spindle cell carcinoma is a rare variant of renal cell carcinoma that shares some overlapping features with papillary renal cell carcinoma, but exhibits compressed, elongated tubular structures with a spindle-shaped appearance and intercellular mucinous material.

deposition, together making up the three components of the tumor's name (Fig. 11). Although the spindle-shaped cell component may be mistaken for sarcomatoid dedifferentiation, this is typically hypothesized to represent compressed, elongated tubular structures with epithelial differentiation, rather than a true mesenchymal component. The mucinous component can be highlighted with histochemical stains for mucin. Despite the resemblance of the tubular component to that of type I papillary renal cell carcinoma, studies have found multiple chromosomal losses involving chromosomes 1, 4, 6, 8, 9, 13, 14, 15, and 22, in contrast to the trisomy (or gain) of chromosomes 7 or 17 that is characteristic of papillary renal cell carcinoma. However, some tumors with overlapping morphologic features of papillary renal cell carcinoma have been reported to show a combination of chromosomal alterations of both entities. Behavior of mucinous tubular and spindle cell carcinoma is largely nonaggressive; however, metastases have been described.

Tubulocystic Renal Cell Carcinoma

Tubulocystic renal cell carcinoma is another subtype of renal cancer that is considered a distinct tumor entity, although again it may have some overlapping characteristics with papillary renal cell carcinoma, and there may be some cases of papillary renal cell carcinoma that overlap in morphology and mimic this entity. This tumor type was initially reported as low-grade collecting duct carcinoma, based on the presence of some areas of similar morphology in collecting duct carcinoma; however, current thinking is that there is no true relationship between these entities. The characteristic gross appearance of this tumor has been described as resembling bubble wrap, in that the cut surface contains multiple cystic spaces. Histologically, tumors are composed of tubular and cystic structures, both of which are lined with eosinophilic cells with prominent nucleoli (Fig. 12). Immunohistochemically, staining is characteristically positive for AMACR, like papillary renal cell carcinoma. Cytokeratin 7 staining may be limited, although as noted previously, this is not necessarily a discriminator from papillary renal cell carcinoma, as those with eosinophilic cells are

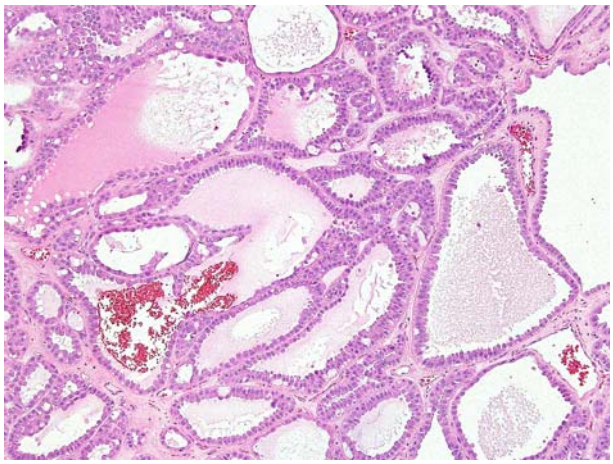

Fig. 12 Tubulocystic renal cell carcinoma is composed of cystic and tubular structures lined by uniform cells with eosinophilic cytoplasm and prominent nucleoli.

characteristically less positive for cytokeratin 7 than type I tumors. Like mucinous tubular and spindle cell carcinoma, there is some debate as to whether this entity is a variant of papillary renal cell carcinoma. Tumors with pure morphology (entirely tubular and cystic) have been found to lack trisomy 7 and 17; however, tumors with mixed papillary and tubulocystic morphology have been found to have gains of chromosomes 7 and 17.

Acquired Cystic Disease Associated Renal Cell Carcinoma

Acquired cystic kidney disease-associated renal cell carcinoma is another tumor subtype that is now acknowledged as a distinct entity in the current 2016 WHO Classification of Tumours; however, like mucinous tubular and spindle cell carcinoma and tubulocystic renal cell carcinoma, it again has overlapping features with papillary renal cell carcinoma and raises debate as to whether it represents a morphologic variant. In contrast to other subtypes of renal cell carcinoma, this histology is thus far considered to be restricted to the setting of end-stage kidney disease with acquired cystic disease (cystic disease usually occurring after long-term dialysis), unless papillary renal cell carcinoma with eosinophilic cells or tubulocystic renal cell carcinoma is considered the non-end-stage renal disease counterpart. The unique morphologic findings that define this entity include a cribriform architecture (tubular growth with multiple secondary glandular lumens) and calcium oxalate crystals within the tumor (Fig. 13). Like tubulocystic renal cell carcinoma, these tumors characteristically stain immunohistochemically for AMACR but may be variable or negative for cytokeratin 7, again not necessarily representing a robust distinction from papillary renal cell carcinoma due to the tendency for papillary tumors with eosinophilic cells to have less labeling for this marker. Behavior of this entity is usually nonaggressive, but metastases have been reported. Like tubulocystic renal cell carcinoma there may be overlapping chromosomal alterations with those of papillary renal cell carcinoma in some cases; however, other chromosomal changes that have been reported include chromosomes 1, 2, 3, 6, 7, 10, and 16, particularly gains and losses of 3 and 16.

Renal Cell Carcinoma, Unclassified

Renal cell carcinoma, unclassified, is not a specific diagnostic entity but rather represents a category for tumors that are interpreted as of renal cell origin but cannot be confidently given a definitive diagnosis. This is often due to either mixed patterns of multiple entities (Fig. 14), unusual morphology or immunohistochemical staining characteristics that do not correspond well to a single entity, or high-grade or sarcomatoid features that obscure any diagnostic low-grade histology. As such, this is a heterogeneous category that cannot be necessarily assigned a specific prognosis or treatment. Some studies have reported that prognosis for these tumors is worse than for conventional renal cell carcinoma types, although this may be influenced by thresholds at a given institution for assigning a diagnosis of renal cell carcinoma unclassified vs categorization with a defined entity. However, as classification of renal cancer is continually being refined, it is likely that more and more tumors from this group will be interpreted as novel diagnostic entities.

Hereditary Renal Cancer Syndromes

Several hereditary renal cancer syndromes are now recognized, and it may be relevant to consider the possibility of a syndrome when encountering a renal tumor in patients of a young age (under age 46 has been proposed as one cutoff) or with multiple tumors. VHL disease, hereditary papillary renal cell carcinoma, and Birt–Hogg–Dubé syndromes were discussed previously with clear cell, papillary, and chromophobe renal cell carcinomas, respectively.

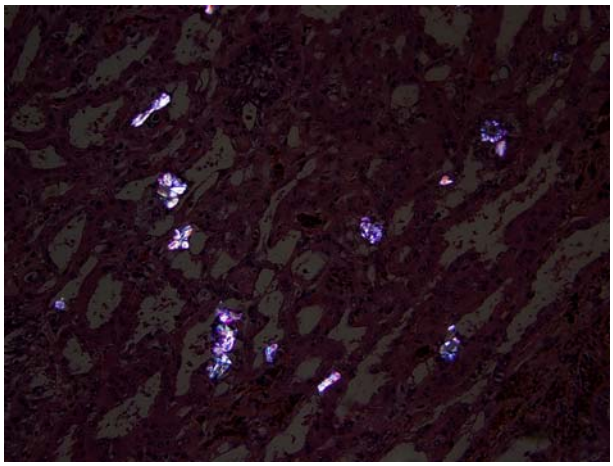

Fig. 13 The prototypical feature of acquired cystic kidney disease-associated renal cell carcinoma is the presence of calcium oxalate within the tumor, highlighted here by polarization microscopy.

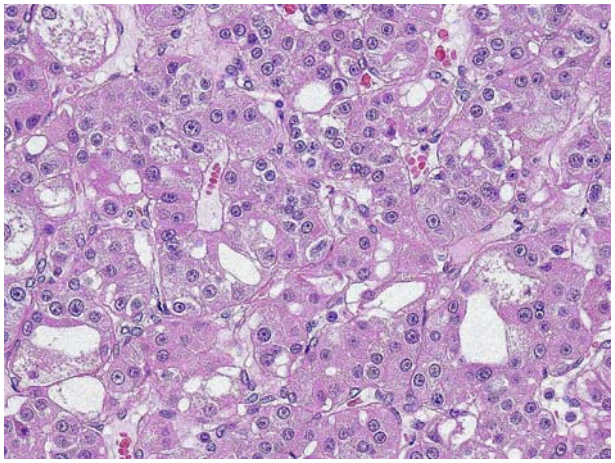

Fig. 14 Unclassified renal cell carcinoma is a category for tumors regarded to be of renal cell origin that do not fit cleanly into a specific category. This example contains cells with eosinophilic cytoplasm and prominent nucleoli.

Although the HLRCC syndrome (germline mutation of *FH*) has been previously considered to be associated with type II papillary renal cell carcinoma, it is now considered that the renal cancers in these patients are a distinct tumor type, that may exhibit not only papillary, but also tubular, solid, cystic, and diffusely infiltrative morphology. The characteristic morphologic feature that may draw attention to this diagnostic possibility is the presence of very large, prominent nucleoli with perinucleolar clearing, although this may be focal. Until recently, diagnostic tumor markers for this syndrome were not specific, other than undertaking germline testing; however, two recent immunohistochemical markers that have been reported as helpful for recognizing tumors associated with this syndrome include abnormal negative staining for fumarate hydratase (FH) protein, corresponding to the same gene that harbors germline mutation in these patients, and increased staining for 2-succinocysteine (2SC), a succinated protein that accumulates in the setting of increased fumarate. The behavior of these tumors is highly aggressive, and in contrast to VHL disease, in which tumors are typically conservatively managed and enucleated (surgically removed with almost no rim of normal tissue) only upon reaching a certain size, current recommendations are to manage HLRCC tumors aggressively, often with radical nephrectomy even for relatively small and clinically localized-appearing tumors.

Another hereditary renal cancer syndrome that is now increasingly recognized is associated with germline mutations of the succinate dehydrogenase (SDH) subunit genes. The syndromes resulting from these mutations are usually referred to as the hereditary pheochromocytoma–paraganglioma syndromes, although patients with these mutations also develop gastrointestinal stromal tumors (GIST) with deficiencies of SDH subunits and renal cancers, usually with deficiency of SDH subunit B (SDHB). Only recently it has been recognized that SDHB-deficient renal cancers have distinctive morphology, typically characterized by solid growth of monomorphic eosinophilic cells, often without much glandular configuration (**Fig. 15**). The tumor cells contain cytoplasmic vacuoles or inclusions that likely correspond to enlarged abnormal mitochondria. Immunohistochemical features of these tumors often

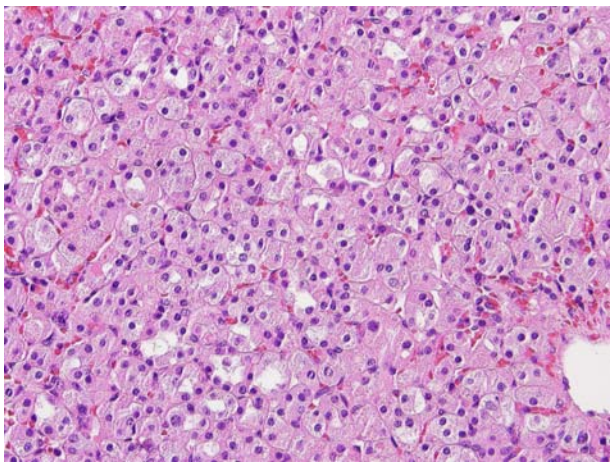

Fig. 15 Succinate dehydrogenase-deficient renal cell carcinoma has been recently recognized to often have distinctive morphology, including uniform, often bland, eosinophilic cells, with cytoplasmic vacuoles or inclusions that may represent defective mitochondria. Recognition of these tumors is important, as most are thought to be associated with inherited mutations in the succinate dehydrogenase subunit genes.

include negative staining for KIT (contrasting to oncocytoma and chromophobe renal cell carcinoma) and cytokeratin 7, and positive staining for kidney-specific cadherin and PAX8. Other epithelial markers may be underwhelming, such as general cytokeratin or epithelial membrane antigen; however, the abnormal absence of SDH protein can be detected by negative staining for SDHB (usually even if the mutation involves another subunit, especially SDHA).

Renal Cancer Grading

For the last few decades, the Fuhrman grading system has been used for renal cell carcinoma, based on several different parameters of the tumor cell nuclei; however, recent refinements by the International Society of Urological Pathology (ISUP) have emphasized the tumor cell nucleoli as the most important parameter, leading to a recent revised ISUP grading system based on this finding. In this system, the presence of nucleoli visible at 100× magnification (10× microscope objective combined with 10× ocular magnification) justifies a modified ISUP grade 3. Nucleoli that are visible only at higher magnification would then correspond to grade 2, and nuclei that are small and condensed without nucleoli at higher magnification correspond to grade 1. Grade 4 conversely represents markedly atypical nuclei that are irregular or multilobated. Rhabdoid cells, as discussed with sarcomatoid features, are also currently classified as grade 4. Other grading systems that incorporate tumor necrosis into a multi-tier system have also been proposed. The ISUP modified grading system appears to work well for clear cell renal cell carcinoma and perhaps papillary renal cell carcinoma. However, there is currently no compelling evidence that it is helpful for chromophobe renal cell carcinoma, since these tumors by their characteristic cytology would often by grade 3 or higher, yet their behavior, as discussed previously, tends to be nonaggressive. Therefore, current recommendations are against grading of chromophobe carcinoma (grading not applicable). Alternative grading schemes for chromophobe tumors have been proposed, based on features such as nuclear crowding and overlap; however, this is not universally agreed upon at present and therefore not widely used. Given the more recent increased utilization of renal mass biopsy, algorithms incorporating tumor histology and grade on tumor biopsy into patient management are now being used in some centers.

Renal Cancer Pathologic Staging

As noted previously, pathologic stage criteria for renal cancer may be subtler than other cancers, as renal tumors typically begin as round or spherical masses. With increasing size, these masses can bulge well beyond the shape of the normal kidney, which does not necessarily indicate invasion alone; however, as size increases, the likelihood of invasion of various structures dramatically increases, especially for clear cell renal cell carcinoma. The pathologic pT stage category (in the TNM system of staging) depends first on tumor size, with pT1a including tumors of 4.0 cm or less, pT1b including tumors >4.0–7.0 cm, pT2a including >7.0–10.0 cm, and pT2b including tumors >10.0 cm without invasion of structures. However, for clear cell renal cell carcinoma, recent data indicate that tumors larger than 7.0 cm without any such invasion are very rare. The pT3a stage category is used when tumors invade either (1) the main renal vein or its branches, (2) the renal sinus (the loose tissue and adipose tissue located in the hilum of the kidney), or (3) the perinephric fat. Interestingly, renal cell carcinoma can extend with elongated, tongue-like extensions (like a finger in a glove) into large blood vessels (Fig. 16), occasionally extending in this manner from the renal vein to the inferior vena, rarely even to the level of heart. Despite this, surgery can sometimes still be attempted by pulling back the finger-like thrombus to a level at which it can be removed. Higher pT stage categories are based on these levels of extension, including pT3b (extending to

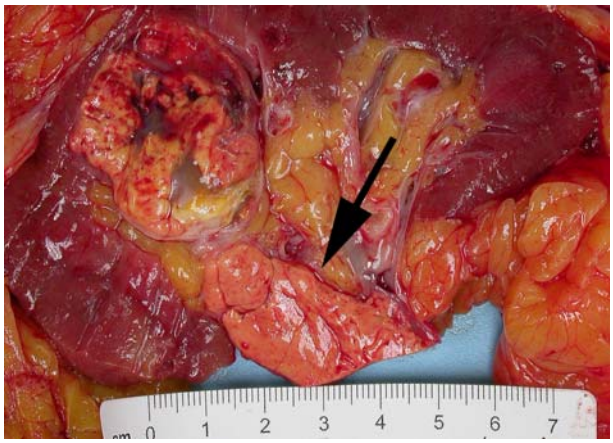

Fig. 16 Higher stage in renal cell carcinoma is somewhat different from other cancers, in that the primary tumor is often spherical or round (upper left), but with invasion manifesting as tongue-like extension into veins (*arrow*) or soft tissue.

vena cava below the diaphragm) and pT3c (extending to vena cava above the diaphragm or invading the wall of the vena cava). The pT4 category includes extension beyond the Gerota fascia or invasion of the adrenal gland (directly). The American Joint Commission on Cancer (AJCC) staging system, which has been revised for implementation in 2018, has made a few refinements to these categories, most critical of which include removing the requirement that vein branches contain muscle to be considered pT3a and that this invasion be identified grossly. Therefore, any vein branch invasion, even if identified microscopically and without a muscular wall, can be regarded as evidence of pT3a pathologic stage category.

Prospective Vision

The future of pathology and genetics of renal cell carcinoma likely lies in continued integration of tumor histology with immunohistochemistry and genetics, to define tumor entities with distinct treatment options and behavior. Although knowledge of tumor genetics has facilitated recognition of multiple new tumor types in the latest classification schemes, it is in most cases possible to extrapolate this knowledge of genetics and recognize these tumor types based on subtle distinctions in their histology. Some have substantial importance for prognosis, and others have implications for inherited tumor predisposition syndromes.

Role of DNA Repair in Carcinogenesis and Cancer Therapeutics

Rachel Abbotts, University of Maryland School of Medicine, Baltimore, MD, United States
Tyler Golato and David M Wilson, III, National Institute on Aging, Intramural Research Program, National Institutes of Health, Baltimore, MD, United States

Introduction and Scope

Every day, each cell in the human body is subjected to tens of thousands of DNA damage lesions, either through environmental exposure or through internal chemical reactions. Unrepaired, these lesions can impair transcription, stall replication, and induce senescence, a permanent state of cell cycle arrest, or apoptosis, a process that results in cell death. If persistent, DNA damage can introduce mutations or genomic instability that can trigger cancer development. This article provides an overview of the major DNA repair pathways that identify and remove substrate lesions, including their associated cancer syndromes and disease predispositions, and summarizes the DNA repair targets that are currently under clinical therapeutic evaluation in the treatment of malignancies.

Sources of DNA Damage

The majority of DNA damage acquired by a cell (see overview in **Fig. 1**) is the result of normal physiological processes. Spontaneous hydrolysis of chemical bonds within DNA produces ~10,000 depurinated (abasic) sites per cell per day, while spontaneous deamination of cytosine nucleotides is an important source of inappropriate uracil or thymine base-pairing (Lindahl, 1993). Endogenously produced reactive oxygen species (ROS), such as hydrogen peroxide and hydroxyl radicals, can result in the modification of all cellular macromolecules, including the formation of various oxidized DNA base lesions, abasic sites, and strand breaks (Cadet and Wagner, 2013). The major source of cellular ROS is mitochondria, generated during oxidative phosphorylation, with minor mechanisms of ROS formation including endoplasmic reticulum stress and peroxisome metabolism (Murphy, 2009; Turrens and Boveris, 1980). Other intracellular metabolites capable of DNA modification include *N*-nitroso compounds (which also arise from exogenous sources such as cigarette smoke) (Murata and Kawanishi, 2011), or methyl groups generated by the activity of the methyl group donor *S*-adenosylmethionine (Rydberg and Lindahl, 1982), both of which induce a range of alkylation adducts. Failure of enzymatic activity that specifically targets DNA, such as during repair or replication (discussed more later), is also a common source of endogenous genomic damage. For example, single base mismatches may be introduced by DNA polymerases during replication or repair, or larger insertions or deletions may result from polymerase slippage and subsequent realignment of the duplex (Lange et al., 2011). Resolution of damage lesions by processes such as base excision (BER) or nucleotide excision repair (NER) features obligate strand breaks that may persist if repair is interrupted, or be converted to DNA double-strand breaks (DSBs) if encountered by a replication fork (Edenberg et al., 2014). Likewise, reversal of the transient strand nicking activity of topoisomerase 1 (TOP1), which relaxes supercoiled DNA ahead of transcription or replication, can fail if the TOP1-DNA cleavage complex encounters a replication fork or DNA damage lesion, resulting in the formation of a complex strand break intermediate (Pommier et al., 2003).

Besides the many natural mechanisms that can generate DNA modifications, there are numerous environmental physical and chemical agents that have the potential to induce DNA damage (**Fig. 1**). A major external source of DNA damage is radiation. Ultraviolet (UV) radiation commonly induces intrastrand crosslinks, such as cyclobutane pyrimidine dimers and 6,4-photoproducts, while ionizing radiation can introduce a wide range of lesions, including clustered base damage and strand breaks (Cadet and Wagner, 2013). Many ingested or inhaled substances can also have effects on DNA. For example, tobacco smoke contains ~60 recognized carcinogens, including polycyclic aromatic hydrocarbons (PAHs), such as benzo[α]pyrene, which intercalates into DNA to induce bulky base lesions, and a variety of alkylating chemicals that cause a range of base adducts (Phillips and Venitt, 2012). Heterocyclic amines, produced by over-cooking meat, generate bulky adducts that are several-fold more mutagenic than tobacco PAHs (Murata and Kawanishi, 2011). Infectious agents also cause DNA damage; for example, the aflatoxin mold induces formation of ring-opened formamidopyrimidine or depurinated base lesions (Bedard and Massey, 2006). In addition to the mostly inadvertent exposure to genotoxins, targeted use of DNA-damaging agents is employed therapeutically, such as via radiotherapy, radioisotopes, and chemotherapy in cancer treatment (see later).

Consequences of Unrepaired DNA Damage

The presence of a DNA lesion triggers a complex DNA damage response (DDR; **Fig. 1**) that is characterized by damage recognition, activation of downstream signaling pathways, and coordination of cellular responses that may include activation of cell cycle checkpoints, induction of DNA repair pathways, persistent cessation of replication (e.g., in senescence), or triggering of programmed mechanisms of cell death, such as apoptosis, autophagy, or necroptosis (Jackson and Bartek, 2009; Sirbu and Cortez, 2013). Alternatively, unrepaired DNA damage may be "mishandled" during replication, leading to mutations and subsequent malignant

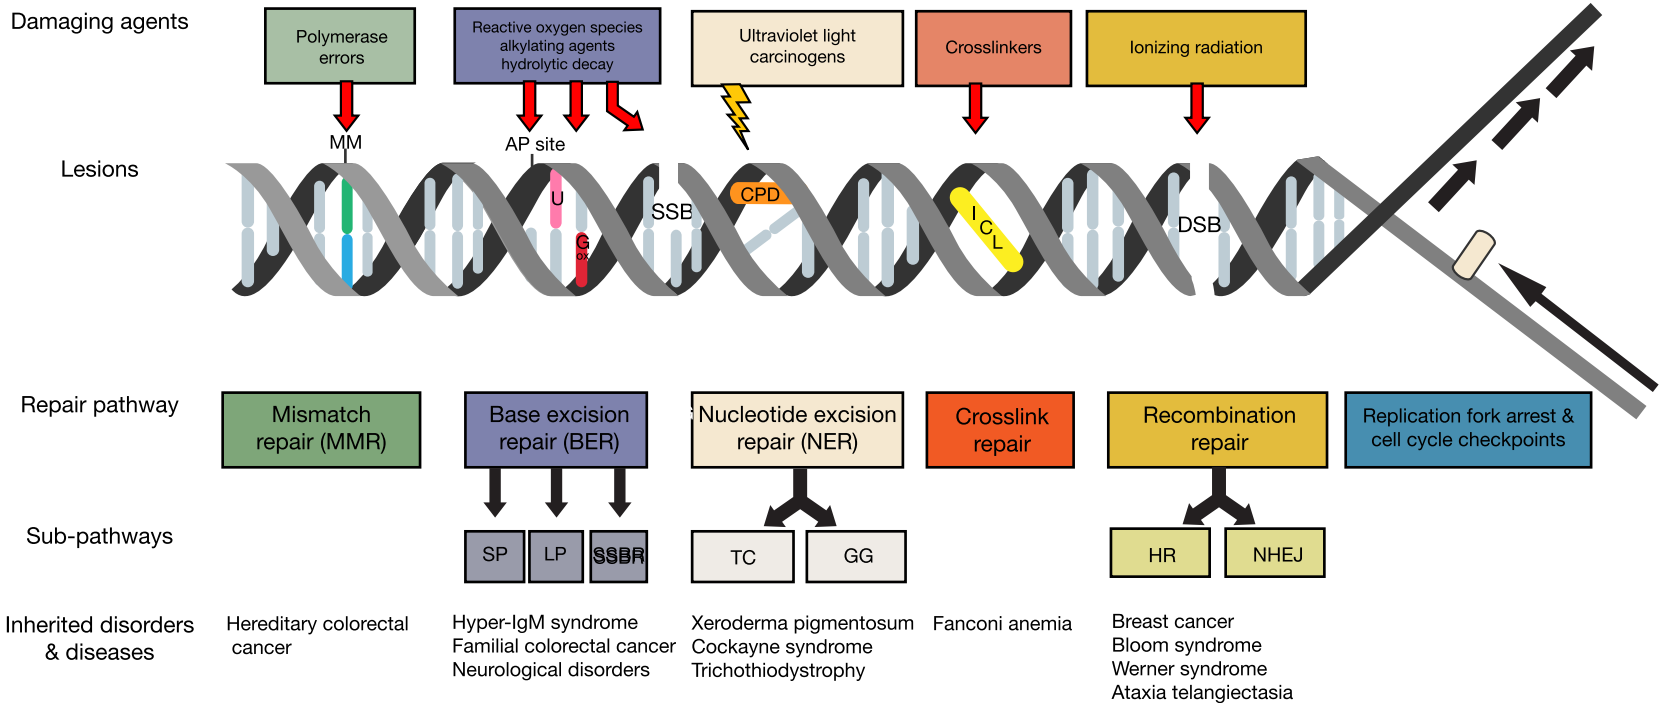

Fig. 1 Overview of DNA damage and DNA repair responses. DNA damage can be introduced by a wide range of internal and external damaging agents. Generally speaking, each type of DNA lesion is recognized and processed by a specific DNA repair pathway, or one of its associated subpathways, in some instances in connection with transcription, replication, or cell cycle checkpoint machinery. Due to the harmful consequences of unresolved DNA damage (see text), mutations in DNA repair genes, within each of the major DNA repair pathways, have been linked to a spectrum of inherited disorders or diseases (listed), which typically involve neurological, immunological, malignant and/or premature aging phenotypes. *MM*, mismatch; *AP*, apurinic/apyrimidinic; *U*, uracil; *Gox*, 8-oxoguanine; *SSB*, single-strand break; *CPD*, cyclobutane pyrimidine dimer; *ICL*, interstrand crosslink; *DSB*, double strand break; *SP*, short patch; *LP*, long patch; *SSBR*, SSB repair; *TC*, transcription-coupled; *GG*, global genome; *HR*, homologous recombination; *NHEJ*, nonhomologous end joining. *Note*: direct reversal is not shown.

transformation. Small, nonhelix-distorting lesions, such as uracil or 8-oxoguanine (8-oxoG), are particularly susceptible to this process. Deamination converts cytosine to a uracil or thymine, ultimately leading to C → T transitions following chromosome duplication, a signature mutation recorded during the sequencing of many cancer genomes (Olinski et al., 2010). Similar mispairings can occur opposite oxidized bases, such as thymine glycol or 8-oxoG, giving rise to T → C or G → T mutations, respectively. These single base mispairings often occur within noncoding regions and are well tolerated; however, in coding regions they can cause a variety of deleterious effects including missense, nonsense, or truncating mutations. Larger DNA base adducts can also be highly mutagenic. For example, benzo[*a*]pyrene, a carcinogen in cigarette smoke, induces G → T transversions that may specifically target genomic regions, such as p53, resulting in inactivation of its tumor suppressor function (Yoon et al., 2001).

Noncoding abasic sites, which primarily arise from purine base hydrolysis, are typically potent blocks to replicative polymerases, but can be bypassed efficiently by one of several error-prone translesion polymerases. In the former situation, the replication fork collapses resulting in a complex DNA intermediate that can promote cell death (Edenberg et al., 2014), whereas in the latter scenario, the polymerase inserts adenine (typically) opposite the abasic site, allowing replication to continue at the expense of potential mutagenesis. Error-prone DNA polymerases are in fact often employed during DNA damage tolerance, which directs bypass of a damage lesion by the replication fork, permitting cell survival at the cost of genomic stability. Polymerases may also suffer slippage during replication or repair synthesis, particularly in highly repetitive DNA or if in close proximity to a damage lesion or stalled fork, which can lead to insertion/deletion events (Lange et al., 2011).

Besides base substitutions and small genomic changes, which often require nucleotide sequencing to identify, larger chromosomal aberrations can also arise from persistent DNA damage. For example, strand breaks, both those induced by exogenous sources such as ionizing radiation and those that are generated as DNA processing intermediates, can promote chromosomal fusions, rearrangements, and large-scale deletions, which are typically visible by simple Giemsa staining of metaphase spreads (Fenech, 2002; Forment et al., 2012). Certain regions of the genome are particularly prone to carcinogenic rearrangements, such as the fusion of immunoglobulin heavy chain genes to the proto-oncogene *c-Myc* during B cell class switch recombination (see later) (Haberl et al., 2016).

Recent studies by Tomasetti et al. have challenged the existing paradigm that the mutations driving carcinogenesis arise from two primary sources, inherited and acquired errors, where the latter are attributed mainly to environmental factors. Instead, the authors describe a model that integrates more robustly unavoidable mutations induced by internal processes (namely, base mispairing, polymerase slippage or errors, base deamination, and endogenous ROS lesions), arguing that mechanisms associated mainly with copying mistakes are responsible for up to two-thirds of carcinogenic driver mutations (Tomasetti et al., 2017). Ultimately, of course, the carcinogenic potential of a mutation is dependent on where in the genome it occurs. One of the major theories behind carcinogenesis is the "mutator phenotype," wherein a cell acquires mutations in genes that are involved in the DDR, thereby driving DNA damage accumulation, genome-wide mutagenesis, and ultimately the activation of oncogenes or inactivation of tumor suppressor genes, accelerating the process of malignant transformation (Loeb, 2016). This phenomenon seemingly explains the susceptibility observed in homozygous cancer syndromes associated with mutations in DNA repair genes (discussed later). It also forms the basis of the "second hits" of the Knudson hypothesis, wherein mutations, loss of heterozygosity (LOH), or promoter inactivation at a second (initially wild type/normal) allele can trigger carcinogenesis in cells with a heterozygous germline or somatic mutation at a DNA repair gene locus (Knudson, 1971).

DNA Repair Mechanisms

Collectively, the many forms of exogenous and endogenous DNA damage pose a tremendous threat to the functional stability of the cell and the entire organism. DNA damage-induced mutations arising in key regulatory genes, for example, can initiate a multistep cascade that ultimately ends in a cancer phenotype. Thus, to maintain genomic stability and cellular integrity in the face of DNA damage, a number of DNA repair mechanisms have evolved (see overview in **Fig. 1**).

DNA Damage Response

The protein kinases ataxia-telangiectasia mutated (ATM) and ataxia telangiectasia and Rad3-related protein (ATR) are central to DDR signaling, being recruited and activated by DSBs and single-stranded DNA (ssDNA), respectively (Awasthi et al., 2015). These proteins activate the serine/threonine-specific protein checkpoint kinases Chk1 (by ATR) and Chk2 (by ATM), which phosphorylate and inactivate the Cdc phosphotyrosine phosphatases (Cdc25A, -B, and -C), thereby preventing downstream signaling to activate the cyclin-dependent kinases that promote cell cycle transition (Jackson and Bartek, 2009). Functionally, this phenomenon arrests the cell cycle and allows DNA repair to operate prior to the potential deleterious effects associated with unchecked cell cycle progression, such as strand break formation associated with stalling and collapse of replication forks on encountering damage lesions. Three main checkpoints exist: G1/S, intra-S phase, and G2/M. The G1/S checkpoint is activated by damage that prevents initiation of replication, via the ATM-Chk2-Cdc25A or ATR-Chk1-Cdc25A cascades, and is maintained by Chk1 or Chk2-mediated phosphorylation of p53, which leads to p21-mediated inactivation of Cdk2 (Bartek and Lukas, 2001). The intra-S phase checkpoint is activated by replication fork stalling, and is probably initiated both by the specialized checkpoint sensors (via inactivation of Cdk2) and by various repair proteins such as the MRE11/Rad50/NBN (MRN) complex (see section "**Homologous Recombination**") and BRCA1 (Iyer and Rhind, 2017). Activation by the latter group of factors is thought to activate a second pathway via phosphorylation

of SMC1 and SMC3, which promotes recombination repair (see later) to recover stalled or collapsed replication forks. The G2/M checkpoint, which prevents initiation of mitosis in the presence of DNA damage, operates via ATM and ATR activation to regulate G2/M transition via inactivation of Cdc25C. Maintenance of the G2/M arrest requires transcriptional repression of Cdc25 expression, mediated via activation of p53 and p21 (Lobrich and Jeggo, 2007).

Ataxia telangiectasia (AT) is a rare autosomal recessive disorder caused by biallelic mutation of the *ATM* gene (Nissenkorn and Ben-Zeev, 2015). Over 300 causative *ATM* mutations have been recognized, with the majority (>80%) resulting in truncation mutants with little to no residual protein expression, although missense mutants with variable expression and kinase activity have been described. Consequently, AT presents with a phenotypically heterogenous group of symptoms dependent on the degree of residual ATM kinase activity (Teive et al., 2015). The most common and most severe form, resulting from biallelic ATM-null or kinase inactivating mutations, typically presents with early onset, progressive ataxia (~2 months to 2 years of age), associated with dysarthria, abnormal ocular movements, and oculocutaneous telangiectasia. Other features include lymphopenia and agammaglobulinemia (particularly IgA and IgG2), and respiratory dysfunction secondary to neuromuscular impairment and immunodeficiency. Malignancies are the main cause of mortality, specifically lymphoid and hematological in children, and solid tumors (including breast, hepatocellular, endocrine, and brain) in adults (Hecht and Hecht, 1990).

The importance of ATM in the maintenance of genomic stability and suppression of carcinogenesis, mediated through its role in DDR and checkpoint signaling, is illustrated by the increased frequency of chromosomal translocations observed in AT patient cells. ATM plays a particularly important role during class switch recombination, the process in which activated B cell immunoglobulin production is modified to alter function without affecting antigenic specificity. During this recombination event, DSB formation upstream of genes encoding the immunoglobulin constant region leads to the removal of unwanted heavy chain exons, with the free ends subsequently rejoined via nonhomologous end joining (NHEJ, see later) (Hecht and Hecht, 1987). In keeping with the important role that ATM plays in initiating the response to DSBs, mutation is associated with a high rate of chromosomal rearrangements around the Ig heavy chain loci, particularly oncogenic *IgH* to *c-Myc* translocations commonly found in AT-associated B cell lymphomas (Hathcock et al., 2015). Indeed, even a heterozygous *ATM* mutation is sufficient to induce tumorigenic genomic instability, as observed by the increased breast cancer susceptibility of the female relatives of AT patients (van Os et al., 2016).

Compared to ATM, which is activated by the comparatively rare event of DSB formation, a wide range of substrates can activate ATR, including not only damage lesions (such as ssDNA associated with stalled replication forks or resected DSBs) but also replication origins arising during S phase in a mechanism that prevents premature onset of mitosis. Given that ATR performs a similar role to ATM in DDR signaling, it also represents a plausible cancer susceptibility gene. This concept is supported by evidence in cell and mouse models that ATR heterozygosity increases genomic instability and tumor incidence. Sequencing of sporadic endometrial, colon, and stomach tumors has demonstrated the acquisition of somatic mutations or LOH in *ATR* exon 10, a region thought to be required for ATR activation of p53 (Lewis et al., 2005). These mutations were observed on a background of microsatellite instability (MSI), suggesting they arose as a consequence of mismatch repair (MMR) deficiency (see later)—a phenotype that has been replicated in double knockout MMR/ATR mouse models (Fang et al., 2004). To date, however, germline *ATR* mutations have not been convincingly shown to increase cancer risk. Specifically, human mutation analysis studies in a variety of familial cancers, including breast and ovarian cancers, have identified a small number of novel sequence variants in ATR, but established no definitive segregation with cancer risk (Heikkinen et al., 2005). The rarity of *ATR* mutation is likely a consequence of the critical importance of protein function, as observed by the early embryonic mortality of *ATR*-null mouse models (Brown and Baltimore, 2000).

Significantly, biallelic *ATR* mutations have been described in a small number of families with the recessively inherited Seckel syndrome, which presents with dwarfism, microcephaly, and mental retardation (O'Driscoll et al., 2003). In these patients, the defect was determined to be a synonymous hypomorphic mutation that generates a splicing variant that produced markedly reduced expression of normal ATR transcript and protein. Despite patient fibroblasts exhibiting an impaired response to DNA damage and increased genomic instability, no association between Seckel syndrome and cancer predisposition has been established (Alderton et al., 2004). Interestingly, Seckel syndrome shares clinical features with Nijmegen breakage syndrome (NBS), which does have increased susceptibility to hematological malignancies. NBS is caused by mutation of the DSB repair protein nibrin (NBN), which makes up part of the MRN complex with MRE11 and Rad50 (see section "**Homologous Recombination**") (Antoccia et al., 2006). MRN acts as a molecular sensor for DSBs, playing a pivotal role in initiating repair, and recruiting and activating ATM and ATR. The precise role of each component of MRN still requires further elucidation to understand why NBS phenotypically segregates with Seckel syndrome, while mutations in *MRE11* cause an ataxia telangiectasia-like disorder (Stracker and Petrini, 2011).

Direct Repair

Several proteins possess the ability to directly repair DNA damage lesions via a single-step mechanism, including reversal of O^6-methylguanine by O^6-alkylguanine DNA alkyltransferase (MGMT), and alkylation adducts (such as 1-methyladenine and 1-ethyladenine) by AlkB homologs 2 (ABH2) and 3 (ABH3). MGMT, in particular, has been investigated in the context of cancer development, as unrepaired substrate lesions can result in G → A transitions or crosslinks. However, *MGMT* knockout mouse models exhibit no cancer phenotype due to the presence of backup repair mechanisms such as NER, BER, and MMR (Glassner et al., 1999). Accordingly, no cancer-related human *MGMT* mutation has been reported, and common polymorphic variants (such as Ile143Val and Lys178Arg) have been found to neither impact protein function nor conclusively segregate with cancer risk (Du et al., 2013). However, MGMT likely plays an important role in the suppression of tumorigenesis following alkylation

damage, with knockout animals developing thymic lymphomas following methylnitrosourea exposure (Kawate et al., 1998), and transgenic *MGMT* overexpression suppressing cancer development in various mouse models of alkylation-induced malignancy (Dumenco et al., 1993). This protective effect is also relevant in the therapeutic setting, where efficient repair of alkylation damage by MGMT is associated with resistance to alkylating agents and poor patient outcomes (Kaina and Christmann, 2002). Promoter methylation resulting in loss of *MGMT* expression has been recognized as a common event in several tumor types, with MGMT expression levels now routinely used as a biomarker for chemotherapy response in glioblastoma and melanoma (Wick et al., 2014).

Mismatch Repair

MMR resolves errors introduced during replication that are not recognized by the proofreading capacity of DNA polymerases (Fishel, 2015; Goellner et al., 2015) (**Fig. 2**). Base mismatches and 1–2 nucleotide insertions/deletions are detected by MutSα (MSH2-MSH6 heterodimer), while larger mismatches (up to 16 nucleotides) are recognized by MutSβ (MSH2-MSH3). Upon binding to DNA, an ATP-dependent conformational change permits MutS to recruit multiple MLH1-PMS2 heterodimers (MutLα), forming sliding clamp complexes that dissociate from the DNA and translocate in either direction. MLH1-PMS1 activation is dependent upon proliferating cell nuclear antigen (PCNA), which may either be recruited by MutS, or may be spatially available if mispair recognition is associated with replication. MLH1-PMS1-mediated nicking of the DNA 5′ to the mispair initiates excision, either by recruitment of the 5′ to 3′ exonuclease EXO1 or by an EXO1-independent mechanism (**Fig. 2**). In EXO1-dependent excision, EXO1 is loaded at the 5′ nick and excises the DNA in a 3′ direction. Processivity is maintained through interaction with the multiple MutLα heterodimers loaded around the mispair, until EXO1 dissociation occurs due to the absence of further 3′ MutLα or presence of a strand terminus such as an Okazaki fragment. Subsequent repair synthesis and ligation completes repair across the newly generated gap. In the EXO1-independent pathway, excision may proceed via multiple nicking events catalyzed by MutLα (generating an identical gapped product as the EXO1-dependent mechanism), or by polymerase loading at a nicked site with subsequent strand displacement synthesis.

Germline mutations in genes involved in MMR (particularly *MSH2* and *MLH1*) are associated with hereditary nonpolyposis colorectal cancer (HNPCC; also known as Lynch syndrome), which imparts a 70%–85% lifetime risk of colorectal carcinoma, along with an elevated risk of endometrial and other cancers (Papadopoulos and Lindblom, 1997). HNPCC is inherited in an autosomal dominant pattern, although a somatic mutation event or epigenetic silencing at the second allele is required to trigger tumorigenesis; in the rare situation where two mutant alleles are inherited, cancers develop during childhood. A small number of familial cases with normal MMR gene sequences are recognized to result from germline "epimutations," wherein inherited promoter methylation of *MLH1* or *MSH2* silences gene expression (Hitchins et al., 2005); approximately 15% of sporadic colorectal cancers (CRC) also exhibit promoter methylation at *MLH1* (Li et al., 2013).

HNPCC is associated with increased variability in the length of short (1–6 nucleotides) tandem repeated DNA tracts—a state known as MSI that arises from failure to repair MMR substrates, such as base mismatches or insertion–deletion loops resulting from DNA polymerase slippage. MSI is a hallmark of a mutator phenotype state, wherein MMR deficiency results in a 100–1000-fold increased mutation rate, associated particularly with base substitutions and frameshift mutations that occur throughout the genome, contributing to malignant transformation when localized at tumor suppressor genes, such as APC, KRAS, and p53 (Loeb, 1994). Although MSI-positive tumors are histologically aggressive, they are associated with favorable clinical outcomes including increased tumor-infiltrating lymphocytes, reduced metastatic potential, and increased overall survival (Gelsomino et al., 2016). This survival benefit persists despite an association between MMR-deficient tumors and alkylating agent resistance. In repair-proficient cells, misincorporation of thymine opposite alkylative guanine lesions (such as O^6-methylguanine) is repeatedly recognized, corrected, and erroneously reestablished, preserving the original lesion and directing futile MMR cycling that eventually causes lethal strand breaks via ATM/ATR-induced apoptosis. Loss of MMR, in contrast, is associated with damage tolerance that does not trigger a cellular response, conferring drug resistance (Colella et al., 1999; Fink et al., 1998).

Base Excision Repair

BER is the primary mechanism by which nonbulky base lesions and abasic sites are resolved (Krokan and Bjoras, 2013; Wallace, 2014) (**Fig. 3**). BER is initiated by one of a group of DNA glycosylases, each of which recognizes a specific collection of base modifications. The substrate base is flipped out of the double helix into the glycosylase active site pocket, permitting cleavage of the *N*-glycosidic bond to yield an abasic site (Dizdaroglu et al., 2017). Apurinic/apyrimidinic endonuclease 1 (APE1) breaks the DNA phosphodiester backbone at the abasic intermediate, producing a single-strand interruption flanked by a 3′ hydroxyl (3′-OH) and a 5′ deoxyribosephosphate (5′-dRP) (Li and Wilson, 2013). Additionally, some members of the glycosylase family ("bifunctional" glycosylases) possess AP lyase activity and can perform strand incision by β- or β,δ-elimination of the abasic site, resulting in a 3′ α,β-unsaturated aldehyde or 3′ phosphate, respectively, adjacent to a 5′ phosphate group. These terminal groups block polymerase extension or nick ligation, and must be resolved to a 3′-OH/5′-P configuration by end-processing enzymes, including polynucleotide kinase-phosphatase (PNKP) (Weinfeld et al., 2011), APE1 (Demple and Harrison, 1994), DNA polymerase β (POLβ) (Matsumoto and Kim, 1995), tyrosyl-DNA phosphodiesterase 1 (TDP1) (Cortes Ledesma et al., 2009), and aprataxin (APTX) (Ahel et al., 2006). Subsequent repair proceeds by one of two mechanisms of polymerase-mediated gap-filling, with pathway choice dependent on factors such as initial damage substrate, local DNA structure, cell cycle, and cellular replicative status. During short patch repair (SP-BER), a single nucleotide is inserted by POLβ, and the remaining nick is ligated by the X-ray cross-complementing 1

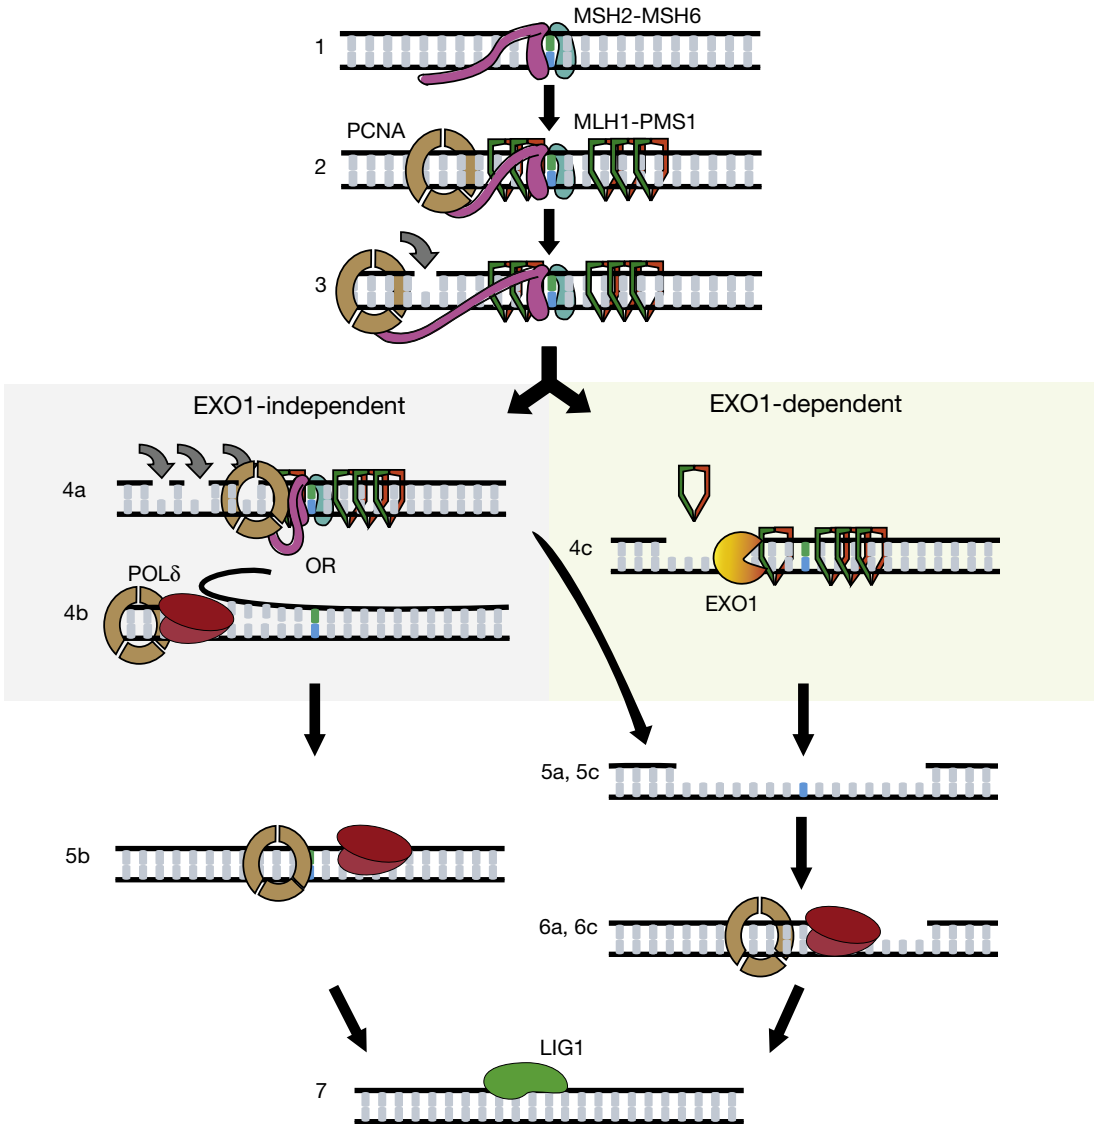

Fig. 2 Mismatch repair (MMR) recognizes and resolves polymerase errors introduced during replication, with MSH2-MSH6 targeting base mismatches and 1–2 nucleotide insertions/deletions (1) and MSH2-MSH3 commencing repair of larger mismatched sections (not shown). MSH2-MSH6 triggers the ATP-dependent recruitment of the MLH1-PMS1 sliding clamp and recruitment/retention of PCNA (2). Following endonucleolytic cleavage by PCNA-activated MLH1-PMS1 (3), MMR proceeds via an EXO1-independent (left) or EXO1-dependent (right) subpathway. One model of EXO1-independent MMR hypothesizes that PCNA stimulates MLH1-PMS1 to perform several endonucleolytic cleavages, leading to degradation of the DNA past the mispair (4a), thereby generating a product similar to that produced by the exonuclease activity of EXO1 (5a). The resulting gap is filled by POLδ (6a), and ligation occurs via LIG1 (7). In the second EXO1-independent model (4b), a 5′ nick is made by MLH1-PMS1, permitting strand displacement synthesis by POLδ past the nucleotide mismatch (5b). The 5′ flap is then cleaved before the nick is sealed by LIG1 (7). In EXO1-dependent MMR, a 5′ nick enables EXO1 recruitment (4c), followed by excision of the newly synthesized strand to a position past the mispair (5c). Gap-filling subsequently proceeds by POLδ (6c), followed by ligation by LIG1 (7). Adapted from Goellner, E. M., Putnam, C. D. and Kolodner, R. D. (2015). Exonuclease 1-dependent and independent mismatch repair. *DNA Repair (Amst)* **32**, 24–32. https://doi.org/10.1016/j.dnarep.2015.04.010, with permission.

(XRCC1)-ligase 3α (LIG3α) heterodimer (Dianov and Lindahl, 1994). Alternatively, long patch repair (LP-BER) involves generation of a 2–10 nucleotide 5′ flap by strand displacement synthesis primarily by POLδ/ϵ (supported by the PCNA sliding clamp), and subsequent excision by flap endonuclease 1 (FEN1), prior to ligase 1 (LIG1) nick sealing (Fortini et al., 1998). A third related pathway (Fig. 3), single strand break repair (SSBR), resolves single-strand DNA breaks induced by ROS or failed enzymatic reactions (such as BER interruptions or incomplete resolution of DNA TOP1 cleavage complexes during replication or transcription). Strand breaks are typically detected and bound by poly(ADP-ribose) polymerase 1 (PARP1), activating poly(ADP-ribosyl)ation to recruit a complex of factors that includes XRCC1, the above end-processing enzymes, DNA polymerases, and DNA ligases that complete repair via a manner analogous to classic BER (Abbotts and Wilson, 2017).

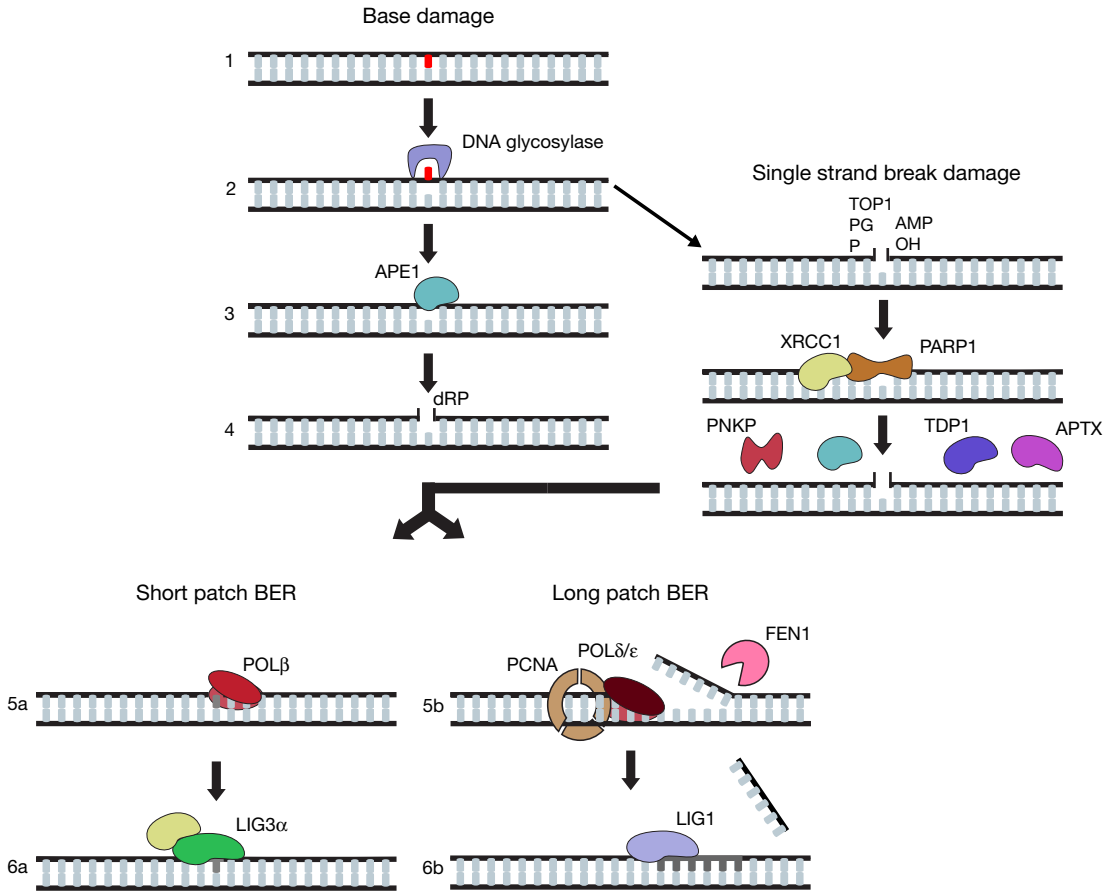

Fig. 3 Base excision repair (BER) typically begins at sites of small, nonhelix-distorting base damages, such as uracil or 8-oxoguanine (1). Damage-specific DNA glycosylases recognize and "flip-out" the base lesion to allow cleavage of the *N*-glycosidic bond and production of an abasic site (2). Most commonly, APE1 incises the DNA backbone at the abasic site (3), creating a single-strand interruption (4). During short patch BER (bottom, left), DNA POLβ removes the 5'-dRP residue and inserts a single nucleotide into the gap (5a), followed by ligation by LIG3α in complex with XRCC1 (6a). Repair synthesis in long patch BER (bottom, right) is mainly performed by DNA POLδ/ϵ (5b), which generates a 2–10 nucleotide flap by strand displacement. FEN1 excises the flap structure (5b) prior to LIG1 nick sealing (6b). Single-strand break damage (some examples shown) is resolved by a third pathway, SSBR, which shares overlap with components of BER, but serves a specialized DNA "clean-up" function. In classic SSBR (top, right), break recognition by PARP1 activates poly(ADP-ribosyl)ation, which recruits XRCC1 and associated end-processing enzymes that function to generate required 3′-OH and 5′-P groups for subsequent polymerase gap-filling and nick ligation. *dRP*, deoxyribose phosphate; *TOP1*, topoisomerase cleavage complex; *PG*, phosphoglycolate; *P*, phosphate; *AMP*, adenosine monophosphate; *OH*, hydroxyl.

The fundamental importance of BER is highlighted by the number of base and sugar damages that arise under normal cellular conditions (>10,000 lesions per cell per day). Consequently, germline mutations in core BER factors are commonly associated with embryonic or early perinatal lethality in mouse models. Where BER-related syndromes are recognized, for example with mutation of end-processing factors (such as *APTX*, *PNKP*, and *TDP1*), or the recently reported case of biallelic mutations in *XRCC1* (Hoch et al., 2017), the associated phenotype is one of neurological deficit rather than cancer predisposition, reflecting the critical role that BER (or more accurately SSBR) plays in the resolution of genomic damage in terminally differentiated cells, such as neurons, where other repair pathways (particularly those associated with replication) are downregulated (Leandro et al., 2015; Sykora et al., 2013).

Numerous polymorphic variants of BER factors have been described, with considerable effort devoted to determining the impact on BER proficiency and cancer risk. Variants of OGG1, a repair enzyme involved in recognition and removal of 8-oxoG, are the best characterized among the DNA glycosylases. Mouse models for Ogg1 are associated with 8-oxoG accumulation and an increase in spontaneous mutation frequency (Larsen et al., 2006), although no increased cancer predisposition is described without exogenous stress (e.g., skin tumors following UVB exposure), or deletion of both *Ogg1* and *MutY* (see later) simultaneously, which is associated with lymphomas, lung and ovarian tumors (Xie et al., 2004). In humans, the OGG1 polymorphic variant Ser326Cys is observed at a population frequency of ~32%. Functional studies suggest a minor catalytic defect (~63% of wild type) that does not impact the rate of 8-oxoG removal (Simonelli et al., 2013), and the ability of the variant to complement the spontaneous mutation frequency of *E. coli mutY*$^{-/-}$ has been under debate. Accordingly, an associated cancer risk has not been clearly established, with epidemiological studies producing inconsistent correlations (Zou et al., 2016), although an association with lung cancer risk seems to be better supported (Hung et al., 2005). More recently, polymorphism of a second BER glycosylase, thymine DNA glycosylase (TDG), has

also been reported as a possible tumor-associated variant (Sjolund et al., 2014). Functionally, this Gly199Ser substitution increases TDG binding of both the damage substrate and the abasic site product, preventing downstream repair. Collapse of replication forks at these lesions creates DSBs that risk genomic instability; consequently, cells expressing the Gly199Ser variant exhibit cellular transformation, although a cancer association has not yet been demonstrated in population studies.

The MUTYH (a.k.a. MutY) DNA glycosylase functions to remove adenine that is incorrectly inserted opposite 8-oxoG by a replicative polymerase (a mismatch that can also be resolved by MMR). MUTYH-associated polyposis (MAP) is a subtype of familial adenomatous polyposis (FAP), a CRC syndrome that presents with colonic polyps, an increased lifetime risk of CRC, and an association with other malignancies, including of the duodenum, ovary, bladder, and skin (Yamaguchi et al., 2014). MAP is almost always associated with somatic mutations in *APC*, the gene responsible for FAP, resulting from GC → TA transversions introduced by failure to remove misincorporated adenine opposite 8-oxoG (Al-Tassan et al., 2002). Inheritance is autosomal recessive, and usually the result of biallelic mutations, with over 30 truncating mutations and over 50 missense variants of *MUTYH* being described (Cheadle and Sampson, 2007). Functionally, the most common missense variants, Tyr165Cys and Gly382Asp, are associated with greatly reduced substrate binding, glycosylase activity, and ability to complement *E. coli mutY* mutation (Al-Tassan et al., 2002). A similar cancer susceptibility syndrome is attributed to mutations in *NTHL1*, which encodes a bifunctional DNA glycosylase that recognizes oxidized pyrimidine bases. As with MAP, NTHL1-associated polyposis is associated with an extended spectrum of cancers, including endometrium, duodenum, skin, breast, and pancreas (Talseth-Palmer, 2017).

The multifunctional protein APE1 accounts for >95% of total cellular endonuclease activity, and has important (and separable) roles in redox regulation of gene expression and nonredox transcriptional repression (Li and Wilson, 2013). While the essentiality of the redox function is unclear, knockout of the endonuclease function rapidly induces apoptosis in a number of cell models, emphasizing the critical importance of APE1 in cell viability (Fung and Demple, 2005). Consistently, nullizygous mouse models are associated with early embryonic lethality, while heterozygous animals, though generally phenotypically normal, exhibit reduced BER activity, increased frequency of spontaneous mutation, sensitivity to oxidative stress, elevated cancer risk, and reduced survival (Ludwig et al., 1998). Cancer susceptibility with several common polymorphisms (particularly Asp148Glu, found in ~46% of the population) has been extensively studied, without definitive evidence of risk association (Karahalil et al., 2012). Functionally, several rare variants (such as Leu104Arg and Arg237Ala) have been shown to exhibit impaired endonuclease activity, although no association with cancer has been reported for these proteins (Hadi et al., 2000). Moreover, while the endometrial cancer-associated variant Arg237Cys displays in vitro impairment of function (including reduced AP-DNA complex stability, 3′-5′ exonuclease activity and 3′-damage processing, and AP site cleavage within nucleosome complexes (Illuzzi et al., 2013)), it was not found to induce cancer cell phenotypes when expressed exogenously in certain cell models (Illuzzi et al., 2017; Lirussi et al., 2016). This suggests that the APE1 variants characterized to date represent possible susceptibility factors, but are not likely to be drivers of carcinogenesis.

The SP-BER polymerase POLβ is associated with embryonic or perinatal lethality in knockout mouse models, with heterozygotes accumulating DNA damage and exhibiting sensitivity to oxidative stress (Ray et al., 2013). A germline polymorphism of *POLβ*, Arg137Gln, has been associated with significant impairment of polymerase activity, DNA damage accumulation, and damaging agent sensitivity, although an association with cancer susceptibility has not been conclusively demonstrated (Guo et al., 2009). Somatic mutations in POLβ have been observed in ~40% of CRC, and have been reported in many other tumor types (Sobol, 2012). Most frequently observed is an 87 bp deletion mutant that produces a truncated protein at the catalytic domain. Tumor cells expressing this mutant exhibit significantly decreased BER capacity as a result of a dominant negative effect of the truncated protein that suppresses the catalytic activity of wild-type POLβ (encoded by the intact allele), possibly through competition for XRCC1 binding (Bhattacharyya and Banerjee, 1997). It is thought that acquisition of this mutation early in tumorigenesis is an important step in the development of a mutator phenotype that promotes further oncogenic mutations. Additional frameshift and missense mutations that similarly alter polymerase activity (e.g., increased infidelity) and/or reduce BER capacity have been implicated in breast and prostate cancer (Sobol, 2012).

As with other central BER factors, XRCC1 nullizygosity is associated with early embryonic lethality (Tebbs et al., 1999). Heterozygote (haploinsufficient) animals, while largely normal phenotypically for many parameters related to disease and aging, develop liver toxicity and precancerous colonic lesions following alkylating agent exposure (McNeill et al., 2011). In addition to the rare pathogenic mutants associated with neurological disease noted above, polymorphic germline variants in XRCC1 that have been extensively studied include Arg194Trp, Arg280His, and Arg399Gln (Karahalil et al., 2012). Reports are mixed regarding possible association of Arg194Trp and Arg399Gln with functional alterations (such as protein interactions or subcellular localization), and although both have been implicated by meta-analyses as possible susceptibility factors for cancer (including breast, prostate, and bladder), no consensus has been reached. Conversely, Arg280His appears to more consistently exhibit impaired function in terms of repair capacity, such as DNA binding or retention at sites of DNA damage (Berquist et al., 2010), and has been associated with a generalized overall increased cancer risk (albeit not observed when stratified by cancer type) (Zhang et al., 2012). For each variant, however, it is interesting to note that subgroup analysis often indicates that XRCC1 genotype–lifestyle interactions (particularly smoking) are strongly associated with cancer risk, including for gastrointestinal, colorectal, and head and neck malignancies.

Nucleotide Excision Repair

NER resolves bulky base lesions associated with distortion of the DNA helical structure (Marteijn et al., 2014) (**Fig. 4**). Two subpathways have been identified: global-genome NER (GG-NER), which removes lesions throughout the actively transcribed and nontranscribed genome; and transcription-coupled NER (TC-NER), which provides a more rapid mechanism for removing lesions from the

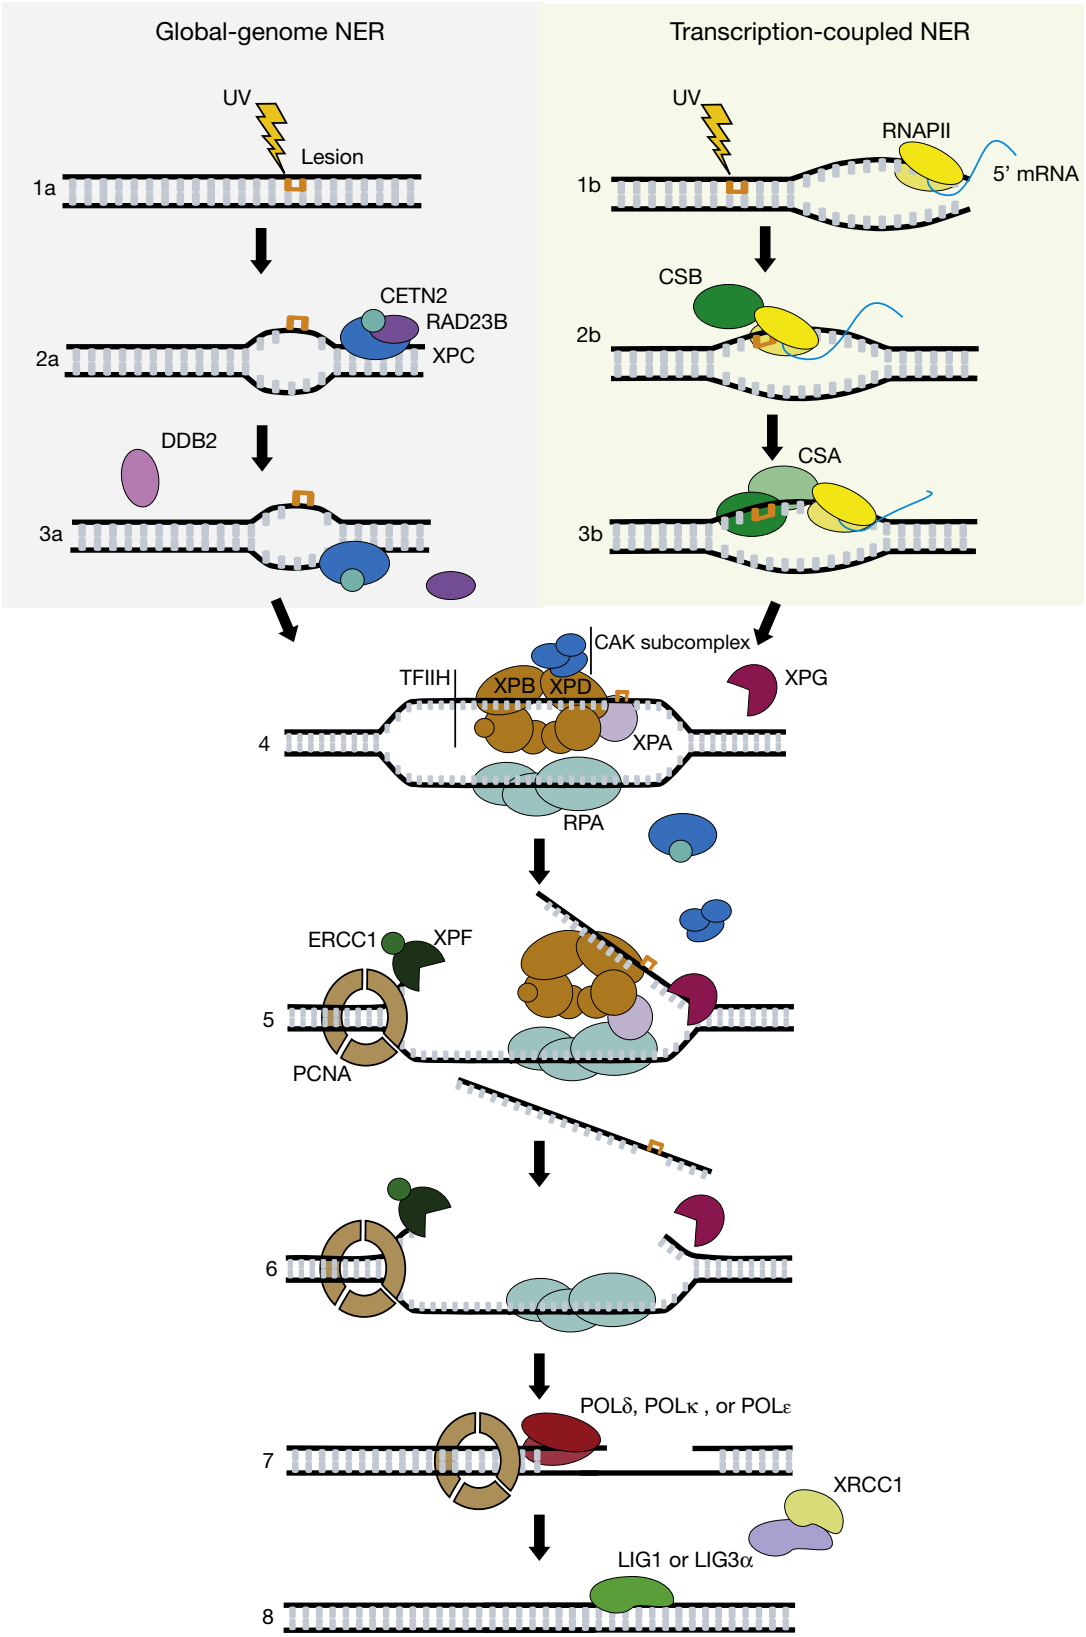

Fig. 4 Nucleotide excision repair (NER). Bulky, helix-distorting lesions (e.g., UV photoproducts) are recognized and repaired by one of two subpathways of NER: global-genome (left) or transcription-coupled (right). GG-NER (1a) functions throughout the genome, and is initiated by a detection complex that includes XPC, RAD23B, CETN2, and possibly an E3 ubiquitin ligase complex (DDB1-CUL4-RBX1) that contains DDB2 (2a); RAD23B dissociates from this assembly upon binding of XPC to the site of damage (3a). Rapid removal of lesions from actively transcribed strands in the genome is performed by TC-NER (1b), which is activated by stalling of RNAPII and subsequent recruitment of CSB and additional factors (not shown) (2b). CSB likely communicates with an E3 ubiquitin ligase complex (DDB1-CUL4-RBX1) that contains CSA (instead of DDB2), resulting in

transcribed strand of active genes. GG-NER is initiated by the xeroderma pigmentosum (XP) complementation factor XPC, in complex with RAD23B and centrin 2 (CETN2), which constantly scans the genome for helix-distorting lesions (Sugasawa et al., 1998). Substrate lesions are also recognized and bound by DDB2, the substrate recognition factor in an E3 ligase complex (also comprised of DDB1-CUL4-RBX1), which ubiquitylates both histones and NER factors (including DDB2 and XPC) to coordinate localized chromatin relaxation and repair factor interactions at the site of damage (Kapetanaki et al., 2006; Scrima et al., 2008). Damage recognition in TC-NER is initiated by stalling of RNA polymerase II (RNAPII) at the site of a lesion (Fousteri et al., 2006). Arrest of the transcription complex increases the affinity of RNAPII for the transcription elongation factor CSB (Cockayne syndrome complementation protein B). CSB is responsible for displacing (or repositioning) RNAPII and coordinating recruitment of downstream NER factors including CSA, which in TC-NER replaces DDB2 as the substrate recognition factor within the DDB1-CUL4-RBX1 E3 ligase complex (Fousteri et al., 2006).

Following damage recognition by either pathway (**Fig. 4**), the transcription initiation factor IIH (TFIIH) complex and the stability factor XPG are recruited to the lesion (Volker et al., 2001). Two TFIIH components, the ATPases/helicases XPB and XPD, induce localized DNA unwinding to create a 20–30-nucleotide bubble (Winkler et al., 2000). XPA is recruited and binds near the 5′ side of the bubble, where it verifies the damage and coordinates the structure-specific endonuclease XPF-ERCC1 to create a 5′ incision (Sugasawa et al., 2009). This in turn activates the endonuclease activity of XPG to incise the 3′ end of the bubble, excising the lesion in a 22–30 nucleotide DNA fragment (Fagbemi et al., 2011). PCNA is loaded at the 5′ end to facilitate gap-filling synthesis by DNA polymerases δ, κ and/or ϵ, and repair is completed by nick ligation via DNA LIG1 or XRCC1-LIG3α (Moser et al., 2007).

Defects in several NER proteins give rise to the autosomal recessive disorder XP (Dupuy and Sarasin, 2015). XP is subdivided into seven complementation groups, which reflect the pathogenic genetic defect: XPC and XPE/DDB2 (involved in GG-NER damage recognition); XPA, XPG, XPB, and XPD (involved in DNA unwinding); and XPF (involved, along with XPG, in excision). A further, milder, variant caused by defects in the translesion synthesis (TLS) polymerase POLH/XPV is also recognized. XP is associated with accumulation of unrepaired NER substrate lesions throughout the genome, where tolerance of this damage by TLS enables cell survival, but markedly increases the mutagenesis rate. Given that UV radiation is a major source of damage repaired by NER, the XP phenotype characteristically manifests with cutaneous symptoms, including extreme UV hypersensitivity, altered skin pigmentation, and a vastly elevated ($>10{,}000\times$) risk of sun-induced skin cancers. The risk of other solid tumors is also elevated, presumably due to the role of NER in the repair of ROS-induced DNA damage, such as cyclopurine lesions.

The precise clinical phenotype of XP depends upon the complementation group affected and the degree to which the associated protein is involved in both GG-NER and TC-NER (Berquist and Wilson, 2012). Accordingly, mutations in XPC or XPE/DDB2, which function as damage sensors in GG-NER, produce a "pure" XP phenotype of UV sensitivity and skin cancer. This contrasts with mutations in TC-NER genes, that is *CSA* and *CSB*, which produce Cockayne syndrome (CS), a progeroid phenotype with significant neurological features (including microcephaly, mental retardation, and sensorineural deafness), cachexia, and a markedly reduced life expectancy (Laugel, 2013). The predominance of neurological features in CS has been proposed to reflect the reliance of post-mitotic cells (such as neurons) on active TC-NER to maintain gene expression by removing transcription-blocking lesions, while compensatory repair mechanisms such as GG-NER are downregulated (Iyama and Wilson, 2013). In this context, damage accumulation due to the loss of TC-NER creates increased stalled RNAP complexes that can activate apoptotic mechanisms that accelerate the segmental premature aging phenotype and simultaneously provide protection from tumorigenic mutagenesis. Predictably, then, mutations in core downstream NER factors that play roles in both GG-NER and TC-NER, such as the TFIIH subunits XPD and XPB, manifest with complex phenotypes that may encompass both XP and CS features (Natale and Raquer, 2017).

Importantly, some factors have roles outside of NER that impact clinical presentation. For example, mutations affecting the endonuclease function of XPG mainly affect NER, resulting in an XP phenotype. However, XPG truncation mutants, which affect the structural role that XPG plays in other repair processes (such as the ability to trigger BER at oxidative damage sites, and interactions with homologous recombination (HR) factors during replication-associated repair), produce a mixed XP/CS disorder. Similarly, TFIIH plays an important role in transcription initiation, with perturbation of this function in certain XPB or XPD mutants underlying trichothiodystrophy, a CS-like disorder that also features brittle hair and scaling of the skin (Yew et al., 2016). Lastly, the CSA and CSB proteins have been shown to play various roles in general transcription regulation, possibly via chromatin remodeling mechanisms.

Interstrand Crosslink Repair

Interstrand crosslinks (ICLs) are a highly toxic form of damage that covalently links both strands of DNA, creating a potent block to transcription and replication. Efficiency of recognition and repair of ICLs varies depending on cell cycle phase and the presence of

reverse translocation or expulsion of RNAPII, creating accessibility for the DNA repair machinery (3b). Following damage verification by XPA in both GG-NER and TC-NER, the TFIIH complex is recruited to the site of the lesion (4), possibly in cooperation with the E3 ligase complex. TFIIH member helicases (XPB and XPD) produce localized DNA unwinding, resulting in RPA binding to single-stranded DNA (4). Incision occurs on both sides of the unwound DNA, first by XPF-ERCC1 at the 5′ end (5), and second by XPG at the 3′ end (6), releasing a damage-containing oligonucleotide of 22–30 nucleotides in length. Gap-filling synthesis is performed by DNA polymerases δ/κ/ϵ in cooperation with PCNA (7), prior to ligation by LIG1 or XRCC1-LIG3α (8). *CAK*, cdc-activating kinase.

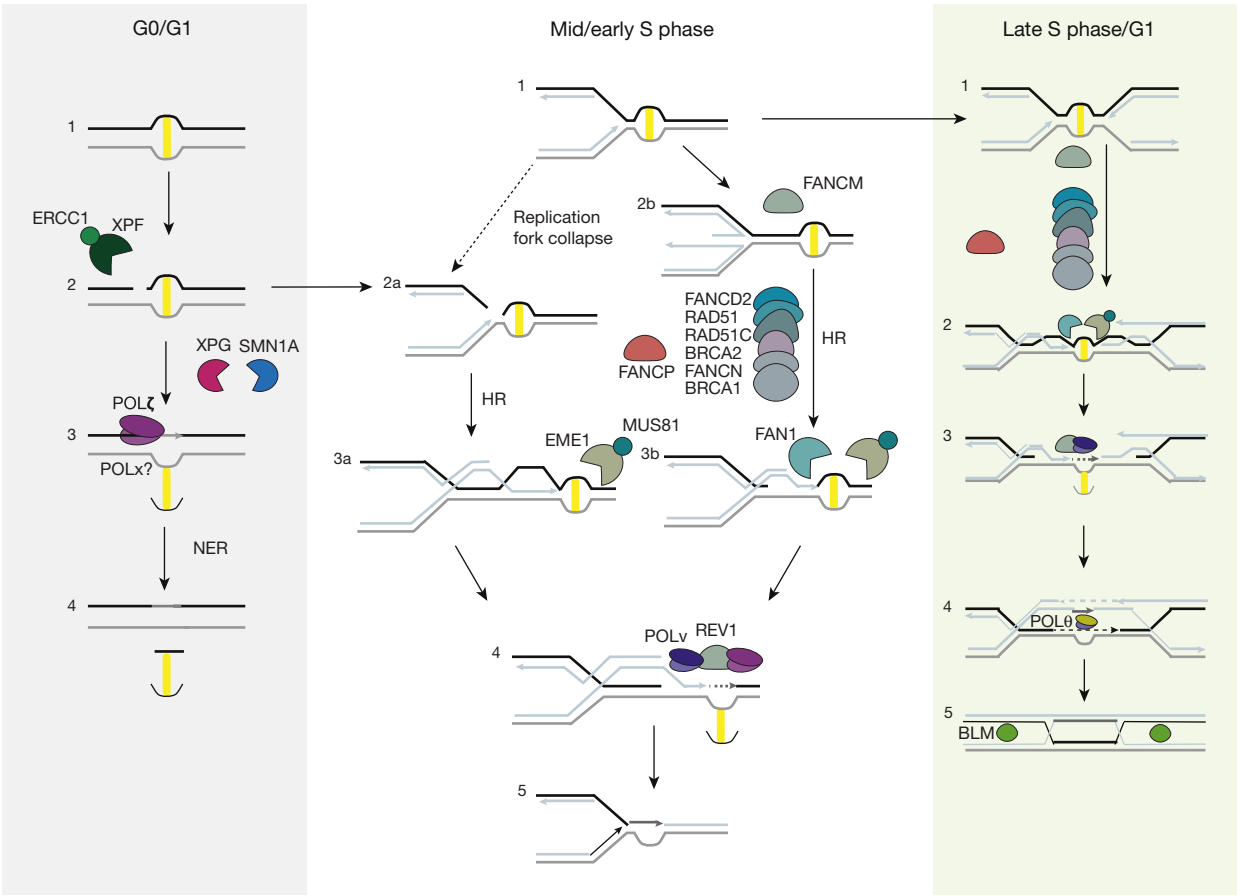

Fig. 5 Interstrand crosslink (ICL) repair. Covalent linkage of bases on opposing DNA strands, that is ICLs (depicted by *yellow line*) are repaired by ICL repair mechanisms. In G0/G1 phase (left panel), or in noncycling cells, ICLs are recognized by one of the two NER subpathways (1; see **Fig. 4**), ultimately resulting in XPF-ERCC1 incision (2), followed by unhooking by one of several nucleases, such as XPG or SNM1A, and gap-filling across the crosslink remnant by a TLS polymerase (3). A second round of classic NER excises the remaining damage from the opposing strand to complete repair (4). In mid/early S phase (center), repair is initiated when the replisome encounters a ICL (1). Collapsed replication forks, which result in the formation of a one-ended DSB (2a), can be avoided by FANCM-mediated fork regression (formation of the so-called chicken foot) and stabilization of the intermediate by the FA protein complex (depicted, 2b). In either case, homologous recombination (HR) and processing by various structure-specific nucleases (e.g., EME1-MUS81 or FAN1) results in unhooking (3a, 3b) and facilitates generation of a stable substrate for TLS polymerases (4). HR then completes the process, reestablishing replication, prior to excision of the crosslink remnant (5). In late S or G1 (right), the ICL is often encountered by a dual replication fork (1), resulting in FA protein-mediated HR and subsequent dual incision by structure-specific nucleases to carry out unhooking (2). TLS polymerases then perform gap-filling synthesis across the remaining crosslink damage (3), before remnant removal and replication completion (4). The Holliday junction intermediate is resolved by the BLM-containing complex (5) or a combination of nucleases/resolvases (see **Fig. 7**). Adapted from Deans, A. J. and West, S. C. (2011). DNA interstrand crosslink repair and cancer. *Nature Review. Cancer* **11**(7), 467–480. https://doi.org/10.1038/nrc3088, with permission.

active replication or transcription (Fig. 5). In G phase, NER proteins play a particularly critical role in damage recognition and excision, although the associated responses can of course take place in any cell cycle phase (Deans and West, 2011). The GG-NER factor XPC has been implicated in ICL recognition throughout the genome, probably in a structure-specific manner that detects extensively kinked or unwound lesions (Muniandy et al., 2009). This function may be supported, particularly for less distorted lesions, by MMR proteins, such as MSH2 (Vasquez, 2010). When a transcribing RNA polymerase collides with an ICL, recruitment of TC-NER proteins, such as CSA and CSB, can initiate repair (Iyama et al., 2015). In either scenario, dual incisions by XPF-ERCC1 and possibly XPG on a single strand 5′ and 3′ to (or SNM1A exonuclease processing across) the ICL "unhook" the covalent linkage, and synthesis by a TLS polymerase (such as DNA polymerase κ, ζ, or REV1) bypasses the remaining lesion and fills the gap prior to ligation. A second round of NER on the opposite strand is required to excise the crosslink remnant, allowing for the repair process to be complete (Kottemann and Smogorzewska, 2013). Notably, studies have suggested that the progressive degeneration in postmitotic (noncycling) tissue, such as the brain, or the broad premature aging phenotypes associated with defects in the XPF-ERCC1 nuclease complex (due to mutation of *XPF* (Niedernhofer et al., 2006) or *ERCC1* (Jaspers et al., 2007)) or the CS proteins may stem specifically from impaired ICL resolution (Iyama and Wilson, 2013).

In S phase of cycling cells (Fig. 5), stalling of helicase progression ahead of a replication fork by an ICL is a substrate for recognition by FANCM, which recruits the Fanconi anemia (FA) core complex, comprised of the FA complementation group proteins

FANCA, FANCB, FANCC, FANCE, FANCF, FANCG, and FANCL (Palovcak et al., 2017). This complex ubiquitinates (via the E3 ubiquitin ligase activity of FANCL) two further FA complementation group factors, FANCD2 and FANCI. This event leads to the recruitment of a number of nucleases, including XPF-ERCC1, MUS81-EME1, SLX4-SLX1, FAN1, and SNM1A, which carry out processing to unhook the lesion and allow bypass via TLS. The critical recruitment of DSB repair (DSBR) factors BRCA1, BRCA2, and RAD51 suggests that the HR pathway (described later) is required for the completion of repair. The mechanism for the generation of a suitable DSB substrate has not been precisely delineated, but may stem from nuclease unhooking, resulting in replication fork collapse or replication fork regression to generate a "chicken foot" structure possessing a double-stranded DNA end (Haynes et al., 2015).

Mutation of one of the genes comprising the 17 FA complementation groups forms the genetic basis for FA, a rare autosomal recessive disorder that commonly causes short stature, subfertility, progressive bone marrow failure, and an increased risk of hematological (particularly acute myeloid leukemia) and solid (head and neck, esophageal, and gynecological) malignancies (Walden and Deans, 2014). Despite the genetic heterogeneity, the clinical presentation of FA is broadly similar. Specific exceptions include biallelic mutations of *PALB2* or *BRCA2*, which present with childhood malignancies and markedly reduced lifespan (5 years of age, compared to approximately 40 years in FANCA, which represents 65% of FA cases). Notably, FA is diagnosed by cellular sensitivity to crosslinking agents, and as such, chemotherapeutic agents of this mode of action are contraindicated in FA patients (Deans and West, 2011). Mechanistically, failure by the FA pathway to repair the DSB produced when an ICL is encountered by a progressing replication fork is associated with a high risk of genetic recombination, including oncogene translocations or tumor suppressor gene deletions that may drive carcinogenesis (Thompson and Hinz, 2009). Unrepaired ICLs are also potent inducers of apoptosis, leading in FA patients to depletion of the hemopoietic stem cell pool that creates a selection pressure for tumorigenic clones that are resistant to apoptotic signaling.

Nonhomologous End Joining

Two major pathways are responsible for the resolution of DNA DSBs. Outside of S/G2 phase, when the sister chromatid is not closely aligned to permit homology-driven repair (see later), canonical NHEJ (c-NHEJ) is the most common mechanism of repair, characteristically joining DNA ends possessing little (<10 bp) or no regions of microhomology (Bunting and Nussenzweig, 2013; Radhakrishnan et al., 2014) (**Fig. 6**). Mechanistically, c-NHEJ is highly flexible, able to recognize and initiate repair on a wide range of terminal substrates, including those resulting from ionizing radiation. DSBs are often recognized by the Ku heterodimer (comprised of KU70 and KU80 subunits), which forms a ring structure that encircles the DSB end and acts as a scaffold to recruit other NHEJ factors (Difilippantonio et al., 2000). The DNA-dependent protein kinase (DNA-PK_{CS}) is recruited early into a complex with Ku (collectively known as DNA-PK) that stabilizes and protects the substrate DSB termini by inhibiting ligation until the DNA ends are appropriately processed and juxtaposed for resolution (Uematsu et al., 2007). In order to remove complex damage lesions that may be present, a number of substrate-specific end-processing enzymes are known to be recruited by Ku to the strand break. These include PNKP (which processes nonligatable 5′-OH or 3′-P termini), Aprataxin (which removes adenylate groups from 5′-termini), polymerases μ and λ (which perform gap-filling activities), and the end resection nuclease Artemis, PNKP-related protein (APLF), and WRN (Davis and Chen, 2013). Also recruited to the site of DNA end joining is XRCC4, a nonenzymatic scaffold protein that plays an additional role in factor recruitment, XRCC4-like factor (XLF), which interacts with XRCC4 to form a filament that bridges the DNA ends, and DNA ligase 4 (LIG4), which ultimately seals the DSB (Kusumoto et al., 2008).

Knockout mouse models of various c-NHEJ proteins have been described, generally characterized by genomic instability, radiosensitivity, and severe combined immunodeficiency (SCID). The SCID phenotype arises from the role of c-NHEJ in the repair of programmed DSBs during V(D)J recombination, the process which generates diversity within the immune repertoire (Roth, 2014). In germ line cells, immunoglobulin and T cell receptor genes contain variable (V), diversity (D), and joining (J) segments, with each segment possessing a coding region flanked by recombination signal sequences (RSS). During immune development, cleavage at the RSS generates blunt-ended DSBs that are processed, rearranged, and rejoined by c-NHEJ in an ordered fashion to introduce recombination diversity, which is amplified by additional variability introduced at the segment junctions during the end-processing step of c-NHEJ. Impairment of V(D)J recombination limits this immune diversity, resulting in immunodeficiency, as well as increasing the risk of inappropriate recombination events that promote lymphoid malignancies. In humans, radiosensitive SCID phenotypes associated with c-NHEJ impairment are rare, but have been described in mutations of DNA-PKcs and Artemis (Le Deist et al., 2004). Mutation of proteins involved in the c-NHEJ ligation complex (XRCC4, XLF, and LIG4) also produces immunodeficiency, but within the context of a syndrome similar to NBS or Seckel syndrome, exhibiting microcephaly, facial dysmorphism, and growth retardation (Woodbine et al., 2014). This phenotypic difference stems from the precise role of each factor in c-NHEJ: for example, mutation of end-processing enzymes affects repair of a subset of DSBs only, with V(D)J-associated breaks being disproportionately affected, whereas mutation in a ligation-associated protein limits the rate of repair of all DSBs processed through the c-NHEJ pathway and hence produces a profound developmental defect and increased malignancy risk.

Due to the absence of homologous DNA to guide repair, NHEJ has a reputation for being an error-prone mechanism. However, the degree of repair accuracy is determined by the complexity of the strand break chemistry and the processing steps required to produce ligatable termini. Accordingly, repair of complementary strand breaks without blocking termini can dispense with the requirement for Ku recruitment and can be directly ligated by LIG4 with minimal introduced error (Frit et al., 2014). Conversely, repair of noncomplementary complex DSBs, such as those introduced by ionizing radiation, requires processing (including resection and/or gap-filling) by a repertoire of NHEJ proteins that introduce genomic alterations (Aparicio et al., 2014; Pannunzio et al., 2014). Furthermore, when c-NHEJ is unavailable (due to mutation or downregulation), a DNA-PK-independent alternative NHEJ pathway (alt-NHEJ) is engaged that is constitutively associated with profound genomic rearrangements (Iliakis et al., 2015) (**Fig. 6**).

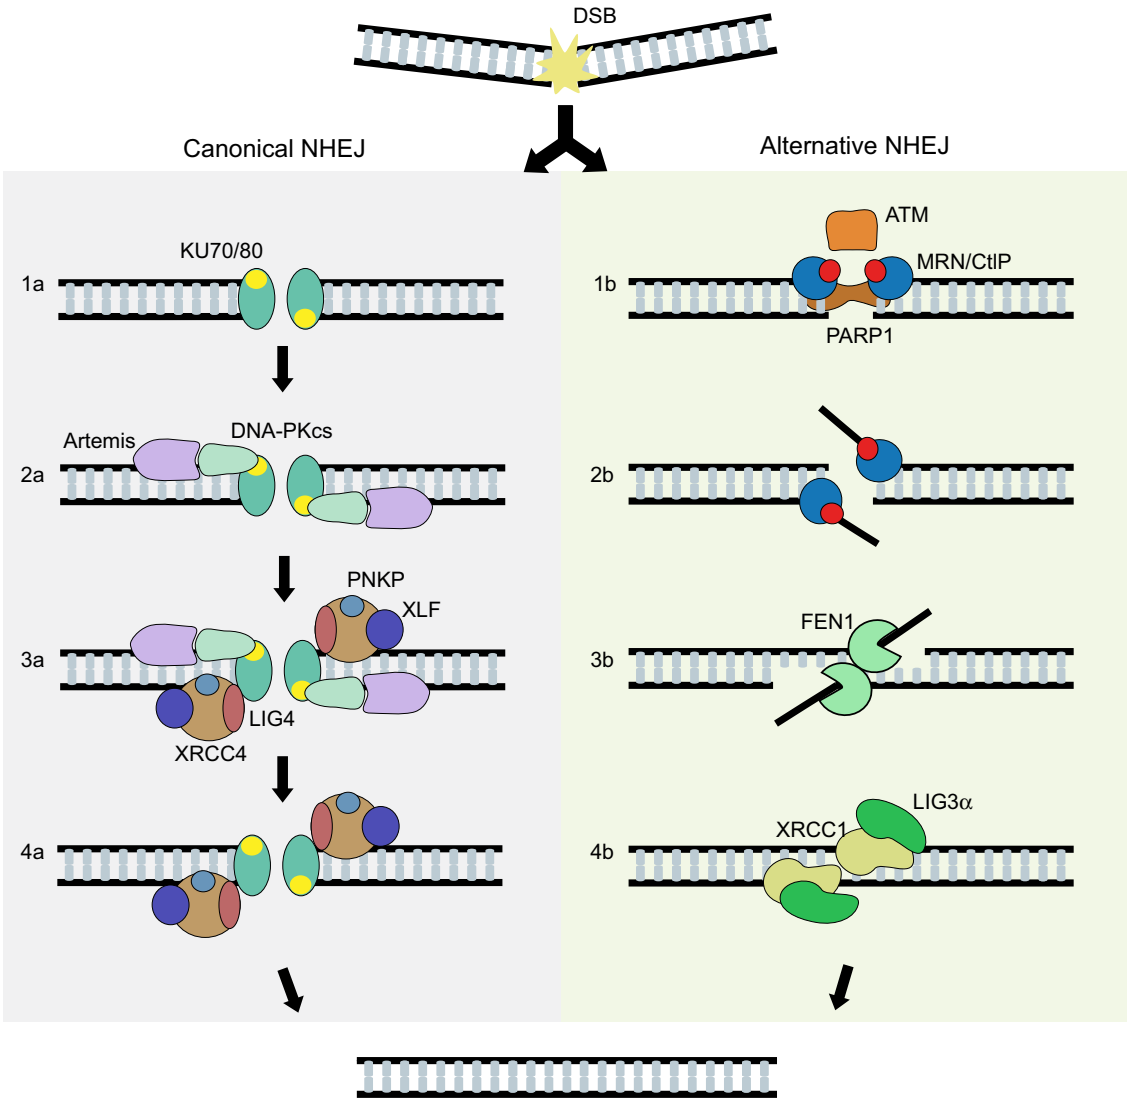

Fig. 6 Nonhomologous end joining (NHEJ) resolves a double-strand break (DSB) that arises typically outside of S/G2 phase. The KU70/KU80 heterodimer recognizes and initiates repair of canonical NHEJ (1a, left), recruiting DNA-PKcs to protect the DNA ends (2a). A range of end-processing enzymes are also recruited, such as Artemis and PNKP (3a), to resect the ends, remove blocking termini, and fill nucleotide gaps to produce ligatable ends, with often loss of genetic material. A ligation complex that includes XLF, XRCC4, and LIG4 seals the processed ends (4a). In the absence of canonical NHEJ, a second alternative pathway is carried out (right). PARP1 is involved in recognition and factor recruitment (1b), including MRE11 and CtIP, which resect the DNA ends to uncover 5–25 bp stretches of microhomology (2b) that are used to align the strand ends, before a nuclease (e.g., FEN1) excises the overhangs (3b) and XRCC1-LIG3α ligates the break (4b). As this microhomology-guided repair results in larger nucleotide deletions than c-NHEJ, the rate of mutagenesis is increased. Furthermore, due to the absence of strand tethering by the DNA-PK complex, alt-NHEJ risks errant recombination with other localized strand breaks and thus is associated with profound genomic rearrangements.

This association is mostly explained by the absence of Ku-mediated strand tethering, leading to increased mobility of DNA ends. DNA synapsis may instead be performed by PARP1, which likely also performs a factor recruitment role (Wang et al., 2006). Furthermore, alt-NHEJ is commonly guided by relatively long (5–25 bp) stretches of microhomology, which are uncovered by end resection by the HR exonuclease MRE11. The strand ends are aligned around the microhomologous regions and the overhangs excised by the flap-endonuclease FEN1, translating to local deletions around the original break. Ligation in alt-NHEJ is believed to require the XRCC1-LIG3α heterodimer (Della-Maria et al., 2011).

To limit the potentially deleterious outcomes (namely genomic instability and cancer manifestation), the presence of c-NHEJ factors such as Ku and DNA-PK suppresses the alt-NHEJ pathway (Bennardo et al., 2008). The importance of this process is exemplified by Werner syndrome (WS), a cancer-associated syndrome that is associated with dysregulation of NHEJ pathway choice. WS is a rare autosomal recessive progeria that manifests with a hierarchical decline in connective tissue integrity, as well as endocrine, immune, and nervous system function (Oshima et al., 2017). Premature mortality (~50 years of age) commonly results from cardiovascular disease or cancer, particularly thyroid, melanoma, meningioma, sarcoma, bone tumors, or leukemias (Lauper et al., 2013). Patient-derived WS cells are hypersensitive to agents that cause DSBs (such as ionizing radiation) and exhibit evidence of genomic instability in the form of chromosomal translocations, large deletions, and telomere fusions (Salk et al., 1981).

Genetically, WS results from defects in the *WRN* gene, of which >70 mutations have been described (Yu et al., 1996). WRN is a RecQ family helicase that also possesses strand annealing and exonuclease activities. It acts preferentially on complex DNA structures, such as G4 quadruplexes, Holliday junctions, and DNA bubble structures, suggesting a role in resolution of complex intermediates formed during DNA metabolism (Opresko et al., 2003). Functionally, WRN was first ascribed a role in end processing in NHEJ, observed via its interactions with c-NHEJ proteins such as Ku, DNA-PK, XRCC4, and LIG4 (Karmakar et al., 2002a,b; Kusumoto et al., 2008). That role has been refined to indicate that it is a regulator of pathway choice between c-NHEJ and alt-NHEJ; specifically, it suppresses recruitment of proteins (such as MRE11 and the CtIP endonuclease) that are involved in end resection and would channel the damage substrate toward alt-NHEJ (Shamanna et al., 2016). By protecting DSBs from end resection and promoting c-NHEJ, WRN therefore limits DNA end mobility associated with potentially oncogenic chromosomal translocations, deletions, and telomere fusions.

Homologous Recombination

The second major pathway for resolving DSBs is HR, which functions in concert with replication when sister chromatids are available to provide homologous guide sequences (Jasin and Rothstein, 2013; Mehta and Haber, 2014; **Fig. 7**). Initiation of repair requires chromatin remodeling, which involves at least two mechanisms: SIRT6 phosphorylation and mobilization to the damage site, which in turn activates PARP1 to subsequently recruit the chromatin remodeler ALC1; and phosphorylation of the histone

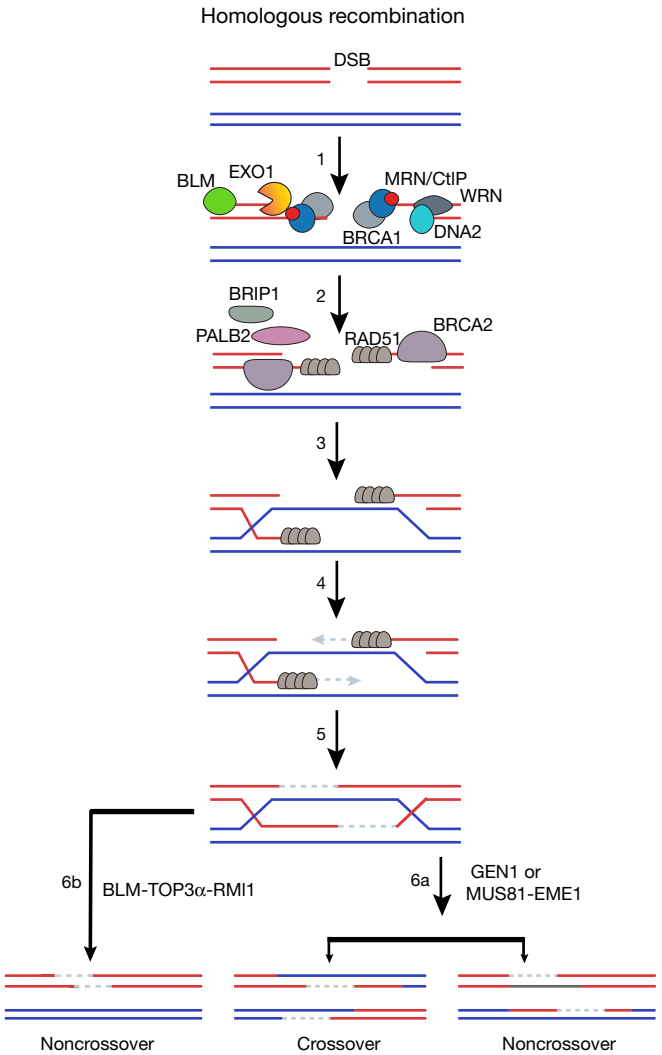

Fig. 7 Homologous recombination (HR). During S phase in replicating cells, a DNA double-strand break (DSB) is repaired by HR. Recruitment of the MRN (MRE11-RAD50-NBS1) complex and CtIP initiates 5′ end resection to generate 3′ overhangs, a process that is stimulated by BRCA1 and assisted by the EXO1 and DNA2 nucleases, in cooperation with the BLM and WRN helicases, respectively (1). RAD51 is then loaded onto the single-stranded DNA overhangs by BRCA2 and PALB2, in cooperation with BRIP1 (2). The RAD51 filament guides strand invasion into the intact duplex DNA of the adjacent sister chromatid or homologous chromosome (3). Polymerase synthesis (likely by POL δ/ϵ/ζ) using the homologous DNA sequences as a template extends the 5′ end to fill the gap (4). End ligation (5) generates double Holliday junctions that are resolved by GEN1 or MUS81-EME1 endonuclease incisions (6a) or topoisomerase-mediated branch migration (6b).

protein H2AX, which stimulates RNF8-mediated chromatin decondensation (Price and D'Andrea, 2013). A 3′ ssDNA overhang is generated by end resection of the 5′ ends flanking the DSB, initiated by the MRN complex in combination with the CtIP endonuclease, and continued by the activities of the BLM helicase and the EXO1 and DNA2 nucleases (Nimonkar et al., 2011; Sartori et al., 2007). End resection also requires the presence of BRCA1, which appears to interact with (and possible recruit) activated CtIP to the damage site, as well as to antagonize 53BP1, a potent inhibitor of resection and promoter of NHEJ (Panier and Boulton, 2014; Yu et al., 1998). CtIP is also important in the recruitment of RPA, which binds and protects the ssDNA 3′ overhangs prior to strand exchange (Sartori et al., 2007).

The process of end resection is an important determinant in DSBR pathway choice: binding of the NHEJ recognition factor Ku inhibits resection to favor c-NHEJ, but can be overcome by CtIP endonuclease clipping of bound Ku from the DNA strand termini (Symington and Gautier, 2011). Furthermore, the production of 3′ overhangs can initiate several repair pathways, including alt-NHEJ and the similar (and equally mutagenic) single-strand annealing (SSA) pathway, in which end resection around a DSB between two repeat sequences is sufficient to allow RAD52-guided annealing (Bhargava et al., 2016). When conditions favor HR, such as in S/G2, RAD51 is recruited and bound to the ssDNA, displacing RPA to form a nucleoprotein filament. Loading of RAD51 requires the presence of mediator proteins PALB2 and BRCA2, which are recruited via an interaction with BRCA1, which persists at the damage site following the end resection activities (Sy et al., 2009). Both RAD51 and BRCA2 are important in directing repair toward the HR pathway, as formation of the nucleoprotein filament directly suppresses SSA and alt-NHEJ (Ahrabi et al., 2016).

Specific to the HR pathway, the RAD51-guided ssDNA filament then invades duplex DNA—most commonly the closely localized sister chromatid ("inter-sister" HR), but also potentially the homologous chromosome ("inter-homolog" HR). The invading 3′ end functions as a primer to initiate repair synthesis using the homologous region as a template. The strand invasion intermediate forms a displacement loop (D loop) that can be resolved by a number of mechanisms. In mitotic cells, synthesis-dependent strand annealing (SDSA) is thought to predominate. The invading strand dissociates from the D loop and anneals to the other 3′ overhang on the damaged chromosome, with the newly synthesized region acting as template for repair synthesis on the opposing strand prior to gap-filling and nick ligation (Morrical, 2015). In contrast, the canonical mechanism of DSBR involves capture of the second 3′ end to form double Holliday junctions (dHJ) that can be resolved by nicking endonucleases (such as EXO1 in meiotic cells, or MUS81-EME1 or SLX1-SLX4 in mitotic cells), or dissolved by the branch migration activity of a BLM-TOP3α-RMI1 complex (Jasin and Rothstein, 2013).

The genetic outcome of HR is dependent on a number of factors. Inter-sister HR, by virtue of identical homology, is genetically silent, while inter-homolog HR can result in both noncrossover and crossover events (**Fig. 7**). In the context of inter-homolog HR, the mechanism of D loop resolution produces a particular outcome: SDSA, for example, always produces a noncrossover product, while Holliday junction resolution can result in both noncrossover and crossover events depending upon the dHJ resolvase involved and the orientation of Holliday junction incision (Moynahan and Jasin, 2010). Noncrossover events (such as in SDSA and most dHJ resolution in mitosis) produce only short stretches of gene conversion that span the homologous template regions. In contrast, crossover events affect the entire chromosome distal to the DSB, thereby forming the basis of genetic recombination during meiosis (Gray and Cohen, 2016), but risk large-scale LOH during subsequent mitotic cell divisions. LOH at various tumor suppressor and oncogene loci, including p53, RB1, MET, and BRCA1 and BRCA2 (see later), has been widely implicated in carcinogenesis, particularly in cancer predisposition syndromes (Thiagalingam et al., 2002).

The most well-known familial cancer predispositions associated with DSBR defects result from mutations in *BRCA1* and *BRCA2* (Paul and Paul, 2014). Heterozygous inheritance of a germline mutant *BRCA1* allele is a major cause of hereditary breast cancer, conferring a disease risk of over 60% by age 70 (and a lifetime risk of ~40% for ovarian cancer, along with rarer pancreatic, prostate and other cancer types), while somatic mutation is a common finding in sporadic breast and ovarian carcinomas (Janatova et al., 2005). *BRCA2* mutation also represents an important inherited cause of breast and ovarian cancer susceptibility, while mutation of its partner *PALB2* contributes to ~1% of hereditary disease (Economopoulou et al., 2015). Homozygous *BRCA* mutation in humans is extremely rare: the few reported cases of homozygous *BRCA1* or *BRCA2* mutations present with congenital abnormalities and hypersensitivity to crosslinking agents, and as such, are considered (along with biallelic mutation of *PALB2* and *RAD51C*) to be distinct subtypes of FA (see earlier) (Howlett et al., 2002; Sawyer et al., 2015). In tumor cells, however, mutation in *BRCA* genes (whether inherited or acquired) is commonly associated with inactivation of the second allele through promoter hypermethylation or LOH (Esteller et al., 2000).

Additionally, certain non-HR genes have been reported to impact HR efficiency. Mutation of *CDK12* has been well established in sporadic ovarian cancer, with loss of function impairing phosphorylation of RNAPII that is required to promote expression of HR pathway genes, such as *BRCA1* (Chila et al., 2016). The tumor suppressor *PTEN*, which encodes a major regulator of the prosurvival phosphoinositide 3-kinase/Akt pathway, acquires somatic mutations in numerous tumor types, including breast and ovarian cancer (Song et al., 2012). PTEN has more recently been ascribed a role in genomic stability that appears to be mediated through interactions with the HR pathway, although this role is controversial and the precise mechanism remains unclear (Ming and He, 2012). Also controversial is the role of EMSY, which is amplified in a subset of sporadic breast and ovarian cancers. EMSY colocalizes with BRCA2 at sites of DNA damage, where it may interact with the BRCA2 N-terminal domain to inactivate BRCA2-mediated RAD51 loading onto ssDNA; however, it is unclear whether this interaction significantly impacts HR efficiency. Given that EMSY maps to chromosome 11q13, a region that harbors a number of potential oncogenes and is often amplified in cancer, it remains to be ascertained whether it genuinely harbors an oncogenic function (Haber, 2003).

As described earlier, WS is caused by mutation in the RecQ family helicase, WRN. A second RecQ helicase, BLM, is also associated with a rare autosomal recessive disorder, Bloom syndrome (BS) (Arora et al., 2014). While BLM and WRN share sequence homology and structural similarity, the clinical manifestations are largely distinct, with BS presenting with growth retardation, immunodeficiency, and photosensitivity. Like WS, however, BS is associated with cancer predisposition (albeit across a considerably wider spectrum of malignancies), arising from marked genomic instability. Characteristically, BLM is associated with a 10-fold elevated rate of sister chromatid exchange (not observed in WS), a likely indication of a defect in HR regulation (Manthei and Keck, 2013). Specifically, the helicase function of BLM plays a critical role in resolution of dHJs to produce exclusively noncrossover products, via branch migration activity that brings together two Holliday junctions into an intermediate structure that is a substrate for dissolution by topoisomerase TOP3α (Wu and Hickson, 2003). In terms of DSBR pathway involvement, the disparate functions of BLM (in HR) and WRN (in NHEJ) likely account for the distinct clinical presentations (Kitano, 2014). However, the two proteins do broadly exhibit functional redundancy in 5′-3′ end resection, wherein their helicase function produces a substrate for nuclease activity during generation of 3′ overhangs for RAD51 strand invasion. It is likely, though, that this activity is nuclease and/or structure specific: BLM is able to specifically stimulate the end resection activities of both the DNA2 endonuclease and the EXO1 exonuclease, whereas WRN interacts with DNA2 alone, but is preferentially recruited over BLM during resection around crosslinked DNA or stalled replication forks (Sturzenegger et al., 2014).

Targeting DNA Repair in Cancer Therapy

The efficacy of many conventional anticancer therapies relies on their ability to induce toxic levels of DNA damage, specifically in the context of a rapidly dividing malignant cell (Cheung-Ong et al., 2013). Ionizing radiation, for example, induces a complex, lethal spectrum of lesions, including base modifications, strand breaks, bulky adducts, and crosslinks, and thus requires careful dosing and targeting to reduce toxicity to healthy cells. Acute but self-limiting toxicity primarily occurs in rapidly proliferating cells, where a high burden of damage lesions induces apoptosis, causing symptoms such as dermatitis, mucositis, proctitis, cystitis, and hair loss. Late effects, which include tissue fibrosis or atrophy, vascular damage, infertility, and secondary malignancies, have a more insidious onset, reflecting their basis in more slowly proliferating tissues, but are often permanent (White and Joiner, 2006). Many conventional chemotherapy agents also rely on DNA damage induction for therapeutic efficacy (**Table 1**). Like radiotherapy, dose management is required to prevent significant off-target toxicity. Acute effects represent the primary concern, because the systemic nature of chemotherapy results in damage accumulation in most body tissues. With respect to the toxicity, as with radiotherapy, rapidly proliferating cells (including tumor cells) are disproportionately affected by DNA damage induction, accounting for the classic side effects, such as hair loss, mucositis, and cytopenia. Secondary malignancies also represent a risk following chemotherapy, particularly those involving proliferative cells, such as found in the bone marrow or lymphatic system. This risk is elevated in certain therapeutic classes (such as alkylating agents or topoisomerase inhibitors), and by patient background (such as the use of crosslinking agents in FA) (Diatloff-Zito et al., 1986).

Given that many anticancer agents elicit their toxicity through the generation of lethal DNA damage, there has been a growing effort to develop targeted small molecule inhibitors against molecular targets in each DNA repair pathway, with the idea that these inhibitory compounds would enhance the efficacy of relevant genotoxins (Gavande et al., 2016). The best known of these compounds are the PARP inhibitors, which mimic the PARP1 substrate NAD^+ to compete for the catalytic pocket, and, with variable

Table 1 Common DNA-damaging chemotherapeutic agents

Class	*Subclass*	*Examples*	*Cytotoxic mechanism*	*Pathway involved*
Alkylating agents	Nitrogen mustards	Chlorambucil, cyclophosphamide, ifosfamide, melphalan	DNA alkylation	BER
	Triazenes	Dacarbazine, temozolomide	DNA alkylation	BER
Dialkylating agents	Nitrosoureas	Carmustine, lomustine, streptozotocin	Bulky DNA adducts, crosslink formation	BER, NER, ICL repair
Alkylating-like	Platinums	Cisplatin, carboplatin, oxaliplatin	Bulky DNA adducts, crosslink formation	NER, ICL repair
Topoisomerase inhibitors	Type I topoisomerase inhibitor	Camptothecin, irinotecan, topotecan	Topo-DNA adducts, DSBs	HR, NHEJ
	Type II topoisomerase inhibitor	Etoposide	Topo-DNA adducts, DSBs	HR, NHEJ
	Anthracyclines	Doxorubicin, daunorubicin	Topo-DNA adducts, intercalation	
Radiomimetics		Bleomycin, enediyne antibiotics	DSBs	HR, NHEJ
Antimetabolites	Pyrimidine analogs	5-Fluorouracil, capecitabine, gemcitabine	Intercalation, replication stalling	DNA replication
	Purine analogs	6-Mercaptopurine, fludarabine	Intercalation, replication stalling	DNA replication
	Antifolates	Methotrexate, pemetrexed	Inhibition of nucleotide synthesis	DNA replication

See text for abbreviations.

efficiency, trap PARP1 on DNA to create toxic PARP–DNA complexes that interfere with replication. Initial strategic development of PARP inhibitors focused on their ability to potentiate the cytotoxicity of DNA-damaging agents classically repaired by PARP-dependent mechanisms (Annunziata and O'Shaughnessy, 2010). As such, several trials evaluating a combinatorial approach have reached the clinic. In glioblastoma, combining the alkylating agent temozolomide, which shows some efficacy as a single agent due to its ability to cross the blood–brain barrier, with an early generation PARP inhibitor (veliparib) produced inconclusive results in terms of overall survival in a phase II study, likely because veliparib is a relatively poor PARP trapper (Robins et al., 2016). Similarly, inconclusive results have been observed in a combination involving the PARP inhibitor olaparib and docetaxel, a taxane. Taxanes, which disrupt microtubule formation during mitosis, produce a response rate benefit in advanced gastric cancers. Over 60% of this group of tumors exhibit mutation in *ATM*, which has been shown in vitro to render cells sensitive to PARP inhibitors due to impairment of DSBR (Bang et al., 2015). Dual therapy, therefore, is hypothesized to improve outcomes by additive cytotoxicities of: (a) gold standard taxane chemotherapy and (b) "synthetic lethality" interaction of *ATM* mutation with PARP inhibitor (see more below). In a phase III study evaluating an olaparib/docetaxel combination in late-stage gastric cancer, however, no survival benefit was established (Drean et al., 2016). Radiotherapy also offers potential benefit in a combination approach, given that generation of DSBs (among other DNA damage lesions) can be specifically targeted to a tumor site. In combination with radiotherapy, phase I secondary outcomes of radiological response and median survival were improved with the use of veliparib in primary breast and nonsmall cell lung cancers (Mehta et al., 2015).

A number of other phase I and II studies assessing various PARP inhibitor/conventional agent combinations remain in recruitment stage, but the value of this approach currently remains limited by the nonspecificity of conventional therapy with regard to normal cell toxicity. In the last decade, focus has instead shifted to examine the use of PARP inhibitors as a targeted monotherapy. This approach was born out of the exciting preclinical observation that PARP inhibitors can be effectively employed in a synthetic lethality context to specifically target cancer cells (Bryant et al., 2005). Synthetic (or synergistic) lethality exploits intergene relationships wherein loss of function of either gene is nonlethal, but loss of both is cytotoxic. The connection between BRCA1/2 and PARP1 represents the first described synthetic lethality relationship. In the context here, inhibition of PARP1-mediated repair prevents SSB resolution, which, along with stable PARP-DNA complex formation, causes replication fork collapse and DSB generation. In a HR-deficient background, such as in the case of a *BRCA* mutation, unrepaired DSBs rapidly activate apoptotic pathways and induce cell death (Lord and Ashworth, 2017). Early phase I and II trials supported a role for PARP inhibition in a *BRCA* mutant background, but results in phase III trials have been mixed—presumably due to PARP inhibitor choice (with one candidate agent iniparib later proved to not inhibit PARP function) and the composition of the patient cohort, which, regardless of tumor type, has generally been expanded to include a range of later stage cancers due to the relative scarcity of BRCA-associated malignancies. More recently, a dual cohort phase III study that specifically recruited a large *BRCA* mutant population ($n = 203$) has reported a statistically significant improvement in the progression-free survival of ovarian cancer patients treated with the PARP inhibitor niraparib (Mirza et al., 2016). Similar results have also been described in phase III trials of metastatic *BRCA*-mutated breast cancers treated with olaparib, again highlighting the importance of appropriate cohort selection (Robson et al., 2017). Thus, with promising results based on the concept of synthetic lethality in place, future efforts will explore in greater depth the ability to clinically target the genetics and functionality of cancer cells with relevant DNA repair inhibitors.

One strategy to evaluate PARP inhibitor efficacy in broader clinical trials has been to target tumors with histopathologically and/or clinically similar phenotypes (BRCAness) (Lord and Ashworth, 2016). For example, *BRCA1*-mutant breast cancers are commonly basal-like and do not express estrogen or progesterone receptors or undergo human epidermal growth factor 2 (HER2) amplification. This "triple negative" pathological presentation is observed in patients without germline *BRCA* mutation, but is often enriched for other mechanisms that give rise to HR deficiency, including *BRCA1* or *RAD51* promoter methylation or somatic mutation. To date, PARP inhibitors have not been successful in phase III studies of triple negative breast cancers; results utilizing later generation, highly specific PARP inhibitors (such as talazoparib) are expected soon (Lord and Ashworth, 2017). Sensitivity to platinum chemotherapy agents may also be a marker of BRCAness, given that *BRCA*-mutant tumors are highly sensitive to platinum compounds, which induce crosslinks that require effective HR for resolution. Accordingly, a placebo-controlled phase II study in platinum-sensitive ovarian cancer reported a doubling in progression-free survival with maintenance olaparib, and phase III trials are now ongoing (Oza et al., 2015).

An additional anticancer agent that targets the BER pathway is methoxyamine, which reacts with abasic sites to create an adduct that indirectly inhibits APE1 activity, producing a lesion capable of inducing cytotoxicity by stalling replication forks. Preclinically, it is able to potentiate the effects of alkylating agents such as temozolomide (Taverna et al., 2001), and a phase II trial testing the combination of methoxyamine/temozolomide in glioblastoma is currently in the recruitment stage. Additionally, methoxyamine enhances the effects of pemetrexed, an antifolate agent that interrupts purine and thymidine synthesis, resulting in uracil misincorporation in DNA. Recognition and excision by the BER protein uracil DNA glycosylase creates an abasic site that is bound by methoxyamine, with the combination increasing the damage load (and hence cytotoxicity) compared to either single agent alone (Bulgar et al., 2012). This therapeutic strategy, along with modified regimens including cisplatin and/or radiotherapy, is currently in phase I/II. In contrast, identification of specific APE1 active site inhibitors has not progressed beyond an early preclinical development stage (due to potency and selectivity issues), although DNA glycosylase inhibition may offer more promise (Jacobs et al., 2013).

Other DNA repair inhibitors are much less advanced in the development pipeline. Small molecules have been designed that target DNA-PK function by stabilizing the protein complex at DSB ends, preventing initiation of downstream NHEJ, and blocking other repair processes. In preclinical studies, one such compound, NU7441, sensitizes cells and xenografts to agents that induce

DSBs (such as ionizing radiation and topoisomerase inhibitors), without significant cytotoxicity as a monotherapy (Zhao et al., 2006). Structure activity relationship analysis of this compound has identified related inhibitors that are currently in phase I trials, both as monotherapy and in combination with radiotherapy or doxorubicin. ATM inhibitors, currently in later stages of development, also target the initiating stages of DSBR. However, the mechanism of action of these compounds is less clear, given that ATM's role in the DDR extends beyond DNA repair initiation. Regardless, preclinical evidence indicates that ATM inhibitors are able to sensitize cells to DSB-inducing agents, such as ionizing radiation and topoisomerase inhibitors (including camptothecin and etoposide) (Hickson et al., 2004). Furthermore, targeting ATM inhibits DSBR, creating a synthetic lethality partner for PARP inhibition, and phase I trials of ATM inhibitor in combination with olaparib are ongoing. Design of ATR inhibitors is following a different strategy, focusing on ATR's activation by ssDNA around a stalled replication fork, which allows the exciting potential to combine ATR inhibitors with agents that target cell cycle checkpoints in a synthetic lethality paradigm. As described earlier, the checkpoint regulator Chk1 is triggered by a signaling cascade downstream of activated ATR, but also has a role in S-phase checkpoint activation via an ATR-independent backup pathway (Sanjiv et al., 2016). As a result, impaired initiation of repair secondary to ATR inhibition rapidly induces cytotoxicity in the context of ATR- and Chk1-deficient checkpoint signaling. Although this combination has not yet been tested in clinical trials, phase I/II studies to evaluate both ATR and Chk1 inhibitors in combination with agents inducing replication-associated DNA damage (such as platinum agents or gemcitabine) are currently underway. Taken together, the many preclinical studies indicate that DNA repair inhibition is a promising therapeutic strategy, although drug development for most targets is currently at an early stage. The challenges faced by PARP inhibitors, whose strong in vitro performance has been tempered by variable success in the clinic, highlight the importance of compound validation and patient cohort selection (Brown et al., 2017).

Summary

The volume of DNA damage, both endogenous and secondary to external insults, that affects every cell each day, has necessitated the evolution of a sophisticated DDR to prevent deleterious outcomes, such as mutagenesis and apoptosis, that underlie carcinogenesis, disease, or aging. Central to this global response is a number of highly conserved DNA repair pathways that can resolve a wide range of damage substrates at various stages of the cell cycle. Defects in members of these pathways, or associated signaling processes, give rise to a variety of inherited syndromes that are associated with an elevated risk of cancer, neurological disease, immunodysfunction, or premature aging phenotypes. Moreover, haploinsufficiency in DNA repair, possibly through heterozygous mutations or single nucleotide polymorphisms, can affect disease risk, likely in a life style- or exposure-dependent manner. The molecular mechanisms of the DNA repair systems, including the interrelationships between pathways, are a current area of therapeutic focus, particularly given the frequent use of genotoxins as anticancer agents. It is therefore anticipated that in the near future tailored treatment regimens will greatly improve cancer outcomes.

Senescence and Cellular Immortality

Marco Demaria, European Institute for the Biology of Aging (ERIBA), University Medical Center Groningen (UMCG), Groningen, The Netherlands; and University of Groningen, Groningen, The Netherlands
Michael C Velarde, University of the Philippines Diliman, Quezon City, Philippines

Introduction

Somatic cells undergo cell proliferation in response to growth stimuli. However, cells have a finite replicative lifespan, rendering these cells permanently unable to divide even when exposed to mitogenic signals. This state of essentially irreversible cell cycle arrest was first observed by Hayflick and Moorhead in 1961, and termed cellular senescence. Senescent cells remain metabolically active and survive in culture indefinitely when supplied with sufficient nutrients.

Through the induction of irreversible growth arrest, cellular senescence acts as an important block against tumorigenesis. Random DNA mutations due to excessive DNA damage may activate proto-oncogenes or inactivate tumor suppressor genes, leading to the formation of tumor cells—cells that proliferate uncontrollably. Cellular senescence can prevent formation of tumor cells by inhibiting their capacity to proliferate. Impairing the senescence pathways causes damaged cells to escape this inhibition, resulting in the development of cancer. While senescent cells play an important role in inhibiting cancer growth, the continuous exposure of cells to DNA damaging agents results in a steady supply of cells undergoing cellular senescence. Since senescent cells are able to survive for extended periods of time, they accumulate in tissues with age. A striking phenotype associated with senescent cells is the expression and secretion of several pro-inflammatory cytokines and growth factors. Through the secretion of such factors, senescent cells actively participate in tissue remodeling and repair after damage. However, when senescent cells accumulate and persist in tissues, they might contribute to chronic inflammation and generate an environment favorable to cell growth. In accordance, several studies have shown that senescent cells contribute to the onset and progression of many age-related diseases, including cancer.

In this article, we will describe the different inducers and effectors of cellular senescence, the phenotypes and features of senescent cells, and the pleiotropic contribution of senescent cells to tumorigenesis. We will further explore potential therapeutic approaches to dampen the effects of cellular senescence as a mean to treat cancer.

Cellular Senescence

Senescence Stimuli

Senescence can be induced by different stimuli promoting DNA or mitochondrial damages, chromatin changes or perturbations of mitosis (Fig. 1). DNA damage is triggered by a number of signals, including telomere shortening, excessive oxidative and genotoxic stress, and oncogene activation. Telomere shortening, a main cause of the replicative lifespan of human cells (replicative senescence), was the first described inducer of senescence. Telomeres are regions at the ends of the chromosome which protects

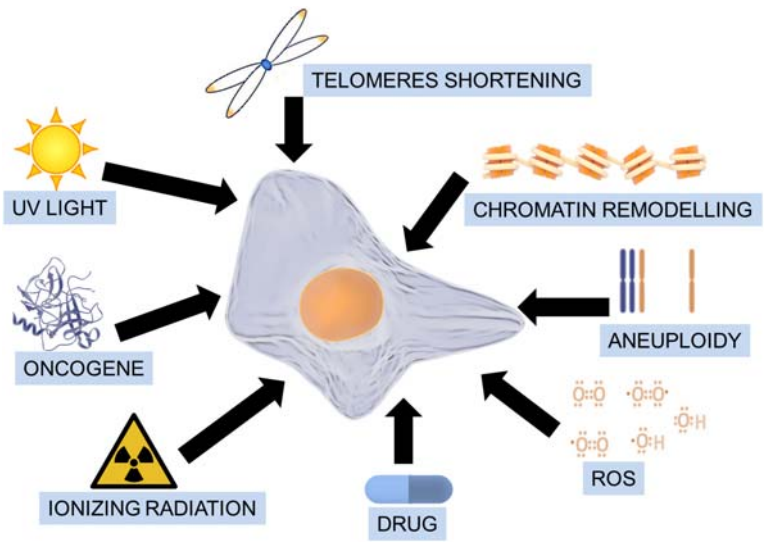

Fig. 1 Inducers of cellular senescence. Different stresses can induce senescence in normal and cancerous cells. Telomeres shortening is the first inducer of senescence being described. Some of the stresses are environmental and include UV light, genotoxic drugs and ionizing radiations.

 https://doi.org/10.1016/B978-0-12-801238-3.65016-X

chromosomes from deterioration or from fusion with other chromosomes. However, due to the intrinsic mechanism of DNA replication, cellular divisions promote a progressive decrease in telomeres length, which eventually become critically short and dysfunctional. This telomere shortening activates a DNA damage response without effective repair, leading to replicative senescence. In addition to replicative senescence, cells may also be induced to senesce prematurely by acute DNA damages.

Reactive oxygen species can cause DNA damage by targeting DNA bases and other associated macromolecules. Reactive oxygen species (ROS), such as superoxides, hydrogen peroxides, and hydroxyl radicals, are produced in the cell through different metabolic reactions. While low levels of ROS may act as signaling molecules, excessive ROS production may destroy the integrity of different proteins, carbohydrates, lipids, and nucleic acids which maintain proper cellular functions. Damage to these macromolecules may inhibit cell cycle progression and cause a cellular senescence response. Moreover, in the presence of oxidative stress, damaged telomeres are repaired inefficiently relative to other parts of the chromosome. Strong genotoxic stress, such as ionizing radiation or drugs that interfere with DNA synthesis, directly induces DNA double strand breaks (DSBs) and activates a persistent DNA damage response (DDR), which then promotes the senescence program and arrests cell proliferation.

Overexpression of oncogenic mitogenic signals also promotes premature senescence in cells through generation of DNA damage. For example, activation of Ras oncogene induces an acute hyperproliferation, which is subsequently followed by a permanent cell cycle arrest as early as 3 days after Ras induction. Ras induces cellular senescence by increasing expression of Cdc6, suppressing nucleotide metabolism, inducing DSBs, and activating the DDR pathway. BRAF(V600E) triggers cellular senescence by upregulating mitochondrial pyruvate dehydrogenase, independent of the DDR pathway. Prolonged exposure to the mitotic signal interferon-β also activates the cellular senescence response.

The contribution of metabolic changes to establishing cellular senescence is further exemplified in cells with mitochondrial dysfunction. Mitochondrial dysfunction can induce cellular senescence, called mitochondrial dysfunction-associated senescence (MiDAS). MiDAS is characterized by reduced NAD^+/NADH levels and increased AMPK and p53 activation, which are important for the establishment of cellular senescence.

Opening chromatin structures in the genome activates the senescence pathway. Inhibition of histone deacetylases can induce formation of euchromatin structures in the genome, resulting in expression of the cell cycle inhibitors $p21^{Cip1}$ and $p16^{INK4a}$. Bmi1 polycomb complex protein and histone H2A K119 are responsible for hypermethylation and inducing heterochromatin structure of the $p16^{INK4a}$ promoter, preventing transcription of the $p16^{INK4a}$ gene. Hence, inhibition of the Bmi1 polycomb complex protein and ubiquitination of the histone H2A K119 results in de-repression of the $p16^{INK4a}$ gene.

Inhibition of mitosis and spindle formation can also induce cellular senescence. Decreased expression of TACC3, BubR1, Bub3, and Rae1 can activate p53/$p21^{Cip1}$ pathway and $p16^{INK4a}$ in the absence of a DDR. BubR1-insufficient mice have elevated levels of p53, $p21^{Cip1}$, $p16^{INK4a}$, and $p19^{Arf}$. These progeroid mouse model elicit early onset of aging-associated phenotypes, including decrease in lifespan, loss of subcutaneous fat, delay in wound healing, and development of cachectic dwarfism, lordokyphosis, and cataracts. BubR1 progeroid mice also develop progressive aneuploidy, which is thought to play a role in the development of senescence in these mice.

Effector Pathways

The main effector mechanisms for the establishment of cellular senescence are p53/$p21^{Cip1}$ and $p16^{INK4a}$/pRB pathways (Fig. 2). DNA damage response activates p53 by the ATM/ATR DNA damage signaling pathway. In senescent cells, sustained p53 activity results in persistent elevated expression of the cyclin-dependent kinase (CDK) inhibitor $p21^{Cip1}$. Inhibition of the cyclin-dependent complexes cyclinD/CDK4/6 and cyclinE/CDK2 prevents phosphorylation of retinoblastoma (Rb) protein. This

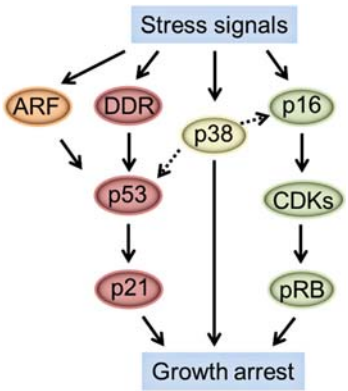

Fig. 2 Pathways associated to cellular senescence. Stress signals can activate distinct pathways that either induce or maintain the senescence phenotype. Many signals promote DNA damage which, in turn, activates a chronic DNA damage response (DDR) dependent on p53 and p21. Other effectors can be activated independent of the DDR. ARF (p19) regulates and activates the p53/p21 pathway. P38 and p16 directly interfere with cellular proliferation.

stabilizes binding of Rb to E2F, preventing E2F from transcribing genes associated with cell cycle progression, resulting in permanent cell cycle arrest.

The CDK inhibitor $p16^{INK4a}$ is an important player for the maintenance of cell cycle arrest during cellular senescence. $p16^{INK4A}$ inhibits CDK4/6 kinase activity and prevents Rb phosphorylation and degradation. Rb remains associated with E2F1 and prevents transcription of E2F1 target genes that are crucial for cell cycle progression. $p16^{INK4A}$ can also crosstalk with the $p21^{CIP1}$ pathway. However, in contrast to p53 activity, $p16^{INK4A}$ activation is less dependent on DDR. The $p19^{Arf}$ protein, an alternate reading frame product of the same locus of $p16^{INK4A}$ (CDKN2A), can activate p53 via DDR-independent mechanisms. The senescence pathways of murine cells in contrast to human cells are more dependent on $p19^{Arf}$, suggesting a species-specific difference in senescence establishment.

Signaling pathways that trigger cellular senescence activates Rb and its family members, p107 and p130. Increasing expression of Rb proteins is sufficient to induce a permanent cell cycle arrest. Moreover, activation of Rb proteins renders cells permanently growth arrested, even after subsequent Rb inactivation. In contrast, ablation of all Rb proteins prevents cells from undergoing cellular senescence. Other signaling pathways may also affect the ability of $p16^{INK4A}$/Rb to promote cellular senescence. For example, PI3K/AKT activation establishes cellular senescence and not quiescence when $p16^{INK4A}$ is induced. This is partly due to increased DNA damage foci and ROS production caused by decreased expression of the mitochondrial antioxidant superoxide dismutase 2 (SOD2). Elevated ROS levels activate protein kinase C delta (PKC delta), which in turn, creates a positive feedback loop between ROS and PKC delta that leads to cellular senescence. In contrast, contact inhibition and serum starvation have decreased DNA damage foci and low ROS production, partly due to increased SOD2 expression and increased FoxO3a expression, which results in quiescence instead of cellular senescence.

Because of the role of $p53/p21^{Cip1}$ and $p16^{INK4A}$/Rb pathways, persistent activation of these signaling molecules is a widely used marker of senescent cells. In addition to DNA damage, activation of RAS oncogene (Ha-RASv12) also increases expression of p53 and $p16^{INK4a}$ to induce permanent cell cycle arrest. Ras activates the Raf1/MEK/ERK pathway, which targets the transcription factors AP-1 and Ets and increases p38δ expression. p38MAPK activity is required for oncogene-induced senescence and is sufficient to induce growth arrest p38α and p38γ are required for RAS-induced senescence in a p53 and $p16^{INK4A}$ dependent manner, while p38δ promotes cellular senescence in RAS-induced senescence independent of p53 and a $p16^{INK4A}$.

Loss of certain tumor suppressors may also trigger a senescent growth arrest phenotype. For example, loss of PTEN, NF1, and VHL induces cellular senescence through $p19^{Arf}$ and $p16^{INK4a}$, independent of DDR.

Phenotypes of Senescent Cells

A number of phenotypical changes accompany the establishment of cellular senescence (Fig. 3). Senescent cells are classically defined by their inability to undergo cell proliferation even in the presence of proliferative signals. Senescent cells are permanently arrested at G1 and G2 phases of the cell cycle and they are more resistant to apoptotic signals than normal cells.

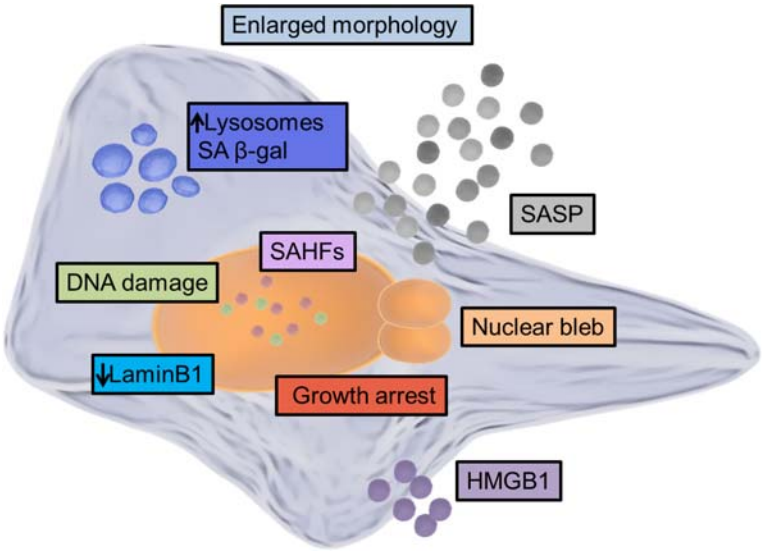

Fig. 3 Markers of cellular senescence. Induction of the senescence phenotype is accompanied by a number of molecular anf morphological changes, and by a permanent growth arrest. Senescent cells display enlarged size and increased number of lysosomes with activation of lysosomal enzymes such as senescence-associated β-galactosidase (SA β-gal). They are also characterized by changes in nuclear composition, measured by loss of LaminB1, and nuclear blebbing. Senescent cells show persistent DNA damage and characteristic senescence-associated heterochromatin foci (SAHFs). Modifications in nuclear composition and/or DNA induce extracellular release of the nuclear alarmin protein HGMB1 and activation of peculiar gene expression patterns, including transcriptional activation of secreted factors (senescence-associated secretory phenotype or SASP).

Another feature of senescent cells is their distinct morphology. Senescent cells have enlarged cell size and flattened appearance. They have increased lysosomal mass, accompanied by increased activity of a lysosomal β-galactosidase, called galactosidase beta 1 (GLB1). This increase in β-galactosidase activity distinguishes senescent cells from proliferating, quiescent, and terminally differentiated cells. Hence, it is termed as senescence-associated β-galactosidase (SA β-gal). SA β-gal activity assay has become a widely used assay to detect senescent cells in culture and in vivo. While SA β-gal activity increases in senescent cells, this activity does not seem to be important for the establishment of cellular senescence. It is also important to note that while SA β-gal is a popular biomarker for cellular senescence the specificity and selectivity of the assay to detect senescent cells have also been questioned. SA β-gal activity may also be detected in non-senescent cells when cultured at low serum conditions for long periods of time or incubated at a very high cell density. Nonetheless, SA β-gal activity is still a well accepted marker for cellular senescence.

Senescent cells are associated with polyploidy. They have increased nuclear size and nuclear bleb formation. Downregulation of lamin B1 is thought to contribute to nuclear blebbing in senescent cells. Lamin B1 are downregulated in senescent cells but not in non-senescent cells. Activation of p53 and pRb pathways induces loss of Lamin B1 independent of p38MAPK, NF-κB, ATM or ROS. Unlike SA β-gal activity, decrease in lamin B1 is an early feature of cellular senescence, suggesting that lamin B1 may be an important step in the development of senescence.

Senescent cells have distinct chromatin regions associated with gene repression called senescence-associated heterochromatin foci (SAHF). Loss of Lamin B1 promotes formation of SAHF in senescent cells. SAHF formation is induced by several proteins known to promote gene silencing. These proteins localize in promyelocytic leukemia (PML) nuclear bodies to initiate chromatin condensation by recruiting proteins such as heterochromatin protein 1 (HP1), methylated lysine 9 of histone H3 (H3K9Me), and macroH2A. SAHF formation is partly activated by Rb and p53 pathways.

Senescent cells have persistent DNA damage foci called DNA segments with chromatin alterations reinforcing senescence (DNA-SCARS). DNA-SCARS are comprised of DNA damage repair proteins, such as ataxia telangiectasia mutated (ATM), Rad3, γH2AX, 53BP1, MDC1, and NBS1, that are unable to fully repair DNA strand breaks. DNA-SCARS are also associated with PML nuclear bodies. DNA damage activates ATM kinase, which phosphorylates histone H2AX (γH2AX). In senescent cells, the activated DNA repair proteins remain bound to the DNA damaged sites forming the persistent DNA damage foci. Unresolved DNA damage foci prevent the cell from completing DNA replication and progressing through the S phase of the cell cycle. DNA-SCARS are distinct from transient DNA damage foci which gets resolved after DNA repair.

Another key feature that distinguishes senescent cells from quiescent and terminally differentiated cells is their ability to secrete factors that may elicit a pro-inflammatory response in the surrounding tissue microenvironment. HMGB1, a member of the Alarmin family, is secreted by senescent cells. HMGB1 is a nuclear protein which translocates outside of the cell shortly after DNA damage in a p53-dependent and ATM- or $p16^{INK4a}$ -independent manner. HMGB1 secretion stimulates a senescence-associated inflammation response by signaling through the toll-like receptor-4 (TLR-4). In addition to HMGB1 release, senescent cells also secrete several cytokines, chemokines, and growth factors, collectively termed as senescence-associated secretory phenotype (SASP). However, in contrast to HMGB1, expression of the SASP gradually develops over time after sustained DNA damage. Components of the SASP include interleukin 6 (IL6), IL1A, IL1B, chemokine C-X-C motif ligand 1 (CXCL1, also known as GRO-α), CXCL8, vascular endothelial growth factor (VEGF), and matrix metalloproteinase-1 (MMP1).

DNA damage, oncogene activation, and telomere shortening can all elicit the SASP. But, it is important to indicate that not all senescent cells express the same SASP expression profile. For example, senescent cells induced by $p16^{INK4A}$ over-expression without DNA damage have reduced expression of SASP, while senescent cells induced by mitochondrial dysfunction show a distinct set of SASP factors.

Cellular Senescence as a Tumor Suppressive Mechanism

Since the first description as an irreversible inhibitor of cell cycle progression, cellular senescence has been considered a potentially powerful tumor suppressor. Currently, senescent cells are thought to prevent tumorigenesis via cell autonomous (growth arrest) and non-cell autonomous (SASP) mechanisms (Fig. 4).

Growth Arrest

Cellular senescence acts as a strong tumor suppressor mechanism. It acts as a brake to prevent tumor cells from further replicating. Unlike apoptosis, cellular senescence does not cause cancer cells to die. They remain in their microenvironment unless cleared by the immune system. Tumor cells must first escape the cellular senescence mechanisms in order to gain their proliferative characteristics. Indeed, senescent cells are more common in premalignant tumors than advanced malignant tumors.

Senescence growth arrest depends on cyclin-dependent kinase inhibitors $p21^{Cip1}$ and $p16^{INK4a}$. Persistent upregulation of either the $p19^{Arf}$/p53/$p21^{Cip1}$ and $p16^{INK4a}$/Rb tumor suppressor mechanisms result in a permanent growth arrest state. The tumor suppressor pathways inhibit the expression and/or function of genes that promote cell cycle progression. Hence, mutation or epigenetic silencing of at least one crucial regulator of these tumor suppressor pathways will render cells to bypass the senescence checkpoint and progress towards tumorigenesis. Decreased expression or gene silencing of at least one of the tumor suppressor pathways allows cancer cells to escape cellular senescence and develop tumors. Escape from the senescence pathways occurs even in cells with activation of Ras oncogene, a known promoter of cellular senescence. Indeed, Ras mutations are found in 20%–30% of all tumors.

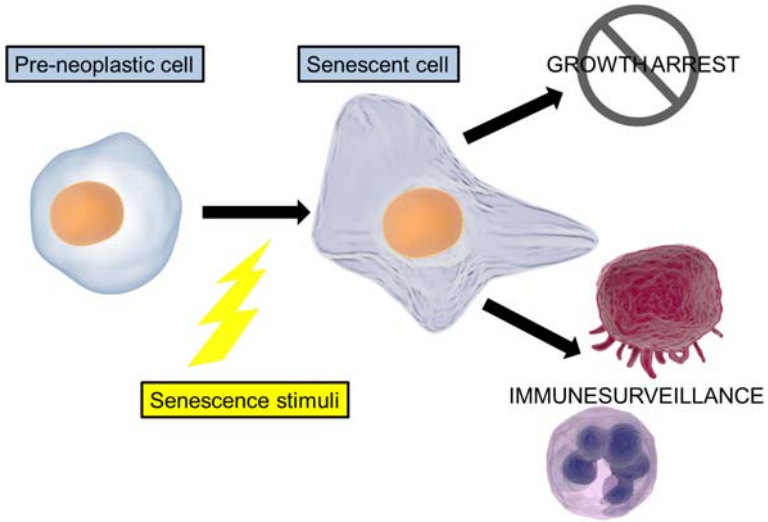

Fig. 4 Tumor suppression. Induction of cellular senescence acts as a potent tumor suppressor via cell and non-cell autonomous mechanisms. The growth arrest (cell autonomous) prevents propagation of potentially pre-neoplastic cells. The secretion of several pro-inflammatory factors (non-cell autonomous) allows for the recruitment of different immune cells that control tumor propagation (immunesurveillance).

Hras mutation is often observed in papillary thyroid cancer, Nras mutation in hepatocellular carcinoma, and Kras mutations in pancreatic, colorectal, and non-small-cell lung carcinomas. In some instances, loss of $p21^{Cip1}$ may also cause tumor cells to go through additional S phases, resulting in polyploidy.

Consistent with the ability of tumor suppressors to induce cellular senescence and prevent tumorigenesis, many human tumors have inactivated tumor suppressor genes. $p16^{INK4a}$ and Rb are inactivated in a large number of human tumors, but their levels may vary depending on the tumor cell. Indeed, tumors that have low $p16^{INK4a}$ expression usually elicit high Rb expression, whereas tumors that have reduced Rb expression show high $p16^{INK4a}$ levels. Tumors that retain both $p16^{INK4a}$ and Rb are accompanied by overexpression of CDK4 or cyclin D1. CDK4 is amplified in sarcomas and gliomas. Mutations that cause resistance to $p16^{INK4}$-mediated senescence are found in melanomas. Overexpression of cyclin D1 are observed in breast tumors and mantle-cell lymphomas.

Tumors also have high expression of telomerase. Telomerase maintains telomere length in tumor cells, preventing these cells from reaching replicative senescence. This causes tumor cells to become immortal, allowing them to proliferate indefinitely. Tumor cells share this high telomerase activity with germ cells, embryonic stem cells, and adult stem cells, which also have very long replicative lifespan. It is important to note though, that high telomerase activity is not the only factor for cellular immortality. For example, DNA damage can still cause cellular senescence in cells with high telomerase activity. Indeed, mouse cells can still senesce after treatment of DNA damaging agents despite high telomerase activity.

SASP factors, such as chemokine (C-X-C motif) receptor 2 (CXCR2) (also called interleukin 8 receptor 2 (IL8R2)), plasminogen activator inhibitor-1 (PAI-1), and the pleiotropic protein insulin-like growth factor binding protein-7 (IGFBP-7), can reinforce the senescence growth arrest in an autocrine manner.

Immunesurveillance

The SASP attracts and activates innate and adaptive immune cells, such as natural killer (NK) cells and T cells. Because senescent cells are also found in premalignant tumors, the SASP produced by senescent cells can also induce immune clearance of premalignant senescent cells and surrounding tumor cells. In premalignant liver cells, senescent cells can activate an immune-dependent clearance, termed "senescence surveillance" through a $CD4^+$ T cell-mediated response. This adaptive immune response is accompanied by recruitment of monocytes and macrophages to eliminate premalignant senescent cells. NK cell-mediated clearance of senescent stellate cells restricts the progression of fibrosis in liver tissue. When senescent cells are surrounded by established liver cancer cells, senescence clearance is facilitated by an innate immune response, composed of macrophages, neutrophils, and natural killer cells. Hence, senescent cells play an important role in immunesurveillance. While senescent cells may elicit different immune responses depending on the tumor microenvironment, the mechanisms involved in senescence surveillance remain unclear.

Senescent Cells and Tumor Promotion

Senescent cells can survive for extended periods of time when supplied with sufficient nutrients. Persistence of cells in a senescence state increases the odds to acquire additional mutations, thus potentially escaping from growth arrest, but also generate an environment rich in pro-inflammatory and pro-growth factors with the potential of generating a pro-tumorigenic niche (Fig. 5).

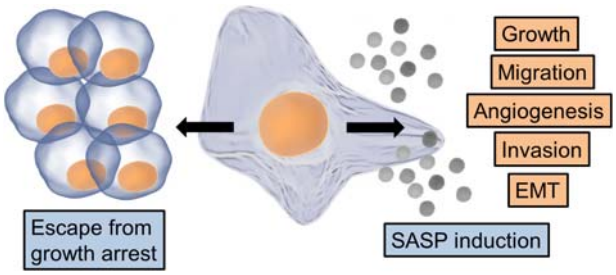

Fig. 5 Tumor promotion. Persistent senescent cells that are not efficiently eliminated can acquire additional mutations and escape from the state of growth arrest. In parallel, secretion of SASP factors can potentiate the development of aggressive phenotype of cancer cells.

SASP

The SASP is thought to promote inflammation. SASP factors may affect cell growth, motility, inflammation, differentiation, tissue repair, vascularization, and angiogenesis. SASP factors can reinforce cellular senescence through paracrine and autocrine signaling and cause surrounding cells to senesce through a bystander effect. However, they may also promote proliferation of surrounding cancer cells which have escaped cellular senescence. Sustainable supply of growth factors in the tumor microenvironment can permit malignant tumorigenesis. Some components of the SASP enhance proliferation of surrounding cancer epithelial cells. Indeed, senescent stromal fibroblasts can alter tissue microenvironment and cause abnormal epithelial cell proliferation in the mammary gland. Senescent fibroblasts also induce hyperproliferation of surrounding prostate epithelial cells. The SASP factors GROα and IL-8 stimulates proliferation of malignant melanocytes, which express high levels of C-X-C chemokine receptor-2 (CXCR2). The SASP factor MMP3 activates mitogenic signals and stimulates tumorigenicity and proliferation of epithelial cells. MMPs may induce proteolysis of the extracellular matrix and the release of mitogens.

The SASP induces neoplastic transformation and tumor vascularization in epithelial cells. Epithelial cancer cells surrounding senescent cells become invasive and less differentiated. They undergo epithelial-mesenchymal transition (EMT), which is an important step for cancer progression. Indeed, the SASP increases growth and invasiveness of surrounding cancer cells in mouse xenograft models. MMPs expressed by senescent cells promote EMT, induce invasiveness, and cause metastasis of epithelial cancer cells. Vascular endothelial growth factor (VEGF), which is also expressed by senescent cells, stimulates endothelial cell proliferation and increases vessel formation in tumors to drive cancer progression. Tumors grown with senescent cells have more blood vessels density than those grown with non-senescent cells in a breast cancer xenograft mouse model. Tumors with oncogenic RAS activation also contain highly vascularized structures. While senescent cells may promote vascularization of surrounding tumor microenvironment, the contribution of the SASP on tumor angiogenesis may depend on cell type.

DNA-damage response increases expression of the SASP factors by activating ATM. Increased expression of IL-1α in senescent cells activates the transcription factors NF-κB and C/EBPβ, which are important for transcription of several SASP factors, including IL-6 and IL-8. IL-1α also promotes its own expression by an NF-κB-mediated positive-feedback loop. High levels of IL-6 enhances invasiveness of breast cancer cells.

Induction of Cellular Senescence During Anti-Cancer Treatments

Chemotherapy and radiation therapy are classical anti-cancer therapies inducing cellular senescence in cancer cells and surrounding normal cells. Chemotherapy drugs promoting senescence include doxorubicin, docetaxel, cisplatin, fluorouracil, etoposide, camptothecin, and bleomycin. Radiation therapy also causes cellular senescence as a consequence of unrepairable DNA damage. Ionizing radiation produces charged particles which ionizes DNA directly or indirectly. Therapy-induced senescence (TIS) can be observed in colon carcinoma, breast cancer, osteosarcoma, and prostate cancer cells.

Induction of TIS is dependent on activation of p53, $p21^{CIP1}$, and $p16^{INK4A}$ pathways. TIS prevents cancer cells from further replicating and stimulates immunosurveillance to remove surrounding tumor cells. While TIS is a tumor suppressive mechanism, TIS may cause proliferation, chronic inflammation, and drug resistance in surrounding tumor cells. TIS may also cause neighboring cells to undergo cellular senescence through a bystander effect and further alter the tumor microenvironment.

Many cancer therapies have side effects. Cancer survivors exposed to chemotherapy develop several age-associated diseases. Side effects of cancer therapy limit the treatment dose that can be used in patients and may even result in the discontinuation of the treatment altogether. Cancer therapies may have off target effects that have not yet been completely explored. TIS may partly contribute to the side effects caused by cancer therapy. Indeed, removing senescent cells minimizes the side effects of chemotherapy. These short-term and long-term side effects, include impaired cardiac function, low bone marrow cell count, increased cancer recurrence, reduced physical activity, and diminished grip strength.

Accumulation of Senescent Cells During Aging

While it is rare to find senescent cells in tissues of young organisms, senescent cells accumulate with age in somatic tissues of several animal species, including humans, primates, and rodents. Aged human skin have increased levels of the senescent

marker SA β-gal. Skin from aging baboons also show markers of senescence, such as shortened telomere, increased heterochromatin foci formation, activated ATM, and elevated $p16^{INK4A}$ expressions. Moreover, several tissues in aging rats and mice also show increased $p16^{INK4A}$ expression. It is still unclear why senescent cells accumulate with age. It is possible that several inducers of senescence also increase with age. Aged tissues might be more prone to cellular damage than would younger tissues. On the other hand, it is also possible that senescent cells are not readily eliminated in older individuals. During aging, the declining function of the immune system may fail to recognize senescent cells, allowing the steady increase in the number of senescent cells.

Senescent cells are associated with age-related diseases, such as osteoarthritis, cardiovascular diseases, diabetes, and Alzheimer's disease. Patients with osteoarthritis have high $p16^{INK4a}$ and $p21^{Cip1}$ expression, decreased telomere length, and increased SA β-gal activity. Mutations in $p16^{INK4a}$ and $p14/p19^{ARF}$ are linked to coronary heart disease and type 2 diabetes. Atherosclerotic plaques have increased SA β-galactosidase activity and $p16^{INK4a}$ and $p21^{Cip1}$ expression. Adipose tissues in obese mice have increased p53 expression and develop insulin resistance. Pyramidal neurons of the hippocampus in patients with amyloid plaques have high levels of $p16^{INK4A}$ expression. Astrocytes of older individuals and those with Alzheimer's disease also have elevated levels of $p16^{INK4A}$. Moreover, induction of senescence by telomere shortening can accelerate aging phenotypes in mice. Genetic elimination of persistent age-related senescent cells is sufficient to improve life span and delay the onset of a subset of age-related diseases in mouse models, including cardiac and renal dysfunctions, atherosclerosis, and osteoarthritis. Aging is associated with a number of loss-of-function phenotypes and diseases, but also marked by an increase in hyperplasias. According to this idea, the rate of cancer exponentially increases with age. Hence, the role of senescent cells in tumor initiation and/or progression could be an interesting target for anti-cancer therapy.

Targeting Senescent Cell

Considering the implication of cellular senescence during aging and cancer, there is mounting interest in developing strategies that can interfere with the deleterious effects of senescent cells (Fig. 6).

Pro-apoptotic Strategy

Identifying the signaling pathways that stabilizes senescent cells may help design therapeutic strategies to mitigate senescence-associated cancer. Drugs that selectively eliminate senescent cells are being developed as means of therapy. Dasatinib and quercetin are effective in synergistically removing senescent cells. Dasatinib, an ephrin B (EFNB) inhibitor, selectively eliminates senescent adipocytes, whereas quercetin, a phosphoinositide 3-kinase inhibitor, effectively removes human endothelial cells. ABT-263 (also Navitoclax) and ABT-737, inhibitors of the Bcl-2 family of anti-apoptotic proteins, are also effective drugs that remove senescent cells. Interestingly, ABT-263 reduces cancer relapse and improves physical activity in mice exposed to doxorubicin. Knockdown of EFNB1 and EFNB3 mRNA transcripts and phosphatidylinositol-4,5-bisphosphate 3-kinase delta catalytic subunit (PIK3CD) will trigger cell death in senescent cells with little effect on proliferating, quiescent, and differentiated nonsenescent cells.

Senescent cells have increased expression of the transcription factor FOXO4 compared to normal cells. Senescent cells depend on FOXO4 for survival. Downregulation of FOXO4 but not other FOXO family members induces apoptosis in senescent but not in normal cells. FOXO4-p53 interaction is important for survival of senescent cells. Pharmacologic inhibition of FOXO4-p53 interaction by the peptide FOXO4-D-retro-inverso (FOXO4-DRI) causes apoptosis in senescent but not normal cells. FOXO4-DRI also suppresses age-associated pathology and doxorubicin-induced tissue dysfunction.

Modulation of the SASP

Another approach to reduce the negative effects of senescent cells is to decrease the expression of the SASP. The tumor suppressor p53, microRNAs miR-146a/b, and membrane protein Klotho are capable of reducing the SASP. C/EBPγ by heterodimerizing with C/EBPβ can also suppress the SASP. Moreover, inhibition of the NF-κB pathway can reduce SASP expression. Indeed, compounds such as resveratrol, apigenin, kaempferol, and wogonin can suppress the SASP by increasing expression of IκBζ and activation of NF-κB. Resveratrol inhibits NF-κB activity and SASP expression. Apigenin, kaempferol, and wogonin also diminish NF-κB activity and exert anti-inflammatory effects.

Summary

The study of cellular senescence in mouse models and human tissues has revealed the complexity of this phenotype and of its biological function. For a long time, senescent cells have been considered potent gatekeepers against initiation of tumors. However, their accumulation during aging and after cancer treatments may cause deleterious effects, including cancer promotion and progression. This has attracted several researchers to develop anti-senescence therapeutic strategies to minimize the negative effects of senescent cells.

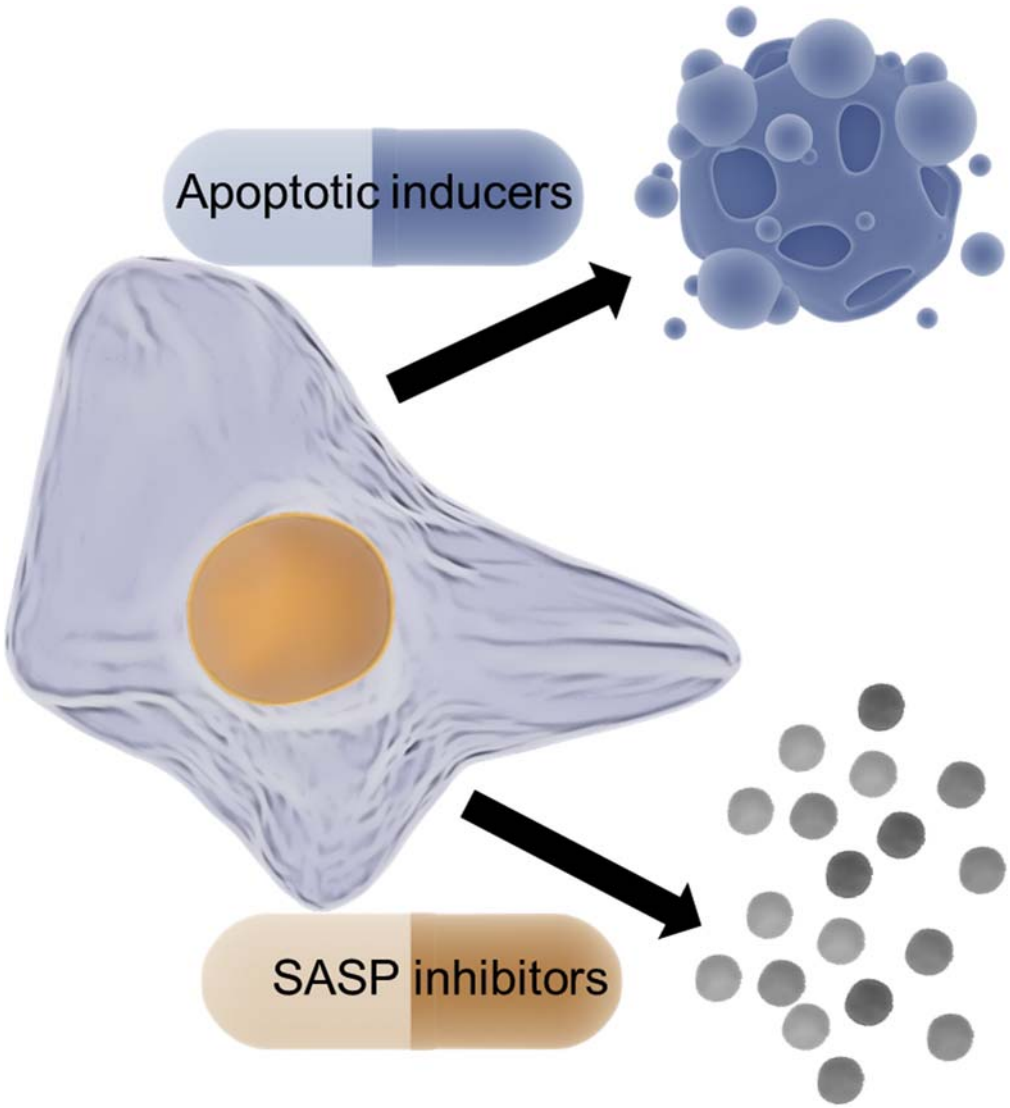

Fig. 6 Therapy against senescence. Interventions against senescent cells can promote apopoptosis or interfere with the secretion of SASP factors.

Prospective Vision

Cellular senescence is a potent block for tumorigenesis. However, recent evidences strongly support the idea that accumulation of senescent cells could be a promoter of pathologies. More interest is growing towards targeting persistent senescent cells. A number of ongoing studies aims at dissecting the importance of senescence for various diseases one-by-one. Current therapeutics against senescence carries intrinsic toxicities which essentially disqualify long-term and systemic treatments. However, efforts will be made for the generation of more safe and less toxic compounds which could extend life span and improve healthspan by delaying a basic mechanism of aging such as cellular senescence.

Sleep Disturbances and Misalignment in Cancer

Eva S Schernhammer, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, United States; and Medical University of Vienna, Wien, Austria
Yin Zhang and Elizabeth E Devore, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, United States

Glossary

Actigraphy Commonly used, easily applicable, and noninvasive research instrument to measure sleep duration and activity levels. Units are typically worn on the wrist and look like wrist watches.
Chronotype A trait that distinguishes among people who are definite morning types (colloquially referred to as "larks"), are definite evening types ("owls"), and who prefer sleep times that are more intermediate compared to these two more extreme forms of sleep timing. Can be assessed via questionnaire (e.g., the Horne–Ostberg Morningness-Eveningness Questionnaire (MEQ)).
Circadian system Comprised of neurons located in the anterior hypothalamus called the suprachiasmatic nuclei (SCN), which acts as the "master clock" and coordinates various "peripheral clocks" throughout tissues of the body. Together, this clock system regulates 24 h ("circadian") rhythms in humans.
Melanopsin receptor Receptor located in the retina that transmits information about environmental light to the SCN.
Melatonin A hormone produced by the pineal gland, which is secreted primarily at night during darkness and is acutely sensitive to light exposure.
Polysomnography An evaluation of sleep-related biophysical changes (e.g., brain waves (EEG), skeletal muscle activation, and heart rhythm (ECG)), which requires individuals to be connected to multiple electrodes overnight.
Sleep apnea A disturbance that affects breathing at night and is tightly linked to obesity.

Sleep Disturbance and Circadian Misalignment

Characteristics of Sleep

Sleep is a state of unconscious changes in brain wave activity and other physiologic parameters (e.g., body temperature, heart rate, and breathing), which occurs primarily at night in darkness. When an individual sleeps, there is a progression through multiple sleep cycles with various distinct stages: stages 1–4 are referred to as "nonrapid eye movement", or non-REM, sleep; stage 5 is referred to as REM sleep, and is characterized by higher sleep quantity and quality (see Fig. 1).

Average sleep durations at night vary across individuals, depending on their age. Currently, the National Sleep Foundation recommends sleep durations of 7–9 h per day for adults ages 24–64. Subjective recall of sleep duration is not always accurate, and objective measures via actigraphy or polysomnography (PSG) provide a less biased method of ascertaining this information. Sleep timing is defined as the times at which a person goes to bed and gets up, and this parameter varies across individuals as well. These differences in preferred sleep timing are referred to as chronotype when they are not driven by social and/or occupational circumstances. In Western society, roughly 15%–20% of the population classify themselves as "definite morning types," 10% as "definite evening types," and the remainder as having an intermediate sleep timing preference. In adolescence, chronotype tends

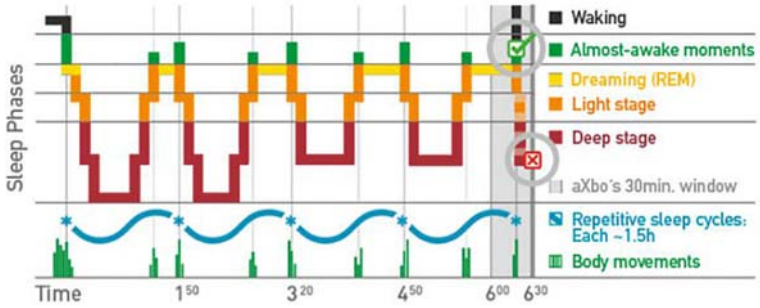

Fig. 1 Typical sleep behavior.

to be more skewed toward evening types across the population, after which time the population gravitates toward morning-type preferences as people age; however, any particular individual will tend to track with their same sleep timing preference throughout their life relative to other individuals of comparable age.

Sleep quality is another important sleep parameter, which has several measurable indicators: (1) time slept in bed (ideally, more than 85% of total sleep time); (2) time in bed before falling asleep (ideally, 30 min or less); (3) number of times waking up at night (ideally, not more than once); and (4) duration of time awake after initially falling asleep (ideally, less than 20 min). Currently, actigraphy and polysomnography are most frequently used to obtain objective data on these sleep quality indicators, although questionnaire-based assessments can be used (most notably, the Pittsburgh Sleep Quality assessment).

Types of Sleep Disturbances

Shortened sleep duration and other sleep disorders have significantly increased over the past century, reaching epic proportions: it has been estimated that sleep disturbances may affect up to 44% of all adults in the United States (see Fig. 2). Sleep disturbances can occur acutely or chronically, and can affect single or multiple sleep characteristics. The most frequently described sleep disorders include: insomnia, sleep-disordered breathing (SDB), restless leg syndrome, and circadian rhythm sleep disorders. Less well-known and rarer sleep disorders include parasomnias (e.g., bed-wetting, tooth grinding, sleep terror) and hypersomnias (e.g., narcolepsy). Medical and psychiatric conditions can also induce sleep disorders.

Insomnia is a condition in which people experience chronic sleeplessness. Their symptoms are characterized by difficulties falling or staying asleep, and early morning awakening with an inability to fall back asleep. DSM-V criteria require these symptoms to recur for at least 3 months before a diagnosis can be made.

Sleep-disordered breathing (SDB) includes conditions such as sleep apnea, snoring, and upper airway resistance syndrome. People with SDB suffer from sleep fragmentation, and as a result spend less time in REM sleep; they can also experience reduced oxygen saturation levels, leading to daytime sleepiness and fatigue.

Restless leg syndrome manifests as a strong urge to move one's legs due to unpleasant sensations in them; these sensations typically occur at rest. Intentional or involuntary leg movements (i.e., periodic limb movement disorder, which involves repetitive cramping of the legs during sleep) relieve the urge, but can make it difficult to initiate or maintain sleep.

Circadian rhythm sleep disorders comprise delayed and advanced sleep phase disorder, as well as non 24 h sleep–wake disorder.

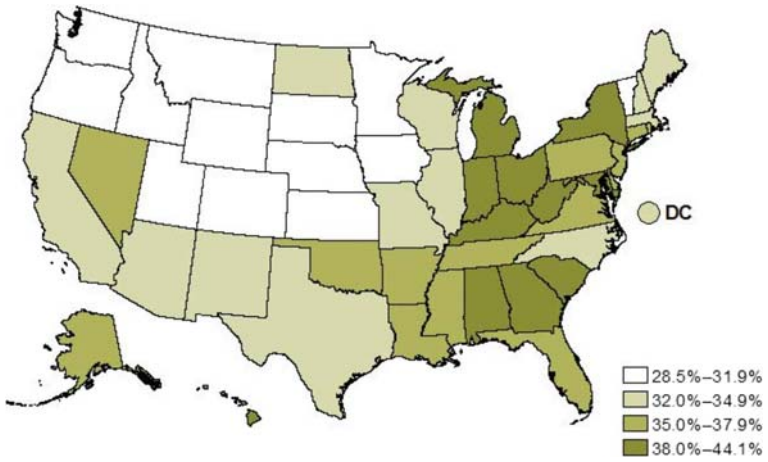

Fig. 2 Prevalence of short sleep duration among adults in the US (CDC, 2014).

The Circadian System

In the brain, the intricate and highly complex interplay between retinal melanopsin receptors, the retinohypothalamic tract, suprachiasmatic nuclei (SCN), and the pineal gland (i.e., the main site of melatonin secretion), as well as receptors and clock genes expressed in virtually every cell of the human body makes up the circadian system (see Fig. 3). This system is acutely sensitive to a small number of "zeitgebers," which includes environmental light (most importantly) as well as meal timing and activity. It directs many bodily functions to follow distinct 24 h rhythms, and keeps them in sync with the environmental light cycles. These functions include: the sleep/wake cycle, body temperature, blood pressure, and production of certain hormones (e.g., cortisol, melatonin, excretion).

Melatonin

Melatonin is a hormone marker of circadian rhythmicity, which also demonstrates cancer-protective properties.

Physiology and pharmacology

Melatonin production is stimulated by darkness and suppressed by light. Production increases in the evening and peaks between 2 and 4 a.m., then gradually declines. It does not vary with the menstrual cycle in premenopausal women. Melatonin diffuses from the pineal gland into the cerebrospinal fluid and capillary blood, freely crossing the blood-brain barrier. The effects of melatonin in the periphery can be roughly divided into direct effects (such as scavenging of free radicals) and receptor mediated effects (via its two receptors, MT_1 and MT_2). Melatonin is metabolized by the liver (90% at first pass) and mainly excreted in the urine. Bioavailability

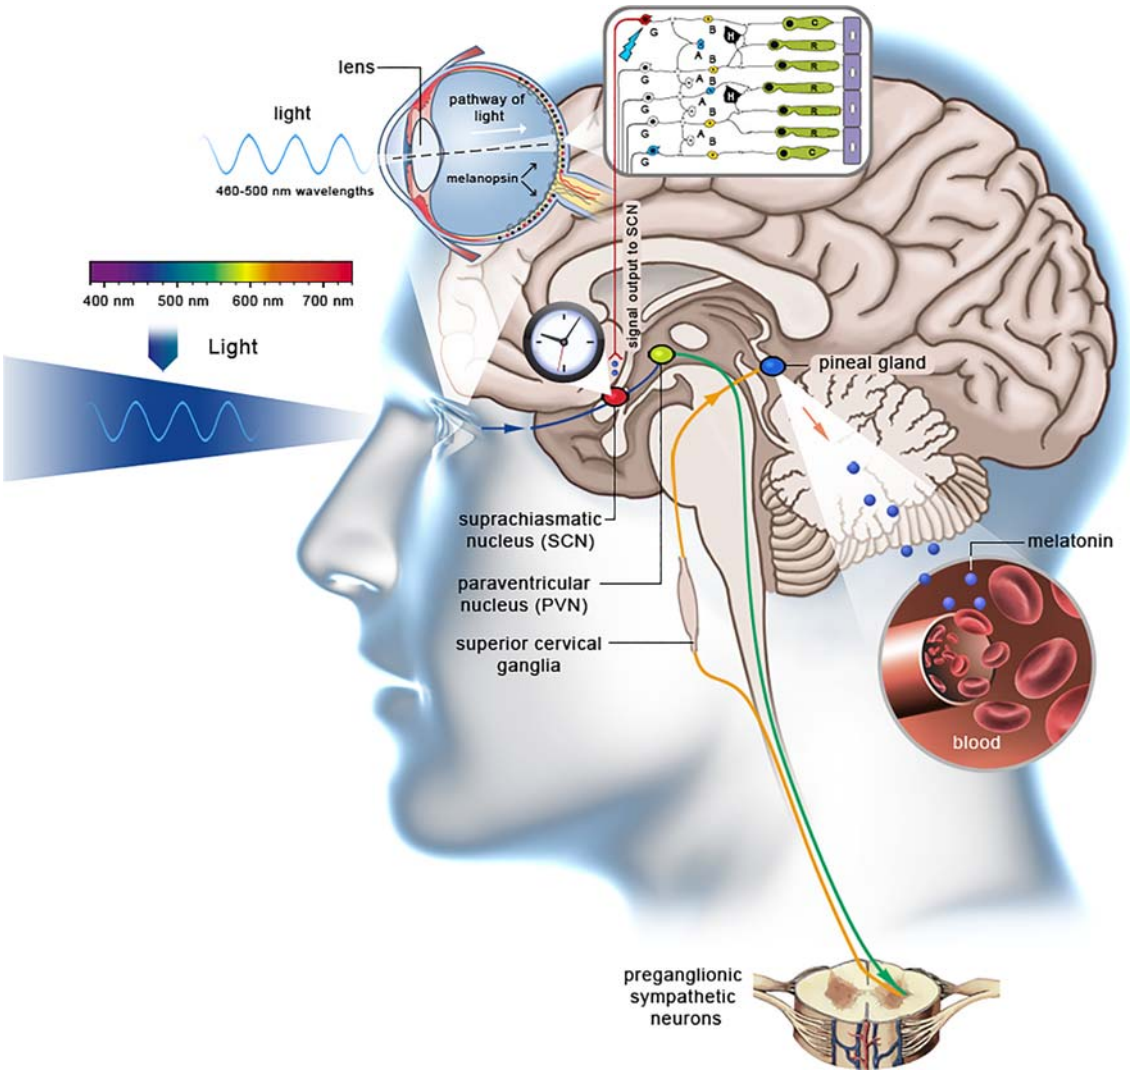

Fig. 3 The circadian system.

of oral melatonin varies, but doses of 1–5 mg generally result in supraphysiologic concentrations (10–100 times the usual peak) within 1 h after ingestion, followed by a decline to baseline within 4–8 h. Melatonin's half-life after oral administration varies between 30 and 60 min. Selective beta-adrenergic blockers (e.g., atenolol, propranolol) have been shown to significantly reduce melatonin release, which is stimulated by norepinephrine effects on beta receptors.

Anticarcinogenic effects

Relevant functions of melatonin related to cancer risk appear to be manifold and complementary. The most prominent mechanisms currently being studied involve melatonin's effects: (1) on estradiol; (2) as an indirect antioxidant and free radical scavenger; (3) on cytokine-mediated immune system function (thereby inhibiting growth of tumor cells); (4) suppression of fatty acid uptake and metabolism; (5) on increasing degradation of calmodulin (a key player in cell proliferation); and (6) on induction of apoptosis (possibly acting as a natural antiangiogenic molecule).

What Is Circadian Misalignment?

To varying degrees, exposure to light at night (as experienced by night workers) or circadian disruption induced by other means (e.g., traveling across time zones, moving to daylight savings time) can disturb synchronization of the central pacemaker in the SCN with peripheral clocks throughout the brain and body. This disruption is commonly referred to as circadian misalignment, and can be felt physically as prolonged fatigue or fatigue/hunger at odd times of the day. For example, once a person has settled into a stable new time zone, it takes the internal clock (i.e., SCN) 5–7 days to adjust to the new time, after which bodily functions return to normal. However, chronic circadian misalignment (as experienced, e.g., by long-term rotating night-shift workers) has been associated with a number of negative health effects on mood, metabolism, the immune system, and cancer risk (see Fig. 4).

Shift work is common, and is becoming increasingly prevalent in the so-called "24/7" society. According to the International Agency for Research on Cancer, about 15%–30% of the working population in Europe and the United States is engaged in shift work. The International Labor Organization defines shift work as "a method of organization of working time in which workers succeed one another at the workplace so that the establishment can operate longer than the hours of work of individual workers"). In the scientific literature and general public, the term "shift work" has been widely used and usually includes any arrangement of daily working hours outside of regular daytime hours (7/8 am–5/6 pm). Therefore, shift workers include all individuals working evening shifts, night shifts, rotating shifts, split shifts, or irregular or on-call schedules both during the week and on weekends. Obviously, people who work shift schedules may be subject to desynchronized circadian rhythm, particularly those working during the night on a rotating schedule. Emerging scientific evidence suggests that daily sleep/wake cycles, hormone regulation, and many physiological processes are often misaligned with behavioral patterns during shift work, especially rotating night shift work, leading to an increased risk of developing cancer and cardiometabolic disorders, including obesity, metabolic syndrome, type 2 diabetes, and cardiovascular disease.

Sleep and Cancer Etiology

Sleep disorders, including short or long sleep duration, sleep disruptions, and sleep-disordered breathing, have emerged as highly prevalent conditions in cancer patients, and have gained increased attention in the past decades. The high prevalence of sleep problems and their potential link with tumorigenesis and cancer prognosis has stimulated interest in both clinical and experimental

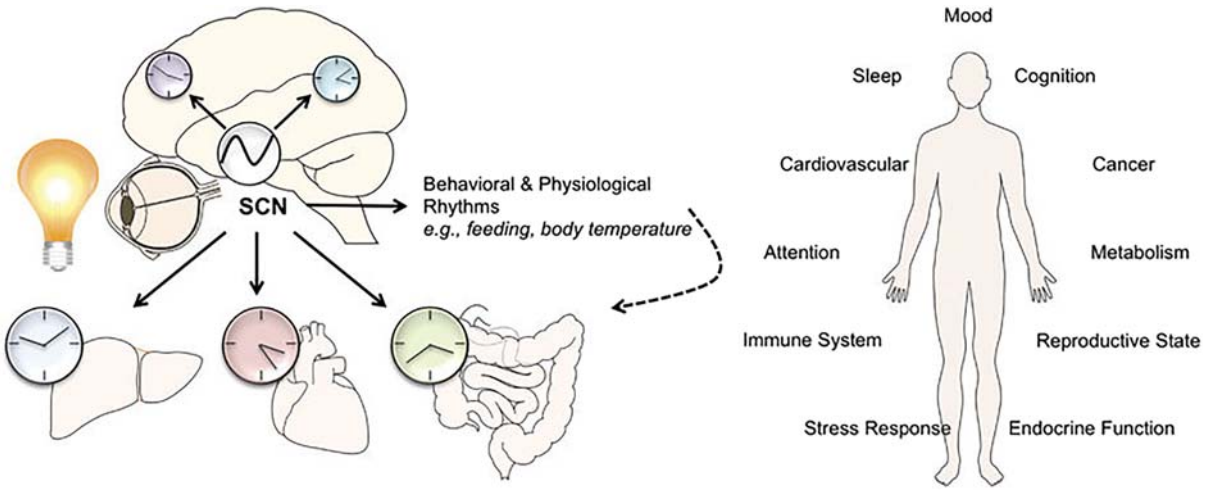

Fig. 4 Health effects of aberrant light exposure.

research. A deeper understanding of epidemiologic links between sleep disturbances, higher cancer incidence, and poorer cancer survival is warranted to improve evidence-based treatment for sleep disruption in the oncology setting. A number of large-scale prospective studies have been conducted worldwide, aiming to investigate this issue based on specific types of sleep problems in populations with and without cancer. While additional studies are still needed to fully elucidate these associations, confirmation of these associations between sleep disorders and cancer would have major clinical implications.

Sleep as Regulator of Carcinogenic Processes

The tight coupling of sleep and the circadian system suggests that circadian misalignment and related pathways essential for cancer development will be similarly central to the link between sleep and cancer. In addition, various general mechanisms of a potential link between particularly long sleep and all-cause as well as cancer mortality have been proposed, including sleep fragmentation, lack of physiological challenge (e.g., exercise), depression, and underlying disease processes (e.g., sleep apnea, heart disease).

Epidemiological Evidence Linking Sleep and Cancer

Due to the growing interest in the role of sleep in carcinogenesis, to date, multiple prospective studies have evaluated sleep duration in relation to cancer incidence and mortality. In these studies, individuals with self-reported short sleep duration (less than 5 or 6 h) or long sleep duration (9 h or more) have been compared to individuals with "average" sleep duration (7–8 h), although studies have classified sleep duration differently (either by number of hours per night or number of hours per 24 h period). This difference in classification might imply that studies examining 24 h sleep durations include napping times in their sleep duration estimates, whereas studies of nighttime sleep durations do not. Results have been inconsistent across individual studies, indicating a range of associations: positive, negative, and null. In meta-analyses, summary estimates across studies have suggested no overall association of short or long sleep duration with total cancer risk, and no association between sleep duration and specific cancer endpoints (breast, prostate, endometrial, thyroid, and ovarian), except that long sleep duration may be associated with an increased risk of colorectal cancer. However, the reason for this particular association is unclear, and could be due to either underlying biology or confounding bias. In addition, associations have been observed to be similar across studies according to gender, sample size, geographic location, participants' occupation, and definition of sleep duration. Furthermore, studies on sleep duration and cancer mortality generally have reported that long, not short, sleep durations may be related to an increased risk of total cancer mortality, although confounding bias may play a role in this association; moreover, studies have produced mixed results when mortality due to specific cancers (e.g., breast, colorectal, prostate) has been considered. Additional large-scale, prospective studies of sleep duration and cancer endpoints, particularly cancer-specific mortality, are needed to better understand these associations.

Epidemiology of Sleep-Disordered Breathing and Cancer

Sleep-disordered breathing and cancer is a related topic of interest that has gained attention. Of particular interest, obstructive sleep apnea is a common type of sleep-disordered breathing, characterized by recurrent bouts of upper airway obstruction while sleeping, resulting in sleep fragmentation and intermittent hypoxia that could have implications for cancer risk. Several studies have explored the associations of sleep-disordered breathing and/or obstructive sleep apnea in relation to cancer incidence and mortality, with exposure assessment relying on various metrics: the apnea-hypopnea index (AHI), the respiratory disturbance index (RDI), or a hypoxia index based on oxygen saturation level. To date, most individual studies have indicated that sleep-disordered breathing/sleep apnea may be associated with a somewhat increased cancer risk, and recent meta-analyses suggested an overall modest association when studies were considered together; however, meta-analysis found no apparent association when these data were stratified according to severity of sleep apnea (mild, moderate, and severe). Still, interpretation of this literature is limited due to study design issues, including lack of prospectively collected data, differences in exposure assessment, and insufficient information on important confounding factors. More well-conducted, prospective studies are needed to evaluate associations of sleep-disordered breathing and both cancer incidence and mortality.

Special Case: (Night) Shift Workers

In 2007, the International Agency for Research on Cancer classified shift work as a possible carcinogen, based on "convincing experimental evidence and suggestive epidemiologic data" to this effect. Indeed, experimental data on the association between shift work and cancer has consistently demonstrated that simulated shift work can lead to a higher incidence of cancer in animal models; specifically, light entrains the biological clock, as the SCN receives environmental dark/light information directly from the retina. This mechanism (also regulated by genes) appears to have evolved to detect changes in daylength/season, perhaps useful for promoting survival through migration and hibernation. Consistent with biologic evidence, the epidemiologic literature suggests that shift work is probably associated with a modestly increased risk of breast cancer. There may also be such an association with prostate cancer, although research on this and other cancers is still limited. A key distinguishing feature of prior studies is the method of exposure assessment: retrospective studies have relied heavily on either company records of shift work, or the

coupling of brief employment histories and job matrices (which make broad assumptions about the amount of shift work involved in specific occupations or occupational settings); in contrast, prospective studies have tended to ascertain more detailed shift work information from participants. Because exposure misclassification is more likely when shift work history is derived from employment records and job matrices, studies that have used this approach tend to be more limited in their ability to detect associations with shift work. This limitation may explain why some studies have reported either no association or a weak association between shift work and cancer. Thus, future research should focus on prospective collection of detailed information on shift work exposure, and investigation of shift work in relation to risk of cancers other than breast cancer.

Sleep and Cancer Survival

One of the most commonly reported complaints in oncology is poor sleep quality; for example, up to 70% of nonmetastatic breast cancer patients report poor sleep quality within the first months following diagnosis. Chronically poor sleep may influence cancer outcomes through impaired immune function, metabolic pathways leading to obesity, and altered melatonin release.

Epidemiology of Sleep and Cancer Survival

Because many cancer patients experience disrupted sleeping patterns, several recent studies have explored the association of postdiagnosis sleep characteristics and survival among cancer patients. Overall, results have indicated that sleep disturbances (defined as extreme sleep durations, subjective report of poor quality sleep, or objectively-measured sleep disruptions) may reduce survival time across multiple cancer populations: individuals with various stages of breast, colorectal, lung, liver/pancreatic, and head/neck cancer. For example, a recent prospective study of breast cancer patients suggested that long sleep durations (nine or more hours per night) and subjective, regular sleeping difficulties at postdiagnosis assessment, as well as increased sleep durations over time (comparing pre- and postdiagnosis assessments), might be related to greater risks of death due to breast cancer. However, as in all observational studies, it is possible that observed associations may reflect some degree of reverse causation (i.e., declining health may have contributed to sleep disturbances, as well as vice versa). More prospective research is necessary to refine our understanding of which sleep parameters are associated with survival across different cancer populations.

Oral Melatonin in Cancer Treatment/Patients

In vitro studies, although not entirely consistent, indicate that both pharmacologic and physiologic doses of melatonin reduce the growth of malignant cells of the breast and other tumors. In cancer patients, melatonin has been used extensively both alone and in combination with chemotherapy, with no significant adverse effects reported thus far. Overall, these reports suggested a statistically significant improvement in clinical response rate and overall survival among people with metastatic solid tumors randomly assigned to chemotherapy and melatonin compared to chemotherapy alone; they also indicated a decrease in chemotherapy-induced toxicity, such as neurotoxicity, thrombocytopenia, cachexia, and asthenia in the melatonin arm. However, larger scale double blind randomized trials are currently still lacking.

Several small uncontrolled pilot studies lend direct and indirect support for an inverse association between melatonin and estradiol levels, although these studies are not entirely consistent. Notably, in a small placebo-controlled, randomized study of the effects of 3 mg melatonin daily on several plasma markers of breast cancer in postmenopausal women with a history of breast cancer, short-term melatonin treatment did not influence circulating estradiol and IGF-1/IGBP-3 levels. However, subjective sleep quality was improved in these breast cancer survivors, which, in combination with the virtual lack of side effects (especially also regarding hormonal side effects), may suggest it is a suitable sleep remedy in these patients.

Melatonin in Cancer Prevention

Does Circulating Melatonin Predict Cancer Risk?

Several retrospective studies have examined melatonin levels in cancer patients, with inconsistent results. The main limitation of these retrospective studies is that blood samples for melatonin are collected after a diagnosis of cancer, thus allowing no assessment of the hormone's predictive value for breast cancer risk. However, more recently, evidence from prospective case–control studies nested in larger cohorts has emerged, largely focused on breast cancer. In these studies, urine was collected in healthy women (to measure the overnight excretion of 6-sulfatoxymelatonin—melatonin's major metabolite), and women were followed for several years until they developed breast cancer. Currently existing prospective studies of melatonin levels and breast cancer risk in postmenopausal women tend to indicate an inverse association. However, results are somewhat mixed, and whether these differences are driven by biology (e.g., effects in subgroups defined by hormone receptor status of the tumor) or methodologic issues (e.g., differences in laboratory methods, or varying times between urine collection and cancer diagnosis) requires larger, pooled studies, which currently do not exist. Evidence for an association between urinary melatonin and breast cancer risk among premenopausal women is also mixed, though also largely pointing toward a lower risk of breast cancer among women with higher

melatonin levels. More recently, some preliminary evidence for inverse associations between higher melatonin secretion and prostate cancer risk has been published, although larger studies are warranted to more fully appreciate the role of melatonin in cancer prevention.

Role of Melatonin in Cancer Prevention?

To date, no studies have examined the potential of oral melatonin, or one of the melatonin receptor agonists, in cancer prevention. These agonists include ramelteon, agomelatine, and tasimelteon, all of which are approved and primarily applied for sleep disorder treatment. Some indirect evidence suggests that any relevant effects of melatonin for breast cancer risk may perhaps not operate through circulating melatonin given that a randomized trial of 3 mg oral melatonin did not demonstrate an effect of melatonin on circulating sex steroids; however, it might operate at the tissue level. Still, a small study of physiologically circulating melatonin did not reveal important differences in the effect of melatonin on breast cancer risk stratified by melatonin receptor status in the tumor tissue, although clearly more research is needed. To date, few short-term side effects of melatonin have been reported in randomized trials of up to 6 months duration; however, longer-term studies have yet to be conducted in humans, to fully eliminate any remaining concerns regarding the long-term potential for melatonin to negatively affect reproduction or exert other adverse health effects.

Summary

In summary, sleep, the circadian system, and their related biomarkers represent a highly active, although fairly young, research area; this is especially true for these factors in regards to cancer endpoints. Despite sparse literature, some studies have suggested a role for sleep and the circadian system in cancer prevention, treatment, and survival.

Limitations of Existing Studies

General limitations of existing studies should be noted and improved upon in future work. The biologic complexity of sleep, the circadian system, and cancer makes it difficult to collect and analyze data that can be used to obtain straightforward answers about causality in these relationships. For example, studies of sleep duration used different definitions/categories to define short and long sleep, which can lead to heterogeneity of results. In addition, most studies have assessed vital sleep variables such as sleep duration and sleep efficiency based on self-reported information from participants (instead of objective measurements), which may lead to potential information bias. Confounding is a major bias that precludes inferences about causality of associations identified in existing studies. Individual studies often take into account information on traditional cancer risk factors (e.g., age, gender, smoking habits, alcohol consumption, and body mass index); however, additional information is needed to adjust for the influence of other potential confounding factors (e.g., sleep apnea, altered immune functioning, shortened light exposure, fatigue). Moreover, it is impossible to account for unknown or unmeasured confounders, which are possible in observational studies and can lead to undetected or unmeasurable bias. It is also true that sleep disorders may affect different malignancies differently, such that studies of overall cancer outcomes may mask associations with specific types of cancer. Finally, the number of high-quality studies that can be utilized in systematic reviews and meta-analyses is relatively small, making it difficult to avoid publication bias when summarizing previous literature.

Future Research Areas

Growing evidence has yielded mixed results but indicates some potential associations of sleep disorders with cancer incidence and mortality, although existing data are limited and more research is necessary. As research progresses, it will be critical to update systematic reviews and meta-analyses to further clarify this body of literature. Large, prospective studies based on population-based cohorts with long-term follow up should be conducted to further examine associations of sleep disorders (using subjective and objective assessments) with specific cancer subtypes across diverse populations. In addition, randomized controlled trials may be warranted to evaluate sleep-related treatment options to determine their effectiveness in reducing cancer incidence and/or mortality.

Prospective Vision (Where the Field Is Moving)

The circadian system and its main correlates, including sleep, are rapidly gaining recognition in medicine as important factors and contributors to virtually every major disease outcome. Research on the circadian clock and sleep is a relatively young discipline, where central findings such as the discovery of a melanopsin-containing receptor in the retina, which transmits information about environmental light (the main zeitgeber for the circadian system) to the SCN, have only been made at the beginning of the 21st century. The 2017 Nobel Prize in medicine for the discovery of genes that drive the circadian rhythm is further testimony to an increasing relevance of this young discipline. It appears likely that, with the emergence of new findings in this highly active research field, and a growing understanding of the mechanisms involved, sleep problems and circadian disruption will be recognized and

added to the small list of key lifestyle factors that account for the majority of adjustable disease risk in humans, and as such will also alter cancer practice.

Nicolas Girard, Curie Institute, Paris, France; and Lyon University, Lyon, France

Definition

Initially called oat-cell carcinoma or small-cell anaplastic carcinoma, small-cell lung cancer (SCLC) has been classified in the 1981 WHO classification as typical SCLC or intermediate variant of SCLC. Since the 2004 WHO classification, only two types were considered: pure SCLC and combined SCLC, when associated with nonsmall-cell carcinoma (adenocarcinomas, squamous-cell carcinoma, large-cell carcinoma, large-cell neuroendocrine carcinoma (LCNEC), or sarcomatoid carcinoma). By definition, SCLCs are malignant epithelial tumors composed of small cells with a scant cytoplasm and a typical granular chromatin. This tumor belongs to the group of neuroendocrine (NE) tumors of the lung along with carcinoids and LCNEC, with whom it shares morphological, immunohistochemical and molecular features; however, SCLC exhibits the highest grade of malignancy and the poorest prognosis.

Burden

Geographic differences in smoking habits combined with gender and ethnic differences still prevent accurate worldwide estimates. While the incidence of SCLC is decreasing in countries with effective smoking cessation policies, it is increasing in low-income and middle-income countries. According to Surveillance, Epidemiology and End Results database, the incidence of SCLC is 10 cases per 100,000 men, and 8 cases per 100,000 women. SCLC remains the seventh most common cause of cancer-related death in the United States. The frequency of SCLC as a proportion of all lung cancer cases peaked at 17%–20% in the late 1980s, but is now ranging from 13% to 15%. Only modest improvements have been seen in SCLC detection, therapy or survival over the past 30 years. From 1973 to 2002, the 5-year overall survival rate only increased from 4.3% to 6.3%. Overall, SCLC is estimated to kill 250,000 people worldwide yearly.

Risk Factors

The primary cause of SCLC is tobacco use, with $>95\%$ of patients being current or former smokers. In the United States, the decreasing prevalence of cigarette smoking together with the changes in the doses and types of carcinogens inhaled, related to the characteristics of cigarettes, has resulted in a decrease in the incidence of SCLC over the past 30 years.

Pathology

Histogenesis

Both carcinoids and SCLC were believed initially to arise from normal bronchial NE cells called Kulchitsky-type cells, acting as airways chemoreceptors involved in lung growth and differentiation. However, given recent gene expression profiling studies, the hypothesis of common multipotent precursor cells for SCLC/LCNEC and non-NE pulmonary tumors is favored, based on the existence of combined tumors. Sutherland et al. have shown in transgenic mice that all lung carcinomas could derive from a common epithelial precursor cell, ASH1-positive cells giving rise either to bronchiolo-alveolar stem cells (BASC) and adenocarcinomas, or to basal-cell progenitor and squamous-cell carcinoma, or to neuroendocrine cells and LCNEC/SCLC. In addition, SCLC could also arise directly from alveolar type II cells through NE markers re-expression, as demonstrated in resistant *Egfr*-mutated adenocarcinomas after oncogenic Kras expression. However, to date, no preneoplastic lesion has been identified for LCNEC or SCLC.

Macroscopy

SCLCs are typically proximal tumors, forming a soft tan-yellow endobronchial mass with extensive necrosis, invading directly peribronchial lymph nodes. However, in 5% of the cases, SCLC can be peripheral, presenting as soft ill-defined and necrotic nodules. It would then be misdiagnosed clinically as early-stage nonsmall-cell lung cancer (NSCLC), leading to surgical resection.

Histology

At low magnification, SCLC presents as a dense proliferation of small size tumor cells, arranged in diffuse sheets or ribbons, and with extensive areas of necrosis. Less frequently, neuroendocrine (organoid) characteristics such as rosettes, palisades and nests

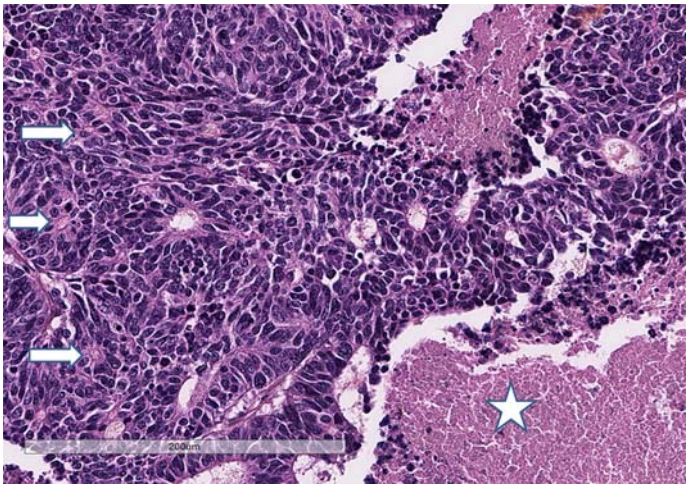

Fig. 1 Surgical sample of SCLC: large sheet of small tumor cells with scant cytoplasm and a typical salt and pepper nucleus. Note the numerous rosettes (arrows), necrosis (star) and mitoses (Hematoxylin Eosin Saffron stain; original magnification $\times 200$).

can be found. At high power fields, tumor cells are round to spindle and measure usually < 3 resting lymphocytes. They present with a scant cytoplasm and a typical salt and pepper nucleus. Chromatin is finely granular with inconspicuous nucleoli. Nuclear molding is frequent as well as nuclear debris known as Azzopardi effect and apoptotic bodies. Mitoses are numerous with an average of 80 mitoses per 2 mm^2 areas (Fig. 1). Those features are more obvious on surgical samples, where tumors cells seem larger with distinct cytoplasm and focal vesicular chromatin (Fig. 2), but on small biopsies, crushed artifacts can be predominant, and necrosis or rosettes and palisades absent. Several studies have shown a considerable overlap between SCLC and LCNEC when nuclear size or chromatin features were considered.

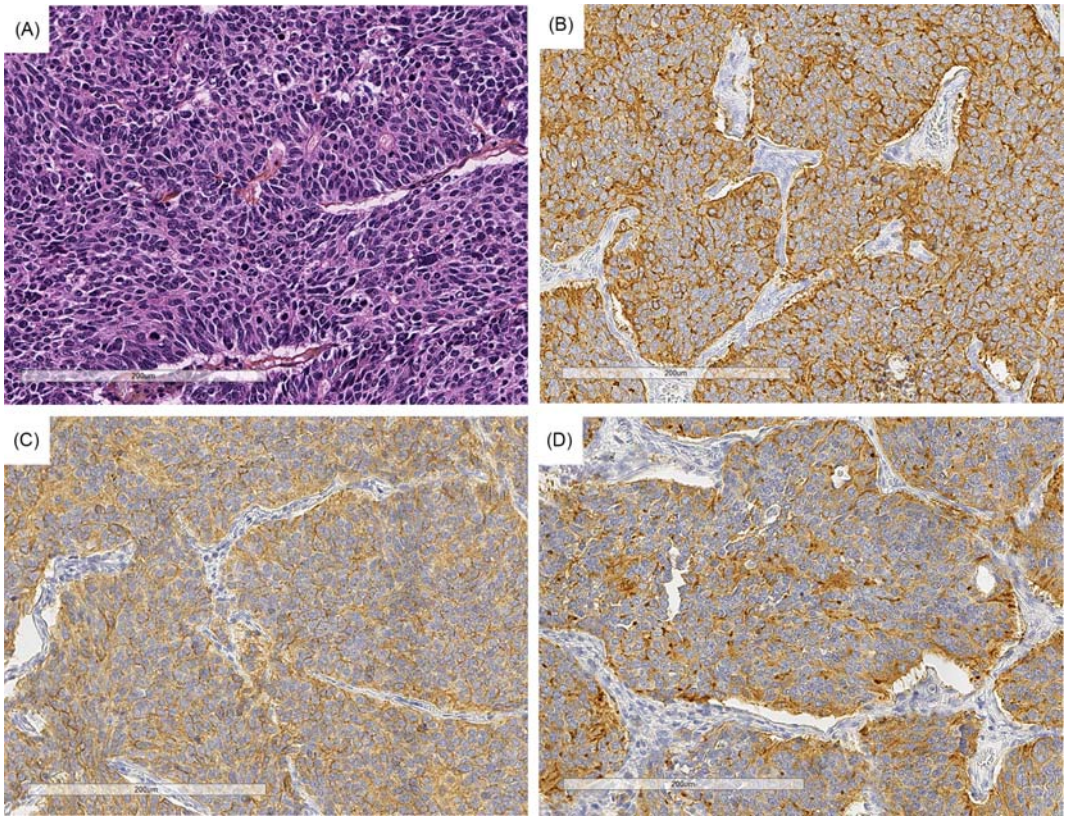

Fig. 2 (A) Surgical sample of SCLC (HES stain; original magnification $\times 200$). (B) Synaptophysin expression by tumor cells (immunoperoxydase; original magnification $\times 200$). (C) CD56 expression by tumor cells with a typical membranar staining (immunoperoxydase; original magnification $\times 200$). (D) Chromogranin A expression by tumor cells (immunoperoxydase; original magnification $\times 200$).

Combined SCLCs are defined by a mixture of pure SCLC areas and of adenocarcinomas, squamous-cell carcinoma, large-cell carcinoma or sarcomatoid (spindle or giant cells) areas, whatever the amount of NSCLC component. In contrast, for combined LCNEC and SCLC, a minimum of 10% of LCNEC is required. Combined SCLCs are more frequently diagnosed on surgical specimens widely sampled in comparison to biopsies. Of note, as for SCLC, there are some variations of interpretation and the overall kappa value for the identification of a SCLC component in SCLC and combined SCLC was 0.41 (moderate agreement). Combined SCLC share with pure SCLC the same epidemiology and clinical presentation, even if combined SCLCs tend to be more peripheral. Regarding prognosis, combined SCLC could harbor a worse prognosis than pure SCLC, possibly due to relative chemoresistance of non-SCLC components. From a clinical standpoint, the hypothesis of combined SCLC has to be raised when facing a SCLC tumor with heterogeneous response to first-line chemotherapy.

Cytology

On sputum and bronchial washings, SCLC cells are loosely arranged in rows or small groups, but maybe more cohesive on brushings and fine needle aspiration. They are often larger than three lymphocytes but cytoplasms are restricted to small rims. Nuclei are finely "salt and pepper," with inconspicuous nucleoli; nuclear molding is often prominent particularly on air-dried preparations. Mitoses are easily found, as well as a necrotic background. In daily practice, most SCLCs are diagnosed on the combination of cytology and biopsy, which increases dramatically the diagnostic yield.

Immunophenotype

SCLC is easily recognized on cytological samples, but on small biopsies a confirmation by immunohistochemistry can be of great help, particularly when tumor cells are crushed. The vast majority (95%) of SCLC diffusely express hASH1 and CD56 (membrane staining), whereas synaptic vesicle protein synaptophysin and dense-core associated protein chromogranin A cytoplasmic stainings are observed in 54% and in 37% of the cases, respectively, and often focally. Interestingly, CD56 expression is often retained in crushed specimens; in contrast, TTF1 is expressed classically in 90% of SCLC, but it may be absent on crushed biopsies (Fig. 3).

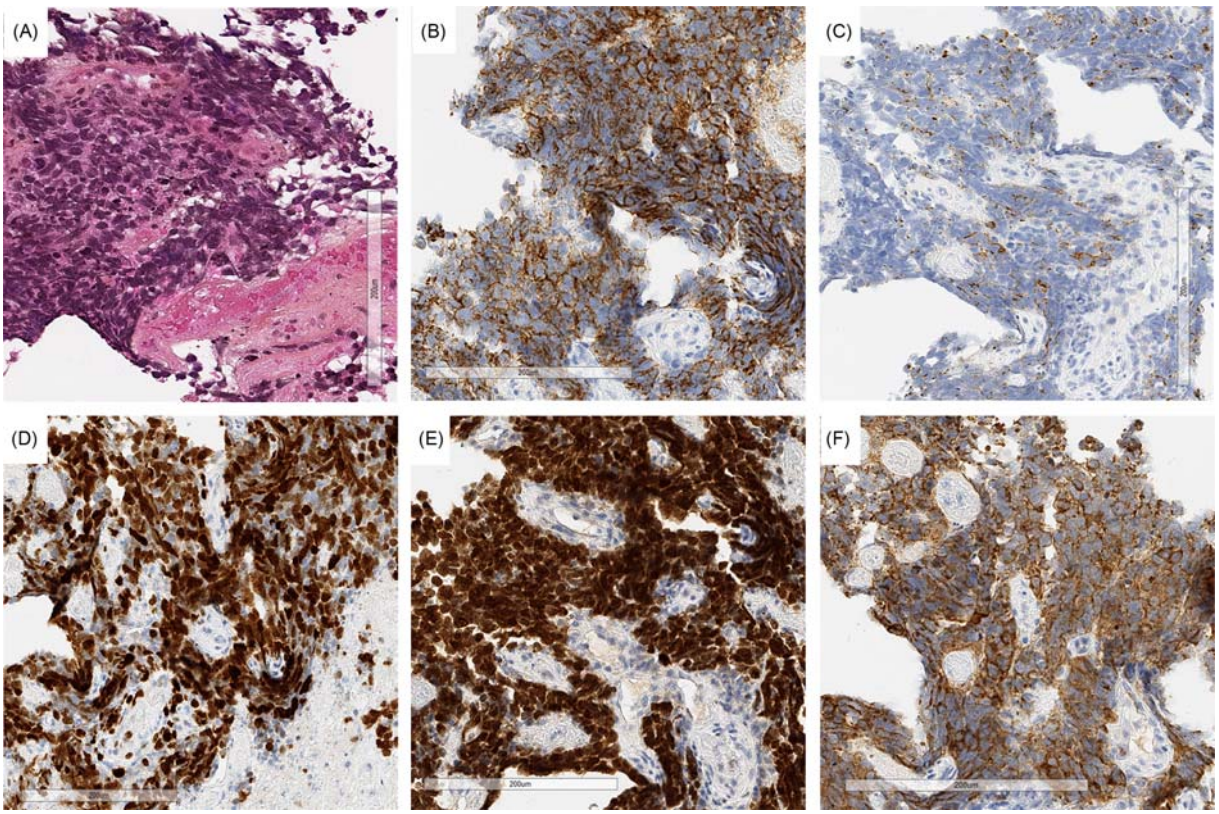

Fig. 3 (A) SCLC on a small bronchial biopsy. Note the crush artifacts (HES stain; original magnification ×200). (B) The same SCLC case: tumor cells express CD56 with a typical membranar staining (immunoperoxydase; original magnification ×200). (C) Chromogranin A expression by tumor cells (immunoperoxydase; original magnification ×200). (D) High Ki67 expression (nuclear staining with MiB1 Ab) (immunoperoxydase; original magnification ×200). (E) TTF1 expression by all tumor cells (nuclear staining with 8G7G3/1 Ab) (immunoperoxydase; original magnification ×200). (F) Synaptophysin expression by tumor cells (immunoperoxydase; original magnification ×200).

The expression of TTF1 in SCLC remains unexplained but it might be a cell lineage-specific phenomenon involving the developing neural cell-specific homeoprotein BRN2. In SCLC, nearly 50% of the nuclei are positively stained for KI67 (MIB1). Accordingly, Pelosi et al. have proposed a new grading system including three categories Lu-NET G1, Lu-NET G2, and Lu-NET G3 based on mitotic count, necrosis and KI67 index.

A recent international study by a group of pathologists of the IASLC has evaluated the impact of immunohistochemistry on the diagnostic reproducibility for SCLC. On selected cases, the agreement rate between pathologists increased from 0.55 to 0.60 when a panel of markers, including NE markers (CD56, chromogranin A and synaptophysin), TTF1 and KI67, was used. The use of such panel also increased the confidence of the pathologists. SCLC always express CK17 and CK19 cytokeratins, and are frequently positive with cocktails of cytokeratins, with a peculiar "punctate and paranuclear dot" pattern, but a diffuse cytoplasmic pattern does not exclude the diagnosis of SCLC. P63 and CK7 stains are of poor help as a minority of SCLC can be positive, but P40 is always negative. Interestingly, P16 nuclear staining is observed in 95%–100% of the SCLC, contrasting with RB1, which is never expressed. The usefulness in clinical practice of other putative diagnostic markers such as BAI3, CDX2, STK11, VIL1 needs to be further evaluated.

Differential Diagnoses

Differential diagnoses include other NE lung tumors, such as typical carcinoids (TC), atypical carcinoids (AC), and LCNEC, other NSCLC with small basal-like cells (basaloid carcinoma, NUT1 carcinoma) and more rarely, small round cell sarcoma, metastatic breast carcinoma and non-Hodgkin lymphoma. LCNEC can present morphological overlaps with SCLC but obvious NE architecture is mandatory for its diagnosis and cells are classically larger, with a vesicular nucleus and prominent nucleoli (Fig. 4A). Immunohistochemistry is of little help as SCLC and LCNEC share the same phenotype regarding NE markers, cytokeratins, P40, P16, and KI67 expression. Conversely, TTF1 is expressed in nearly half of the cases and LCNEC can be positive or negative for RB1.

Carcinoids in crushed or small specimen can also mimic SCLC, particularly when they are composed of spindle cells; however (Fig. 4B), clinical presentation differs dramatically and NE markers as well as cytokeratins are more diffusely expressed. In addition, carcinoids only focally and weakly express TTF1, and are RB1 positive. More interestingly, KI67/MIB1 antibody stains $<25\%$ of the tumor nuclei.

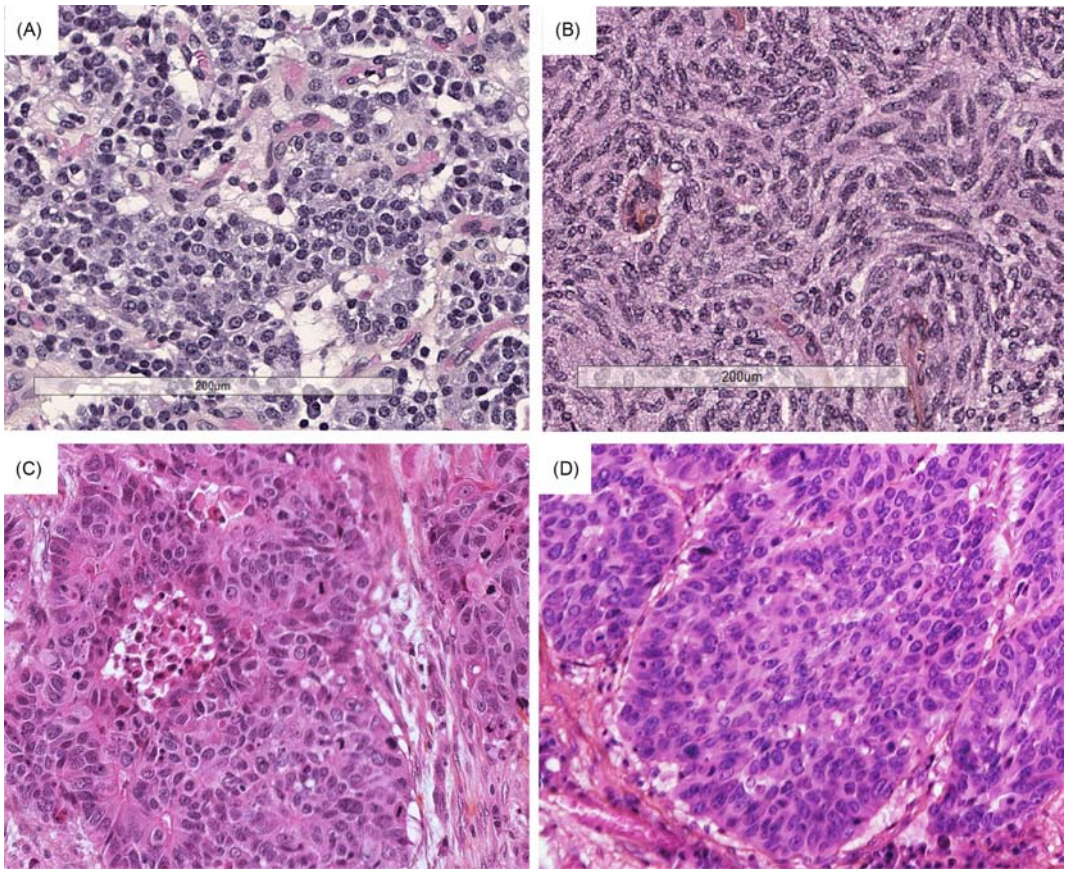

Fig. 4 Differential diagnoses for SCLC: (A) Typical carcinoid tumor (HES stain; original magnification $\times 200$). (B) Spindle cell carcinoid tumor (HES stain; original magnification $\times 100$). (C) Large-cell neuroendocrine carcinoma (HES stain; original magnification $\times 200$). (D) Basaloid variant of squamous-cell carcinoma (HES stain; original magnification $\times 100$).

Distinction of SCLC form basaloid carcinoma can be tricky on small specimens, particularly when they are poorly preserved or crushed (Fig. 4C). Immunohistochemistry is very helpful, with no NE markers and TTF1 expression, contrasting with strong and diffuse P63/P40 and high-molecular weight keratins (CK5–6 or CK1,5,10,14) stainings. NUT-rearranged carcinoma can be either P40 or TTF1 positive, but they are positive with NUT1 antibody and show typical *NUT1* gene rearrangement by FISH (Fig. 4D).

SCLC never expresses estrogen and progesterone receptors, which can be useful for the differential diagnosis with metastatic breast carcinoma. At least, SCLC needs sometimes to be distinguished from reactive or malignant lymphoid infiltrates on small crushed bronchial biopsies, justifying in doubtful cases the use of a panel of antibodies including lymphoid markers.

Molecular Pathology and Genetics

As mentioned above, SCLC is strongly associated with smoking exposure, with only 2% of cases occurring in never-smokers. Accordingly, SCLCs have a high load of somatic mutations induced by tobacco carcinogens (C:G > A:T transversions). The mean mutation rate of SCLC estimated to 8.62 nonsynonymous mutations per-million-base-pairs is similar to that of other tobacco-associated (lung) cancers.

Despite the difficulties in obtaining material suitable for genomic studies, large sequencing efforts have been made in recent years to molecularly characterize this deadly and untreatably disease. The genomes/exomes of around 200 resected SCLCs have been sequenced to date. These studies have revealed that SCLC is a disease of *TP53* and *RB1* since bi-allelic inactivation of these two genes is near ubiquitous in these tumors. In most cases, the inactivation of these genes happens due to bi-allelic inactivation through mutation, loss of heterozygosity (LOH), and inactivating rearrangements. In few cases the inactivation of *RB1* can occur through chromothripsis events leading to overexpression of cyclin D1 (encoded by the *CCND1* gene). In addition, homozygous loses in the *CDKN2A* locus (indirect activator of TP53 and RB1) and inactivating mutations and translocations in *RBL1* and *RBL2* (closely related to *RB1*) were also identified (Fig. 5A). These data suggest that the loss of the tumor suppressors *TP53* and *RB1* is required for the development of SCLC. In fact, this has already been inferred from mice studies, in which the inactivation of these two genes in pulmonary cells led to the development of SCLC tumors (Fig. 5B). Interestingly, both neuroendocrine (NE), and alveolar type 2 (SPC-expressing) cells led to SCLC upon inactivation of *Tp53* and *Rb1*, albeit SPC-expressing cells at a lesser efficiency. These data suggest that, although NSCLC and SCLC are commonly thought to be different diseases originating from different pulmonary cells (Alveolar type 1 and 2 and Clara cells for NSCLC, and neuroendocrine cells for SCLC), these malignant disorders might share common cells of origin. This idea has been supported by the unexpected findings that one of the resistant mechanisms of *EGFR*-mutated NSCLCs treated with EGFR tyrosine kinase inhibitors (TKI) is through transdifferentiation to SCLC (Fig. 5B). In a study on nine patients, which NSCLC tumors underwent transdifferentiation to SCLC at the time of acquired

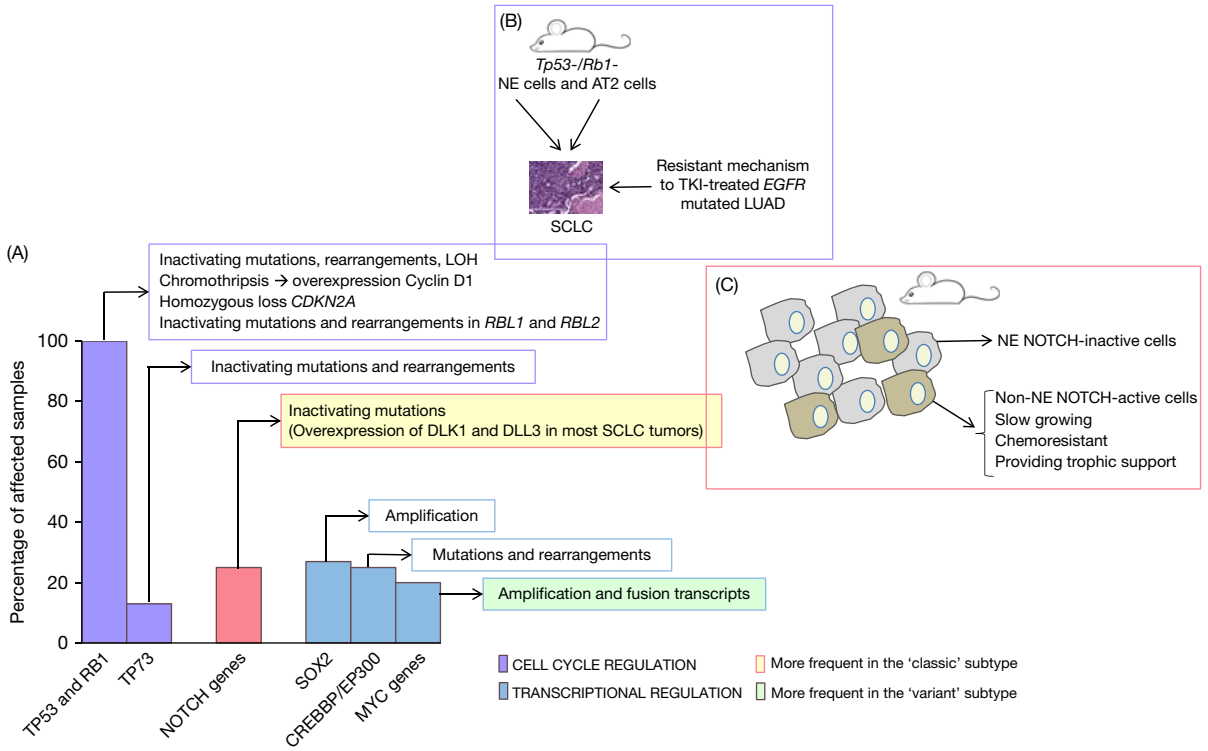

Fig. 5 Overview of the main biological and molecular characteristics of SCLC tumors.

resistance to EGFR TKI therapy, *RB1* has been found lost in 100% of these SCLC transdifferentiated cases. This rarely happened in those that remained NSCLC. Moreover, in another study with genome data on 21 patients with advanced *EGFR*-mutant NSCLCs that were transdifferentiated into EGFR TKI-resistant SCLCs, the authors found that EGFR TKI-resistant SCLCs branched out early from the NSCLC clones that harbored completely inactivated *RB1* and *TP53*.

The TP53 family of proteins also includes TP63 and TP73 based on their gene structures and functions; however, the functions of these three transcription factors diversified in the higher vertebrates. It has being found that TP73 is somatically inactivated by mutations and genomic rearrangements in 13% of the SCLC cases (**Fig. 5**A). Transcriptome analyses proved that the identified somatic genomic rearrangements generated the N-terminally truncated transcript variants p73Dex2 and p73Dex2/3, as well as p73Dex10. TP73 with N-terminal truncations are oncogenic through the dominant-negative functions on wild-type TP73 and TP53. C-terminal truncations, such as p73Dex10, can similarly exert dominant-negative effects on wild-type TP73.

Notch is inactivated in the majority of SCLC tumors (especially in those expressing the full set of NE cell markers), either by expression of the Notch inhibitors DLK1 and DLL3 or through mutations in Notch genes, which are detected in 25% of human SCLC (**Fig. 5**A). Although these receptors have been validated as tumor suppressors in mouse models of SCLC, it is known that the Notch signaling pathway mediates cell fate decisions and is tumor-suppressive or oncogenic depending on the context. In this context, a recent study has shown that Notch signaling might also be pro-tumorigenic in SCLC (**Fig. 5**C). The authors showed in mouse models that endogenous activation of the Notch pathway resulted in a neuroendocrine to nonneuroendocrine fate switch is 10%–50% in tumor cells. These nonneuroendocrine Notch-active SCLC cells are slow growing, consistent with the tumor-suppressive role, but these cells are also relatively chemoresistant and provide trophic support to neuroendocrine tumor cells, consistent with a pro-tumorigenic role. These data suggest that SCLC tumors generate their own microenvironment via activation of Notch signaling in a subset of tumor cells. This switch was partially mediated by the RE1-silencing transcription factor (Rest). Interestingly, in the first genome-scale analyses of methylation changes in SCLC tumors, it has been found that methylated gene promoters are enriched in binding sites for the neurogenic transcription factors NEUROD1, heart and neural crest derivatives-expressed protein 1 (HAND1), zinc finger protein 423 (ZNF423), and REST, which the authors interpreted as being indicative of a defect in neuroendocrine differentiation.

Another group of genes frequently inactivated in SCLC are those implicated in transcriptional regulation, including the transcription factors SOX2 and the MYC family of proteins. *SOX2* is amplified in ~27% of SCLC cases and MYC genes are also mostly altered through copy number amplification (9% *MYCL1*, 4% *MYCN*, and 6% *MYC*) and fusion transcripts (RLF-MYCL1) (**Fig. 5**A). Also included in transcriptional regulation are the histone modifying enzymes CREBBP and EP300 altered by mutation and genomic rearrangements in 15% and 13% of SCLC cases, respectively (**Fig. 5**A). Alterations in these genes suggest a role for epigenetic regulators in SCLC. In line with this, a recent study reported specific overexpression of the histone methyl-transferase EZH2 in primary SCLCs. EZH2 plays a major role in SCLC via regulation of stem cells maintenance, apoptosis, cell proliferation, expression of ASCL1, and induction of chemoresistance. It might also be that both groups of transcriptional regulators interact in this disease since it has been recently reported that an aberrant ATP-dependent chromatin remodeling SWI/SNF complex–MYC network is essential for SCLC development. In normal conditions, MYC forms a heterodimer with its primary partner MAX to bind gene promoters and activate transcription. Romero and colleagues detected mutations in *MAX* in 6% of the SCLC tumors and cell lines they analyzed, and these mutations were mutually exclusive with amplifications in genes of the MYC family and with *BRG1* mutations. BRG1, the ATPase of the SWI/SNF complex and regulator of MAX, seems also to upregulate MYC targets, both events required for the activation of the neuroendocrine transcriptional programs.

Finally, recurrent somatic alterations in receptor kinases and members of the PI3K signaling (KIT, FGFR1, IRS2, PIK3CA, and PTEN) and regulators of the actin cytoskeleton (SLIT2, EPHA7, and ROBO1) have also been detected in SCLC.

Due to its tendency for early dissemination, two-thirds of SCLC are diagnosed with extensive-stage disease (ES-SCLC, with distant metastasis); however, the genomic comprehensive studies above described are enriched for SCLC with limited-stage disease since these are probably the cases suitable for surgical resection and therefore providing the necessary material for such studies. A recent study analyzing 50 ES-SCLC found lower frequency of *TP53* (86%) and *RB1* (58%) mutations in comparison with the above-mentioned studies. In addition, it has recently been found that *NFIB* is almost universally overexpressed in human metastatic high-grade neuroendocrine lung tumors. Similarly to *Mycl1*, *Ezh* is frequently amplified in SCLC mouse models based on the inactivation of *Rb1* and *Tp53*. In this models, Nfib promotes metastatic spread and its high levels are associated with expansive growth of a poorly differentiated and almost exclusively E-cadherin (CDH1)-negative invasive tumor cell population.

Expression Profiles

The "classic" SCLC subtype (75% of the cases) expresses the transcription factor ASCL1, which is required for the survival and growth of these cells. ASCL1 is a master regulator that induces neuronal and NE differentiation. It regulates the expression of *DLL3*, which encodes an inhibitor of the Notch pathway, and the expression of *REST*, which encodes an inhibitor of neuronal and NE differentiation. ASCL1 also drives the expression of many proto-oncogenes implicated in SCLC progression and cell survival, including *MYCL1*, *RET*, *SOX2*, *NFIB*, and *BCL2*. The so-called "variant" subtype is formed by SCLC tumors with high expression of NEUROD1, often in association with ASCL1. ASCL1 and NEUROD1 target different gene sets for NE function, being one of the NEUROD1 targets, the gene *MYC*. In a genetically engineered mouse model (GEMM), conditional Cre-mediated excision of the *Tp53* and *Rb1* genes in lung epithelial cells gave rise to lung tumors resembling the classic, but not to the variant, subtype. Ascl1, but not NeuroD1, would be required for tumor initiation in this model. The switch from ASCL1 to NEUROD1 expression

might be associated with a change from the classic to the variant form. Overexpression of Myc in a GEMM of SCLC promoted the development of SCLC tumors with high NeuroD1 and low Ascl1 expression. Finally, there is a third and minor SCLC subtype that contains those tumors on which neither ASCL1 nor NEUROD1 are expressed. The clinical implications of these three distinct SCLC groups are still unknown.

Microenvironment Including Immune Response

The immune cell microenvironment has not been extensively studied in SCLC. Presence of CD45+ immune cells within the SCLC stroma, so-called tumor infiltrating lymphocytes TILs, correlates with a better overall survival, independently of stage and performance status. A high number of intratumoral T cells and CD8 cells is associated with a low tumor size (<3 cm) and low tumor stage (stages I–II) and effector T cells are more abundant in LD-SCLC. In addition, $CD8^{(high)}CD57^{(+)}$T-cells in the peripheral blood stroma could be an independent predictor of response to chemoradiation therapy in ES-SCLC. As regulatory T cells (Tregs) downregulate immune response to tumor cells in SCLC, in the same way than in other tumor types, low effector-to-regulatory T-cell ratio is associated with a shorter survival. SCLC could also evade the immune response by reducing the transcription of HLA-A, B, and C and beta 2m genes more effectively than other lung cancer types.

High macrophage content correlates with a better prognosis. Those macrophages harbor a CD68, CD163, CD14 and CD47 receptor SIRPalpha expression in relation with an immunosuppressive M2 phenotype and SCLC tumor cells strongly express CD47, justifying the use of CD47 blockade agents to enhance SCLC phagocytosis.

PD-1 is another key immune checkpoint receptor expressed by activated T cells after binding to its ligand PD-L1 that mediates immunosuppression. PD-L1 expression has been demonstrated in nearly 5% of SCLC (and in 10% of LCNEC and in none of carcinoids) using E1L3N clone. In another study involving 74 SCLC, PD-L1 expression was observed in 19% of cases using the same clone and the same threshold. Interestingly, in both studies, PD-L1 expression was associated with significantly longer overall survival. Using SP142 and 28-8 clones, the percentage of positive cases was around 16% with a cut-off of 1%. Conversely, Schultheis et al. found no PD-L1 protein expression in tumor cells using E1L3N clone in 94 SCLC (pulmonary and extrapulmonary), but 48% of the cases exhibited PD-1 positive lymphocytes. Overall all those discrepancies seem mainly related to the antibody used and need to be further reevaluated with PD-L1 pharmDx assays.

Clinical Presentation, Staging and Grading

Symptoms reflect central location and loco-regional spread, as well as rapid tumor growth. While hemoptysis are rare, superior vena cava and vocal cord paralysis are common. However, clinical symptoms more often reflect disseminated disease. Brain metastases are frequent. The average age at diagnosis is 70. At imaging, SCLC appears as hilar or perihilar masses often with mediastinal lymphadenopathy and lobar atelectasis. Paraneoplastic syndromes are also a hallmark of SCLC. Most fall into endocrine or neurological classes, with the endocrine symptoms due to ectopic hormonal production by tumor cells and the neuronal symptoms largely due to the production of antineuronal antibodies. The most common endocrine syndromes include inappropriate antidiuretic hormone production and adrenocorticotropic hormone (ACTH)-associated Cushing syndrome.

The International Association for the Study of Lung Cancer (IASLC) recommends the recently published 8th edition of the TNM Classification for Lung cancer for SCLC staging. However, the 1957 classification system developed by the Veterans Affairs Lung Study Group is still the most relevant staging system clinically; this classification divides SCLC into limited-stage (LS) disease and extensive-stage (ES) disease, depending on whether or not the affected area can be included in the radiotherapy (RT) field. Unfortunately, only 20%–30% of patients are diagnosed with LS-SCLC. Even with treatment, prognosis remains poor, with a median survival of 16–22 months in LS-SCLC and only 10 months in ES-SCLC. The proportion of patients diagnosed with ES-SCLC has increased substantially in recent years due to the inclusion of positron-emission tomography computed tomography (PET-CT) and magnetic resonance imaging (MRI) in the routine practice setting. A brain magnetic resonance imaging scan will detect brain metastases in 10%–15% of newly diagnosed patients without neurologic symptoms. A systematic review of studies comparing FDG-PET imaging with conventional imaging procedures reported that 16% of patients with LS-SCLC by conventional imaging were up-staged to ES by FDG-PET imaging, whereas 11% of patients with ES-SCLC by conventional imaging were down-staged to LS.

Prognostic and Predictive Biomarkers

A number of multivariate analyses of adverse prognostic factors have been performed in SCLC. Poor outcome has been associated with poor performance status, extensive disease, elevated lactate dehydrogenase, high alkaline phosphatase, low sodium, low serum albumin, high aspartate aminotransferase and low bicarbonate; those factors have been included in the Manchester prognostic score. A potential novel prognostic factor might be the "CpG-island methylator phenotype" (CIMP). In a recent study on which SCLC samples were stratified according to CIMP status, patients with CIMP-positive tumors had a poorer prognosis than those with CIMP-negative disease, consistent with observations among other lung carcinoma epitypes.

SCLC is rarely diagnosed at early stages. However, these patients have considerably improved survival rates relative to late-stage patients, principally as the localized nature of the disease affords the widest range of treatment options. The routine use of FDG-PET and brain MRI has also led to a better selection of patients with LS-SCLC, associated with better outcome.

Unfortunately, predictive markers that might increase the number of SCLC patients diagnosed with limited-stage disease are widely unknown. In a study aiming at the characterization of the SCLC methylome, the authors found that among the hundreds of tumor-specifically methylated genes discovered, 73 gene targets were methylated in >77% of primary SCLC tumors, most of which have never been linked to aberrant methylation in tumors. These methylated targets might have potential for biomarker development for early detection. Another study has focused on the study of the potential use of cell-free DNA (cfDNA) for the early detection of SCLC and, although they were able to detect *TP53* mutations in the cfDNA of ~36% early-stage SCLC patients, they also detected mutations on this gene in 11% of the noncancer controls they analyzed, posing a serious specificity problem for the development of screening tests.

Treatment

For LS-SCLC, standard of care is concurrent chemoradiation, while for ES-SCLC chemotherapy alone is used; the most commonly recommended chemotherapy regimen is platinum-etoposide (PE), which has been proven to increase survival with less toxicity than other regimens that combine anthracyclines, vinca-alkaloids, methotrexate, and/or cyclophosphamide. SCLC shows chemosensitivity in the first-line setting, as response rate range from 70% to 80% with up to 50% complete responses. Many other systemic approaches have been assessed, but none have proven superior to PE, including combination of platin plus irinotecan or topotecan. Still the majority of patients die from recurrences, which are refractory to chemotherapy. Recurrent SCLC is divided into two categories: refractory/resistant (progression <3 months from completion of initial therapy) or relapsed/sensitive (progression >3 months). Rates of response to second-line therapy are substantially lower in patients with refractory/resistant disease. The reinitiation of the front-line chemotherapy regimen is proposed if the initial response duration is 6 months or more based on reported response rates of 50%–60%. The benefit of second-line chemotherapy in recurrent SCLC was evaluated in a randomized trial comparing oral topotecan with best supportive care. Although topotecan induced response in only 7% of patients, it did significantly improve overall survival.

As for thoracic radiotherapy, the results available so far have not yet answered the questions concerning optimum timing, schedule and doses. The randomized controlled study published by Turrisi et al. in 1999 is considered a landmark. A total of 471 patients were randomized to either 45 Gy in 5 weeks (25 daily sessions of 1.8 Gy) or 45 Gy in 3 weeks (1.5 Gy, twice daily, 30 fractions) beginning with the first of four platin and etoposide cycles. The 5-year OS in the hyper-fractionated group was 26% versus 16% in the conventional-treatment group ($P = 0.04$). The more recent CONVERT phase III trial compared the standard 45 Gy in 30 fractions (twice daily for 3 weeks) to 66 Gy in 33 fractions (once daily over 6.5 weeks) starting on day 22 of chemotherapy; no significant between-group differences were found in 1-, 2- or 3-year overall survival. After response to chemotherapy, the opportunity to deliver prophylactic cranial irradiation (PCI) is highly debated. The use of PCI in the treatment of LS-SCLC is mostly supported by the fact that approximately 50% of patients with SCLC develop brain metastases.

SCLC Developing From Adenocarcinoma

EGFR-mutant lung adenocarcinoma can trans-differentiate to SCLC, especially when resistance to tyrosine kinase inhibitors (TKIs) develops. This phenomenon has repeatedly been described in several case reports and small patient series, and may occur in other oncogene-driven adenocarcinoma subsets. This may also explain reports of *EGFR*-mutant SCLCs. In a pooled analysis of 39 of those cases, the median time from initial diagnosis of lung adenocarcinoma to the transformation to SCLC was 19 months (range 1–61 months). Median survival after SCLC diagnosis was 6 months. Male gender and smoking were associated with poor outcome. The management of SCLC developing from *EGFR*-mutant adenocarcinoma may rely on chemotherapy; meanwhile, SCLC retain the same *EGFR* mutation, and transformation may be associated with other mechanisms of resistance, such as T790M or C797S. SCLC-trans-differentiated tumors also harbored activating mutations in *PIK3CA*, inactivating mutations of *TP53*, and *RB1* loss that are common features associated with the SCLC phenotype.

Immunotherapy

Immune checkpoint inhibitors targeting PD-1 and CTLA-4 have been showing promise in SCLC. In a phase I/II trial, 216 patients with recurrent SCLC were treated with nivolumab alone ($n = 98$), or one of two combination regimens: nivolumab 3 mg/kg with ipilimumab 1 mg/kg every 3 weeks, or conversely, nivolumab 1 mg/kg with ipilimumab 3 mg/kg on the same schedule. In general, the toxicity spectra observed were similar to those reported in other studies of these agents in patients with cancer, with still some patients experiencing exacerbation of paraneoplastic neurological syndromes. Nivolumab alone was associated with a 10% response rate and a 32% disease-control rate, while the combination treatment cohorts had response rates of 19%–23% and disease-control rates of 36%–42%. The 1-year survival was 33% with nivolumab alone, and 35%–43% in the combination arms. While PD-L1 positivity is rare in SCLCs, and does not seem to correlate with benefit from PD-1 directed therapy, ancillary

analyses indicated that tumor mutation burden may represent a predictive biomarker in this setting: an elevated tumor mutational burden was associated with a 22 months median overall survival with nivolumab and ipilimumab.

Other available results with immunotherapy are reports with the use of pembrolizumab, in the second-line or even the maintenance setting. Of note, although most SCLC show low expression of PD-L1, a subset (1.9%) of human SCLC patient cases exhibits massive expression of PD-L1 caused by focal amplification of CD274. Such tumors may be particularly susceptible to immune checkpoint blockade.

DLL3 Targeting

Targeting of the Notch pathway in SCLC relies on inhibiting the Notch inhibitor DLL3, which is expressed as a neoantigen on the cell surface of SCLC cells. Rovalpituzumab tesirine (ROVA T) is a DLL3 targeted antibody–drug conjugate that, in a phase I study, was shown to have highly encouraging single-agent antitumor activity in DLL3 expressing SCLC. This trial enrolled a total of 74 patients with recurrent metastatic SCLC; among the patients with SCLC treated at active dose levels, an overall objective response rate of 18% was observed. DLL3 expression may represent a predictive biomarker as among all patients in this DLL3 high cohort (around two-thirds of patients with SCLC) the confirmed objective response rate was 38% (10 of 26 patients), the disease-control rate 88% (23 of 26 patients), and 1-year survival rate was 32%. Phase III trials are ongoing.

Additional Therapeutic Opportunities

In vitro targeted drug screening has revealed that SCLC with high MYC expression is vulnerable to Aurora kinase inhibition, which, combined with chemotherapy, strongly suppressed tumor progression and increased survival.

UV Ultraviolet radiation

Definition and Classification

Basal cell and squamous cell carcinoma are the two most common types of skin malignancies. They belong to keratinocytic tumors (also called keratinocyte tumors), one of the families of non-melanoma skin cancers (NMSCs).

Basal cell carcinomas (BCC) of the skin, or cutaneous basal cell carcinomas (ICD-O code: 8090/3; also called basal cell epithelioma and trichoblastic carcinoma), are a group of malignant tumors which arise from basal cells of the epidermis and pilosebaceous units and are histologically characterized by the presence of lobules, columns, bands or cords of basaloid ("germinative") cells surrounded by an outer palisade of cells. The associated stroma is loose and fibromucinous. There are several BCC subtypes. The most common of them is nodular BCC (ICD-O code: 8097/3) which occurs in approximately 60% of cases, followed by multifocal superficial BCC (8091/3; also called multicentral BCC; 30% of BCC cases) and infiltrating sclerosing BCC (8092/3; also called morpheic BCC or morpheaform BCC; 5%–10% of cases). The less common subtypes are cystic, linear, and micronodular BCC. A BCC variant which is frequently confused with SCC is basosquamous carcinoma (ICD-O code: 8094/3), also called mixed basal squamous carcinoma. It arises from basal cells but displays squamous differentiation with a more abundant cytoplasm and more marked keratinization than those of typical basal cell carcinomas, and has a more aggressive behavior and a higher metastatic capacity than other BCC types, thus resembling SCC. That is why it is often incorrectly referred to as a particular variant of squamous cell carcinoma.

Squamous cell carcinomas (SCC) of the skin, or cutaneous squamous cell carcinomas (ICD-O code: 8070/3) are malignant neoplasms of epidermal and mucous membrane keratinocytes characterized by variable degrees of squamous differentiation, with atypical, often pleomorphic squamous cells. SCCs are graded as well, moderately, or poorly differentiated. Well differentiated carcinomas are usually associated with keratin production and the presence of intercellular bridges between adjacent cells.

A particular form of SCC in situ is Bowen disease (ICD-O code: 8081/2; also called intraepidermal SCC, Bowen type). It is a distinct clinicopathological entity which arises from the skin or the mucocutaneous junction and is characterized by the presence of hyperkeratosis, parakeratosis, dyskeratosis, and acanthosis.

Presentation and Diagnosis

Keratinocytic tumors vary in their clinical presentation based on the type of lesion and the stage of development.

BCCs develop on hair-bearing skin, most commonly on radiation-exposed areas, with a majority occurring on the head and neck, followed by the trunk and extremities. Less frequent sites of involvement are penis and vulva. Nodular BCC arises predominantly on the head and neck as a well-circumscribed nodule with pearly or rolled borders and telangiectasias. Some lesions are pigmented and clinically indistinguishable from melanoma. Larger tumors may develop central necrosis and ulceration, forming the so-called rodent ulcer. Superficial BCC usually arises on the trunk, often as multiple lesions. It appears as red, scaly patches

 https://doi.org/10.1016/B978-0-12-801238-3.65320-5

with areas of brown or black pigmentation, which spread over the skin surface and may have areas of nodularity. Sclerosing BCCs usually affect the face. The tumors resemble scars and may have an ivory-colored, poorly delineated, indurated border. Histologically, the cancer cells are surrounded by a dense bed of fibrosis ("morphealike"). Despite excellent prognosis, BCC can produce substantial local destruction with disfigurement and may involve extensive areas of soft tissue, cartilage, and bone.

SCCs may arise on all cutaneous surfaces and mucous membranes but they most commonly develop in areas of direct exposure to the sun, such as the forehead or ears. The lesions present as shallow ulcers, often with a keratinous crust and elevated, indurated surrounds, or as plaques or nodules. Actinic damage to the surrounding skin is typical. Histologically, cutaneous squamous cell carcinomas are characterized by nests, sheets and strands of squamous epithelial cells which arise from the epidermis and extend into the dermis. Sixty percent of SCCs arise from actinic keratoses. In case of Bowen disease, the tumor most frequently develops on sun-exposed glabrous skin areas, particularly on the head, face and neck, but it may also arise in mucous membranes. It presents as an erythematous, scaly, keratotic patch or plaque, with frequent multiple contiguous lesions. Metastatic SCC most frequently involves the draining lymph nodes but in late stages distant organs may also be involved.

Patients presenting with suspicious skin lesions are offered a physical examination, with an emphasis on a complete skin examination. The latter is particularly important as individuals with skin cancer often have additional, concurrent lesions, either precancerous or cancerous, at other, usually sun-exposed sites. For the same reason, an interview with an emphasis on history of cancerous lesions should be conducted. All suspicious lesions are biopsied, including deep reticular dermis if the lesion is suspected to be more than a superficial process. This procedure allows to detect infiltrative histology which is present only at the deeper advancing margin of the tumor and may thus be missed by a superficial biopsy. In high-risk populations, clinical evaluation of suspected lesions is more difficult and so a low threshold of performing biopsies is necessary. If the lesion suggests SCC, examination of regional lymph nodes should additionally be performed. Imaging analyses should be conducted when extensive disease is suspected, such as bone involvement, perineural invasion or deep soft tissue involvement. Magnetic resonance imaging (MRI) with contrast is preferred over computed tomography (CT) in case of suspected perineural disease or deep soft tissue involvement.

Epidemiology ad Risk Factors

Burden

Non-melanoma skin cancers (NMSCs) are the most common type of malignancy but they account for less than 0.1% of cancer-related deaths. Among those, keratinocytic tumors are the most common skin neoplasms, accounting for approximately 90% of all skin malignancies. Basal cell and squamous cell carcinomas (BCCs and SCCs, respectively) are by far the most prevalent, with BCC being four to five times more frequent than SCC. In lower latitudes, the proportion of SCC is higher and some studies show that the overall SCC incidence is rising quicker than that of BCC. The exact incidence is not known as the data on these two tumor types are typically not reported to cancer registries. It is estimated that in the US alone 2 million new BCC cases and 2.5 million new SCC cases occurred in the year 2012. The BCC incidence rates are estimated to have been rising by 2% a year in the United States and 5% a year in Europe in recent decades. This increase may be partly due to increasing awareness among the general population and among physicians as well as to the fact that more surgical treatments are followed by a histopathological confirmation of the diagnosis. The highest BCC rates are reported in Australia where one in two inhabitants will be diagnosed with BCC by the age of 70.

Etiology and Risk Factors

The major risk factor for developing NMSC is exposure to ultraviolet radiation (UV), in particular in childhood and adolescence, with 90% of BCC cases being attributable to UV exposure. However, the skin's ability to tan modulates the UV-induced risk. Also indoor tanning has been shown to be associated with an increased risk of BCC. This can also explain a higher prevalence of BCC in young women compared to men. In the same line, UV-based therapies have been associated with a moderately increased risk of BCC. Fair skin, red or blond hair, and bright eyes are independent risk factors for both BCC and SCC as they increase susceptibility to UV-induced damage. Not surprisingly, BCC incidence is inversely correlated with the latitude combined with the pigment status of the population. Hereditary conditions resulting in an increased sensitivity to sunlight: xeroderma pigmentosum (impaired DNA damage repair) and oculocutaneous albinism (generalized decrease in pigmentation), predispose to UV-induced skin cancers from early childhood.

Individuals who were exposed to ionizing radiation (uranium miners, radiation-treated patients, cancer survivors), in particular those exposed at young age, have a higher risk of NMSC. The risk of radiation-induced BCC seems to also increase with lighter pigmentation.

Ingestion of inorganic arsenic and its arsenic compounds predisposes to the development of Bowen disease, multiple BCC, and SCC. From among other putative environmental risk factors, some studies have pointed out to smoking (and/or benzo(a)pyrene exposure) and alcohol consumption but the evidence is not conclusive.

Treatment with psoralens (used for psoriasis) combined with phototherapy is also associated with an increased risk of BCC. The same association has been suggested for other photosensitizing drugs but the evidence is still limited.

Table 1 Risk factors for basal cell and squamous cell carcinoma of the skin[a]

Environmental factors and medical conditions
Exposure to ultraviolet radiation (UVA and UVB), including indoor tanning and UV therapies (BCC)
Exposure to ionizing radiation
Inorganic arsenic exposure
Chronic immunosuppression and chronic use of glucocorticoids (SCC)
Psoralens combined with phototherapy (BCC)
Scars and chronic wounds (SCC)
Infection with some HPV types (SCC; conflicting reports for BCC)
Lifestyle and phenotypic factors
Living at low latitude
Light pigmentation
Age
Male gender
Hereditary conditions
Xeroderma pigmentosum
Oculocutaneous albinism
Gorlin syndrome (BCC)

BCC, basal cell carcinoma of the skin; *HPV*, human papillomavirus; *SCC*, squamous cell carcinoma of the skin.
[a]Association shown for both cancer types unless indicated otherwise.

Chronic immunosuppression, in particular in the context of organ transplantation, lymphoma, chronic lymphocytic leukemia and HIV, and chronic use of glucocorticoids, is associated with the risk of developing SCC. Organ transplant recipients have a 60- to 250-fold higher risk of developing the disease than the general population.

SCC is also known to develop in association with scars and chronic wounds (e.g., Marjolin's ulcer) as well as with thermal burns and chronic draining osteomyelitis. It is the most common malignancy arising in chronic ulcers.

Moreover, infections with human papillomaviruses (HPV), in particular type 5, 8, 16, and 18, have been associated with SCC. HPV type 5 and 8 cause epidermodysplasia verruciformis, which may lead to the development of SCC in situ and invasive SCC, synergistically with other carcinogens, such as sunlight. Sexually transmitted HPV infections increase the risk SCC of the genitals and the anal regions.

Finally, Gorlin syndrome (basal cell nevus syndrome), characterized by germline mutations in the *PTCH* gene, is associated with multiple BCC lesions over the face, arms, and trunk, which appear during the late teenage years. **Table 1** lists all confirmed risk factors for developing BCC and SCC.

Pathology and Genetics

As NMSC carcinogenesis is associated with exposure to radiation and resulting DNA damage, genetic alterations in pathways involved in DNA damage repair and in the control of cell cycle and apoptosis are the most prevalent events. Somatic mutations are frequent, with a mutational signature characteristic for UV-induced cancers (tandem CC to TT transitions) affecting multiple oncogenes, tumor-suppressor genes and important housekeeping genes, which results in deregulation of keratinocyte cell cycle and substantially contributes to carcinogenesis.

Alterations in the sonic hedgehog signaling pathway seem to play a pivotal role in the pathogenesis of BCC and are found in up to 90% of cases (**Table 2**). Mutations in the *PTCH1* (patched 1) encoding the sonic hedgehog transmembrane receptor are the underlying cause of the nevoid BCC syndrome and are also found in 30%–90% of sporadic BCC. Loss of heterozygosity on chromosome 9q22, encompassing the *PTCH1* gene, is the most frequent genetic alteration in sporadic BCC. About half of *PTCH1* mutations are C to T and tandem CC to TT transitions. However, the UV radiation origin of *PTCH1* mutations is controversial since other factors, such as oxidative stress, have been implicated in the mutagenesis of this gene. The second frequently altered gene of the hedgehog pathway is *SMO* which is activated by gain-of-function mutations. Also *PTCH2* and *SUFU* have been reported to be mutated in BCCs, however in a low proportion.

Specific UV-induced mutation in *TP53* are also common events in BCC pathogenesis, with a high prevalence of characteristic UV-induced CC to TT tandem mutations. Mutations in the *TP53* gene have been reported in about half of sporadic BCC cases, whereas LOH has been described with a much lower frequency in BCC than in other tumors. Hot spots occurring specifically in BCC have been found at codons 177, 196, and 245. Codon 177 seems to be specific for BCC since it is not frequently mutated in other malignancies. In a mouse model investigating BCC pathogenesis, loss of *TP53* has been shown to upregulate the activity of the hedgehog pathway by increasing *SMO* expression and rendering the mouse interfollicular keratinocytes susceptible to develop X-ray induced BCCs.

Recent genomic analyses have identified new driver genes for BCC, suggesting the existence of a more complex genetic network of cancer-associated genes than it had been hypothesized. It is noteworthy that there are discrepancies regarding the list of driver

Table 2 Gene loci that are most frequently altered in basal cell (BCC) and squamous cell skin carcinoma (SCC)

Pathway	*Gene (locus)*	*Alteration type*	*Prevalence*
p53 signaling (cell-cycle control)	*TP53* (17p13.1)	Mostly point mutations (high prevalence of CC to TT transitions in BCC)	About half of BCC cases and up to 85% of SCC cases
	CDKN2A (9p21.3)	Point mutations and deletions	About 60% of SCC cases
Telomere maintenance	*TERT* (5p15.33)	Promoter alterations and point mutations	Found in all skin cancers, including BCC (up to 40%) and SCC (20%–40%)
Translation fidelity	*DPH3-OXNAD1* (3p25.1)	Promoter alterations	Common in all skin cancers, including BCC
Sonic hedgehog signaling	*PTCH1* (9q22.32)	Inactivating point mutations, loss of heterozygosity (LOH), and copy-neutral LOH (due to uniparental disomy)	Point mutations in 10%–75% of BCCs, LOH in 40%–70% of BCCs; germline mutations in nevoid BCC syndrome
	SMO (7q32.1)	Gain-of-function mutations	BCC
Hippo–YAP pathway (organ size control)	*LATS1* (6q25.1)	Inactivating mutations	BCC
	PTPN14 (1q32-q41)	Inactivating mutations	BCC
Histone modifications	*MLL2* (*KMT2D*; 12q13.12)	Point mutations	27%–50% of SCC cases
NOTCH signaling	*NOTCH1* (9q34.3)	Point mutations	43%–57% of SCCs
Low density lipoprotein (LDL) receptors	*LRP1B* (2q21.2)	Point mutations	50% of BCC and 20%–65% of SCC cases

genes identified across different studies, probably reflecting the clinico-pathological heterogeneity of analyzed tumors. Inactivating mutations in two key components of the Hippo-YAP pathway: *LATS1* and *PTPN14*, have been identified in BCC. In addition, three candidate genes known to be associated with melanoma development: MYCN, PPP6C, and STK19, have emerged as putative new BCC driver genes. Finally, some studies report that somatic, non-coding mutations within promoter regions of *TERT* and *DPH3-OXNAD1* genes are common in all types of skin cancer, including BCC (Table 2).

Only few studies have analyzed comprehensive genetic alteration profiles in cutaneous SCC. In a recent study by the Cancer Genome Atlas Research Network, which analyzed 122 tumors, the most frequently altered gene was *TP53*, followed by *CDKN2A*, *NOTCH1*, *MLL2*, *LRP1B*, and *TERT* (Table 2). *TP53*, *NOTCH1*, and *TERT* alterations have been systematically found in various studies, albeit with variable prevalence. Overall, the major difference between SCC and BCC appears to be a less frequent involvement of genes of the hedgehog and Hippo pathways in SCC carcinogenesis.

Management and Therapy

Most patients with a primary cutaneous NMSC have an excellent prognosis. BCCs are usually indolent tumors. However, if untreated, they may invade subcutaneous fat, skeletal muscle and bone. Still, distant metastases are extremely rare, with the exception of basosquamous tumors which are usually more aggressive and may produce regional or widespread metastases. SCCs may be more aggressive but most of them just locally.

The primary goal of both BCC and SCC treatment is the complete removal of the tumor while preserving the maximum of skin function and cosmesis. The therapeutic approach is customized to the particular factors, and the individual needs and preferences of the patient.

Surgery is often the most effective mean to achieve cure. Mohs micrographic surgery (MMS) with intraoperative frozen section assessment has the highest primary tumor cure rate (99% for BCC and 96% for SCC) and excellent cosmetic effects. As it allows to assess 100% of the surgical margins, it is also the recommended option for high-risk tumors. Standard surgical excision with postoperative margin assessment is also an option. However, intraoperative assessment of all tissue margins is key to complete curative removal of high-risk tumors. Curettage (scraping the tumor tissue with a curette down to a layer of normal dermis) and electrodessication may be effective for low-risk tumors with free caveats appearing in hairless areas. However, some studies suggest that it may be associated with higher recurrence rates than surgery. In order to reduce that risk, a biopsy taken during curettage should be evaluated. Moreover, surgical excision should follow if the subcutaneous layer is reached.

Cosmesis and patient's preferences may lead to choosing radiotherapy (RT) as primary and definitive treatment of localized BCC or SCC without lymph node involvement. RT is also recommended as an adjuvant therapy following surgery in patients with high-risk tumors with the large nerve and extensive perineural involvement, and in all patients in whom clear surgical margins could not be achieved. Intensity-modulated RT (IMRT) has been gaining popularity is this respect. Given that exposure to radiation is one of the risk factors for developing NMSCs, potential benefits and risks of using RT need to be carefully weighed up. Generally, RT is not recommended in patients below 40 years of age or with tumors recurring after previous RT, and in individuals with inherited syndromes that increase skin's sensitivity to radiation, like xeroderma pigmentosum.

SCC occasionally spreads to regional lymph nodes. In case of enlarged lymph nodes, fine-needle aspiration (FNA) or biopsy should be performed. If lymph node involvement is confirmed, elective lymph node dissection follows. Sentinel lymph node biopsy has been used to try to identify SCC patients likely to benefit from completion lymph node dissection or adjuvant RT. However, the results are conflicting and also the criteria of selecting patients for this procedure are not clear.

In patients with low-risk superficial tumors in whom surgery and radiotherapy are contraindicated or simply not preferred, topical therapies with 5-fluorouracil or imiquimod, photodynamic therapy, or vigorous cryotherapy using liquid nitrogen may be considered. However, the cure rates may be lower than those achieved with surgery.

Systemic treatment is indicated as an adjuvant therapy—in combination with RT or alone—for BCC patients after surgery without clear surgical margins. In particular, two FDA-approved inhibitors of the sonic hedgehog pathway: vismodegib and sonidegib, give promising results in the treatment of locally advanced BCC. Using these molecular therapeutics is also associated with reduced recurrence rates in metastatic BCC. Of note, vismodegib has also been tested as a BCC treatment and prophylaxis in patients with nevoid BCC syndrome, with promising results. However, a key limitation of using hedgehog inhibitors is that advanced BCC may become resistant to these treatments, mainly due to de novo mutations in the gene encoding the drug target, *SMO*. Other hedgehog pathway inhibitors are currently under clinical trials testing whether they would give higher and more durable response rates. A phase II clinical trial evaluating the efficacy of combining a hedgehog pathway inhibitor (vismodegib) with immunotherapy (pembrolizumab, anti-PDL1) for treatment of metastatic or unresectable BCC is currently under way.

Regional SCC has been shown to respond to systemic cytotoxic therapies and to inhibitors of the epidermal growth factor receptor (EGFR), most commonly cetuximab, in several studies. However, it remains unclear whether these treatments provide any additional clinical benefit when used postoperatively with RT. Due to low metastasis rates, experience with systemic treatment of metastatic disease is very limited. Metastatic SCC patients have been shown to respond to a combination of cytotoxic (cisplatin-based) and EGFR inhibitor therapy, and this remains the most common approach.

About 40% of NMSC patients will develop another NMSC within 5 years. These individuals are also at a higher risk of developing melanoma. Therefore, the success of secondary prevention depends on a regular follow-up and patient education in order to allow for early detection and treatment of pre-cancerous lesions and early-stage cancers. Actinic keratoses (precancerous lesions for SCC) may be treated with cryosurgery, surgery, photodynamic therapy (PDT), or topical treatments, such as 5-fluorouracil or imiquimod. Using nicotinamide may be effective in reducing the risk of developing BCC, whereas oral retinol and retinoids reduce the incidence of SCC in high-risk individuals, such as transplant recipients, psoriasis and xeroderma pigmentosum patients, and patients with a history of multiple lesions and/or extensive diffuse actinic keratosis.

Symptom Control

Vithusha Ganesh, Leila Malek, Carlo DeAngelis, and Edward Chow, Odette Cancer Centre, Sunnybrook Health Sciences Centre, Toronto, ON, Canada; and University of Toronto, Toronto, ON, Canada

Glossary

Activities of daily living Activities in self-care done routinely without needing assistance, including eating, bathing, toileting, dressing, walking or transferring.

Patient-reported outcomes A report directly from the patient of their own health condition, including symptoms, physical and social function, mental health and wellbeing.

Patient-reported outcome measurements (PROMs) Instruments used in clinical and research settings for the measurement of patient-reported outcomes.

Prophylactic Treatment given to prevent symptom occurrence.

Quality of life A multidimensional concept that encompasses an individual's sense of physical, emotional, and social wellbeing and ability to carry out various activities.

Rescue Fast-acting treatment given as needed for immediate symptom relief.

Symptom cluster A group of two or more concurrent, interrelated symptoms.

Introduction

On the eve of its 50th anniversary in 2014, the American Society of Clinical Oncology conducted a poll wherein healthcare providers and patients across the country voted on what they perceived to be the top medical advancements in modern oncology. Alongside pivotal discoveries in prevention and chemotherapy, antiemetics were voted among the top five for their role in improving quality of life in patients undergoing treatment. With a range of more effective and convenient therapies available, patients may continue to lead active lives outside of, and following their treatment. In recognition of this, there has been increasing attention on identification and management of symptoms, and on patient-reported outcomes in quality of life.

A symptom is defined as a subjective experience reflecting changes in the biopsychosocial functioning, sensations, or cognition of an individual. Symptoms are multidimensional and are described using a patient's perception of prevalence, intensity and distress. Patients with advanced cancer have been reported to experience an average of 11 concurrent symptoms, either due to the disease itself or as a consequence of anticancer or supportive therapies.

Symptoms are often multifactorial and interrelated, posing challenges in measurement and elucidation of underlying pathophysiology. Patient-reported outcomes or "self-report" are considered primary sources of information, as opposed to caregiver- or physician-reported symptoms. Often generated through extensive literature reviews and interviews with patients and health care professionals, several questionnaires have been validated for measurement of patient-reported outcomes such as symptoms, function, and quality of life. In addition to assessment of traditional biomedical outcomes, patient-reported outcomes are widely measured and reported on in oncological clinical trials, and are also clinically significant for their value in prognostication.

Despite advances in symptom research and control, a large proportion of cancer patients continue to report inadequate treatment. Contributing to this issue is underestimation of symptom intensity by healthcare providers. In addition to being a major detriment in patients' function, wellness and quality of life, symptom distress may also lead to dose reductions or termination of treatment, or negatively affect post-treatment rehabilitation. Basic principles in symptom management in oncology include active symptom evaluation and treatment at each encounter, starting at diagnosis through to survivorship or end-of-life care.

This article will outline some of the most prevalent symptoms in this patient population, current approaches in symptom management, and patient-reported outcome measures available for clinicians and investigators.

Common Symptoms in Oncology

Pain

The International Association for the Study of Pain defines pain as an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage. A systematic review conducted by van den Beuken-van Everdingen et al. of 40 years of literature reported prevalence of pain at 33% in patients following curative treatment and at 64% in patients with advanced disease. Persistent pain can significantly compromise patient function, wellbeing and overall quality of life. Almost 70% of patients who experience pain at least weekly reported pain-related difficulties in activities of daily living on the European Pain in Cancer Survey.

There are several sources of pain throughout the course of the disease and associated treatments. *Malignancy-related pain* can arise from the primary tumor, metastases, or complications such as spinal cord compression, pathologic fracture or malignant bowel obstruction. *Iatrogenic pain* follows diagnostic or surgical procedures (e.g., mastectomies and axillary resection, thoracotomy), or as a side effect of chemotherapy, hormone therapy, radiation therapy or pharmaceuticals (e.g., osteonecrosis of the jaw from bisphosphonates). Patients undergoing chemotherapy may report specific forms of pain, such as infusion-related pain syndrome, taxane-induced arthralgia and myalgia, peripheral neuropathy, and palmar plantar erythrodysesthesia. Similarly, patients undergoing radiation to the bone may report "pain flare" or transient worsening of bone pain at the site of irradiation.

Nociceptive pain is caused by tissue damage in the body, and can be somatic (e.g., skin, bone, muscle), or visceral (internal organs). *Neuropathic pain* is caused by dysfunctional or injured nervous tissue. *Psychogenic pain* is related to psychological factors such as anxiety and depression. Pain can be further classified by duration, as acute (several weeks to months) or chronic (>6 months). *Breakthrough pain* is a transient increase of pain with rapid onset arising at moderate or severe intensity from background pain.

Pain can be managed with a variety of non-pharmaceutical and pharmaceutical methods depending on its pathophysiology. The World Health Organization first presented the analgesic ladder in 1986 as a framework for management of cancer-related pain. The analgesic ladder is three-step, with the first offering non-opioids such as acetaminophen or nonsteroidal antiinflammatory drugs (NSAIDs) with or without adjuvants. With persistent, moderate or severe pain, the second step suggests use of a weak opioid (e.g., codeine) with or without non-opioids or adjuvants, and the last step involves substitution with a strong opioid (e.g., morphine, oxycodone). Since its publication, several groups such as the National Comprehensive Cancer Network (NCCN) and European Society for Medical Oncology have composed guidelines that are available to clinicians for assessment and management of the symptom.

Adjuvant medications which can be used with non-opioids and opioids for added relief include steroids, antidepressants, anticonvulsants, and topical anesthetics. At present, there is insufficient evidence for the support of cannabinoids as a first or second line therapy. Its action on endocannabinoid receptors may make it effective in treating cancer-related pain; however, this requires more investigation.

In the management of neuropathic pain, which is considered insensitive to opioids, recommended treatments include antidepressants (e.g., tricyclic antidepressants, dual serotonin-norepinephrine reuptake inhibitors), and anticonvulsants (e.g., gabapentin, pregabalin). The American Society of Clinical Oncology provides a moderate recommendation for the use of duloxetine in chemotherapy-induced peripheral neuropathy after positive results from a phase III trial.

It is estimated that 10% of patients will experience insufficient pain relief despite treatment in adherence to the World Health Organization analgesic ladder principles. Some alternatives include anesthetic interventions such as nerve blocks, epidural and intrathecal infusions, and neurosurgical procedures (e.g., cordotomy). Patients with life expectancies exceeding 3 months may benefit from the mobility and convenience of implanted intrathecal drug delivery (ITDD) pumps. Surgical procedures may relieve localized pain through resection of tumors. Patients with bone pain from metastases may benefit from external beam radiation, surgical stabilization or procedures such as vertebroplasty which will be revisited later in this article. Although the evidence for complementary treatment of cancer-related pain remains weak, patients may also undergo therapies such as massage, acupuncture, transcutaneous electrical nerve stimulation or hypnotherapy. The NCCN recommends use of acupuncture as part of integrative interventions, delivered as needed with pharmacologic interventions.

Nausea and Vomiting

Nausea is a sensation in the back of the throat, or a feeling of sickness or discomfort in the stomach, which may or may not lead to vomiting, the expulsion of gastric contents. There are several emetogenic pathways that may be impacted, depending on the cause(s). Structures for coordinating nausea and vomiting include the vomiting center and the chemoreceptor trigger zone in the medulla oblongata.

Patients with advanced disease may experience multifactorial nausea, and six common causes identified by Stephenson and Davies include:

1. *Chemical:* Triggered by drugs, chemotherapy, metabolic issues (e.g., renal failure, liver failure, hypercalcemia, hyponatremia, ketoacidosis), and toxins (e.g., ischemic bowel, tumor products, infection).
2. *Impaired gastric emptying:* Triggered by drugs, tumor ascites, hepatomegaly, autonomic dysfunction, tumor infiltration.
3. *Visceral/serosal:* Triggered by bowel obstruction, severe constipation or fecal impaction, liver capsule stretch, ureteric distention, mesenteric metastases, difficult expectoration or pharyngeal stimulation.
4. *Cranial:* Triggered by raised intracranial pressure, meningeal infiltration, radiotherapy.
5. *Vestibular:* Triggered by drugs, motion sickness, tumor in the base of the skull.
6. *Cortical:* Triggered by anxiety or pain.

Prior to the introduction of antiemetics to clinical practice, patients undergoing chemotherapy were often debilitated by chemotherapy-induced nausea and vomiting (CINV). Without prophylaxis, it is estimated that up to 80% of patients are at risk of experiencing the symptom. Chemotherapy-induced nausea can be classified as: *acute*, occurring within the first 24 h of initiation of therapy; *delayed*, occurring within 2–5 days following therapy; *breakthrough*, occurring despite prophylactic treatment; *anticipatory*, occurring before initiation of therapy as a conditioned response from previous experience; and *refractory*, occurring in subsequent

cycles of therapy. Patients who are female, <50 years old, and have a history of chronic heavy alcohol abuse or motion sickness are at a higher risk of developing CINV. There are several different signaling mechanisms involved in CINV, with the main three neurotransmitters being serotonin or 5-hydroxytryptoamine (5-HT_3), substance P, and dopamine with bind to 5-HT_3 receptors, neurokinin-1 (NK_1) receptors and dopamine receptors respectively. Damage of the enterochromaffin cells in the gastrointestinal mucosa cause the release of 5-HT_3 by these cells. Substance P and dopamine act in auxiliary capacities to evoke the CINV response.

Oral and intravenous chemotherapeutic agents are differentiated as highly ($>90\%$ risk), moderately ($>30\%$–90% risk), low (10%–30% risk), and minimally ($<10\%$) emetic. Several organizations have provided antiemetic guidelines for the management of CINV, namely using one or a combination of 5-HT_3 receptor antagonists (RAs) (e.g., palonosetron, ondansetron, granisetron), NK_1 RAs (e.g., aprepitant, rolapitant, netupitant), dopamine RAs (e.g., metoclopromide) and dexamethasone. As a function of their pharmacological profile and mechanism of action, it is understood that different antiemetic classes offer protection in acute versus delayed phases of chemotherapy. Dual action medications such as NEPA are thought to provide coverage in both acute (through 5-HT_3 RA palonosetron) and delayed (through NK_1 RA netupitant) phases.

Based on site of irradiation, radiotherapy is differentiated into the following levels of risk: high ($>90\%$), moderate ($>30\%$–90%), low (10%–30%), and minimal ($<10\%$). Several organizations have compiled guidelines in the treatment of RINV.

The Multinational Association for Supportive Care in Cancer, European Society for Medical Oncology, and the National Comprehensive Cancer Network recommend the following regimens for RINV:

- High (total body irradiation): prophylaxis with a 5-HT_3 RA and dexamethasone
- Moderate (upper abdomen, craniospinal): prophylaxis with a 5-HT_3 RA with optional dexamethasone
- Low (cranium): prophylaxis or rescue with dexamethasone
- Low (head, neck, thorax, pelvis): prophylaxis or rescue with dexamethasone, a dopamine RA or 5-HT_3 RA
- Minimal (extremities, breast): rescue with dexamethasone, a dopamine RA, or 5-HT_3 RA

In addition to chemotherapy and radiotherapy, opioid analgesics are another chemical trigger of nausea and vomiting. Opioid rotation and route switching are recommended in patients who experience nausea and/or vomiting as a consequence of the analgesic. No recommendations have been made about specific antiemetics in the management of this side effect.

There are several non-chemical causes of nausea and vomiting that can be corrected. Nausea and vomiting due to hypercalcemia may subside with bisphosphonates. Cancer-related hyponatremia may be precipitated by cancer treatments, or the syndrome of inappropriate antidiuretic hormone (SIADH) which is frequently observed in patients with small-cell lung cancer. Tumor-related SIADH may resolve with treatment of the malignancy. Otherwise, fluid restriction or pharmacologic treatment with vasopressin antagonists can be delivered. Patients who experience nausea or vomiting as a consequence of delayed gastric emptying may benefit from domperidone or metoclopramide. Nausea or vomiting due to vestibular causes may be relieved with agents such as cyclizine or levomepromazine.

Non-pharmacologic aspects of treatment include patient and caregiver education about the symptom, consultations on appropriate dietary or nutritional advice, environmental modification (e.g., elimination of strong smells), and counselling on oral hygiene.

Fatigue

Cancer-related fatigue, with feelings of tiredness, weakness and lack of energy, is characteristic in its lack of relief with rest and sleep, and disproportionality with the patient's level of exertion. This type of fatigue is distressing in its impairment of usual functioning. Approximately 40% of patients report the symptom at diagnosis, and its prevalence increases to 80%–90% during chemotherapy and radiotherapy. It persists chronically in more than a third of patients following completion of treatment.

Despite the universality of this symptom in patients with cancer, there is no effective treatment for fatigue, due largely in part to the unclear pathophysiology of the symptom. Several mechanisms for cancer-related fatigue have been proposed, including activation of the immune system by the disease or treatment leading to a release of pro-inflammatory cytokines and subsequent peripheral inflammation. Downstream effects of immune cell activation and release of pro-inflammatory cytokines include impairment of endocrine function, function of the hypothalamic–pituitary axis and mitochondrial activity in the peripheral and central nervous system.

In the National Comprehensive Cancer Network (NCCN) guidelines for management of cancer-related fatigue, Berger et al. advocate for a focused history and physical examination in patients reporting moderate-to-severe levels (≥ 4 out of 10). Such an assessment would include an evaluation of physical, emotional and cognitive symptoms, as well as social support. Other contributing factors that should be assessed include pain, emotional distress, sleep disturbance, poor sleep hygiene, anemia, nutrition, activity level, medication side effects, alcohol/substance abuse and co-morbidities.

In patients undergoing treatment, Berger et al. recommend education and counseling on strategies. Purposeful management of personal energy resources to prevent depletion, or "energy conservation," helps to maintain realistic expectations. Habits and practices conducive to sleep, or "sleep hygiene" can be improved by sleeping in a dark room, reducing stress (e.g., yoga, reading, listening to music), limiting electronic use and limiting naps in the daytime.

Specific and manageable causes of fatigue can include infection, fluid and electrolyte imbalances, and cardiac dysfunction. If cause(s) of fatigue remain unidentified, the NCCN recommends appropriate pharmacological and nonpharmacological treatment.

Although the evidence of effectiveness is limited, several organizations suggest use of non-pharmacologic interventions such as physical activity during and after treatment, physical-based therapies and complementary therapies (e.g., acupuncture, massage therapy, yoga, and muscle relaxation), psychosocial interventions (e.g., cognitive behavioral therapy), sleep therapy and nutrition consultation. In patients who are able to engage in physical activity, at least 30 min of moderate intensity exercise on at least 5 days of the week, or at least 20 min of vigorous exercise on at least 3 days of the week is recommended. There is sufficient evidence for psychosocial or educational interventions wherein patients are equipped with information on the symptom, self-care, coping techniques and activity management. Additionally, group psycho-education related to self-management of fatigue in patients and survivors may allow for positive peer-enforcement, and the opportunity to share similar experiences. There is also sufficient evidence for use of cognitive behavioral therapy facilitated by fatigue clinics. The effectiveness of pharmacologic treatment of fatigue (e.g., methylphenidate) in this patient population is limited.

Although its effectiveness in treating cancer-related fatigue requires more investigation, use of modafinil benefited patients with severe baseline fatigue undergoing chemotherapy in a randomized controlled trial. Short-term (up to 14 days) use of glucocorticoids may improve fatigue in patients with terminal disease near the end of their lives.

Dyspnea

Dyspnea is defined by shortness of breath or difficulty breathing. Patients with dyspnea may report physical tiredness from expending effort on breathing, and tightness in the chest. The inability to breath and the feeling of suffocating or choking can be frightening for patients. Over 60% of patients with cancer report dyspnea in palliative care.

There are several possible specific underlying causes of dyspnea, including issues in the respiratory system (e.g., airway obstruction, pleural effusion), cardiovascular system (e.g., atrial fibrillation, congestive heart failure, superior vena cava obstruction), anemia or severe ascites. The sensation of hypercapnia by the medullary chemoreceptors, and hypoxemia by carotid and aortic body chemoreceptors can work on the respiratory centre to cause dyspnea. However, the majority of patients with dyspnea are not hypoxemic. Another hypothesized mechanism is the dissociation between the brain's desired respiration and the sensory information it receives.

The symptom can exist continuously in the background for prolonged periods of time, and/or can arise acutely with high intensity in durations typically <20 min, as episodic dyspnea or breathlessness. Episodic dyspnea can be especially distressing for patients and caregivers, impairing quality of life through anxiety.

Dyspnea is often undertreated, compared to other symptoms of advanced cancer such as pain or nausea. The European Society for Medical Oncology advocates that non-pharmacological interventions be offered first if possible, and these include proper positioning, breathing exercises, and teaching of techniques (e.g., cooling the face). Education about the symptom, management, and supportive measures can help to reduce accompanying anxiety. Oxygen supplementation may provide relief in patients with hypoxemia, or those who have comorbid chronic obstructive pulmonary disease. The Supportive Care Guidelines Group of the Cancer Care Ontario Program in Evidence-Based Care conducted a systematic review of pharmacological therapies: opioids, benzodiazepines, phenothiazines, and systemic corticosteroids. Controlled trials using opioids produced contradictory results, however overall, favored a benefit in dyspnea and exercise tolerance. The action of opioids on opioid receptors in the cardio-respiratory system and central nervous system are hypothesized to reduce dyspnea. There is less controlled trial evidence to support the use of non-opioid pharmacological therapies, however the group recommended use of phenothiazine or promethazine as an alternative in the event systemic opioids could not be used. Although several benzodiazepines (e.g., lorazepam, midazolam) are used in this cancer population in an anxiolytic capacity, they have been considered to reduce the intensity of the symptom through muscle relaxation. The review found no evidence to support the effectiveness of benzodiazepines on dyspnea. Bronchodilators, mast cell stabilizers, leukotriene inhibitors and/or corticosteroids can be used in patients with bronchospasms.

Since the publication of this review, a few studies have been conducted using similar treatments for dyspnea in patients with cancer. A randomized controlled trial of 20 patients with cancer observed significant improvements in breakthrough dyspnea with prophylactic fentanyl. Rubiales et al. reported patients pre-medicated with subcutaneous fentanyl had significantly improved scores in dyspnea at the end of a 6 minute walk test. In another randomized controlled trial of 41 patients, dexamethasone was administered at 8 mg twice daily for 4 days then 4 mg twice daily for 3 days. Although there were was no statistical significant between-arm difference, those in the treatment arm demonstrated a significant reduction in dyspnea by day 4. This pilot study suggests improvement in dyspnea, however the findings require further investigation.

Constipation and Diarrhea

Treatment or disease-induced gastrointestinal complications include diarrhea or constipation, which can be described in terms of stool bulk/water content, as well as frequency or difficulty of stool passage. Diarrhea is often described as passing more than three watery stools in a 24 h period. Under the Rome III Diagnostic Criteria for functional constipation, there must be at least of two of the following criteria in at least 25% of defecations: straining; lumpy or hard stools; sensation of incomplete evacuation; sensation of anorectal obstruction; requirement of manual maneuvers; or fewer than three defecations per week. In addition, there must be insufficient criteria for irritable bowel syndrome, and a lack of loose stools without laxatives. It is recommended that clinicians consider the patient's perceptions of the symptoms as well gather a history of bowel patterns, dietary changes and medications.

Constipation can be caused or influenced by medications (e.g., chemotherapy, opioids, antiemetics, excessive use of laxatives/enemas), reduced food or fluid intake, neuromuscular disorders of bowel innervation, reduced mobility, metabolic disorders (e.g., hypercalcemia), depression, inability to increase intra-abdominal pressure, muscular atony, environmental factors (e.g., excess heat, bathroom inaccessibility due to disability) and bowel obstruction. It can be accompanied by nausea and/or abdominal pain.

Patients can be encouraged to integrate natural laxatives into their diet, and increase dietary fiber and fluid intake where possible. Bulk producers (e.g., methylcellulose, psyllium) are natural or semisynthetic polysaccharide and cellulose. Osmotic laxatives (e.g., magnesium sulfate, polyethylene glycol) attract water to the intestinal lumen; stimulant laxatives (e.g., Senekot) directly increase motor activity of the bowels; and lubricant laxatives (e.g., mineral oil) soften stool by lubricating the intestinal mucosa. Physical activity, appropriate to the patient's performance status and health status, is also recommended.

The MD Anderson Cancer Center practice algorithm for cancer pain recommends starting patients on a laxative bowel regimen (e.g., stimulant laxative plus stool softener) and providing education on bowel management upon initiation of opioids. The guidelines outlines four steps: (1) assessing the potential cause of constipation with consideration of changes in medications; (2) increasing senekot-S and supplementing with milk of magnesia oral concentrate and/or polyethylene glycol; (3) performing a digital rectal exam to rule out low impaction if there continues to be no response; and (4) prescribing methylnaltrexone for patients with suspected opioid-induced constipation.

Diarrhea can also be caused by treatments (e.g., chemotherapy, intestinal surgery, pelvic radiation) and by certain cancers (e.g., colon cancer). It can be induced by stress and anxiety.

It is encouraged that patients increase their daily liquid intake, and avoid irritants such as caffeine or alcohol. Pharmacologic treatments include loperamide and octreotide. Parenteral hydration may be required for fluid replenishment in patients with severe diarrhea.

Radiation enteritis, inflammation of the small intestine, is a risk associated with radiation to the abdomen or pelvis. Patients with radiation enteritis may experience nausea, vomiting, abdominal cramping, rectal pain and diarrhea. Acute enteritis (<3 weeks) may be treated with antidiarrheal agents (e.g., kaopectate, paregoric, immodium), donnatal (anticholinergic agent), cholestyramine (bile salt sequestering agent) or lomotil. Chronic enteritis may present up to 6–18 months following radiation therapy, and if severe, can be surgically managed with an intestinal bypass or resection.

Chemotherapy may induce diarrhea through acute damage to the intestinal mucosa, causing an imbalance between absorption and secretion. Loperamide is commonly prescribed to decrease motility and increases anal sphincter tone. Somatostatin analog octreotide decreases hormone secretion and reduces motility to promote absorption.

Loss of Appetite and Weight Loss

Appetite loss, weight loss and malnutrition are often observed preceding diagnosis, and can arise or worsen with treatment and/or disease progression. Although these symptoms can go hand in hand, malnutrition, weight loss, and appetite loss are not interchangeable. Despite its association with survival, the clinical utility of weight loss without the context of time course or type of tissue lost (e.g., fat, muscle) is limited. Anorexia is the abnormal loss of appetite for food, which is present in at least 15% of patients at diagnosis and has been observed in a quarter of patients during chemotherapy. Anorexia is an important predictor of symptom burden and survival in patients with cancer, compared to those with weight loss alone. Malnutrition is marked by inadequacy of key vitamins and minerals, caused by altered or reduced food intake and/or impaired absorption. Observational studies have placed prevalence of malnutrition in patients with cancer at around 30%, and identified pre-existing obesity and primary cancers of the head and neck or upper digestive tract as risk factors. Common nutrition impact symptoms such as dry mouth, nausea, and constipation negatively impact nutritional status, increasing risk of malnutrition and are associated with lower quality of life in patients treated with chemotherapy.

It is estimated that over half of patients with advanced cancer develop cachexia, or continued loss of adipose and skeletal muscle mass despite nutritional support leading to progressive functional impairment. Diagnostic criteria of muscle sarcopenia or weight loss $>5\%$ (or $>2\%$ in individuals with a BMI <20 kg/m^2) in the past 6 months were established in an international consensus published by Fearon et al. A two-group model using the later criterion of weight loss was validated, and demonstrated an ability to distinguish between cachectic versus non-cachectic patients in all domains of food intake, catabolism and function, as well as in survival. Cancer cachexia can be graded using BMI and weight loss. Martin et al. observed that the prognostic discrimination of the grading system was clinically significant, with median survival ranging from 4.3 months (grade 4) to 29 months (grade 0), irrespective of factors such as type of cancer or stage, age or performance status. Secondary cachexia may be due to correctable causes. Patients who do not meet the diagnostic criteria for cachexia, may be defined as pre-cachectic if they exhibit unintentional weight loss in the past 6 months, anorexia or anorexia-related symptoms, and chronic or recurrent systemic inflammatory responses. Refractory cachexia is observed in terminal stages of un-responsive and procatabolic disease, wherein patients have poor performance status and limited life expectancy.

Cancer cachexia is caused by a negative protein and energy balance stemming from reduced food intake and/or abnormal metabolism. Associated anorexia and reduced food intake in this syndrome can be altered directly by chemosensory disturbances, nausea, or decreased motility of the gastrointestinal tract. Hypercatabolism can be caused by tumor metabolism, systemic inflammation or neuro-hormonal alterations.

Counseling with a dietician and behavioral strategies (e.g., eating small and frequent meals, limiting liquid intake during meals) can help to alleviate loss of appetite, and can be targeted to specific nutrition impact symptoms (e.g., dry mouth). Exercise that is

appropriate for the patient's performance status and health status is recommended. Patients may be recommended to use commercially available oral nutrition supplements to increase lean body mass. In those who are malnourished and are unable to receive adequate nutrition orally, enteral or parenteral nutrition support may be indicated. In patients with moderate to severe decrease in functional status, pharmacological treatment may be prescribed. Megestrol acetate and medroxyprogesterone have been shown to increase appetite, food intake and weight gain in patients. Ghrelin, a gastric peptide hormone, can work to facilitate acid secretion and motility in the gastrointestinal tract. Randomized controlled trial evidence indicated improvement in body mass and arm strength in patients with cancer cachexia. Metoclopramide may be prescribed to decrease nausea and early satiety. Corticosteroids are widely used for limited periods to stimulate appetite. Polyunsaturated fatty acids (e.g., omega-3-fatty acids, eicosapentaenoic acid) are used in a lesser extent for treatment of cancer cachexia, however there is insufficient evidence to support their effectiveness.

Depression and Anxiety

Cancer-related distress is pervasive, and extends along a continuum ranging from sadness to debilitating feelings. It was defined by the National Comprehensive Cancer Network as "a multifactorial, unpleasant, emotional experience of a psychological (cognitive, behavioral, and emotional), social, and/or spiritual nature that may interfere with the ability to cope effectively with cancer, its physical symptoms, and its treatment". Given the difficult circumstances surrounding cancer diagnosis and treatment, it may be difficult to detect morbid anxiety. Patients may also experience heightened anxiety with "fear of recurrence" following treatment. Depression and anxiety may be complications of the disease itself (e.g., brain, parathyroid, lung cancers) or treatments. Depression is a recognized potential effect of certain chemotherapeutic agents (e.g., etoposide, cisplatin), molecular target agents, monoclonal antibodies, and hormonal treatments (e.g., letrozole, androgen deprivation). Radiation to certain sites such as the brain, head and neck, or pelvis can also cause depression through TSH, growth hormone, melatonin, and/or B12 deficiencies.

Depression should be considered in the presence of affect and prolonged impairment of function, with major depressive disorder being characterized by the presence of at least five of the following symptoms in a 2-week period: depressed mood most of the day; markedly diminished interest in activities; significant change in weight or appetite; insomnia or hypersomnia; psychomotor agitation or retardation; fatigue or loss of energy; feelings of worthlessness or guilt; diminished ability to think, make decisions or concentrate; recurrent thoughts of death or suicide, or plans or attempts to commit suicide. It is estimated that approximately 15%–25% of patients with cancer are affected by comorbid depression; however, lack of standardized methods in terms of instruments and diagnostic criteria make it challenging to estimate prevalence in this patient population. Possible medical causes for depressive symptoms include uncontrolled pain, metabolic abnormalities (e.g., anemia, hypercalcemia), endocrine abnormalities (e.g., hyperthyroidism), and certain medications. Anxiety can induce or heighten symptoms such as pain or nausea. Depression may negatively impact treatment compliance.

The American Society of Clinical Oncology guidelines provide an algorithm for assessment of depression in adults with cancer using the validated 9-item Personal Health Questionnaire (PHQ-9). Anhedonia and depressed mood require further investigation. In those who indicate moderate symptomology (score 8–14), low-intensity interventions are recommended such as individually-guided self-help based on cognitive behavioral therapy, group-based cognitive behavioral therapy for depression, group psychosocial interventions, structured physical activity programs or appropriate pharmacologic therapies. In those who indicate moderate-to-severe (score 15–19) or severe (score 20–27) symptomology, pharmacologic therapies and/or high-intensity interventions such as individual psychological cognitive behavioral therapy or interpersonal therapy. Also emphasized is support in the form of patient and family education on stress reduction strategies (e.g., progressive muscle relaxation), availability of supportive care services and financial support, information on sleep hygiene and self-management of fatigue, and signs and symptoms of worsening depression.

There is a similar algorithm for assessment of anxiety in adults with cancer using the 7-item generalized anxiety disorder questionnaire. It is recommended that patients with moderate symptomology (score 10–14) be offered low-intensity interventions such as education and active monitoring, non-facilitated or guided self-help based on cognitive behavioral therapy, group psychosocial interventions or appropriate pharmacologic therapies. Under this algorithm, patients with moderate-to-severe or severe symptomology should be offered high-intensity psychological (individual cognitive behavioral therapy or applied relaxation) and/or pharmacologic interventions.

Psychological interventions can be low- or high-intensity depending on symptom severity. They are delivered in a group or individual settings and provide psycho-education and training in coping skills and mindfulness based stress reduction. There is some evidence for the use of multi-component interventions including a structured physical program, visual imagination, and progressive relaxation techniques for acute stress or post traumatic disorder in this patient population. Antidepressants have demonstrated effectiveness in treating clinically significant depression in patients with cancer. However, routine use of antidepressants in patients with sub-threshold depressive symptoms or mild depression is discouraged. Major classes include selective serotonin reuptake inhibitors (SSRIs), serotonin and norepinephrine reuptake inhibitors (SNRIs), norepinephrine-dopamine reuptake inhibitors (NDRIs), atypical antidepressants, tricyclic antidepressants (TCAs), monoamine oxidase inhibitors (MAOs), and psychostimulants. Sertraline and citalopram are most commonly used in patients with cancer since they are generally well tolerated and have the least interactions with chemotherapy agents. SNRIs (e.g., desvenlafaxine) are often used in patients with comorbid pain syndromes. Buspirone is often used adjunctively to treat comorbid anxiety. Nonpharmacological interventions may include psychotherapies such as cognitive behavior therapy, which aims to change behavior by altering how patients think or feel about certain things.

Symptom Management in Advanced Cancer

The World Health Organization definition of palliative care describes it as focused on improving quality of life in patients and their families associated with life-threatening illness. A goal of palliative care is to prevent and provide relief of suffering from pain and other distressing symptoms. Complications of advanced cancer can produce varied symptomology. There is a range of options in palliative interventions, including surgery, minimally invasive procedures, radiation therapy, chemotherapy, and pharmacologic agents.

Bone metastases are the most common source of moderate-to-severe pain, with 75% of patients with advanced disease reporting the symptom. The clinical course of metastatic disease from the bone can be relatively long, spanning several years in patients with prostate or breast cancers. Patients can experience nociceptive and neuropathic pain from skeletal complications such as pathologic fractures, and spinal cord compression. External beam radiation, bone-targeting agents (e.g., bisphosphonates, calcitonin), and radiopharmaceuticals (e.g., radium-223) can provide analgesic relief while reducing risk of skeletal complications. Percutaneous vertebroplasty involves the injection of acrylic bone cement into the vertebral body to restore stability and/or height loss, and therefore relieves pain and functional impairment. Surgical stabilization of the long bones, and joint replacements may also reduce bony pain.

Metastatic spinal cord compression is an oncological emergency as it can lead to irreversible paralysis and neurological damage. While patients typically first experience back pain, progression may lead to limb weakness, decreased sensation and numbness of the toes and fingers, and autonomic dysfunction (e.g., incontinence, constipation). Corticosteroids and/or analgesics for the bony and neuropathic pain can be provided. Definitive treatment for spinal cord compression includes radiotherapy, surgery or chemotherapy. Surgery can decompress the spinal cord to reconstruct and stabilize the structure. Radiation can be used as an adjunct to surgery, or as primary treatment in patients who are not surgical candidates to prevent neurological deterioration, improve neurological function and provide pain relief. Chemotherapy may play a role in sensitive malignancies (e.g., lymphoma, small cell lung cancer).

Depending on the site of disease and degree of mass effect, brain metastases can cause various symptoms such as fatigue, impaired sight or hearing, nausea and vomiting, incontinence and limb immobility. Dexamethasone can provide rapid relief of symptoms due to swelling. Surgical resection may be used to treat solitary brain metastases. There is evidence of the ablative efficacy of stereotactic radiation therapy in the treatment of four or less metastases. In more extensive disease, whole brain radiation therapy can be used. Leptomeningeal carcinomatosis, or the spread of disease to the meninges of the brain and spinal cord, is a rare complication of advanced cancer. In patients with favorable risk status (e.g., high performance status, no major neurological deficits, minimal systemic disease), the MD Anderson Cancer Center suggests consideration of radiotherapy and systemic therapy, intraventricular catheters and/or a ventriculoperitoneal shunt for intrathecal chemotherapy. Although there is a concern for tumor seeding, ventriculoperitoneal shunts can provide palliation in patients with limited survival.

Malignant bowel obstruction occurs when there is a blockage of gastric or intestinal contents, and can cause abdominal pain, nausea and vomiting. Patients may be considered for palliative surgical resection (e.g., colostomy). In non-operable obstruction, procedures such as nasogastric tubes, percutaneous decompression gastronomy tubes or percutaneous endoscopic gastronomy may alleviate symptoms. Self-expanding metal stents can also be considered an option for patients with single points of obstruction. Although use of morphine as an analgesic is supported by clinical guidelines, lesser risk of constipation and availability as a transdermal formulation make fentanyl a convenient option for patients with malignant bowel obstruction. Nausea and vomiting due to malignant bowel obstruction can be managed with antisecretory drugs, octreotide, and antiemetics.

Patients with metastatic disease in the lung may produce dry cough, shortness of breath or chest pain due to a malignant blockage of the airway. Radiation therapy or laser ablative therapy through a bronchoscope may shrink pulmonary metastases to provide symptomatic relief. Oxygen supplementation may be recommended. Due to a high rate of recurrence, aspiration is only recommended in patients with limited life expectancy ($<$1 month). Pleural effusion can be treated with a thoracentesis or indwelling pleural catheters to drain fluid. The pleural space can be obliterated by pleurodesis to treat pleural effusion and prevent repeated fluid build-up. Similarly, fluid buildup in the pericardium, which can result in shortness of breath and tiredness, can be treated with pericardiocentesis and recurrence can be prevented with a pericardial window.

Patients with liver metastases may experience tiredness, loss of appetite, and abdominal pain. The inability of the liver to remove toxins may eventually cause hepatic encephalopathy, leading afflicted patients to feel confusion or fatigue. Patients with limited disease may undergo hepatic resections. Percutaneous radiofrequency ablation is a minimally invasive option. Blood supply to non-operative liver metastases can be obstructed with embolization therapy. Embolization can be combined with chemotherapy in trans-arterial chemoembolization, or with radiation in trans-arterial radioembolization. Hepatic artery infusion of chemotherapy allows direct delivery of treatment to the site of metastases to prolong drug exposure while minimizing toxicity to unaffected areas. Stereotactic radiation therapy to limited disease has been proven effective in symptom palliation.

Patient-Reported Outcome Measurement

In an effort to increase rigor and transparency in reporting of patient-reported outcomes, the Consolidated Standards of Reporting Trials (CONSORT) checklist underwent an extension in 2013 to include guidance on the reporting of these outcomes in randomized clinical trials. Item 6a stipulates use of an instrument with evidence of reliability and validity. A variety of instruments are

available for measurement of health-related quality of life in patients with cancer. Standardized pain assessment tools using visual analogue scales or verbal rating scales, which have been validated in patients with cancer, are recommended. Two widely used examples are the European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire Core 30 (EORTC QLQ-C30) and the Functional Assessment of Cancer Therapy-General (FACT-G). Developed in the early 1990s, these two core questionnaires have since been revised and translated, and supplementary modules have been developed for subpopulations categorized by primary cancer site (e.g., lung cancer, bone metastases), symptoms (e.g., cancer related fatigue, neutropenia), and treatment (e.g., taxane therapy, bone marrow transplantation). The EORTC QLQ-30 is composed of 30 items, and evaluates five types of functioning (physical, role, emotional, social, cognitive) in addition to several independent symptoms and overall quality of life. The FACT-G is composed of 27 items, and evaluates symptoms classified under four types of well-being (physical, social/family, emotional, functional) and also includes an overall quality of life item.

Supplementary modules allow evaluation of other interrelated symptoms or influencing factors. The Functional Assessment of Anorexia/Cachexia Treatment (FAACT) for example assesses 12 items in domains of cancer cachexia (e.g., appetite, weight loss), and additional and/or interrelated symptoms (e.g., nausea, abdominal pain). It also assesses satiety, taste, difficulty eating certain foods, patient perception and concern regarding weight and food intake, and pressure from caregivers to eat. The FACIT-D is a diarrhea-specific module, with 11 items assessing frequency of bowel emptying, control of bowels, disruption of sleep, emotional impact, and limitations on physical, social, and sexual activity. The 13-item FACIT-F and the 12-item QLQ-FA12 are fatigue-specific assessments, and include items such as level of energy, weakness, sleepiness during the day, as well as ability to start tasks and complete usual activities.

Outside of the EORTC and FACIT, several multidimensional instruments are available to measure patient-reported outcomes. The 11-item Brief Pain Inventory was developed by the Pain Research Group of the World Health Organization Collaborating Centre for Symptom Evaluation in Cancer Care for assessment of pain intensity, functional interference and pain relief with analgesics. The Cancer Dyspnoea Scale (CDS) is a multidimensional measure of dyspnea, with three subscales assessing sense of effort, sense of anxiety and sense of discomfort. Originally developed to assess impact of chemotherapy-induced nausea and vomiting, the Functional Living Index-Emesis (FLIE) is an 18-item instrument assessing level of nausea and vomiting and their impact on various aspects of function and quality of life (e.g., appetite, making meals, social interactions). There are also validated questionnaires for use in the palliative setting. An example, EORTC QLQ C15-Palliative, is a brief questionnaire of 15 items assessing walking ability, independence in self-care and completing daily activities, overall quality of life as well as symptoms such as weakness, shortness of breath, pain, sleep disturbance, nausea, constipation, and feelings of tenseness and depression.

Alternatively, there are several brief symptom screening tools available for use in the clinical setting. The Edmonton Symptom Assessment System (ESAS) evaluates eight items of pain, tiredness, nausea, depression, anxiety, drowsiness, appetite and sensation of well-being on a scale from 0 to 10. Similarly, the validated MD Anderson Symptom Inventory (MDASI) assesses 13 core symptoms of pain, fatigue, nausea, sleep disturbance, distress, shortness of breath, difficulty remembering, lack of appetite, drowsiness, dry mouth, sadness, vomiting and numbness/tingling on a 0 to 10 scale.

Symptom Clusters

Due to common etiology or causal relationships, two or more symptoms may present concurrently in clinically significant "clusters." Clusters were originally defined as three or more concurrent, interrelated symptoms. Later definitions described symptom clusters as being composed of two or more related symptoms that form a stable group, and are independent of other clusters. The "partial mediation model" explains how two symptoms can influence each other indirectly through the effect of another common symptom (e.g., pain impacting fatigue through impairment of sleep). Frequency, severity and distress of symptoms have been reportedly higher in patients who experience clustered symptoms versus those who do not.

Methodology in symptom cluster research has yet to be standardized. Statistical methods include factor analyses, which are often used to identify groups of symptoms related through shared underlying causes; and cluster analyses, which can group symptoms exhibiting similar patterns.

Highlighted by the National Cancer Institute at the State-of-the-Science Conference in 2012, the symptom cluster of pain, depression and fatigue is highly prevalent in patients with cancer. The symptoms are thought to share common pathophysiological mechanism of systemic inflammation, and have been induced as "sickness behavior" in animal models following administration of inflammatory agents. This model of sickness behavior consists of physiological components (fever, pain, wasting) and behavioral components (e.g., decreased activity, cognitive impairment, somnolence, decreased social interaction) and has been hypothesized to be the common mechanism behind this symptom cluster. Other studies report emotional symptom clusters including distress, sadness, lack of appetite, sleep disturbances, anxiety and depression in both patients with early and advanced disease.

The gastrointestinal symptom cluster of nausea, vomiting and appetite loss has been identified in patients undergoing chemotherapy with consistency across the treatment trajectory. It has been recommended that interventions focus on nausea and vomiting as core symptoms in patients who present with this particular symptom cluster, with supplementary strategies appended to target associated symptoms (e.g., weight loss, gastrointestinal reflux, diarrhea, bloating).

Certain physical and psychological symptom clusters have consistently been identified in palliative cancer patient populations. Physical symptoms such as tiredness, pain, nausea, drowsiness, dyspnea and loss of appetite consistently cluster together; whereas,

psychological symptoms such as depression and anxiety often appear together. Smaller clusters of physical symptoms have also been highlighted in the literature, such as nausea and dyspnea.

Dodd et al. were among the first to demonstrate the clinical significance of this phenomenon as they provided early insights into the effects of symptom clusters on individual functional status. Analyses indicate compounding effects of clusters on quality of life exceeding effects observed with individual symptoms. Understanding of symptom clusters may help prepare clinicians and patients for increased burden and distress associated with particular symptoms, and allow for more strategic prophylaxis and management preceding, during and following interventions. Symptom clusters may help in the elucidation of common pathophysiology. Alternatively, information gained from this type of research may help to prioritize certain upstream symptoms, therein highlighting routes through which downstream symptoms can be relieved. Clinicians may also use clustering to identify sub-groups of patients at risk of experiencing higher symptom severity, thereby aiding in the targeting of high-risk individuals for particular interventions.

Due to the potential implications in targeting supportive and palliative oncological care, symptom cluster research in this patient population has recently been named a priority by the Oncological Nursing Society. More investigation is needed to clarify the composition of clinically significant clusters, and to support relationships between symptoms with underlying mechanisms in order to design and test appropriate interventions.

Conclusion

Patients with cancer can experience a constellation of symptoms preceding diagnosis, throughout the trajectory of treatment and into survivorship or end-of-life care. Symptom burden has profound impacts on patient function and quality of life, and its measurement has demonstrated prognostic value. Increased attentiveness to symptom experience, improved communication between patients and health care providers and adherence to clinical guidelines in symptom management may reduce reported rates of inadequate symptom control.

Systems Biology Approach to Study Cancer Metabolism

Stefan Kempa and Nadine Royla, Berlin Institute for Medical Systems Biology at the MDC Berlin-Buch, Berlin, Germany

A Systems View on Metabolism

Cancer is a complex disease. In 2000 Hannahan and Weinberg specified the complexity by defining the six hallmarks of cancer—resisting cell death, sustaining proliferative signaling, evading growth suppressors, activating invasion and metastasis, inducing angiogenesis, and enabling replicative immortality (Hanahan and Weinberg, 2000). Eleven years later they expanded their concept by adding the features of avoiding immune destruction, deregulating cellular energetics, genome instability, and mutation- and tumor-promoting inflammation (Hanahan and Weinberg, 2011). It became clear that the tumor cell has to be considered an interactive network of biological functions. Cells randomly acquire mutations throughout life. These mutations can be either selective neutral or beneficial as they confer cell growth and survival advantages (Martincorena et al., 2017). Cancer develops as a consequence of clonal selection for cells that have sequentially accumulated advantageous mutations, so called driver mutations. A typical tumor exhibits two to eight driver mutations, while the selective neutral mutations, termed passenger mutations, occur more frequently (Vogelstein et al., 2013). Each small genetic alteration has extensive effects on the molecular characteristic of a cell by affecting levels of DNA, RNA, proteins, and metabolites (Werner et al., 2014). Considering the multitude of mutations that occur in a tumor cell, cancer is a complex adaptive system with emerging properties at various levels that cause multivariate dysregulations within the molecular network (Kreeger and Lauffenburger, 2009). Thus, cancer systems biology aims to understand the complexity of the disease via the combination of experimental, mathematical, and computational tools that enable the integrative analysis of networks (Werner et al., 2014).

Impact of Metabolism on Different Omics Layers

Traditionally, cancer studies focused on the examination of individual mutations with a distinct phenotype as guided by the central dogma of molecular biology (Crick, 1970). The concept implies the unidirectional flow of information from genes to proteins via transcripts. The linear logic was questioned by the discovery that proteins and metabolites, the functional units subsequent of the dogma, can loop back and regulate transcriptional as well as translational processes (**Fig. 1**) (Buescher and Driggers, 2016). On the one hand, metabolism provides building blocks in form of nucleotides and amino acids to build up DNA, RNA, and proteins. These processes are highly energy-consuming and thereby once more dependent on metabolism, which assures the sufficient supply of energy carriers such as ATP and GTP. On the other hand, metabolites allosterically control the activity of enzymes that act on distinct regulatory levels (Buescher and Driggers, 2016). For example, the activity of the 5′ adenosine monophosphate-activated protein kinase (AMPK) is dependent on the competitive binding of the metabolites AMP and ATP (Wegner et al., 2015). In case the cellular energy state is low, AMP binds to the regulatory domain of AMPK which leads to a conformational change of the protein resulting in its phosphorylation and thereby activation. The dominant presence of ATP reverts the conformational change and dephosphorylates the kinase leading to its inactivation (Wegner et al., 2015).

Furthermore, the translation of messenger RNA (mRNA) is regulated by metabolites. The RNA binding protein Musashi-1 is known to be allosterically inhibited by unsaturated fatty acids that eventually results in the transcriptional inhibition of stearoyl-CoA desaturase, a fatty acid desaturase (Wegner et al., 2015). Moreover, it was reported that metabolite-sensing RNA elements, namely riboswitches, which regulate the gene expression in bacteria, algae, fungi, and higher plants (Garst et al., 2011). In the presence of a metabolic ligand riboswitches form alternative secondary structures that interfere with the transcriptional and/or translational machinery. The transcriptional control via metabolites is either achieved by allosteric inhibition of transcription factors, for example, inhibition of carbohydrate-responsive element-binding protein by xylulose-5-phosphate, or by chromatin remodeling (Wegner et al., 2015). Wellen et al. (2009) provided evidence that histone acetylation is dependent on the enzyme ATP citrate lyase (ACLY) that catalyzes the conversion of citrate into acetyl coenzyme A, which is the major substrate of histone acetyltransferases (HATs). HATs transfer the acetyl group of acetyl-CoA to lysine residues of histones allowing the transcriptional access to the DNA and thereby epigenetic control of gene expression.

Time-Resolved Omics Studies

The expression of genes, transcripts, and proteins reflect mainly the genotype of a cell, while metabolites transmit the phenotype. The regulation of metabolism is dependent on control processes that occur on each regulatory level, starting with the gene that encodes for different enzyme isoforms, the transcriptional activation via transcription factors, followed by the control of alternative splicing, mRNA stability as well as translation and protein degradation processes (Wegner et al., 2015). These gene expression-dependent regulations are time- and energy-consuming processes that are not easily reversible and therefore realized upon chronic environmental alterations. In contrast, the response to acute environmental cues is a gene expression independent process and thereby flexible and fast since it is based on the allosteric regulation or posttranslational modification of enzymes (Wegner

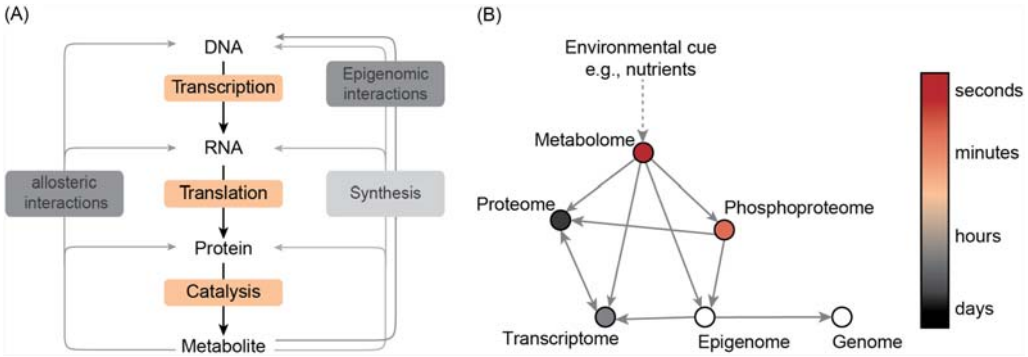

Fig. 1 Metabolomics in systems biology. (A) Regulation of omics levels (*gray arrows*) via metabolites beyond the central dogma of molecular biology. (B) Time-resolved trans-omics interactions in response to a nutritional cue. (A) Adapted and modified from Buescher, J. M. and Driggers, E. M. (2016). Integration of omics: More than the sum of its parts. *Cancer & Metabolism* **4**(1), 4; (B) Adapted and modified from Yugi, K. and Kuroda, S. (2018). Metabolism as a signal generator across trans-omic networks at distinct time scales. *Current Opinion in Systems Biology* **8**, 59–66.

et al., 2015; Yugi and Kuroda, 2018). Accordingly, the maintenance of the cellular homeostasis upon environmental stress is assured by a two-dimensional regulation: different omics levels which act on defined time scales (Yugi and Kuroda, 2018). The time-based delimitation is further discernible in the averaged half-lives of cellular metabolite (1 min), mRNA (10 h), and protein pools (24 h) estimated in HeLa cells (Yugi and Kuroda, 2018). The cellular function of each omics regime is defined by an inherent time scale allowing the dissection of sequential cellular processes in response to a stimulus. Upon a nutritional alteration the metabolome adapts first, within seconds, signaling reactions via kinases take seconds to minutes, whereas gene expression-dependent regulations are detectable after minutes, but rather hours (**Fig. 1**B) (Buescher and Driggers, 2016; Shaw et al., 2014; Yugi and Kuroda, 2018). Tahus, the recording of changing events on each omics layer over time provides information about the directionality of cellular processes that are induced upon a stimulus (Buescher and Driggers, 2016). Time-resolved experiments require frequent sampling in short intervals to monitor the response of the system. Each cellular response has a specific dynamic. The comparison of these inherent dynamics give information about the sequential interactions within the network (Buescher and Driggers, 2016). Especially in the field of cancer research the integrative multiomics approach provides the opportunity to: (i) uncover bypass reactions leading to drug resistance, (ii) identify biomarkers, (iii) and predict the most beneficial therapy for patients (Werner et al., 2014).

Required Tools for Metabolism-Centric Systems Biology

In order to conduct systems-level analyses, highly multivariate data sets are required. Advances in microarray and high-throughput methods enable the comprehensive analysis of all omics regimes. Genomics, transcriptomics, and epigenomics analyses are predominately based on DNA and RNA sequencing, whereas proteomics and metabolomics approaches rely on mass spectrometry (MS)-based methods that allow the direct identification of subjected molecules (Buescher and Driggers, 2016). Chromatographic methods, such as liquid and gas chromatography (LC and GC), are usually connected upstream of mass spectrometers performing the preseparation of biological compounds on the basis of their chemical properties. Proteins are usually subjected to LC–MS, while metabolites are analyzed with both methods. GC–MS is less sensitive than LC–MS, instead it enables the separation of structural isomers, such as glucose and fructose, and is thereby a suitable tool to examine the central carbon metabolism (Pietzke and Kempa, 2014).

Recently, metabolism-centric systems biology gained attention, because it links the biological phenotypes to environmental information. The metabolic adaptation in response to environmental cues might remain undetected due to interconnected, parallel, and circular pathways that balance the metabolic homeostasis (Pietzke et al., 2014). Differences in the abundance of metabolites are only detectable upon clear impairments of metabolic pathways as seen for knockdowns of key metabolic enzymes (Zasada, 2017). The application of stable isotope substrates overcomes this limitation as it allows to trace the isotope flow throughout the metabolic network (Lane et al., 2011; Wittmann and Heinzle, 1999; Metallo et al., 2009). A single GC–MS measurement provides the simultaneous analysis of metabolite abundance and isotope incorporation (Zasada, 2017). Usually stationary incorporation patterns are observed as a result of long labeling times that might reflect steady-state changes on the genome, transcriptome or proteome level. In contrast, the dynamic characterization of sequential metabolic events upon altered environmental conditions requires the application of stable isotopes in an instationary manner. Accurate kinetic studies require short sampling intervals and the uninterrupted supply of essential nutrients to minimize metabolic and mechanic stress that might affect nutrient conversion rates (Chokkathukalam et al., 2014). Accordingly, the experimental handling is technically challenging regarding the rapid replacement of carbon sources and the terminal quenching of metabolism. These vulnerabilities were overcome as Pietzke et al. (2014) developed an optimized work flow for stable-isotope incorporation in cell culture, termed pulsed stable isotope-resolved metabolomics (pSIRM). The method, optimized to reduce any kind of perturbation, allows a time- and atom-resolved tracing of the routing of ^{13}C- or ^{15}N-labeled nutrients within the central carbon metabolism (CCM) by GC–MS (**Fig. 2**).

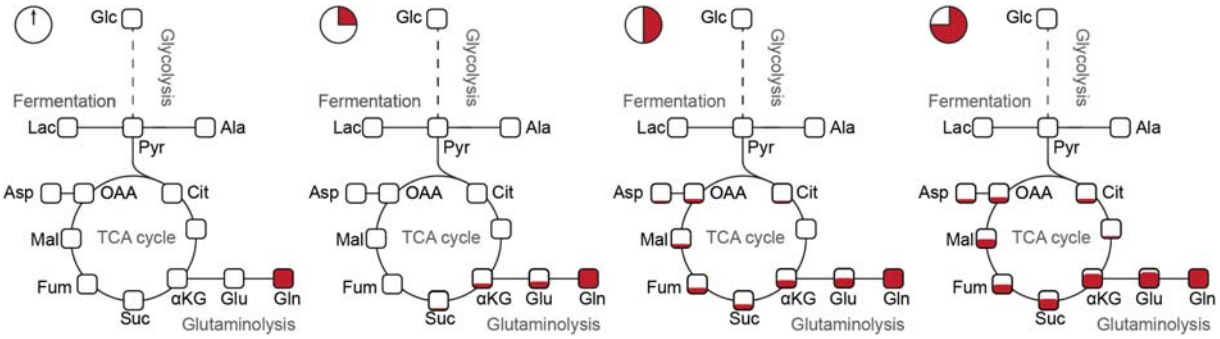

Fig. 2 Pulsed stable isotope-resolved metabolomics (pSIRM). Dynamics of ^{13}C incorporation (*red*) are shown for the application of u-^{13}C-labeled glutamine. Time-resolved pulsed labeling enables the monitoring of the turnover-dependent replacement of carbon-12 with carbon-13 (*red*) of each single metabolite pool. The comparison of these dynamics allows the estimation about the preferential routing of applied substrates in different conditions (*arrow*). Abbreviations: *Ala*, Alanine; *αKG*, α-Ketoglutarate; *Asp*, Aspartate; *Cit*, Citrate; *Fum*, Fumarate; *Gln*, Glutamine; *Glu*, Glutamate; *Lac*, Lactate; *Mal*, Malate; *OAA*, Oxaloacetate; *Pyr*, Pyruvate; *Suc*, Succinate.

Glossary

Anabolic reactions Energy-requiring reactions involved in the production of macromolecules from smaller units.

Carboxylases Enzymes that catalyze the introduction of a carboxylic acid group to a substrate in an ATP-dependent manner. The opposite reaction is decarboxylation, with release of CO_2 and ATP.

Dehydrogenases Enzymes that couple the oxidation of a substrate with the reduction of an electron acceptor, usually NAD^+ or $NADP^+$, or a flavin coenzyme such as FAD.

Hydratases Enzymes that perform a reaction of hydration in which a substance combines with water.

Isoforms Proteins that can perform the same or similar biological roles. In the case of enzymes, they can perform the same enzymatic reaction.

Isomerization A chemical process through which a molecule is transformed into another with same atoms but different structural arrangement.

Oncometabolite A metabolite whose accumulation can promote the transformation of a cell or confer a cancer-associated phenotype.

Reactive oxygen species (ROS) Reactive chemical species deriving from partial reduction of molecular oxygen. They include superoxide ($^{\bullet}O_2^-$), hydrogen peroxide (H_2O_2) and hydroxyl radical ($^{\bullet}OH$).

Introduction

Metabolic reorganization is a typical trait of cancer cells necessary to sustain the intensive proliferation rate and, more importantly, to face tumor environmental fluctuations in terms of nutrient limitations, changes in oxygen tension and response to therapeutic insults. The inherent intertwined nature of metabolic reactions actually renders difficult to foresee metabolic features of a specific tumor, which largely depend on the basal metabolic setting of the normal tissue and on the type of oncogenic signaling that has given rise to the tumorigenic event. Nevertheless, some specific characteristics of cancer metabolism have been traced; for instance, it is well established that some tumor types can favor glycolysis with respect to oxidative phosphorylation also in the presence of normal tension of oxygen, can have an intense utilization of glutamine, can activate de novo lipid biosynthesis. Many of these events rely on alterations of the tricarboxylic acid (TCA) cycle, also known as Krebs cycle or citric acid cycle. This is a multistep and central metabolic pathway occurring inside the mitochondrial matrix conveying carbohydrate, lipid, and protein metabolism for energetic or biosynthetic purposes.

Beginning from the canalization of carbohydrate-derived pyruvate into mitochondria and its conversion to acetyl-CoA by the pyruvate dehydrogenase complex, the conventional starting point of the TCA cycle is considered the reaction catalyzed by citrate synthase (CS), which combines an acetyl unit to oxaloacetate (OA) to produce citrate. This intermediate is isomerized by the hydratase activity of the mitochondrial aconitase or aconitase 2 (ACO2) into isocitrate, which becomes substrate for the oxidative decarboxylation reaction carried by the $NADP^+$-dependent IDH2 and NAD^+-dependent IDH3 isocitrate dehydrogenase enzymes, with release of α-ketoglutarate (α-KG). The activity of the α-KG dehydrogenase complex (α-KGDHC) further decarboxylates α-KG to form succinyl-CoA, an unstable intermediate subsequently converted in succinate by the succinyl-CoA synthetase. Succinate is then oxidized by the succinate dehydrogenase (SDH) complex in fumarate, to which a water molecule is added by the fumarate hydratase enzyme producing malate. Finally, OA is regenerated from malate by the activity of the malate dehydrogenase (MDH2) and it can be used for a further cycle in presence of acetyl-CoA (Fig. 1).

The overall yield of a single turn of TCA cycle starting from one acetyl-CoA unit consists of one molecule of GTP or ATP, three molecules of NADH and one of $FADH_2$. More importantly, the continuous production of NADH and $FADH_2$ in repeated TCA cycle turns and their re-oxidation in the electron transport chain (ETC) permit the generation of a mitochondrial intermembrane proton electrochemical gradient which is extinguished by the ATP synthase for ATP production.

The central position of the TCA cycle in cell metabolism is held by an intrinsic plasticity also determined by: (i) reversibility of most of TCA cycle reactions, apart from those of CS, IDH3 and α-KGDHC, (ii) the presence of two cytosolic proteins, namely aconitase 1 (ACO1) and isocitrate dehydrogenase 1 (IDH1), which recapitulate a portion of the TCA cycle outside mitochondria, (iii) participation of substrates in alternative reaction pathways. Consistently, most metabolites produced in the TCA cycle can function as precursors for biosynthesis of different types of macromolecules (cataplerotic reactions) which, in turn, can be used to replenish TCA cycle by anaplerotic reactions.

Among the others, the anabolic reactions based on TCA cycle intermediates and largely employed in tumorigenesis are lipid and aspartate biosynthetic pathways. De novo fatty acid biosynthesis, or lipogenesis, permits the production of new phospholipids for

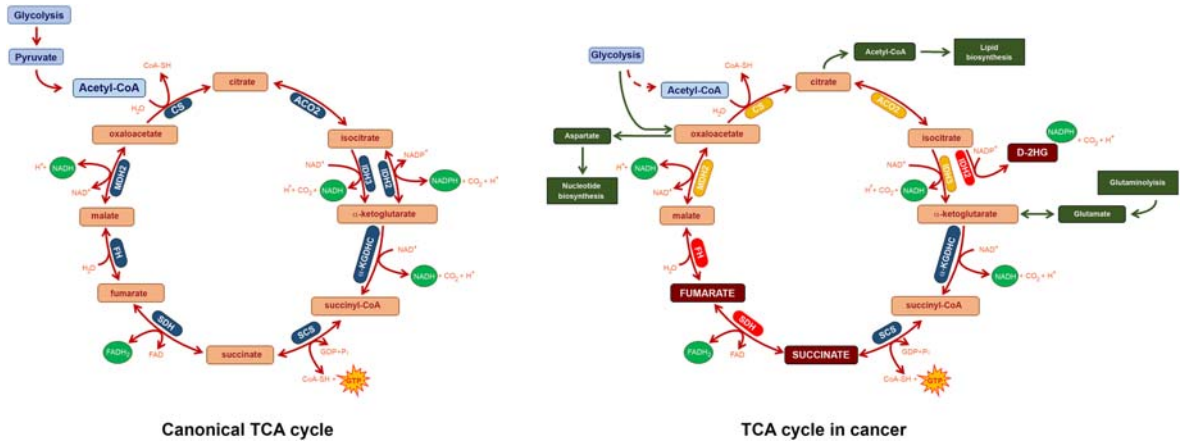

Fig. 1 *Canonical TCA cycle and aberrations in cancer.* Canonical TCA cycle (left) conventionally starts from glycolysis-derived acetyl-CoA condensation with a molecule of oxaloacetate (OA) to produce citrate. Seven further reactions (see text) are responsible for reconstitution of OA to permit the launch of another cycle in presence of acetyl-CoA. The overall yield of a cycle is three molecules of NADH (or two, plus one NADPH, depending on the IDH isoform used), one $FADH_2$ and one GTP. Most reactions are reversible, as shown by the *arrows*, except those of CS, IDH3 and α-KGDHC. Aberrations of the TCA cycle in cancer (right) can depend on either mutations (*red ellipses*) or altered gene expression (*orange ellipses*) of the enzymes. In particular, IDH2 mutants acquire neomorphic activity with production of D-2HG, while deficient SDH and FH activities lead to succinate and fumarate accumulation, respectively. A reduction of acetyl-CoA production from pyruvate (*dashed arrow*) can be compensated by anaplerotic reactions (in *green*), such as derivation of OA from pyruvate and of α-KG from glutaminolysis-derived glutamate. On the other hand, TCA cycle supports cancer-associated metabolic anabolism (in *green*) through citrate for lipid biosynthesis and OA for aspartate production, involved in nucleotide biosynthesis.

membranes. This is achieved through the translocation of citrate via the citrate transporter protein (CTP or SLC25A1) from mitochondria to cytosol, where it is cleaved back by the ATP citrate lyase (ACLY) to OA and acetyl-CoA, which becomes substrate for acetyl-CoA carboxylase (ACC) and then fatty acid synthase (FASN). Citrate for fatty acid biosynthesis can also be obtained from either pyruvate-derived acetyl-CoA or reductive carboxylation of α-KG by IDH2. Accumulation of aspartate can support proliferation by favoring nucleotide biosynthesis via activation of the trifunctional multidomain enzyme carbamoyl-phosphate synthase 2, aspartate transcarboxylase and dihydroorotase. Aspartate production from TCA cycle is mediated by the aspartate aminotransferase that catalyzes the reversible transamination of glutamate and OA to aspartate and α-KG. Aspartate biosynthesis can be sustained by pyruvate carboxylase, which replenishes OA from pyruvate and is one of the anaplerotic reactions largely up-regulated in cancer. Together with this, cancer cells depend on glutamine as main alternative fuel of the TCA cycle providing α-KG. This important anaplerotic reaction is supported in mitochondria by two consecutive deaminations into glutamate, via glutaminase 2, and then into α-KG by glutamate dehydrogenase 2 or by transaminases (Fig. 1).

TCA Cycle Alterations in Cancer

Defects in TCA cycle reactions in cancer have been attributed to altered activity of almost all enzymes, primarily as consequence of genetic mutations or aberrant gene expression. In many cases, oncogene activation or mutated tumor suppressors have been directly or indirectly linked to altered transcription of TCA cycle components or of genes involved in related pathways. Genetic mutations identified in TCA cycle genes can both disable enzymatic activity, inducing accumulation of specific metabolites, or bring to neomorphic enzymatic activity. Very interestingly, mutations of a specific gene of the TCA cycle are often responsible for predisposition to a particular type of tumor, indicating that some organs or tissues are more susceptible to alterations of certain TCA cycle reactions rather than others. Hereafter, information available for all TCA cycle enzymes in cancer will be provided with emphasis on the kind of alterations identified and on the associated metabolic and nonmetabolic outcomes.

Citrate Synthase

CS is a homodimeric protein conventionally designated as first enzyme of the TCA cycle, performing the irreversible condensation of acetyl-CoA with OA to form citrate. Indeed, the reaction is highly esoergonic and determines the whole TCA cycle rate. The number of reports showing alterations of CS in cancer are very limited and mainly demonstrating changes of gene expression rather than genetic mutations. Most data indicate that CS expression and/or activity is enhanced in cancer, as shown in ovarian malignant tumors and cell lines, pancreatic carcinoma and benign renal oncocytoma as well. Nevertheless, an antineoplastic role of CS was also shown as its decrease in cervical cancer cell lines contributed to the switch from oxidative to aerobic glycolytic metabolism,

a typical feature of many tumors also known as "Warburg effect". The different impact of CS in cancer may depend on the metabolic requirement of each cancer type. More specifically, upregulation of CS activity may be required by those cancer cells that rely on citrate to increase fatty acid biosynthesis or to burst TCA cycle rate for energetic or other anabolic purposes. On the contrary, cancer cells may exploit CS down-regulation to dampen oxidative metabolism in favor of aerobic glycolysis or to mainly rely on glutamine anaplerosis.

Aconitase

ACO2 represents the second enzyme of the TCA cycle, catalyzing the isomerization of citrate to isocitrate. The protein possesses a 4Fe-4S iron–sulfur cluster that directly interacts with the substrate. The regulation of citrate availability and of its utilization has been demonstrated as the only mechanism currently known for ACO2 in cancer metabolism. In particular, these events have been mainly characterized in prostate cancer due to the relevant role of ACO2 in normal prostate epithelium. This tissue physiologically relies on massive accumulation of citrate achieved through aconitase inhibition by high levels of zinc. Instead, prostate cancer cells restore aconitase activity thus permitting citrate isomerization at the expense of fatty acid synthesis. Notably, reduction of citrate levels is a suitable in vivo marker of transformed prostate epithelium. On the other hand, gastric cancer biopsies showed reduced expression of *ACO2* gene, which functions as prognostic factor for disease progression. Although no mechanisms have been proposed, disabling ACO2 activity or expression can be employed to truncate citrate flux permitting its extrusion outside mitochondria for lipogenesis.

Isocitrate Dehydrogenase

IDH is the third enzyme of the TCA cycle, performing a two-step reaction, starting with the oxidation of isocitrate to oxalosuccinate (a ketone) which is further decarboxylated, forming alpha-ketoglutarate. Pro-neoplastic mutations of IDH1 and IDH2 are typically observed in a large number of brain tumors, including astrocytomas, oligodendrogliomas and secondary glioblastomas, and are among the most frequent mutations (about 20%) in acute myeloid leukemia (AML). Although rare, IDH1/2 mutations also occur in osteosarcoma, intrahepatic cholangiocarcinoma, prostate and colon cancer. Instead, it has to be mentioned that no cancer-associated mutations in IDH3 subunits have been identified. Nevertheless, upregulation of IDH3 subunit α was shown to potentiate tumor growth, metabolic reprogramming and angiogenesis and was associated with reduced overall survival in patients with lung or breast cancer. Based on this evidence, it is conceivable that inactivation of NAD^+-dependent IDH3 would be detrimental for mitochondrial homeostasis and cancer survival, differently form mutations of $NADP^+$-dependent IDH1 and IDH2 enzymes. A potential explanation may lie in the key role of IDH3 in the TCA cycle, where it irreversibly catalyzes the first reaction deputed to the production of the electron carrier NADH. IDH3 critical relevance in the TCA cycle is also suggested by its tight regulation by substrate availability (i.e., isocitrate and NAD^+) and inhibition by ATP, α-KG and NADH. On the contrary, IDH2 and IDH1 contribution to mitochondrial energetic homeostasis is only partial as they produce α-KG, permitting TCA cycle to run, but in combination with NADPH instead of NADH. Moreover, IDH1/IDH2-catalyzed reaction is reversible allowing the reductive carboxylation of α-KG in isocitrate, which, once converted in citrate by ACO1/ACO2, can contribute to anabolic pathways together with NADPH.

IDH1/2 mutations mainly occur at substrate-binding amino acid residues, specifically Arg-132 of IDH1 and Arg-140 or Arg-172 of IDH2, and are somatically acquired. Moreover, the occurrence of IDH1 mutations in low grade gliomas is more frequent than IDH2 mutations, while both defects have a similar incidence in AML. The phenotypic outcome of IDH1/2 mutations is a neomorphic activity leading to the formation of D-2-hydroxyglutarate (D-2HG). Human cells normally produce low levels of D-2HG, mainly by the activity of D-3-phosphoglycerate dehydrogenase (PHGDH), but its accumulation is impeded by its conversion to α-KG through the FAD-dependent 2-hydroxyglutarate dehydrogenase (D2HGDH). In the case of IDH1/2 mutations, the accumulation of D-2HG is massive, reaching about a 50-fold increase and therefore it acts as an oncometabolite. Interestingly, the acquired mutation is heterozygous, permitting IDH enzymes to retain also wild-type activity. This mutational status is suitable for cancer cells, which can take advantage of D-2HG side effects in combination with canonical IDH1/2 activity highly useful for tumor-related anabolic reactions.

Experimental in vitro models based on either the use of cell permeable forms of D-2HG or overexpression of IDH mutants demonstrated their negative impact on cell differentiation in a wide panel of cell lines, including immortalized astrocytes or neuronal stem cells. This evidence, coupled with the early identification of IDH1 Arg-132 mutation in low-grade diffuse astrocytomas and oligodendrogliomas, actually supports a leading role of this TCA cycle aberration in glioma pathogenesis. However, the sole IDH1 mutation is not sufficient to trigger tumorigenesis in in vivo mouse models and it is frequently associated with secondary genetic alterations in human gliomas, particularly p53 and ATRX mutations or 1p/19q deletions. Similar evidence has been also collected for IDH2 mutations in leukemogenesis, as expression of mutant IDH in mouse myeloid progenitor and primary hematopoietic bone marrow cells was associated with a very low prevalence of myeloproliferative-like neoplasms or lymphoma. The long latency of these manifestations and the cooccurrence in AML patients of IDH2 aberrations with other frequent mutations in NPM1, FLT3, and DNMT3A also indicate a pivotal but synergistic effect of IDH2 mutants to tumor initiation.

Metabolic consequences arising from IDH1/2 mutations mainly consist in a preferential utilization of glutamine to feed the TCA cycle and in a reduction of NADPH production mining redox balance and antioxidant response. Beyond these events,

pro-tumorigenic properties of D-2HG largely rely on the competitive inhibition of several classes of α-KG–dependent dioxygenase enzymes, which impinge on epigenetic regulation, DNA damage response and hypoxia signaling.

Epigenetic modifications mediate a coordinated control of genome information regulating transcriptional programs in response to both extrinsic and intrinsic cues. Altered epigenetic regulation is a key feature of cancer cells that highly contributes to repression of tumor suppressor genes as well as activation of oncogenes. IDH1/2 neomorphic activity negatively impacts the Ten-eleven-translocation (TET) family enzymes, which act on DNA epigenetic modifications, and lysine demethylases (KDM) containing the Jumonji C domain, which instead act on histone lysine residues. The TET family members (TET1, TET2, and TET3) are α-KG/Fe (II) dioxygenases involved in DNA demethylation processes, driving the active removal of 5-methylcytosine (5mC), which generally mediates transcriptional silencing when present at gene promoters. This TET-dependent mechanism is accomplished through the sequential oxidation of 5mC into 5-hydroxymethylcytosine (5hmC), 5-formylcytosine and 5-carboxylcytosine followed by active excision of modified base through DNA repair pathways. Therefore, the inhibition of TET enzymes due to accumulation of D-2HG actually induces DNA hypermethylation. In particular, a specific subset of gliomas exhibited conserved DNA methylation changes at specific loci, a phenomenon strongly associated with the presence of IDH1 mutations and termed as DNA hypermethylator phenotype. The same picture was also identifiable in AML patients bearing IDH1/2 mutations resulting in impaired differentiation of hematopoietic cells. This was largely ascribable to DNA methylation-mediated transcriptional repression of genes that favor expansion of progenitor cell. Consistently, the use of inhibitors affecting DNA methyltransferases induced cell differentiation reversing the DNA hypermethylated phenotype.

Concerning histone methylation, the transcriptional outcome of D-2HG-mediated inhibition on KDMs is not predictable as it depends on the specific lysine residue targeted. For instance, histone H3 lysine 9 trimethylation (H3K9me3), as well as histone H3 lysine 27 trimethylation (H3K27me3), are associated with inactive chromatin state while histone H3 lysine 4 trimethylation (H3K4me3) is a mark of permissive chromatin. In particular, a high affinity for D-2HG was demonstrated for the H3K9 demethylases KDM4A and 4C, the inhibition of which induced accumulation of H3K9me3 associated with defects in differentiation of lineage-specific progenitor cells into terminally differentiated cells. An indirect effect of KDM4A/B inhibition by D-2HG is persistence of DNA double-strand breaks due to impaired repair via homologous recombination. In fact, those demethylases contribute to chromatin remodeling necessary for the recruitment of DNA repair factors at sites of DNA damage. On the other side, a direct influence of IDH mutants on cell sensitivity to alkylating agents can be recognized due to inhibition of α-KG-dependent alkB homolog (ALKBH) DNA repair enzymes, which reverse alkylation of DNA bases including 1-methyladenine and 3-methylcytosine.

A complete different scenario in IDH1/2-mediated tumorigenesis involves the regulation of hypoxia signaling through the inhibition of important modulators of hypoxia-inducible factors (HIFs) 1 and 2, oxygen sensors transcriptionally involved in the regulation of multiple pathways. HIF signaling actually orchestrates angiogenesis, metabolism, proliferation and cell death pathways in order to restore oxygen homeostasis. Due to the limited availability of oxygen, especially in solid tumors, HIF proteins are frequently stabilized in cancer. HIF1 and HIF2 proteins are heterodimers composed of a common and stable subunit (HIF-1β) and a specific α subunit (HIF-1α and HIF-2α), the stability of which is highly regulated by hydroxylation catalyzed by two class of α-KG/Fe(II)-dependent dioxygenases. In normoxic environments, prolyl hydroxylase domain proteins (PHD1 and 2) and the asparaginyl hydroxylase activity of factor inhibiting HIF (FIH) modify HIF proteins targeting them for proteasomal degradation by means of the von Hippel-Lindau protein (pVHL) complex E3 ubiquitin ligase. Considering this, the accumulation of D-2HG can induce the inhibition of PHDs and/or FIH with subsequent stabilization of HIF proteins independently of oxygen availability, a condition referred to as "pseudohypoxia." However, the consequences of IDH1/2 mutations on hypoxia signaling seem more complex and controversial. In fact, a number of studies demonstrated a reduction of HIF stabilization, a dampened signaling following D-2HG-mediated inhibition of FIH and, even more, only a weak inhibitory effect on PHDs.

α-KG Dehydrogenase Complex

The α-KG dehydrogenase complex (α-KGDHC) is the fourth enzyme of the TCA cycle performing the decarboxylation of α-KG to succinyl-CoA. The α-KGDHC consists of three multirepeated enzymes, each one implicated in a specific reaction. The E1 enzyme is encoded by the *OGDH* gene and is the proper dehydrogenase catalyzing the decarboxylation of α-KG requiring thiamine pyrophosphate (TPP) as cofactor. The transfer to CoA and the final reduction of NAD^+ to NADH to generate the end product (succinyl-CoA) are respectively carried out by the E2 (dihydrolipoamide succinyl-transferase, DLST) and the E3 (dihydrolipoamide dehydrogenase, DLD) enzymes. As for CS, the reaction catalyzed by α-KGDHC is irreversible.

To our best knowledge, no report has described changes either in the expression or in the activity of α-KGDHC in cancer to date. However, a role for α-KGDHC in cancer can be conceived, mainly based on the evidence that α-KGDHC activity can be influenced by cancer-associated conditions. In fact, α-KGDHC activity strongly relies on thiamine (vitamin B1) availability. Thiamine is an essential water-soluble vitamin, critical for the activity of α-KGDHC, but also of pyruvate dehydrogenase, transketolase and branched chain α-keto acid dehydrogenase complex. Its conversion to the active coenzyme TPP is performed by thiamine pyrophosphokinase-1 (TPK1) upon intracellular transport. Thiamine uptake is performed by the thiamine transporter SLC19A3, whose decreased expression has been extensively demonstrated in breast, gastric and colon cancer as consequence of hypermethylated promoter. It is noteworthy mentioning that SLC19A3 expression results recovered upon hypoxic stimulation in breast cancer cells and this effect was ascribed to HIF-1α. Indeed, results obtained upon HIF-1α knockdown support the evidence that SLC19A3 could be an additional gene involved in the metabolic rewiring during hypoxic stress. In addition to this, a significant decrease of

TPP in patients with advanced stages of nonsmall cell lung cancer was observed in whole blood and a concomitant increased thiamine urinary excretion was also assessed in cancer patients. Thus, it is enticing to hypothesize that decreased thiamine levels in cancer could impair α-KGDHC activity.

α-KGDHC is both generator (by the E3 subunit) and target of reactive oxygen species (ROS). Notably, as many aspects of tumor initiation/progression implicate increased ROS production and/or signaling, it is tempting to speculate that α-KGDHC-mediated ROS production could contribute to the redox-dependent transduction pathways that control cell cycle progression and growth of cancer cells. On the other hand, excessive oxidative stress can impinge upon α-KGDHC reaction without a complete inactivation, contrarily to ACO2 activity, which is totally inhibited. In this scenario, ACO2 sensitivity to ROS impedes the first reactions of the cycle to occur and thus the anaplerotic derivation of α-KG from glutaminolysis becomes indispensable to guarantee TCA cycle flux. Based on this, α-KGDHC can be considered the driving force of the TCA cycle upon oxidative stress and a critical junction with glutaminolysis.

Importantly, a recent study uncovered a role for DLST in MYC-mediated leukemogenesis. Indeed, inactivation of the enzyme resulted in delayed tumor onset in a zebrafish model of MYC-mediated tumorigenesis and decreased cell viability and induction of apoptosis in human T-cell acute lymphoblastic leukemia cell lines. Moreover, recent insights have envisaged that OGDH activity could be used as marker for metabolic classification of cancer cell lines in subsets. In addition, α-KGDHC inhibition has been associated with altered autophagic signaling, an important process involved in the maintenance of cancer cell homeostasis. Altogether, these findings lend support for further investigation of α-KGDHC role in cancer.

Succinyl-CoA Synthetase

SCS, also known as succinyl CoA ligase (SUCL), is the fifth enzyme of the TCA cycle. The protein is a heterodimeric enzyme, the α subunit of which, encoded by the *SUCLG1* gene, couples the reversible conversion of succinyl-CoA to succinate bringing to the formation of a nucleoside triphosphate molecule (either GTP or ATP). The β subunit is encoded by either the *SUCLG2* or the *SUCLA2* gene, determining the specificity for GDP or ADP, respectively.

To date, no evidence about the presence of mutations in the genes coding for SCS subunits in cancer has arisen yet. However, a deleterious homozygous mutation in the *SUCLG1* gene has been detected and associated with a lethal neonatal disorder known as fatal infantile lactic acidosis (FILA). In particular, this metabolic disorder is characterized by lactic acidosis, ascribed to forced ATP production by glycolysis as effect of impaired TCA cycle. As this phenomenon is overlapping with the cancer-associated metabolic feature known as "Warburg effect", it is conceivable that *SUCLG1* mutation(s) -or at least its down-regulation- could be possible candidate(s) in the modulation of cancer metabolic rewiring. However, no data exist in this regard. In this scenario, down-regulation of *SUCLA2* in prostate malignancies has been related to altered metabolic flux and increased levels of succinate, whose role as oncometabolite will be discussed in the next sessions. In addition, though no mutation in *SUCGL2* has ever been described (and, for this reason, likely referred to as lethal), *SUCLG2* knockdown has been shown to markedly impair growth in fibroblasts. This could be an interesting starting point for unraveling putative *SUCGL2* role(s) in cancer. In this regard, the only evidence available concerns the diverse *SUCLG2* expression in thyroid follicular carcinoma and follicular adenoma as biomarker for diagnostic distinction of the two cancer types. However, no relevance for therapeutic treatments was disclosed.

Succinate Dehydrogenase

SDH complex, also designated as succinate: ubiquinone oxidoreductase or mitochondrial complex II, is the bridge enzyme between the TCA cycle and the ETC. SDH catalyzes the sixth step of TCA cycle, that is the oxidation of succinate to fumarate with the reduction of ubiquinone to ubiquinol. The enzyme is heterotetrameric and composed of four subunits. The flavoprotein SDH-A and the iron'sulfur protein SDH-B are the two catalytic subunits, while SDH-C and SDH-D are the hydrophobic membrane-anchoring subunits also deputed to ubiquinone binding for ETC reactions.

Germinal *SDH* mutations have been implicated in increased occurrence of several neuroendocrine tumors, including hereditary paraganglioma (PGL) and pheochromocytoma (PCC). *SDH-B* mutations commonly cause type-4 PGLs (PGL4), including familial adrenal PCC. Malignant PGLs deriving from *SDH-B* mutations are commonly extra-adrenal (i.e., metastatic), such as abdominal and thoracic PGLs. Moreover, *SDH-B* mutations have been related to serous ovarian cancer, gastrointestinal stromal tumor (GIST), and familial renal cancer carcinoma (RCC). More than 30 mutations on the *SDH-C* gene have been found to increase the risk of type-3 PGL (PGL3). *SDH-D*-related tumors are typically benign type-1 PGLs (PGL1) and originate in head and neck (HNPGLs). Different *SDH-D* mutations have been found in people with the Cowden syndrome, which is characterized by multiple tumor-like lesions defined hamartomas and by predisposition to certain cancer types. Markedly, *SDH-D* gene is located in a hotspot locus on chromosome 11q23 which is commonly mutated in many types of cancer, including bladder, breast, lung, ovary and nasopharyngeal tumors. Furthermore, mutations in *SDH-D* have been found in individuals with GIST. The link between *SDH-A* mutation(s) and PGL/PCC is instead very weak as only one heterozygous germline *SDH-A* mutation has been identified in a rare malignancy known as catecholamine-secreting abdominal paraganglioma. Interestingly, germline loss-of-function mutations on the *SDHAF2*/*SDH5* gene, encoding for the mitochondrial protein needed for flavination of the SDH-A subunit, have been

implicated in hereditary type-2 PGL (PGL2). To date, it remains unclear whether the effect of *SDH* mutations are causative of papillary thyroid cancers, adrenal neuroblastoma or colon cancer.

The compromised -or completely lost- enzymatic activity driven by *SDH-x* mutations tightly affects the electron flow to ubiquinone, which is indispensable for electron transfer through the ETC. The main outcome of such alteration is the wrecked reduction of oxygen which promotes increased production of superoxide anion ($^{\bullet}O_2^-$), an oxygen reactive species, in mitochondria. Elevated $^{\bullet}O_2^-$ implicates augmented oxidative stress which results in protein carbonylation, DNA damage (by conversion of deoxyguanosine to 8-OH-deoxyguanosine), decreased mitochondrial membrane potential and structural changes in mitochondria. Consistently, a single Val-69 mutation in SDH-C has been suggested to promote a tumor-like phenotype in murine fibroblasts and to support tumorigenesis as consequence of $^{\bullet}O_2^-$-derived oxidative stress.

An additional consequence of mutations in *SDH* genes is the abnormal increase of succinate levels. Accumulation of succinate transforms it in an oncometabolite impinging on α-KG-dependent dioxygenase enzymes due to structural similarity with α-KG. As in the case of D-2HG produced by IDH mutants, the main target of succinate is the activity of epigenetic enzymes. Indeed, SDH-mutated PGL/PCCs exhibit low levels of 5hmC, giving rise to a hypermethylated DNA profile, and elevated histone H3K27 methylation, supporting the evidence that succinate inhibits both TET- and KDM-mediated demethylation. Coherently, chromaffin cells from *Sdhb* knock out (KO) mice have been demonstrated to possess higher 5mC/5hmC ratio with respect to wild-type cells, and this effect was reversed by exogenous addition of α-KG, revealing that succinate inhibition of α-KG-dependent dioxygenase occurs in competitive manner. Furthermore, reduction of 5hmC levels was also ascribed to nuclear exclusion of TET1 in *SDH*-deficient tumors. Interestingly, tumors harboring *SDH-B* mutations are characterized by a higher methylation profile across CpG islands than other *SDH*-mutated cancers. This could suggest that SDH-B activity is prevalent with respect to other SDH subunits fostering higher succinate accumulation and more relevant α-KG-dependent dioxygenases inhibition. Moreover, *SDH-B* mutations confer a peculiar more aggressive and metastatic phenotype. In this regard, SDH-B silencing has been also demonstrated to contribute to epithelial-to-mesenchymal transition (EMT) of mouse ovarian cancer cells by high histone methylation, in this case dependent on up-regulation of genes involved in S-adenosyl methionine (SAM) metabolism, the methyl donor of histone and DNA methyltransferase enzymes.

Similarly to *IDH*-mutated cancers, also *SDH*-deficient tumors display a HIF-dependent activation of a "pseudohypoxic" response. Indeed, as for TETs and KDMs, succinate can also inhibit the activity of PHD, resulting in HIF-1α stabilization. As the outcomes of HIF-1α stabilization by succinate in *SDH*-mutated cancers are very similar to those arising from fumarate accumulation in *FH*-related tumors, the concerning phenomena will be comprehensively described in the next session.

Fumarate Hydratase

FH, encoded by the *FH* gene, is the seventh enzyme of the TCA cycle performing the reversible hydration of fumarate to L-malate. Germline mutations can be found throughout the *FH* gene with consequent expression of inactive or even total loss of the enzyme. *FH* mutations strongly predispose to multiple cutaneous and uterine leiomyomas (MCUL) and to hereditary leiomyomatosis and renal cell cancer (HLRCC), including type-2 papillary renal cell cancer (PRCC2), with aggressive phenotype and untimely metastatization. Whole-exome sequencing has revealed, in an international cohort of patients, that *FH* mutations also bias for malignant PCC and PGL occurrence, with a SDH-like molecular phenotype. Moreover, some evidence supports that *FH* mutations might also be involved in the pathogenesis of breast, bladder and testis cancer. Importantly, beyond germline mutations, a decreased expression prolife of *FH* has been detected in some cancer types, including brain cancer, lung cancer, gastric cardia cancer (GCC) and sporadic renal cell cancer (RCC).

FH-deficient kidney cancers are characterized by a metabolic shift to aerobic glycolysis. Indeed, kidney cancer cell lines display enhanced glycolytic rate in order to overcome the impaired oxidative phosphorylation. In this context, increased expression levels of the glucose transporter *SLC2A1*/*GLUT1*, hexokinase 2 (*HK2*), pyruvate kinase (*PK*) and the vascular endothelial growth factor (*VEGF*) have been documented. In this scenario, glucose addiction of HLRCC may justify both the ATP production and the sustained proliferation rate of kidney cancer cells. The increased expression of the aforementioned genes in HLRCC can be explained by stabilization of HIF-1α. In fact, *FH*-mutated tumors, together with *SDH*-mutated ones, induce pseudohypoxic response due to accumulation of intracellular fumarate as the main outcome of FH deficiency. Consistently, high levels of fumarate, as D-2HG and succinate, can inhibit the activity of the α-KG-dependent dioxygenases due to structural similarity to α-KG. As a matter of fact, both fumarate and succinate contribute to competitive inhibition of PHDs resulting in HIF-1α stabilization. Over the years, more detailed models for HIF-1α stabilization in HLRCC tumors have been proposed. Indeed, the increased glucose uptake upon FH deficiency has been associated with depletion of intracellular Fe^{2+}, a PHD necessary cofactor, as consequence of boosted ROS production due to massive NADPH oxidase activation. The ROS-mediated inhibition of PHD activity has been validated by a reduction of tumor formation upon antioxidant treatment in HIF-driven models of tumorigenesis. Another mechanism proposed for increased HIF-1α stabilization in *FH*-deficient kidney tumors relies on the altered cytosolic iron concentration coming from reduced expression levels (and protein activation, i.e., phosphorylation) of both α and β1 subunits of the cellular energy sensor AMP-activated protein kinase (AMPK). Though the molecular mechanisms underlying this down-regulation in HLRCC are still elusive and controversial, AMPK reduction stabilizes HIF-1α upon iron depletion. Moreover, FH-mediated AMPK reduced expression/activation also results in increased activity of ACC, the enzyme that triggers the synthesis of fatty acids, likely promoting cell growth and proliferation of tumors due to increased lipid building blocks availability.

The pseudohypoxic response deriving from FH inactivation in mice kidney was identified as causative for renal cysts formation, plausibly by increased cell proliferation. However, as renal cysts formation still occured in *Fh* KO mice with depleted *Hif1a*, the involvement of further molecular mediator(s) in these processes was conceived. Remarkably, fumarate is a thiol-reactive compound capable to react with the sulphydryl moiety of cysteine residues to produce 2-succinyl-cysteine. This reaction is documented as succination and alters the activity of many cysteine-containing proteins, among which is Kelch-like ECH-associated protein 1 (KEAP1). In PRCC2, KEAP1 is highly succinated preventing ubiquitination and degradation of its molecular partner nuclear factor (erythroid-derived 2)-like 2 (Nrf2). Coherently, Nrf2 targets are over-expressed in FH-inactivated tissues and its antioxidant signaling pathway was encouraged to promote renal cysts formation in FH-deficient mice, independently from HIF-1α-mediated signaling. Among the Nrf2 targets is *HMOX1*, the gene encoding for heme oxygenase, the enzyme that cleaves the heme ring to form biliverdin. *FH*-deficient murine kidney cells have been described to possess altered biosynthesis and degradation of heme, with high bilirubin excretion. This metabolic alteration is likely achieved through the accumulation of succinyl-CoA, the precursor for heme biosynthesis together with glycine, and is pivotal for maintaining mitochondrial functionality and mitochondrial NADH production. HMOX1 is a hot point target in HLRCC research since its inhibition has been demonstrated to be lethal for *FH*-inactive kidney cells.

It is noteworthy mentioning that there is no direct evidence indicating the dominancy either of Nrf2 or of HIF-1α pathway upon FH deficiency. Nevertheless, the activation of Nrf2 is a common feature of many cancer types, including PRCC2, lung, breast and colorectal cancers, and is mainly achieved by *Nrf2* gain-of-function mutations or *KEAP1* loss-of-function mutations. Importantly, the expression of constitutively active Nrf2 in embryonic renal cells showed severe and aggressive phenotype, thus revealing that Nrf2 activation could be oncogenic in kidney cancer.

Fumarate accumulation in *FH*-deficient tumors also implicates changes in the urea cycle. Indeed, the reaction of the argininosuccinate lyase (ASL) is reverted, promoting the production of argininosuccinate from fumarate and arginine. This metabolic alteration renders renal carcinoma cells auxotrophic for arginine and sensitive to arginine-depriving agents. On the basis of this, depletion of arginine has been proposed as novel therapeutic approach for renal carcinoma treatment.

Fumarate, similarly to succinate in *SDH*-deficient tumors, has been found to inhibit TET-catalyzed hydroxylation of 5mC in *FH*-deficient kidney cancer. Indeed, in vivo evidence supports the notion that fumarate accumulation markedly decreases 5hmC levels upon FH deficiency with outcome on transcriptional regulation. In this regard, lack of FH in both mouse and human cells has been linked to TET-mediated activation of EMT pathway via inhibition of the antimetastatic *mir-200ba429*. Overall, considering the well-characterized tumor suppressor function of TETs in several contexts, it is tempting to propose that fumarate- and succinate-mediated TET inhibition may contribute to the tumorigenesis of *FH*- and *SDH*-mutated cancers, respectively.

Interestingly, a methylome analysis performed in *IDH*-, *SDH*- and *FH*-mutated cancers has revealed that 17 genes are concordantly hyper-methylated and down-regulated in all tumors analyzed. This reveals a connection in the methylation profile of cancers carrying mutations in such genes, reflecting a similar inhibitory role for D-2HG, succinate and fumarate on epigenetic α-KG-dependent dioxygenases.

Malate Dehydrogenase

MDH2 is the eighth and last enzyme of the TCA cycle that reversibly couples the reduction of NAD^+ to NADH to the oxidation of L-malate to OA, thus permitting the launch of another cycle. Eukaryotic cells display two main isoforms of MDH. The first isoform, designated MDH2 and encoded by the *MDH2* gene, is located in the mitochondrial matrix and directly participates in the TCA cycle for L-malate oxidation. The second isoform, designated MDH1 and encoded by the *MDH1* gene, is cytosolic and coordinates the metabolic intersection between cytosol and mitochondria by the malate-aspartate shuttle.

Although limited information is available, a role for MDH2 in cancer has been envisaged. Indeed, *MDH2* has been proposed as new susceptible gene in PGL/PCC as a germline mutation in it, responsible for reduced gene expression, has been identified. Contrarily, elevated expression of MDH2 was depicted in different cancer types. High expression levels of MDH2 have been associated with resistance to chemotherapeutic agents both in prostate and in uterine cancer. Increased expression of both MDH2 and MDH1 was reported also in lung carcinomas. However, only high expression of MDH1 was associated with poor prognosis. In lung carcinomas and breast cancer, MDH1 displays a higher activity with respect to MDH2. This is aimed at supporting the increased glycolytic rate by NAD^+ regeneration, alternatively from the activity of the lactate dehydrogenase, the main enzyme involved in such process in glycolysis-addicted cancers.

Conclusions and Prospective Vision

The TCA cycle is a central metabolic hub funneling and redistributing metabolites with the ultimate aim of creating the electrochemical gradient necessary for ATP production in a normoxic environment. Beyond this classical standpoint, the TCA cycle has been demonstrated to be also engaged in hypoxic conditions. In this context, TCA cycle reactions produce reducing equivalents that can contribute to redox signaling instead of being used by respiratory complexes. Moreover, the generation of high-energy phosphates through substrate-level phosphorylation as well as of intermediates for macromolecule biosynthesis continues to be a prerogative of the TCA cycle. These features are largely managed by cancer cells to satisfy the metabolic demand necessary for proliferation and survival both in normal and hypoxic conditions. As described in this article, the induction of pseudohypoxic response is

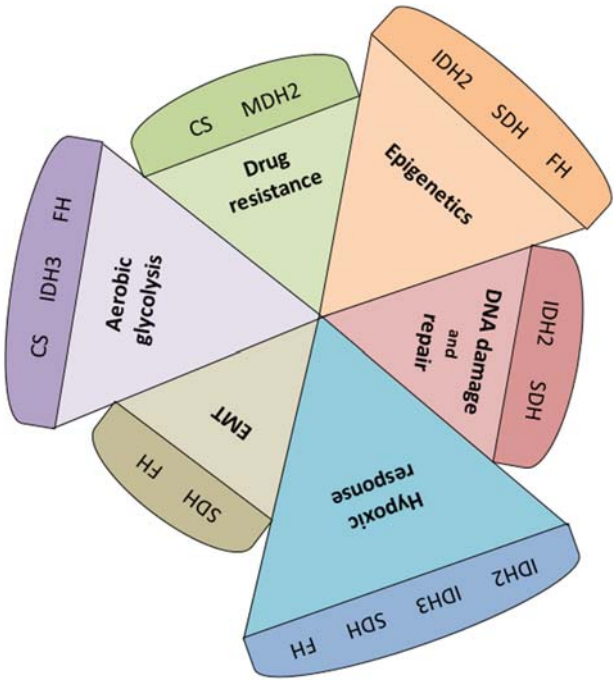

Fig. 2 *Effects of TCA cycle aberrations in cancer.* Each slide refers to the main events coming from the alterations of the enzymes of the TCA cycle in cancer. The different dimension of slides refers to the number of the enzymes involved in the described process.

a common trait of altered activity of several TCA cycle enzymes together with other cancer-related events, including epigenetic deregulation, drug resistance or metastatic potential (Fig. 2). Although outcomes of TCA cycle aberrations are shared among several enzymes, the complexity and dynamicity of the cycle do not simplify the selection of suitable enzymatic targets for cancer treatment. In this regard, the scientific community is now committed to the characterization and validation of metabolic antagonists to be employed in cancer therapeutics. Several approaches impinging on TCA cycle and its accessory pathways have been tested. An example is the use of glutaminolysis inhibitors in glutamine-addicted tumors. Interestingly, selective targetability of mutant metabolic enzymes has been recognized as a useful strategy for treatment of cancer patients. Promising results are being obtained in clinical trials for small molecule inhibitors targeting IDH1/IDH2 mutants in advanced solid tumors and hematological malignancy. In addition to the development of new efficient and safe molecules, future efforts should be addressed to the profiling of metabolic adaptations of each tumor in order to design personalized therapeutic plans based on metabolic inhibitors.

Telomeres, Telomerase, and Cancer

Kazunori Tomita and Laura C Collopy, University College London, London, United Kingdom

Glossary

Aneuploidy Abnormal and uneven number of chromosomes in a cell.
G-quadruplex Secondary structure made of four repeats that contains three guanines, forming three tandem G-tetrads.
Processivity Ability of polymerases to catalyze continuously on the substrate.
Senescence Cell status that is unable to re-enter cell division cycle.
Telomere crisis Activation of DNA damage response pathways caused by telomere shortening and loss of telomere protection.
Telomere length homeostasis Telomere maintenance achieved via stable equilibrium between telomere attrition and telomere addition by telomerase activity.
Telomeropathy Diseases associated with telomere shortening.

Nomenclature

ALT Alternative lengthening of telomeres
APB ALT-associated PML body
BFB Breakage-fusion-bridge
CTE C-terminal extension
DCs Dendritic Cells
DDR DNA-damage response
d-loop Displacement loop
DSBs Double-stranded breaks
FISH Fluorescence in situ hybridization
HDR Homology-directed repair
HR Homologous recombination
MMqPCR Monochrome Multiplex quantitative polymerase chain reaction
NHEJ Non-homologous end-joining
PARP Poly(ADP-ribose) polymerase
PML Promyelocytic leukemia
PNA peptide nuclei acid
ROS reactive oxygen species
RT Reverse-transcriptase
scaRNA Small Cajal body-specific RNA
STELA Single telomere length analysis
STORM Stochastic optical reconstruction microscopy
TEN Telomerase N-terminal
t-loop Telomere loop
TRAP Telomeric repeat amplification protocol
TRBD Telomerase RNA binding domain
TRF Telomere restriction fragment
T-SCE Telomere-sister chromatid exchange
t-stump Telomere stump
TWJ Three-way junction

Biology of Telomeres and Telomerase

Telomere maintenance is a hallmark of cancer and an essential factor for tumor propagation and immortality. This chapter will discuss how telomeres and telomerase function in cancer cells and the importance of telomeres as a potential target for cancer

therapies and a tool for cancer diagnostics. To understand the biology of telomeres and telomerase in cancer, it is first important to understand how they function in healthy cells. In this section, we introduce the concepts of chromosome replication and end protection, and summarize the structure and functions of telomeres and telomerase in humans.

The History of Telomere Discovery

In 1891, August Weismann suggested that: "Death takes place because worn out tissue cannot forever renew itself and because a capacity for increase by means of cell division is not everlasting but finite". This proved to be a remarkably prescient observation, made at a time before the concept of cellular aging existed. A number of milestone discoveries gave credence to this idea, beginning with cytogenetic studies in the 1930s. At this time, Hermann Muller began to reveal that the ends of linear chromosomes harbored special properties that distinguished them from DNA double-stranded breaks (DSBs). Using fruit flies, he examined how chromosomes responded to breakage induced by X-rays. He observed that, where DSBs were prone to rearrangement and fusions, the terminal ends of the chromosomes were exempt from these repair mechanisms. Although unsure of their significance, Muller termed these regions 'telomeres', from the Greek *telos* (end) and *meros* (component). At the same time, Barbara McClintock observed similar characteristic of chromosome ends in corn.

Moving into the 1960s, Leonard Hayflick described that normal somatic cells do not have an indefinite proliferative capacity. Rather, they divide approximately 50 times before undergoing a growth arrest, termed *replicative senescence*. In this state, cells are alive and can be maintained in culture yet remain irreversibly unable to divide. This is termed the 'Hayflick limit'; the number of times a cell can divide before undergoing senescence. Although the purpose of this growth limit was unknown at the time, it certainly echoed the idea of Weismann some 70 years earlier.

By the late 1970s, work was underway to sequence telomeric DNA, as Muller had initially predicted that a gene necessary for survival was located there, exempting telomeres from the repair mechanisms he had observed. Working in the ciliate *Tetrahymena thermophila*, Elizabeth Blackburn made use of their palindromic 'minichromosomes' which are relatively short and thus simpler to sequence. They discovered that they terminated in guanine-rich repeats with a 3′ end single-stranded overhang. Jack Szostak showed that *Tetrahymena* guanine-rich (G-rich) terminal sequence has an ability to protect linear DNA in yeast, proving Barbara and Muller's hypothesis. At a similar time, Alexey Olovnikov realized that chromosome ends had an issue when dividing; the end replication problem (**Fig. 1**). He described how a dead zone must exist at the ends of our DNA which cannot be replicated. He likened DNA to a train track with a train advancing, akin to the action of DNA polymerase. He suggested the enzyme must be unable to replicate the DNA beneath it at the very ends of chromosomes, analogous to the inability of a train to progress along the end of a track.

DNA is extended only in the 5′ to 3′ direction and thus cannot be copied where primers are laid down on the parental G-rich strand. Furthermore, both strands are processed to produce a sufficient length of the 3′ overhang to serve a structural purpose in end protection at chromosome ends (t-loop and shelterin formation, discussed below). Hence, each round of cell division results in the loss of 50–200 base pair from the ends of chromosomes (**Fig. 1**). Thus, rather than a crucial gene being situated at the chromosome ends, the repetitive telomeric sequence serves as an expendable source of DNA during replication. Consequently, telomeres get shorter with age. The Hayflick limit is therefore the number of divisions before telomeres become critically short. Hence, replicative senescence occurs to prevent the degradation of chromosomal DNA and telomeres act as a 'mitotic clock', defining the proliferative potential of a cell.

Telomeres must be replenished in certain cells, such as unicellular eukaryotes and stem and germ cells in plants and animals, in order to maintain cell division. Telomerase is a ribonucleoprotein enzyme capable of counteracting telomere shortening and was first identified by Elizabeth Blackburn and Carol Greider. Telomerase synthesizes the telomeric G-rich strand using its own RNA template. A sensitive telomerase detection assay, celled telomeric repeat amplification protocol (TRAP), was developed to determine the level of telomerase activity in different cell types. Using this method, the group of Jerry Shay and Wood Wright showed that telomerase activity was very low in most human cells. They screened a number of cancer cell types and found 85–90% of cancers expresses telomerase to maintain their telomeres. Hence, tumors are able to evade replicative senescence in order to grow indefinitely; a fundamental feature of cancer.

Telomere Structure and Chromosome End Protection

T-loops

Human telomeres are composed of the double-stranded 'TTAGGG' DNA repeats that span 5–10 kilobases (kb) in humans, and terminate at the 3′ end in a single-stranded G-rich overhang, or G-tail, which is approximately 130–210 bases in length. Telomeric DNA is folded and structured in such a way as to ensure chromosomes are fully protected and not inappropriately recognized as a broken fragment of DNA (**Fig. 2**A). The 3′ tail coils back on itself to form a 'telomeric loop', or *t-loop*. The end reaches the telomeric double-stranded DNA (dsDNA), imbedding itself to form a 'displacement loop' (or *d-loop*). This lariat-like structure effectively seals off the chromosome end in a protective manner and explains the differences Muller observed earlier, between DSBs in the DNA and the terminal ends. The t-loop configuration formed was first revealed in vitro and its existence later proved in cells using stochastic optical reconstruction microscopy (STORM).

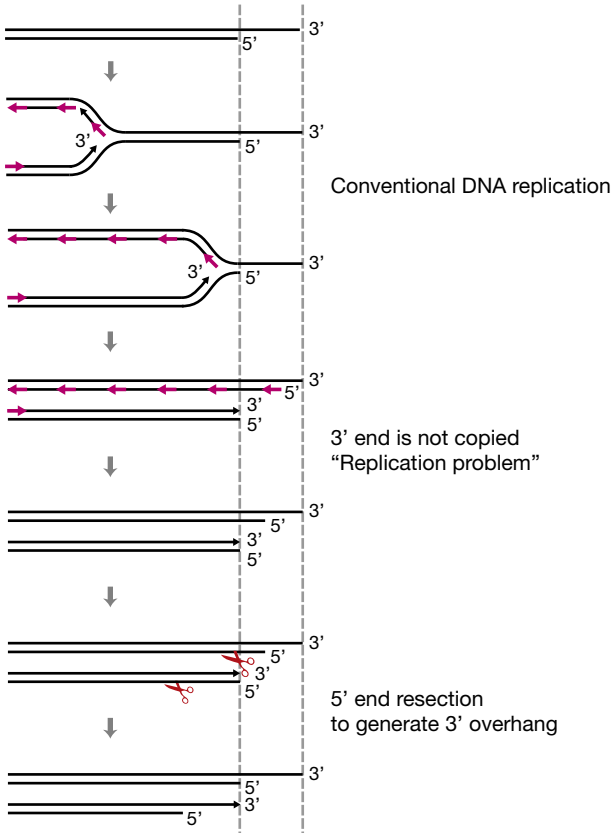

Fig. 1 Telomere replication and the end replication problem. Schematic representation of semi-conservative chromosome end replication. The DNA strands containing 3′ and 5′ ends are replicated via lagging strand synthesis and leading strand synthesis, respectively. Magenta represents RNA primer; black allow represents DNA polymerization. The leading strand is fully copied but the lagging strand is unable to replicate the 3′ end region (classical replication problem or lagging strand problem). Since the leading strand end is blunt, the 5′ end is digested to generate the 3′ end (resection). Both leading strand and lagging strand ends are subjected to resection to produce a sufficient length of overhang in mammalian genomes. The resulting sister chromatids are shorter than the mother strands (leading strand problem).

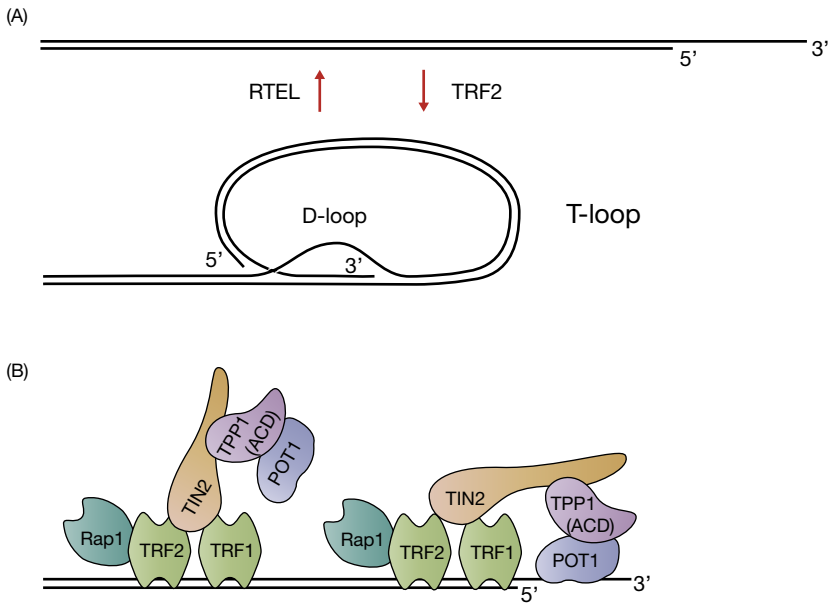

Fig. 2 Telomere structure. (A) Formation of t-loop. The telomeric dsDNA binding protein TRF2 promotes d-loop formation to form a lariat structure, termed telomere-loop or t-loop. The DNA helicase RTEL binds to TRF2 and dissolves the d-loop to expose the 3′ end overhang. (B) Telomeric proteins and shelterin formation. TRF1 and TRF2 bind to dsDNA and recruit TIN2. POT1 and TPP1 form a complex and are recruited to the telomere via TIN2 interaction. POT1 binds to telomeric ssDNA if available. Rap1 binds to TRF2.

The shelterin complex

The shelterin complex is made up of six family members that bind along the length of the telomere: TRF1 (*TERF1*), TRF2 (*TERF2*), RAP1 (*TERF2IP*), TIN2 (*TINF2*), TPP1 (*ACD*) and POT1 (*POT1*) (Fig. 2B). TRF1 and TRF2 bind to the telomeric dsDNA. They interact with TIN2, which recruits TPP1 and POT1. POT1 associates with the telomeric single-stranded DNA (ssDNA) at the 3′ overhang as well as at the d-loop within the t-loop structure. TRF2 controls the topology of telomeric DNA to aid t-loop formation. RAP1 binds TRF2 to support its function. Whereas TRF1 counteracts telomerase activity, the POT1-TPP1-TIN2 complex is essential for telomerase recruitment and activation. Thus, each shelterin protein has distinct roles in telomere maintenance.

If telomeres fail to interact with the shelterin complex and form t-loops, chromosome ends risk being recognized as damaged DNA ends. Interaction with shelterin serves to inhibit DNA damage response pathways to ensure senescent signaling pathways or apoptosis are not triggered. Furthermore, interaction with shelterin also facilitates DNA replication and prevents aberrant recombination events, which leads to genetic instability and aneuploidy, a key step in the development of cancer.

Regulation of DNA-Damage Response (DDR) Factors

Telomeric DNA is a repetitive sequence located at every end of chromosomes. Hence, DNA damage sensor proteins could potentially recognize telomere ends as DSBs. Activation of such DSB repair pathways must be avoided as it leads to chromosome end-to-end fusions or entanglements that cause chromosome segregation defects and catastrophic cell death during mitosis. The shelterin complex interacts with many DDR factors and serves to control the activation of DNA damage checkpoints as well as to suppress two major DNA DSB repair pathways: homologous recombination (HR) and non-homologous end-joining (NHEJ) (Fig. 3).

TRF2 directly binds to the kinase ATM (ataxia telangiectasia mutated) and a DNA repair complex called MRN (Mre11, Rad50 and Nbs1). By doing so, ATM and MRN are unable to activate p53 and H2AX (to generate γH2AX), which induce cell cycle arrest and trigger the DNA DSB repair pathways. TRF2 also binds to the Ku heterodimer complex, required for the canonical NHEJ (c-NHEJ) pathway. Interaction of TRF2 with Ku prevents downstream activation of ligase IV, crucial for the c-NHEJ pathway. TRF2-Ku also prevents activation of HR between sister chromatids (telomere sister chromatid exchange, T-SCE; described in the section: Alternative lengthening of telomeres/ALT). The shelterin protein RAP1 also plays a role in these inhibition activities. Shelterin formation itself and Ku redundantly suppress the alternative NHEJ pathway that utilizes micro-homology mediated DNA end-joining.

Like TRF2, the shelterin protein POT1 also has a role in repressing DNA damage response signaling. POT1 binding to telomeric ssDNA blocks the association of replication protein A (RPA), which recruits another DNA damage checkpoint kinase, ATR (ataxia telangiectasia and Rad3-related). The ssDNA-bound RPA can be replaced by RAD51, which plays a central role in HR. Therefore, POT1 inhibits the initiation of homology-directed repair (HDR). Importantly, recruitment of POT1 to the telomere requires the TRF2 analogue TRF1 and other shelterin components TIN2 and TPP1, highlighting the importance of the shelterin complex as a whole.

TRF1 binding to telomeric dsDNA is required for telomere replication. Lagging strand synthesis of telomeric dsDNA temporally exposes G-rich ssDNA, which can form a secondary structure termed a G-quadruplex. TRF1-bound BLM helicase removes such secondary structures to aid telomere replication. The stalled strand at the replication fork stall also recruit RPA and ATR, and ATR phosphorylates and temporary releases TRF1 from the telomere. Dissociation of TRF1 promotes recruitment of telomerase.

While telomeres are able to suppress DSB repair pathways, DNA single-strand breaks (SSBs), caused by factors such as reactive oxygen species (ROS), are repaired via the base excision repair pathway (BER). TRF1 interacts with tankyrase 1, a telomere-associated poly(ADP-ribose) polymerase (PARP). Enzymes of the PARP family covalently add polymers of ADP-ribose to modify

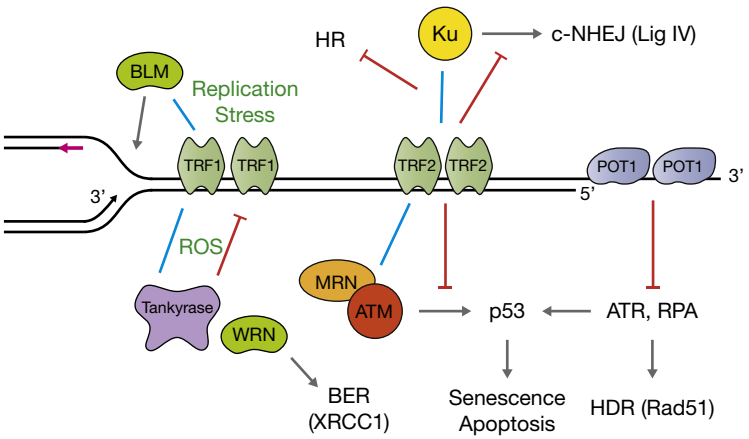

Fig. 3 Telomere protection. Schematic diagram of DDR control by telomeric proteins POT1, TRF2 and TRF1. POT1 binds to ssDNA and inhibits RPA and ATR, which activates p53 and Rad51 dependent HDR. TRF2 binds Ku to suppress HR and c-NHEJ. TRF2 also binds to MRN and ATM, which activate p53 and HR. TRF1 binding facilitates telomere replication by interacting with BLM. TRF1 also binds to tankyrase to efficiently repair telomeres damaged by ROS. PARylated TRF1 recruits WRN and BER factors including XRCC1.

proteins in a process called PARylation. Tankyrase 1 PARylates TRF1 and this stimulates the association of SSB repair proteins, including the Warner syndrome helicase WRN and XRCC1 to the telomere. PARylated TRF1 is then released from telomeric DNA and subjected to proteolytic degradation. Inhibition of tankyrase stabilizes TRF1, results in suppression of telomerase activity and telomere shortening. Mutation of WRN also accelerates shortening of telomeres. Thus, telomere protection mediated by TRF1 is crucial for telomere maintenance and protection from ROS.

When a telomere becomes critically short, it has fewer shelterin proteins bound along its length which may result in less efficient t-loop formation. In healthy cells, this situation can trigger the ATM/ATR pathways, leading to p53 activation and replicative senescence or apoptosis. This acts as a tumor suppressor mechanism as it prevents the cell from dividing further and leaves chromosome ends unprotected.

Telomerase Biogenesis and Telomere Addition

Telomerase assembly

The core component of telomerase is composed of a telomerase-specific RNA component, TERC, and a reverse transcriptase enzyme, TERT. Association of TERC and TERT alone is sufficient to extend telomeric DNA in vitro. However in vivo, telomerase requires several other components to be imported into the nucleus and recruited to the telomere to replenish telomeric repeats. TERC encodes a template sequence for telomeric DNA reverse transcription and recruits several RNA binding proteins to function in vivo.

In humans, TERC is 451 nucleotides in length, although this varies greatly between species. For example, the telomerase RNA molecule in fission yeast, TER1, is 1413 nucleotides long. TERC belongs to the family of small Cajal body-specific RNAs, termed scaRNAs. Although TERC is transcribed by RNA polymerase II, the 3′ poly-adenosine tail is enzymatically removed to produce a 'mature' molecule. Mature TERC has several domains, crucial for its stability and function (Fig. 4A). The 3′ end stem loop (the CR7-domain) contains a small motif called a 'Cajal body (CAB) box', which allows it to be recruited to small organelles called Cajal bodies. There is also an 'H/ACA box' within the scaRNA domain, which binds proteins to stabilize the RNA. The CR2/3 domain, also

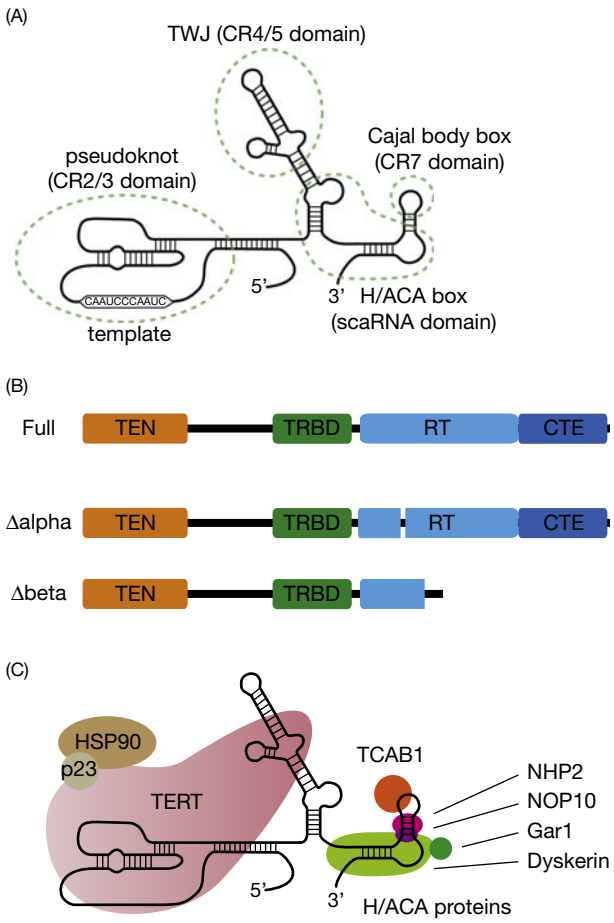

Fig. 4 Telomerase structure. (A) TERC contains 4 structural domains. CR = conserved region. (B) Schematic of the TERT protein with 4 domains and its major splice isoforms Δalpha and Δbeta. (C) Telomerase holoenzyme formation.

termed the *pseudoknot* domain, contains the telomeric C-strand template sequence 5′-CAAUCCCAAUC-3. TERT associates with TERC via the pseudoknot and the 'three-way junction (TWJ) domain' (or CR4/5). This assembly is required for its catalytic activity.

The telomerase catalytic subunit, TERT, contains four largely conserved domains; the N-terminal domain (TEN), the telomerase RNA binding domain (TRBD), the reverse-transcriptase domain (RT) and the C-terminal extension domain (CTE) (Fig. 4B). The RT and CTE domains together hold template RNA and substrate DNA hybrid duplex and are enzymatically essential for the reverse-transcription. The TRBD domain is required for stable association with TERC. The TEN domain is dispensable for enzymatic activity, but is required for telomerase recruitment and its processivity. Further, TERT associates with the chaperon proteins HSP90 and p23 at the TEN domain for its stability and telomerase activity in vivo. The TEN domain also contains a nuclear localization signal sequence and the mitochondrial targeting signal sequence, making it crucial for the correct localization of telomerase in the cell.

In order for the active telomerase complex to form, TERC must join together with TERT (Fig. 4C). For this to happen, mature TERC associates with four so-called 'H/ACA proteins' comprised of dyskerin, NOP10, NHP2 and NAF1, and traffics to the nucleolus. Here, TERC replaces NAF1 with GAR1 to become a stable and 'mature' form. TERT associates with p23 and HSP90 molecular chaperons and traffics to the nucleus where is assembles with TERC, forming the complete telomerase RNP. A mammalian conserved protein TEP1 associates with telomerase to aid telomerase activity. The pontin and reptin ATPases bind to both TERT and dyskerin during S-phase in order to aid the assembly of telomeres. However, they are excluded from the complex when telomerase becomes active. Finally, TCAB1 interacts with the TERC CAB-box motif when TERC has complexed with TERT. This facilitates its trafficking to the Cajal bodies where active telomerase can be stored.

Telomerase recruitment and processivity

Telomerase activity is controlled at multiple levels (Fig. 5). Telomerase localization to the telomere and telomere extension are observed only during S-phase. Outside of S-phase, chromosome ends are hidden from telomerase access and telomerase components are also modified or destroyed in a cell cycle-dependent manner. A helicase enzyme, RTEL1 (Regulator of Telomere Length 1), interacts with TRF2 only in S-phase. This recruitment specifically unfolds t-loop structures and exposes the telomeric 3′ end that serves as a telomerase substrate. During this time, Cajal bodies localize to the telomeres, facilitating the recruitment of mature telomerase where it can act.

Telomerase does not directly bind to telomeric DNA in vivo, instead binding to the shelterin protein TPP1 in order to dock at the chromosome end. TIN2 also mediates this recruitment of telomerase. Further association of TIN2-TPP1 with TRF1/2 or Pot1 is required for their telomere localization. Recruitment of telomerase is telomere-length dependent and is stimulated by local activation of ATM or ATR, which destabilize TRF1; telomerase preferentially extends shorter telomeres thereby maintaining an appropriate mean length.

Human telomerase is processive. This means that during telomere extension, TERT copies the template provided by TERC and, before dissociating from the telomere, repositions towards the 3′ end and proceeds to add additional repeats. This is a more efficient means of extending telomeres, and the rate at which it occurs is termed *processivity*. The telomeric ssDNA-bound TPP1 and POT1 complex aids this processivity by assisting in its repositioning to improve the efficiency of telomere elongation.

Telomerase activity must also be terminated. This is achieved by the CST complex (formed of CTC1, STN1 and TEN1). The CST complex associates with the polymerase α-primase complex to aid the restarting of the fork-stalled replisome as well as G-rich lagging-strand synthesis. CST interacts with POT1-TPP1 in late S/G2-phase, and is thought to replace telomerase and initiate lagging strand synthesis of the newly synthesized G-rich strand. This prevents telomerase from being recruited to the telomere and ensures an appropriate level of extension occurs.

Function of Telomeric Proteins and Telomerase outside the Telomere

Telomere function is not limited to chromosome ends (Fig. 6). Telomeric proteins locally establish a heterochromatic state. This means that the internal telomeric repeats are able to repress or modulate transcription. The shelterin protein RAP1 (repressor/activator protein 1) was first identified in budding yeast where it is known as a transcriptional regulator. Budding yeast Rap1 directly binds the telomeric DNA sequence and controls gene expression. Similarly, human telomeric proteins TRF2 and RAP1 appear to be involved in transcriptional regulation via their binding to internal telomeric repeats or interstitial telomeric sequence. TRF2 regulates neuronal gene expression during development and RAP1 controls transcription of metabolic genes in some tissues including the liver. In the cytoplasm, mammalian RAP1 is also an activator of NFκB signaling, by binding to IKKs activator kinases. NFκB signaling is responsive to stimuli including infections, cytokines and ROS, and has a crucial role in cancer development. Further, TIN2 can localize to mitochondria when it is not complexed with TPP1. Here it represses oxidative phosphorylation for ATP synthesis to reduce levels of ROS. Thus, telomeric DNA can store these signaling regulators, and their shortening may result in aberrant changes in metabolism, signaling and transcriptional regulation.

The function of telomerase in telomere lengthening is limited to a short time frame of the cell cycle. Away from telomeres, telomerase is also involved in regulation of RNA transcription. During development, the Wnt pathway activates the β-catenin coactivator to initiate transcription of Wnt response genes. TERT is predominantly expressed during embryonic development. Interestingly, TERT can co-localize with β-catenin and BRG1, a SWI/SNF-related chromatin remodeling factor, on promoters to modulate transcription. Similarly, TERT also promotes transcription of the NFκB signaling target genes by interacting with RelA, a p65 subunit of the NFκB complex. The significance of the ability of TERT to contribute towards transcription still needs to be validated.

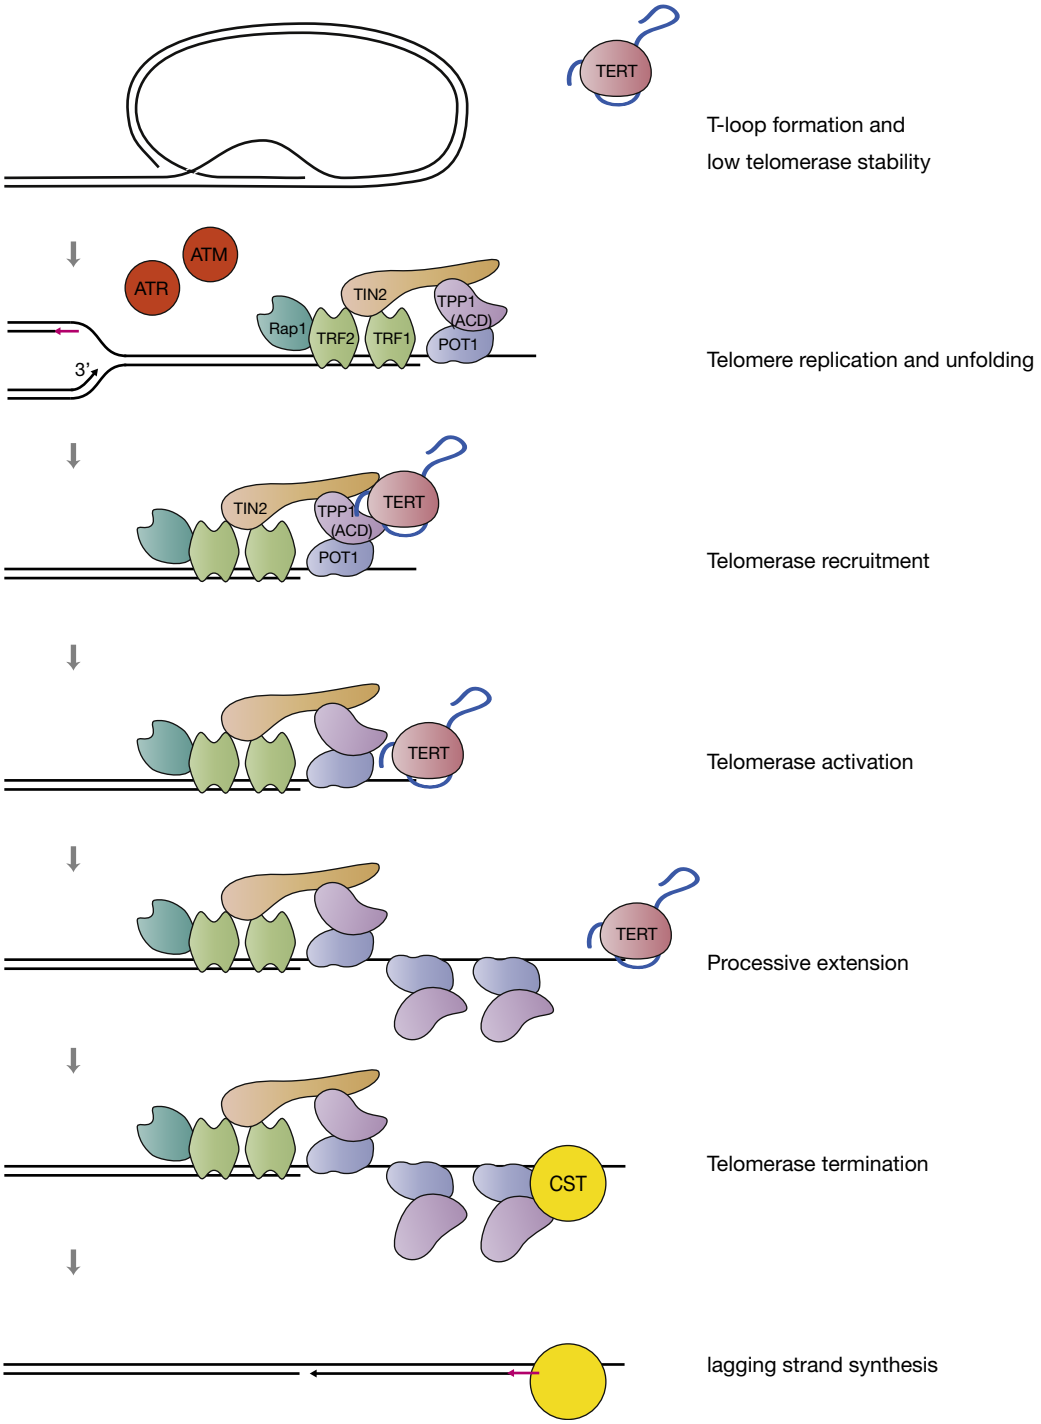

Fig. 5 Telomerase action. Schematic representation of telomerase action. Outside S-phase, telomeres are not extendible, presumably by t-loop formation. Telomeric 3′ ends are exposed during S-phase and bound by Pot1. Local and transient activation of the DDR checkpoint proteins, ATR and ATM, mark short telomeres that promote telomerase recruitment. TERT binds to TPP1 and is translocated to the tip of the telomere ssDNA via annealing of the RNA template region within TERC. Processive telomere G-strand synthesis is supported by the POT1-TPP1 complex. At later stages of S-phase, the CST complex is recruited to POT-TPP1 and terminates telomerase activity. CST recruits the polymerase α-primase complex to complete telomere extension.

TERT also travels to mitochondria. Upon oxidative stress, TERT is excluded from the nucleus and re-localizes to mitochondria. Mitochondrial TERT is involved in reducing ROS and the integrity of mitochondria. Here, TERT complexes but mitochondrial tRNA, and localizes to the mitochondrial matrix and binds to mitochondrial DNA. The functional significance of these activities at the mitochondria remains to be establish. Another intriguing function is the silencing of mitochondrial gene expression. TERT also

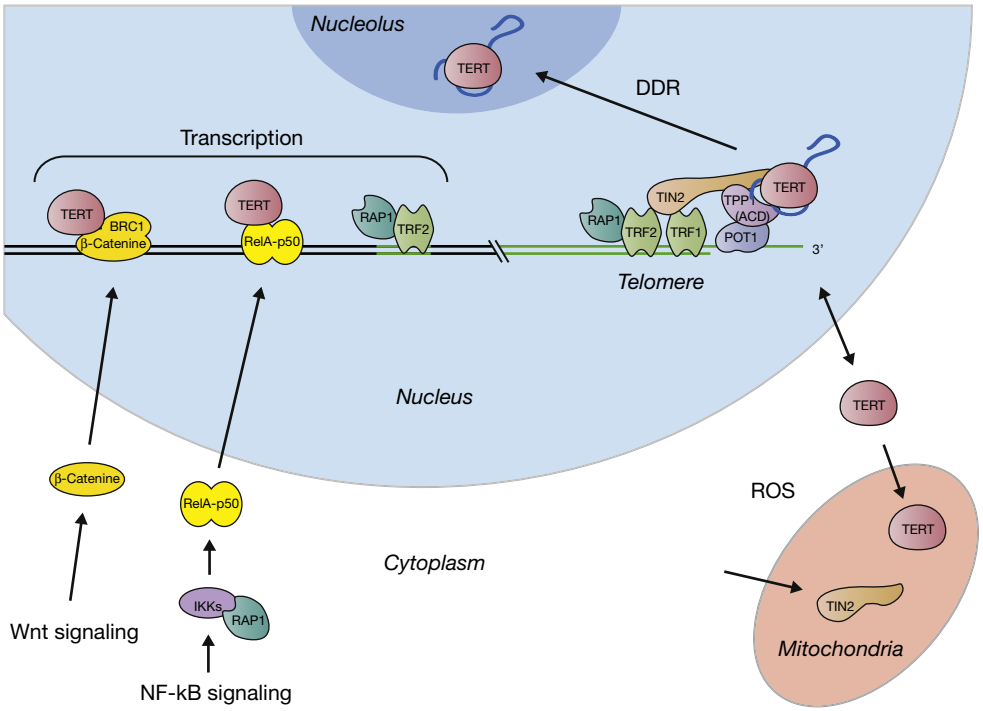

Fig. 6 Non-canonical functions of telomeric proteins and telomerase. Schematic diagram showing trafficking and non-canonical functions of telomeric proteins and telomerase. TERT is shuttled between the nucleus and the cytoplasm via its post-translational modifications. Upon DDR, telomerase accumulates in the nucleolus. TERT and TIN2 are trafficked to the mitochondria under ROS stimuli. Cytoplasmic RAP1 binds to IKKs to promote NFκB signaling. TERT associates with the NFκB (RelA and p50) and the β-Catenin complexes to facilitate gene expression. TRF2 and RAP1 localize to internal telomeric sequence loci and control local transcription.

complexes with the non-coding RNA subunit of mitochondrial RNA processing endoribonuclease, and functions as a RNA-dependent RNA polymerase, generating dsRNA from mitochondrial mRNA resulting in their degradation through an RNA interference pathway. All of TERT's functions in the mitochondria require its enzymatic activity but they are independent of TERC. These extra-nuclear activities are also observed in cancer cells.

Telomere Maintenance in Cancer

In this section, we summarize our current knowledge of telomere biology in cancer and how telomeres and telomerase can contribute to tumorigenesis and its evolution. Telomere maintenance is essential for cancer cells in order to sustain proliferation. However, paradoxically telomerase-expressing cancer cells often maintain very short telomeres. This can cause end-protection defects that activate DDR pathways, promoting chromosomal rearrangements and genetic instability, aiding cancer progression. The ability of telomeric proteins and telomerase to function as transcriptional modulators can also potentially contribute to tumorigenesis.

Maintenance of Short Telomeres in Cancer

Despite that fact that cancer cells express telomerase, many cancer cells, including glioma, colorectal, lung, breast and prostate cancers, maintain their telomeres shorter than normal healthy somatic cells (see the section: telomere length and cancer risk). The molecular mechanisms behind this phenomenon have not been fully elucidated. In normal cells, telomere length homeostasis is established by the balance between the degree of telomere erosion and the level of active telomerase expressed. Adult stem cells and progenitor cells can express TERT, but the level is insufficient to fully extend telomeres, so their telomeres still gradually shorten (Fig. 7). Only spermatocytes express high levels of telomerase and therefore maintain long telomeres. Hence, the regulation of telomerase in cancer, resulting in stably maintained short telomeres, must be different from telomerase regulation in normal cells.

Telomerase action in cancer

In cancer cells, telomerase is still carefully regulated and is only active during S-phase. Curiously, during S-phase, just 5–7% of telomeres associate with telomeres at any one time, however all telomeres get extended during cell division. Analysis of synchronized cancer cells suggested that telomerase can extend telomeres from the beginning of the S-phase, independently of the replisome and

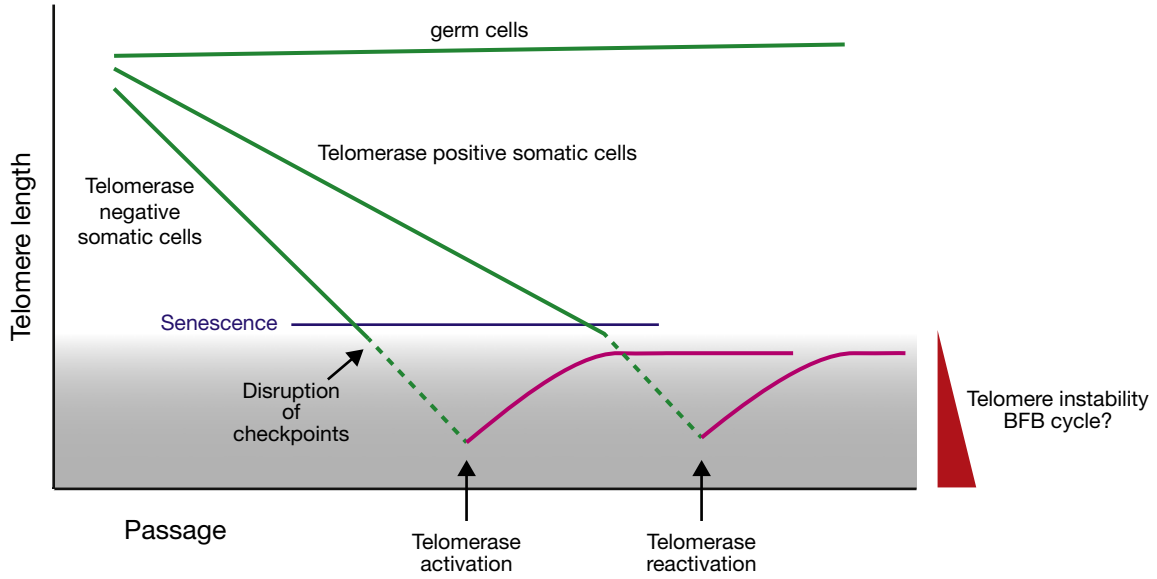

Fig. 7 Telomere shortening and crisis. Graph representing cell division-associated telomere loss and eventual telomere crisis and immortalisation. Y- and X-axis indicate length of telomeres and passage of cells, respectively. Telomeres are progressively shortened through generations until cells activate senescence checkpoint (*green line*). TERT positive cells display slower telomere shortening but eventually reach replicative senescence. Only germ cells maintain telomere length homeostasis. Cells that escape this cell cycle arrest system further lose telomere repeats (*green dotted line*). Shortened telomeres elicit DDR pathways, leading to BFB cycling (telomere crisis: *gray area*). Cells that gain the ability to maintain chromosome ends (by activation of telomerase) dominate and establish their lineage. Survivors retain short telomeres.

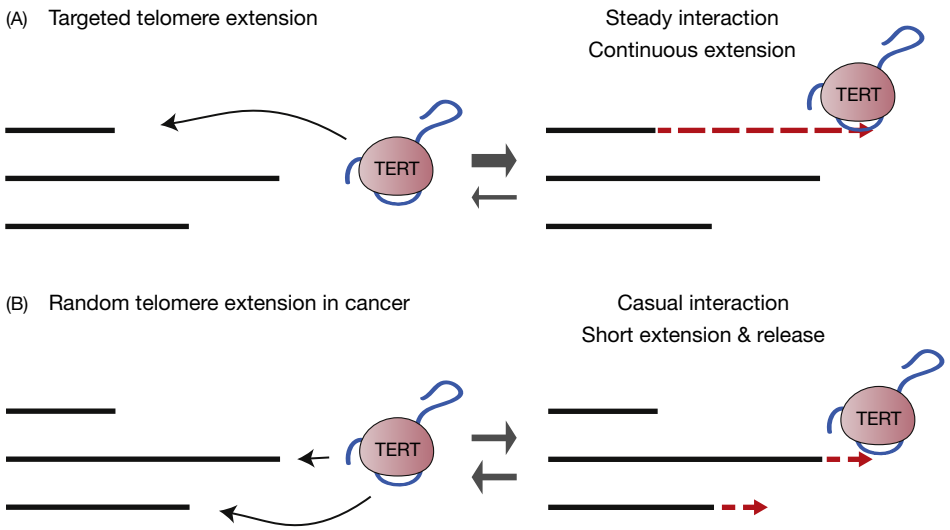

Fig. 8 Telomerase action in cancer. Schematic models depicting two modes of telomere length homeostasis in (A) normal and (B) cancer cells. (A) Telomerase is recruited to the shortest telomere and it is progressively extended until it is elongated. (B) Telomerase probes every telomere and randomly extend. Telomerase activity seems transient at the telomere. Images are adapted from Armstrong, C. A. and Tomita, K. (2017). Fundamental mechanisms of telomerase action in yeasts and mammals: understanding telomeres and telomerase in cancer cells. *Open Biol 7*.

the lagging strand synthesis complex. However, the number of telomeric repeats added is minimal, resulting in short telomere extension (Fig. 8). This is different from canonical telomerase activity, in which telomerase typically targets chromosomes with the shortest telomere. Nevertheless, telomerase appeared to repeatedly probe every telomere, thus achieving overall extension.

Some chromosomes in cancer cells have very short telomeres termed *t-stumps*, that are rarely found in normal cells. It is common in cancer to lose cell-cycle checkpoint proteins and this likely contributes to the failure of t-stumps to trigger replicative senescence. T-stumps appear to be capable of binding shelterin proteins and, to a certain degree, protecting the chromosome ends, allowing the cell to continue dividing. However, retention of critically short telomeres in cancer cells suggests that the ability of telomerase to selectively elongate only the shortest telomeres, is disrupted.

Telomere instability and the chromosome breakage-fusion-bridge cycle

Retention of t-stumps is likely beneficial for tumor growth due to the associated genetic instability driving cancer development. Failure to extend t-stumps leads to loss of protection of chromosome ends, a state termed 'telomere crisis'. This elicits activation of DDR pathways in an attempt to protect genomic integrity (Fig. 9). The cell cycle checkpoint is activated with remaining shelterin complex helping prevent chromosome fusions. However, chromosome end-to-end fusion (between sister chromatids or different chromosomes) can still occur, and the resulting fused dicentric chromosomes cause chromosome segregation defects. Breakage-fusion-bridge (BFB) cycles are initiated, whereby dicentric chromosomes break and undergo subsequent fusion events in a daughter cell. This can have several outcomes, including non-reciprocal translocations. This happens when a broken chromosome that has not undergone telomere repair, invades and copies part of another in a one-way transfer. Loss of heterozygosity can also occur when a dicentric chromosome breaks and lacks a large terminal region, potentially encompassing whole genes. Reactivated telomerase can seal broken chromosome ends and, when inherited by a daughter cell, lost chromosomal fragments result in gene deletion. This is a common occurrence in cancer and is especially damaging when tumor suppressor genes are lost. Thus, short telomeres in cancer cells provide sufficient chromosome stability for their propagation whilst generating diversity for selective pressure to allow further development of the tumor. Prolonged mitotic cell cycle arrest often triggers apoptosis or senescence, but can bypass the chromosome segregation phase and re-enter S-phase; this leads duplication of chromosomes.

Telomerase Expression and Carcinogenesis

The *TERT* gene is silenced in most cells, meaning that telomerase is not expressed and telomeres are programmed to shorten with age. Cancer progenitor cancer cells must gain the ability to maintain chromosome ends in order for them to propagate indefinitely. Although dependent on the type and subtype of cancer, most cancer cells express telomerase. Therefore, expression of TERT is a hallmark of cancer. However, it remains to be established how cancer precursor cells reactivate telomerase.

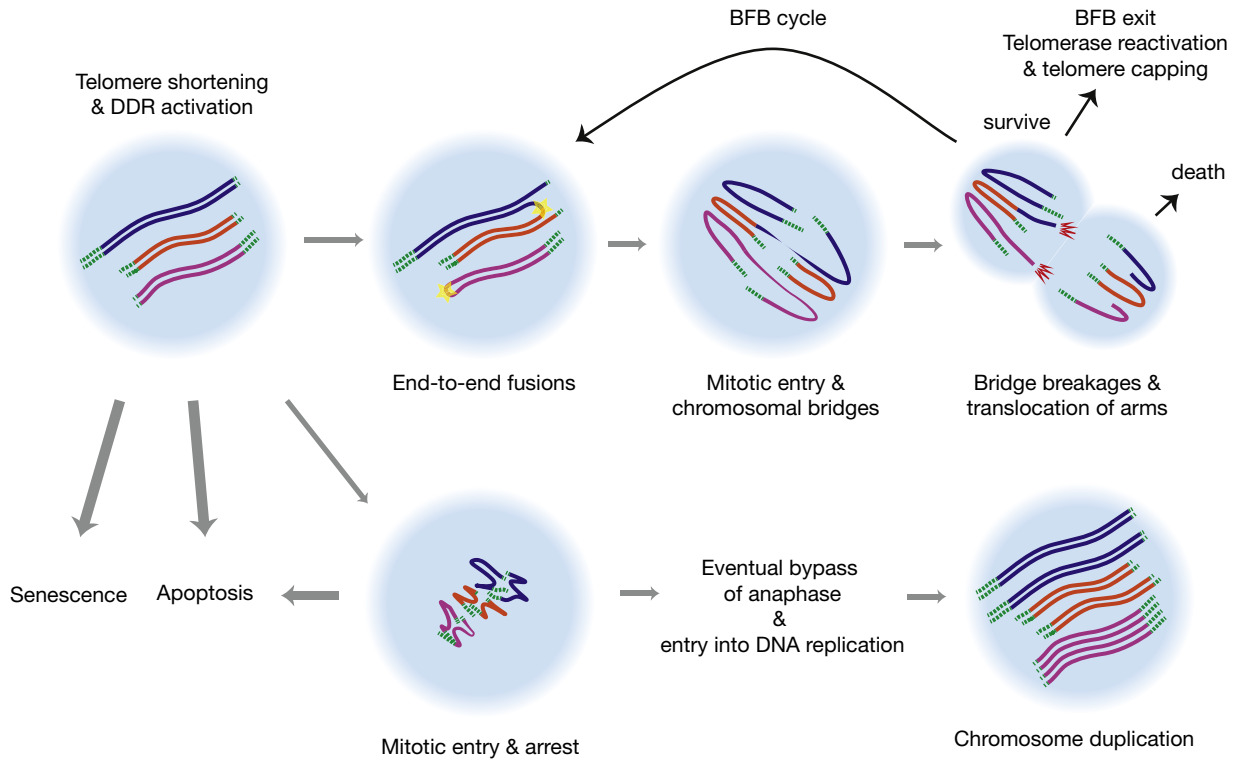

Fig. 9 Telomere-induced chromosome instability. Short telomeres activate persistent DDR and the senescence checkpoint to arrest cell cycle, leading to cellular senescence or apoptosis. Loss of telomere function allows chromosome end-to-end fusions. Chromosome segregation at mitosis can be stalled by catenation of two chromosomes during mitosis. Nucleases digest chromosome bridges to complete mitosis. This causes translocation of chromosomes and the generation of new telomere-free ends. A cell fuses the broken ends and moves to the next round of cell cycle. A cell that has lost a chromosome arm is likely to die. This, so-called "Breakage-fusion-bridge cycle" continues until the broken ends are capped by telomeres (by telomerase reactivation). Alternatively, cells that arrest in mitosis for extended periods can eventually evade the chromosome segregation phase. *Re*-entry of S-phase results in chromosome duplication.

Telomerase reactivation

The stage at which telomerase reactivation occurs in cancer remains unknown and is likely variable. One possibility is that it occurs at the time or following telomere crisis (Fig. 8). Early in tumorigenesis, the loss of tumor suppressor genes such as p53/p21 or the Retinoblastoma protein (Rb) allows the evasion of replicative senescence resulting in continued cell division. Telomeres become progressively shorter until the state of telomere crisis. Loss of telomere protection triggers genetic alterations (via constant BFB cycles). This results in the acquisition of spontaneous mutations and chromosomal rearrangements, including aneuploidy (another hallmark of cancer). As tumors develop, telomeres must be re-stabilized and recover from telomere crisis. Such selective pressure is believed to reactivate the *TERT* gene, permitting the continued growth of these aberrant, selected cancer cells. Hence, inactivation of the senescence checkpoints and consequent telomerase reactivation are crucial for cancer immortality. Most tumors require 4–6 critical mutations in order to become malignant. In the normal lifespan of a cell, this is unlikely to occur as pre-malignant cells undergo senescence before having the opportunity to develop into a cancerous tumor. Thus, the events of telomere crisis and telomerase reactivation result in the evasion of senescence and both allow the cell to continue dividing and enhance the rate of mutation.

TERT expression is tightly controlled through the action of transcriptional activation and repressor complexes. The *TERT* promoter is GC-rich and contains binding sites for various transcription factors, including two canonical *E*-boxes for the transcription factors, c-Myc and USF, and consensus sequences for ETS (E26-transcription-specific) family transcription factors. Importantly, NFκB and β-Catenin, which associate with TERT, are known to localize and promote transcription. c-Myc is also activated by β-Catenin. Hence, reactivated TERT protein may further enhance its transcription via NFκB and Wnt/β-Catenin pathways. Conversely, the tumor suppressor proteins p53 and p21 can negatively regulate *TERT* expression. Collectively, combination of transcriptional activator and repressor complexes appears to tightly control telomerase expression.

Cancer associated mutations within the TERT promoter

Analysis of the *TERT* promoter region in tumors from patients with different cancers has revealed some common mutations that correlate with *TERT* expression. The frequency of mutations within the promoter is considerably high in some cancer types. Common mutations are found upstream of the start codon at the −124 position and −146 positions, which in both cases represent cytosine to thymine changes (−124C/T and −146C/T respectively). These are seen in various cancers, including melanomas, glioblastomas, thyroid cancers, hepatocellular carcinomas and bladder and urothelial carcinomas. Mechanistically, both mutations generate additional ETS binding sequence. In addition, the -146A/C mutation also creates binding site for the NFκB complex. Another common mutation has been found at the −57 position, resulting in a change from adenine to cytosine (−57A/C). Site-directed mutagenesis studies using embryonic stem cells, whereby mutated stem cells were differentiated into fibroblast, suggested that the introduction of these mutations increased transcription 4–12 fold in differentiated mutant fibroblasts, compared to non-mutated fibroblasts. Among these mutations, −124C/T resulted in the highest transcription efficiency, where activity levels were comparable to those observed in cancer cells.

It is worth mentioning that mutations at the *TERT* promoter that enhance its expression have been observed at all stages in a number of cancers. These mutations can trigger the reactivation of telomerase expression and may do so at an earlier stage than telomere crisis; however, *TERT* expression alone is insufficient to maintain telomeres and does not promote carcinogenesis. Hence, additional oncogenic mutations that permit the evasion of cell cycle arrest/senescence pathways and accelerate the cell cycle must also occur in progenitor cancer cells during tumorigenesis.

TERT as an oncogene

Many scientists have attempted to create 'model' cancer cell lines from normal epithelial cells and fibroblasts. These stepwise cancer transformation studies have demonstrated that co-expression of three factors, an oncogenic mutant form of H-Ras (G12 V), the simian virus 40 Large T-antigen and TERT, is sufficient for malignant transformation of various differentiated cells. Induction of oncogenic H-Ras expression induces a replication defect at telomeric regions, leading to the induction of DDR pathways and cellular senescence (so called 'telomere dysfunction-induced senescence', TDIS). Large T-antigen in turn suppress p53 and RB activation. Enforced *TERT* expression then allows cells to evade senescence by facilitating telomere replication. Hence, TERT is able to support oncogenic H-Ras signaling to establish tumors.

Activation of the NFκB and Wnt/β-catenin pathways is known to promote tumor development. As TERT complexes with NFκB and β-catenin for transcription, contribution of TERT in tumorigenesis is anticipated. Moreover, TERT associates with the RNA polymerase III complex and promotes expression of tRNAs. This enhances translational capacity, enabling efficient cell division. Cancer cells are exposed to elevated levels of ROS and TERT function in mitochondria may help to mitigate this. Therefore, TERT functions not only in telomere maintenance but also may contribute to transcription and metabolisms that assists tumor development.

Cancer-Specific Isoforms of Telomerase

The aberrant regulation of telomere length homeostasis in cancer suggests that the regulation of telomerase activity differs somehow to that of healthy cells. Mounting evidence suggests that there is only a weak correlation between the level of *TERT* expression and telomerase activity in cancer cells, i.e. it is not simply a case of the amount of telomerase present in the cell.

This raises additional questions regarding mechanisms that might regulate TERT function. Two interesting areas of investigation involve studies on the expression of different TERT splice-isoforms and the existence and function of post-translational modification on TERT protein.

TERT is a large gene, spanning 42 kb and containing 15 introns. Alternative splicing of *TERT* mRNA can result in exon skipping, trimming of exons and insertion of intronic regions. While approximately 22 splice variants have been reported, many of these are degraded via mRNA surveillance mechanisms including the non-sense mediated decay pathway. However, although some splice variants may be translated, only full length TERT exhibits reverse transcriptase activity. Two alternative *TERT* isoforms are particularly well documented (Fig. 4B). One carries a 36 bp truncation in exon 6, resulting in the loss of 12 amino acids within the RT domain (termed the '△ alpha-isoform'). Another lacks exons 7 and 8, resulting in a frame-shift after exon 6 generating a stop codon leading to a short isoform containing only the TEN and the telomerase RNA binding domain (termed the '△ beta-isoform'). Over expression studies suggest that the dysfunctional △ alpha-isoform can compete with endogenous TERT and impair telomerase activity. Although the △ beta-isoform is recessive to endogenous telomerase activity, it retains the ability to bind TERC and localizes to the nucleus and the mitochondria. Over expression of the isoform in breast cancer confers resistance to the anti-cancer drug cisplatin, implying retention of non-canonical functions. Although determination of the ratio for these translated splice isoforms remains challenging, they may contribute to tumorigenesis and the modulation of telomerase activity.

Phosphorylation of TERT is known to have a pivotal role in regulating its localization, which is tightly controlled during the cell cycle. Translocation of TERT from the nucleus to the cytoplasm or to the nucleolus prevents telomerase activity at the telomere. In many cancer cells, kinase and phosphatase activity is modified resulting in aberrant phosphorylation of TERT leading to its accumulate within the nucleoplasm. This change in TERT trafficking might contribute to differences in the regulation of telomerase activity in cancer.

Alternative Lengthening of Telomeres (ALT)

Although the majority of cancers express telomerase, ~10% maintain telomeres via an alternative telomerase-independent mechanisms; this phenomenon is termed alternative lengthening of telomeres or ALT. As well as a lack of detectable telomerase expression, a distinctive hallmark of cancers active in ALT is an increase in DNA DSBs at the telomere. Rather than telomeric repeats being added processively, ALT-positive cells use a method of HR, whereby DNA is copied from telomere to telomere. The ALT pathway is particularly common in osteosarcomas, soft tissue sarcomas and astrocytic brain tumors.

Various recombination pathways

There are a few pathways by which telomeres can potentially clone their repeats (Fig. 10). The template may be *inter-telomeric* in fashion (occurring between sister chromatids or different chromosomes), or i*ntra-telomeric*, where the template derives from within an existing d-loop at the same telomere. As a result, the telomeres in ALT cells are highly heterogeneous in length and can range 2-50 kb. ALT cells also carry abundant extrachromosomal telomeric repeat circles (t-circles), which again range from 1 to 50 kb in length.

Since telomere terminate in a 3′ overhang, which resembles to the processed broken DNA end for the double-strand break repair, shortened telomere ends can directly invade homologous telomeric dsDNA to form a d-loop. The complementary template strand of the recipient telomere is then copied to extend the invading telomere 3′ end via elongation of the d-loop (Fig. 10A). Displacement of the elongated telomere strand results in cloning of the telomere. As telomeres can form a t-loop, the 3′ end can therefore be directly replicated through the loop (Fig. 10B).

Telomeres are fragile and can generate G-quadruplex structures. Replication fork stalling or collapse at the telomere can also activate HR (Fig. 10C). In this case, the broken telomere is most likely to restart DNA replication by displacing telomeric DNA from the sister chromatid (a process called break-induced replication). The d-loop can be resolved by the Holiday junction nucleases. Cross-over resolution of telomere recombination intermediates between the sister chromatids leads to taking over of the telomere duplex (telomere-sister chromatid exchanges, or T-SCE) (Fig. 10D). T-circles are generated by cross-over resolution of a d-loop at intra-telomere recombination or t-loop (Fig. 10E). Such telomere trimming results in immediate shortening of telomeres. Conversely, crossover recombination between a chromosome end and a t-circle results in incorporation of telomere stretches. ALT cells contain t-circles and exhibit T-SCE in many chromosomes, implying that telomere exchanges are a common occurrence.

Biology of ALT

Strand invasion requires the recruitment of the RAD51 protein complex. The 3′ single-strand of the telomere is usually bound to the shelterin protein POT1, which outcompetes HR factors RPA and RAD51. TRF1 facilitate telomere replication and TRF2 suppress HR. However, ALT telomeres appear to have mutations (e.g. TTAGGG > TCAGGG), which impairs shelterin binding and promotes the recruitment of HR factors required for ALT.

Telomeres of ALT cells cluster together and are often found at promyelocytic leukemia (PML) nuclear bodies. Hence, telomere recombination is thought to take place in PMLs. Specifically, these are termed ALT-associated PML bodies, or APBs and are suborganelles found predominantly in the nucleus. The PML complexes dramatically change with the cell cycle and stress responses,

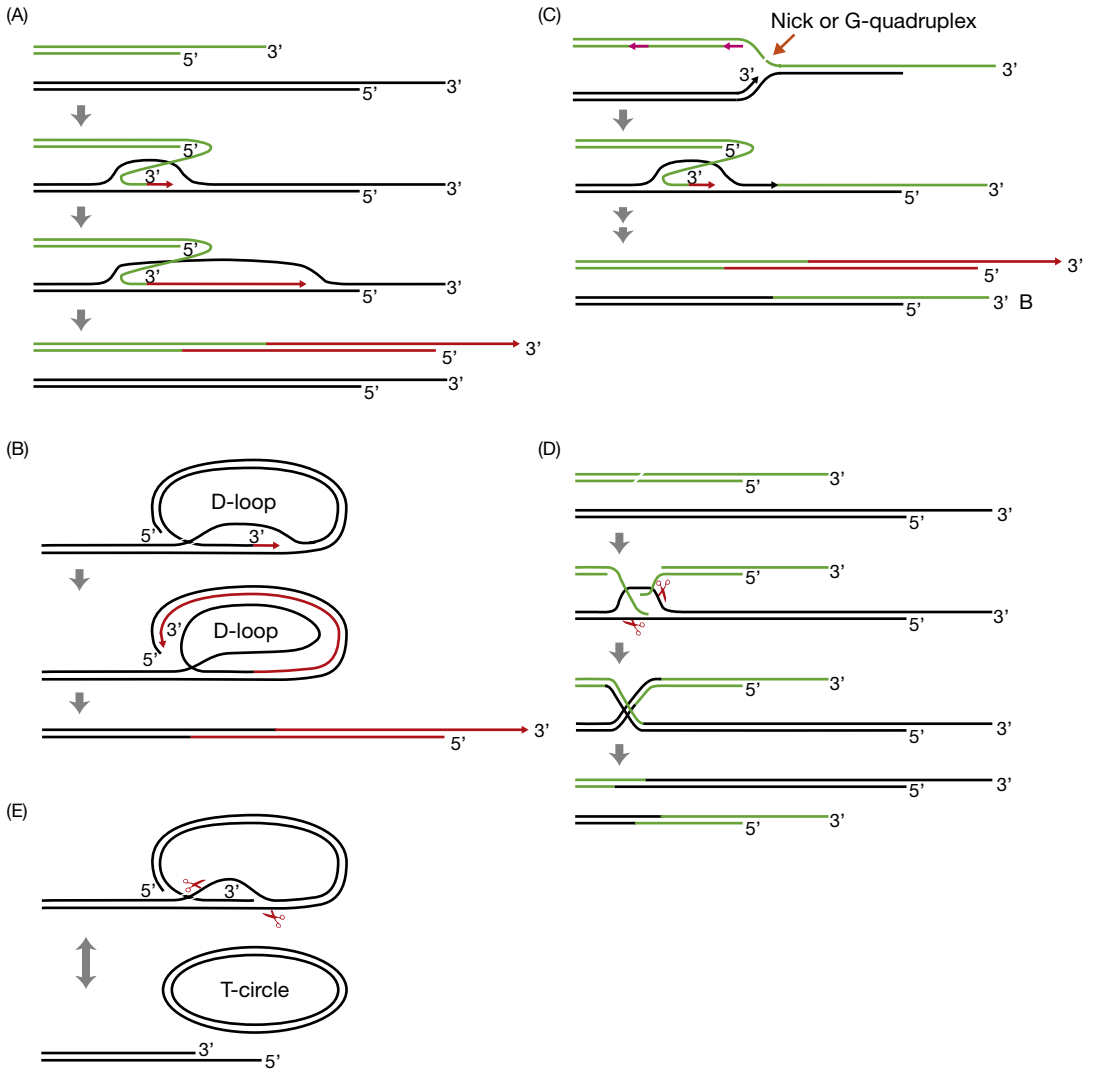

Fig. 10 Alternative lengthening of telomere. Models for telomere recombination and replication in ALT. (A) Pirate telomere copy model—shortened telomere G-tails invade long telomeres to form d-loops. The invading 3′ end can extend by unwinding the double strand. After dissolution, the lagging strand is filled. (B) 3′ ends within t-loops can be extended. (C) Replication fork collapse caused by SSB (nick) or G-quadruplex formation induces break-induced repair pathway. Broken 3′ end invades (newly synthesized) sister chromatid telomere. (D) Robbing telomeric repeat model—The damaged telomere recombines with sister chromatid telomere. d-loop can be resolved by nucleases. Crossover resolution of the junction results in T-SCE. (E) Crossover resolution at t-loop results in telomere trimming and generation t-circles. T-circles can be used as a template for the strand invasion and recombination/replication.

and accommodate many transcription regulators, DNA replication and DNA damage response proteins, including p53, ATRX and the histone chaperon DAXX.

De-repression of ALT

Mutations in *ATRX* and *DAXX* has been observed in many ALT cancer types. ATRX is a chromatin remodeling protein that binds to tandem repeat sequences and G-quadruplex and localizes to telomeric and peri-centromeric heterochromatin regions. ATRX binding to DAXX is necessary for the loading of Histone 3.3 and telomere cohesion. Although the mechanism remains to be established, loss of ATRX-DAXX interaction alters chromatin characteristics of telomeric region, leading to telomere replication defects. This is likely to induce replicative stress and the break-induced replication pathway. In fact, re-installation of ATRX by ectopic over expression can suppress telomere recombination in ALT cells, implicating ATRX as a key ALT repressor. However, mutation of ATRX itself does not activate ALT in normal or telomerase-positive cancer cells. Hence, further alterations such as evasion of shelterin function may be required to de-repress ALT. Since the mutations in either ATRX or DAXX are common in ALT, downstream functions of the ATRX-DAXX complex, such as histone H3.3 deposition and further its post-translational modifications, may be crucial in facilitating telomere replication. Given their frequent occurrence, mutations in *ATRX* and *DAXX* are also considered a hallmark of ALT type cancers.

Telomere Length and Cancer Risk

Cancer is an aging-associated disease. Epidemiological studies support this notion and that many cancers may arise from aged cells with shortened telomeres. The overall telomere length in the body is defined/established at the time of embryonic development (except for spermatocytes). Telomeres shorten throughout an individual's life, and highly propagating tissues are more likely to have shorter telomeres (Fig. 11A, B). With age, cells may accumulate oncogenic mutations, particularly in those that have short telomeres. As discussed, they are active in the mechanisms that give rise to increased genomic instability. In some cases, short telomeres can be detected from progenitors of cancers in rapidly regenerating tissues including the gastrointestinal tract, and cancer cells often harbor shorter telomeres than found in healthy blood cells (Fig. 11B). These facts reveal a strong correlation between telomere shortening and carcinogenesis. Short telomeres also induce cellular senescence to counteract carcinogenesis, but this in turn impairs tissue regenerative ability. For this reason, cancer is considered to be a disease of aging.

Leukocyte Telomere Length and General Cancer Risk

Since blood cells are one of the most heavily dividing, the length of telomeres in blood cells can be used as a surrogate to represent the overall telomere length of every tissue and thereby serve as an indicator of tissue aging. Among blood cells, leukocytes are crucial immune cells that protect the body from infection. The immune system also identifies and rejects irregular cells, cancer precursors and neoplastic cells. This means that telomere shortening in leukocyte is predicted to impair the ability of immune response against cancers.

Telomere length of peripheral blood mononuclear cells has been assessed from patients with different cancers at various stages. A correlation between telomere length and tumor progression was found in many cancer types, including glioma, lung, pancreatic, kidney, esophageal, gastric, colorectal, bladder, breast and ovarian cancers. Hence, it is likely that telomere shortening generally increases risk of carcinogenesis. Furthermore, patients with shorter telomeres are more likely to have poor prognosis and lower overall survival.

In some cancer types, such as melanoma, leukemia and kidney and lung cancer, long rather than short telomeres are associated with disease. Indeed, studies in healthy individuals have indicated that those with either extremely short or long telomeres have between a 1.3 to >2 fold higher chance of developing cancer within 20 years (Fig. 11C). Hence, mounting data suggests a correlation between telomere length and cancer risk. Possible explanation of these phenomena would be that short telomeres promote cellular senescence and tissue aging, increasing the possibility of telomere crisis. Longer telomeres might trap telomeric protein such as TRF2 and RAP1 that serve as transcriptional modulators. Instances of telomere replication defects and oxidative damages of telomeric DNA might be associated with alterations in their length. Although the scientific significance that supports the rationale of this relationship needs to be validated, leukocyte telomere length may have prognostic value in cancer development and progression.

However, it should be noted that epidemiological studies of telomere length are not always consistent and are often unable to take into account the different environmental variables existing between individuals. Categorical variables of the telomere length are not universal but are grouped among its distribution within samples in each study. Further developments in the standardization of methods/procedures and more universally defined ways to measure telomeres would be required to improve the utility of telomere length-based diagnostics in cancer prediction and prognosis.

Inherited Telomere Mutations and Cancer Risk

A number of inherited disorders exist caused by mutations in genes encoding telomerase or telomerase regulatory proteins. These cause short telomeres in patients which can manifest in a broad range of phenotypes, referred to as telomeropathies. Dyskeratosis congenita (DC) is an inherited bone marrow failure syndrome caused by short telomeres that result in the premature death of rapidly dividing blood progenitor cells. DC patients have an enhanced risk of developing cancer as a result of their short telomeres, as a state of telomere crisis is reached early on which promotes further genetic instability.

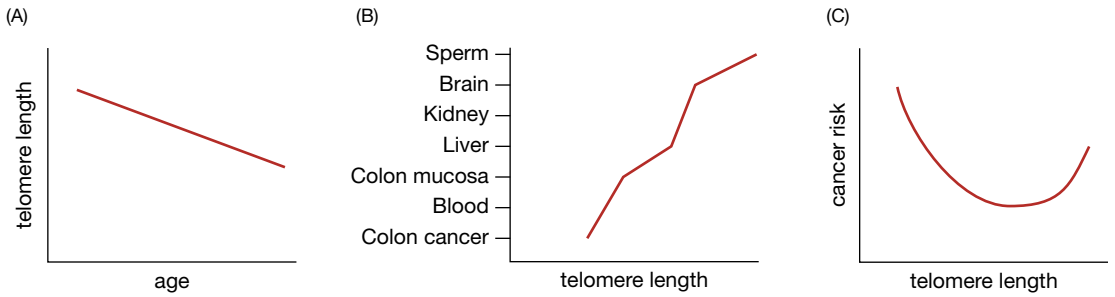

Fig. 11 Telomere length and cancer risk. (A) Graph showing telomere shortening with age. (B) Graph representing telomere length of each organ and cancer. (C) Graph showing telomere length in leukocyte and cancer risk in general.

Several germline mutations in the *POT1* and *ACD* (encoding TPP1) genes have been reported in cases of familial melanoma, glioma and chronic lymphocytic leukemia. These mutations either impair protein stability or impact the interaction of POT1 with TPP1 or the telomeric ssDNA. Mutations in other shelterin components such as *TE2IP* (encoding telomeric RAP1) have also been reported in patients with these cancers. These mutations destabilize shelterin formation, and lead to genetic instability associated with cancer progression. This therefore emphasizes the importance of the shelterin complex in protecting and regulating telomeres, as its disruption can result in cancer.

Telomeres and Cancer Therapeutics

Telomere maintenance is a key feature of cancer biology, as all cancers must sustain their telomeres in order to proliferate. In 85–90% of cancers, this is achieved through the reactivation of telomerase making this as ideal molecular diagnostic for cancer. Furthermore, telomerase is a highly attractive target for cancer therapeutics, providing an excellent opportunity to eliminate a wide range of cancers without damaging normal tissues. In this section, we introduce experimental methods applied to clinical diagnostics and discuss current strategies in telomere targeted cancer therapeutics.

Detection of Telomerase Activity

Typically, telomerase is expressed at low levels in most cells. In addition, TERT expression does not necessarily reflect the level of active telomerase. Hence, direct detection of telomerase activity is a better indicator when determining telomerase reactivation. The telomerase repeat amplification protocol (TRAP, developed by the groups of Shay and Wright) is a biochemical assay that detects reverse-transcriptase activity of telomerase. A useful method for detecting/measuring telomerase activity simply involved the mixing of a telomere substrate oligo (telomere seed) with cell lysate in the presence of dNTPs. Telomerase present can then incorporate a radioisotope-labeled dNTP as it extends the telomere seed. The level of extension can then be visualized. Alternatively, the TRAP assay use a unique non-telomeric oligo as a telomerase substrate. The product of telomerase extension can be amplified by quantitative polymerase chain reaction (qPCR) to measure the activity, instead of direct detection of telomere extension. This assay is robust and can be used to quantify the level of telomerase activity with material from only 100–1000 cells. As telomerase activity is below detectable levels in most somatic cells, the TRAP assay therefore makes for a highly sensitive test to detect telomerase activity in cancer biopsies when the number of cells in limiting.

Telomere Length Diagnostics

As we discussed in the previous section, measuring patient telomere length can give an indication of either cancer risk or the status of disease progression. A number of methods exists for measuring telomere length, and these have distinct advantages and disadvantages.

Telomere southern blot: TRF analysis

The gold standard to measure telomere length is terminal restriction fragment (TRF) analysis using a Southern blotting method. Here, genomic DNA is digested into fragments using restriction endonucleases that do not cut within telomere sequence. Isolated telomeric DNA fragments are resolved through an agarose gel and the DNA is transferred onto a membrane which can then be detected using a labeled telomere probe. This assay is non-biased and robust and allows for the range of telomere lengths in the cell population tested to be visualized. However, this method requires a large quantity (at least 1–4 μg) of DNA which is often not possible to acquire from patient biopsies or fixed specimens.

Single telomere length analysis (STELA)

Shorter telomeres are more difficult to detect. Duncan Baird developed the method to measure telomere length of a specific chromosome arm, using a PCR-based method. This was achieved by ligation of a specific probe to the telomere 3′ overhang and identification of unique sequence on the subtelomeric region (i.e. telomere-adjusted region). PCR may then be used, which preferably amplifies shorter telomeres. The variation in PCR products may then be resolved through an agarose gel, and the telomeric products detected by Southern blot. Universal STELA adapted this method to amplify every chromosome arm, allowing for detection of any short telomeres. Long telomeres are not favorable for PCR thus this method cannot determine average and variation of telomere length. Nevertheless, since one short telomere can elicit replicative senescence, this method is well suited for detection of critically short telomeres such as t-stumps.

Telomere monochrome multiplex qPCR (telomere MMqPCR)

In this method, developed by Richard Cawthon, both telomeric DNA (T) and a reference gene (S) are amplified by multiplex qPCR and the amount of T relative to S is expressed ratio metrically. Using synthetic DNA oligos as a standard curve, the absolute total telomere length can be calculated. As this is a PCR-based method, only a small sample of genomic DNA is required, making this system more feasible than Southern blotting. This assay is widely used to measure relative telomere length from patients' blood or biopsy samples. However, as the result reveals only the relative telomere quantity, variations in telomere length cannot be assessed.

Telomere qFISH

Fluorescent in situ hybridization (FISH) of telomeric DNA has been developed to quantify signal intensity and assess telomere length of each chromosome ends. Metaphase chromosome spreads are prepared and telomeric DNA is hybridized with a stable oligonucleotide telomere C-strand probe (three tandem 5′-CCCTTA-3′, synthesized as peptide nucleic acids, PNA). As PNA/DNA hybrids are more stable than DNA duplexes, all telomeric DNA can be labeled with PNA probes. As each telomere end is observed as a concentrated dot, variations in telomere length within a cell can be assessed. Furthermore, this is the only assay capable of detecting telomere loss as well as telomere damage, fusions and recombination on each chromosome. For post-mitotic cells, although assessment of each telomere is not possible, interphase qFISH can still provide the relative telomere length when compared to centromere qFISH. In this case, because of the simplified manner in sample preparation, it is well-suited for use in high throughput and automated screens.

Flow-FISH

By combining qFISH and Flow cytometry, Flow-FISH allows the separation of different cell types. Telomere length is provided as an average length for the cell population. Therefore, this method is suitable with hematopoietic cell subtyping, and is often used in clinical studies. As this method does not use microscope, non-specific signal needs to be taken in account.

Telomerase as an Anti-Cancer Drug Target

Since telomerase is expressed in the majority of cancer cells and rarely in normal tissue, telomerase has been considered as one of the best targets to uniquely kill cancer cells. However, telomere attrition, leading to cells death, takes time, which provides a window for further potentially oncogenic mutations to accumulate. In addition, hematopoietic progenitor cells have a high proliferative capacity and themselves express telomerase, meaning side-effects must also be considered. Nevertheless, different characteristics of telomere maintenance in cancer cells provide an opportunity for the development of targeted drugs. Combination chemotherapy with telomerase inhibition and TERT-targeted cancer immunotherapy might also help improve therapeutic strategies.

Telomerase targeting drugs

Telomerase activity requires the complexing of both TERC and TERT. BIBR1532 is a non-competitive inhibitor that specifically binds to the CTE domain of TERT and inhibits association with TERC via the CR4/5 domain (Fig. 12A). Treatment of cells with BIBR1532 causes telomere shortening and induces replicative senescence or apoptosis in telomerase-positive cancer cells. However, it remains unknown if it also inhibits non-canonical telomerase activities.

Telomerase copies the template sequence within TERC onto chromosome ends in order to extend telomeric DNA. Imetelstat, formally named GRN163L, is an oligonucleotide-based compound that is complementary to the template sequence within TERC (Fig. 12B). It binds with a high affinity, blocking the interaction between TERC and the 3′ telomere overhang, thereby preventing template annealing and polymerization activity. To conquer issues relating to nucleotide stability, aqueous solubility and cellular uptake, this template antisense oligonucleotide is fused to a palmitoyl lipid moiety. To date, Imetelstat is the best evaluated telomerase inhibitor. It has demonstrated high specificity against many telomerase-positive cancer types, including glioblastoma, esophageal, lung and pancreas cancers in in vitro and pre-clinical models. Imetelstat has proven effective when used with other anti-cancer drugs (combination chemotherapy) or radiotherapy (radiosensitization).

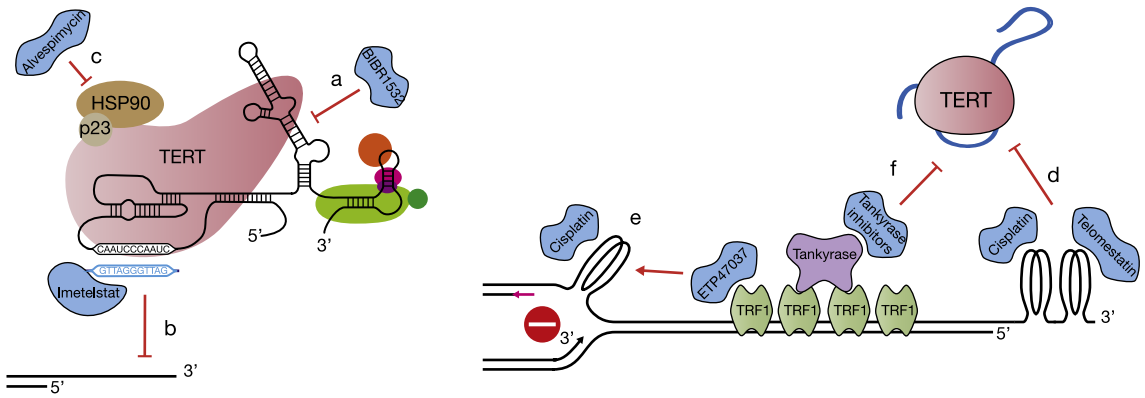

Fig. 12 Drugs that target telomerase and telomere. Schematic overview of telomere and telomerase targeting drugs. (A) BIBR1532 binds to CTE domain and inhibit TERC (CR4/5) interaction. (B) Imetelstat nucleotide complements RNA template and blocks telomere 3′ end binding. (C) HSP90 inhibitors such as Alvespimycin destabilize TERT. (D) Telomestatin and Cisplatin stabilize G-quadruplex at the 3′ end to block telomerase interaction. (E) G-quadruplex formation during lagging strand synthesis and TRF1 destabilization by ETP47037 accumulate telomere replication damage. (F) Tankyrase inhibitors stabilize TRF1 binding and suppress telomerase recruitment.

HSP90 is an essential chaperon for telomerase assembly and stability. HSP90 is often upregulated in cancer and contributes to the stabilization of client (substrate) proteins, including oncogenic proteins, to promote tumor development and heterogeneity. HSP90 inhibitors geldanamycine analogues, tanespimycin (17-AAG) and the more advanced alvespimycin (17-DAMG) reduce telomerase activity and block oncogenic signaling pathways (Fig. 11C). Telomere shortening can be synergized with Imetelstat.

Telomeres targeting drugs

Telomeres themselves are also potential targets for anti-cancer therapeutics. Cisplatin is a drug that binds preferentially to guanine bases, causing intra-strand crosslinks in dsDNA and G-quadruplex formation in ssDNA. Telomeric DNA is G-rich, making it an ideal target for Cisplatin, which can act to both impair telomerase activity as well as limit telomeric DNA replication (Fig. 12D, E). A natural compound, telomestatin, specifically stabilizes telomeric G-quadruplex structures with minimal effect on duplexed DNA found in non-telomeric regions. With further development, telomestatin could prove useful for the targeting of telomeric DNA in cancer.

Alternate telomeric nucleotides can also be exploited to disrupt telomere protection. The GTP analogue, 6-thio-2′-deoxyguanosine can also be used to take advantage of the G-rich state of telomeric DNA. An analog of 6-thio-guanosine, which is used for leukemia treatment, 6-thio-2′-deoxyguanosine also mimics GTP and has high affinity towards telomerase. Hence, it can be incorporated into the telomere by telomerase. This causes telomere de-protection and rapid cell death. Unlike 6-thio-guanosine, damaging to healthy telomerase negative cells seems low. However, further development is necessary to specifically target telomerase and an important issue remains the emergence of alternative methods of telomere lengthening, caused by destabilizing telomeric proteins such as TRF2.

Telomeric proteins can also be anti-cancer drugs targets. Telomerase activity is repressed by the presence of TRF1, which in turn is stabilized by tankyrase 1. Inhibition of tankyrases leads to impaired telomere maintenance and shortening of telomeres in vitro (Fig. 12F). Notably, tankyrases also control Wnt/β-catenin signaling, Hippo/YAP signaling and mitotic progression, which contribute tumor development, making them all potential targets for cancer therapy. A number of PARP inhibitors have been developed but selectivity and efficacy on other superfamily members remain an issue. A novel TRF1 inhibitor ETP-47037 that has been tested on lung carcinoma leads to proliferation defects via telomere replication catastrophe and apoptosis (Fig. 12E). Although effects on normal tissues must be validated, altering shelterin function at fragile telomeres in cancer cells represents an attractive strategy in the development of cancer therapy.

TERT Targeting Cancer Immunotherapy

Immunotherapy is a promising new approach for targeting cancer. Many cancer cells express TERT and therefore present TERT peptides on their surface via MHC Class I. Given that most normal cells express low levels of this protein, this could serve as an effective cancer-targeting antigen. TERT peptide-based vaccines such as GV1001 and Vx-001 have been developed to stimulate immune responses against TERT-expressing tumor cells. As an alternative approach, Dendritic Cells (DCs) have also been genetically modified to express TERT-peptide antigens. Such engineered DCs (GRNVAC1/2) efficiently stimulate immune responses. These vaccines seem to be well- tolerated in patients indicating this as a promising approach for cancer therapy. However, further trials and larger studies to prove significant curative effects are necessary to determine the long-term effects and potential toxicity.

Prospective Vision

The telomere biology field holds some exciting prospects for improving our understanding of cancer and for the development of new anti-cancer therapies. Further research aims to provide a greater understanding of how and when telomerase becomes reactivated during oncogenesis. In addition, understanding how telomerase regulation differs in cancer cells, resulting in the ability to maintain short telomeres that promote chromosomal damage, will be a crucial step in improving our knowledge of cancer progression and identifying new potential therapeutic targets.

Although telomerase itself is not oncogenic, its non-canonical functions may contribute to tumor progression. Recent studies have started to unveil relationships between telomere/telomerase and Wnt/β-catenin and NFκB signaling pathways. These pathways promote TERT expression and TERT facilitates their transcription activities. Establishing the function of their interaction in the context of cancer biology is anticipated.

Epidemiological studies will continue to reveal correlations between telomere length and risk of carcinogenesis and may well provide new insights into cellular aging. An exciting area for the future is the use of telomerase as an antigen to target cancer. With telomerase expression occurring in the majority of cancers, strategies to target this and telomeres promise the development of novel, broadly applicable anti-cancer therapies.

TGF-β in Cancer Progression: From Tumor Suppressor to Tumor Promotor

Chuannan Fan*, Jing Zhang*, Wan Hua, and Peter ten Dijke, Oncode Institute, Leiden University Medical Center, Leiden, Netherlands

Glossary

Angiogenesis A process in which new blood vessels arise from pre-existing vessels.

Anti-sense oligonucleotides Short single-stranded RNAs that are complementary to transcribed messenger RNAs within a cell.

Cyclin-dependent kinases A family of serine/threonine protein kinases that phosphorylate various proteins involved in cell cycle progression. CDKs form complexes with cyclins to become functionally active.

Deubiquitinating enzymes A family of proteases that cleave the peptide or isopeptide bond between ubiquitin and substrate proteins.

Epithelial to mesenchymal transition A process in which epithelial cells lose their cell polarity and cell–cell adhesion, demonstrate a decrease in the expression of epithelial markers such E-Cadherin and zonula occludens-1, and acquire spindle cell morphology and mesenchymal traits (showing a decrease in the expression of mesenchymal markers such as N-cadherin and a-smooth muscle actin). Upon EMT, the cells become more migratory and invasive.

E3 ubiquitin ligases A family of enzymes that mediate the attachment of ubiquitin molecule(s) onto lysine residues of proteins, thereby regulating their function, for example, stability, cellular localization, protein–protein interactions and activity.

Metastasis The process in which cancer cells spread from the initial or primary site to a different or secondary site.

Phosphatases A family of enzymes that remove phosphate groups from substrates; their function opposes that of kinases, which catalyze the ATP-dependent transfer of phosphate groups onto substrates.

Smad transcription factors A family of proteins that act as intracellular effectors of TGF-β family members. The proteins in this family were named for their similarity to the *Caenorhabditis elegans* SMA protein and the *Drosophila* gene product mothers against decapentaplegic (MAD).

Nomenclature

ALK Activin receptor-like kinase
ANGPT4 Angiopoietin-like 4
AON Anti-sense oligonucleotide
CAR Coxsackie and adenovirus receptor
CDK Cyclin dependent kinase
CSC Cancer stem cell
CTGF Connective tissue growth factor
DAPK Death associated protein kinase
ECM Extracellular matrix
EMT Epithelial to mesenchymal transition
ER Estrogen receptor
ERK Extracellular regulated kinase
GRB2 Growth factor receptor-bound protein 2
HGF Hepatocyte growth factor
HIF-1 Hypoxia inducible factor-1
IL Interleukin
JNK Jun amino-terminal kinase
LLC Large latent complex
MAPK Mitogen activated protein kinase
MEG3 Maternally expressed gene 3

*Both these authors contributed equally.

miR Micro RNA
MMP Matrixmetalloproteases
mTOR Mammalian target of rapamycin
NEDD4L Neural precursor cell expressed, developmentally down-regulated 4-like
NK Natural killer
PAK2 p21-activated kinase
PDP Pyruvate dehydrogenase phosphatase
PI3K Phosphatidylinositol-3-kinase
PP Protein phosphatase
PTHrP Parathyroid hormone-related protein
RANKL Receptor activator of nuclear factor κB ligand
ROS Reactive oxygen species
S6K S6 kinase
SCL Small latent complex
SDF-1 Stromal cell-derived factor 1
SHC SH2 containing protein
SHIP SH2-containing inositol phosphatase
SMA Smooth muscle actin
Smad Sma and Mad related protein
SMURF Smad ubiquitin regulatory factor
SOS Son of sevenless
TAB1 TAK1 binding protein
TAK1 TGF-β activated kinase-1
TGF-β Transforming growth factor-β
TIEG TGF-β-inducible early-response gene
TIMΠ Tissue inhibitor of MMP
TRAF Tumor necrosis factor receptor associated factor
TβR TGF-β receptor
USP Ubiquitin specific protease
VEGF Vascular endothelial growth factor
XIAP X chromosome-linked inhibitor of apoptosis
ZO-1 Zonala occludence-1

Introduction

Transforming growth factor (TGF)-β is a multifunctional secreted cytokine that exerts highly context dependent effects on many different cell types, including growth inhibition, extracellular matrix (ECM) production, apoptosis and differentiation (Massagué, 2012; Ayyaz et al., 2017). TGF-β1 is the prototype of a large family of evolutionarily conserved structurally and functionally related dimeric proteins that includes TGF-βs, activins and bone morphogenetic proteins (BMPs). Signaling occurs via transmembrane serine/threonine kinase type I and type II receptors (Feng and Derynck, 2005). TGF-β induces the formation of a complex of type I and type II receptors, upon which the type II kinase phosphorylates type I, thereby transmitting the signal across the membrane. Inside the cell, the activated type I receptor phosphorylates specific down-stream effector molecules, among which are canonical Smad and non-Smad signaling components. Smads can act as transcription factors and thus relay the signal from the membrane into the nucleus (Hill, 2016). Each step of the signaling pathway is intricately regulated to fine tune the potent cellular responses of TGF-β (Xu et al., 2016).

Misregulation of TGF-β signaling has been causally associated with many diseases, including cancer, fibrosis and cardiovascular diseases (Zhang et al., 2017; Kim et al., 2017a; Goumans and ten Dijke, 2017). In this review, we focus on its dual role in cancer. Moreover, because TGF-β stimulates invasion and metastasis, this pathway has been subject to therapeutic targeting by academic and industrial laboratories. We provide an update on the latest clinical developments of TGF-β targeting agents for the treatment of cancer (Colak and ten Dijke, 2017; Akhurst, 2017).

TGF-β Signaling

Ligands and Their Receptors

Shortly after the discovery of TGF-β1 in 1985, the structurally and functionally related TGF-β2 and TGF-β3 were identified (Moses et al., 2016). In this review, we indicate specific TGF-β isoforms when relevant, for example, when they have distinct functional properties; otherwise we refer to them as TGF-β. TGF-β is a conserved 12.5-kDa polypeptide that forms a disulphide-linked dimer (Galat, 2011). While predominantly present as homodimers, heterodimers between different TGF-β isoforms have been described (Cheifetz et al., 1987). Of note, TGF-β may exert diverse, sometimes even opposing, regulatory roles depending on the various cell types and different development stages (Massagué, 2012; Ayyaz et al., 2017). The three TGF-β isoforms are differentially expressed. TGF-β1 is highly abundant in platelets and bone and is widely expressed and synthesized among diverse tissues. TGF-β is secreted in an inactive form in which the amino-terminal pro-peptide (also termed the latency-associated peptide) is non-covalently associated with the carboxy-terminal mature peptide (Robertson and Rifkin, 2016). Activation can be mediated via specific proteases and cell surface-associated integrins that liberate the mature peptide, which can then interact with cell surface receptors (Khan and Marshall, 2016; Jenkins, 2008). This activation step is an important control mechanism that regulates the local bioavailability of TGF-β.

Activated TGF-β initiates cellular responses by binding to cell surface single transmembrane TGF-β type I and type II serine/threonine kinase receptors, that is, TβR1 and TβRII, respectively (Wrana et al., 1994). TGF-β induces the formation of a heterotetrameric complex containing two TβRIIs and two TβRIs (Yamashita et al., 1994). Initially, TGF-β1 and TGF-β3 (but not TGF-β2) bind to TβRII, and thereafter, TβRI is recruited. The TGF-β type III coreceptor (also termed betaglycan), which lacks intercellular enzymatic activity, can facilitate the interaction between TβRI and TβRII (López-Casillas et al., 1993). In particular, TGF-β2 requires TβRIII for efficient binding to signaling receptors (Villarreal et al., 2016). Upon the ligand-induced TβRI/TβRII complex formation, TβRI is phosphorylated by TβRII kinase on specific serine and threonine residues in the glycine/serine-rich (GS) domain. The extracellular ligand signal is thereby transduced across the membrane, and the activated TβR complex is then ready to initiate intracellular responses by phosphorylating intracellular effector proteins (ten Dijke and Hill, 2004; Shi and Massagué, 2003; Heldin et al., 1997) (**Fig. 1**).

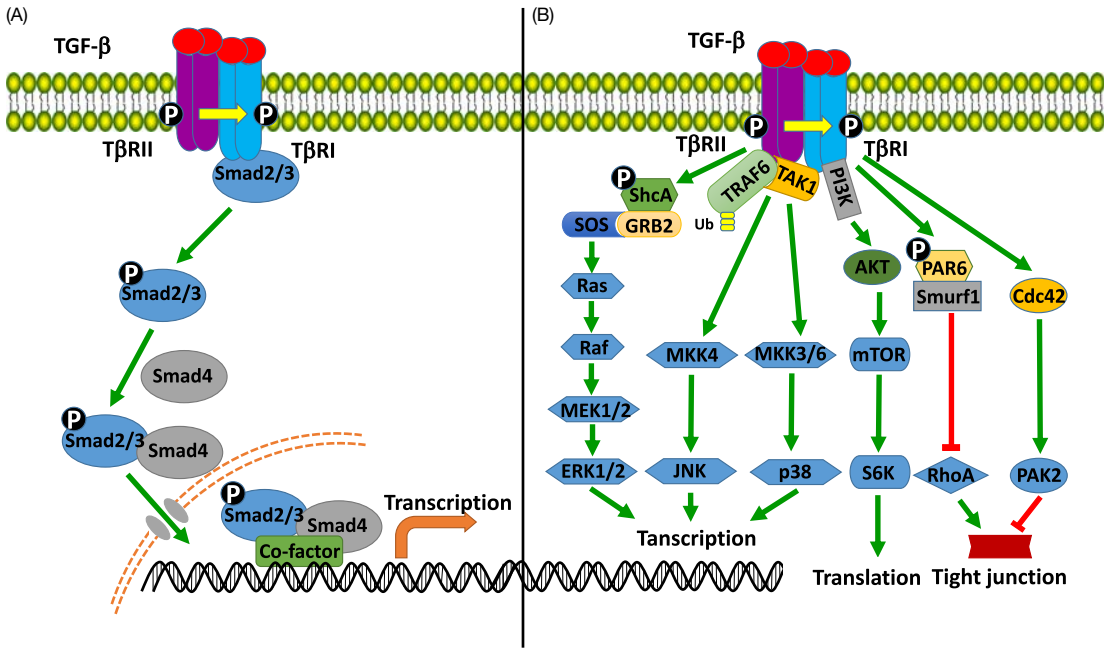

Fig. 1 TGF-β/Smad and non-Smad signaling. (A) In the Smad-dependent pathway, binding of active TGF-β induces the assembly of TβRI and TβRII into a complex in which TβRI is phosphorylated by TβRII kinase. Activated TβRI subsequently signals by recruiting and phosphorylating Smad2 and 3, which form heteromeric complexes with Smad4. The Smad complexes then translocate into the nucleus and regulate target gene transcription by cooperating with other cofactors. (B) In the non-Smad signaling pathways, TGF-β receptors activate other pathways including MAPKs (such as ERKs, p38 and JNK) and PI3K-AKT signaling to modulate transcription and translation events and regulate Rho-like GTPase activity for tight junction dissolution. Abbreviations: ERK, extracellular regulated kinase; GRB2, growth factor receptor-bound protein 2; mTOR, mammalian target of rapamycin; PI3K, phosphatidyl inositol-3-kinase; S6K, S6 kianse; Smurf, Smad ubiquitin regulatory factor; SOS, son of sevenless; TAK1, TGF-β activated kinase; TβR, TGF-β receptor; TGF-β, transforming growth factor-β; TRAF, TNF associated factor; Ub, ubiquitin.

TGF-β/Smad and Non-Smad Signaling

With the help of genetic approaches in worms and fruit flies, Sma- and Mad-related proteins, termed Smads, were identified in vertebrates as unique and pivotal intracellular effectors of TGF-β (Derynck et al., 1996). Smads are classified into three groups: the receptor-regulated Smads (R-Smads), the common Smads (Co-Smads) and the inhibitory Smads (I-Smads) (Nakao et al., 1997a, 1997b; Hayashi et al., 1997). R- and Co-Smads share two conserved domains, termed an amino-terminal Mad Homology 1 (MH1) and C-terminal MH2 domain. Both domains are separated by a proline-rich linker region. I-Smads also have an MH2 domain.

Upon activation, TβRI recruits and phosphorylates R-Smad family members, Smad2 and Smad3, at their carboxy-terminal regions at two serine residues. Activated Smad2 and 3 form heteromeric complexes with Smad4 that subsequently translocate into the nucleus. Activated Smad complexes can form transcriptional complexes in conjunction with a large variety of DNA binding cofactors and thereby gain high affinity and specificity for DNA. The intrinsic binding activity of Smad3 and Smad4 (via their MH1 domain) is weak, and their ability to bind directly with DNA is lacking in the predominantly expressed splice variant of Smad2. These Smad-containing transcription factor complexes interact with coactivators, corepressors and chromatin remodeling factors to regulate the transcription of target genes in a cell type-dependent manner (**Fig. 1**A) (Shi and Massagué, 2003; Nakao et al., 1997a) (Derynck and Zhang, 2003).

In addition to the canonical Smad-dependent pathway, non-Smad signaling pathways can be initiated by activated TGF-β receptor complexes in specific cell types (**Fig. 1**B). These pathways can also modulate Smad pathways (Zhang, 2017). Via phosphorylation or direct interaction with signaling modules, TGF-β receptors can activate pathways such as the mitogen-activated protein kinase (MAPK) signaling cascade, which includes extracellular signal-regulated kinases (ERKs), p38 and c-Jun amino terminal kinase (JNK), phosphatidylinositol-3 kinase (PI3K)-AKT signaling and Rho-like GTPase activity (Zhang, 2017; Mu et al., 2012; Lee et al., 2007; Arsura et al., 2003). The ERK MAPK pathway is initiated when tyrosine residues of the adaptor ShcA are phosphorylated by TβRI. Tyrosine phosphorylated ShcA provides a docking site for adaptor GRB2 that interacts with the exchange factor SOS, which activates the pro-oncogenic Ras-Raf-MEK1/2-ERK1/2 signaling pathway (Lee et al., 2007). Phosphorylated ERK1/2 then translocates into the nucleus and regulates gene transcription by phosphorylating target transcription factors (Zavadil et al., 2001). TGF-β activated kinase 1 (TAK1), a MAP kinase kinase kinase (MAPKKK), which is recruited on the TGF-β receptor complex by polyubiquitylated TRAF6, phosphorylates specific MAP kinase kinases (MKKs), leading to the further phosphorylation of JNK and p38 (Wang et al., 2001). In addition, TGF-β stimulation triggers the interaction between TβRI and the PI3K subunit p85, leading to AKT phosphorylation and the activation of downstream effectors (e.g., mTOR, P70S6K and 4E-BP1) (Yi et al., 2005; Lamouille and Derynck, 2007). PAR6 can also be phosphorylated by TβRI and recruits Smurf1 to degrade RhoA, which regulates cell–cell interactions via tight conjunctions (Ozdamar et al., 2005). Cdc42, another GTPase, can be recruited to the TGF-β receptor complex and mediate the activation of p21-activated kinase 2 (PAK2), which stimulates tight conjunction disassociation (**Fig. 1**B) (Wilkes et al., 2003; Barrios-Rodiles et al., 2005).

Regulation of TGF-β/Smad Signaling

As a pivotal cytokine in cell homeostasis, TGF-β signaling activity is under precise regulatory control, from ligand bioavailability to receptor and Smad activation (**Fig. 2**). After synthesis and intracellular furin-mediated cleavage of the precursor protein (removal of the signal peptide), the bioactive growth-factor domain (mature TGF-β) and prodomain, also termed the latency-associated peptide (LAP), are secreted in a small latent complex (SLC) form. The binding of TGF-β to its receptors is prevented by LAP. The large latent complex (LLC), a more commonly deposited complex, contains the SLC and latent TGF binding protein (LTBP), which is covalently bound to LAP (Robertson and Rifkin, 2016; Shi et al., 2011; Costanza et al., 2017; Robertson et al., 2015). LTBP has an important function in facilitating TGF-β secretion. Stromal-derived molecules including proteases and reactive oxygen species (ROS) substantially contribute to the increase in active TGF-β levels by interacting with the latent TGF-β complex (Costanza et al., 2017; Mu et al., 2002; Yu and Stamenkovic, 2000; Jobling et al., 2006). In addition, contractile forces exerted by integrins across the LLC play a vital role in the release of mature TGF-β (Shi et al., 2011; Annes et al., 2004; Dong et al., 2017; Munger and Sheppard, 2011). Fibronectin that is deposited in the ECM prior to the formation of the LLC impairs TGF-β1 bioactivity by interacting with LTBP (Dallas et al., 2005). Decorin, a member of the proteoglycan family, also exerts a suppressive role on TGF-β activity via binding to all isoforms of soluble TGF-β (Merline et al., 2011).

Apart from the ECM level, TGF-β responsiveness is tightly controlled at the cell membrane. Glycosylation of the extracellular domain of TβRII inhibits its transportation to the cell membrane and lowers the affinity for TGF-β binding (Goetschy et al., 1996; Kim et al., 2012). E3 ubiquitin ligases such as Smad-specific E3 ubiquitin protein ligase 1/2 (Smurf1/2) cooperate with inhibitory Smad7 to regulate the availability of TβRI receptors on the cell surface by ubiquitylation and degradation (Ebisawa et al., 2001; Kavsak et al., 2000). Deubiquitinating enzymes ubiquitin-specific protease (USP) 4, 11 and 15 inhibit the degradative ubiquitination of TβRI and stabilize this receptor (Liu et al., 2016). Two phosphatases, protein phosphatase (PP)1c and PP2A, impair receptor activation by targeting TβRI for dephosphorylation (Shi et al., 2004; Batut et al., 2008). Akin to ubiquitylation, sumoylation and neddylation have also been implicated in the regulation of TGF-β receptor stability. The interaction between TGF-β receptors and the coreceptors located on the cell membrane is another determinant for signaling strength (ten Dijke and Hill, 2004; Budi et al., 2017). The coreceptor betaglycan stabilizes the receptor complex between TβRI and TβRII and propagates the signaling transduction initiated by TGF-β2 (Stenvers et al., 2003). Endoglin, another accessory protein at the plasma membrane that is structurally

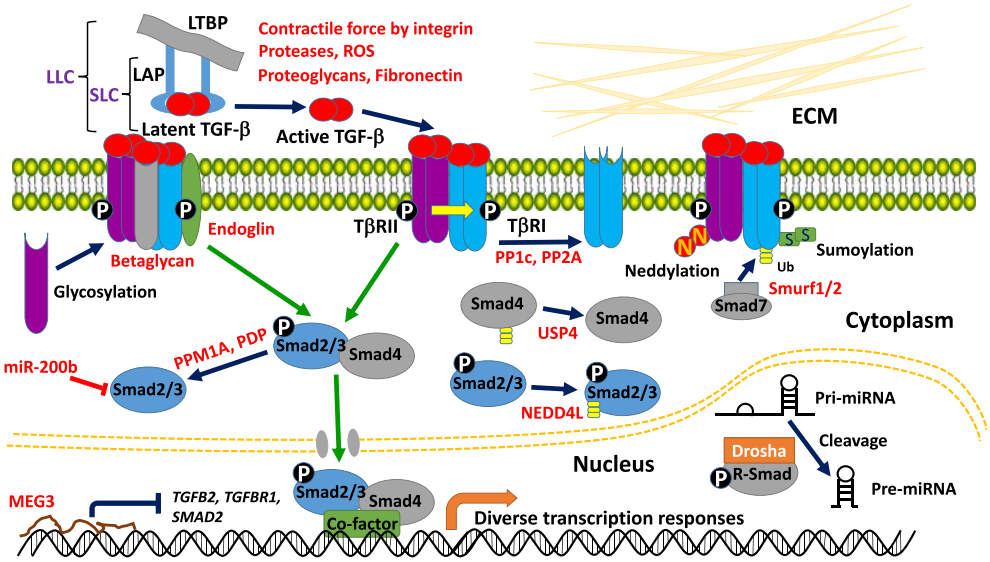

Fig. 2 Regulation of TGF-β/Smad signaling. Proteases, ROS, integrin-mediated contractile forces and stromal-derived factors modulate the bioavailability of TGF-β and accessibility to its receptors. On the cell membrane level, the activity of TβRs is modified by glycosylation, phosphorylation, ubiquitylation, deubiquitylation, sumoylation and neddylation, as well as the interaction with coreceptors and other accessory proteins. At the cytoplasmic level, Smad proteins are under tight control of phosphatases, ubiquitylating enzymes, deubiquitylating enzymes and miRNAs. In the nucleus, the Smad complex affects different transcriptional responses in combination with diverse cofactors. Smad proteins are also required for the maturation process of miRNAs. Moreover, transcription levels of TGF-β pathway components are regulated by modulators such as lncRNAs.

related to betaglycan, inhibits the TGF-β/ALK5-mediated Smad2/3 pathway but promotes TGF-β/ALK1-induced Smad1/5/8 signaling in endothelial cells (Lebrin et al., 2004; Scherner et al., 2007).

At the cytoplasmic level, phosphorylated Smad proteins can be deactivated by phosphatases such as PPM1A and PDP, leading to signal termination (Chen et al., 2006; Sapkota et al., 2006; Lin et al., 2006). Similar to the TGF-β receptors, Smads are under the intricate regulation of multiple ubiquitylating enzymes such as Smurf1/2 and NEDD4L, which inhibit Smad2/3 stability (Lo and Massagué, 1999; Gao et al., 2009). Conversely, USP4 promotes Smad4 activity by removing the suppressive monoubiquitination triggered by Smurf2 (Zhou et al., 2017). MicroRNAs (miRNAs) also modulate TGF-β signaling by inhibiting various signaling components of this pathway (Gulei et al., 2017). MiR-200b, one miRNA that is downregulated by TGF-β1, attenuates the TGF-β signaling response by targeting Smad2 at the post-transcriptional level, thereby forming a negative feedback loop (Chen et al., 2013).

Upon activation, phosphorylated Smad2/3/4 translocate into the nucleus and form a transcription complex with other cofactors. In combination with different sequence-specific transcription factors, the Smad complex generates a vast variety of transcriptional responses in a context and cell type-dependent manner (Massagué, 2012; Itoh et al., 2000; Piek et al., 1999; Mullen et al., 2011). In addition, activated Smad proteins participate in the maturation of microRNAs (miRNAs) by recruiting the RNA helicase p68 (DDX5) to the Drosha complex (Davis et al., 2008). MEG3, an intranuclear long noncoding RNA (lncRNA), can bind to the distal regulatory elements of genes encoding TGF-β signaling components, including *TGFB2*, *TGFBR1* and *SMAD*, and inhibit their transcription (Mondal et al., 2015).

TGF-β as a Tumor Suppressor

TGF-β-Induced Growth Inhibition

TGF-β-induces growth inhibition (**Fig. 3**) and the induction of apoptosis (**Fig. 4**) of normal epithelial (and certain premalignant) cells; these properties are associated with its function as a tumor suppressor (Schuster and Krieglstein, 2002). The molecular mechanisms by which TGF-β elicits these processes involve multiple intracellular pathways (Macias et al., 2015; Fabregat et al., 2014; Chandrasinghe et al., 2017). Numerous studies support the notion that TGF-β inhibits the proliferation of cells by arresting cells in the G1 phase of the cell cycle (**Fig. 3**). Smad-containing protein and transcriptional coactivator complexes can activate the transcription of two major cell cycle inhibitors, CDK inhibitors (CKIs), p15 and p21 (ten Dijke et al., 2012; Liu, 2006). In keratinocytes, TGF-β/Smad signaling induces the expression of cyclin-dependent kinase inhibitors p15INK4b and p21CIP/WAF1, which inhibit the CDK4/6-cyclin D complex (Massagué et al., 2000). These cyclin-dependent kinase inhibitors inhibit CDK activities associated with the G1 to S phase progression, prevent phosphorylation of Rb by cyclin-dependent kinases, and arrest cells in G1 (Tarasewicz and Jeruss, 2012). The activated Smad proteins target the promoters of the c-Myc and CDK genes and repress their transcription in cooperation with nuclear corepressors (Chen et al., 2002). Non-Smad signaling TGF-β receptor-initiated signaling can also be implicated in an antiproliferative effect in some cell types (Siegel and Massagué, 2003).

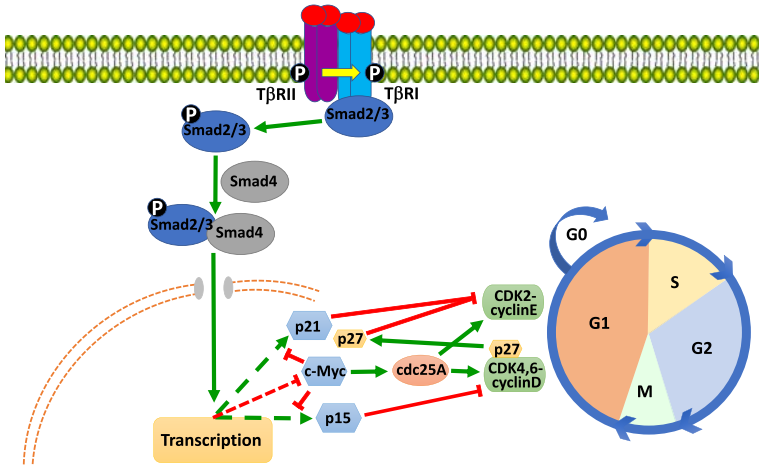

Fig. 3 Gene regulation in TGF-β-induced cell cycle arrest. TGF-β receptor activation leads to Smad2/3 phosphorylation. Phosphorylated Smad2/3 then binds Smad4, and the Smad2/3–Smad4 complex translocates to the nucleus to modulate transcription. c-Myc and cdc25A genes are repressed, while p15INK4[b] and p21CIP/WAF1 expression can be induced by TGF-β and cause a G1 arrest of the cell cycle. Abbreviations: CDK, cyclin dependent protein kinase; TβR, TGF-β receptor kinase; TGF-β, transforming growth factor-β.

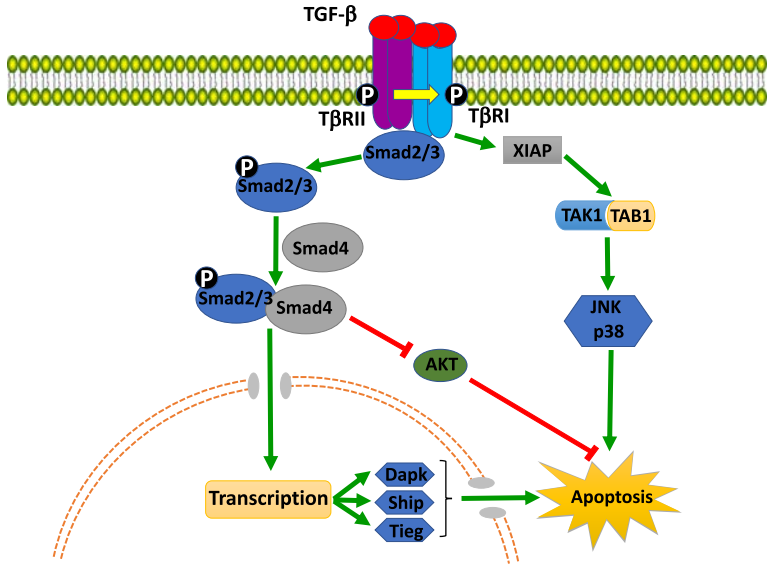

Fig. 4 TGF-β-induced cell apoptosis. TGF-β promotes the activation of Smads and the expression of pro-apoptotic genes such as Dapk, Ship and Tieg. Smads also bind and inactivate the survival kinase AKT, thereby inducing apoptosis. TGF-β-induced activation of the JNK and p38 pathways can also lead to apoptosis. TGF-β can also induce, via the adaptor XIAP, the activation of the TAK1-TAB complex, leading to JNK or p38 activation, both of which can lead to apoptosis. Abbreviations: Dapk, death associated protein kinase; Ship, SH2-containing inositol phosphatase; TAB1, TAK1 binding protein; TAK1, TGF-β activating kinase; TGF-β, transforming growth factor-β; Tieg, TGF-β-inducible early-response gene; XIAP, X-chromosome-linked inhibitor of apoptosis.

TGF-β-Induced Apoptosis

TGF-β can induce cell apoptosis in normal epithelial (and some premalignant) cells (Fig. 4). Several apoptotic regulators have been implicated downstream of the TGF-β signaling pathway, often in a cell- or tissue-specific manner (Ozaki et al., 2011). Stimulation and inhibition of expression of pro-apoptotic genes such as Ship and Tieg have been implicated in TGF-β-induced apoptosis (Moustakas and Heldin, 2005). In liver cancer cells, the Daxx adaptor protein couples the TGF-β signaling pathway to cell death machinery through its interaction with the type II TGF-β receptor (TβRII) (Perlman et al., 2001). In liver cancer cells, TGF-β can induce the expression of the death-associated protein kinase DAPK, which promotes cell death (Jang et al., 2002). In addition, TGF-β-induced activation of TGF-β-activated kinase-1 (TAK-1), a protein of the MAPKKK family, which activates p38 and JNK signaling, has been shown to be involved in TGF-β-induced apoptosis (Kokkinakis et al., 2004). TGF-β can also induce apoptosis through repressing the phosphoinositide 3-kinase/AKT/survivin pathway in colon cancer cells (Wang et al., 2008) (Fig. 4).

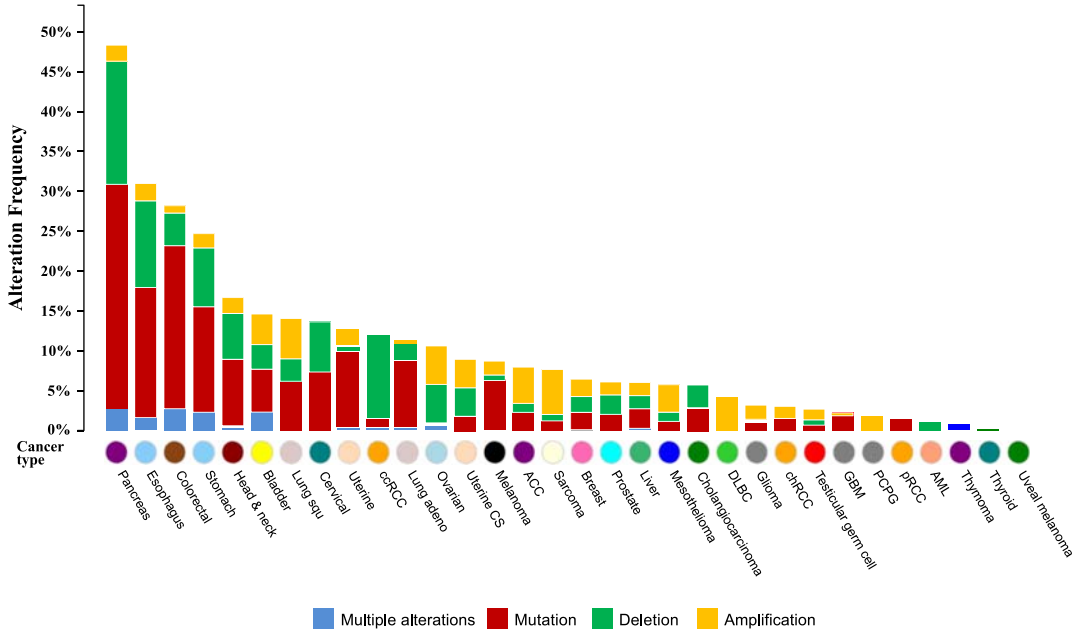

Fig. 5 Frequency of genetic alterations in *TGFBR1*, *TGFBR2*, *Smad2*, *Smad3* and *Smad4* by cancer type. The graph displays the frequency of genetic alterations (point mutations, deletions, amplifications, or multiple alterations) in *TGFBR1*, *TGFBR2*, *Smad2*, *Smad3* and *Smad4* in different types of cancer. Data were derived from TCGA datasets (The Cancer Genome Atlas, cancergenome.nih.gov/) at the time of this writing. Analysis was done using cBioPortal (www.cbioportal.org/).

Mutation in TGF-β Signaling Components in Cancer

Analysis from clinical tumor samples reveals that TGF-mediated signaling is indeed strongly implicated in the regulation of cancer (Wels et al., 2008). Recent studies have shown that in various human tumor types, components of the TGF-β signaling pathway, namely, *TGFBR2*, *TGFBR1*, *SMAD2*, *SMAD3* and *SMAD4*, are commonly inactivated through mutation (Macias et al., 2015; Massagué, 2008). Multiple genetic alterations in genes encoding central components in the TGF-β signaling pathway are found in human cancers of various origin, in particular in pancreatic, esophagus, colorectal and head and neck cancer (**Fig. 5**) (Derynck et al., 2001). Indeed, *TGFBR2*-inactivating mutations in its poly A gene tract are frequently found in cancers associated with microsatellite instability (MSI) (Alvi et al., 2001). Smad point mutations associated with cancer are loss-of-function mutations that either target functional elements or affect the overall stability of the protein. Studies in cultured cells have shown that these inactivating mutations mediate an escape from TGF-β-induced growth arrest and apoptosis. In addition to the known mutations in the TGF-β receptors and Smad pathway, other types of (epi)genetic alterations may also affect TGF-β signaling and tumor formation (Siegel and Massagué, 2003). For example, oncogenic activation of the Ras-Raf-MAPK pathway and c-Jun NH2-terminal kinase in hepatocellular carcinoma has been reported to induce phosphorylation of the Smad3 linker domain by MAPK, further preventing C-terminal phosphorylation of Smad by the TβRI kinase domain and thereby inhibiting the TGF-β cytostatic effects (Nagata et al., 2009).

TGF-β as a Tumor Promotor

TGF-β-Induced EMT and Invasion

In the late stage of tumor progression, TGF-β switches from a tumor suppressor to a tumor promotor by inducing EMT, tumor invasion, distant dissemination, angiogenesis and immune evasion (Meulmeester and ten Dijke, 2011; Seoane and Gomis, 2017; Drabsch and ten Dijke, 2012; Huang and Blobe, 2016). During EMT, the tumor cells dedifferentiate from an epithelial phenotype into a mesenchymal phenotype, upon which they gain higher migratory and invasive abilities. Moreover, they acquire cancer stem cell (CSC) properties and become more resistant to detachment-induced apoptosis (Thiery et al., 2009). During EMT, tumor cells downregulate genes encoding epithelial markers, for example, Epithelial (E)-cadherin, Occludin and Zonula occludens-1 (ZO-1), upregulate genes encoding mesenchymal markers, for example, N-cadherin, Vimentin and α-smooth muscle actin (SMA), and dissolve tight junctions. These EMT changes greatly facilitate tumor cell invasion (**Fig. 6**A) (Nieto et al., 2016; Lamouille et al., 2014). In response to TGF-β, the Smad complex directly increases the expression of multiple EMT-transcription factors including Zeb, Twist and Snail family proteins by activating their promotors. In addition, in combination with Zeb2 or Snail1, the Smad complex suppresses the transcription of genes encoding E-cadherin and Occludin, conferring a mesenchymal trait to tumor cells (Comijn et al., 2001; Vincent et al., 2009). In addition, Smad4 binding enhances the promoter activity of miR-155. Increased

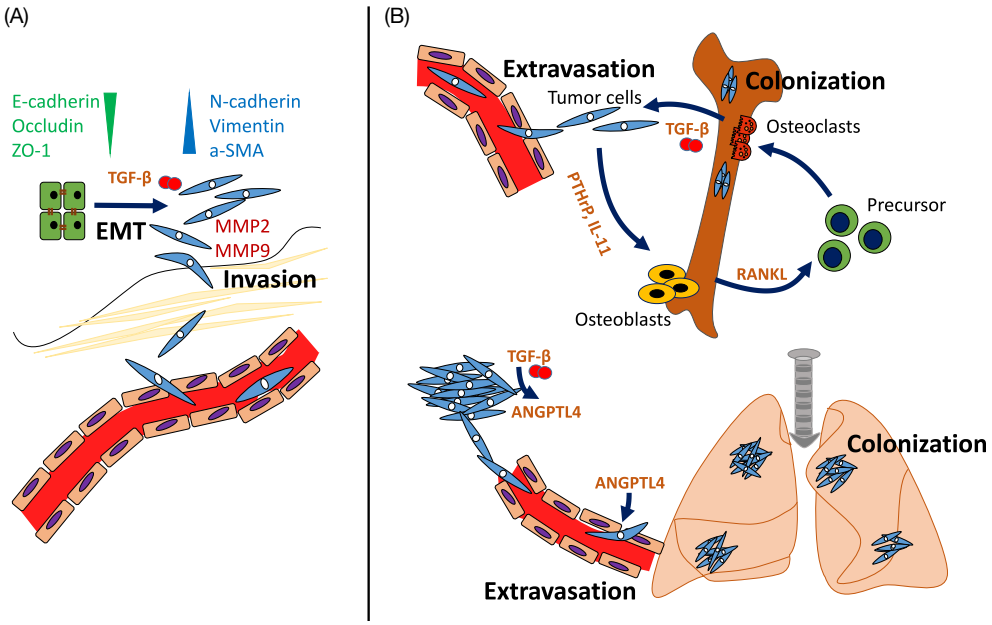

Fig. 6 TGF-β-induced EMT, invasion and metastasis. (A) TGF-β induces the EMT of epithelial cells by decreasing levels of epithelial makers (in *green*) and increasing mesenchymal markers (in *blue*). TGF-β also promotes the secretion of MMP2 and MMP9, thereby further conferring an invasive ability to tumor cells. (B) Bone-derived TGF-β increases the secretion of PTHrP, which activates osteoclast activity through interacting with RANKL, thereby promoting osteolytic metastasis. IL-11 and CTGF are also key modulators induced by TGF-β in this process. Osteolysis leads to more local TGF-β release, leading to the formation of a positive feedback loop. Moreover, TGF-β-driven ANGPTL4 secretion plays a vital role in disrupting junctions between pulmonary endothelial cells and contributes to seeding metastases to the lung. Abbreviations: ANGPTL4, angiopoietin-like 4; EMT, epithelial to mesenchymal transition; MMP, matrixmetalloproteinase; SMA, smooth muscle actin; RANKL, receptor activator of nuclear factor κB ligand; TGF-β, transforming growth factor-β.

expression of miR-155 dissolves tight junctions by targeting RhoA mRNA and downregulates E-cadherin expression by inhibiting the transcriptional activator C/EBPβ (Kong et al., 2008; Johansson et al., 2013). LncRNA-ATB, a long noncoding RNA activated by TGF-β, serves as a sponge for the miR-200 family, which restrains protein levels of Zeb1/2, thereby promoting EMT and hepatocellular carcinoma progression (Yuan et al., 2014). In combination with the Smad-dependent pathway, Smad-independent pathways also serve as promoters in TGF-β-induced EMT (Zhang, 2017; Lamouille et al., 2014; Moustakas and Heldin, 2016). Activation of proto-oncogenes such as Ras and receptor tyrosine kinase pathways cooperate with the TGF-β pathway to promote EMT (Janda et al., 2002; Zhang et al., 2013a). By directly modulating the activity of AP1 transcription factors that can partner with Smads through their phosphorylation or by phosphorylation of R-Smads in their linker region, the ERK, p38 and JNK MAPK pathways play key roles in TGF-β-induced EMT and tumor invasion (Bakin et al., 2002; Yamashita et al., 2006; Zhang et al., 2013b; Kretzschmar et al., 1999). In addition, PI3K/AKT signaling participates in TGF-β-triggered EMT by activating mTOR and EMT-related transcription factors such as Snail and Twist1 (Lamouille and Derynck, 2007; Zhou et al., 2004; Julien et al., 2007; Xue et al., 2012). Activation of Rho family GTPases including RhoA, Rac1, and Cdc42 by TGF-β receptors can contribute to cell–cell junction dissolution and cytoskeletal reorganization, which are important determinants for EMT (Ozdamar et al., 2005; Bhowmick et al., 2001; Menezes et al., 2016).

Local invasion through the surrounding ECM and stromal cell layers is the first step of the invasion-metastasis cascade (Hanahan and Weinberg, 2011). Evidence from human cancer specimens suggests that coexpression of Smad3/4 and Snail is correlated with loss of E-cadherin and coxsackie and adenovirus receptor (CAR), a tight junction-associated cell adhesion molecule, at the invasive front (Vincent et al., 2009). Apart from conferring EMT properties to cancer cells, TGF-β induces the expression and secretion of matrix metalloproteinases 2/9 (MMP2/9) in tumor cells or/and stromal cells (e.g., myofibroblasts). These two proteinases promote the proteolysis of ECM and collagens, leading to the invasion of tumor cells into their stromal compartment (**Fig. 6**A) (Wiercinska et al., 2011; Stuelten et al., 2005). In addition, TGF-β employs miR-181b to inhibit the protein level of TIMP3, an inhibitor of metalloprotease. The latter results in an enhancement of the activity of MMP2 and MMP9 and promotes the invasion of hepatocellular carcinoma cells (Wang et al., 2010).

TGF-β-Induced Metastasis to Bone, Lung and Other Organs

The metastasis of cancer cells from the primary site to distant organs contributes to the death of most cancer patients (Valastyan and Weinberg, 2011). Bone metastasis is a common event in specific cancer types, including breast, lung and prostate cancers. The interaction between disseminated tumor cells and resident skeletal cells disrupts bone integrity, conferring a receptive microenvironment

for the outgrowth of metastatic tumor cells (Mundy, 2002; Suva et al., 2011). Bone-derived TGF-β can act on breast cancer cells and promotes the activation of the Smad-dependent pathway, which increases the secretion of parathyroid hormone-related protein (PTHrP), a major osteoclastogenic factor. PTHrP subsequently activates osteoclast activity by interacting with receptor activator of nuclear factor κB ligand (RANKL), thereby promoting bone metastasis (**Fig. 6**B) (Suva et al., 2011; Yin et al., 1999; Kakonen et al., 2002; Lacey et al., 1998). By employing *in vivo* selection of highly metastatic cell lines and functional imaging, Kang et al. identified a bone metastasis gene set signature that includes *chemokine receptor CXCR4*, *interleukin 11* (*IL-11*) and *connective tissue growth factor* (*CTGF*), which contribute to metastasis by mediating the homing of breast cancer cells to bone, osteolysis and angiogenesis, respectively (Kang et al., 2003; Kang et al., 2005). IL-11 and CTGF are induced by TGF-β. Bone degraded by cancer cells in turn increases the secretion of stored factors including TGF-β, thus forming a positive feedback loop called a "vicious cycle" (Zheng et al., 2016).

Apart from contributing to the spreading to bone, TGF-β signaling also contributes to seeding metastases to the lung. A TGF-β-induced gene expression signature in estrogen receptor (ER)-negative breast cancer cells was found to correlate with the potential to form lung metastases. Blockade of TGF-β signaling impaired the extravasation of ER-negative breast cancer cells through the tight endothelial junctions in lung capillaries, while prior and transient treatment of TGF-β increased the metastatic abilities of tumor cells (Padua et al., 2008). The expression of the TGF-β-driven adipokine *angiopoietin-like 4* (*ANGPTL4*) was identified to play a vital role in the disruption of junctions between the pulmonary endothelial cells (**Fig. 6**B). However, bone metastasis was not affected by TGF-β preincubation or ANGPTL4 knockdown, which can be explained by the difference in the microvasculature of these two organs (Welm, 2008).

TGF-β also participates in the metastatic growth of tumor cells to the liver (Kang et al., 2011; Tu et al., 2015). Upon extravasating into liver parenchyma, TGF-β released by colorectal cancer cells acts on surrounding hepatic satellite cells (HSCs) and promotes the transformation of HSCs into myofibroblasts. Tumor-associated myofibroblasts in turn increase the expression of SDF-1 and hepatic growth factor (HGF), which triggers the metastatic growth of tumor cells (Liu et al., 2013).

Stimulation of Angiogenesis and Immune Evasion by TGF-β

Angiogenesis, the formation of new blood vessels, is indispensable for solid tumors larger than 2–3 mm^3 to obtain oxygen and nutrients, remove waste products and spread through the circulatory system (Carmeliet and Jain, 2000). An elevated level of TGF-β in plasma is correlated with an increase in tumor angiogenesis and poor clinical outcome in many cancer types (Ito et al., 1995; Ivanovic et al., 1995; Wikstrom et al., 1998; Hasegawa et al., 2001). TGF-β can directly activate endothelial cells by activating the TGF-β/ALK1 signaling pathway (de Vinuesa et al., 2016). The coreceptor endoglin, which is highly expressed on activated endothelial cells, can promote this signaling response (Paauwe et al., 2013). Moreover, in the tumor niche with low oxygen, hypoxia and TGF-β signaling can cooperate to initiate an angiogenic program in tumor cells. Mechanistically, hypoxia-induced HIF-1, in cooperation with Smad3, enhances the transcription of *vascular endothelial growth factor* (*VEGF*), which is of pivotal importance in capillary formation and the migration of endothelial cells, thereby promoting tumor angiogenesis (Pertovaara et al., 1994; Sanchez-Elsner et al., 2001). Silencing Smad2 (in contrast to Smad3 depletion) in the MDA-MB-231 breast cancer cell line enhanced TGF-β-induced VEGF secretion *in vitro* and promoted the formation of bone metastases *in vivo* (Petersen et al., 2010). TGF-β also enhances the transcription of *CTGF*, another key angiogenic factor, in breast cancer cells with high bone metastatic potential (Kang et al., 2003).

In addition to supporting EMT, invasion, metastasis and tumor angiogenesis, TGF-β also contributes to tumor progression by stimulating tumor evasion from immune surveillance. CD8+ cytotoxic T cells are a cell population that can induce cancer cell apoptosis. TGF-β represses the transcription of *granzyme*, *perforin* and *interferon-γ* through Smad and ATF1 in CD8+ T cells, thereby inhibiting its cytotoxic activity (Thomas and Massagué, 2005; Ahmadzadeh and Rosenberg, 2005). TGF-β can also induce the differentiation of regulatory T-cells (Tregs), which further suppress the proliferation and activation of CD8+ cytotoxic T-cells, resulting in immunosuppression and a decrease in immunosurveillance (Fu et al., 2004; Liu et al., 2008; Somasundaram et al., 2002). The activation of natural killer (NK) cells, another cytotoxic cell type, is attenuated by TGF-β-induced downregulation of IL-15 and NKG2D, an activating receptor of NK cells (Wilson et al., 2011; Crane et al., 2010). In addition, TGF-β-triggered miR-183 represses the DAP12 protein level, leading to the destabilization of the NK receptor and inhibition of cytotoxicity (Donatelli et al., 2014). In addition, TGF-β is a driver for the transition of the tumor-suppressive M1 macrophage phenotype into the tumor-promoting M2 phenotype, thereby promoting the production of tumor-promoting factors and inhibiting the activity of T cells (Sica et al., 2006; Gong et al., 2012).

Targeting the TGF-β Signaling Pathway in Cancer

Due to the strong pro-oncogenic effects of TGF-β, TGF-β inhibitory targeting agents have been developed, including antisense oligonucleotides (AON), small molecule receptor kinase inhibitors and neutralizing antibodies. The mechanisms of these inhibitors involve inhibition of TGF-β and receptor expression, interference in receptor kinase signaling, and blockade of TGF-β ligand and receptor binding (**Fig. 7**, **Table 1**). These agents have been tested in the preclinical and clinical stages. While inhibiting tumor progression by blocking the TGF-β signaling pathway is a promising approach, the biphasic action of TGF-β in cancer progression and its multifunctionality make it a challenging target.

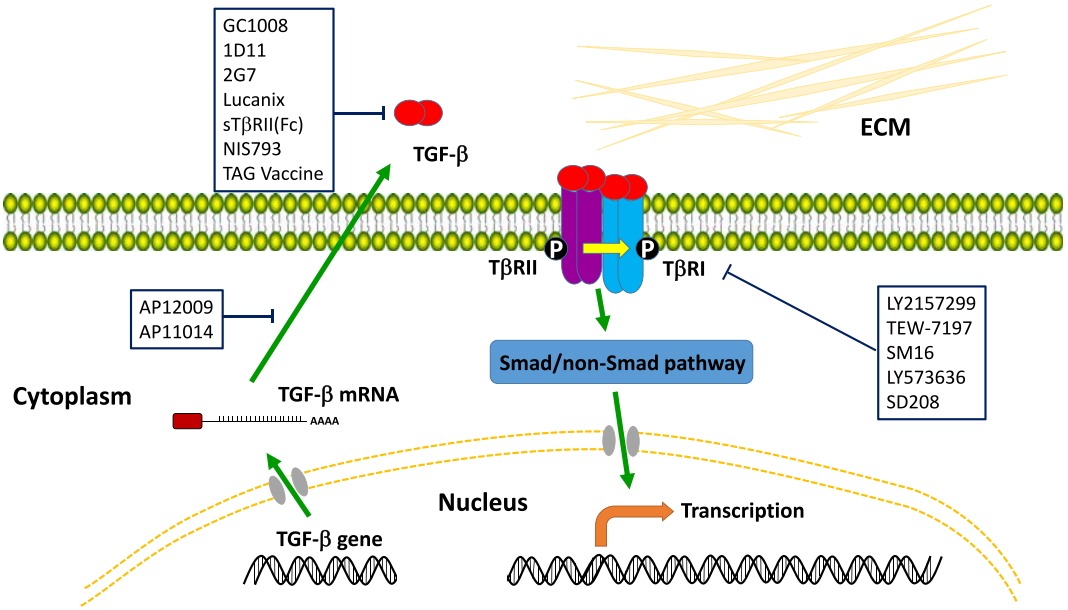

Fig. 7 Targeting TGF-β in cancer. The TGF-β signaling pathway has an important effect on tumor progression and provides a new approach for tumor targeting therapy. Many inhibitors of the TGF-β pathway (including kinase inhibitors, AON, and antibodies) have already been applied in preclinical and clinical trials (see **Table 1**). Abbreviations: ECM, extracellular matrix; TβR, TGF-β receptor; TGF-β, transforming growth factor-β.

Table 1 Overview of clinical trials with TGF-β targeting agents

Stage	*Drug*	*Type*	*Target*	*Disease*	*Clinical trial identifier*
Phase 1	AP 12009	AON	TGF-β2	Multiple cancers	NCT00844064
	TAG Vaccine	Vaccine therapy	TGF-β2 and immune	Carcinoma/advanced metastatic	NCT00684294
	TEW-7197	Kinase inhibitor	TβRI	Advanced stage solid tumors	NCT02160106
	NIS793	Antibody	TGF-β	Multiple cancers	NCT02947165
	Paclitaxel/Carboplatin + Galunisertib	Kinase inhibitor	TβRI	Carcinosarcoma, ovarian	NCT03206177
	TEW-7197	Kinase inhibitor	TβRI	Multiple myeloma	NCT03143985
	LY2157299	Kinase inhibitor	TβRI	Multiple myeloma	NCT00689507
	LY573636	Kinase inhibitor	TβRI	Hematopoietic malignancies	NCT00718159
	Fresolimumab(CG1008)	Antibody	TGF-β2	Multiple cancers	NCT00356460
Phase 1| Phase 2	Fresolimumab(CG1008)	Antibody	TGF-β2	Multiple cancers	NCT02581787
	LY2157299	Kinase inhibitor	TβRI	Multiple cancers	NCT02423343
	LY2157299	Kinase inhibitor	TβRI	Glioma	NCT01220271
Phase 2	LY2157299	Kinase inhibitor	TβRI	Prostate cancer	NCT02452008
	Lucanix (belagen-pumatucel)	Vaccine therapy	TGF-β2 and immune	Multiple cancers	NCT01058785
	PF03446962	Antibody	ALK1	Transitional cell carcinoma of bladder	NCT01620970
	Fresolimumab(CG1008)	Antibody	TGF-β2	Primary brain tumors	NCT01472731
	LY2157299	Kinase inhibitor	TβRI	Metastatic breast cancer	NCT02538471
	LY2157299	Kinase inhibitor	TβRI	Rectal adenocarcinoma	NCT02688712
	AP 12009	AON	TGF-β2	Glioblastoma/anaplastic astrocytoma	NCT00431561
	Fresolimumab(CG1008)	Antibody	TGF-β2	Pleural malignant mesothelioma	NCT01112293
	Fresolimumab(CG1008)	Antibody	TGF-β2	Renal cell carcinoma	NCT00923169
	LY2157299	Kinase inhibitor	TβRI	Hepatocellular carcinoma	NCT02178358
	Fresolimumab(CG1008)	Antibody	TGF-β2	Metastatic breast cancer	NCT01401062
	LY2157299	Kinase inhibitor	TβRI	Hepatocellular carcinoma	NCT01246986
	LY573636	Kinase inhibitor	TβRI	Melanoma	NCT00383292
	LY573636	Kinase inhibitor	TβRI	Non-small cell lung carcinoma	NCT00363766

Table 1 Overview of clinical trials with TGF-β targeting agents—cont'd

Stage	*Drug*	*Type*	*Target*	*Disease*	*Clinical trial identifier*
	Fresolimumab(CG1008)	Antibody	TGF-β2 and immune response	Kidney cancer	NCT00899444
Phase 3	AP 12009	AON	TGF-β2	Anaplastic Astrocytoma| glioblastoma	NCT00761280

Antisense Oligonucleotides

The binding of ligands and receptors is the first step in activating the TGF-β signaling pathway; antisense oligonucleotides (AON) that promote TGF-β mRNA degradation and lead to a decreased biosynthesis of TGF-β have been developed (**Fig. 7**) (Crooke, 1999). The antisense RNA drugs AP12009 and AP11014 targeting TGF-β2 and TGF-β1, respectively, have been used in (pre)clinical cancer treatment studies. AP12009 has been reported to inhibit neovascularization and tumor invasion and has been used to treat high-grade glioma and anaplastic astrocytoma patients (Bogdahn et al., 2008; Hau et al., 2007; Nagaraj and Datta, 2010). In addition, AP11014 has been reported to display an anti-tumor effect in animal models for colon cancer, prostate cancer and lung cancer and is currently being studied in preclinical research (Bogdahn et al., 2010; Schlingensiepen et al., 2004).

TGF-β Receptor Kinase Inhibitors

Small ATP-mimetic compounds have been identified that selectively inhibit TβRI (and TβRII) kinase activity (**Fig. 7**). These compounds have been tested in preclinical and clinical studies of a wide range of cancer types. Systemic administration of the TβRI kinase inhibitor SD208 can increase the median survival of mice with malignant glioma vaccination (Mohammad et al., 2011) and reduce tumor metastasis in pancreatic cancer and breast cancer (Gaspar et al., 2007; Ge et al., 2006). LY2157299 is the first TGF-β kinase inhibitor that has been reported to inhibit primary tumor growth in breast and lung cancer cell lines (Bueno et al., 2008; Herbertz et al., 2015). To optimize the applicability of LY2157299 to tumor therapy, a first-in-human dose evaluation found that LY2157299 administration at 300 mg per day is safe (Rodon et al., 2015). Another kinase inhibitor, LY2109761, inhibits both the activity of AKL5 and TβRII. A large number of studies have indicated that LY2109761 exhibited great potential in the prevention of tumor metastasis, including colon (Zhang et al., 2010) and pancreatic cancer (Melisi et al., 2008), glioblastoma (Zhang et al., 2011) and ovarian cancer (Alsina-Sanchis et al., 2016; Gao et al., 2015). TEW-7197 is an orally administered small molecule that targets TβRI kinase activity. It stimulated apoptosis and suppressed TGF-β-induced activation of Smad2/3 in human and murine MM cells *in vitro*, leading to the inhibition of MM cell growth and viability (Kim et al., 2017b). While the preclinical results of these studies are encouraging, the clinical translation has been difficult. On-target side effects on the cardiovascular system have halted clinical advancement. By using an intermittent dosing strategy, these adverse side effects may be overcome (Colak and ten Dijke, 2017; Herbertz et al., 2015).

Antibodies Against TGF-β Ligands and Extracellular Domains of TGF-β Receptors

1D11, an antibody that recognizes all three TGF-β isoforms, interferes with TGF-β-receptor binding and, thus, neutralizes (**Fig. 7**) TGF-β activity. This antibody has been used in (pre)clinical studies. 1D11 significantly increases NK cell and nuclear T cell invasion, as well as NKG2D expression and cytotoxic perforin and granzyme B release in breast cancer, thereby enhancing the anti-tumor effect of CD8+ T cells and NK cells (Nam et al., 2008). Additionally, 1D11 has also been found to suppress bone metastasis in prostate cancer (Sturge et al., 2011). Like 1D11, 2G7 also inhibited the invasion of MDA-MB-231 cells (a human breast cancer cell line). Additionally, the combination of dendritic cell (DC)-based vaccines and 2G7 potently inhibited the development of established murine mammary tumors (Kobie et al., 2003; Nam et al., 2006). A clinical trial of another monoclonal antibody, fresolimumab (CG1008), which inhibits all three TGF-β isoforms, demonstrated its safety and efficacy in improving metastatic melanoma and renal cell carcinoma (Morris et al., 2014). Fresolimumab may help to stabilize the condition of patients during malignant

pleural mesothelioma therapy. Importantly, adverse effects, such as skin toxicity (including formation of cutaneous squamous-cell carcinomas and basal cell carcinoma), have been reported in cancer patients after treatment with fresolimumab (Morris et al., 2014).

Similar to neutralizing antibodies, soluble TβRII and TβRIII ligand traps are also used to block the TGF-β signaling pathway. These molecules are expressed in the extracellular domain of the receptor, which prevent ligands from binding to TGF-β receptors (Drabsch and ten Dijke, 2012). The ligand trap TβRII:Fc (a fusion of the extracellular TGF-β-binding domain of TβRII with IgG1 Fc domain) showed anti-tumor effects on multiple cancers, including inhibition of mesothelioma growth and suppression of breast cancer cell viability and migration (Muraoka et al., 2002; Suzuki et al., 2004). The expression of soluble TβRIII (sBetaglycan) could effectively suppress tumor growth in human breast carcinoma MDA-MB-231 xenograft-bearing athymic nude mice (Bandyopadhyay et al., 2002) and inhibit glioma and non-small cell lung cancer progression in other mouse models (Finger et al., 2008; Naumann et al., 2008). Due to the risk of tumor development caused by the TGF-β soluble receptor (Huntley et al., 2004; Tang et al., 2003), these receptors have not yet entered clinical research.

Targeting the TGF-β signaling pathway provides a new approach and opportunity for tumor therapy. Since the TGF-β pathway is also involved in many normal biological functions, the exact mechanism of action in the patients and the adverse reactions caused by systemic inhibition of TGF-β are still not clear. A further understanding of the dual roles of TGF-β will be beneficial to the development of therapeutics specifically targeting TGF-β in tumor progression. Sole treatment with TGF-β-targeting agents will likely not be successful in curing cancer patients, and a combination of TGF-β targeting therapies with chemo- and radiotherapy or other forms of targeted therapy should be explored.

Concluding Remarks

TGF-β has a dual action in cancer by acting as a tumor suppressor in early stages and a tumor promotor in the late phases of tumor progression. Cancer cells are insensitive to the cytostatic effects of TGF-β through the activation of proto-oncogenes and inactivation of tumor suppressor genes. The latter (epi)genetic changes also cooperate with TGF-β to mediate EMT, thereby facilitating invasion and metastasis. Moreover, TGF-β promotes tumorigenesis by stimulating immune evasion and promoting angiogenesis. The biphasic role in cancer and its multifunctional properties in the maintenance of tissue homeostasis make TGF-β a challenging pathway to target for treatment of cancer patients. A more detailed understanding of the mechanism of action in cancer patients, careful dosing and the selection of patients who will most benefit from the TGF-β targeting agents will be important for their clinical implementation.

rhTSH Recombinant human thyroid-stimulating hormone
Tg Thyroglobulin
TSH Thyroid-stimulating hormone

Definition and Classification

Cancer of the thyroid is a group of diseases comprising a variety of tumor types differing in morphology, etiology, biological behavior, and molecular characteristics. They include the differentiated papillary and follicular carcinomas, carcinomas lacking characteristic differentiation which include undifferentiated carcinomas and anaplastic carcinomas, and medullary carcinoma as a separate category. The 2017 WHO classification also describes a variety of subtypes and rare tumor types which are not discussed in this entry.

Over 95% of thyroid cancers derive from follicular cells, with a vast majority being well-differentiated tumors (differentiated thyroid carcinomas, DTCs). The classification of thyroid cancers has been a subject of debate and several changes in recent years, in particular concerning controversial variants rendering differential diagnosis challenging. Recent genomic and transcriptomic data suggest that further reclassifications of some of the variants based on their molecular profiles combined with histological features may soon be worth considering.

The predominant form of thyroid cancer, in both adults and children, is papillary thyroid carcinoma (PTC; ICD-O code: 8260/3), also called papillary thyroid adenocarcinoma, which accounts for up to 90% or even 95% of all thyroid carcinomas. PTC is a malignant epithelial tumor with follicular cell differentiation, distinctive nuclear features and a papillary growth pattern. A number of PTC histological variants exist, including follicular variant (ICD-O code: 8340/3), encapsulated variant (8343/3), papillary microcarcinoma (8341/3), columnar cell variant (8344/3), and oncocytic variant (8342/3).

The second most common thyroid cancer is follicular thyroid carcinoma (FTC), also referred to as follicular thyroid adenocarcinoma or follicular carcinoma. It accounts for 5%–15% of all thyroid cancer cases. FTC is defined as a thyroid malignancy derived from follicular cells in which the diagnostic nuclear characteristics of PTC are absent. It includes three variants: minimally invasive FTC (ICD-O code: 8335/3), encapsulated angioinvasive FTC (8339/3) and widely invasive variant (8330/3).

Medullary thyroid carcinoma (MTC; ICD-O code: 8345/3), a malignant tumor of the thyroid gland composed of cells with evidence of C-cell differentiation, accounts for no more than 2%–3% of cases and is mainly associated with familial cancer syndromes.

The most aggressive primary thyroid malignancy is anaplastic thyroid carcinoma (ATC; ICD-O code: 8020/3) which is composed of undifferentiated follicular cells. Also this thyroid cancer is very rare (0.8%–5% of cases).

Epidemiology ad Risk Factors

Thyroid Cancer Burden

Thyroid cancer accounts for about 90% of all endocrine malignancies. With nearly 300,000 new cases diagnosed in 2012, it was the 16th most common cancer when considering both sexes together and the 7th most common in women worldwide. The incidence rates are two to four times higher in women than in men (Fig. 1). The peak incidence is at about 50 years of age. Even though thyroid cancer is rare in children, it is the third most common solid malignancy and the most frequent endocrine childhood malignancy. There has been a big increase in the reported thyroid cancer and in particular PTC incidence since the introduction of new high-resolution techniques into clinical practice. However, overall mortality from thyroid cancer is very low. PTC, the most common form of the disease, tends to be biologically indolent, giving rise to the 5-year survival rates of 96% and 20-year survival rates still over 90%. Follicular and medullary carcinoma have a relatively good prognosis as well, with 5-year survival rates of 50%–90% for FTC (for widely invasive and minimally invasive FTC, respectively), and 80% for MTC. The thyroid carcinoma-associated mortality is mainly due to ATC which gives median 1-year survival rates of only 10%–20%, and 5-year survival rates below 1%.

Etiology and Risk Factors

As thyroid cancer is more frequent in women, female sex has been suggested as a risk factor. However, the disparity in incidence between the two sexes decreases with increasing patient age. Some studies also suggest that Asian race is associated with a higher risk of thyroid cancer.

Since the mortality associated with thyroid cancer is very low, the etiology of this cancer type has been less studied than that of cancers arising at other sites. The major and best documented cause of thyroid cancer is exposure to radiation. Environmental exposure to ionizing radiation is a well-established risk factor for both papillary (PTC) and follicular thyroid carcinoma (FTC), although it presents a much lower risk for developing the latter. In contrast, the risk of medullary thyroid carcinoma (MTC) is not associated with ionizing radiation exposure at all.

Radiation therapy administered in infancy or childhood for benign conditions of the head and neck increases the risk of thyroid cancer, with diagnosis occurring in as few as 5 years after exposure. Radiation exposure as a consequence of nuclear fallout has also been associated with a high risk of thyroid cancer, especially in children. Insufficient dietary iodine intake is an important risk factor for follicular carcinoma (Table 1). Introducing iodine supplementation in iodine-insufficient areas results in a decreased FTC to PTC ratio. However, it is unclear whether it affects the overall rates of thyroid carcinoma.

Other factors, such as obesity, diabetes, reproductive factors, smoking, alcohol consumption, and dietary nitrates have been identified as putative risk factors for PTC. However, their exact link with the disease is unclear.

The causative factors of anaplastic thyroid carcinoma (ATC), the rare and highly aggressive form of the disease, remain unknown. However, the existence of differentiated areas in these tumors suggests that they may evolve from differentiated tumors, like PTC or FTC. MTC, in contrast, seems to be mostly associated with familial cancer syndromes.

Most thyroid cancers are sporadic. However, a family history of thyroid disease (including cancer) is associated with a higher risk of thyroid cancer. Moreover, there are two groups of familial thyroid cancers which are associated with familial cancer syndromes: familial non-medullary thyroid carcinoma (FNMTC, also called familial follicular cell-derived carcinoma) arising from follicular cells and familial medullary thyroid carcinoma (FMTC) which arises from calcitonin-producing C cells.

Overall, approximately 30% of MTCs are associated with germline mutations in the *RET* proto-oncogene manifesting as the multiple endocrine neoplasia (MEN) type 2A (which includes familial MTC as a variant) or type 2B. The genetic susceptibility background of FNMTC is less straightforward. Hereditary cancer syndromes underlying the development of this disease include among others familial adenomatous polyposis, Carney complex and Werner syndrome. Among PTC patients, approximately 5% of cases are familial, developing in the context of the Familial adenomatous polyposis (FAP) syndrome. This is caused by a mutation in the *APC* gene. About 1%–2% of FAP patients develop PTC.

Familial FTC occurs in the context of the PTEN hamartoma tumor syndrome, a rare syndrome associated with mutations in the *PTEN* gene. Patients with a germline *PTEN* mutation have a 35% lifetime risk for the development of FTC.

Presentation and Diagnosis

Both PTC and FTC can occur in any location of the thyroid gland and anywhere where ectopic thyroid tissue may be present, whereas MTCs are usually located at the junction of the upper and mid portions of the thyroid lobe where the C cells (parafollicular cells) are typically concentrated.

PTC usually presents as an asymptomatic painless mass in the thyroid with or without enlarged cervical lymph nodes. Later symptoms may include hoarseness and dysphagia or dysphonia.

The clinical presentation of FTC is as an asymptomatic painless single thyroid nodule. Larger tumors may compress cervical structures leading to dyspnea or dysphagia. Hoarseness may also appear. Rarely, the tumor may be hyperfunctional, associated with clinical signs and symptoms of hyperthyroidism.

Most patients with sporadic MTC present with a painless single thyroid nodule. In an iodine scan, this will be a cold nodule. Regional lymph node enlargement is frequent as a large proportion of patients have lymph node metastases at initial presentation.

Table 1 Risk factors for thyroid cancer

Carcinogenic agents classified by IARC Monographs on the Evaluation of Carcinogenic Risks to Humans (volumes 1–120)
Agents of sufficient evidence for kidney carcinogenicity in humans
Radioiodines, including iodine-131
X-radiation and gamma-radiation
Other carcinogenic agents and lifestyle risk factors
Nuclear fallout

Later symptoms may include hoarseness and dysphagia or dysphonia. MTC produces carcinoembryonic antigen (CEA) and this is a much used test for initial diagnosis and follow-up. Tests for calcitonin secretion are also positive. As far as familial MTC is concerned, screening for production of calcitonin in MEN2 families allows early diagnosis even at a stage of (premalignant) C-cell hyperplasia.

Poorly differentiated thyroid carcinomas present as large thyroid masses. In about 15% of cases, patients present with metastases. The tumor spreads by local invasion into perithyroidal tissues, and by distant metastases to the lungs, bone, and other organs.

ATC patients typically present with a rapidly enlarging, firm and widely infiltrative neck mass associated with pain, hoarseness, difficulty breathing, and dysphagia. Less common symptoms include vocal cord paralysis, cervical pain, and dysphonia. ATCs present with considerable local invasion, and frequently with local and distant metastases (one third of patients have distant metastases at presentation).

As thyroid nodules are very common and most of them are relatively inoffensive, differentiating between benign and malignant thyroid nodules in the initial workup is crucial for proper management choices. A combination of serum thyroid-stimulating hormone (TSH) testing, imaging techniques (usually ultrasound) of the thyroid and neck, and clinical features is used to determine whether there is a suspicion of a malignant potential. If it is the case, a fine-needle aspiration (FNA) biopsy is taken to allow for a cytological and immunohistochemical evaluation. Some clinicians, especially in Europe, recommend measuring serum calcitonin levels to evaluate for MTC, however the cost-effectiveness of this procedure remains controversial. Molecular testing to detect individual mutations (e.g., in the *BRAF* or *RET* gene) or specific patterns may be useful to evaluate biopsy samples that are indeterminate and thus guide management decisions (see "**Biomarkers**" section).

Pathology and Genetics

The thyroid hosts two different organ systems. The most conspicuous is the follicular compartment, responsible for the production of thyroid hormones and origin of neoplasms with follicular differentiation. Less conspicuous are the parafollicular or C-cells, responsible for the biosynthesis of calcitonin. Parafollicular cells are of neural crest origin and arrive in the thyroid by migration. Therefore, they represent a lineage which is entirely distinct from that of follicular epithelium. They are considered part of the diffuse neuro-endocrine system.

Papillary Thyroid Carcinoma

Pathology

PTC may arise anywhere in the thyroid or in the isthmus and occasionally in ectopic thyroid tissue in the neck region. At gross examination, it presents as a poorly circumscribed solid mass, with a granular white cut surface. Calcification may be found. Occasionally the tumor is encapsulated. Usual size is 2–3 cm. In about 20% of cases, multifocal PTC is found.

The name of this entity comes from characteristic architectural features of a papillary carcinoma: the presence of papillae (long, straight or arborizing stromal stalks covered with neoplastic epithelium). These architectural features or characteristic nuclear features (irregular nuclear contour, nuclear pseudo-inclusions responsible for the "ground glass" appearance of the nucleoplasm, prominent nuclear grooves) are essential for a diagnosis of a papillary carcinoma (**Fig. 2**). Some thyroid carcinomas have a follicular architecture but nuclear features characteristic of a papillary carcinoma—these are classified as a follicular variant of papillary carcinoma (**Fig. 3**). PTCs are often surrounded by a dense fibrous capsule, representing the encapsulated variant. Some show diffuse dense fibrous stroma, representing the diffuse sclerosing variant. Microscopic structures classically associated with PTC are psammoma bodies. Invasion of lymphatic vessels is not unusual and is associated with a tendency for lymphogenous metastasis. Immunohistochemically, PTCs are positive for thyroglobulin, TTF-1, PAX8, and cytokeratin (pancytokeratin and CK7).

Progression of PTC consists primarily of metastasis to cervical lymph nodes. Distant metastases are rare. The relative indolence of PTC is reflected in its excellent prognosis, with 5-year survival rates of about 95% and overall mortality rates of 1%–5%.

Genetics

PTC has a more stable genome with few chromosomal rearrangements and a lower number of mutations than carcinomas arising in other organs. *BRAF V600E* is the most common driver mutation found in PTC (found in up to 95% of *BRAF*-mutant tumors). The follicular variant has a much lower frequency of *BRAF* mutations. Other, less frequent *BRAF* alterations include *K601E* mutations

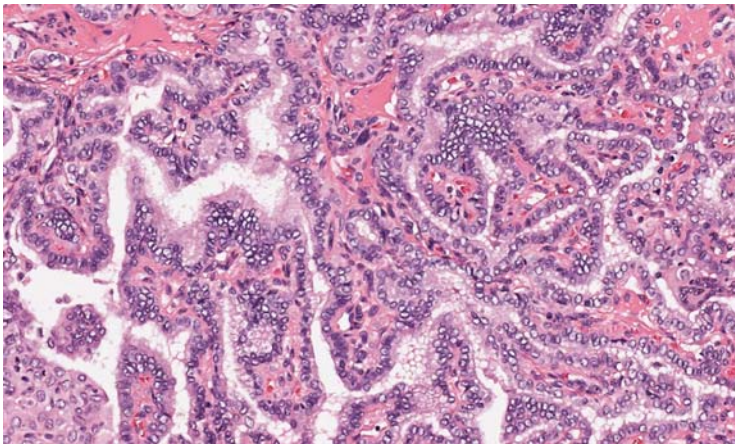

Fig. 2 Papillary carcinoma. Note the papillary architecture with fibrovascular stalks covered with a single layer of cuboid epithelial cells. Nuclei show irregular contour, pseudo-inclusions responsible for the "ground glass" appearance of the nucleoplasm, and prominent nuclear grooves, characteristic of papillary carcinoma.

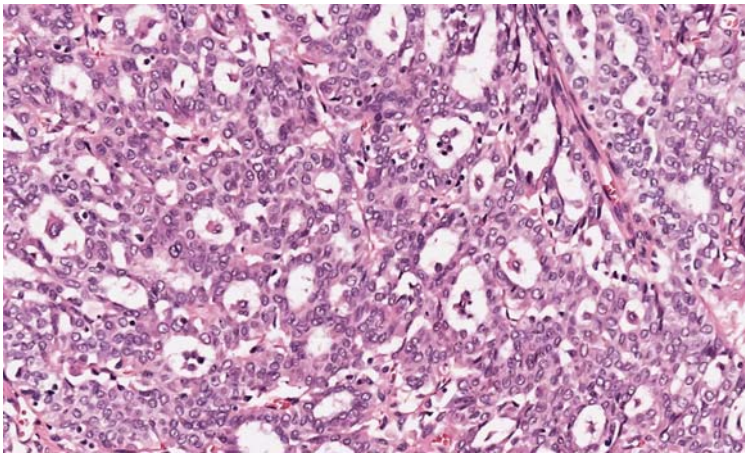

Fig. 3 Papillary carcinoma, follicular variant. Note the follicular architecture but nuclear features typical of papillary carcinoma.

and small insertions or deletions surrounding codon 600 as well as chromosomal rearrangements, such as *AKAP9-BRAF* fusions. Mutations in the *RAS* genes (mostly *HRAS* and *NRAS*) are also common (up to 30% of cases) and often mutually exclusive with *BRAF* alterations. The most frequent chromosomal rearrangements leading to gene fusions involve the *RET* gene, the most common being *RET*/PTC rearrangements, followed by those involving *NTRK3*, *NTRK1*, *ALK*, and other genes. Rearrangements are typical for radiation-related PTC and for younger patients, including children. PTC progression is associated with accumulation of mutations in other genes, such as *TP53*, *PIK3CA*, and *AKT1*. Mutations in the promoter of the telomerase reverse transcriptase (*TERT*; *C228T* and *C250T*) are found in more advanced PTCs and are associated with a higher risk of recurrence, distant metastasis, and PTC-related mortality (**Table 2**). The Cancer Genome Atlas Research Network has identified two major subgroups of PTCs based on their gene expression profile: *BRAF V600E*-driven tumors and *RAS* mutation-driven tumors (**Fig. 9**), with striking molecular signaling differences and also distinct histological features between the two subtypes. However, the prognostic utility of *BRAF V600E* remains controversial, with conflicting literature reports. The mutation profile of PTC has been changing over the past decades, with a sharp increase in the prevalence of *RAS* mutations and a steady decrease in the prevalence of *RET*/PTC rearrangements, while the proportion of tumors carrying the *V600E BRAF* mutation has remained stable or even increased. Familial PTC (about 5% of cases) is associated with mutations in the *APC* gene, typically proximal to the mutation cluster region located centrally in the open reading frame and overlapping with the region encoding the 20 amino acid repeats which bind with β-catenin.

Follicular Carcinoma

Pathology

FTC cannot be adequately covered without dedicating a few words to follicular adenoma. The term "follicular" refers to the typical architecture of the tumor, which mimics follicles in the normal thyroid. By definition, follicular adenoma is a benign epithelial

Table 2 Gene loci that are most frequently altered in thyroid carcinoma

Pathway	*Gene (locus)*	*Alteration type*	*Estimate*
MAPK signaling	*BRAF* (7q34)	Point mutations (most frequent: *V600E*), small insertions or deletions, chromosomal rearrangements	30%–90% of PTCs; *BRAF V600E* identified as a driver mutation in a specific PTC subset and also present in about 20% of ATCs
	RET (10q11.21)	Rearrangements (most common: *RET/PTC*)	5%–35% of sporadic PTCs; characteristic of radiation-induced tumors and young patients
		Point mutations	40%–60% of sporadic MTCs
	RAS family (*HRAS, NRAS*)	Point mutations	0%–35% of PTCs, 30%–50% of FTCs; 20% of ATCs
Telomere maintenance	*TERT* (5p15.33)	Promoter mutations	5%–25% of PTCs and about 20% of FTCs; associated with more aggressive tumor behavior and worse prognosis
Fatty acid storage and glucose metabolism	*PPARG* (3p25.2)	Rearrangements/fusions frequently involving the thyroid transcription factor *PAX8*	20%–50% FTCs; *PAX8-PARG* fusions associated with younger patient age and tumor vascular invasion
PI3K/PTEN/Akt: control of cell metabolism	*PTEN* (10q23)	Inactivating mutations	Up to 10% of FTCs; variable proportions of ATCs
	PIKCA3 (3q26)	Mutations and copy number gains	Mutations in up to 10% of FTCs; variable proportions of ATCs
p53 signaling	*TP53* (17p13.1)	Mutations	Late events, associated with tumor progression, particularly frequent in ATCs (40%–80% of cases)

ATC, anaplastic thyroid carcinoma; *FTC*, follicular thyroid carcinoma; *PTC*, papillary thyroid carcinoma.

tumor in the thyroid with follicular architecture. Epidemiological data are not very reliable because follicular adenomas occur most frequently in females in the 5th or 6th decade of life, when nodular goiter is relatively frequent, in particular in iodine-deficient regions. In a multinodular thyroid, it is rather difficult to distinguish between a (polyclonal) hyperplastic nodule and a (monoclonal) follicular adenoma. Molecular analysis would be necessary to make the distinction and in this context many pathologists will not make this diagnosis. Large autopsy series suggest an incidence of about 5%. In iodine-sufficient regions, palpable single thyroid nodules have been reported in 3%–5% of the population, consistent with these autopsy data.

At gross examination, a follicular adenoma presents as a regular round encapsulated solid gray-white to yellow or tan mass. The yellow/tan color is indicative of the presence of well-developed follicles containing colloid. Microscopically, the tumor shows a follicular architecture. The follicles are composed of cuboidal epithelial cells surrounding a lumen that may contain colloid (Fig. 4). Nuclear features are bland. Mitotic activity is rare. In a relatively normal thyroid, the presence of an encapsulated lesion is sufficient for a diagnosis of adenoma. In a nodular goiter, the presence of fibrosis complicates this criterion. It is often impossible to distinguish a hyperplastic nodule from an adenoma as their cytonuclear features can be indistinguishable. When a diagnosis of follicular adenoma is considered, a careful examination of the tumor capsule becomes crucial as the only distinction between a follicular adenoma and a follicular carcinoma may be the presence of capsular or (preferably) vascular invasion.

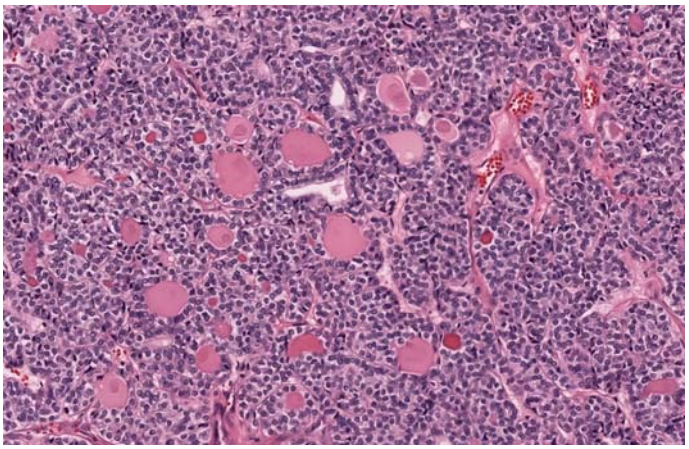

Fig. 4 Follicular adenoma. The lesion is composed of small follicles, occasionally with a lumen filled with colloid. The follicular cells show bland nuclear features, little pleomorphism, and no mitotic activity.

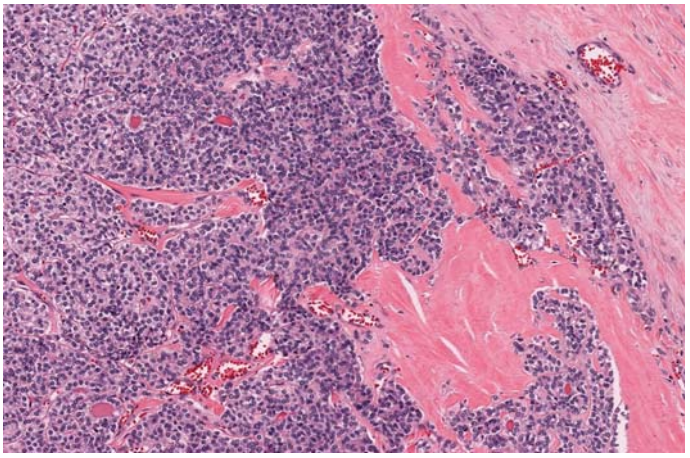

Fig. 5 Minimally invasive follicular carcinoma. Architectural and cytonuclear features are almost identical to those of follicular adenoma but the capsule shows areas of unequivocal capsular invasion.

FTC is an epithelial malignancy arising from follicular cells in the absence of nuclear features of papillary carcinoma. This somewhat odd definition "by exclusion" is due to the fact that nuclear features determine the diagnosis more than architecture, which has been corroborated by molecular genetic findings. Like PTC, it can occur anywhere in the thyroid and even in ectopic thyroid tissue in the neck region.

Grossly, FTCs are usually encapsulated solid gray-whitish lesions. Occasionally, macroscopic invasion into surrounding thyroid tissue can be found. Microscopically, the tumor is characterized by epithelial cells in follicular architecture, surrounded by a delicate fibrovascular stroma. Often, cytonuclear features are bland, complicating the distinction between adenoma and carcinoma. As stated above, in such cases the diagnosis relies entirely on the evidence of capsular or (preferably) vascular invasion (Fig. 5). Based on this criterion, FTCs have been subdivided into minimally invasive FTC (exclusively capsular invasion), encapsulated angioinvasive FTC, and widely invasive FTC. Vascular invasion is typically in veins. This explains the strong tendency for hematogenous metastasis of FTC. Lymphovascular invasion is rather uncommon. FTCs express the lineage-specific markers thyroglobulin, TTF-1, and PAX8.

Progression of FTC is primarily by invasive growth into adjacent organs and by hematogenous metastasis, with bone, lung, brain, and liver being the most frequently affected organs. Prognosis depends on the extent of invasion. Minimally invasive carcinomas have an excellent prognosis, while in carcinomas with vascular invasion, prognosis depends on the extent of vascular invasion (the more vessels involved, the higher the likelihood of distant metastasis).

FTC has a higher number of numerical chromosomal aberrations as well as gains and losses of chromosomal regions than PTC, with cytogenetic changes found in about 65% of the tumors. Hyperploidy with extra copies of chromosome 7 is particularly frequent. The most common somatic mutations are *RAS* point mutations (in particular in codon 61 of *NRAS* and codon 61 of *HRAS*) and gene fusions involving the *PPARG* gene, a member of a nuclear receptor superfamily. *PAX8-PPARG*-positive tumors tend to present in younger patients and more often in tumors with vascular invasion. Mutations in the PI3K/PTEN/Akt pathway genes are also found in FTC, however with a lower prevalence. *TERT* promoter mutations are found in about 20% of FTC cases and have been shown to be associated with a more aggressive tumor behavior (more advanced stage at diagnosis, higher rates of tumor recurrence and tumor-related mortality; Table 2). Recent data suggest that they may be an early event in FTC tumorigenesis, occurring before tumor invasion. Familial FTC occurs in the context of germline *PTEN* mutations associated with the PTEN hamartoma tumor syndrome.

Poorly Differentiated Thyroid Carcinoma

Pathology

Some tumors arising from follicular epithelial cells show limited evidence of follicular differentiation with a solid or trabecular growth pattern. These are called poorly differentiated thyroid carcinomas (PDTCs) and display a behavior which is in between that of FTC and that of anaplastic carcinoma. PDTC is distinctly rare, its proportion among thyroid cancers varying between less than 1 to about 7%. An association with longstanding goiter has been substantiated.

At gross examination, the tumors are usually large (> 5 cm), often partially encapsulated, with extension into adjacent parenchyma or perithyroidal structures.

As stated above, PDTC is histologically characterized by neoplastic follicular cells growing in solid masses (so-called insular) or trabecular structures. Colloid is minimally present or altogether absent. The tumor cells tend to show hyperchromatic pleomorphic nuclei with easily demonstrable mitotic activity (Fig. 3A). Necrosis may be extensive. Immunohistochemically, PDTC shows expression of thyroglobulin, although usually less intense than well differentiated tumors and with a microfollicular or perinuclear distribution, as well as of TTF-1 and PAX8, providing evidence of follicular differentiation.

Genetics

Genome aberrations in PDTC are in part comparable to those found in FTC. The karyotype is unstable with complex karyotypic abnormalities. *RAS* mutations occur with the same frequency as in FTC. Also mutations in the *TERT* promoter are relatively frequent. *BRAF* mutations are distinctly less frequent (5%–15%) than in FTC. *TP53* is mutated in up to 30% of cases, while *ALK* and *PTEN* mutations are found in 5%–10% (Table 2).

Anaplastic Thyroid Carcinoma

Pathology

Anaplastic thyroid carcinoma (ATC) is a highly aggressive malignancy composed of undifferentiated cells, presumably of follicular origin. The latter is supported by cases in which areas of follicular cell differentiation are still found in the tumor.

ATC often presents as a large bulky mass in the region of the thyroid, with invasion into adjacent structures. Gross examination will show a firm, solid, whitish mass, often with areas of necrosis and hemorrhage, extending into perithyroidal structures.

Histology of ATC is complex and highly variable. The sarcomatous variant shows pleomorphic spindle cells reminiscent of a high-grade sarcoma. The giant cell variant additionally shows the presence of numerous multinuclear pleomorphic giant cells. The epithelial variant shows masses of epithelial-like cells with abundant eosinophilic cytoplasm, occasionally with signs of squamous differentiation (Fig. 6). In all the three variants, a high mitotic rate, striking infiltrative growth with evidence of vascular invasion, and necrosis are found. Markers for thyroid lineage, for example thyroglobulin, TTF1 and PAX8, are negative. Evidence of epithelial differentiation defined by cytokeratin expression may be found but its absence does not favor a diagnosis of sarcoma.

Genetics

ATC is characterized by a wide variety of molecular alterations resulting in a dysregulation of multiple pathways, the most common being *TP53* mutations which are found in up to 80% of ATC cases while relatively rare in PTCs and FTCs without a differentiated component. Other alterations include many of those found in PTC and FTC, like *BRAF V600E* mutation as well as mutations involving *RAS*, *ALK*, and members of the PI3K/PTEN/Akt pathway (Table 2), which is consistent with the hypothesis that ATC evolves from differentiated thyroid tumors (Fig. 9).

Medullary Thyroid Carcinoma

Pathology

At gross examination, sporadic MTC presents as a mass of on average 2–3 cm but the lesions may also be very small or involve an entire thyroid lobe. In familial cases, the lesions may be small, often microscopic, multiple and in both thyroid lobes. Microscopically, MTCs show various histological patterns. Tumor cells can be polygonal, plasmacytoid or spindle-shaped and can be arranged in solid, lobular, trabecular or insular structures (Fig. 7). These tend to be surrounded by a varyingly voluminous stroma. Characteristically, the stroma contains appreciable amounts of amyloid. In familial cases, the tumors may be small (<5 mm, called microcarcinomas) and in some cases only C-cell hyperplasia is found (Fig. 8).

Familial MTCs are a heterogeneous group of tumors comprising MTC with parathyroid hyperplasia and pheochromocytoma/paraganglioma which are associated with MEN2A, as well as MTC with parathyroid hyperplasia and pheochromocytoma/paraganglioma, and ganglioneuromatosis, which are associated with MEN2B.

Immunohistochemically, MTCs usually express calcitonin but some express only calcitonin-related peptide. A whole range of neurohormonal peptides have been reported in MTC, including ACTH, somatostatin, gastrin-releasing peptide, and neurotensin.

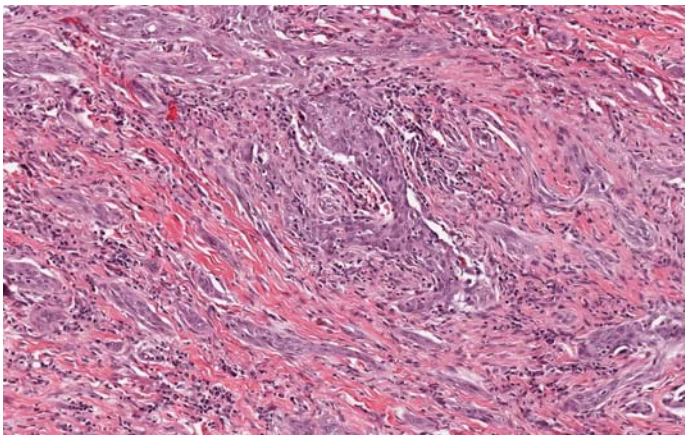

Fig. 6 Anaplastic carcinoma, epithelial type. Nests and strands of highly atypical epithelial cells are embedded in a dense fibrous stroma. There is a hint of squamous differentiation.

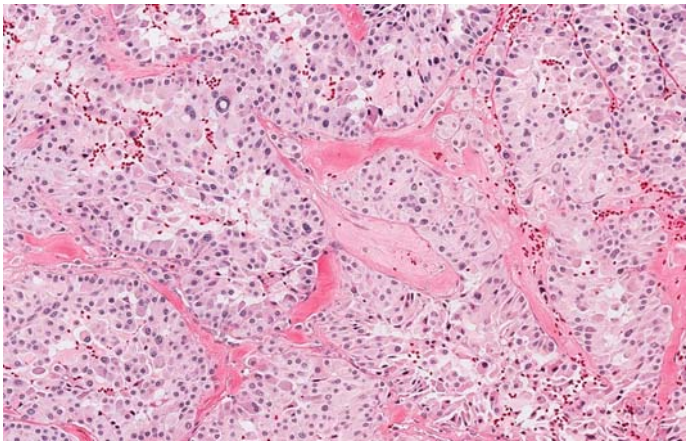

Fig. 7 Medullary carcinoma. Large nests and fields of epithelial cells are surrounded by strands of fibrous stroma. This is focally amorphous and hypereosinophilic, evidence of amyloid deposition. The tumor cells show voluminous slightly granular eosinophilic cytoplasm and moderately pleomorphic nuclei with finely granular chromatin. Some nuclear inclusions are seen.

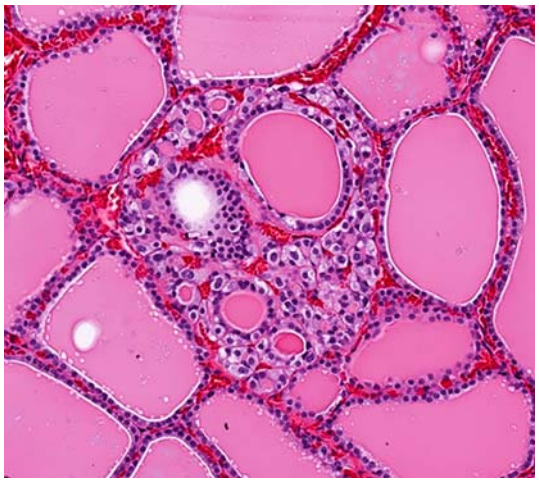

Fig. 8 C-cell hyperplasia in a MEN2 patient. In the center, small follicles show partial replacement of follicular cells by C-cells with clear cytoplasm, which have also diffusely proliferated around the follicles.

For basic diagnostic purposes, generic neuroendocrine markers chromogranin A and synaptophysin can be used. CEA is usually positive. TTF1 can be positive but PAX8 expression is often weak and focal.

Prognosis of MTC is stage-dependent. In young patients with early stage disease, 5-year survival rates of 90% have been reported, while in aged patients with advanced disease, these have been reported to be as low as 65%. Early diagnosis is therefore of paramount importance. As for other neuroendocrine neoplasms, Ki67 labeling index reflecting proliferative activity has been reported as prognostic.

Genetics

Mutations in the *RET* proto-oncogene are the major genetic alteration associated with MTC, both inherited and sporadic. *The M918T RET* (exon 16) is present in a vast majority of MEN2B-associated MTC cases and is also the most frequent somatic mutation in sporadic tumors. The *M918T* mutation confers the highly aggressive capacity to MTC tumors and only few other molecular alterations have been reported. These were mainly *RAS* mutations and *ALK* fusions, at a relatively low prevalence. Complex genotype–phenotype relations in familial MTC are still under study.

Thyroid Carcinoma Molecular Pathogenesis: Conclusion

Overall, somatic rearrangements of *RET* and *TRK* are almost exclusively found in PTC and may be found at early stages. The most distinctive molecular features of FTC are the prominence of aneuploidy as well as the high prevalence of *RAS* mutations and *PAX8-PPARG* rearrangements. *TP53* alterations seem to play a crucial role in the dedifferentiation process of thyroid carcinoma and its

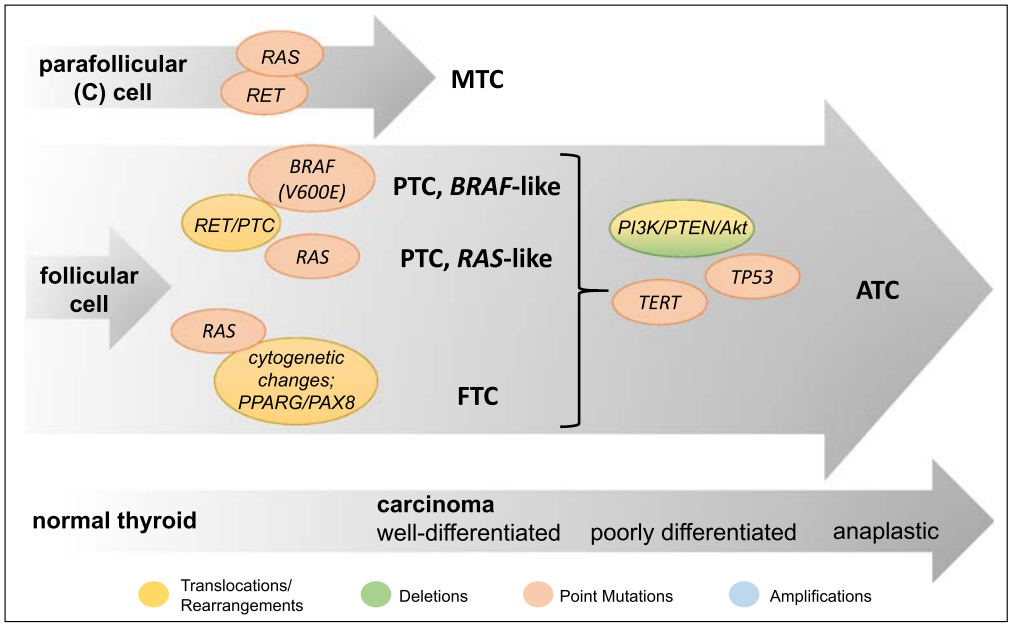

Fig. 9 A model of molecular progression of normal thyroid cells to thyroid carcinoma. Medullary thyroid carcinoma (MTC) develops from thyroid parafollicular (C) cells and is mainly associated with mutations in the *RAS* and *RET* genes, the latter being also affected by germline mutations in familial MTC. Papillary and follicular thyroid carcinomas (PTC and FTC, respectively) develop from follicular thyroid cells through distinct pathways. Moreover, molecular analyses have identified two molecular subtypes of PTC, driven by *BRAF* or *RAS* mutations. Accumulation of genetic alterations in other genes, such as *TERT* or *TP53* in either PTC or FTC may result in tumor dedifferentiation and their progression to anaplastic thyroid carcinoma (ATC), the highly aggressive form of thyroid cancer. Modified from Acquaviva, G. et al. (2018). Molecular pathology of thyroid tumours of follicular cells: A review of genetic alterations and their clinicopathological relevance. *Histopathology* **72**, 6–31.

progression to more aggressive variants. MTC develops through a distinct molecular progression pathway, with *RET* mutations being the most prevalent events (Fig. 9).

Biomarkers

Diagnostic Biomarkers

As thyroid nodules are extremely common, the key to effective screening for thyroid cancer is differentiating between benign nodules and those with a malignant potential. Elevated serum TSH levels found at the initial evaluation of a thyroid nodule are a biomarker of possible malignancy, indicating the need for further examination. In patients with a family history of medullary thyroid cancer or other features of the MEN2 syndrome, elevated serum calcitonin and/or carcinoembryonic antigen (CEA) levels are associated with MTC diagnosis.

The panel of markers determining the thyroid lineage has been discussed above: thyroglobulin, TTF1 (which is not entirely specific for the thyroid as it may be expressed also by other lineages) and PAX8. As a rule, this panel will be used to establish thyroid origin of a neoplasm. Ki67 can be useful to establish proliferative activity. Staining for p53 is negative in PTC and FTC but can be positive in PDTC and is usually positive in ATC. MTC expresses neuroendocrine markers (chromogranin A and synaptophysin) as well as calcitonin.

Molecular testing may be useful in diagnostic evaluation of fine-needle thyroid aspirates which have been classified as indeterminate (about 25% of cases). This may include individual mutation analysis and multigene assays. The presence of the *BRAF V600E* mutation alone is highly specific for thyroid cancer diagnosis. Testing for this mutation is particularly useful to confirm PTC diagnosis in patients with higher-risk fine-needle aspirates with suspected nuclear features of papillary carcinoma but uncertain cytological diagnosis. Several multiple gene diagnostic assays have also been proposed as either rule-in or rule-out tests for classifying thyroid nodules before surgery, the most used being the Afirma® Gene Classifier (Table 3). However, their clinical usefulness and accuracy remain to be confirmed and none of them has yet been approved for routine clinical practice.

Prognostic Biomarkers

A majority of thyroid cancers have excellent prognosis, with the clinicopathological features being reliable prognostic markers. Measuring serum thyroglobulin (Tg) levels has the highest sensitivity (95%–100%) to detect persistent or recurrent disease in a post-surgical evaluation of DTC patients. Additionally, *TERT* promoter mutations have been reported to be associated with a worse

Table 3 Biomarkers for the detection and management of thyroid carcinoma

Biomarker	*Characteristics and clinical utility*
Early detection (screening) and diagnostic biomarkers	
Serum TSH	Elevated levels in patients with thyroid nodules suggest a possibility of a malignancy
Serum calcitonin and CEA	Recommended for patients with a family history of thyroid cancer, the MEN syndrome or a suspicion of MTC; elevated levels are suggestive of MTC
Thyroglobulin	Immunohistochemical marker specific for thyroid cancer; less expressed in poorly differentiated cancers
HBME-1	Immunohistochemical marker relatively specific for thyroid cancer, with a membranous staining pattern; used in combination with Galectin-3 and CK19
Galectin-3	Immunohistochemical marker relatively specific for thyroid cancer, with a nuclear and cytoplasmic staining pattern; used in combination with HBME-1 and CK19
Cytokeratin 19	Immunohistochemical marker expressed in thyroid cancer but with limited specificity; used in combination with HBME-1 and Galectin-3
TTF-1 and PAX8	Immunohistochemical marker combination to establish thyroid origin of a cancer metastasis; TTF-1 is also expressed in lung cancer, while PAX8 is not expressed in lung cancer; both show a nuclear staining pattern
BRAF V600E mutation	Used to confirm PTC diagnosis in suspected PTC aspirates with uncertain cytological diagnosis; over 99% specific for thyroid carcinoma
Afirma® Gene Expression Classifier (GEC; Veracyte, United States)	mRNA profiling for indeterminate thyroid nodules; used in the US (not FDA-approved) as a rule-out test, in particular in cases when surgery is not desirable
Thyroseq2® v.2 (CBLPath, Inc., United States)	Next-generation sequencing-based test simultaneously detecting over 400 mutations and gene fusions in overs 60 genes associated with thyroid cancer to identify malignant (diagnostic marker) and more aggressive tumors (prognostic marker)
Prognostic and monitoring biomarkers	
Serum thyroglobulin (Tg) levels/anti-Tg antibodies	High sensitivity for detecting persistent or recurrent DTC
Serum calcitonin and CEA	Elevated levels in post-surgical MTC patients indicate relapsing or metastatic disease
TERT promoter mutations	Independent markers of adverse prognosis in PTC and FTC patients
Ki-67 staining	Increased staining indicating higher proliferation rates is associated with aggressive tumor behavior in MTC patients
RET mutations	the *RET M918T* mutation associated with poor clinical outcome in sporadic MTC and with more aggressive behavior in MEN-associated MTC
Thyroseq2® v.2 (CBLPath, Inc., United States)	*See above*
Predictive biomarkers	
BRAF mutations	Used to select patients for targeted treatment with BRAF inhibitors in DTC
EGFR expression and *VEGFR* alterations	Allows to select ATC patients for therapies targeting these molecules

ATC, anaplastic thyroid carcinoma; *CEA*, carcinoembryonic antigen; *DTC*, differentiated thyroid carcinoma; *FDA*, US Food and Drug Administration; *MEN*, multiple endocrine endoplasia: *MTC*, medullary thyroid carcinoma; *TSH*, thyroid-stimulating hormone.

prognosis in PTC and FTC patients. It has also been suggested that the *BRAF V600E* mutation may be associated with an increased risk of recurrence but the data on its usefulness as an independent prognostic factor remain controversial. Prognosis of PDTC is distinctly less favorable than that of PTC or FTC, with 5-year survival rates of 60%–70%. Extensive tumor necrosis, tumor size (>5 cm), extrathyroidal extension and distant metastases are unfavorable prognostic factors. Postoperative radio-iodine treatment is less effective as less differentiated tumor cells take up iodine less effectively. No markers predicting clinical behavior of ATC exist. These tumors, however, are generally very aggressive and have a very poor prognosis.

In MTC patients, regular elevated serum calcitonin and CEA levels following surgery are markers of relapsing or metastatic disease. Higher proliferation rates as assessed by Ki-67 staining have been associated with aggressive tumor behavior, while vascular invasion and stromal desmoplasia have been suggested as indicative of a relapsing disease and a metastatic potential, respectively. Mutations of the *RET* gene have a high prognostic value in MTC patients. Tumors in patients with the MEN2B syndrome (carrying the *M918T RET* mutation) are commonly more aggressive than those in MEN2A patients (*RET C634R*). The *RET M918T* mutation has also been associated with poor clinical outcome in sporadic MTC. Moreover, it has been suggested that patients with *RAS*-mutated sporadic MTC may have a less aggressive clinical course than those with non-*RAS*-mutant tumors but this remains to be validated.

Predictive Biomarkers

With the development of molecular testing, targeted therapeutic approaches are being developed for different thyroid cancer types, in particular for advanced or metastatic disease which is refractory to standard surgery and radioactive iodine (RAI) treatment. *BRAF* mutations in DTC are an indication for treatment with BRAF inhibitors (e.g., vemurafenib in RAI-refractory PTC). In ATCs, the epidermal growth factor (EGFR) is expressed and has been used to guide targeted therapy decisions in selected patients. Alterations in the vascular endothelial growth factor receptor (*VEGFR*) may also be considered as markers for therapeutic patient stratification, with several targeted drugs being already in use or under clinical trials.

Management and Therapy

Surgery is the treatment of choice for all types of thyroid cancer. For the two most common follicular cell-derived differentiated thyroid cancers (PTC and FTC), lobectomy is recommended for small and low-risk tumors, and total or nearly total thyroidectomy for higher-risk tumors. The stratification of patients so as to the risk of recurrence following surgery is essential for determining further management choices. It is mainly based on patient characteristics (e.g., age at diagnosis) and on clinicopathological features of the tumor. Several scoring systems taking into account these variables have been proposed.

For many years, it has been standard practice to give radioactive iodine (^{131}I; RAI) to all thyroid cancer patients after surgery. However, its benefits are hard to evaluate and it is currently recommended only for patients at an intermediate and high risk of recurrence, at different doses. RAI may be accompanied with administration of recombinant human thyrotropin (rhTSH) or with thyroid hormone withdrawal in order to stimulate thyroid-stimulating hormone (TSH/thyrotropin). Compared with thyroid hormone withdrawal, administering rhTSH maintains quality of life and reduces the radiation dose delivered to the body while stimulating ^{131}I uptake in thyroid remnants in patients after thyroidectomy. For patients with low recurrence risk, observation is recommended, with monitoring serum thyroglobulin (Tg) levels and relevant imaging biomarkers.

For medullary thyroid carcinoma, total thyroidectomy is recommended in all cases, with measurements of serum calcitonin and CEA levels as baseline tumor markers being part of the preoperative planning. Screening for *RET* mutations is also recommended. In case of known metastatic nodal disease, central and lateral neck dissections are performed simultaneously with the thyroidectomy. Whether these dissections should be performed in patients without known nodal disease, remains controversial. Thyroxine is indicated to replace thyroid function following surgery. However, it does not suppress tumor growth in MTC patients as is the case with follicular-derived tumors (PTC and FTC). Similarly, there is no role for radioiodine. Regular monitoring of serum calcitonin and CEA as markers of relapsing or metastatic disease is done following surgery.

Relapsing PTC and FTC that are not treatable by a combination of surgery, thyroxine therapy, and repeat doses of ^{131}I respond poorly to external beam RT and systemic therapy. Tyrosine kinase inhibitors, such as lenvatinib and sorafenib, showed efficacy in metastatic disease. Vemurafenib or dabrafenib can be used in *BRAF*-mutant PTC. Persistent MTC disease is managed with a combination of surgical resection, external beam RT, local ablation, and—in some cases—observation, depending upon bulk of metastatic foci and tumor marker doubling time. Tyrosine kinase inhibitors (vandetanib, cabozantinib) have shown some efficacy in prolongation of disease-free survival.

Anaplastic thyroid cancer has a mortality that approaches 100%. Therefore, the treatments are mainly palliative. Surgery is done for smaller tumors that are limited to the thyroid but most cases are detected after extrathyroidal invasion has occurred. External beam radiotherapy and chemotherapy are used both as primary and adjuvant therapy, and there is some evidence of benefit in the combination of the two.

Glossary

p53 Response element (p53RE) The short DNA sequence motif that is specifically recognized by the p53 transcription factor.
Transactivation domain (TAD) A transcription factor domain which contains binding sites to recruit cofactors that promote transcription.
Posttranslational modification (PTM) An enzymatic modification of amino acids following protein biosynthesis.
Li-Fraumeni syndrome (LFS) An autosomal dominant, hereditary disorder that is linked to germline mutations of p53.
Neomorph A dominant gain of function that is different from the normal function.
Missense mutation A single nucleotide change in a codon that results in a different amino acid code.
Nonsense mutation A single nucleotide change that forms a premature stop codon.
Alternative splicing A process that turns transcripts into different processed mRNAs through inclusion or exclusion of particular exons.
The cancer genome atlas (TCGA) A project that generates, stores and analyzes high-throughput genome and transcriptome data from cancers.

Introduction

The recent explosion of sequencing of cancer genomes unequivocally identifies p53 as the most frequently mutated gene across the spectrum of human cancers. It is therefore unsurprising that the p53 protein and its encoding gene *TP53* (OMIM 191170) are the most frequently cited protein/gene in the literature (approaching 90,000 entries in PubMed), positioning this "guardian of the genome" as the most important tumor suppressor.

The p53 transcription factor is activated in response to a range of stress to affect diverse transcriptional programs. Canonically activation by acute DNA damage results in growth suppression by inducing cell cycle arrest to enable DNA repair or if damage is insurmountable induces senescence or cell death (Fig. 1). Despite functional genomics rapidly advancing our understanding of the mechanisms and diversity of downstream signaling networks regulated by p53 transcriptional activity, it remains incompletely understood how differential cell fates are affected and their relative contribution to tumor suppression. This article provides an

overview of p53 structure and function, the diverse mechanisms through which cancers circumvent p53 activation, and highlights how functional genomic approaches have increased our understanding of the direct and indirect mechanisms through which p53 regulates diverse transcriptional programs. Finally, we discuss the burgeoning range of strategies aimed at exploiting p53 status therapeutically and highlight the importance of emerging roles for p53 in regulating the interaction with the stromal, immune and microbial microenvironment.

Discovery of the p53 Tumor Suppressor

The p53 protein was discovered more than 30 years ago as a 53 kDa binding partner of simian virus 40 (SV40) Large T antigen oncoprotein at the height of breakthroughs in the identification of viral oncogenes. Paradoxically this resulted in its initial classification as an oncogene, a presumption that was supported by the oncogenic properties exhibited by tumor derived forms of p53, which were in fact missense mutant p53 neomorphs. This misnomer was eventually rectified upon the cloning of Wild-type p53 and discovery that it exhibited tumor suppressive properties in vitro; that p53 knockout (KO) mice were highly cancer prone and the identification of germ-line autosomal dominant p53 mutations as the causal variants associated with highly cancer prone Li-Fraumeni Syndrome (LFS) families. Together establishing p53 as a *bona fide* tumor suppressor.

p53 Structure and Function

While a number of nontranscriptional activities of p53 in the nucleus, cytoplasm and mitochondria with potential tumor suppressive functions have been identified, the majority of p53s' tumor suppressive functions are thought to be exerted through its role as a sequence specific transcription factor. This is supported by observations that mutations identified sporadically in tumors and in germ-lines of LFS families predominantly affect the DNA-binding domain with the exception of the R337H mutation, which is found at high frequency in Brazil (Fig. 2).

Canonically in response to a variety of stress signals post-translational modification and stabilization of p53 results in binding of a p53 tetramer to internal or upstream p53 response elements (p53RE), enabling p53 to coordinate transcription of an expanding repertoire of genes affecting diverse biological processes. This is facilitated by the activities of the two N-terminal transcription activatory domains (TAD1 and TAD2), adjacent to a proline rich domain (PRD), the central DNA-binding domain (DBD) and a multifunctional carboxy terminus encoding oligomerization domain (OD), nuclear localization signals (NLS) and a flexible lysine-rich C-terminal domain (CTD) (Fig. 2). Understanding p53 function is complicated by the existence of at least 12 p53 protein isoforms, as a result of extensive alternative splicing, internal initiation and alternative promoter usage (Fig. 3). This is perhaps unsurprising given that the two additional p53 family members p63 and p73 discovered in the late 1990s, which function in development stratifying epithelia and neuronal derived tissues respectively, are known to undergo extensive alternative splicing; resulting in both

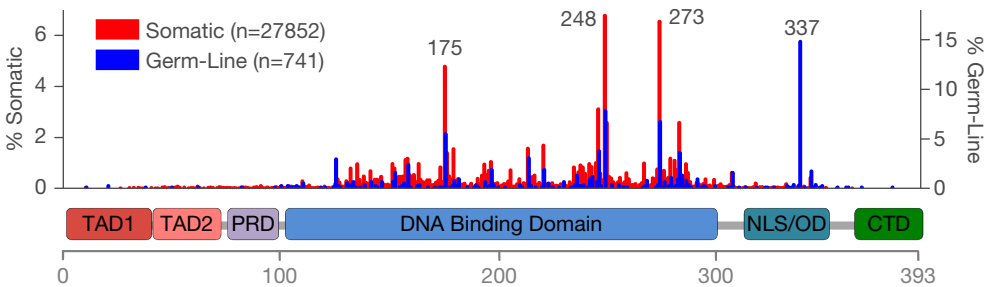

Fig. 2 *Schematic overview of p53 domain structure and mapping of frequency of somatic and germ-line mutations.* p53 protein domain structure includes two N-terminal transcription activatory domains (TAD1 and TAD2), proline rich domain (PRD), central DNA-binding domain (DBD), multifunctional Carboxy terminus encoding oligomerisation domain (OD), nuclear localization signals (NLS) and a flexible lysine rich-domain C-terminal domain (CTD). Frequency plot of p53 mutations detected in 27,852 somatic tumors (*red*) and 741 germ-line Li-Fraumeni patients (*blue*) for each of 393 amino acids in full length p53 from IARC p53 mutation database.

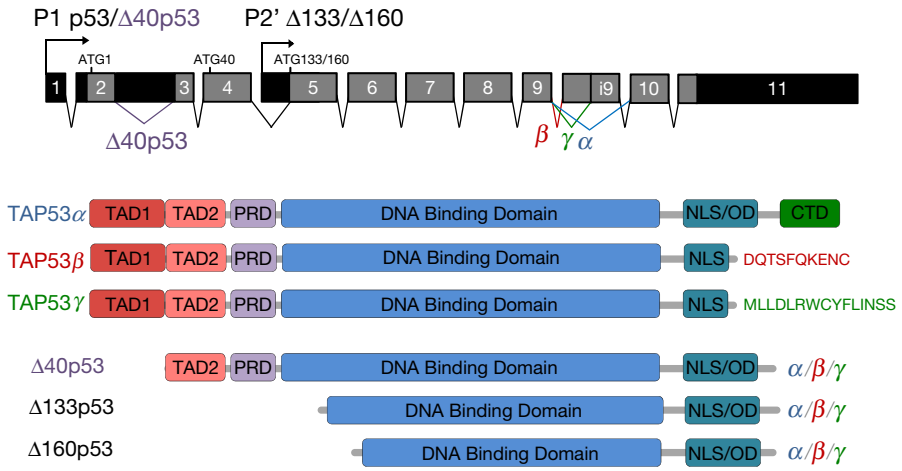

Fig. 3 *Schematic representation of TP53 Gene structure, mRNA splicing and resulting protein isoforms.* (A) Canonical full–length pTAP53α, originates from P1, containing both transcriptional activatory domains (TADs), while the Δ40 forms initiate from an internal ATG as result of alternative splicing or an internal ribosome entry site (IRES). truncated ΔN forms Δ133 and Δ160 originate from the P2 promoter, which along with the TA and Δ40 can be combined with alternative C-terminal splicing resulting in α, β and γ variants to generate a total of 12 protein isoforms.

tumor suppressive and oncogenic roles depending on the specific isoforms expressed. Similar to *TP63* and *TP73*, *TP53* encodes for several isoforms through conserved mechanisms resulting in combinations of alternative N- and C-termini. Canonical full–length p53, or TAP53α, originates from P1, containing both TADs and the longest C-term, and the Δ40 forms initiate from an internal ATG as result of alternative splicing or an internal ribosome entry site (IRES). Similarly, truncated ΔN forms Δ133 and Δ160 originate from the P2 promoter, which like the TA and Δ40 can be combined with alternative splicing of the C-term α, β and γ variants to generate 12 protein isoforms. Importantly, like p63 and p73, there is emerging evidence indicating that these different isoforms exhibit strikingly different expression patterns in different tissues, stages of development and differential activities. However, precise roles remain poorly understood. For example, expression of Δ133 has been shown to exhibit dominant negative activity over full-length TAP53α and elevated expression is associated with poor prognosis in certain cancer types.

Loss of p53 Tumor Suppressive Function in Cancer

Loss of the tumor suppressive functions of p53 is thought to be a prerequisite for the development of most tumors. This occurs through mutation in greater than 50% of tumors or in tumors retaining wild-type p53, its functions are often suppressed as a consequence of other oncogenic events that circumvent p53 tumor suppressive functions.

The vast majority of p53 mutations in both sporadic tumor and germ-line LFS occur in the DBD, highlighting the importance of DNA-binding and transcriptional function for tumor suppression. In the majority of sporadic and germ-line related tumor p53 mutation is accompanied by loss-of-heterozygosity (LOH) of the wild-type allele, however unlike canonical tumor suppressors such as RB or BRCA1 the majority of p53 mutations encode missense mutations (Fig. 4), with the most frequent somatic mutations R175H, Y220C, R249S, R248Q/W, R273C/H and R282W. The prevalence of missense mutations relative to nonsense, frameshift

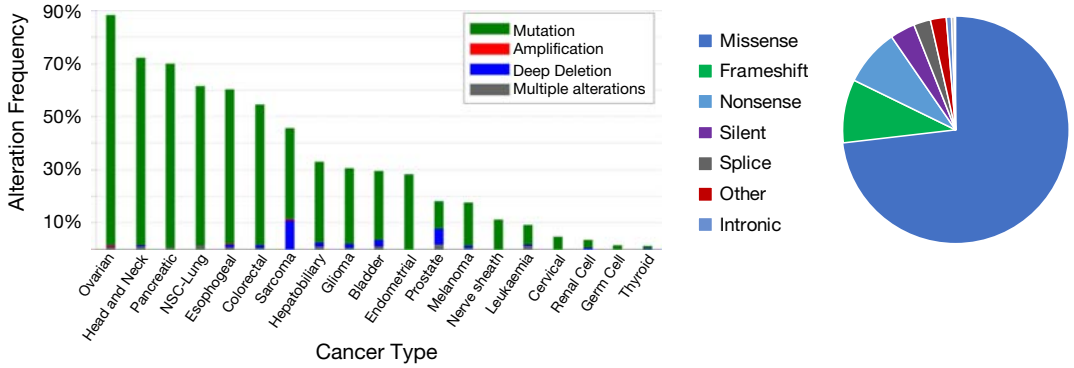

Fig. 4 *Frequency of p53 mutation and impact of mutations*: (A) Frequency of p53 mutation, copy number alterations, deep deletions and multiple aberrations in TCGA provisional datasets with >150 patients. (B) Frequency of different types of p53 mutations in IARC p53 mutation database.

and deletions suggest selection for expression of mutant p53. Missense mutations cluster in hot-spots in the DNA-binding domain (Fig. 2), result in expression of full length mutant forms of p53 with a dramatically reduced capacity to bind to p53REs and activate canonical target genes. Importantly, these neomorphic p53 proteins are expressed at high levels in tumors and have been shown to exhibit oncogenic gains-of-functions as well as dominant negative effects on residual wild-type p53 in tumors retaining a wild-type p53 allele. Missense mutations can be broadly separated into two groups: *Contact mutants* affect key arginine residues 248, 273 and 280 which are required for p53 to directly contact DNA and these generally retain wild-type confirmation and p53's ability to form tetramers. The effect of *conformation mutants* depends on the location and type of mutation, but in general they significantly alter p53 secondary structure and/or zinc binding, which affects the capacity to form tetramers, and they are prone to aggregate. The ability to form aggregates is an emergent property of mutant p53, which occurs due to an aggregation prone region surrounding Ile254 in the DBD that nucleates aggregates that are thought to play important roles in mutant p53 GoF. Interestingly, recent data further suggests that the frequent hot-spot nonsense mutation R213* results in expression of a truncated form of p53 with *de-novo* oncogenic functions. The emerging paradigm is that p53 mutant GOFs are likely context dependent in terms of the nature of the selection for different mutations, the tumor type, its microenvironment and the availability of binding partners through which a mutant exerts its GOF activity. It is also important to note that the role of mutant p53 isoforms remains largely unexplored.

What is evident from burgeoning studies of cancer genomes is that *TP53* mutational profiles differ in frequency and nature depending on tissue, molecular subtype and disease stage, suggesting specific underlying selection for different *TP53*-genotypes. The frequency of mutation is highly variable between cancer types: *TP53* is mutated in more than 95% of primary high grade serous ovarian cancer (HGSOC) where TP53 mutation has been shown to be a signature genetic event, whereas mutation frequencies are $<5\%$ in primary renal, germ cell and thyroid cancers (Fig. 4). While homozygous deletion of p53 is a rare event, distribution of these events also differs between disease site, being most frequently observed in primary Sarcomas and Prostate cancer. Genomic analyses are also revealing that most cancer types comprise several molecular subtypes that go beyond tissue/organ or histological classification. Dramatic differences in both frequency and nature of *TP53* mutation are observed in different subtypes of disease; for example, mutation rates in breast cancers range from 12% in Luminal A tumors to greater than 75% in triple negative basal-like tumors, which exhibit higher rates of nonsense and frameshift mutations than other subtypes. In colon cancers *TP53* mutations are very infrequently observed in microsatellite stable or BRAF mutant cancers despite being mutated in $>50\%$ of all primary colorectal cancers. Importantly, mutation rates for *TP53* show a strong association with late stage and metastatic tumors of various cancers and as increasing numbers of drug resistance tumor recurrences are sequenced it is evident that there is often strong selection of *TP53* mutation even in diseases where *TP53* mutation frequency in primary tumors is low. This is perhaps best exemplified by prostate cancer where *TP53* mutation is observed in only 12% of primary resected prostatectomies (Fig. 4), whereas *TP53* mutations are detected in $\sim 50\%$ of metastatic castrate resistant prostate cancers and selected for in vivo studies of resistance to antiandrogen therapies. *TP53* mutation rate and mutation type are also influenced by carcinogen exposure, where for example both Lung Adeno- and Squamous carcinoma exhibit high p53 mutation rate and similar mutation types and hepatocellular carcinomas have high levels of R249S driven by G-T transversions linked to aflatoxin exposure. Notably, very low *TP53* mutation rates are detected in cervical cancers in which the initiating event is high-risk human papilloma virus infection in greater than 95% of tumors, which inactivates p53 through the activities of the oncoprotein E6 that targets p53 for degradation. Similarly, *TP53* mutations are infrequently observed in the $\sim 50\%$ of Head and Neck Squamous Cell Carcinomas of the oropharynx associated with high-risk HPV infection.

Regulation of p53 Activity and Its Suppression in Cancer

As highlighted by the absence of p53 mutations in HPV-driven cervical and head and neck squamous cell carcinomas, the majority of the $\sim 50\%$ of tumors retaining wild-type p53 are presumed to circumvent or suppress p53 tumor suppressive functions through aberrations in the many regulatory pathways that impact on p53 function.

In homeostasis p53 is actively suppressed by a range of negative regulators, the best described of which is the E3 ligase mouse double minute 2 (MDM2). MDM2 binds to the p53 N-terminus and suppresses its transcriptional activity, exposing the p53 nuclear export signal (NES), and also acting as a specific E3 ubiquitin ligase that mediates poly-ubiquitination of multiple lysines in the p53 C-terminus leading to degradation by the proteasome (Fig. 5). This is further regulated by MDM4 and USP7, which augment MDM2 activity through inhibiting or removing MDM2 auto-ubiquitination. Canonically this is best understood in response to DNA damage when the ATM and/or ATR kinases directly and indirectly through CHK1/CHK2 kinases, sequentially phosphorylate a number of serine residues in the p53 N-terminus to block its interaction with MDM2. This leads to reduced of ubiquitination of the C-terminus and stabilization and decreasing nuclear export and alleviating repression of TAD to activate p53. These phosphorylation events can be removed by competitive activity of PPM1D phosphatase, affording an additional level of negative regulation. Consequently, this results in oscillating cycles of p53 activity in response to DNA damage, the amplitude and frequency of which is regulated by nature and intensity of upstream signal and is thought to ultimately impact transcriptional output and cell fate. Oncogene activation induced stress leads to up-regulation of the tumor suppressor p14-ARF, which through an alternative mechanism sequesters MDM2 in the nucleolus also leading to p53 stabilization. The central importance of this axis is further highlighted by observations that embryonic lethality observed in MDM2 and MDM4 knockout mice are rescued by p53 inactivation, and predisposition to early onset cancer in human patients with an SNP in MDM2 associated with elevated MDM2 levels.

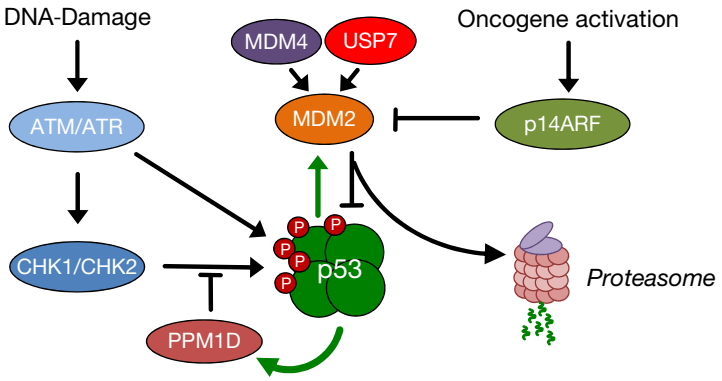

Fig. 5 *Core p53-MDM2 regulatory loop*: MDM2 binds to the p53 N-terminus suppressing transcriptional activity and also targets the p53 C-terminus for polyubiquitination leading to degradation by the proteasome. MDM4 and USP7 augment MDM2 activity through inhibiting or removing MDM2 auto-ubiquitination. This is inhibited by phosphorylation of N-terminus of p53 in response to DNA damage activated by ATM, ATR, CHK1 and CHK2, a subset of which can be competitively removed by activity of PPM1D phoshphatase. Oncogene activation induces p53 activation through inducing p14ARF which sequesters MDM2 in the nucleolus.

Unsurprisingly, tumors hijack this core p53 regulatory apparatus to suppress p53 function through amplification and overexpression of negative regulators including MDM2, MDM4, USP7, PPM1D and many other; mutation or deletion of upstream activators ATM/ATR and INK4A-ARF or oncogene-induced inhibition of p53 activation through activation of MDM2 or suppression of p53 activity.

Differential p53 activities are regulated through coordinated posttranslational modification (PTM) of amino acids scattered throughout the modular structure of p53, which collectively function to alter p53 stability, localization and transcriptional activity. This is affected through changes in affinity of p53 for DNA-binding and cofactor recruitment for transcriptional initiation as well as modulation of local chromatin environment. Large regions of flexible disorder between domains provide conformational flexibility to enable interaction with a large range of binding cofactors extensively regulated by competitive PTM. While important PTMs are observed throughout the p53 protein, these are particularly rich within intrinsically disordered N- and C-terminal regions.

The N-terminal TAD is involved in important negative regulatory interactions with MDM2/MDMX as discussed above, which not only enables targeting for degradation but also competes for binding coactivators p300 and CREB-binding protein (CBP). This competition is regulated by phosphorylation of multiple residues in the TAD (including S15, S20, T18), which block interaction with MDM2 stabilizing p53 and incrementally increasing affinity for coactivators enabling a stepwise response to genotoxic stress. Specific events such as phosphorylation of S46 by HIPK2 and other stress induced kinases have been suggested to enhance activation of cell death in part through breaking interaction with inhibitor iASPP (PPP1R13L).

The flexible C-terminal domain also plays a critical role in regulating p53 activity through PTM of the same six lysines residues (K370, 372, 373, 381, 382, 386) that are targeted for polyubiquitination by MDM2. Upon activation, recruitment of p300 to the phosphorylated N-terminus induces activatory acetylation of these and other key lysine residue (K120, 164, 320) in p53's DNA-binding and oligomerization domains. These residues are all are subject to extensive competitive PTM by acetyl-transferases (p300, PCAF, CBP, TIP60 and others) and de-acetylases (including HDAC1, 2 and SIRT1). This provides perhaps the best studied paradigm for p53 PTM and target selectivity and cofactor recruitment to differentially affect transactivation of pro-apoptotic target genes. This can be further influenced by phosphorylation of S366/T387 or S378/T377 or methylation (regulated by methyltransferease and demethylases) of the same lysine residues. Moreover, recent data has shown that loco-regional changes in charge of the acidic lysine rich C-terminal domain which forms a strong interaction with negative regulator SET that is abrogated upon neutralization of charge through acetylation of six lysine residues.

Specific acetylation of K373 and K120 has been suggested to favor apoptosis and K320 antagonizes such activity in cancer cells; however findings in terms of individual residues vary significantly between cell and tissue type, genotype and different stress responses. For example, paradoxically K373 acetylation induced by HDAC inhibitors in combination with DNA damage enhances death of cancer cells and survival of normal neuronal cells.

Importantly, our understanding of the inter-dependence and temporal interaction of even these relatively well described p53 PTMs remains limited and is further complicated by additional sites and moieties including mono- and di-methylation, sumoylation, neddylation, O-GlcNAcylation and ADP-ribosylation. The myriad of posttranslational modifications of p53 are regulated downstream of ever increasing diversity of stresses including DNA damage, oncogene activation, replication stress, ribosomal stress, hypoxia, telomere erosion, nucleotide depletion, oxidative stress, hypoxia, nutrient starvation and mechanical stress. The complex interaction of PTM and the burgeoning number of p53 direct targets (see later) likely underlies our limited understanding of how differential p53 activation results in a diversity of cell fates and their relative contribution to tumor suppression which almost certainly extends far beyond the classical view of cell cycle arrest, apoptosis and senescence (Fig. 6).

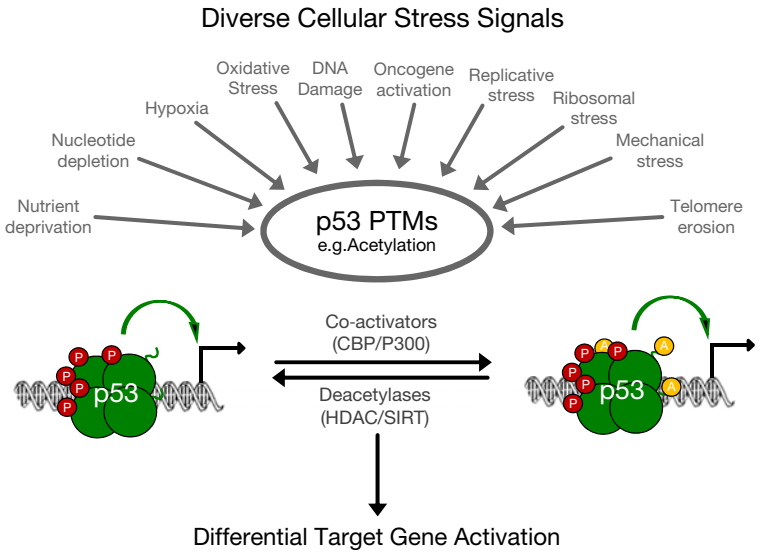

Fig. 6 *Overview of p53 regulatory signals.* Activation of p53 is mediated by a range of post-translational modification (PTM) downstream of sensors of highly diverse range of stress signals. These modifications are added or removed by competitive activity of enzymes with opposing functions. For example P300/CBP mediated acetylation of p53 C-term and other residues in the DNA-binding domain are removed by opposing activities of Histone- and Sirtuin de-acetylases. Combined effects of PTM of p53 tetramer influences the range of diverse transcriptional targets induced.

Transcription Regulation by p53

As illustrated above the prevailing function through which p53 exerts its tumor suppressive activities is transcriptional control of target genes that in turn regulate numerous downstream cellular processes. While it is clear that p53 activation leads to both the up- and down-regulation of a plethora of genes, it has long been disputed how p53 discriminates between activation and repression with numerous models for p53-dependent gene down-regulation being suggested over the years. Recent genome-wide studies, however, provide evidence that in the vast majority of cases, p53 itself functions solely as an activator of gene expression and that transcriptional down-regulation by p53 is mediated indirectly and largely dependents on the up-regulation of the best described and most robust p53 target gene the cyclin dependent kinase inhibitor p21 (CDKN1A) (Fig. 7).

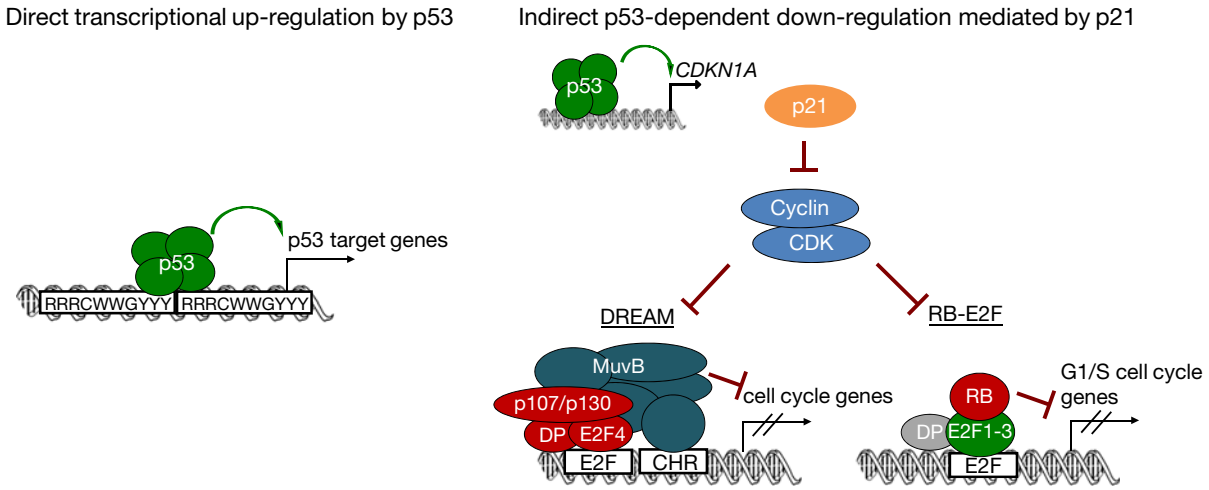

Fig. 7 *Mechanisms of p53-mediated transcription control.* Mechanisms involving direct target gene up-regulation by p53 and indirect down-regulation through p53-p21-DREAM/RB are supported by genome-wide data. When activated, p53 accumulates and binds target genes as a tetramer, which comprises two dimers that each binds a decameric half site with the consensus sequence RRRCWWGYYY. The highly responsive p53 target p21 inhibits CDK1 and CDK2 to re-activate RB family proteins that block E2F1–3 activity and form the DREAM repressor complex that down-regulates most cell cycle genes.

Activation of p53 Target Genes

As described earlier, in unstressed conditions, the transcriptional activity of p53 is masked by the ubiquitin ligase MDM2, which also promotes the degradation of p53. When activated, p53 accumulates and binds target genes as a tetramer, which comprises two dimers that each binds a decameric half site with the consensus sequence RRRCWWGYYY (R = A/G, W = A/T, Y = C/T). The two decameric half sites that form the p53RE can be separated by a spacer of 0–13 base pairs. Most functional p53REs contain no spacer and an increasing spacer length makes it less likely that the motif is functional and bound by p53. Notably, also decameric half sites without a nearby second decamer, have been identified to bind p53 and to mediate target gene activation. Unlike most transcription factors, p53 has pioneer like functions and can bind to DNA regardless of open or closed chromatin, however, only in some cases, p53 can open the closed chromatin to activate gene expression. In that regard p53 is lacking full pioneer function as it is unable to open most of the closed chromatin it can bind to and it likely requires other accessory proteins to induce transcription. Consequently, p53 can bind to DNA harboring its consensus binding sequence regardless of the local context such as chromatin state, cell type or binding of cofactors. However, the context is relevant for enabling p53-mediated recruitment of RNA polymerase II and to initiate target gene expression following DNA binding. To bind DNA, p53 functions as a dimer of dimers and it employs two transactivation domains (TADs) to recruit RNA polymerase II and to drive target gene transcription. Most p53 activated target genes recruit p53 in proximity (~2.5 kilo bases) to their transcription start site (TSS). In some cases, however, p53 has been shown to bind to an alternative TSS or enhancer elements located at intronic regions. When p53 binds to intronic regions, it can induce expression of an isoform that is shorter than the longest isoform and misses, for example, the 5′UTR or the first exon. The transactivation potential of p53 tends to decline with increasing distance to a gene's TSS.

The discovery of the first p53 target genes, including *CDKN1A* (*p21*) and *MDM2*, inspired numerous researchers to identify additional genes that mediate p53's tumor suppressor function. Today several hundred genes are known to be directly bound and upregulated by p53, which has been rapidly advanced by the use of next generation-based genomic approaches such as ChIP-seq and RNA-seq.

Indirect Gene Down-Regulation Mediated by the p53 Target p21

Numerous mechanisms have been proposed for mediating gene down-regulation and transcriptional repression in response to p53 activation, including sequestration of transcriptional activators by p53 or recruitment of p53 to specialized p53 response elements. However, multiple studies integrating ChIP-seq with global transcriptional profiling over the past few years provide evidence that p53 binding to promoters almost exclusively is associated with activation of transcription. While the vast majority of genes down-regulated in a p53-dependent manner are not associated with direct binding of p53 to promoter associated p53 REs, the data shows rather that suppression is largely mediated indirect through the highly responsive p53 target p21. The cyclin-dependent kinase (CDK) inhibitor p21 (also known as CDKN1A) performs important function in cell cycle regulation: it inhibits CDK1 and CDK2 that are essential for a cell to progress through the cell cycle. The cell cycle is divided into four phases that include mitosis (M), DNA synthesis (S), and the gap phases G1 and G2. Cell cycle entry and progression require that specific proteins are expressed at well-defined time points. Progression through the cell division cycle is driven by CDKs, which are bound and activated by cyclins. A critical step in the cell cycle is passage through the restriction point, which is also known as G1/S checkpoint. Cyclin D-CDK4/CDK6 and cyclin E-CDK2 complexes control the RB protein family that consists of RB, p107 and p130. During quiescence in G0, when cells have exited the cell cycle, and early during G1 phase, the RB family proteins are un-phosphorylated. In this state, hypo-phosphorylated RB binds to and sequesters the activating E2F transcription factors E2F1, E2F2 and E2F3 (E2F1–3), and RB's siblings p107 and p130 bind to E2F4 and to the MuvB complex to form the transcription repressor complex DREAM. When bound to RB, the activating E2F1–3 are incapable of activating their target genes, which comprise cell cycle genes critically required for entry to and progression through S phase. The DREAM complex represses transcription of both major classes of cell cycle genes: those with important function during S phase (G1/S genes) and those that function during mitosis (G2/M genes). G1/S cell cycle genes are largely controlled through an E2F (adenovirus early gene 2 binding factor) promoter element that recruits E2F transcription factors, and G2/M cell cycle genes are largely controlled through a CHR (cell cycle genes homology region) promoter element that recruits the MuvB complex. CDK-mediated phosphorylation of the RB family proteins leads to their inactivation and release of the activating E2F1–3. When the CDKs are inhibited by p21, RB family proteins become re-activated to block E2F1–3 activity and to form the DREAM repressor complex that down-regulates most cell cycle genes (Fig. 7). Thus, genes down-regulated in response to p53 activation are usually cell cycle genes. In addition to p21, several noncoding RNAs, including miRNAs and long noncoding RNAs, were reported to support gene down-regulation as downstream effectors of p53.

Cellular Responses

The tumor suppressor p53 functions primarily as a transcription factor that exerts its tumor suppressor function through many target genes (Table 1). These targets function in multiple processes that include, but are not limited to, programmed cell death, cell cycle arrest, senescence, DNA repair, autophagy, senescence, angiogenesis, stem cell renewal, stromal and immune interactions, metabolism, translation control and feedback mechanisms. Notably, knockout studies in mice and shRNA screens in human cell

lines revealed that there is no key p53 target gene that confers p53's tumor suppressor function but p53 distributes this function across numerous of its targets.

Programmed Cell Death: Apoptosis and Autophagy

Programmed cell death is important for multicellular species to maintain tissue homeostasis and to eliminate individual cells that may be harmful for the organism as a whole. Several different types of an ever-increasing number of cell death types including apoptosis, autophagy, necrosis and ferroptosis have been linked to p53.

Apoptosis in particular is the predominant p53 function that is conserved among p53's ancestral homologs. Both types of apoptosis, intrinsic and extrinsic, are regulated by direct p53 target genes (Fig. 8). The extrinsic apoptosis signaling pathway is largely controlled by the tumor necrosis factor (TNF) receptor family. These death receptors can be activated by external stimuli such as binding with FAS ligand, TRAIL or TNF-α, thereby leading to direct caspase activation that effects the destruction of the cell. The TNF receptor family encoding genes *FAS*, *TNFRSF10A*, *TNFRSF10B*, *TNFRSF10C* and *TNFRSF10D* are direct p53 target genes that become up-regulated in response to p53 signaling. Thus, p53 induces the expression of death receptors that can sense external stimuli to trigger apoptosis. On the other hand, the intrinsic apoptosis pathway is activated cell-autonomously and involves mitochondria. The BCL-2 family of proteins controls the release of cytochrome *c* from mitochondria. Pro-apoptotic BCL-2 family proteins, such as BAX and BAK, can homo-oligomerize at the outer mitochondria membrane to form pores that cause permeabilization of the membrane and release of cytochrome *c*. Antiapoptotic BCL-2 family members, such as BCL-2 and BCL-X, block interaction between pro-apoptotic BCL-2 proteins. BCL-2 family proteins characterized by a BH3-only region, including BBC3 (also known as PUMA) and PMAIP1 (also known as NOXA), can either activate the pro-apoptotic BCL-2 proteins or block the antiapoptotic BCL-2 proteins. Upon stress signaling, p53 directly up-regulates the expression of *BAX*, *BBC3* and *PMAIP1* to trigger the release of cytochrome *c* from mitochondria. Additionally, p53 up-regulates expression of the ceramide synthase CERS5 leading to the de novo production of C16-ceramide, which supports BAX translocation from the cytoplasm to the mitochondria. When released from mitochondria, cytochrome *c* binds to APAF1 and procaspase 9 to form the apoptosome. The apoptosome activates effector caspases to effect the destruction of the cell. Through direct up-regulation of *APAF1*, p53 further supports the intrinsic apoptosis pathway. Additionally, p53 induces the apoptosis enhancing nuclease *AEN* that supports apoptosis through digestion of double stranded DNA.

Autophagic cell death is another type of programmed cell death and autophagy represents a catabolic process engaged under metabolic stress. Autophagy starts with the activation of a preinitiation complex containing the Unc-51-like kinase 1 (ULK1) and autophagy related (ATG) proteins ATG13 and ATG17. This preinitiation complex is controlled by the metabolic checkpoint complexes AMP-activated protein kinase (AMPK) and mammalian target of rapamycin complex 1 (mTORC1). Under metabolic stress, when AMP and ADP accumulate in the cell, AMPK activates the preinitiation complex and suppresses the activity of mTORC1. In contrast, mTORC1 inhibits the preinitiation complex in unstressed cells. When activated, the preinitiation complex recruits and activates the initiation complex containing the scaffold Beclin 1 and the kinases VPS34 and VPS15 that produce phosphatidylinositol 3-phosphate (PI3P) and promote formation of the autophagosome. The autophagosome can fuse with a lysosome to form an

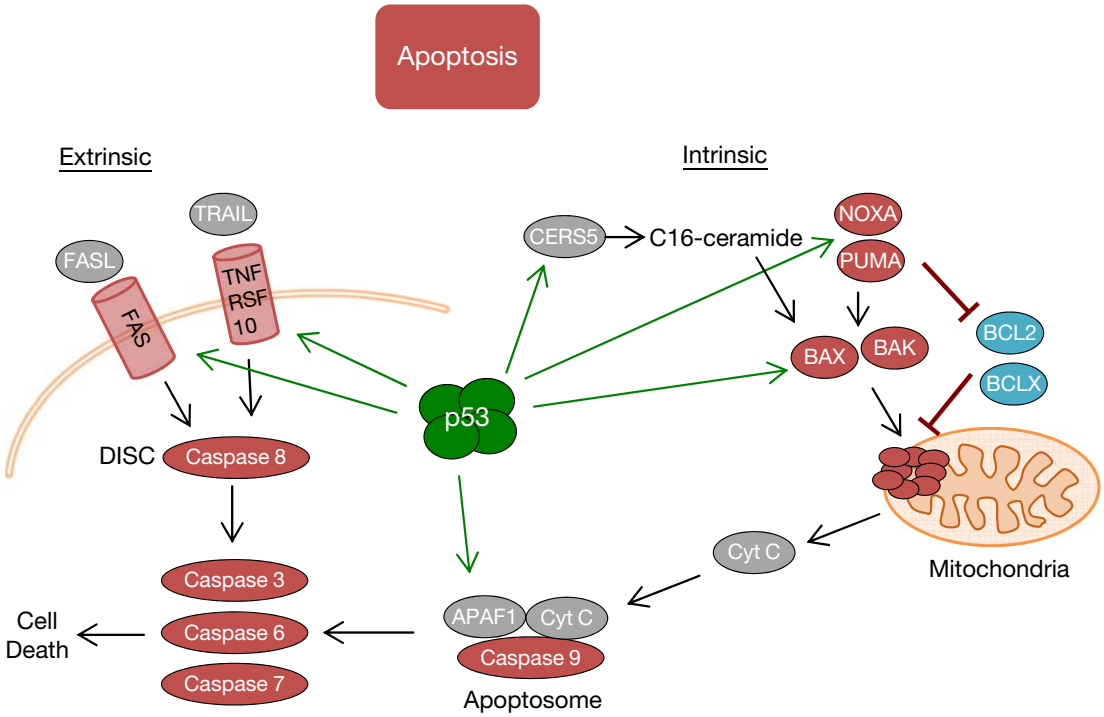

Fig. 8 *p53 can induce apoptosis through multiple direct target genes.* Genes directly up-regulated by p53 control the extrinsic and intrinsic apoptosis pathways. p53 up-regulates the expression of death receptors that can sense external stimuli to trigger apoptosis. A complex interplay of BCL-2 family proteins including BAX, BAK, NOXA, PUMA, BCL2 and BCLX regulates integrity of the outer mitochondrial membrane and release of cytochrome C (Cyt C). The initiator caspases (Caspase 8 and 9) can activate the effector caspases (Caspase 3, 6 and 7) that affect cell death. (*Green arrows* indicate direct transcriptional up-regulation by p53).

autolysosome that degrades any engulfed material. While autophagy, in general, is a survival process to eliminate protein aggregates and damaged organelles, it accompanies and often is required for autophagic cell death. Activation of p53 in response to nutrient deprivation, hypoxia or endoplasmic reticulum stress can induce the autophagy pathway through direct up-regulation of *PRKAB1*, which encodes for the catalytic subunit of AMPK and through up-regulation of *SESN1* and *SESN2*, which encode for proteins that activate AMPK. Together p53 can induce multiple programmed cell death types through direct up-regulation of various target genes.

Cell Cycle Arrest and Senescence

To maintain genomic integrity, it is important for cells to monitor and repair DNA damage. Cell cycle arrest is a critical means employed by a cell to allow for DNA damage repair before continuing the cell division cycle. To understand DNA damage-induced cell cycle arrest, it is critical to appreciate what drives the cell cycle in the first place and the checkpoints that are in place to monitor successful completion of different stages of division (Fig. 9). Cells resting in G0 or dividing cells are stimulated to enter the cell cycle by a mitogenic signal that activates cyclin D-CDK4/CDK6 complexes to drive G1 entry and progression. In late G1 phase, cyclin E-CDK2 complexes hyper-phosphorylate and inactivate RB, leading to the release of the activating transcription factors E2F1, E2F2 and E2F3 (E2F1–3) and passage through the restriction point. Once the G1/S boundary is passed, cells are usually committed to progress though one full cell division cycle. E2F1–3 induce the expression of cell cycle genes that are important for DNA replication during S phase. Cyclin A-CDK2, cyclin A-CDK1 and cyclin B-CDK1 complexes then enable progression through S, G2 and M phases. The transcription factors B-MYB and FOXM1 together with the MuvB complex are important for the expression of proteins that function in mitosis. These cell cycle checkpoints can be "activated" by a variety of stress signals to halt cell cycle progression. In the case of DNA damage this is largely affected through the activation of the checkpoint kinases ATM and ATR directly and indirectly through CHK1 and CHK2 kinases, which together can activate both p53-dependent and -independent cell cycle checkpoints. A rapid, p53-independent, cell cycle arrest involves inactivation of CDC25 phosphatases by CHK1 and CHK2 that are required for activation of CDK2 and CDK1 complexes. p53, however, is critical for a slower but sustained cell cycle arrest. p53 up-regulates the expression of the CDK inhibitor p21, which blocks CDK2 and CDK1 activity. Moreover, abrogated CDK2 and CDK1 activity leads to re-activation of the RB protein family that blocks the transcription factors E2F1–3 and re-shapes the MuvB complex to form the transcriptional repressor complex DREAM. Most, if not all, cell cycle genes become down-regulated through the DREAM complex. Moreover, p21 can bind to and block PCNA, a protein critical for DNA replication. Thus, by activating p21, p53 can block cell cycle progression through abrogation of CDK activity, inhibiting DNA replication and through depletion of hundreds

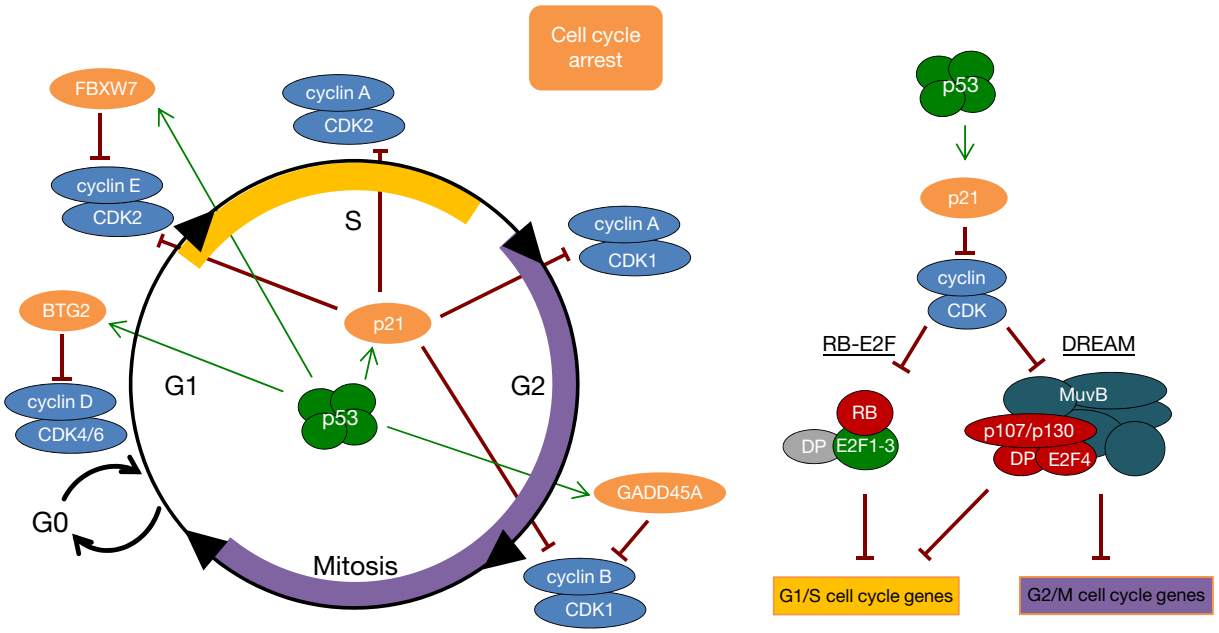

Fig. 9 *p53 controls the cell cycle.* Direct p53 target genes function in the regulation of the cell cycle. Through direct up-regulation of *CDKN1A* (*p21*), *BTG2*, *GADD45A* and *FBXW7* p53 can halt the cell cycle at multiple check points. The highly responsive p53 target p21 inhibits CDK1 and CDK2 complexes to re-activate RB family proteins that block E2F1–3 activity and form the DREAM repressor complex to down-regulate most cell cycle genes. (Green arrows indicate direct transcriptional up-regulation by p53.)

of cell cycle proteins. Notably, induction of p21 is sufficient to induce cell cycle arrest and both, p21 and RB, are required for cell cycle arrest. Additional p53 targets that contribute to cell cycle arrest include BTG2, which inhibits cyclin D expression and leads to G1/S arrest, and GADD45A, which dissociates cyclin B-CDK1 complex and leads to G2/M arrest (Fig. 9). Moreover, the p53 target SFN (also known as 14–3-3σ) translocates cell cycle proteins from the nucleus to the cytoplasm and the p53 target FBXW7 mediates degradation of the cell cycle proteins cyclin E and c-MYC through the SCF ubiquitin ligase complex.

Cell cycle arrest triggered by DNA damage is reversible after the damage is repaired and p53 becomes inactive. In contrast, excessive DNA damage, telomere shortening through too many cell divisions or oncogene-activation can trigger cellular senescence. A senescent cell displays larger cell size, autophagy and high lysosomal β-gal activity, and is usually incapable of re-entering the cell cycle. Senescence is largely controlled by the CDK inhibitors p21 and p16. Sustained expression of p21 or p16 is sufficient to induce cellular senescence. Excessive or un-repaired DNA damage or telomere shortening, which activates the DNA damage response, can continuously activate p53, which in turn sustains p21 expression. The senescent effect of p21 is largely mediated by RB. Oncogene-activation or excessive mitogenic signals can activate p16, which blocks CDK4 and activates RB independent of p53. Notably, oncogene-activation or excessive mitogenic signals also induce ARF, which in turn activates the p53 pathway. Thus, p21 is often activated in addition to p16. Abrogation of p21, p16 or RB impairs the senescence phenotype.

DNA Repair

As a key signal transducer in the DNA damage response, it is not surprising that p53 can activate DNA repair processes. Although it is still actively debated whether p53-mediated DNA repair is part of p53's function as tumor suppressor, it clearly supports cell viability. There are different types of DNA repair. The p53 target XPC, for examples, binds to RAD23B and is the initial DNA damage recognition factor in the global genomic nucleotide excision repair pathway that repairs thermodynamically destabilized DNA duplexes. Similarly, the p53 target DDB2 binds to DDB1 to form the UV-damage DNA binding complex that specifically recognizes UV-induced cyclopyrimidine dimers and recruits proteins for nucleotide excision repair. The cell cycle protein and p53 target PCNA is used in nucleotide excision repair to allow for incision of a new nucleotide by a polymerase after the erroneous nucleotide has been removed. Another process in response to DNA damage is translesion DNA synthesis (TLS), which allows insertion of a base opposite a lesion and bypass of the damaged DNA during replication. The p53 target POLH constitutes such a TLS polymerase that improves bypass of DNA damage and enhances cell survival. Importantly, p53 employs its target RRM2B, a ribonucleotide reductase, to fuel DNA repair by supplying precursors.

Most DNA repair genes, however, are also cell cycle-regulated genes that are critical to solve DNA damage that occurs during DNA replication, and as cell cycle genes these DNA repair genes become down-regulated in response to p53 activation through p21 and the DREAM complex. Thus, only a few DNA repair proteins become up-regulated in response to p53 activation and most of them are involved in nucleotide excision repair, which is particularly important in response to UV-induced DNA damage.

Interestingly, response to UV-induced DNA damage has been suggested to be one of the key drivers for the evolution of the p53 response in multicellular organisms.

Metabolism and Translation Control

Nutrient stress caused by nutrient deprivation can trigger a p53 response through AMPK activation and p53 targets participate in multiple metabolic pathways. Tumor cells often utilize aerobic glycolysis to fuel ATP levels, which is particularly important during hypoxic conditions when a tumor outgrows the blood supply. The p53 target TIGAR (TP53-induced glycolysis and apoptosis regulator) degrades fructose-2,6-bisphosphate leading to decreased activity of phosphofructokinase 1, which catalyzes an essential step in the glycolysis pathway (Fig. 10). Thus, through induction of TIGAR, p53 can impair aerobic glycolysis to decrease energy levels in tumor cells. P53 is also involved in regulating the synthesis and processing of coenzyme A (CoA) (Fig. 10). The p53 target *PANK1* encodes for a pantothenate kinase that catalyzes the initial rate-limiting step in the synthesis of CoA. At the same time, p53 up-regulates AMPK's catalytic subunit PRKAB1 and AMPK deactivates acetyl-CoA carboxylase (ACC) and beta-hydroxy beta-methylglutaryl-CoA reductase (HMGCR). Inactivation of ACC and HMGCR leads to reduced production of lipids and further increases the pool of acetyl-CoA that is available for entering the tricarboxylic acid (TCA) cycle. Additional metabolic enzymes among p53 targets include the fucosidase FUCA1 that degrades the carbohydrate fucose and is required for complete breakdown of glycolipids and glycoproteins; the mitochondrial flavoprotein FDXR that initiates electron transport for cytochromes P450 that also function to metabolize potentially toxic compounds; and GLS2 that catalyzes the hydrolysis of glutamine to glutamate and ammonia. Together, p53 employs a variety of targets to regulate metabolic pathways in the cell.

Protein biosynthesis and mRNA translation are linked to metabolism and p53. The mTOR protein can form the TORC1 complex that controls cell growth and protein biosynthesis. TORC1 is controlled by a TSC1-TSC2 complex, which inhibits TORC1 function.

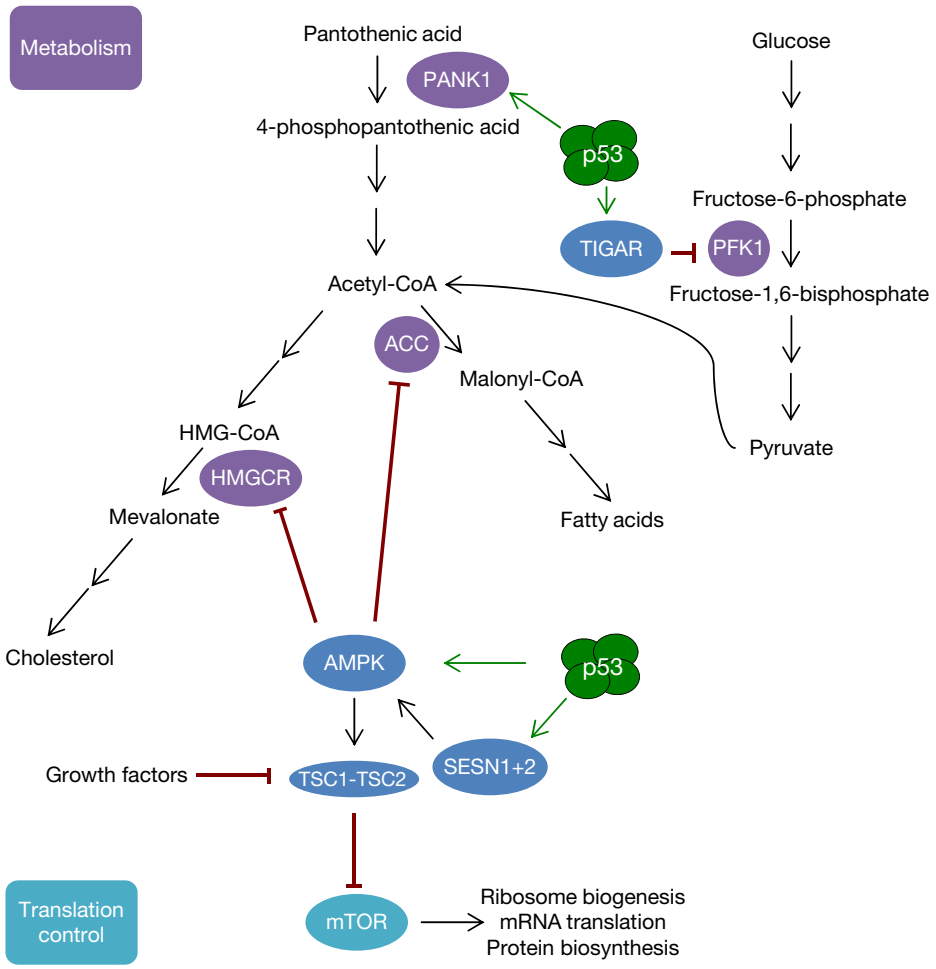

Fig. 10 *Metabolic pathways influenced by p53.* Cellular metabolism and translation is regulated by p53 through direct p53 target genes such as *PANK1*, *TIGAR*, *PRKAB1*, *SESN1* and *SESN2*. Through its direct targets, p53 inhibits glycolysis, reduces production of fatty acids and increases coenzyme A (CoA) levels. Moreover, p53 target genes negatively regulate mTOR to decrease protein biosynthesis. (Green arrows indicate direct transcriptional up-regulation by p53.)

TSC2 is negatively regulated by growth factors but activated by AMPK. The p53 targets SESN1 and SESN2 activate AMPK to positively regulate TSC2 leading to inhibition of mTOR (Fig. 10). Inhibition of TORC1 activity decreases protein biosynthesis, mRNA translation and cell growth. Moreover, p53 signaling leads to down-regulation of ribosomal RNA (rRNA) that is required for mRNA translation. Thus, p53 employs multiple means to impair protein biosynthesis and cell growth.

Feedback Regulation

Through activation of its target genes, p53 activates several feedback loops, both positive and negative. The best-known feedback loop employs the p53 target MDM2, a ubiquitin ligase, which mediates degradation of p53 (Fig. 5). Additionally, the p53 target cyclin G1 activates MDM2 through dephosphorylation. Thus, while phosphorylated active p53 cannot be bound by MDM2, it increases levels of active MDM2. At the same time, the p53 target PPM1D (also known as WIP1) accumulates and can dephosphorylate p53 leading to its MDM2-mediated degradation. Together, p53 signaling becomes abrogated through its own targets. Moreover, multiple p53 targets dampen lethal programs induced by p53. The p53 target TRIAP1, for example, is an inhibitor of apoptosis and the p53 targets PGF, TGFA and KITLG are growth factors that can stimulate cell proliferation. Thanks to these negative feedback circuits, cells that are able to resolve stress conditions can survive instead of rapidly committing to lethal processes such as programmed cell death or senescence.

Exploiting p53 Status

The near ubiquitous nature of de-regulation of p53 function in cancer has led to significant effort in therapeutic strategies to exploit the different underlying mechanisms and consequences of p53 inactivation.

Activating Wild-Type p53

Re-activation or hyper-activation of the tumor suppressive functions of p53 in the ~50% of tumors which harbor wild-type p53 represents an attractive therapeutic target particularly since genetic reactivation is highly effective at inducing tumor regression in mouse models. The central regulatory importance of MDM2-p53 has received significant attention and led to the development of the Nutlins. These small molecule protein-protein interaction inhibitors block the interaction between MDM2 and p53 N-terminus, mimick the effects of phosphorylation and are highly effective at stabilizing p53. However, these first-generation agents promote variable fates depending on cell type in all but MDM2-amplified cells, in which they induce cell death and while tolerated in vivo, toxicities including neutropenia and thrombocytopenia have proven to be dose-limiting for first generation MDM2 inhibitors (MDM2i) in the clinic. Nonetheless, there are significant ongoing efforts to develop next-generation small molecule and peptide inhibitors of MDM2 which overcome these potentially on-target toxicities. Moreover, an increased recognition that inhibition of both MDM2 and MDMX may be required for full p53 activation has led to the development of dual targeting inhibitors and stapled peptides and most recently novel agents targeting MDM2 stability through inhibition of USP7.

Direct effectors of oncogenic repressive post-translational modifications of p53 also potentially provide a rich source of potential targets. For example, PPM1D inhibitors that block removal of Ser15 and block p53-MDM2 interactions have been developed to target PPM1D amplified tumors. p53 activity has also be shown to be increased by inhibitors of sirtuins and histone deacetylases. Such p53 activatory strategies along with those targeting a burgeoning number of interactions associated with chromatin-modifying enzymes which impact on p53 function are targets for drug-development. These represent tractable targets alone or in combination with conventional or targeted agents (including MDM2i) or indeed with agents that restore wild-type p53 conformation.

Targeting Mutant p53

A number of strategies have been developed to re-activate abundantly expressed missense mutant p53 and one such molecule, PRIMA-met, is already in clinical trials in HGSOC. The use of suppressors of premature termination codons and resulting nonsense mediated decay for mutations such as R213* have also shown some promise. While the mechanism and partners responsible for mutant p53 GOF are diverse and context dependent, recent evidence suggests that the transcriptional mechanisms endowed through interaction or sequestration of transcription factors may alter expression of core set of target pathways or processes (e.g., chromatin modification). These may be clinically targetable; for example targeting activation of SREBP targets in the mevalonate pathway in mutant p53 expressing tumors with statins. While alternative strategies exploiting addiction to mutant p53 stabilization indirectly with inhibitors of HDACs and heat shock proteins or peptide inhibitors of aggregation exhibit preclinical efficacy.

Exploiting p53 Deficiency

A number of strategies aimed at exploiting synthetic lethal liabilities induced by homeostatic or therapy induced DNA-damage in p53 deficient cells have also been identified. These are mostly related to induction of DNA damage induced cell cycle checkpoints. Strategies involving inhibitors of ATM, CHK2, ATR, CHK1, PLK1, CDC7 and WEE1 are actively being investigated alone or in combination with genotoxic agents. p53 mutant tumors are also being targeted with oncoloytic tumor viruses capable of replicating only

in p53 deficient cells and viral and mRNA re-introduction of chimeric hyperactive wild-type p53. Inhibitors of POL2RA that exploit collateral effect of p53 deletion resulting in haploinsufficiency of POL2RA open a therapeutic window for POL2RA inhibitors. Moreover, MDM2 inhibitors are also being explored for their use in cyclotherapy wherein the transient induced arrest induced in normal cells protects cells from the cytotoxic side effects of chemotherapies that require cell division and enables the use of higher drug doses.

Prospective Vision

As highlighted above, genomic technologies are rapidly increasing our understanding of the spectrum of genes and pathways regulated directly and indirectly downstream of p53 activation and how they are differentially affected by the various mechanisms of p53 inactivation. Deployment of such technologies to profile responses across 1000's of single cells in the lab or across 1000's of cancer patients will significantly increase our understanding of the contribution of different processes to cell fate, prognosis, response to different treatments and inform novel personalized treatment strategies to improve cancer patient outcome. Mutant p53 is one of the first to describe tumor specific, immune stimulatory neoantigens. Excitingly, there is increasing evidence to support important roles for p53 in tumor immunology and immune homeostasis, which once better understood will hopefully inform novel treatment strategies in combination with burgeoning number of immune-modulatory therapies.

Introduction

For well over a century, macrophages, as their name implies, have been recognized for their ability to phagocytose foreign particles and dying cells. Early observations of macrophages ingesting microbes suggested a role in host defense in infection and injury but Élie Metchnikoff was the first to recognize the physiological importance of macrophage phagocytosis in organismal development and homeostasis. Despite Metchnikoff's prescience, throughout most of the 20th century the primary function of macrophages was considered to be immune surveillance. However, the recent development of powerful molecular biological and imaging techniques combined with macrophage-specific stains has allowed us to study the origins, distribution and functions of tissue resident macrophages in much greater detail. It is now evident that macrophages have a much broader role than just immune protection. They form an integral part of every organ system from the earliest stages of embryonic development and contribute to normal development and maintenance of their host tissues. Indeed, macrophages have been aptly described as housekeepers or accessory cells to the highly specialized parenchymal cells in each tissue as they support optimal functioning of the primary cells. For nascent macrophages to successfully integrate into different tissues throughout the body, they adapt their form and function in response to specific

 https://doi.org/10.1016/B978-0-12-801238-3.96124-5

physiological demands of each tissue or organ. In addition, as recognized by the earliest macrophage researchers, macrophages respond to tissue damage and contribute to tissue repair mechanisms through a process of inflammation to eventually restore homeostasis. This intimate connection with host tissues in health and disease can also have deleterious outcomes as macrophage functions can be co-opted by the disease process, leading to progression of the pathological condition. This maladaptive pathophysiological response is particularly true of tumor-associated macrophages (TAMs).

Origins, Distribution and Diversity of Macrophages

Just as our understanding of the many immunophysiological roles of macrophages has developed rapidly in recent years, our knowledge of the origins of different macrophage populations has undergone a paradigm shift. Previously, all tissue macrophages were thought to originate from circulating monocytes derived from hematopoietic stem cells (HSC) in the adult bone marrow. A corollary of this notion was that tissue macrophages were considered to be terminally differentiated and unable to divide. Macrophages are now known to arise from at least three different sources; yolk sac-derived erythro-myeloid progenitor cells, fetal liver HSCs and post-natal bone marrow HSCs (Fig. 1). Depending on its particular demands and functions, each tissue or organ has its own distinct mix of embryonic or adult derived macrophage populations. Furthermore, most tissue macrophage populations are embryonically derived and maintained by self-renewal without replenishment by circulating monocytes.

Whether embryonic or adult in origin, macrophages are highly plastic and rapidly change their expression profile to adapt to the diverse environments and demands of tissues throughout the body. Parenchymal cells instruct newly arrived macrophages to alter their morphology and behaviour, including secretion of specific trophic factors required for development and homeostasis of the host tissue. For example, yolk sac derived microglia develop a ramified shape in the brain where they secrete brain derived neurotrophic factor to promote synapse formation. Tissue macrophages are also required for remodeling of the extracellular matrix (ECM) and removal of apoptotic cells as exemplified in the breast, which undergoes striking changes not only at puberty but also during each menstrual cycle and pregnancy with phagocytosis of large numbers of dying epithelial cells required during involution. Considering the variety and functions of different tissues, the heterogeneity of tissue macrophages is not surprising.

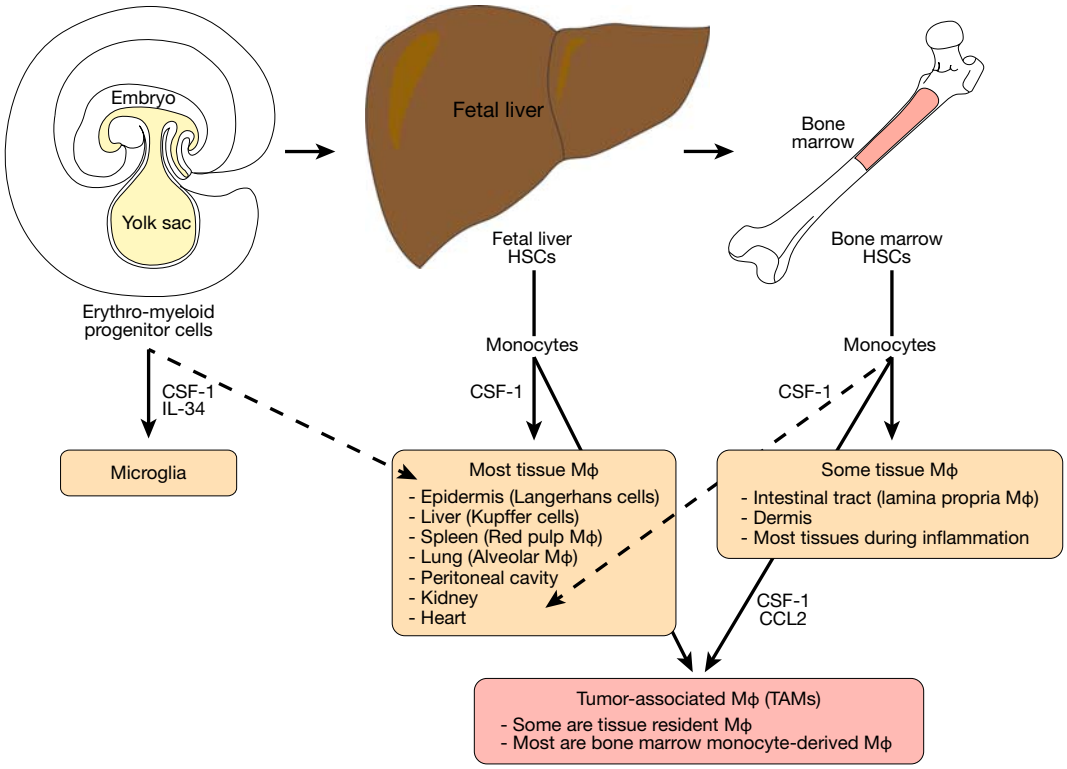

Fig. 1 Origins of macrophages in tissues and tumors. Macrophages arise from three different sources. Yolk sac-derived erythro-myeloid progenitor cells give rise to 100% of microglia in the brain and some Langerhans cells in the epidermis. Most tissues are seeded during embryogenesis with macrophages that are self-renewing and develop from fetal liver hematopoietic stem cells (HSC) and differentiate into monocytes. Macrophages in the intestines and dermis are continually replaced by differentiating monocytes derived from adult bone marrow HSCs. There is some evidence that bone marrow-derived macrophages may also contribute to kidney and heart macrophage populations. Inflammatory conditions lead to an influx of bone marrow-derived macrophages. Irrespective of their origins, all tissue macrophages differentiate under the influence of CSF-1 although IL-34, another ligand for the CSF-1R, drives development of microglia and Langerhans cells. While some TAMs are derived from tissue resident macrophages, the majority are recruited from bone marrow HSCs under the influence of CSF-1 and CCL2.

Nevertheless, macrophages share the common capacities of phagocytosis and migration as they also patrol their host tissues to detect and respond to infection or injury.

Macrophages undergo additional transcriptional reprogramming or "activation" in tissues as a result of exposure to cytokines, growth factors and other local influences. The best known of these activating factors are interferon γ (IFNγ) which, along with the microbial stimulus lipopolysaccharide (LPS), induces a pro-inflammatory, classically activated state in macrophages while the cytokines interleukin (IL)-4 and IL-13 induce an anti-inflammatory, alternatively activated state. Earlier studies of macrophage activation gave rise to the simplistic binary concept of M1 (classically) versus M2 (alternatively) activated macrophages. However, more recent transcriptomic analyses of macrophages derived from different tissues or exposed to various cytokine combinations demonstrate remarkable plasticity and diversity in their activated phenotypes. Thus, a more appropriate framework in which to consider macrophage activation is that of a spectrum, which allows for the presence of different macrophage populations within the same tissue depending on the precise mix of cytokines and conditions such as oxygenation in the immediate vicinity (Fig. 2). In this context, the primary macrophage lineage regulator, colony-stimulating factor-1 (CSF-1, also known as macrophage-CSF, M-CSF), is considered a baseline cytokine that is essential for the production of most tissue macrophages. Consistent with this, macrophages derived from the yolk sac, fetal liver and adult bone marrow progenitors all express the receptor for CSF-1 (CSF-1R). Macrophages that have differentiated under the influence of CSF-1 but have not yet been further influenced by other cytokines are sometimes described as M0 macrophages (Fig. 2). CSF-1 not only induces macrophage proliferation and differentiation but also stimulates macrophage migration, both acutely as a chemokine and through increased expression of motility-regulating proteins. CSF-1-induced macrophage migration is not only important for normal development and homeostasis but also the promotion of tumor invasion by TAMs.

Tumor-Associated Macrophages

Background

Cancers do not consist solely of tumor cells but contain an abundance of nonmalignant host cells, including large numbers of immune cells along with other cell types such as endothelial cells, fibroblasts and other mesenchymal cells. Immune infiltrates are found to a greater or lesser extent in all tumors with innate and adaptive immune cells and their cytokine products flooding the tumor microenvironment. Indeed, chronic, non-resolving inflammation has long been recognized as a premalignant condition and is now recognized as an enabling characteristic of the malignant process itself. Untreated, long-term infections caused by microbes ranging from viruses to parasites produce chronic inflammation in the infected tissues, which leads to cancer in those tissues, for example Hepatitis B and C viruses in the liver, *Helicobacter pylori* in the stomach and *Schistosoma haematobium* in the urogenital tract. It is thought that at least 15% of cancers world-wide are caused by chronic infections. Non-infectious causes of chronic inflammation also lead to cancer, including inflammatory bowel disease, which predisposes to colorectal cancer, and tissue irritants such as inhaled asbestos fibers and now perhaps carbon nanotubes, which can work their way through to the pleural cavity where they drive chronic inflammation to induce malignant mesothelioma.

As macrophages normally constitute up to 20% of tissue mass in organs such as the liver, it is not altogether surprising that TAMs are usually the most abundant immune cell in cancers where they can make up more than 50% of the tumor mass. Growing tumors have extensive metabolic and housekeeping demands, causing macrophage numbers to swell further. However, the considerable

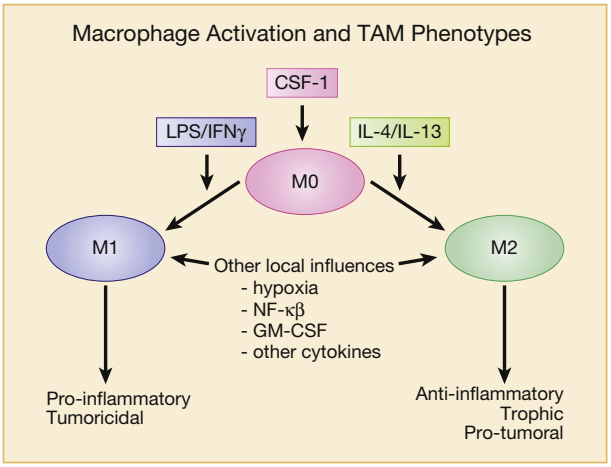

Fig. 2 Macrophage precursor cells, including erythro-myeloid progenitors and mononuclear phagocytic lineage cells are induced to mature into adherent, migratory baseline macrophages (M0) under the influence of CSF-1. M0 macrophages then differentiate under instruction by the specific mix of cytokines and other conditions in the local environment of their tissue of residence. While the binary notion of M1/M2 activation in macrophages is highly simplistic, conceptually it demonstrates the primary influences driving phenotypic changes towards tumoricidal or tumor supporting behavior in macrophages.

accumulation of TAMs was only routinely detected in tumors with the advent of antibodies specific for macrophage markers. Subsequently, TAMs were found to exist in large numbers in solid tumors such as breast, ovarian, bladder, stomach, head and neck and non-small cell lung cancer. Moreover, their density was shown to correlate with poor outcomes. TAMs are now known to accumulate in hematological tumors such as lymphoma, both Hodgkin's and non-Hodgkin's, and chronic lymphocytic leukemia also, with deleterious outcomes in each. Thus, increased TAM density correlates with poor outcomes in tumors of widely different origins, although a striking exception exists in the case of colorectal cancer in which increased numbers of TAMs are associated with positive outcomes.

Origin, Recruitment and Activation of TAMs

In steady state conditions, most tissue macrophage populations are maintained by self-renewal of the largely yolk sac or fetal liver-derived macrophages. However, in inflammatory conditions where demands for macrophages are dramatically increased, the self-renewal capacity of resident macrophages is overwhelmed and their numbers are augmented by circulating monocytes. Tumors themselves are chronic, sterile inflammatory environments where there is evidence that both infiltration of monocytes and proliferation of local tissue macrophages play a role in the accumulation of TAMs during tumor growth. Nevertheless, the balance of evidence in several mouse models of cancer, including breast cancer, lung cancer and glioblastoma multiforme, indicates an influx of monocyte-derived TAMs predominates over proliferation of locally-derived macrophages in the accumulation of TAMs (Fig. 1).

Circulating monocytes are recruited to tumors by a range of chemokines, the most important of which are CSF-1, vascular endothelial growth factor (VEGF) and chemokine (C−C motif) ligand 2 (CCL2) and CCL5. Interestingly, monocytes entering tumors may not always come directly from the bone marrow as some appear to be deployed from a splenic reservoir. In addition, not all incoming monocytes differentiate fully into macrophages although they do respond to influences in the tumor microenvironment to become tumor-induced effector monocytes, which are also known as myeloid-derived suppressor cells. It is important to note that the studies contributing to these observations used mouse models of cancer and much less is understood with respect to the origins and recruitment of macrophages and other myeloid cells in human tumors. Nevertheless, elevated circulating levels of CSF-1 are associated with poor outcomes in several human cancers, including breast, ovarian and pancreatic cancer as well as Hodgkin's lymphoma.

Consistent with the plasticity of macrophages, TAMs evolve with tumors as they progress to invasion and metastasis. There is strong evidence that, early in the evolution of a tumor, TAMs are pro-inflammatory and anti-tumoral in their activities as they try to eliminate tumor cells. However, as the tumor progresses and produces signals to subvert the behavior of its resident macrophages, TAMs transition to a pro-tumoral, immunosuppressive phenotype. Anti-tumoral TAMs are commonly described as M1 macrophages while pro-tumoral TAMs express many markers of an M2 phenotype. However, TAMs often show a mixed phenotype with both M1 and M2 markers, supporting the notion of a spectrum of activation depending on particular signals produced in the immediate vicinity of each TAM. Consequently, TAMs exhibit significant heterogeneity in function and gene expression within a single tumor according to local influences such as the level of hypoxia or whether the TAM resides within tumor nests or are found at the invasive front. In addition to this intra-tumoral plasticity, populations of TAMs exist that express specific, fixed phenotypic markers such as perivascular TAMs, which express Tie2. These macrophages have a particular patho-physiological function to stimulate angiogenesis in ischemic conditions to thereby restore homeostasis. Tumors exploit their angiogenic capacity to produce a neovascular network for the tumor. Despite the heterogeneity of TAM phenotypes, secretion of IL-4, IL-10, IL-13 and other cytokines by tumor immune cells, especially T cells, and tumor cells themselves as the tumor progresses, leads to a strong pro-tumoral TAM phenotype. Interestingly, the phenotype of TAMs in human colorectal cancer is anti-tumoral, supporting the correlation of high TAM numbers with positive outcomes in this cancer. Pro-tumoral TAMs contribute to the promotion of malignant progression in a number of ways, culminating in tumor dissemination.

Pro-Tumoral Mechanisms of TAMS

Almost 20 years ago, Hanahan and Weinberg described a set of six capabilities that tumors must acquire to become fully invasive and metastatic. More recently their conceptual framework was extended to include additional hallmarks and enabling characteristics. TAMs have been shown to contribute to several of these hallmarks of cancer via a range of mechanisms, the most important of which are described in more detail below (Fig. 3). In many ways, TAMs recapitulate in tumors the behavior of embryonic macrophages in development. As well as phagocytosis of cells that are no longer required during organogenesis, the trophic, interstitial migratory and matrix remodeling capacities of macrophages are needed for processes as diverse as blood vessel anastomosis during vascular development and branching morphogenesis in the developing lung, pancreas, kidney, and mammary gland. In the developing brain, microglia are essential for normal neuronal patterning. Central to these trophic functions, embryonic macrophages secrete a number of growth factors and, similar to their embryonic counterparts, TAMs are capable of producing a range of growth factors such as epidermal growth factor (EGF), VEGF and other angiogenic factors, and insulin-like growth factor (IGF)-1 and IGF-2, to support tumor cells. Both EGF and IGF-1/2 can stimulate tumor cell survival and proliferation, which comprise two hallmarks of cancer; sustained proliferative signaling and resistance to cell death. Furthermore, exposure of TAMs to either CSF-1 or IL-4 leads to increased secretion of EGF.

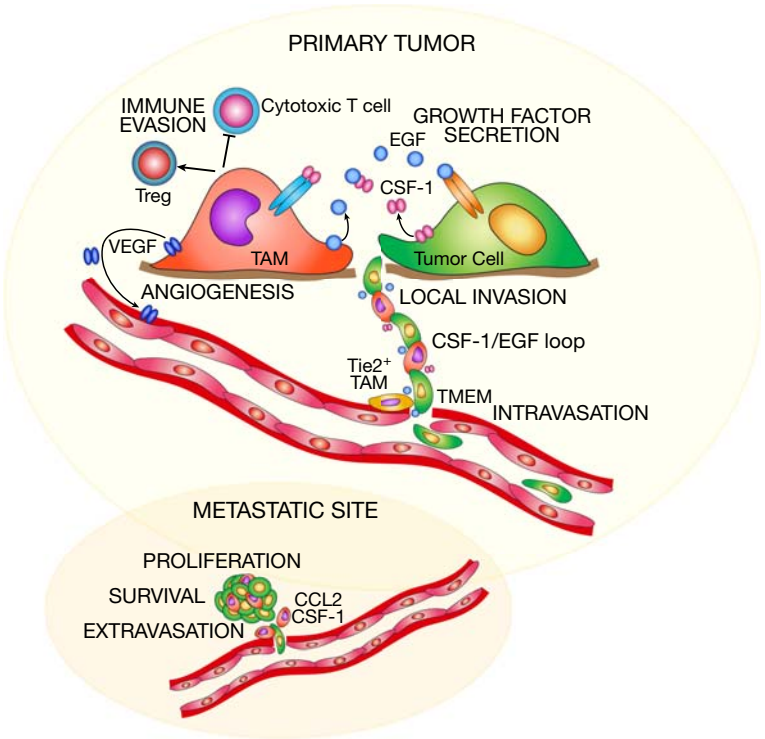

Fig. 3 Contribution by tumor-associated macrophages (TAM) to tumor progression. In the primary tumor, TAMs secrete growth factors, including epidermal growth factor (EGF) and vascular endothelial growth factor (VEGF) to support tumor cell survival and proliferation, and angiogenesis respectively. TAMs also inhibit cytotoxic T cells and recruit regulatory T cells (Treg) to suppress the anti-tumor immune response. Tumor cells secrete colony-stimulating factor-1 (CSF-1) to set up a CSF-1/EGF paracrine loop between tumor cells and TAMs that drives tumor invasion. Co-migrating TAMs and tumor cells migrate towards a blood vessel where $Tie2^{+}$ perivascular TAMs interact with endothelial cells and tumor cells in the tumor microenvironment of metastasis (TMEM) to facilitate tumor cell intravasation. At the metastatic site, TAMs help prepare the pre-metastatic niche then, through secretion of CCL2 and CSF-1, encourage tumor cell extravasation, survival and proliferation.

Angiogenesis

TAMs have long been known to regulate tumor angiogenesis through secretion of VEGF and other pro-angiogenic factors such as placental growth factor. VEGFA in particular drives the angiogenic switch that is necessary for continued tumor growth. The strategically placed perivascular $Tie2^{+}$ macrophages are particularly important for this hallmark capability in tumor progression. Unlike normal vascular development, tumor vessel patterning is aberrant with highly variable vascular branching and caliber. This results in leakiness and dead-end vessels, which impacts interstitial pressure, oxygenation and drug delivery in tumors. Consistent with this, therapies that normalize tumor vasculature rather than ablate it have been shown to enhance cytotoxic drug delivery and response to treatment. Since at least two populations of TAMs, $Tie2^{-}$, and $Tie2^{+}$ macrophages, contribute to tumor angiogenesis and therapies differentially affect them, targeting TAMs in general to normalize tumor vasculature does not appear to be a useful therapeutic approach.

Invasion

Interstitial migration, which requires both motility and matrix degradation, is another capacity of tissue macrophages that is integral to the deleterious behavior of TAMs. Indeed, the ability of TAMs to move through tissues and degrade basement membranes and other barriers is arguably their most important contribution to tumor progression. It was shown some time ago in a mouse model of breast cancer that a lack of TAMs, due to CSF-1 deficiency, significantly slowed malignant progression from early adenomas to late stage carcinomas in the primary mammary tumors and almost completely abrogated further progression to invasion and subsequent metastasis to the lung. These findings highlighted the central importance of TAMs in tumor invasion and metastasis, at least in this model. Subsequent studies revealed the presence of a paracrine interaction between CSF-1-secreting tumor cells and EGF-secreting TAMs that stimulated directed motility and invasion of both cell types along collagen fibers towards blood vessels (Fig. 3). Consistent with this, high TAM densities correlate strongly with metastatic breast cancer, and high CSF-1 levels are measured alongside dense collections of TAMs at the invasive fronts of human breast cancers. Once invasive tumor cells have reached the blood vessel, they intravasate into the circulation at specific sites called "tumor microenvironment of metastasis" (TMEM). TMEMs are a three-cell structure comprising a tumor cell, a $Tie2^{+}$ macrophage and an endothelial cell that functions as a trapdoor to release the tumor cell into the circulation. Importantly, human correlates for this metastasis facilitating structure have been demonstrated.

Metastasis

Once in the circulation, tumor cells acquire a sheath of platelets that facilitates attachment to the endothelium at the secondary site. Just as in the primary tumor, macrophages play several important roles at the metastatic site. Firstly, they prepare the pre-metastatic niche, perhaps under instruction by tumor-derived exosomes. Subsequently they are essential for tumor extravasation and seeding. In the lung for example, once the tumor cell has lodged in the pulmonary vasculature, they secrete CCL2 to attract monocytes to the lung. The recruited monocytes differentiate into metastasis associated TAMs, which facilitate extravasation of the tumor cells from the blood vessel into the lung parenchyma and then support their survival and proliferation. Importantly, inhibition of the macrophage CCL2 receptor or ablation of macrophages at the metastatic site blocks tumor cell extravasation and metastatic growth in the lung. Similar processes occur in other tissues that are common sites for metastatic seeding. In these tissues, macrophages or other mononuclear phagocytic lineage-derived cells, such as osteoclasts in the bone, facilitate several of the steps required for successful colonization by circulating tumor cells.

Immune suppression

Another powerful mechanism by which TAMs (and MDSCs) contribute to tumor progression is through suppression of the immune response to tumors. Consistent with this, tumors containing high numbers of TAMs and $CD4^+$ regulatory T cells (Treg) and fewer cytotoxic $CD8^+$ T cells are associated with poor outcomes. This is true of a range of different human cancers, including melanoma, breast, lung, pancreatic and gastric cancers among others although again colorectal cancer is a standout with increased infiltrating Tregs associated with a better prognosis. As part of their immunosuppressive action in tumors, TAMs secrete cytokines such as CCL17 and CCL22 to recruit Tregs, which are highly immunosuppressive. In addition, TAMs express ligands for inhibitory regulators of T cell function. By expressing ligands for both programmed death 1 (PD-1) and cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4), TAMs activate these negative regulators of T cell function to prevent T cells from attacking tumor cells, despite a frequently high burden of foreign antigens expressed by tumor cells. An increased immunosuppressive tumor environment through a combination of these mechanisms may also contribute to the higher incidence of cancer in the elderly.

Treatment resistance

As well as contributing to multiple processes driving tumor progression, TAMs contribute to the development of resistance to cytotoxic therapies. Considering a central purpose of tissue macrophages is to service their host tissues, it follows that TAMs will work to help tumor cells to survive treatments such as chemotherapy and radiotherapy. They do so by providing survival factors and blocking apoptosis in the case of chemotherapy. This notion was confirmed when neoadjuvant chemotherapy in women with breast cancer was shown to increase TAM numbers. Examination of the phenomenon in a mouse model of breast cancer revealed that paclitaxel treatment induced tumor cell secretion of CSF-1 and IL-34 and TAM recruitment. Importantly, combining CSF-1R inhibition with paclitaxel slowed tumor progression. There is also evidence for another type of paracrine interaction between tumor cells and TAMs that stimulates IL-6 production by TAMs and leads to malignant cell survival and proliferation. In addition, TAMs may secrete tumor necrosis factor (TNF)-α to mediate chemoresistance through NF-$\kappa\beta$ signaling.

Similar to chemotherapy, radiotherapy induces recruitment of large numbers of TAMs to the irradiated region in response to tissue damage inflicted by irradiation. Once again CSF-1 appears to be important for TAM recruitment as radiotherapy increases tumor and circulating CSF-1 levels. The recruited TAMs adopt a pro-tumoral phenotype, which limits treatment efficacy, and prevention of their recruitment enhances the therapeutic response to radiotherapy. Both radiotherapy and anti-angiogenic therapies disrupt the tumor vasculature and thereby cause hypoxia, which stimulates TAMs, especially $Tie2^+$ TAMs, to secrete VEGF. As a consequence, tumor vasculature and growth are restored. Consistent with this, ablation of $Tie2^+$ TAMs improves the therapeutic response to anti-angiogenic therapies.

TAMs as Therapeutic Targets

Considering the involvement of TAMs in several critical areas of cancer progression, as well as therapy resistance, it is not surprising that they have been the focus of a number of strategies aimed at either reducing their numbers or re-educating their pro-tumoral phenotype. Targeting stromal cells in tumors has the additional benefit that they are not malignant and thus are unlikely to acquire mutations leading to treatment resistance. It is clear that specific cytokines and chemokines are key drivers of TAM recruitment and activation towards a pro-tumoral phenotype. Hence, current therapeutic strategies have targeted those key molecules.

CSF-1/CSF-1R inhibition

An obvious pathway to target in macrophage recruitment to and subsequent function in tumors is the CSF-1/CSF-1R axis. The pleiotropic signaling of the CSF-1R supports diverse macrophage functions, including survival, proliferation, differentiation, and migration. Furthermore, CSF-1 was unequivocally shown to promote tumor progression to metastasis in a mouse model of breast cancer where CSF-1 secretion by tumor cells leads to macrophage recruitment and activation into a pro-tumoral TAM phenotype. TAMs recruited by tumor-secreted CSF-1 trigger angiogenesis, block anti-tumoral immune responses and secrete EGF to activate the CSF-1/EGF motility loop. This paracrine chemokine interaction underpins co-invasion of tumor cells and TAMs away from the tumor towards blood vessels, where tumor cells intravasate and begin their march towards metastasis. At the metastatic site,

CSF-1 is again important, this time in combination with CCL2, where they enable tumor cells to extravasate and colonize the secondary site. Hence, a number of clinical trials are currently underway to investigate the effects of CSF-1R inhibitors or anti-CSF-1/CSF-1R antibodies on a variety of advanced solid tumors, either as monotherapy or in combination with chemotherapy or radiotherapy. Despite encouraging therapeutic responses to targeted CSF-1R therapies in several experimental models of cancer, CSF-1R inhibitor-induced depletion of TAMs in preclinical models of breast cancer did not reduce primary tumor growth unless additional chemotherapeutic agents were administered concomitantly. Nevertheless, notable clinical success has been achieved with emactuzumab, an anti-CSF-1R antibody, in the treatment of a rare synovial cell-derived tumor where uncontrolled CSF-1 production by synovial cells leads to a massive influx of macrophages. However, there is concern that indiscriminate ablation of TAMs by CSF-1R blockade may have deleterious effects through depletion of tumoricidal pro-inflammatory TAMs or due to subsequent accumulation of other tumor promoting immune cells such as tumor-associated neutrophils. Thus, new drug development is aimed at either reprogramming pro-tumoral TAMs or targeting specific CSF-1R signals that support pro-tumoral TAM behavior. Unexpectedly, a blood-brain barrier penetrant small molecule CSF-1R inhibitor, BLZ945, did not deplete TAM numbers in a mouse model of glioblastoma multiforme. Instead, the phenotype of the tumor promoting TAMs was switched to a tumor inhibitory one through secretion of granulocyte-macrophage colony-stimulating factor (GM-CSF) by glioma cells, leading to tumor shrinkage. This finding suggests that CSF-1R inhibition may re-educate TAMs in some tumors and ablate TAMs in others. The outcomes of clinical trials examining the effects of CSF-1R inhibition in solid tumors, particularly in combination with immune checkpoint inhibitor therapies, are awaited with interest.

CCL2/CCR2 inhibition

CCL2 has also been shown to be a key chemokine for recruitment of TAMs, which express its cognate receptor CCR2, particularly to metastatic tumor sites. Consistent with this, inhibition of CCL2 or its receptor has been shown to reduce tumor growth in several experimental models. However, concerns were raised when withdrawal of CCL2 inhibition in several breast cancer models led to rebound tumor growth and accelerated rates of pulmonary metastasis. Furthermore, clinical trials of an antibody targeting CCL2, carlumab, showed that it failed to produce a sustained reduction in CCL2 levels and may even have provoked higher rebound levels. Consistent with these observations, carlumab failed to produce any evidence of tumor response. Alternatively, the CCR2 could be targeted but outcomes from a completed clinical trial that tested an anti-CCR2 antibody in patients with bone metastases have not been disclosed. Thus, results of CCL2/CCR2 targeting are not encouraging.

Other therapeutic strategies

Other strategies to selectively target or reprogram TAMs have been tested. Although the transcription factor NF-κβ is well known to be a driver of cancer-associated inflammation, it also causes TAMs to maintain a pro-tumoral, immune suppressive phenotype. Consequently, blocking NF-κβ activation in TAMs may increase their tumoricidal activity and experimental models support this notion. Other mechanisms to re-educate TAMs towards a cytotoxic rather than a trophic phenotype include use of inflammatory agents such as CpG-DNA or agonists of CD40, which is a member of the TNF receptor superfamily expressed on macrophages and is a key driver of tumor-specific T cell priming.

An important consideration in all TAM-specific therapies is that their successful use in the treatment of cancer is likely to rely on co-administration of other therapies such as chemotherapy or radiotherapy.

Conclusion and Future Directions

Macrophages integrate with parenchymal cells in every tissue to facilitate development, function and repair. It is not surprising, therefore, that macrophages in cancers are subverted by tumor cells to turn their trophic functions towards supporting the enemy from within, making TAMs compelling targets in the treatment of cancer. Consequently, the list of clinical trials investigating the effects of anti-TAM therapies is long but the results are thus far underwhelming, indicating a need for more selective therapies targeting TAMs.

To support their remarkable plasticity, macrophages have a complex transcriptome and selectively express a number of proteins or isoforms not expressed in other immune cells. Selectively blocking these unique proteins and the pathways they regulate may prove to be Achilles heels for macrophages. Thus, while reprograming TAMs to enhance their tumoricidal activity may prove successful, drug development aimed at blocking particular macrophage functions that are more important for pro-tumoral than anti-tumoral functions, such as TAM motility, may prove to be more successful.

On a final note, the disappointing clinical results of therapies aimed at reducing TAMs illustrate a core problem of research directed at identifying molecular targets for cancer treatment. Robust responses to newly developed cancer therapies in preclinical models frequently do not translate to clinical cases, particularly where immune cells are involved. Perhaps this is not surprising considering the highly variable expression profiles of key proteins and their homologues in human immune cells compared to those in mice and other animals. Much work remains to be done to tease apart the complexities of the immune environment in tumors and to identify core differences between species.

Tumors and Blood Vessel Interactions: A Changing Hallmark of Cancer

Francesco Pezzella, University of Oxford, Oxford, United Kingdom
Frank Winkler, University Hospital Heidelberg, Heidelberg, Germany; and German Cancer Consortium (DKTK), German Cancer Research Center (DKFZ), Heidelberg, Germany

Glossary

Angiogenesis The formation of new vessels from the existing one. There are three types of angiogenesis: sprouting, intussusceptive, and glomerular.

Nonangiogenic tumors Tumors growing in the absence of *angiogenesis* or *postnatal vasculogenesis*. The commonest mechanism is exploitation of preexisting vessels by *cooption*, the alternative is *vasculogenic mimicry*.

Perivascular niche Perivascular microenvironment(s) including distinct nonmalignant cell types and stroma, where cancer cells find specific cues for survival, invasion, proliferation, stemness, and therapy resistance.

Postnatal vasculogenesis The formation of tumor-associated new vessels from normal stem cells.

Vascular cooption Is defined as the mechanism(s) by which nonangiogenic cancer cells relate to preexisting normal vessels.

Vascular mimicry The ability of tumor cells to form vessel-like channel networks inside tumors. According to the degree of "stemness" of these cancer cells, the spectrum goes from rough channels lined by neoplastic-looking cells up to normal-looking vessels which are however derived from the cancer stem cells rather than normal.

Introduction

Awareness that cancers contain, and have a close relationship with, blood vessels goes back to the dawn of medicine. According to legend, Paul of Aegina reported in the 7th century AD that some diseases had been called "cancer" (karkinos, i.e., crab) because these lesions "has the veins stretched on all sides as the animal the crab has its feet, whence it derives its name." However, the first historical description of blood vessels related to cancer is recognized to Galen of Pergamon (AD 129—c. 200/c. 216) in his treaty "On abnormal swellings": "Whenever black bile attacks the flesh, because it is corrosive, it eats into the surrounding skin producing an ulcer. If it arises with less intensity, it causes a cancerous swelling without ulceration. As I have said before, the veins are distended by black bile to a greater extent than in inflammatory swelling, regardless of the colors that they appear to be."

In 1787 the concept of new vessel growth in tumors was formally introduced by Horton, who illustrated the process by which new blood vessels originated from the existing ones. In 1903 the word "angiogenesis" was introduced by JM Flint to describe this phenomenon and has been used since. In the first decade of the 20th century the first papers were published describing that blood vessels multiplies inside tumors. In 1971 Judah Folkman formally introduced the hypothesis that tumor growth is always and strictly dependent on angiogenesis, at least when the tumor wants to outgrowth a microscopic state where the limits of diffusion of oxygens and nutrients are reached. Folkman's hypothesis was based not only on his work but was following also a series of earlier studies. In 1939 Ide described that tumor implants in the ears of rabbits were accompanied by the formation of new capillaries and later on, between 1943 and 1945, a series of investigations using wound chambers in mice demonstrated that new vessels sprout and migrate toward tumors. In 2000, the concept of "Sustained angiogenesis" was included as one of the six hallmarks of cancer by Hanahan and Weinberg and 11 years later was modified to "Inducing angiogenesis."

The Case for Angiogenesis Dependence and the First Two Angiogenesis Hallmarks

In 1971 Folkman published a seminal paper in which the idea that "the growth of solid neoplasm is always accompanied by neovascularization" was put forward. This hypothesis was generated mostly on the ground of in vitro work and animal models. Animal experiments had been conducted usually in a-vascular sites, such as the work on the cornea of a rabbits, regarded as classic proof of concept. Following undertakings on mice had not only confirmed the need for angiogenesis but also indicated that its induction is an early occurrence. Immunohistochemical studies of "in situ" breast carcinomas and cervical carcinomas on human biopsies showed an increased number of microvessels in the basal membrane leading to suppose that angiogenesis may be an intermediate event between the appearance of an "in situ" lesion and the progression as infiltrating carcinoma. A large series of studies also started to appear indicating that the higher microvessel density in a tumor, the worse the outcome, further strengthening the idea of a link between angiogenesis and tumor growth. However, as more studies appeared, such a strict association has been put in question.

The Different Types of Angiogenesis

Angiogenesis is defined as formation of new vessels originating from the preexisting ones. It follows the hypoxia suffered by cancer cells as the neoplastic lesion becomes larger outgrowing the blood supply. Three different types have been described which can coexist in the same neoplastic lesion: sprouting (classic) angiogenesis, intussusceptive microvascular growth (IMG), and glomeruloid microvascular proliferation (Fig. 1).

Classic Angiogenesis: Vascular Sprouting

This appears the most common type of angiogenesis occurring in neoplasm. Mature vessels in the body are quiescent and their homeostasis is mainly controlled by the Angiopoietin family (ANG1, ANG2—which however can also destabilize vessels—and ANG4) and their receptors (TIE-1 and TIE-2).

Following hypoxia, transcription and secretion of angiogenic factors is induced. The most important among these factors are proteins belonging to the VEGF family: four ligands, VEGF A, B, C, and D and three receptors, VEGF1R/flt-1, VEGFR2/kdr, and VEGFR3/flt4. The VGFA isoforms 121 and 165 plus the VGFR-2, a type III receptor tyrosine kinase, are the most relevant. Another membrane protein, Neuropilin, links to VEGFA165 to produce an angiogenic effect similar to that observed following activation of VEGFR-2.

At the same time, endothelial cells loosen their junctions and detach by the basal membrane through the action of matrix metalloproteases (MMPs) making the vessels leaky. Endothelial cells can break through the basal membrane and migrate toward the areas of higher concentration of angiogenic proteins. As the endothelial cells migrates, they start to secrete ANG2, which competes, with ANG1 for the TIE2 receptor, further inducing endothelial cell detachment, vascular permeability and proliferation among the nearby endothelium.

As the VEGFR-2 is activated it triggers the PLC gamma/PKC/RAF MEK/MAPK pathway inside the endothelial cell, inducing cell proliferation, and the PI3K/AKT pathways, maintaining cell survival. As the endothelial cells proliferate and accumulate they form a cord of cells in which two types can be seen: the Stalk cells, forming most of the growing new vessel, and the most advanced cell, the Tip cell, leading the migration as they follow the gradient of angiogenic molecules. The differentiation into either Stalk or Tip cells is regulated by the NOTCH/WNT signaling pathway. All the endothelial cells express NOTCHs (1, 2, 3, and 4) and NOTCH ligands (Jag 1, 2 Dll1, 3, and 4). Activated endothelial cells transcribe higher levels of DLL4: the Tip cells, those microenvironment is richer in VEGFA, will accumulate more DLL4 resulting into a higher DLL4: NOTCH ratio compared to the endothelial cells further back along the vascular sprout.

In these tip cells, the intracellular domain of NOTCH, freed from the extracellular portion, acquires transcription factor activity and moves from membrane to cytoplasm where induces transcription of factors belonging to pathways that reduce the proliferative effect of VEGF. As VEGF is inactivated, the endothelial cells move to a mature phenotype. In summary, the Tips cells have a phenotype characterized by low proliferation and lack of vascular lumen formation, but VEGFA-dependent production of filopodia rich in actins, resulting in increased motility. The Stalk cells will have instead a phenotype characterized by proliferation which is progressively switched off as NOTCH activation increases leading to vascular lumen formation, establishment of inter endothelial junctions, and deposition of basal membrane. Therefore the number of stalk cells increases, enlonging the vessels, but the number of tips remains small. As a lumen is formed, oxygenated blood starts flow and eliminates the hypoxia and its proliferative effect,

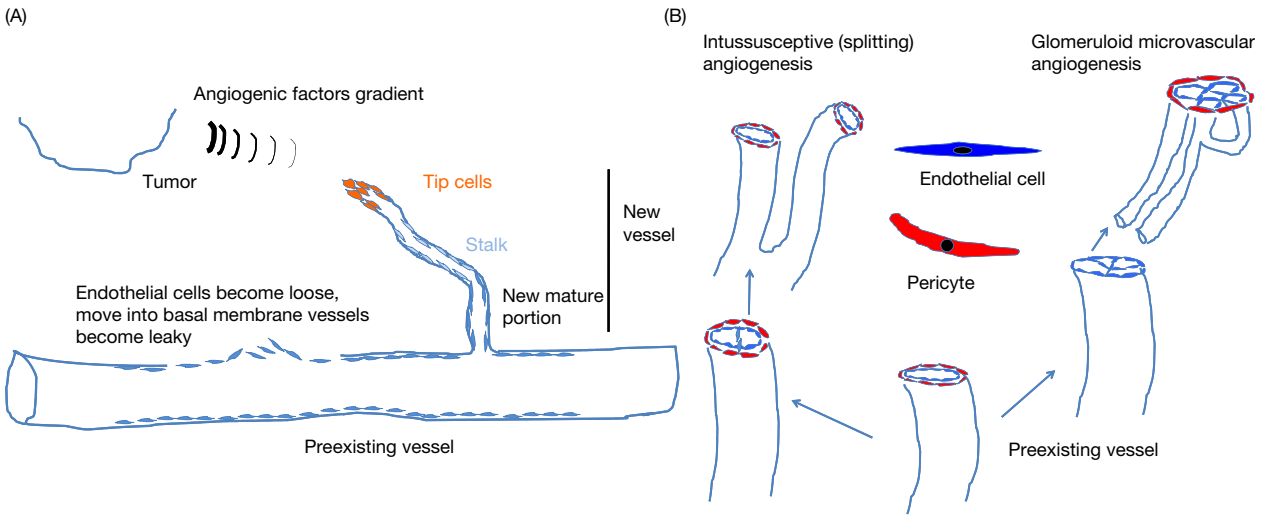

Fig. 1 The different types of angiogenesis (A) classic sprouting. (B) Intussusceptive and glomeruloid (original picture).

pericyte recruitment follows, and vessels maturation is completed. Eventually the newly formed branches will fuse with other vessels and a new vascular network is ready.

Intussusceptive Microvascular Growth (Splitting Angiogenesis)

In this type of angiogenesis, the longitudinal splitting of a preexisting vessel in two, forms the new vessels. This appears to be the fastest way of increasing the number of blood vessel, more rapid than the induction of sprouting angiogenesis. The first step is the growth of endothelial cells inside the vascular lumen, forming a transluminal septum. Endothelial cells than reorganization in order to cover the two newly formed channels. Then connective tissue moves into the septum, completing the division into two vessels. A variation can occur: rather than starting with the creation of the endothelial bridge, the process can also begin with the two sides of the vessel getting into contact. Fenestration follows in the opposite endothelial cells getting into touch, and through these holes the stroma infiltrates, creating a connective septa ultimately completely covered by new endothelial cells. During the whole process blood is circulated and actually the way it flows can affect how the process occurs. The biology underlying IMG is still not very well understood, but some data are available. In the chicken embryo chorioallantoic membranes model, VEGF121 isoform and recombinant human erythropoietin preferentially induce IMG rather than sprouting angiogenesis. TIE1 and TIE2 are also involved, as TIE2 induces endothelial cell stretching, motility, and adhesion to the extracellular matrix while TIE1 inhibits motility.

Glomeruloid Microvascular Proliferation

This type of angiogenesis leads to the formation of the so-called glomeruloid bodies: small vascular structures which morphologically resemble glomeruli in the kidney, hence their name. This type of angiogenesis occurs frequently, but not only, in glioblastomas (GBM). They are formed by small vessels lined by high endothelial cells surrounded by a discontinuous layer of pericytes and by a basal membrane. Few capillaries with flat endothelium are also seen, possibly the vessels from which the glomeruli are generated. The VEGF pathway also mediates their formation.

Postnatal Vasculogenesis

There is a fourth way in which new vessels can appear in tumors. It differs form angiogenesis as the vessels do not originate from the preexisting ones, but from circulating endothelial progenitor cells (EPCs). It is a process that recapitulates the formation of vessels from stem cells during embryogenesis (vasculogenesis). EPCs are not only mainly found in the bone marrow but also found in the peripheral blood, fetal liver, and umbilical cord blood. They have a variable phenotype, according to which tissue they are isolated from but expression of CD34 and VEGFR2 is always present. EPCs are attracted to the growing tumors by the secretion of hypoxia-related molecules and cytokines. Once recruited inside the growing neoplasm the EPCs differentiate into mature endothelial cells and ultimately, into vessels. This model however is rather an exemplification as the biology of the intratumor vasculogenesis is a rather complex event. There are also other bone marrow-derived cells, other than EPCs, which are possibly able to generate endothelial cells like Tie-2 positive monocytes, CD11b positive myeloid cells, VEGFR1 positive hemangiocytes, VE cadherine positive leukocytes, lymphocytes stimulated by pleiotrophin, and intratumor macrophages, but their role is still speculative. It is not yet clear whether these cells can truly form endothelium or just stay closely adjacent to the vessels influencing their formation by a paracrine effect. It also not established how much intratumor vasculogenesis relays on the marrow-derived stem cells rather than those from other tissues.

Can Tumor Cells Become Parts of Blood Vessels?

Finally, two groups have suggested that tumor stem-like cells in GBM can transdifferentiate into bonafide endothelial cells, contributing to tumor vascularization. Using different animal models, other groups have found it difficult to recapitulate many of these findings, questioning the relevance of these observations for the formation of new blood vessels in human tumors.

Tumor Growth Without Angiogenesis

Nonangiogenic tumors are defined as neoplasm growing in the absence of new vessel formation. Two main mechanisms exist: exploitation of preexisting vessels and vascular mimicry.

An increasing amount of data, initially from histopathology studies and subsequently from preclinical and clinical studies has revealed that the formation of new vessels is not essential for a tumor to grow. There are malignant neoplasms able to develop and progress in the absence of neoangiogenesis by exploiting the preexisting vasculature. Such “nonangiogenic” cancers, primaries and secondaries, have been first identified and described in the lung and, subsequently, in several other organs.

Evidence That Tumors Can Be Nonangiogenic

"Nonangiogenic" cancers were first described, as such, in the lung where they grow by filling the alveolar space (Fig. 2). The only vessels present in such tumors are those trapped ones from the alveolar septa and highlight the alveolar structure of the lung tissue by neoplastic cells. The fact that the vessels are the preexisting alveolar vessels is suggested not only by their pattern but also by the conservation of anthracitic pigment alongside the vascular septae, which is similar to the surrounding uninvolved lung parenchyma. Neither endothelial cells nor tumor-associated stroma is present among the neoplastic cell masses within the alveolar sacs. Besides being purely nonangiogenic, tumors having both angiogenic and nonangiogenic areas are a common features.

These initial findings were further supported by a three-dimensional reconstruction, and comparison of normal lung, nonangiogenic and angiogenic lung cancers.

Serial sections were cut and immunostained both for cytokeratin, present in the malignant epithelial cells and normal pneumocytes, and CD34, expressed by the endothelial cells. When looking at the blood vessels in the 3D reconstruction, vascular architecture from normal lungs was indistinguishable from that of the vessels in the nonangiogenic tumor. In contrast, a disorganized network of randomly disposed vessels was seen in the angiogenic tumors.

More details have been subsequently unveiled of how cancer cells dispose themselves in these tumors: animal models have shown that the metastatic cells, after having extravasated, form small aggregates within the alveolar wall in the space between the epithelial cells and the basal membrane of the vessels. The cancer cells then move inside the alveolar space and fill it, moving then to nearby spaces throughout the alveolar pores. Once the alveolar space is filled, some cells transit again between the alveolar cells and infiltrate again the basement membrane dissecting the normal alveolar epithelium from the endothelial cell/alveolar wall. Eventually the alveolar epithelial cells detach and die, and the neoplastic cells lie directly in continuity with the alveolar capillaries.

The absence of newly formed vessels and the persistence of preexisting lung vasculature have been confirmed by immunohistochemical studies fort the expression of LH39 and aVb3 which demonstrated that the vessels present in the nonangiogenic tumors had the phenotype of those in the normal lung with only occasional proliferating cells.

Nonangiogenic tumors have been since also formally described in several other organs in particular in the liver, brain, and lymph nodes. Of note, these organs (including, and particular, the lung) share a very characteristic blood vessel tissue architecture, which

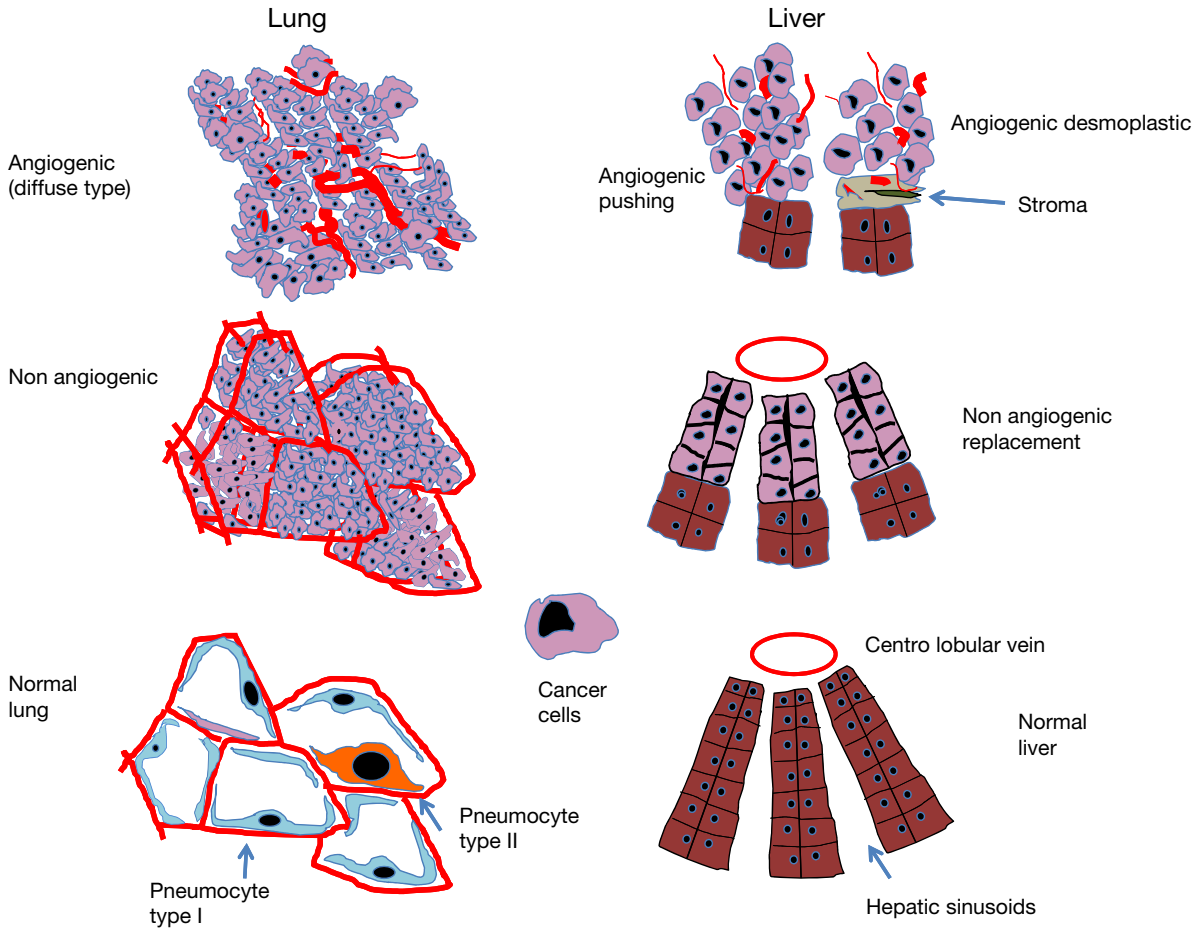

Fig. 2 Architecture of the nonangiogenic tumors compared to angiogenic in the lung and in the liver (original picture).

has probably made it much easier to detect preservation of the normal vasculature in growing tumors. It is likely that vascular cooption can also be found in other organs; this will require careful histological studies, but—if possible—intravital imaging studies that have already greatly contributed to the study of vascular cooption. For melanoma, for example, the dorsal skinfold chamber has contributed to the identification of vascular cooption, which has later been confirmed by careful histology. Likewise, long-time imaging through the brain cranial window had an important role to detect vascular cooption, including the mandatory role it plays during the early stages of brain metastasis formation.

In the liver, three different patterns of hepatic metastatic growth of colorectal and breast adenocarcinomas have been identified. In the desmoplastic and the pushing types, the architecture of the liver parenchyma was not preserved and an angiogenic tumor is present. However, in the replacement growth pattern, the metastatic cells infiltrate the liver parenchyma without any disturbance of the preexisting liver structure. There is no fibrosis, minimal inflammation, and tumor cells, and hepatocytes have intimate cell–cell contact. The tumor cells are growing by coopting the stroma with the sinusoidal blood vessels. As in the lung, liver metastases can have a pure or mixed pattern of growth with some patients who have multiple metastases displaying both "pure" angiogenic and nonangiogenic tumors. The patients with nonangiogenic metastases appeared to have a slower but still aggressive disease as they had a better prognosis at 24 but not at 60 months. The incidence of these liver patterns of metastases depends on the tissue of origin: breast, pancreatic, and urothelial secondaries have a prevalent nonangiogenic growth pattern while only one-third of colorectal metastases grow in this fashion.

A second nonangiogenic growth pattern, in which the neoplastic cells colonized the sinusoid, rather than replace the hepatocytes, has also been identified.

It is a long-standing neuropathological wisdom that diffuse and malignant gliomas, including GBM multiforme, consistently show a highly diffuse infiltrative growth pattern, even of otherwise normal appearing brain, next to a core region which is typically highly angiogenic in GBM, mainly depending on VEGF and angiopoietin signaling. From early on, this makes high-grade gliomas to a whole-brain diseases with both angiogenic and nonangiogenic tumor parts. Glioma cells coopt preexisting brain blood vessels to slowly infiltrate the brain, even single cells far away from the main tumor mass, which is contributing to the very diffuse growth pattern, next to alternative infiltration routes along axonal tracks. The perivascular niche is a preexisting anatomical space that allows easy mechanical passage of cells, next to providing crucial cues for survival, proliferation, cancer cell stemness, and therapy resistance. However, in contrast to the extensive study of molecular factors contributing to brain tumor angiogenesis, it is much less clear which pathways are involved in vascular cooption in the brain; VEGF-A is apparently not involved, while serpins and c-MET have been suggested as candidates that can drive cooptive growth in brain tumors.

In the direct peritumoral region, in vivo imaging discovered IMG, and subsequent cooption of these newly formed blood vessels in the brain, which provides an interesting mechanism how tumors can combine angiogenesis and subsequent vascular cooption in the very same microenvironment.

Furthermore, the early growth of many brain metastatic tumor cells is also purely cooptive, particularly in melanoma and breast cancer animal models, but also some lung cancer cell lines. Of note, strict perpetuation of a perivascular niche position is mandatory to survive in the brain metastatic process, particularly directly after extravasation when the alien tumor cells have to adapt to the new "soil" of the brain.

Finally nonangiogenic metastases from solid tumors can also grow in lymph nodes as demonstrated using a mouse with a lymph node window installed. TRITC-Dextran angiography was performed to visualize the lymph node vessels, whereas the metastatic carcinoma cells were detectable since they were transfected with a gene-encoding green fluorescent protein. The first neoplastic cells are detected in the subcapsular sinuses, initially as single cells than as small aggregates after which they invade deeper in the lymph node cortex where they start to dispose themselves along the vessels when they reach a depth of 509–100 μm. Monitoring by angiography of the vessels did not reveal any change or evidence of angiogenic blood vessel sprouting while the metastatic cells colonized lymph nodes over a period of 40 days. The vascular counts showed consistently that the reactive nodes have the same or even a higher vascular density than the nodal metastases and detected using immunohistochemistry by the expression of Ki67 in the endothelial cells.

Nonangiogenic Tumor Growth: Why and How Does It Happen?

As this is a newly discovered field only some first data are available and we are still far away from fully understanding how tumor cells take the nonangiogenic path (and vice versa!). Different nonangiogenic patterns, intraalveolar in the lung, hepatocyte replacement in the liver, and parenchyma infiltration in the brain, suggest that different mechanisms are at the basis of these patterns of growth.

In the lung, an histological comparison of lung nonsmall cell carcinomas, only minor differences were found as far as necrosis is concerned whereas chronic inflammation and fibrosis characterized the angiogenic tumors, but no differences with respect to microvessel density or cells with morphological features suggesting apoptosis. Immunohistochemical studies failed to demonstrate any major difference in the expression of markers of angiogenesis and hypoxia, the only exception being differences in stromal thrombospondin, almost absent in nonangiogenic tumors but widely present in the angiogenic ones. A high level of thrombospondin (an antiangiogenic protein) in stroma where vascular remodeling occurs is easily explained by its well-known involvement in the remodeling activity of newly generated vessels.

mRNA expression profiling by microarray studies on tumor samples confirmed that no differences in classic hypoxia/angiogenesis pathways could be found with the exception, again, of thrombospondin-1 higher in angiogenic cancers. An unexpected finding

was the increased expression in nonangiogenic tumors of a set of genes linked to oxidative phosphorylation, suggesting the possibility of metabolic reprogramming in the nonangiogenic tumors. The second major finding was the decreased level of a set of adhesion molecule genes, raising the hypothesis that diminished cell-to-cell contact could again be associated with failure to develop a vascular.

A third finding was the association between expression of cytoplasm p53 and nonangiogenic tumors. A pilot study on a small number of these cases demonstrated a higher incidence of P53 mutations in these cases. If confirmed, these data would be consistent with the report that, in animal models, inactivation of P53 leads to resistance to antiangiogenic drugs by increasing the ability of the cells to survive in hypoxia.

Less data are available as far as the biological characterization of the nonangiogenic liver metastases is concerned. However the different type of spreading compared to the lung (replacement of normal cells versus filling empty spaces) and the finding so far that very scanty CA9 expression at the edge of the replacement pattern in the liver indicates that these metastases are not very hypoxic which suggests that liver and lung nonangiogenic tumors could have different underlying mechanisms of development and biology.

The key question however is why and how a cell becomes nonangiogenic rather than angiogenic. We still do not know about "why" and very little on "how."

The gene that has so far better been described as able to regulate such a choice is IRE1. In a murine orthotopic and in a chorioallantoic membrane model of GBM using the cell line U87, the IRE1 gene, which encodes a stress-sensing protein that triggers the unfolded protein response, is a key regulator for angiogenesis. Wild type of U87 glioma cells expressing this gene grows as a discrete, highly angiogenic mass, while the U87 cells, in which the expression of IRE1 has been blocked, grow as nonangiogenic and more infiltrative tumors coopting preexisting vessels. These nonangiogenic cells have a lower expression of proangiogenic genes encoding proteins such as IL1beta, IL6, IL8, BEFGA, MMP1, MMP9, and PLAU while there is upregulation of SPARC. Whether this gene has a role in actual human tumors is not known. It has been reported to carry missense mutation in several types of tumors but whether it causes an effect on angiogenesis is not known.

In addition, there are several studies consistently showing that inhibition or downregulation of the VEGF-A pathway leads to a more invasive growth pattern, partly via vascular cooption. This mechanism of resistance against anti-VEGF therapies, called evasive resistance, has been found for not only primary brain tumors but also other tumor entities. From analyzing the published data carefully, it is impossible to say whether this invasive growth pattern is merely a default, fall-back option for tumors that are deprived of rapid angiogenic growth, or whether interference with VEGF-A signaling by itself is inducing this growth pattern.

Vascular Cooption

Vascular cooption is defined as the mechanism by which nonangiogenic cancer cells exploit preexisting normal vessels, and this is the commonest way nonangiogenic tumors grow. Cells come into contact with the abluminal side of the blood vessels in order to thrive. This is a physiological phenomenon, for example, plasma cells can be seen to coopt vessels in bone marrow. In tumors, so far, cooption has been identified as a mechanism by which nonangiogenic neoplastic cells "parasitize" normal vessels to obtain oxygen and nutrients. However, as cooption is an active mechanism that allows the cancer cell to exploit the presence of vessels, it is likely angiogenic cancer cells to interact and exploit with the newly formed vessels also use that cooption. This is also a newly opened field and only a few studies are so far available addressing the mechanism of vascular cooption. These studies are predominantly focused on brain growth models.

In primary brain tumors the first step is the attraction of neoplastic cells toward the vessel. An important player is a bradykinin-signaling pathway: the glioma cells express bradykinin 2 receptor (B2R), which is activated by the endothelial cells through secretion of bradykinin. Once activated by its ligand, B2R induces intracellular Ca^{2+} oscillations, which mobilize the neoplastic cells toward the vessel along the gradient of secreted bradykinin.

The second step is the interaction with the vessels, once it has been reached. GBM cells produce cytoplasm extensions, denominated flectopodia, which rely on CDC42, a GTPAse that regulates the actins-dependent cytoplasm extension. Once the cell has reached the abluminal side of the vessel, flectopodia adhere to the pericytes through the adhesion molecule CD44. Fusion between the cytoplasm of the GBM cells and the pericytes occurs, with some hybrid cells formation demonstrated "in vitro." If CDC42 activity is blocked, vascular cooption does not occur in this model with some pericytes acquiring a macrophage-like phenotype and showing antitumor activity. The possibility that this occurs in actual human primary brain malignancies in humans is supported by immunohistochemical stains demonstrating increased levels of CDC42 and CD44 expression in perivascular GBM cells as assessed by GBM histological sections.

With respect to brain metastases by other types of tumor, the question is why the cells, after extravasation, stick to the vessel and coopt it. From animal models, serpin seems to play a key role. Early metastatic cells resist apoptosis and coopt brain vessels by expressing the protein neuroserpin, which blocks the generation of plasmin. Plasmin is a protein able to protect the brain from metastatic cells by inducing their apoptosis and inhibiting their ability to move along the vasculature. Astrocytes link these two events, the entering of metastatic tumor cells and the production of plasmin. Following metastatic cancer cells appearance, inflammation, and parenchyma damage astrocytes express high levels of Fas ligand (FasL) and plasminogen activator (PA). PA cleaves the plasminogen, secreted by neurons, into the active form, plasmin, which subsequently acts on several other proteins, including FasL and the adhesion molecule L1CAM. FasL is bound to the membrane of astrocytes, but plasmin is able to cleave and release it as soluble form, sFasL, which in turn can link to its receptor, Fas, on the tumor cell and trigger apoptosis. However, in the presence

of cancer cells expressing high levels of neuroserpin, the astrocyte's production of PA is inhibited, thereby blocking the release of plasmin from plasminogen, and suppressing the secretion of sFasL and thus apoptosis of tumor cells.

Once the increased survival of the cancer cells is achieved, there is the problem of coopt the vessels: a few different mechanisms have started to be unveiled. One mechanism follows again neuroserpin expression: by inhibiting generation of plasmin, the L1CAM molecule expressed by the tumor cell is not cleaved and remains intact, thus allowing the metastatic cells to adhere to the outbound surface of the vessels. In metastatic breast cancer and melanoma, vascular cooption in vivo is reported to be dependent upon the induction of connexin 26 and connexin 43 expression by the "twist" transcription factor. These two connexins induce the formation of functional gap junctions between cancer cells and endothelium. Silencing of these connexins in both breast adenocarcinoma and melanoma cells results in loss of the ability to coopt vessels in zebra fish, chicken embryos, and mouse models, while the presence of the beta1 integrin mediates the adhesion between neoplastic cells and the vascular basal membrane.

Vasculogenic Mimicry

Alongside exploitation of normal vessels, vasculogenic mimicry (VM), that is, the ability of tumor cells to form vessel-like networks, is the second, less common, way for tumors to grow in the absence of angiogenesis. It was discovered and described for the first time in uveal melanoma but now is known to occur in several different tumors. Tumors growing by VM are not angiogenic as formation of new vessels originating by preexisting vessels does not occur, nor are vasculogenic has there is no vascular formation from the normal stem cells of the body.

In these malignancies there are channels in which blood can flow; however these channels originate from the cancer cells themselves. VM appears to recapitulate vasculogenesis network as the neoplastic cells possibly reverse to an embryonic-like phenotype therefore becoming competent to mimic endothelial cells. According to how much of cancer stem cell properties these cancer cells maintain, the intratumor channels can go from resembling morphologically a normal vessels, although carrying the same genetic abnormalities of the tumor, up to rogue channels lined up by clearly malignant cells.

Little is known about the underlying biology. The main signaling pathway regulating VM is ignited by upregulation of VE-cadherin through HIF2. VE-cadherin colocalizes with and phosphorylates EphA2 which in turn activates PI3K both directly and throughout the FAK/ERK1/2 pathway. PIK3 induces the cleavage of pro-MT1-MMP and pro-MMP2 into their corresponding active forms which promote the cleavage of laminin 5γ2 to the promigratory fragments 5γ2′ and 5γ2x. These two latter protein fragments induce and guide the arrangement of the neoplastic cells into channel structures. This pathway can be on one side inhibited by cAMP, inhibiting ERK1/2 function. However cAMP can also sustain VM by positively regulating VE-cadherin expression throughout the Nodal/Notch 1/4 pathway with Gal-3 having a similar positive effect on VM.

The Perivascular Niche: Where It All Happens

When tumor cells coopt preexisting blood vessels of the host in order to grow, and/or when single tumor cells invade the host tissue, they regularly colonize a highly specific microenvironment: the perivascular niche (Fig. 3).

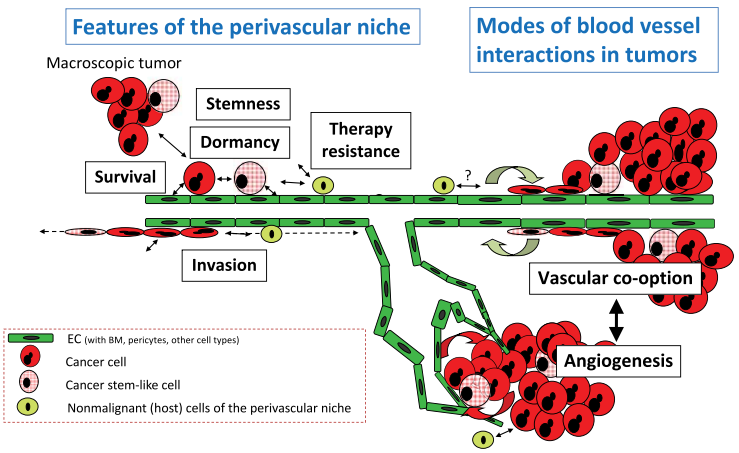

Fig. 3 The perivascular niche and blood vessel exploitation, either by vascular cooption or by angiogenesis, is one hallmark of cancer. (Right) Two principle ways of how tumors get access to blood vessels exist: first, the formation of new blood vessels by sprouting and other types of angiogenesis. Second, cooption of preexisting blood vessels of the host. Incorporation of existing blood vessels and the formation of new blood vessels can occur simultaneously in tumors, but can also be regarded as alternative mechanisms of tumor progression when one of these basic mechanisms is blocked. (Left) The perivascular niche can provide central cues for tumor initiation, progression, and therapy resistance. *EC*, endothelial cell; *BM*, vascular basement membrane (original picture).

In this particular anatomical, physiological, and molecular space that also fosters colonization by new cells due to preformed loose tissue structure in many organs, tumor cells certainly find optimal access to oxygen and nutrients from the blood stream. However, both in the brain and in the lung, it has been demonstrated that neoplastic metastatic cells need to reside in this perivascular niche in order to survive and thrive despite the fact that oxygen and nutrient would be available also away from those blood vessels. Not only the presence of angiocrine factors seems to be one of the reasons but also the presence of special cell types like pericytes, endothelial cells, immune cell subtypes, and others (e.g., astrocyte in the brain). Furthermore, the presence of a specific extracellular matrix including the vascular basement membrane (e.g., collagens, laminin) appears to be another crucial factor. As perivascular niches are important for normal stem cells, it is therefore been raised the hypothesis that these microenvironments are also essential for survival of cancer stem cells. A particular stemness of tumor cells and resistance of tumor cells against established therapies have been best demonstrated for the perivascular niche in the brain yet. The perivascular niche as a place that allows efficient invasion of the host tissue at the tumor borders has been demonstrated for many organs (see earlier). It is therefore very likely that conditions in this perivascular space could decide tumor cell destiny.

Prospective Vision

The discovery of nonangiogenic tumors has opened a new field in cancer biology, in which several important new research areas are present. Several new questions are now facing cancer biologists and clinicians:

- The first question is why and subsequently how a neoplastic cell decides in favor of the angiogenic, or nonangiogenic status.
- Is this process different in different organs?
- As the angiogenic status can change from angiogenic to nonangiogenic and vice versa, is this due to selections of clones, or some neoplastic cells can switch their behavior?
- Which are the mechanism of vascular cooption of preexisting vessels and, again, are they different throughout the body?
- Are there also specific biological mechanisms regulating the interaction between cancer cells and newly formed vessels?
- What exact advantage has cancer cells from perivascular niche colonization?
- And finally, how can we best identify new targets for effective treatment?

A Therapeutical Outlook

It is clear that therapeutic targeting of vessel exploitation has the potential to add to the armamentarium of cancer therapy. This has been extensively shown for antiangiogenic drugs, like antibodies targeting VEGF-A, and tyrosine kinase inhibitors that often target multiple angiogenic pathways. Primary and adaptive resistance to those antiangiogenic drugs, however, has compromised the efficacy of these therapies in patients. From what is known today, a rational attack on the cooptive growth that appears to be a frequent mechanism of primary and adaptive resistance against antiangiogenic therapies might provide even more benefits: it holds the promise of interfering with multiple central traits of tumor biology, since the tumor-promoting factors of the perivascular niche are targeted. The molecular pathways and cell types that have already been suggested as being relevant for vascular cooption and perivascular niche habitation can provide a cue for future directions of research and drug development.

Cancer and Blood Vessels: The New Hallmark

Robust evidences have now confirmed the finding that tumors can grow in the absence of angiogenesis. Contrary to the original theory of Folkman, it is now well established that the requirement of induction or sustainability of angiogenesis for tumors to growth is not essential. The blood supply of a tumor can also be provided by the ability of tumors to exploit the preexisting vasculature by coopting it, or by VM. We have now a more complete view of the role of blood perfusion in cancer, and therefore the current hallmark of cancer, "Inducing angiogenesis," needs to be modified. As the role of blood perfusion remains central to cancer biology we proposed a new hallmark:

"Exploitation of blood vessels, preexisting and/or newly formed."

Intercellular Connections in Tumors

Solid tumors and hematological malignancies are considerably heterogeneous tissues. This heterogeneity comes from the tumor cells themselves that include cancer stem cells (CSCs), believed to be responsible for tumor progression and recurrence following therapy, and cancer cells stratified at different stages of differentiation. Neoplastic tissues also include non-cancer cells. These comprise residing mesenchymal, epithelial and endothelial cells, as well as cells recruited by the tumor such as immune cells and mesenchymal stem cells (MSCs). Importantly, although non-cancerous, these cells nonetheless often present a modified and abnormal phenotype due to their location in the tumor microenvironment and consequently favor tumor progression, metastasis and resistance of the cancer cells to therapy.

Cell communication within the tumor, amongst cancer cells themselves and between cancer and non-cancer cells is now fully acknowledged as widely used by the tumor to grow and circumvent therapeutic treatments. In the last decades, this intercellular communication was believed to heavily rely on secreted cytokines/chemokines, metabolites and extracellular vesicles. In the past few years, a new means of cell-to-cell communication that uses tunneling nanotubes (TNTs) was shown to enable cells to connect to far-off cells and to transfer them biological cargos, ranging from ions to whole organelles, as it will be detailed in this chapter. This donation is qualified horizontal, to distinguish it from the vertical donation from a parental cell to its offspring during mitosis. The number of scientific publications describing this TNT-mediated new mode of communication between cells, including cancer cells, steadily increased since 2004, when they were initially described (Fig. 1). Importantly, TNTs involving cancer cells were also observed in situ, in patient resected solid tumors from both malignant pleural mesothelioma and lung adenocarcinoma, demonstrating their relevance in the cancer pathology.

The occurrence of TNTs in tumors and the ensuing intercellular trafficking are now bringing about a radical turmoil in the current paradigm of the intercellular communications that take place in tumors as TNTs guide and allow the dynamic fluxes of biological cargos, notably mitochondria, that are literally passed from the cytoplasm of the donor cell to that of the recipient cell. This TNT-mediated trafficking occurs from cells of the microenvironment to the cancer cells, modifying the functional properties and response to therapy of the tumor cells. It also occurs in the reverse direction, from the cancer cells to non-cancer cells of the tumor microenvironment, likely contributing to the observed changes in phenotype of these normal cells that ultimately further contribute to tumor progression and resistance to therapy.

General Features of TNT-Dependent Cell-to-Cell Exchanges

TNTs are long tubular structures, with diameters ranging from 50 and 1500 nm and lengths that can span several tens to hundreds of microns. The most important feature of TNTs is definitely the fact that they allow cytoplasm continuity between the connected cells

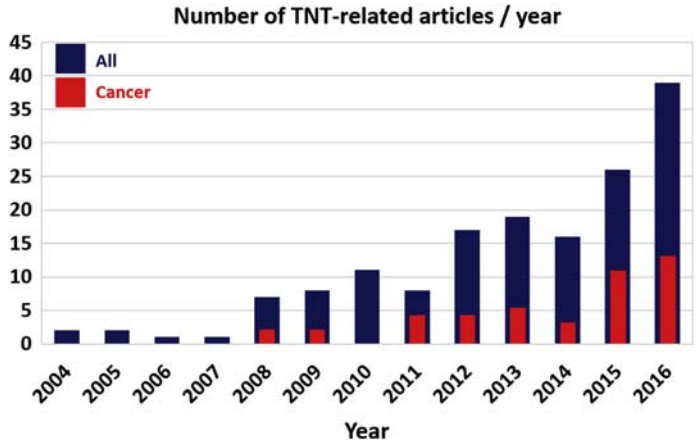

Fig. 1 Number of TNT-related scientific publications. The scheme shows the number of original research articles related to tunneling nanotubes, including studies involving cancer cells, published between 2004 and 2016.

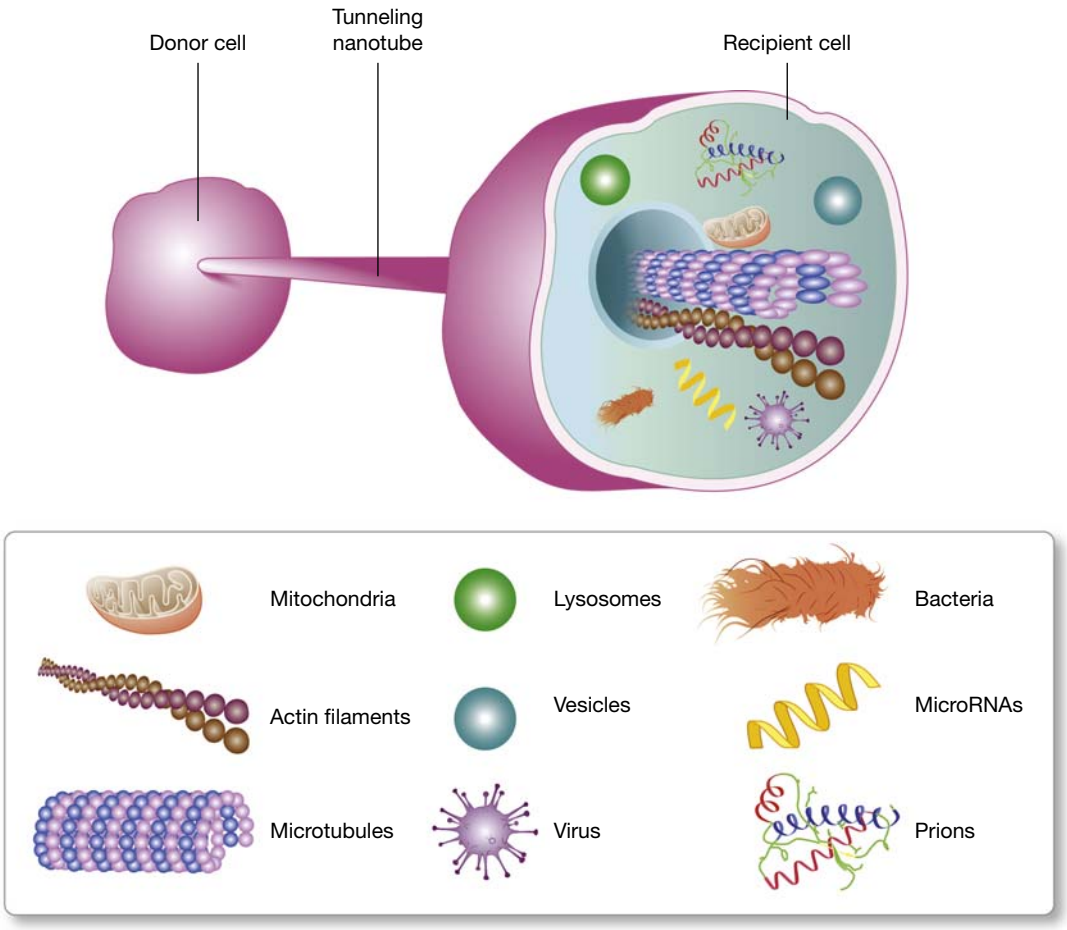

Fig. 2 Tunneling nanotube (TNT). Tunneling nanotubes mediate physical connections between different cells. TNTs allow the horizontal transfer between these cells of diverse cargos, such as mitochondria organelles, viruses, bacteria, proteins, miRNAs and ions. The intercellular trafficking occurs along cytoskeleton fibers of actin microfilaments, microtubules, or both.

and consequently enable the transport of cellular components between these cells. The transported cargos include a whole panel of cellular components, from ions, miRNAs, proteins and virus to whole organelles like lysosomes and mitochondria, as schematized in Fig. 2.

In this review, we provide a general overview of what is currently known about tunneling nanotubes: the cells involved, the cargos transported and the mechanisms that allow this intercellular trafficking. We further focus on the specific signals that induce the formation of nanotubes in tumors and on the biological outcome of these TNT-dependent communications, that ranges from metabolic reprogramming to induced survival in response to therapy. A special attention will be given to the TNT-mediated intercellular transfer of mitochondria as it has been the focus of intense scrutiny over the past few years and gives rise to remarkable biological effects in the recipient cells.

Cell Types Involved in TNT Connections

Tunneling nanotubes were first described, in 2004, in pheochromocytoma-derived PC12 cancer cells and in normal immune cells. Ever since, the number of cell types described to undergo such connecting processes has grown to more than 50, comprising both normal and cancerous cells, as shown in Table 1. These include bladder, breast, colon, and ovarian cancer cells as well as laryngeal squamous cell carcinoma, malignant mesothelial, pheochromocytoma, and osteosarcoma cells. TNTs can provide connections between cells of the same type as for astrocytomas. TNT formation was also observed between normal and cancer cells, including human ovarian epithelial benign and cancer cells, murine stromal osteoblast and osteosarcoma cells, fibroblasts, and HeLa breast cancer cells. A number of the TNTs described between normal and cancer cells involve mesenchymal stem cells (MSCs), known to be recruited to tumor sites. MSCs are stem cells characterized by their capacity to differentiate along several lineages including

osteocytes, adipocytes and chondrocytes. They are found in many tissues, notably the bone marrow and the adipose tissue. They are recruited to the inflammatory tumor microenvironment where they have been shown to make TNT connections in vivo.

It is worth noting that the occurrence of TNTs is not limited to pathological and cancerous tissues. TNTs also constitute a means of intercellular connection in physiological conditions. This was shown for renal tubular, kidney and retinal pigment epithelial cells. TNT formation was also reported for connecting endothelial progenitor cells with endothelial cells and cardiac myocytes. Likewise, TNTs were described between hippocampal neurons and astrocytes. The immune system, notably macrophages, monocytes, dendritic cells, natural killer and B cells, appear particularly prone to use TNT-mediated communication, with measurable effects on the immune response. MSCs are also recruited to damaged or inflammatory tissues where they contribute to tissue repair. TNT-dependent connections have been observed between MSCs and diverse cell types such as renal tubular cells, cardiomyocytes, bronchial epithelial cells, macrophages, endothelial cells, and vascular smooth muscle cells. Even though TNT-mediated connections appear as a widespread process, not all cell types are endowed with this connecting capacity. For instance, astrocytic brain tumors can develop TNT connections that allow intercellular calcium waves and resistance to radiotherapy, but oligodendroglial tumors do not.

Beyond Humans and the rat and mouse mammalian models, it is worthwhile noting that TNTs were also described in *B. subtilis* and *E. coli* bacteria, in Drosophila and in the zebrafish, thus underlining the evolutionary conservation of this cell-to-cell connecting mechanism.

Cargos Transported Between TNT-Connected Cells

Mitochondria

Mitochondria have been the TNT cargos most extensively studied so far. This stems from the extent of the biological effects of the transported mitochondria, both on the metabolism and functional capacities of the target cells but also, and more practically, from the available tools to observe this mitochondria trafficking, both in vivo and in vitro. Detection of the mitochondria transfer was performed using fluorescent mitochondrial vital dyes and viral expression of GFP-tagged proteins targeting the mitochondria (Fig. 3). In heterologous systems, human mitochondria could be detected with antibodies specific for human mitochondrial organelles. At the genetic level, taking advantage of the SNPs present in the mitochondrial DNA (mtDNA), mitochondria originating from different donors could be detected and their concentration evaluated on the basis the mtDNA SNP quantification. In addition, and independently of TNTs, mitochondria (isolated beforehand) display the remarkable capacity to be directly internalized by cells in a macropinocytosis-like process. This provided a useful tool to analyze the biological effects of the transferred mitochondria in the target cells.

TNT and gap junction-mediated mitochondria trafficking involves both normal and cancer cells, and cells as diverse as renal tubular epithelial cells, endothelial cells, macrophages, neuronal cells, astrocytes, astrocytomas, laryngeal squamous cell carcinoma, and leukemia cells. A vast majority of studies so far focused on mitochondria transport originating from MSCs and targeting a whole series of different cells, notably cardiomyocytes, endothelial cells, pulmonary alveolar epithelial cells, renal tubular cells, macrophages as well as cancer cells such as acute myeloid leukemia cells, breast cancer cells and glioblastoma stem cells (Fig. 4).

Other Cargos

Lots of cargos, outside from mitochondria, can be transported between TNT-connected cells. This is the case for the lysosomal organelles. Transported cargos also include the prion and the Tau infectious proteins, possibly contributing to the related pathologies. The HIV virus was described to traffic through TNTs from infected to non-infected cells, thus precluding the need for a fully mature HIV virus to infect neighboring cells. The variety of TNT-transported cargos is amazingly large as, in addition to the above, it also includes microRNAs, lipid droplets and Ca^{2+} calcium ions.

Mechanisms of TNT and Gap Junction-Dependent Cell-to-Cell Exchanges

Gap junctions (GJCs) are intercellular channels that connect the cytoplasms of different cells and allow the exchange of molecules and ions between these cells. First observed in 1958, their role in cardiac tissue has been largely studied. GJCs are composed

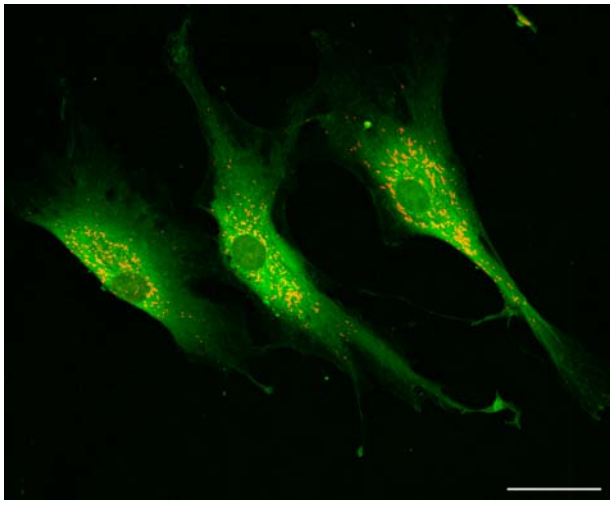

Fig. 3 Mesenchymal stem cell mitochondria network. MSCs were labeled with the green CellTracker CMFDA while their mitochondria were labeled with the MitoTracker Red CMXRos. The MSC mitochondria networks as well as thin intercellular connections can be observed using these vital dyes. Scale bar, 50 μm.

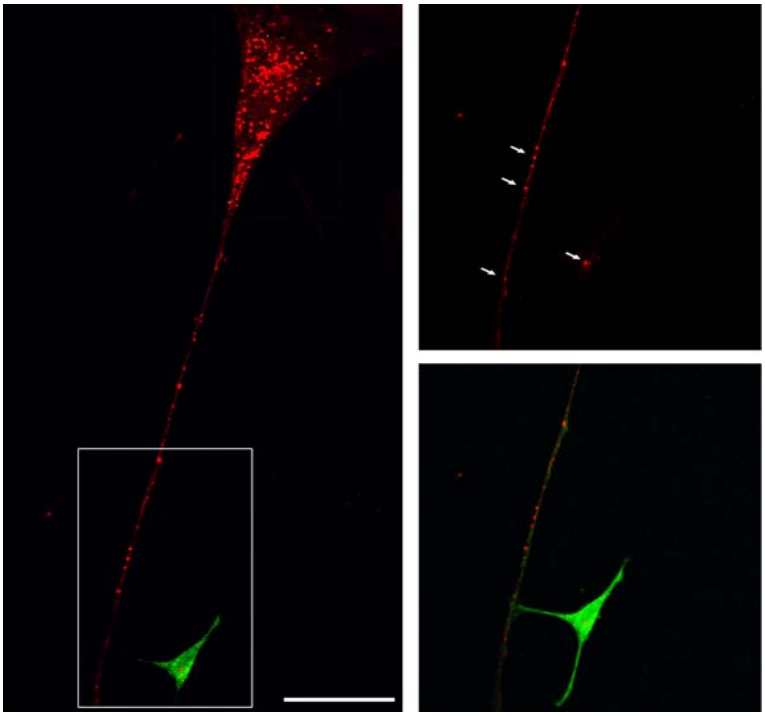

Fig. 4 Mitochondria transfer between mesenchymal stem cells (MSCs) and glioblastoma stem cells (GSCs). Tunneling nanotube formation and mitochondria trafficking between MSCs (labeled with the MitoTracker Red CMXRos) and GSCs (labeled with the green CellTracker CMFDA) after 72 h of coculture. In the enlarged images: MSC mitochondria in the MSC-GSC TNT and inside the GSC (*arrows*). Scale bar, 50 μm.

of two hemi-channels (one for each cell), each of them composed of a hexamer of transmembrane connexin proteins. The connexin 43 (Cx43) was shown, both in vitro and vivo, to play an essential role in the formation of the TNT and gap junction-dependent cell-to-cell connections and subsequent cargo trafficking. Since GJCs only allow passage of molecules smaller than ATP, their precise implication in the TNT-mediated intercellular transfer of organelles like mitochondria obviously deserves further investigation. Additional mechanisms for TNT-mediated intercellular cargo trafficking have also been described to involve M-Sec/TNFaip2 and the exocyst complex as well as various GTPases. However, the precise role of the different GTPases, notably Cdc42, RalA, Rab8, that have been analyzed so far for their involvement in TNT elongation and cargo trafficking, still needs to be fully clarified. Importantly though, the Rho GTPase Miro1 (also called RhoT1/2), well known for taking part with the Milton adapter protein and the kinesin molecular motor in mitochondria transport in axons, is now established to play a key role in the TNT and gap junction-dependent mitochondria transport. Cargo transport within the TNTs occurs along cytoskeleton fibers. The nature of this cytoskeleton depends on both the types of cells connected and the cargos transported. Both microtubules and actin microfilaments, either alone or together inside the same tunneling nanotubes, mediate the active cargo trafficking inside the TNTs.

Signals That Regulate TNT Formation and Cargo Trafficking

Identifying the factors that promote, or inhibit, the formation of TNTs and the subsequent cargo trafficking is of great importance to fully understand the role of this process in tissue homeostasis and, most of all, in pathologies. Different genetic and chemical stresses initiate or stimulate TNT formation and intercellular organelle exchange. These stimuli can be classified in two categories of stress: those affecting the cellular energy metabolism and those related to cell defense in response to inflammation or DNA damage.

Mitochondrial deficiency is a cellular stimulus sufficient to trigger exchange of mitochondria between mitochondria-competent and deficient cells. For instance, lung carcinoma cells treated over long periods with the mitochondrial DNA damaging agent ethidium bromide have non-functional mitochondria but are still viable. These carcinoma cells trigger TNT formation from bone marrow MSCs toward the carcinoma cells leading to the exchange of functional mitochondria and to the recovery of mitochondrial function in the cancer cells. Mitochondrial chemical poisoning with agents such as rotenone or antimycin, that block the electron transport chain, also increases the mitochondria donation from untreated cells to the chemically treated cells. In a consistent manner, glucose starvation and oxygen deprivation also constitute inducer stimuli. Reactive oxygen species (ROS) that are produced during metabolic or physical stress conditions are also involved in the cross talk signaling between the requesting

and donor cells. Actually, the experimental increase in cellular ROS, upon cell exposure to hydrogen peroxide for instance, is a strong TNT inducer.

Alternatively, inflammatory signaling induced by bacterial lipopolysaccharides or TNFα treatment of the recipient cells are also strong stimuli identified as promoters of mitochondria exchange. In addition, a number of DNA damaging agents, mostly employed for cancer treatment, are also potent inducers of TNT-mediated mitochondria exchange. Zeocin, a DNA intercalating agent related to bleomycin, was found to increase by a factor of 10 the number of TNTs formed between renal proximal tubular epithelial cells. Cytarabine (ARA), a nucleoside analog used for the treatment of acute myeloid leukemia (AML), as well as the topoisomerase II inhibitor etoposide and the anthracycline doxorubicin were found to promote the acquisition of MSC mitochondria by AML cells.

Inhibition of the horizontal mitochondrial organelle exchange can be achieved by targeting different steps of the TNT exchange process including: (1) the initial stress signal produced by the cargo-requesting cells, (2) the plasma membrane protrusion formation, (3) the contact/docking between the TNT-involved cells, and (4) the "railway motorization" allowing the cargo trafficking along the cytoskeleton fibers contained within these TNTs. Stress signals leading to local ROS increase can be lessened with antioxidizing agents such as *N*-acetylcysteine. Cell directional polarization and TNT formation can be opposed by virtually all cytoskeleton inhibitors, including agents that either stabilize or depolymerize microtubules and actin microfilaments. Inhibiting the connexin mediated cell-cell docking or shielding the cargo-recipient cells with annexin-V, a protein that recognizes phosphatidylserines abnormally exposed extracellularly by the stressed cargo-requesting cells, can target the cell-cell docking. Finally, even when bridging TNTs have already been established, inhibiting the actin or microtubule-based molecular motors can block cargo trafficking between the donor and acceptor cells.

TNT/Gap Junction-Dependent Connections in Cancer

The occurrence of intercellular organelle exchange is established for solid tumors as well as for hematological malignancies, using immortalized cell lines or fresh primary cancer cells isolated from patients resected tumors. With regard to the cancer cells, organelle exchange can be either inbound (organelle intake by the cancer cell) or outbound (organelle unloading toward the cellular microenvironment). The tumor microenvironment, although not transformed and mutated, plays a direct role in cancer initiation, progression and response to therapeutic treatments. In particular, cells of the microenvironment interact with the cancer stem cells (CSC) present in the tumor and display instructive and protective functions to maintain CSC quiescent and immature properties. Cancer cells educate their microenvironment for the benefit of the CSCs and at the expense of the normal tissue adult stem cells present within the tissue. In this particular context of microenvironment remodeling, cancer cells can use the outbound transfer of mitochondria or lysosomes, to the non-cancer cells of the microenvironment and consequently modify their cytokine secretion pattern. Acute lymphoblastic leukemic cells use TNTs to signal to MSCs and drive the stroma secretion of the pro-inflammatory cytokines CXCL10, CCL2, and interleukin 8. Beyond the outbound transfer to modify their microenvironment, cancer cells can use this unloading system to detoxify during chemotherapy exposure. The outbound transfer of lysosomal vesicles containing the chemotherapeutic agents was shown to reduce the concentration of these toxic agents in leukemic cells.

Regarding the intake of mitochondria, its main reported outcome is a survival benefit for the recipient cells, for both normal or cancer cells. For instance, leukemic cancer stem cells that capture mitochondria during cytarabine exposure become more resistant to cell death and boosted with a long-term regrowth potential. In line with these observations, mitochondria horizontal transfer directly modifies the energetic metabolism of the recipient cells. Many cancer cells predominantly produce energy through a high rate of glycolysis, which converts glucose to pyruvate, followed by the production of lactic acid from this pyruvate. On the contrary, most normal cells use an alternative pyruvate metabolic pathway that takes place in the mitochondria where the oxidation of pyruvate ultimately leads to the phosphorylation of ADP in ATP, in a pathway called oxidative phosphorylation (OXPHOS). The complete eradication of OXPHOS for a cancer cell is a disadvantage. This can be achieved experimentally by a long-term exposure to mitochondrial DNA damaging agents, leading to cells named ρ0 cells. These OXPHOS-incompetent ρ0 cancer cells have a lower tumorigenic and metastatic potential compared to the mitochondria-competent parental cancer cells. Over time ρ0 cancer cells, placed in vivo within a mitochondria-competent surrounding environment, recover their OXPHOS activity through mitochondria horizontal transfer and retrieve their tumorigenic potential. Independently of the organelle exchange, different anticancer radiation or chemical therapies can switch cancer cell glycolytic metabolism toward an OXPHOS metabolism. In different cancer models, an OXPHOS metabolism was shown to confer cancer cells an increased drug resistance compared to a glycolytic metabolism. Antineoplastic agents stimulate intercellular mitochondria exchange, which further favors the OXPHOS metabolism in the recipient cancer cells. This survival benefit associated with the intake of exogenous organelles is observed not only for differentiated cancer cells but also for cancer stem cells. These observations, while questioning our long-standing view of cancer metabolism, offer new opportunities for developing innovative and more efficient therapeutic treatments. For instance, blocking the microenvironment-mediated drug resistance acquisition by interfering with the TNT-based intercellular organelle exchange combined with the inhibition of the OXPHOS metabolism is expected to improve the current treatment standards and tackle cancers at their roots.

Noteworthily, outside from cancer, TNT and gap junction-dependent cargo exchange also has important biological effects, resulting notably in tissue repair. As demonstrated in murine models of lipopolysaccharide and rotenone-induced damage of pulmonary alveoli, lung instillation of MSCs leads to in situ connections between the MSCs and the damaged pulmonary alveolar epithelial cells and to the subsequent transfer of MSC mitochondria, resulting in the regeneration of the affected alveoli and mice

survival. In another context, that of *E. coli*-induced pneumonia (murine model), acquisition of MSC mitochondria by lung alveolar macrophages results in increased phagocytic activity and antimicrobial response. Consequently, in non-tumor injured tissues, therapeutic strategies would aim at increasing the mitochondria transfer occurrence and efficacy, both by increasing the local number of mitochondria donor cells in the wounded environment and by pharmacologically promoting cell–cell interactions and organelle trafficking from these cells.

Prospective View

The discovery of TNT-mediated organelle exchange provides new perspectives in the field of cancer cell biology. The discovery of this new mode of intercellular communication stems from the efforts of the scientific community, in the past two decades, to improve the physiological relevance of the studied cancer models. Although immortalized cancer cell lines were helpful to study the intrinsic cellular and molecular deregulations responsible for cancer cell transformation, these models were less suited for studying the biology of the primary tumors and their interactions with their microenvironment. For example, standard cancer cell lines are generally cultured in vitro with high glucose and oxygen concentrations, at least double their actual physiological concentrations. The recent advances in engineering organotypic co-culture systems, in 2- or 3-dimensions, as well as the development of humanized xenograft systems using immunodeficient mice, are prompting the discovery of new features in cancer biology.

It is worth mentioning, at this point, that most of our current knowledge of the TNT-mediated intercellular exchanges originates from in vitro observations. Even though TNT connections and mitochondria intercellular trafficking were also demonstrated to occur in vivo, it will be worthwhile extending these in vivo studies. For instance, it is presently unknown whether current anti-cancer therapies do increase TNT formation in vivo. A number of likewise unanswered questions remain to be explored, such as the actual amplitude of the TNT phenomenon in the different types of cancer, its frequency as well at its prognostic value. The time scale during which cells remain biologically modified, following TNT-mediated mitochondria organelle acquisition, needs as well to be better assessed. It also remains to be determined whether there are "quality control" checkpoints for mitochondria donated by the donor cells as well as for those accepted by the recipient cells. It will most likely depend on both the donor and recipient cells biological properties. Furthermore, technical issues will need to be settled, notably the monitoring of chemical probes and the development of novel markers for selectively tracking the exchanged mitochondria organelles over longer periods of time.

As a conclusion, it now clearly appears that the discovery and characterization of TNT intercellular connections, and of cargos transported from one cell to the other through these connections, bring a novel understanding of the cancer cell biology that takes place within tumors. As this cargo trafficking has consequences on tumor progression and resistance to therapy, the challenge will now be to exploit this new knowledge to conceive and develop novel anticancer therapeutic strategies.

Glossary

BRDT Bromodomain testis-specific is a gene encoding a double bromodomain protein of the bromodomain and extra terminal (BET) protein family.
Cancer testis (C/T) genes Testis-specific genes that are aberrantly active in tumor cells.
Cancer testis antigens (CTA) The products of cancer testis genes that are unknown to the immune system and hence are antigenic.
Cell identity Molecular systems that ensure a specific pattern of gene expression conferring functional specificities to a given cell type.
CT-X genes C/T genes that are localized on the X chromosome.
Quiescent stem cells Non-proliferative resting stem cells.
Supervised transcriptomic analysis Comparison of transcriptomes from sample groups defined a priori.
Tissue-specific genes Genes within the genome that are exclusively expressed in a given tissue.
Tissue-restricted genes A term that has the same meaning as tissue-specific genes.
Tissue-privileged genes Genes within the genome that are predominantly expressed in a given tissue but are also expressed in other tissues at a lower or background level.
Transcriptome The repertoire of cellular RNAs in a given cell.

Abbreviations

ALL Acute lymphoblastic leukemia
AML Acute myeloblastic leukemia
CAR-T Chimeric-antigen receptor T cell therapy
CLL Chronic lymphocytic leukemia
CML Chronic myeloid leukemia
DLBCL Diffuse large B-cell lymphoma
MDS Myelodysplastic syndrome
MHC Major histocompatibility complex
MLL Mixed lineage leukemia

Introduction

Cell differentiation corresponds to a physiological cell programming process that instructs the genome for a stepwise control of specific gene expression. A tight interconnection between the genome, metabolism and the epigenome is of primordial importance in correctly driving cell differentiation. The stability of gene expression that characterizes adult cells and their different functional states or, in other words, their identity, largely relies on the stable relationship between the metabolism and the epigenome. Specific epigenetic barriers prevent unprogrammed changes in gene expression and ensure the stability of the differentiated cell states. Pre-cancerous situations and malignant cell transformation involving changes in cell metabolism and hence in the epigenome, destabilize gene expression states and favor events that may also affect genome integrity. A direct consequence of these alterations is the aberrant desilencing of hundreds of tissue-specific genes in various considered tumors. Cancer cells aberrantly express a large number of tissue-restricted or tissue-privileged genes. The expression of some of these normally silent genes, such as testis-specific genes, has already attracted attention. Indeed, one of the most visible awakening of normally dormant genes in cancer concerns the so-called testis-specific genes, also known as C/T genes. Sporadic identification of these genes in various cancers has led the investigators to see them as a particular category of genes identified and studied over time and listed as such. However, other investigations indicate that the C/T genes are not the only tissue-specific genes activated in cancer and that desilencing could actually affect a variety of dormant genes. In fact, a systematic identification of genes with tissue-restricted patterns of expression by

Rousseaux and colleagues revealed that testes express the highest number of restricted genes, which suggested that this could also be a reason why testis-specific genes are the ones most frequently identified as aberrantly expressed in cancer. Whether cancer cells express testis-specific genes in a biased or unbiased manner remains one of the important open questions that will be specifically discussed here.

Another important point is that both the establishment of the list of testis-specific genes and the systematic consideration of their ectopic expression in various cancers are now demonstrating that the list of genes already classified as C/T genes actually only corresponds to a subset of the genes that are potentially activated in cancer. It is therefore important that the notion of C/T genes is revised not only to highlight the fact that C/T genes could potentially correspond to any testis-specific genes but also to consider that ectopic gene activation includes other tissue-restricted genes. In fact, cancer cells express genes that are normally active in placenta, in embryos and during development, in ovary and trophoblasts, in fetal ovaries or in various differentiated cell types, including the nervous system and megakaryocytes/platelets, as well as in many other tissues that will be discussed in more details below.

A global vision of the phenomenon of cancer cell identity loss and of large-scale aberrant activations of tissue-specific or tissue-privileged genes in all tumors now appears as an essential issue. It is important to place C/T gene activation in the true context of general cell identity loss in cancer cells, and specifically apprehend the biology which is behind the ectopic activation of genes and more specifically behind the aberrant male germ cell genes activation during malignant transformation. Here, answers to some of these crucial questions regarding the nature of the ectopic activation of genes in cancer and the specific place of testis-specific genes are provided. Indeed, it is essential to establish once and for all, whether, among all the tissue-restricted genes, cancers preferentially express testis-specific genes and whether or not the extent of ectopic gene activation in cancer depends on the type of cancers. It is also of importance to establish whether some genomic regions/chromosomes are more prone than others to desilencing and ectopic gene activations in cancers. These are all unanswered questions and their consideration could open a new avenue to the understanding of the biology of cancer and to envision new therapeutic approaches based on the general phenomenon of ectopic gene activations.

Revisiting the Concept of Cancer Testis Genes

Cancer-associated expressed genes encoding antigenic proteins were identified and named “cancer testis antigens” (CTA) genes, and have attracted attention for several years. The interest for this category of genes is now becoming more acute with the possibility to use them as antigens for anti-cancer immunotherapy in improved therapeutic proocols in combination with inactivation of the immune checkpoints. The original discovery of C/T genes was based on the use of T-cell or antigen recognition by antibodies from melanoma patients. The analysis of the normal pattern of expression of the corresponding genes revealed that they are mostly testis-specific gene, hence the name cancer testis (C/T) genes. Since that time, sporadic reports on the identification of testis-specific genes expressed in tumors has fed the growing list of C/T genes which can be consulted on dedicated web sites.

However, a careful consideration of the tissue-of-origin of the expression of the genes listed in the database shows that actually they are not all testis-restricted, and that many of them could also be testis/brain restricted or be preferentially expressed in testis but also expressed at lower levels in other tissues, as noted by Hofmann and colleagues. The accumulation of transcriptomic data from various normal tissues and cancers prompted several investigators first to establish a list of testis-specific genes and second to systematically consider their expression in cancers. The resulting data indicate that the previously established list needs to be reconsidered to include new members as noted by Rousseaux and colleagues and different groups including McFarlane’s.

Additionally, other investigations that aimed at the unbiased identification of genes or proteins aberrantly expressed in tumors compared to their normal counterparts using transcriptomic and proteomic data, revealed that the identified mRNAs and proteins could correspond to genes normally expressed in testis as expected, but also to genes expressed in other tissues types. The question therefore arises whether C/T activation is a specific property of cancer cells or whether C/T gene activation is merely one aspect of the general desilencing of tissue-restricted genes in cancer.

Testis-Specific Genes Are Preferentially Activated in Cancer

Taking into account the aberrant activation of a variety of tissue-restricted genes in cancer, it becomes important to establish whether tumors specifically activate C/T genes rather than other normally silenced genes, and if the apparent enrichment for testis-specific gene activation in cancers is a biologically meaningful phenomenon.

An element that needs to be considered to answer these questions is that, compared to other human cell and tissue types, male germ cells express the highest number of genes with a restricted pattern of expression at both mRNA and protein levels, as established by Rousseaux and colleagues.

In order to have a more precise vision of the genes with tissue-restricted expression, taking into account recent data that are now publically available, including RNA-seq of various normal tissue and cancers, we re-established a list of tissue-restricted genes. Fig. 1A confirms our previous observation showing that indeed testes express the highest number of tissue-restricted genes and that the number of tissue-specific genes drops when somatic tissues are considered. In addition, the number of testis-restricted genes found with this new approach ($n = 1597$) largely exceeds that of the genes recorded in the C/Tdatabase ($n = 243$).

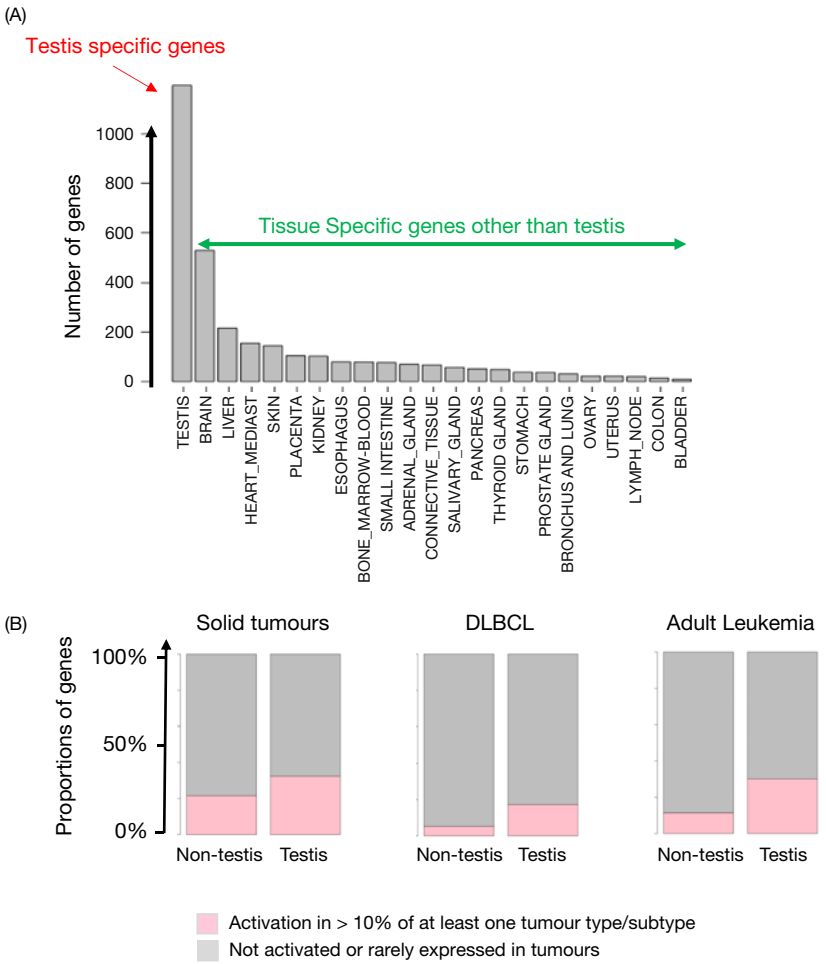

Fig. 1 (A) Numbers of genes with a tissue restricted expression as a function of the tissue of expression (based on RNAseq data, E-MTAB-1733). A gene was considered tissue specific if the corresponding normalized value of read counts (FPKM: Fragments Per Kilobase Million) was above a threshold defined by the mean value of read counts in all tissues +10 standard deviations (std) in this particular tissue. Of the 3823 identified tissue restricted genes, 1597 were testis-specific. (B) Respective proportions of tissue restricted genes, of testis or non-testis origin, which are activated in at least 10% of the cases of at least one of the cancer types/subtypes according to the transcriptomic data (obtained with the Affymetrix array Human Genome U133 Plus 2.0) from three series of malignancies, including a large series of solid tumors (multicancer study, GSE2109), Diffuse Large B-cell Lymphomas (DLBCL, GSE10846) and adult Leukemia (GSE13159). After matching with updated gene identifiers, 3270 genes out of the 3823 tissue-restricted genes identified in A were found represented on the array. For each gene the threshold of activation corresponds to the mean value +3 std. of the signal obtained on the same array in a series of normal tissues (GSE3526), following a protocol published by Rousseaux and collaborators.

Therefore the question arises whether the observed predominancy of C/T genes among genes ectopically activated in cancers merely reflects the larger number of testis-restricted genes as compared to the numbers of silenced genes of other tissues of origin. In other words, a higher probability of silent gene reactivation due to a larger number rather than to a specific biology could explain the high frequency of C/T gene activation.

To answer this important question the respective numbers of testis-specific genes or of tissue restricted genes of other origin activated in cancers were calculated and compared. The observation of a higher proportion of testis-specific genes in cancer would argue for a biased activation of male germ cell genes in cancer. Taking into account the rather low number of tissue-specific genes compared to testis-specific genes, we pooled all non-germline tissue-specific genes and compared the proportion of these that are frequently activated in various cancer types with the proportion of testis-specific genes expressed with similar frequencies in the same tumor types.

Interestingly, Fig. 1B shows that cancer cells clearly preferentially activate testis-specific genes compared to all other tissue-restricted genes, irrespectively of the studied cancer sample series of solid tumors or hematological malignancies.

This observation has important biological significance. It may indicate that the mechanisms that are used to repress testis-specific genes are more sensitive to deregulation in cancer compared to the other tissue-restricted silenced genes. It may also indicate that the activation of male germ cell-specific genes could selectively contribute or stimulate malignant transformation and cancer

progression. Although there is not much evidence for a particular sensitivity of testis-specific genes to desilencing in cancer, an important body of data is now accumulating that clearly demonstrates the oncogenic activities of testis-specific genes (see below).

Revisiting the Notion of CT-X

Considering the established list of C/T genes, several authors noticed an important enrichment of these genes on the X chromosome. These genes named CT-X genes attracted attention and their preferential localization on the X chromosome fired many discussions and speculations as presented in a timely review by Simpson and colleagues (Fig. 2, left panel).

The new data showing that C/T genes are actually only part of a larger number of genes with a testis-specific pattern of expression also invites us to reconsider the notion of CT-X genes. Indeed the list of CT-X genes was based on the list of established C/T genes, which, as discussed above, is incomplete.

In order to evaluate the possibility of a chromosome-biased localization of the identified C/T genes, we used the list of C/T genes that we found active in tumors (identified in Fig. 1A and B) and considered their distribution on chromosomes.

Fig. 2 (right panel) shows that the updated list of deregulated C/T genes actually does not show any significant enrichment on the X chromosome. This figure also indicates that, at the chromosome scale, there are no specific genomic regions which seem more prone to ectopic gene activation in cancer, taking into account differences between chromosomes in gene densities.

These data demonstrate that a localisation on a specific chromosome does not account for ectopic gene activation and suggest that the mechanisms involved could hit various regions of the genome. It is therefore important to revise the discussions concerning the preferential activation of C/T-X genes in cancer.

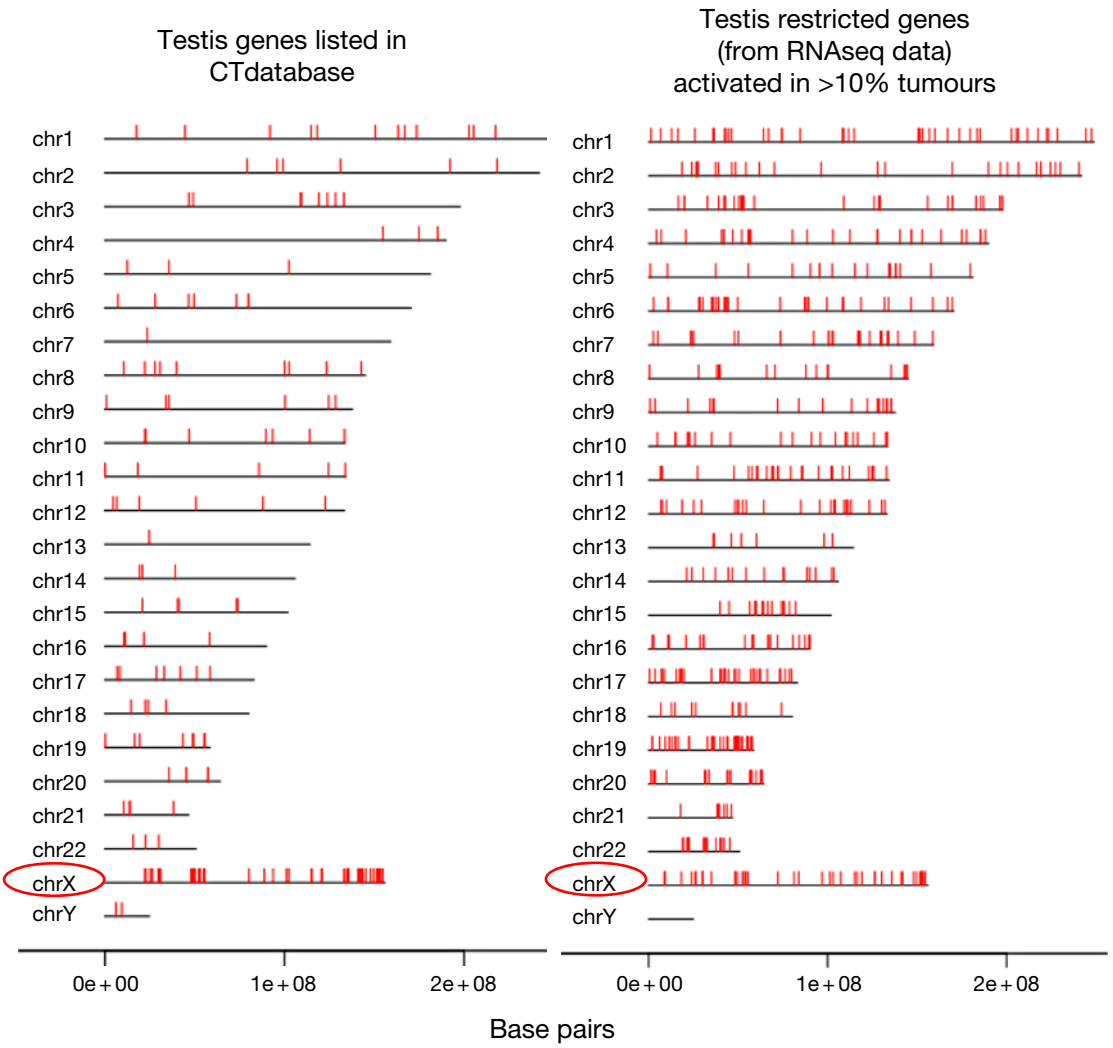

Fig. 2 Distribution of testis-restricted genes on chromosomes (using Stoda R Package, Ycart et al. personal communication) comparing the positions of C/T genes listed in the CT database (*left panel*) and of the testis-restricted genes selected using RNAseq data as explained in Fig. 1A and activated in at least 10% of tumor types/subtypes as explained in Fig. 1B (*right panel*).

Cancer Type-Biased Activation of C/T and Tissue-Restricted Genes

Another question is the relationship between cancer types and the ectopic gene activation. Do all cancer types activate tissue- or testis-specific genes to the same extent? To this end we calculated the respective proportions of all genes with a restricted expression in testis or other tissue (identified in Fig. 1A), that are frequently activated in various solid tumors types and hematological malignancies subtypes. A gene was considered "frequently" activated when it was aberrantly expressed in 10% or more of the samples of each tumor type/subtype.

Fig. 3 confirms that all solid tumors types and hematological malignancies activate tissue- and testis- specific genes. In addition it shows that various types of solid tumors and hematological malignancies of different origins have similar proportions of aberrantly reactivated genes.

However, it is important to note that an individual C/T gene may become active in a tumor-dependent manner, as recently shown by Bourova-Flin and colleagues. In fact, *BRDT*, a particular testis-specific gene, was recently shown to be more frequently activated in lung cancers compared to other solid tumors. Additionally, within lung cancers, this gene is preferentially activated in adenocarcinomas whereas its aberrant activation is not observed in carcinoid tumors or in small cell carcinomas. These observations suggest that the biology of the tissue-of-origin of cancers that leads to the activation of tissue-specific genes could somehow condition the ability of cells to particularly activate a given set of C/T or tissue-specific genes. An interesting issue to address and explore in future research remains the impact of the tissue-of-origin in gene desilencing.

C/T Gene Expression and Immunotherapy

The discovery of C/T genes relied on melanoma patients immune response to the expression of a series of testis-specific genes. Indeed, C/Ts are thought to be normally expressed in the immune isolated environment of the seminiferous epithelium, which is protected against immune cells by the so-called blood-testis barrier. Additionally, spermatogenic cells are unable to present their proteins to the immune cells because they lack the MHC class I molecules. Finally, the interstitial epithelium is unfavorable to the survival and growth of immune cells. All these characteristics make testis an immune-privileged site and consequently proteins specifically expressed in spermatogenic cells should remain unknown to the immune system. However, the situation is more

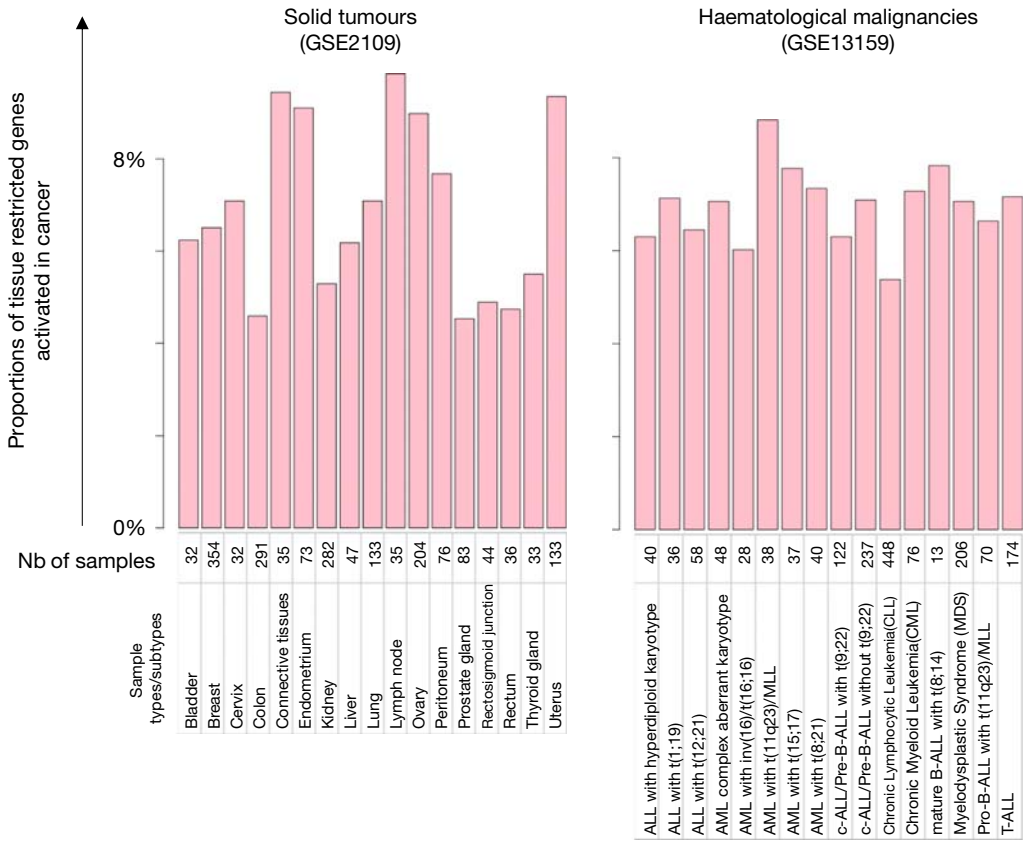

Fig. 3 Proportions of tissue-restricted genes expressed in at least 10% of tumor samples considering each of the tumor types or subtypes in solid tumors (*left panel*) or in hematological malignancies (*right panel*).

complex, since the thymus appears to express a large number of tissue-specific antigens due to the expression of a particular transcription factor, named autoimmune regulator (AIRE), which turns on a variety of normally silent genes in the thymic epithelial cells, exposing the immune cells to the corresponding antigens. The question arises whether C/T antigens are really unknown to the immune system and whether they can be considered as privileged targets for immunotherapy. However, the recent advent of Chimeric-Antigen Receptor T (CAR-T) cell therapy brings the interest in the products of C/T genes at the forefront of the collective efforts to define new antigens as targets of cancer immunotherapy.

Unbiased Discovery of Ectopic Gene Activation in Cancer

The early identification of tumor antigens as testis-specific genes aberrantly activated in cancers, prompted investigators to develop various approaches to identify ectopically activated genes in cancer, which were all biased towards the identification of testis-specific genes. It is interesting to note that unbiased approaches were also considered to identify ectopically active genes in cancer and to define their normal tissue-of-origin.

An example is the use of proteomic data from a well-characterized diffuse large B-cell lymphoma (DLBCL) cell line, B593, by Emadali and colleagues to pinpoint ectopically expressed proteins and evaluate their values as a biomarker and as an oncogenic driver.

In this study, to gain sensitivity and deepness in sequencing for a better protein identification, the nuclear acid soluble (NAS) protein fraction was considered. NAS proteins are basic proteins and hence have the potential to interact with the negatively charged nucleic acids, DNA and RNA. Mass spectrometry sequencing of these proteins and their identification proved that the majority of these proteins, 66%, are annotated as DNA-binding, i. e., histones or RNA binding proteins, including a number of ribosomal proteins. An analysis pipeline was established to identify, among these proteins, those that are in fact the result of ectopic gene activation. As part of this pipeline, the data from a published lymphoma transcriptomic study with survival data was recovered and analyzed to identify, within the out-of-context expressed proteins, the encoding genes whose expression is associated with poor prognosis (shorter survival probability). This approach identified a protein that is highly expressed in Diffuse Large B-cells Lymphomas (DLBCL), known as CYCLON, whose encoding gene expression is associated with poor prognosis in lymphoma patients. The consideration of the tissue-of-origin of CYCLON gene expression showed that the encoding gene is, in fact, a testis-specific gene that is aberrantly active in lymphoma.

The identification of a testis-specific gene following an unbiased approach as an oncogenic ectopically activated gene in lymphoma brings an additional argument supporting a preferential activation of C/T genes in cancer and their contribution to oncogenesis.

Ectopically Activated Testis-Restricted Genes Are Robust Drivers of Cancer

The analysis shown in Fig. 1B, demonstrates that tumor cells preferentially activate testis-specific genes. A reason for this observation could be that, compared to other tissue-restricted genes, male germ cell-specific genes more efficiently contribute to oncogenesis. In fact this hypothesis is now strongly supported by many experimental data showing a direct oncogenic role for C/T gene products.

An elegant study using the induced tumorogenesis in Drosophila reported by Janic and colleagues clearly demonstrated the determinant contribution of ectopically activated germline genes in cancer development. Indeed, the inactivation of a Drosophila tumor suppressor gene leading to brain tumor development was accompanied by the activation of germ cell-specific genes that corresponded to almost 25% of the significantly activated genes. This study also showed that these activations did not occur only as by-products of malignant transformation and that the products of these genes were directly involved in tumorogenesis.

In another global approach that aimed at testing the contribution of CT genes in oncogenesis, Whitehurst and colleagues first identified cancer cell lines corresponding to six different cancer types that significantly expressed a chosen list of 135 C/T genes. Most of the considered C/T genes were expressed in at least two of the eleven selected cell lines and 20% of the C/T genes were expressed in all cell lines.

Systematic knock-down of these CT genes identified 26 genes that were essential for cell viability or were involved in various oncogenic mechanisms.

All published data on the cell transforming role of C/Ts, in addition to the two comprehensive studies described above, definitively support the wide-spread involvement of the ectopic activation of male germ cell-specific genes in oncogenesis. It is therefore possible now to confirm that C/T gene activation is part of the malignant cell genome reprogramming process and this conclusion should prompt investigators to set up research programs in order to decipher the underlying oncogenic mechanisms.

C/T Gene Activation: A Homogenous Ground over Cancer Heterogeneity

A systematic evaluation of the association of ectopic tissue-restricted gene activation with prognosis in lung cancer and in acute lymphoblastic leukemia (ALL) conducted by Wang and Rousseaux and colleagues led to the discovery of specific gene expression signatures that biologically identify lung cancer and leukemic cells respectively which, despite their apparent heterogeneous nature,

share some fundamental and homogeneous properties closely associated with their aggressiveness. This observation suggests that the aberrant activation of some of the tissue-restricted genes, although apparently heterogenous, is associated with the profound nature of cancer cells and is not merely a manifestation of malignant transformation.

The approach carried out to investigate the biological/molecular profile of tumor aggressiveness is based on a supervised comparison of the whole transcriptomes between tumors classified as aggressive according to their ectopic gene expression signature and other tumors. Remarkably, this strategy identifies thousands of genes whose expression differs between the two compared tumor populations, highlighting a specific biology associated with the aggressive tumors ectopically expressing a specific set of C/T genes. For instance, aggressive lung tumors identified according to the ectopic expression of genes of a subset of 26 classifying testis- or placenta- restricted genes, also upregulate genes whose products are nuclear and associated with cell proliferation while down-regulating other genes that are responsible for the immune response.

In ALL cells, the identity of some of the genes up- and down- regulated in aggressive forms of leukemia associated with the ectopic expression of genes of a specific tissue-restricted genes signature supports the hypothesis that the nature of the corresponding malignant cells is close to that of quiescent stem cells.

A major issue in cancer biology is the notoriously heterogenous nature of tumors. The investigations discussed above could represent a way to apprehend common shared properties between tumors beyond their obvious heterogenous nature. In fact one could propose that tumor heterogeneity is fueled by a common and relatively homogenous nature of malignant cells and that the expression of some of the C/T genes could be associated with or indicative of this ground nature of tumor cells.

Prospective Vision

The function of most the C/T genes, including those within the prognostic classifying gene signatures, remains unknown and functional investigations of these factors should open new doors to a better understanding of yet unexplored oncogenic mechanisms. Additionally, a knowledge of the activity of the encoded factors at the molecular level would set a basis for new therapeutic approaches that would directly target the nature of malignant cells rather than the consequences of the oncogenic transformation such as cell proliferation.

In addition to their use for prognosis purposes, cancer-specific ectopic gene activations constitute a repertoire of excellent biomarkers which could be primarily used for diagnosis and follow-up of cancer through non-invasive approaches. Indeed, since under normal conditions the products of these genes should be mostly unknown to the immune system, serological approaches could be used to detect their activation and hence to develop simple and efficient diagnostic tests. Finally, the immunogenic nature of these gene products also makes them excellent candidate targets for new immunotherapy approaches, which hence could constitute the basis for future developments of anticancer therapy or anti-cancer vaccine approaches.

Definition

The most common type of uterine cervix cancer is squamous cell carcinoma (SCC; about 80% of cases), followed by adenocarcinoma (20%). This entry does not cover other, rare, cervical cancer types.

Presentation and Diagnosis

Precancerous lesions of the uterine cervix are asymptomatic and are usually detected by routine cytological screening and colposcopy. The earliest stages of cervical carcinoma are frequently asymptomatic as well. They may also be associated with a watery vaginal discharge and postcoital bleeding or intermittent spotting. These symptoms are frequently not recognized by the patient. In more advanced stages, vaginal discomfort, pelvic pain, and/or dyspareunia may also appear. The lateral growth of the tumor into the parametrium may cause ureteral obstruction leading to anuria and uremia. Pelvic side wall involvement may manifest as sciatic pain and, less commonly, lymphedema of the lower extremities.

Palpation can detect induration or nodularity of the cervix or of the parametria in more advanced lesions. Tumor gross appearance is variable. Some early cancers are not easily detected and even deeply invasive tumors may be somewhat deceptive on gross examination. Visual inspection of the cervix can reveal gray, discolored areas as well as visible bleeding and/or evidence of cervicitis. The tumor may appear as a red, friable, exophytic or ulcerated lesion.

As the uterine cervix is easily accessible, accurate diagnosis can usually be made based on a cytological examination (Papanicolaou (Pap) smear) and a cervical biopsy. However, cytological screening methods are less useful for detecting adenocarcinoma as adenocarcinoma in situ develops in areas that are less accessible (like upper parts of the endocervical canal) and so more difficult to sample. Moreover, the accuracy of the Pap smear test may be questionable as it depends on a subjective morphological evaluation of the sample and a high proportion of inadequate specimens has been reported. Since cervical cancer frequently develops in association with a human papilloma virus (HPV) infection and HPV DNA can be found in nearly all cases of cervical cancer, testing for high-risk HPV DNA is now widely advocated as a mean to improve screening sensitivity.

Abnormal cervical cytology and/or a positive high-risk HPV test should lead to colposcopy and biopsy or excisional procedures, such as loop electrosurgical excision or conization. Biopsy specimens of all visibly abnormal areas should be taken, regardless of the findings on the Pap smear.

Endocervical curettage (ECC) is required when the Pap smear shows a high-grade lesion but colposcopy does not reveal a lesion, when the entire squamocolumnar junction cannot be visualized, when atypical endocervical cells are present on the Pap smear, or when women previously treated for cervical intraepithelial neoplasia (CIN) show new high-grade findings on cytology. If the ECC reveals a high grade squamous intraepithelial lesion, patients should undergo cervical conization or

a loop electrosurgical excision procedure (LEEP). Diagnostic conization (cone biopsy) may also be indicated if adenocarcinoma in situ is suspected from cytology, if standard cervical biopsy is not sufficient to define invasiveness, or if accurate assessment of microinvasive disease is required.

Management and Therapy

Risk assessment is based on tumor size, stage, depth of tumor invasion, lymph node status, and lymphovascular space invasion (LVSI). Lymph node status and number of lymph nodes involved are the most important prognostic factors. There are conflicting reports on whether the tumor histological type has some prognostic value. However, a majority of studies suggest that adenocarcinoma is associated with a worse prognosis than SCC.

High-grade precancerous lesions (CIN) can often be treated with cryotherapy, laser ablation, or other ablative procedures. Conization with a scalpel is preferred for lesions which are not entirely visible on colposcopy or in case adenocarcinoma in situ is suspected.

The management of cervical cancer usually involves some kind of surgery, although definitive radiotherapy (RT) may be an option in early-stage disease. The kind of surgical procedure applied is strictly correlated with disease stage as defined by the TNM and the International Federation of Gynecology and Obstetrics (FIGO) classification. Conservative fertility-sparing approaches may be considered in highly selected patients who have been thoroughly counseled on the disease risks and also on related prenatal and perinatal issues.

Adenocarcinoma in situ can be successfully treated with loop excision and a close cytological follow-up in most cases. Microinvasive cancer without LVSI can be managed with conization or simple trachelectomy to preserve fertility. A conservative approach may also be an option for stage IA patients with evidence of LVSI, in which case conization with sentinel lymph node (SLN) mapping algorithm or pelvic lymphadenectomy is performed. The aim of conization is the *en bloc* removal of the ectocervix and the endocervical canal. The expert panel of the US National Comprehensive Cancer Network (NCCN) recommends cold knife (scalpel) conization as the preferred approach. If properly performed, loop electrosurgical excision procedure (LEEP) is also acceptable. LEEP is often recommended for excising high-grade precancerous lesions. Vaginal or abdominal radical trachelectomy may be a fertility-sparring option for selected patients with stage IA-II disease, with the exception of the minimal deviation adenocarcinoma whose aggressive nature makes it inappropriate for conservative treatment. Radical trachelectomy consists in removing the cervix, vaginal margins, and supporting ligaments, while preserving the main body and fundus of the uterus, with simultaneous laparoscopic pelvic lymphadenectomy.

If the patient does not wish to preserve fertility or is not eligible for fertility-sparring treatment, hysterectomy is usually performed, either simple (extrafascial), modified radical, or radical. Radical hysterectomy with extensive parametrial resection and bilateral lymph node dissection is standard treatment, with minimally invasive approaches (laparotomy or laparoscopy) becoming increasingly common. As some studies suggest the para-aortic lymph node involvement is closely related to the presence of metastases to the pelvic and iliac lymph nodes in patients with stage I or II disease, para-aortic lymph node sampling during pelvic lymph node dissection may also be performed. Radical hysterectomy is preferred to simple hysterectomy due to its wide paracervix resection margin. However, some studies suggest that radical hysterectomy may be an overtreatment in patients with small localized tumors and that radiotherapy (RT) may be equally effective. In the US, chemoradiation is typically preferred over radical surgery for selected patients with bulky FIGO stage IB2-IIA2 tumors. In European countries, radical hysterectomy with or without prior neoadjuvant chemotherapy is a frequent choice.

The clinical benefit of sentinel lymph node dissection (SNLD) in cervical cancer is not perfectly established and no international consensus exists. However, recent data suggest that SNL biopsy may be useful in decreasing the need for pelvic lymphadenectomy in early-stage cervical cancer patients and most guidelines suggest at least considering SNLD in patients with lower stage (FIGO I, tumors no bigger than 4 cm) disease. The NCCN panel recommends considering a SNL mapping algorithm for patients with tumors smaller than 2 cm.

Patients who are not eligible for hysterectomy or who refuse surgery, may be treated with chemoradiation as a definitive therapy. In this case, external beam RT (EBRT) with brachytherapy is usually performed concurrent with the administration of a cisplatin-containing chemotherapeutic regimen, most commonly cisplatin alone or cisplatin with 5-fluorouracil (5-FU). Cisplatin may be replaced by carboplatin or gemcitabine in patients with renal dysfunction. The concept of delivering chemotherapy before RT (neoadjuvant or induction chemotherapy) has also been explored, however with conflicting results. Pelvic RT and chemoradiation invariably lead to ovarian failure in premenopausal women. In order to preserve intrinsic hormonal function in younger women, ovarian transposition prior to RT may be considered.

Performing completion surgery (adjuvant hysterectomy) following primary chemoradiation in patients with lower-stage disease (I–II) is controversial. Adjuvant hysterectomy after RT has been shown to improve pelvic control but not overall survival. It is also associated with increased morbidity. However, this approach may be considered in case the disease extent or uterine anatomy precludes adequate coverage by brachytherapy.

Surgery with concurrent chemoradiation is usually the primary treatment of choice for patients with advanced disease. If surgery is not possible, chemoradiation remains the primary treatment. Of note, the meaning of "advanced disease" is not clearly

defined. In particular stage IB2 and IIA2 disease may be classified as early-stage or advanced-stage disease, depending on the oncologist and the center. Radiological imaging, including positron emission tomography with computer tomography (PET/CT) and often pelvic magnetic resonance imaging (MRI) are essential for defining disease local extent and for adequate RT planning. The treatment consists of EBRT with concurrent cisplatin-based chemotherapy (usually cisplatin alone or cisplatin with 5-FU) and brachytherapy.

Women with a high risk of recurrence should receive adjuvant therapy following hysterectomy. The exact criteria for selecting high-risk patients slightly differ between different guidelines. Overall, women with early-stage disease, small primary tumors, negative margins, negative parametria and no lymph node involvement are usually considered to be at low risk of recurrence, whereas higher-stage disease, large primary tumor, parametrial involvement, positive lymph nodes, deep stromal invasion and/or LVSI qualify for post-surgical adjuvant treatment. The usual choice is chemoradiation consisting of EBRT with concurrent cisplatin-based chemotherapeutic regimen. Additional vaginal brachytherapy may be useful in patients with positive vaginal resection margins. Adjuvant therapy is also indicated for patients with cervical cancer that was found incidentally at hysterectomy performed for other reasons. However, no consensus guidelines so as to optimal regimens for these patients exist.

Recurrent cancer is usually manifested by pelvic pain, particularly in the sciatic nerve distribution, vaginal bleeding, malodorous discharge, or leg edema. Recurrence must be confirmed by a pathological evaluation of a biopsy specimen because these symptoms and even physical findings can be similar to those associated with radiation changes. Patients with a localized recurrence after initial treatment may be candidates for radical re-treatment, that is RT and/or chemotherapy, or surgery, depending on the recurrence localization, extent, and previous treatments. Lower vaginal recurrence can occasionally be cured by RT or exenteration. Pelvic exenteration may also be considered for central pelvic recurrent disease after primary RT when the spread is confined to the vagina, bladder, or rectum. RT is usually not offered if the patient develops recurrence following previous RT, in particular if it appears within a previously irradiated field. Typical chemoradiation regimen for the treatment of recurrence includes cisplatin or cisplatin/5-FU and EBRT, with or without brachytherapy. In patients who have relapsed soon after completing initial chemoradiation with this regimen, alternative chemotherapeutics, such as carboplatin, paclitaxel, or gemcitabine, may be considered.

Distant metastatic disease, whether at initial presentation or following treatment of the primary tumor, is rarely curable. However, occasional log-term survival has been reported for patients with isolated distant metastases amendable to local treatment with surgical resection or local ablative therapies with or without EBRT, and EBRT alone or with concurrent chemotherapy. Still, for most metastatic patients the treatment is palliative. It involves either chemoradiation, or chemotherapy alone.

Cisplatin is considered to be most effective in treatment of metastatic cervical cancer. However, most patients with metastases had been treated with concurrent cisplatin RT and may have become insensitive to single-agent platinum therapy. Therefore, a number of cisplatin combinations have been tested. Cisplatin-based doublets with paclitaxel and topotecan have been shown to give better outcomes than cisplatin monotherapy. The cisplatin/topotecan regimen has been approved by the US Food and Drug Administration (FDA) for treatment of advanced cervical cancer. However, this regimen may be more toxic than the two other cisplatin-based doublets. The addition of bevacizumab, an angiogenesis inhibitor, to the cisplatin-based doublets may improve overall survival. However, bevacizumab is associated with higher toxicities and may lead to, among others, hypertension and an increased risk of venous thromboembolic events, which is why the overall quality of life of patients is not necessarily improved with this treatment regimen. For patients who are not candidates for cisplatin-based therapy, carboplatin with paclitaxel may be a reasonable option. For those who may not be treated with a taxane, cisplatin with topotecan or with gemcitabine may be considered. A number of single-agent chemotherapeutic regimens is used for palliative treatment of recurrent and/or metastatic cervical cancer. The NCCN expert panel recommends cisplatin, carboplatin, and paclitaxel as the first-line treatment to this effect, whereas bevacizumab, docetaxel, 5-FU, gemcitabine ifosfamide, irinotecan, mitomycin, albumin-bound paclitaxel (nab-paclitaxel), topotecan, permetrexed, and vinorelbine may be considered as second-line choices.

Cervical cancer survivors are at risk of second cancers. Moreover, patients who had undergone RT for pelvic cancers are at an increased risk of cancers at irradiated sites (e.g., colon or urinary bladder). Therefore, appropriate surveillance not only for cervical cancer recurrence/metastasis but also for primary cancers at other sites is of utmost importance. Of note, abnormal Pap smears on follow-up may represent post-irradiation dysplastic changes and not a new primary cancer. Therefore, suspected areas should be diagnosed by biopsy.

Compared to other cancers, personalized medicine for cervical cancer patients seems a rather far perspective, with a limited number of targeted molecular therapeutics that are currently in clinical development. A combination of a MEK inhibitor (trametinib) and an Akt inhibitor (GSK2141795) for treatment of recurrent and/or persistent cervical cancer is being investigated in a phase II trial. Another phase II trial tests apatinib, a tyrosine kinase inhibitor, for treatment of recurrent and metastatic cervical cancer in a sequential regimen with standard chemotherapy (phase II).

Uterine Cervix Cancer: Pathology and Genetics

C Simon Herrington, University of Edinburgh, Edinburgh Cancer Research Centre, Institute of Genetics and Molecular Medicine, Western General Hospital, Edinburgh, United Kingdom

Glossary

Carcinoma A malignant tumor of epithelium.
Genome The complete set of genetic material present in a cell or organism.
Grade The degree to which a tumor resembles its putative tissue of origin.
Integration The insertion of DNA (usually viral) into the chromosomes of a human cell.
Stage The extent to which a tumor has spread.

Carcinoma of the Cervix

Burden

Cervical cancer is relatively uncommon in developed nations. For example, cervical cancer was the 13th most common cancer in women in the United Kingdom in 2014, with 3224 new cases; and the 17th commonest cause of cancer-related death, with 890 deaths. Cervical cancer mortality has fallen by 72% since the early 1970s. However, worldwide, cervical cancer was the 6th commonest cancer and the 8th commonest cause of cancer death in women in 2012, with approximately 520,000 new cases and 265,000 deaths. A number of factors underly these differences, including the presence of a quality-controlled cervical screening program in many developed nations. HPV vaccination is also likely to impact the incidence and mortality statistics as implementation varies across the world, being much less in resource-poor settings.

Risk Factors and Population Health

The major risk factor for cervical cancer is high-risk HPV infection, particularly infection with either HPV type 16 or HPV type 18. The strength of association between HPV infection and cervical carcinoma is extremely high (relative risk/odds ratio >100), surpassing that for smoking and lung cancer; and hepatitis B infection and liver cancer. A significant secondary risk factor is smoking. This has prompted consideration of the use of HPV testing in cervical screening, both for follow-up of patients after treatment, and as the primary screening modality, in place of cytology. Thus, rather than using HPV testing to triage women with cytologically abnormal cervical smears, HPV testing will soon be implemented in some countries as the primary screening test, with cytology performed only on those samples that are positive for high-risk HPV. HPV vaccination has been offered in the United Kingdom since 2008 and has been associated with a reduction in the incidence of preinvasive disease. It is likely that this will translate over time into a reduction the incidence of invasive disease.

Table 1 Classification of common cervical carcinomas and their precursors[a]

Carcinoma	*Precursor lesion*
Associated with HPV infection	
Squamous cell carcinoma	CIN/SIL
Adenocarcinoma, usual type	CGIN/AIS
High grade neuroendocrine carcinoma (small and large cell types)	Often CGIN/AIS
Not associated with HPV infection	
Gastric-type adenocarcinoma	Lobular endocervical glandular hyperplasia
Clear cell carcinoma	Unknown
Mesonephric carcinoma	Mesonephric duct remnants

[a]Classification is according to association with HPV infection. Only the common tumor types are shown. See text for explanation of abbreviations.

Classification and Pathology (See Table 1)

Precursor lesions

There are well-defined precursors to invasive cervical carcinoma and cervical screening programs are designed to detect and treat these precursor lesions, particularly squamous precursors, in order to prevent mortality from invasive disease.

Squamous cell carcinoma is preceded by non-invasive abnormality of the squamous epithelium, the terminology of which has been debated over many years. In the 1960s, a three-tier system using the term cervical intraepithelial neoplasia (CIN) was introduced to reflect the then preferred concept of a continuum of abnormality, which could be subdivided into grades that correlated with progression risk. Improved understanding of the biology of HPV infection, however, has led more recently to the adoption by many of a two-tier system based on the concept that low-grade abnormalities (termed low-grade squamous intraepithelial lesions (SIL)) represent productive HPV infections, whereas high-grade abnormalities (high-grade SIL) represent transforming HPV infections with a much greater potential to progress to invasive disease. In North America this two-tier system is used both for cytology (smears) and for histopathology (biopsies), whereas in the United Kingdom it is currently used only for cytology, with the three-tier CIN system still used for histopathology.

There is also an HPV-associated precursor lesion for most cervical adenocarcinomas, termed adenocarcinoma in situ (AIS) in North America and cervical glandular intraepithelial neoplasia (CGIN) in the United Kingdom. AIS is not graded. CGIN is subdivided into low and high-grade categories although there is debate about the existence of a reproducible and clinically meaningful category of low-grade CGIN. The current WHO recommendation is that only p16 positive CGIN lesions are considered significant (see below and the WHO classification given in section "Further Reading").

Rarer precursor lesions are associated with the less common types of cervical carcinoma. Gastric type adenocarcinomas are associated with lobular endocervical gland hyperplasia (thought to represent gastric foveolar metaplasia) and its atypical form; and mesonephric carcinomas are often associated with mesonephric duct remnants, with or without mesonephric duct hyperplasia. These precursors are not associated with HPV infection.

Invasive carcinoma

Squamous cell carcinoma

Squamous cell carcinoma (Fig. 1) differs from CIN/SIL by the presence of invasion into the cervical stroma and/or metastasis to distant sites, particularly lymph nodes. Invasive squamous cell carcinomas retain squamous morphological features, for example the formation of intercellular bridges between tumor cells and keratinization; and express markers of squamous differentiation such as cytokeratin 5, cytokeratin 14 and p63 (Fig. 1). A number of different histological types are recognized, although these do not influence clinical management. Thus, squamous cell carcinomas can be classified as keratinizing, non-keratinizing, papillary, basaloid, warty and squamotransitional types. Rarely, the tumor may be associated with a marked inflammatory cell infiltrate,

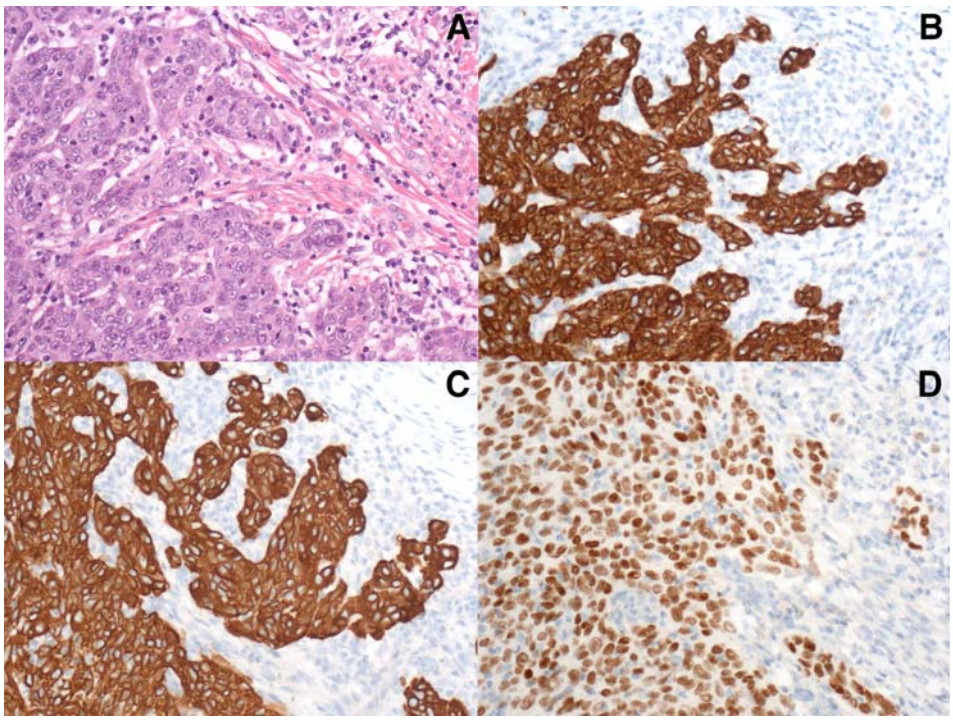

Fig. 1 Squamous cell carcinoma showing the invasion of tongues of malignant squamous epithelium into an inflamed stroma (A). The malignant cells express cytokeratin 5 (B), cytokeratin 14 (C) and p63 (D), which are markers of squamous differentiation.

which obscures the infiltrating epithelial cells—this variant is termed lymphoepithelioma-like carcinoma. These types are all associated with high-risk HPV infection and behave similarly, their clinical progression being largely related to invasion of local structures rather than distant metastasis.

Verrucous carcinoma is also described in the cervix, but is much less frequent here than in the vulva. Most lesions traditionally referred to as verrucous carcinomas are either usual type squamous cell carcinomas with a pushing infiltration pattern; or giant condylomas (warts), the latter being benign and associated with low-risk HPV infection.

Adenocarcinoma

Adenocarcinoma of usual type

Most adenocarcinomas of the cervix are of "usual type" (Fig. 2). These tumors show evidence of glandular differentiation with, typically, formation of glandular structures lined by endocervical type epithelium with varying degrees of mucin depletion. This mucin depletion can impart an "endometrioid" appearance, which does not however reflect true endometrioid differentiation. Well differentiated tumors may form papillary structures and, when prominent, this has been termed villoglandular type of adenocarcinoma which, in the past, was thought to be associated with well differentiated indolent tumors. However, it is now recognized that these tumors often show a more typical infiltration pattern elsewhere, particularly at the invasive front, and are not necessarily associated with a good clinical outcome, so this feature is best regarded as a pattern rather than a type. Endocervical adenocarcinoma of usual type is associated with HPV infection and AIS/CGIN is its precursor. Adenocarcinomas are less common than squamous cell carcinomas, as might be predicted from the relationship between HPV infection and squamous differentiation (see below). However, cervical screening is less effective for adenocarcinoma as the tumors are more often located further up the cervical canal, in a less accessible position for cervical smear sampling, and typically grow into the cervix, sometimes producing a "barrel cervix" (Fig. 2) as a result of this endophytic growth pattern. Adenocarcinomas appear to be more common now than in the past: whether this represents a true rise in incidence rather than an increase in proportion due to the prevention of cervical squamous cell carcinoma by cervical screening is not clear.

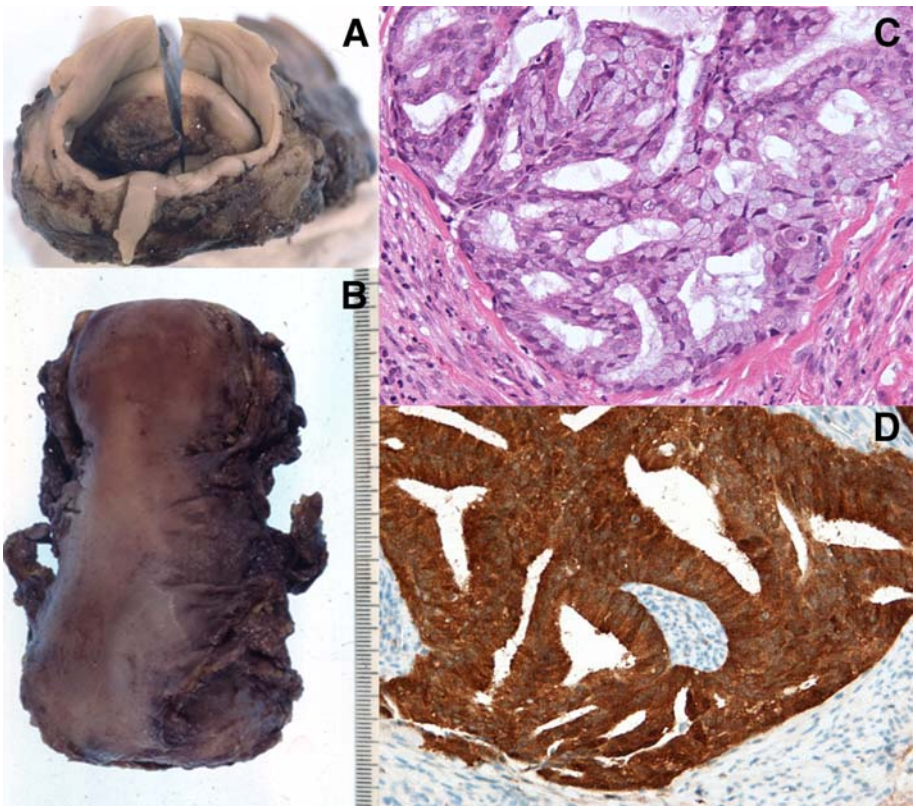

Fig. 2 Adenocarcinoma of the cervix in which there is a visible tumor at the ectocervical surface (A) but the bulk of the tumor extends into the cervical wall, producing the appearance of a "barrel cervix," seen here from the posterior aspect (B). Histologically, the tumor forms glandular structures lined by mucinous epithelial cells (C) that strongly express p16 (D), consistent with an HPV-driven lesion. Immunostaining for estrogen receptor (ER) and vimentin was negative in this case, providing further support for a primary endocervical adenocarcinoma of usual type. The smallest divisions in the ruler in B are millimeters.

Gastric type adenocarcinoma

Some cervical adenocarcinomas show evidence of gastric differentiation. These tumors are not associated with HPV infection and are typically negative for markers of high-risk HPV infection such as p16. It has been recognized in recent years that these tumors form a spectrum, with the very well differentiated adenocarcinoma previously termed "adenoma malignum" representing the best differentiated end of this spectrum. The importance of this phenomenon lies in the difficulty of diagnosis of this tumor type in superficial cervical biopsies: their well differentiated morphology can be extremely difficult to distinguish from normal endocervical glands. Increasing awareness of this tumor type, and the use of immunohistochemical markers such as HIK1083 and MUC6, is leading to its more frequent identification. This is important as it has been shown that this tumor type behaves more aggressively than usual-type adenocarcinoma, presenting at higher stage and with lower survival, even when very well differentiated. It is also of note that these tumors will not be identified by HPV testing, as they are not associated with HPV infection.

Other adenocarcinomas

Rare adenocarcinomas include intestinal type and signet-ring cell carcinomas, which show intestinal differentiation. Clear cell carcinoma can also occur as a primary tumor in the cervix, although it is rare. Most serous carcinomas presenting in the cervix represent extension from a uterine serous carcinoma. Mesonephric carcinomas are rare. They are typically found in the lateral wall of the cervix, where mesonephric duct remnants are most commonly found, but can present as tumors involving the endocervical canal, where they can mimic other tumor types.

Neuroendocrine tumors

Neuroendocrine tumors of the cervix are classified into low-grade tumors and high-grade carcinomas. Low-grade neuroendocrine tumors (carcinoid and atypical carcinoid tumors) are extremely rare as primary neoplasms of the cervix. High-grade neuroendocrine carcinomas are also uncommon but are encountered reasonably regularly in clinical practice. They are most frequently of small cell type, analogous to the tumors found more commonly in the lung, but may be of large cell type. These carcinomas are associated particularly with AIS and adenocarcinoma of usual type, and are almost always HPV positive. Their importance lies in their aggressive behavior and they are typically treated initially with chemotherapy rather than surgery.

Other epithelial tumors

Some tumors show both squamous and glandular differentiation and are termed adenosquamous carcinomas. These are usually associated with HPV infection. When poorly differentiated they can have a typical morphological appearance, termed glassy cell carcinoma.

Adenoid basal carcinoma is considered by some not to be a carcinoma, but rather a basaloid proliferation. This lesion typically occurs in post-menopausal women and is associated with the presence of CIN 3/HSIL.

Adenoid cystic carcinoma has a classical appearance, similar to that found in the salivary glands. Some basaloid carcinomas can have a rather adenoid cystic appearance but others appear to be true adenoid cystic carcinomas and are associated with the *myb-NFIB* translocation found in the equivalent salivary gland tumors.

Molecular Pathology and Genetics

The dominant molecular events in squamous cell carcinoma of the cervix relate to HPV infection. Persistent infection with high-risk HPV types (particularly HPV16 and HPV18) is associated with lesion progression, often accompanied by integration of the viral genome into host chromosomes. Integration leads to disruption of the long control region of the viral genome, with loss of coordinated expression of viral genes, loss of viral capsid production, and failure of productive viral infection. Continued expression of viral oncogenes, particularly E6 and E7, in cycling basal cells induces genetic instability and accumulation of secondary genetic events. The E6 and E7 proteins have multiple cellular effects, which represent the equivalent of multiple genetic events. For example, the E6 protein binds to and inactivates p53; and the E7 protein binds to and inactivates pRB1. In addition, E6 activates telomerase. These molecular drivers underpin the strong association between high-risk HPV infection and the development of carcinoma. The predominance of squamous cell carcinoma follows from the link between productive HPV infection and squamous differentiation, which is required for HPV replication and virus production. However, most cervical adenocarcinomas are also associated with HPV infection, as are neuroendocrine carcinomas. It is likely that these types derive from infection of reserve/stem cell populations that have the ability also to differentiate along non-squamous pathways.

Staging and Grading

The grading of cervical carcinomas is type-specific but the staging of all types of cervical carcinoma follows the FIGO and TNM systems. Grading of squamous cell carcinoma of the cervix usually follows the poorly reproducible Broder system, whereby nuclear grade is assessed in order to assign the tumor to well (grade 1), moderately (grade 2) and poorly differentiated (grade 3) categories. Keratinization does not influence grade. Similarly, grading of adenocarcinomas is determined by the degree of glandular differentiation (formation of glandular structures) and nuclear atypia but, again, is subjective. Neuroendocrine carcinomas are by definition high grade. Less attention has been paid to grading than to staging, as the latter is strongly associated with clinical outcome and is

the primary parameter used to determine patient management. Staging follows both the FIGO and the TNM systems, TNM being used in addition to FIGO as the latter does not assess lymph node status. Table 2 details and compares the FIGO and TNM systems.

Microenvironment Including Immune Response

Little is know about the influence of the microenvironment and immune response on cervical carcinoma. Recently, there has been renewed interest in this area in view of the availability of checkpoint inhibitors for therapy but, to date, our knowledge is poorly developed. This area is likely to develop more rapidly in the near future.

Diagnostic, Prognostic and Predictive Biomarkers

The most important and commonly used biomarker in this context is p16 protein expression. Diffuse strong expression of this protein, detected by immunohistochemistry, is a marker of retinoblastoma pathway disruption and, as high-risk HPV infection leads to abrogation of pRB1 function, p16 overexpression can be used to identify lesions associated with these viruses. The specificity of this overexpression is, however, dependent on context. For intraepithelial lesions, either CIN/SIL or CGIN/AIS, p16 overexpression in a "block-type" pattern for squamous lesions or diffuse consistent expression for glandular lesions is an excellent marker of lesions driven by high-risk HPV infection. However, interpretation of this biomarker requires care as focal expression is common in the absence of high-risk HPV infection. "Block-type" positivity refers to strong nuclear (with or without cytoplasmic) positivity consistently involving basal keratinocytes and extending at least one third up the involved epithelium: this pattern correlates with expression of the high-risk HPV E7 protein. When accurately defined, the correlation with high-risk HPV infection is high. However, "block-type" staining does not aid in the grading of CIN/SIL, which should be performed using standard histopathological criteria. For CGIN/AIS, true positivity requires diffuse and consistent overexpression throughout the lesion; more focal, "patchy" expression can be seen in a number of contexts, for example tubo-endometrioid metaplasia, which is common in cervices that have been previously treated, particularly by surgical excision therapies. p16 immunohistochemistry is often combined with staining for Ki67 as coordinate overexpression of p16 and Ki67 provides useful confirmation that the biomarkers are identifying a significant HPV-associated lesion.

For invasive tumors, the situation is more complex as p16 can be overexpressed by a wider range of tumors. It should therefore be used as part of a panel rather than being relied upon as a single marker. Primary cervical adenocarcinoma of usual type (see Fig. 2), for example, is typically negative for estrogen receptor (ER) and vimentin, whereas low-grade endometrioid carcinoma of the endometrium, which is often the differential diagnosis, would normally express both of these proteins.

No prognostic or predictive biomarkers are currently routinely used for cervical carcinomas.

Malignant Non-epithelial and Mixed Epithelial/Mesenchymal Tumors

Almost any sarcoma can occur in the cervix. None is common. Leiomyosarcoma may arise in the cervix or the cervix may be involved by a leiomyosarcoma arising elsewhere in the uterus. Embryonal rhabdomyosarcoma can present as a cervical mass (sarcoma botryoides). Other sarcomas include alveolar soft-part sarcoma, angiosarcoma, malignant peripheral nerve sheath tumor, liposarcoma, and Ewing sarcoma. Mixed tumors include adenosarcoma and carcinosarcoma, both of which are rare.

Malignant melanoma can occur in the cervix, as can other rare tumors such as germ cell tumors, lymphomas and myeloid neoplasms. Finally, tumors may metastasise to the cervix, for example lobular carcinoma of the breast.

Prospective Vision

The classification of tumors of the cervix is currently based on traditional morphological features. As data accumulate, and the non-HPV-associated tumors are better defined, it is likely that the classification will be based on their association with HPV, as given in simplified form in Table 1. This is not just an academic exercise as HPV testing will only detect, and HPV vaccination will only prevent, HPV-associated tumors. It therefore seems logical to segregate the tumors accordingly.

HPV testing is already used in some screening programs for the triage of women with low-grade cervical cytological abnormalities, and for follow-up after treatment. Extension of HPV testing to become the primary screening modality is likely to be adopted in the very near future in some countries. This will change the spectrum of lesions identified by screening as cervical cytology analysis will only be performed in samples that are HPV positive. Non-HPV-associated lesions will therefore not be detected directly. HPV vaccination is already reducing the incidence of HPV-associated precursor lesions but what effect that will have on HPV-driven lesions that are not associated with the HPV types present in the vaccine is not yet clear. Expansion of the HPV types included in the vaccine through use of the more recently developed multivalent vaccines will also alter the demographics of HPV-associated lesions in the countries in which they are used.

There is increasing interest in the use of immune checkpoint inhibitors, which target for example cytotoxic T-lymphocyte associated antigen 4 (CTLA-4), programmed cell-death 1 (PD-1) and programmed cell-death ligand 1 (PD-L1), for the treatment of

Table 2 TNM and FIGO pathological staging of cervical carcinoma

TNM category	*FIGO stage*	*Definition*
TX	–	Primary tumor cannot be assessed
T0	–	No evidence of primary tumor
Tis	–	CIN (carcinoma in situ)
T1	I	Cervical carcinoma confined to the uterus (extension to the corpus should be disregarded)
T1a	IA	Invasive carcinoma, diagnosed by microscopy only (all macroscopically visible lesions even those with superficial invasion are pT1b/Stage IB)
T1a1	IA1	Stromal invasion 3.0 mm or less in depth[a] and 7.0 mm or less in horizontal spread
T1a2	IA2	Stromal invasion more than 3.0 mm in depth and not more than 5.0 mm with a horizontal spread 7.0 mm or less
T1b	IB	Clinically visible lesion confined to the cervix or microscopic lesion greater than T1a2/IA2[b]
T1b1	IB1	Clinically visible lesion 4.0 cm or less in greatest dimension
T1b2	IB2	Clinically visible lesion more than 4.0 cm in greatest dimension
T2	II	Tumor invades beyond the uterus but not to pelvic wall or to lower third of vagina
T2a	IIA	Tumor without parametrial invasion
	IIA1	Clinically visible lesion 4.0 cm or less in greatest dimension
	IIA2	Clinically visible lesion more than 4.0 cm in greatest dimension
T2b	IIB	Tumor with parametrial invasion
T3	III	Tumor extends to the pelvic wall and/or involves the lower third of the vagina, and/or causes hydronephrosis or non-functioning kidney[c]
T3a	IIIA	Tumor involves lower third of vagina, no extension to pelvic wall
T3b	IIIB	Tumor extends to pelvic wall and/or causes hydronephrosis or non-functioning kidney
T4	IVA	Tumor invades the mucosa[d] of bladder or rectum and/or extends beyond true pelvis
M1	IVB	Distant metastasis

Regional lymph nodes (N) (TNM staging system): NX, regional lymph nodes cannot be assessed; *N0*, no regional lymph node metastasis; *N1*, regional lymph node metastasis. Regional lymph nodes include paracervical, parametrial, hypogastric (obturator); common, internal and external iliac; presacral and lateral sacral nodes. Metastasis to lymph nodes outside the regional nodal group is classified as distant metastasis.

Distant metastasis (M) (TNM staging system): MX, distant metastasis cannot be assessed; *M0*, no distant metastasis; *M1*, distant metastasis (excludes peritoneal metastasis).

Additional/optional descriptors in TNM classification

Sentinel lymph node: The following designations are applicable for sentinel lymph node assessment: *pNX(sn)*, sentinel lymph node could not be assessed; *pN0(sn)*, no sentinel lymph node metastasis; pN0(sn), sentinel lymph node metastasis.

Isolated tumor cells: Isolated tumor cells (ITCs) are single tumor cells or small clusters of cells no more than 0.2 mm in greatest dimension detected by routine H&E stains or immunohistochemistry. Cases with ITC in lymph nodes or distant metastatic sites should be classified as N0 or M0 respectively. This also applies to findings suggestive of tumor cells or tumor cell components detected by non-morphological techniques such as flow cytometry or DNA analysis.

The following designations are applicable to ITC in regional lymph nodes: *pN0*, no regional lymph node metastasis histologically; no examination for ITCs. *pN0(i−)*, no regional lymph node metastasis histologically; negative morphological findings for ITCs. *pN0(i+)*, no regional lymph node metastasis histologically; positive morphological findings for ITCs. *pN0(mol−)*, no regional lymph node metastasis histologically; negative non-morphological findings for ITCs. *pN0(mol+)*, no regional lymph node metastasis histologically; positive non-morphological findings for ITCs.

The following designations are applicable to ITCs in sentinel lymph nodes: *pN0(i−)(sn)*, no sentinel lymph node metastasis histologically; negative morphological findings for ITCs. *pN0(i+)(sn)*, no sentinel lymph node metastasis histologically; positive morphological findings for ITCs. *pN0(mol−)(sn)*, no sentinel lymph node metastasis histologically; negative non-morphological findings for ITCs. *pN0(mol+)(sn)*, no sentinel lymph node metastasis histologically; positive non-morphological findings for ITCs.

Multiple primary tumors: The suffix "m," in parentheses, is used to indicate the presence of multiple primary tumors at a single site.

Classification following multimodality therapy: The prefix "y" is used to categorize tumors examined following multimodality therapy. This indicates the extent of tumor present at the time of that examination and is not an estimate of the extent of tumor prior to multimodality therapy.

Recurrent tumors: Recurrent tumors classified after a disease-free interval, are identified by the "r" prefix.

Classification at autopsy: The prefix "a" indicates that classification is first determined at autopsy.

Lymphatic invasion—L: LX, lymphatic invasion cannot be assessed; *L0*, no lymphatic invasion; *L1*, lymphatic invasion.

Venous invasion—V: VX, venous invasion cannot be assessed; *V0*, no venous invasion; *V1*, microscopic venous invasion; *V2*, macroscopic venous invasion. Note: Macroscopic involvement of the wall of veins (with no tumor within the lumen of the veins) is classified as V2.

Perineural invasion—Pn: PnX, perineural invasion cannot be assessed; *Pn0*, no perineural invasion; *Pn1*, perineural invasion.

[a]The depth of invasion is measured from the base of the epithelium, either surface or glandular, from which it originates and should always be reported in mm, even in those cases with "early (minimal) stromal invasion" ($\sim$ or <1 mm). The depth of invasion is defined as the measurement of the tumor from the epithelial-stromal junction of the adjacent most superficial epithelial papilla to the deepest point of invasion. Vascular space involvement, either venous or lymphatic, does not alter the staging. Further guidelines on lesion measurement, including multifocal disease, are given in the Royal College of Pathologists dataset document, referenced below.

[b]All macroscopically visible lesions—even with superficial invasion—are allotted to stage IB carcinomas.

[c]On rectal examination, there is no tumor-free space between the tumor and the pelvic wall. All cases with hydronephrosis or non-functioning kidney are included, unless they are known to be due to another cause.

[d]Presence of bullous edema is not sufficient evidence to classify a tumor as T4 or IVA. The lesion should be confirmed by biopsy.

cervical carcinoma and a number of clinical trials that incorporate these therapies are underway. It is likely that these agents will become incorporated into therapeutic strategies in the future.

Neil J Sebire, Great Ormond Hospital for Sick Children, London, United Kingdom

Glossary

Genetic predisposition A genetic makeup which leads to a person being at increased risk of (Wilms) tumor.
Histologic types Different histologic appearances which depend on the presence of different tumor's components.
Molecular markers Chromosomal or genetic abnormalities that can be used in stratification of treatment.
Wilms tumor—Nephroblastoma A malignant embryonal tumor of the kidney histologically resembling fetal phase of renal development.

Wilms tumor or nephroblastoma, an embryonal renal tumor, is one of the most common solid malignant tumors in children. It comprises 85%–90% of all renal tumors under 15 years of age, with more than 80% of children diagnosed under the age of 5 years (median age 3.5 years). They very rarely also occur in adults. Other pediatric renal tumors include mesoblastic nephroma (2%–3%), clear cell sarcoma (2%–3%), renal cell carcinoma (4%–5%), rhabdoid tumor (2%), and others (2%–4%). Wilms tumor is one of the most curable human tumors, with an overall survival of over 90% for unilateral non-metastatic cases.

Clinical Features

Wilms tumor is one of the rare tumors in children with a female preponderance among Caucasian patients. It usually presents as an asymptomatic abdominal mass discovered incidentally, but in 20%–30% of cases it presents with abdominal pain, malaise, hematuria, and hypertension. The most commonly used investigation to detect a renal mass is ultrasound examination but cross-sectional imaging, such as computed tomography and magnetic resonance imaging, is also considered standard practice.

The incidence of Wilms tumor varies significantly between ethnic groups. In the United States, the incidence is slightly higher among Black compared to Caucasian children. In the United Kingdom Wilms tumor is considerably more frequent among children of West Indian ethnic origin compared with Caucasians. The lowest rates are in South and East Asia, but also among children of East and South East Asian ethnicity in the United States and among South Asian children in the United Kingdom. Data from the National Wilms Tumor Study (NWTS) in North America indicates that among Asian children with renal tumors, 17.5% are non-Wilms tumors (clear cell sarcoma and rhabdoid tumor), compared with 4.6%–6.4% of non-Hispanic white, Black, and Hispanic children.

The presence of ethnic rather than geographical variation in incidence suggests a role of genetic predisposition in its etiology. A significant number of patients have a recognizable underlying predisposing genetic syndrome. Over 50 syndromes have been described in association with Wilms tumor, including various congenital anomalies and constitutional chromosomal abnormalities.

Genetics

Most Wilms tumors are sporadic, but very rarely they occur with autosomal dominant inheritance. The first gene discovered to be mutated in Wilms tumor was the *WT1* gene, located on chromosome 11p13, and somatic and germ-cell line mutations of *WT1* have been found in Wilms tumor. Other genes implicated in Wilms tumor genetics include β-Catenin (*CTNNB1*) and *WTX* gene. *WT1* mutations are often associated with monoallelic *CTNNB1* mutations and Wilms tumors which are early onset, often bilateral, stromal type, and associated with prominent rhabdomyogenesis, intralobar nephrogenic rests and genitourinary anomalies in males. Another type of Wilms tumor is associated with epigenetic alterations in the 11p15 region, and is characterized by later onset, blastemal or epithelial type histology, and perilobar nephrogenic rests.

Although only 1%–2% of Wilms tumor patients have a relative with Wilms tumor, the underlying constitutional predisposition accounts for a substantial proportion of cases. Many syndromes, congenital anomalies and constitutional chromosomal abnormalities have been reported as being associated with WT in 9%–17% of cases, which is higher than in any other malignancy.

The conditions with increased risk of Wilms tumor may be of high risk (>20%), moderate risk (5%–20%), and low risk (<5%). The high risk group includes familial WT, *WT1* deletions, *WT1* mutations, Perlman syndrome, Fanconi anemia, and mosaic variegated aneuploidy. The moderate risk group includes 11p15 overgrowth syndromes, Beckwith–Wiedemann syndrome (BWS),

Fraiser syndrome, and Simpson–Golabi–Behmel syndrome. The low risk group includes isolated hemihypertrophy, Bloom syndrome, Li–Fraumini syndrome, Mulibrey nanism, trisomy 18, trisomy 13, and 2q37 deletion.

There are at least 50 known familial Wilms tumor pedigrees, and they usually present with nonsyndromic Wilms tumor, with no recognized underlying cause. In a minority of cases they are associated with syndromes such as *WT1* mutations/deletions, 11p15 defects, mosaic variegated aneuploidy, and biallelic *BRCA2* mutations. At present, two familial Wilms tumor genes have been recognized. *FWT1* is an autosomal dominant nonsyndromic familial WT gene, mapped to 17q21 but not yet characterized. The *FWT2* gene, associated with an autosomal dominant nonsyndromic condition, has been proposed to be at 19q13 but there is no firm evidence favoring this locus. However, the finding of families not linked to *FWT1*, *FWT2*, *WT1*, or 11p15 indicates further genetic heterogeneity in familial Wilms tumor.

The group of *WT1*-associated syndromes includes those which are caused by mutations or deletions in the *WT1* gene predisposing to Wilms tumor. Individuals are diagnosed at younger age, with bilateral tumors (38% vs. 5% in unselected Wilms tumor cases), which are often stromal predominant/stromal type, and with intralobar nephrogenic rests. Constitutional *WT1* defects are associated with a variety of overlapping phenotypes, showing various combinations of three features: Wilms tumor predisposition, genitourinary abnormalities, and renal dysfunction.

WAGR syndrome (Wilms tumor–aniridia–genitourinary abnormalities–mental retardation) is found in about 7–8 per 1000 individuals with Wilms tumor. It is caused by monoallelic deletions at 11p13 including the *WT1* and *PAX6* genes—deletion of *WT1* results in Wilms tumor predisposition and deletion of *PAX6* results in aniridia. Some 30% of individuals with aniridia harbor *WT1–PAX6* deletions, and many of the remainder harbor point mutations or intragenic deletions of *PAX6*. Individuals with isolated *PAX6* defects are not at increased risk of Wilms tumor.

Denys–Drash syndrome is the combination of Wilms tumor, nephropathy (mesangial sclerosis), and genitourinary abnormalities which in males vary in severity from mild hypospadias to pseudohermaphroditism. Some females have gonadal dysgenesis, but the majority has normal genitourinary development.

Frasier syndrome consists of nephropathy, gonadal dysgenesis, and gonadoblastoma. It is caused by mutations in intron 9 of *WT1* that alter splicing and prevent formation of *WT1* isoforms. The nephropathy (focal segmental glomerulosclerosis) progresses to renal failure by the second or third decade of life. In males, genitourinary abnormalities are severe and sex reversal is common.

In some patients only one or two characteristic features of *WT1*-associated syndromes occur (such as Wilms tumor with cryptorchidism, or Wilms tumor with isolated nephropathy). They may also have *WT1* mutations but are more likely to have intragenic truncating mutations than missense mutations in the zinc finger domains. Most germline *WT1* mutations are de novo, but rare families have been reported with *WT1* defects that have presented with familial Wilms tumor.

The risk of Wilms tumor in individuals with *WT1* deletions, truncating mutations, or pathogenic missense mutations targeting the zinc finger domains is probably at least 50%. The risk of Wilms tumor in individuals with *WT1* intron 9 splice mutations (Frasier syndrome) is considerably lower than for other mutations—only 6% of patients with Frasier syndrome develop Wilms tumor, but the risk of gonadoblastomas is high.

Perlman syndrome is a rare, high mortality, autosomal recessive overgrowth disorder caused by biallelic mutations in *DIS3L2* gene. It is characterized by prenatal overgrowth with polyhydramnios, visceromegaly, cryptorchidism, facial dysmorphism, developmental delay, renal dysplasia, and Wilms tumor (reported in ~30% of cases).

Fanconi anemias are recessive chromosome breakage disorders with overlapping clinical and cellular phenotypes. Characteristic clinical features include short statute, microcephaly, radial ray defects, hyper- and hypopigmentated skin lesions, and bone marrow failure. There are 13 types and only Fanconi anemia types D1 and N are associated with an increased risk of Wilms tumor (~30%). Fanconi anemia type D1 is caused by biallelic mutation in *BRCA2*, whereas biallelic mutations in *PALB2* cause type N.

Mosaic variegated aneuploidy is a rare autosomal disorder characterized by constitutional mosaicism for gains and losses of whole chromosomes resulting in variable clinical features such as microcephaly, developmental delay, congenital heart defects, cataracts, and others.

In the moderate risk group the most common disorders are overgrowth syndromes. They represent a heterogeneous group of disorders characterized by pre and/or postnatal overgrowth often in association with other abnormal phenotypic features. Several of them are associated with Wilms tumor. Beckwith–Wiedemann syndrome is caused by dysregulation of various imprinted growth-regulating genes at 11p15 and carries an elevated (4%–21%) risk for several tumor types, Wilms tumor being the most frequently reported (in 1%–8% of affected children). Conversely, about 1% of children with Wilms tumor have Beckwith–Wiedemann syndrome. Beckwith–Wiedemann syndrome is characterized by pre- and postnatal overgrowth, macroglossia, anterior abdominal wall defects, ear lobe creases and posterior helical pits, neonatal hypoglycemia, and hemihypertrophy. The individuals may also have other abnormalities, including nephromegaly, renal cysts, medullary sponge kidney, medullary dysplasia, and hydronephrosis.

Simpson–Golabi–Behmel syndrome is an X-linked overgrowth syndrome characterized by coarse facial features, cardiac abnormalities, urinary tract abnormalities (renal dysplasia, nephromegaly) polydactyly, accessory nipples and, in some individuals, learning difficulties. Wilms tumor has been reported in 9% of patients with *GPC3* mutations. The condition is caused by loss of function mutations or deletions of *glypican-3* (*GPC3*) located at Xq26, which are identifiable in about 70% of affected individuals. The cause of the remainder is unknown.

The low risk group includes some syndromes and constitutional chromosomal abnormalities. In Bloom syndrome, hereditary hyperparathyroidism-jaw tumor syndrome and mulibrey nanism, the risk is probably below 5%. There also appears to be an increased risk of Wilms tumor associated with three constitutional chromosomal abnormalities including trisomy 18, trisomy

13, and 2q37 deletion. Although their prevalence at birth is relatively high, the first two of these account for a very small proportion of all cases of Wilms tumor as infant mortality is very high.

Isolated hemihypertrophy carries a low risk of Wilms tumor (~3%). Approximately 20% of individuals with hemihypertrophy have an identifiable 11p15 defect. Interestingly, tumors occur at similar frequency in the larger and smaller kidney in asymmetric individuals.

Somatic Mutations in Wilms Tumor

Wilms tumors usually show few genetic changes, even by deep sequencing. Karyotypes may show trisomies (chromosomes 18 and 12), but translocations are uncommon in spite of several reports of t(1;16). Tumors with the most genetic changes are aneuploid in association with anaplasia. Some chromosomal losses (1p and 16q) and 1q gain are associated with a poorer prognosis (without features of anaplasia), but the genetic basis of this are not yet known. Loss of heterozygosity is seen at various sites, especially at 11p15 (the Beckwith–Wiedemann syndrome locus which is also found in sporadic hepatoblastoma and rhabdomyosarcoma) and 11p13. Changes at these two loci can be considered as somatic mutation in sporadic tumors, as well as in cases with syndromic features a second (somatic) hit.

In Wilms tumor a variety of genetic pathways disturb the normal development of committed nephrogenic mesenchyme, and these can be grouped into about five different types, arising at different stages of development and with involvement of different genes. Some, such as epigenetic loss of imprinting at 11p15 (as in children with BWS), serve as a background for subsequent changes, as they can be found in histologically normal kidney around the tumor. The first identified pathway involves *WT1* but *WT1* mutations are only seen in around 15% of Wilms tumors. More recently mutations of *WTX* identified a second pathway and also the WNT pathway is involved with mutations of the *CTNNB1* gene. Another group involves pathways involving noncoding RNA, as in the Perlman syndrome and *DICER1* mutations. Furthermore, mutations of the nuclear homologue to *DICER1*, *DROSHA* are also found in a significant number of tumors. Dominant mutations of *SIX1* and *SIX2*, which are highly expressed in fetal nephrogenic blastema and in blastema of WTs also, appear to be early drivers of Wilms tumor development. Rather than considering Wilms tumor pathogenesis as a result of mutation of individual genes, it is becoming more likely that Wilms tumors arise through genetic and epigenetic changes in common gene pathways such as the Wnt pathway, with a crucial role of noncoding RNA in gene regulation in these pathways. *TP53* mutations are found usually in association with anaplasia, and should be considered a late event in Wilms tumor oncogenesis.

Next generation sequencing is starting to identify and confirm other changes, including low level N-myc amplification and new potential oncogenes, as causal factors of Wilms tumor. Wilms tumors are genetically heterogeneous, containing various clones with different genome changes, some of which are likely to be passenger mutations, others representing drivers of clonal evolution of the tumor. This implies that a tumor tissue sample may not be representative for all important genome abnormalities, which may impact on treatment planning. Furthermore, Wilms tumors conceivable contain a small population of cancer stem cells that might have to responsible for secondary chemoresistance.

Nongenetic Causes of Wilms Tumor

In adult tumors, environmental factors usually play a dominant role in oncogenesis but in childhood tumors the genetic background is usually more important. There have been some reports of environmental exposure inducing Wilms tumors but the evidence is not strong. A rat model of triphasic Wilms tumor has been developed following nitrosamine exposure in utero, affecting *CTNNB1* in the Wnt pathway. In humans Wilms tumor incidence is higher with increased birthweight, suggesting increased growth factors in utero as factor, which is supported by few reports of increased risk for Wilms tumor in infants of diabetic mothers, as insulin is a potent growth factor for the fetus.

Future Developments

Wilms tumor pathogenesis clearly recapitulates normal nephrogenesis. As nephrogenesis becomes better understood, it will help us understand Wilms tumor development. The final pathogenetic pathway for Wilms tumor will involve in the cells of origin not only driver mutations in genes but also epigenetic changes, such as chromatin structure, histone architecture, DNA methylation, and noncoding RNA, as well as external cellular factors including cell adhesion molecules and external growth factors. Tumors rarely arise in older children and adults, and understanding normal differentiation pathways may provide novel insight guiding new treatment modalities.

Pathologic Features

Macroscopically, Wilms tumors are usually large and distort the renal contours. They are rarely multicentric (5%–10% of cases) or bilateral (5%–8% of cases)—unique features which may be helpful in differentiating them from other childhood renal tumors. Cut surface appearance varies, depending on the histological composition of the tumor—blastemal tumors are soft and fragile, whereas stromal tumors are firm. If treated with preoperative chemotherapy, large areas of necrosis and cystic changes are often seen.

Histologically, Wilms tumors show a wide range of patterns with three histological components—blastemal, epithelial, and stromal—represented in variable proportions. Classical, triphasic tumors contain all three components (Fig. 1), but cases with only two (Fig. 2) or even just one component are not rare.

Blastema represents an undifferentiated component and is regarded as the major malignant element. It consists of small, round, blue cells with overlapping nuclei and usually high mitotic activity. The blastemal cells may be arranged in several patterns (diffuse, serpentine, nodular, or basaloid) but these have no prognostic significance. Unlike other histological Wilms tumor types, blastemal tumors frequently have no capsule separating them from the renal parenchyma. Sometimes blastema may show signs of early epithelial differentiation, with cells arranged in very primitive epithelial structures such as rosettes, and this may cause diagnostic difficulties when assessing the percentage of blastemal relative to epithelial components, which is of significance in the SIOP histological classification (see below). Similarly, blastema may contain areas composed of spindle cells, which may be difficult to distinguish from the stromal component. As no exact histological or immunohistochemical criteria exist to discriminate between the components, Wilms tumor subtyping is subjective and dependent on the experience of the pathologist. This justifies central pathology review, which has been part of all multicenter studies around the world in the last 40–50 years.

The epithelial component may display both nephrogenic and heterologous epithelial elements. The former includes the whole spectrum of differentiation from primitive epithelial rosette-like structures to well differentiating tubules or glomeruli-like structures resembling different stages of nephrogenesis. The heterologous epithelial elements include squamous and mucinous epithelium.

The stromal component may also show a variable architecture between loose, hypocellular, myxoid areas and densely packed undifferentiated mesenchymal cells. Heterologous differentiation in the stroma includes well-differentiated skeletal or smooth muscle cells, fat tissue, cartilage, bone, and even glial tissue (in rare cases), especially in tumors which have undergone preoperative chemotherapy.

Preoperative chemotherapy influences the histological presentation of Wilms tumors due to chemotherapy-induced changes, including induction of maturation of the pretreatment components. Chemotherapy induced changes include necrosis, fibrosis, and areas with foamy macrophages and/or hemosiderin-laden macrophages. Usually it is the blastema, representing the least differentiated component, that responds to chemotherapy, whereas mature epithelial and stromal components are often less

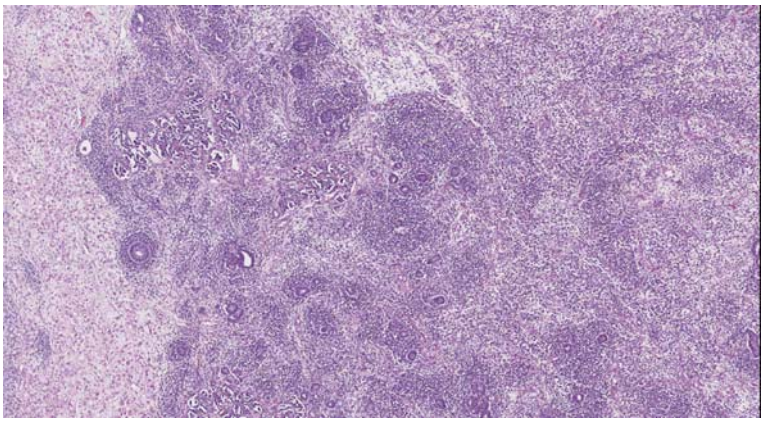

Fig. 1 Mixed (triphasic) Wilms tumor showing blastemal, epithelial, and stromal components.

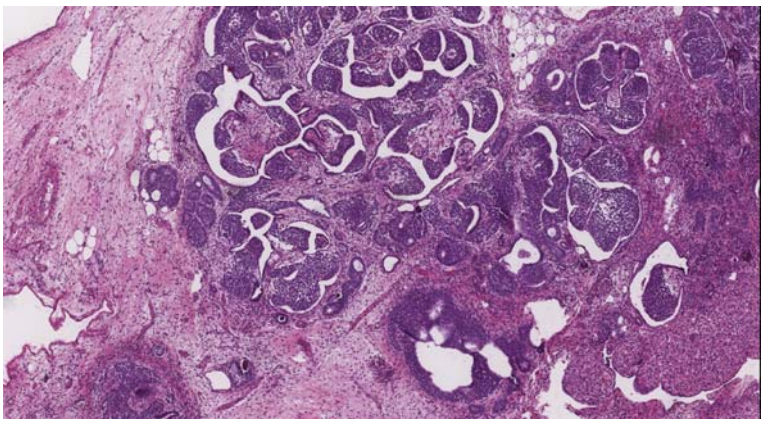

Fig. 2 Mixed (biphasic) Wilms tumor consisting of blastemal and stromal components.

chemotherapy sensitive. Tumors predominantly composed of mature epithelial or stromal components often show no preoperative therapy modifications.

Cystic partially differentiated nephroblastoma is a cystic variant of Wilms tumor which occurs as a solitary, unilateral, multilocular cystic lesion that usually measures 5–10 cm in diameter, with cysts ranging in size from a few mm to 4 cm. It is sharply demarcated from surrounding renal parenchyma and secondary changes such as necrosis and hemorrhage are rare. Diagnostic criteria for cystic partially differentiated nephroblastoma are clear demarcation from the non-cystic renal parenchyma, uniquely composed of cysts and their septa, septa representing the only solid portion of the tumor as composed of fibrous tissue with blastemal cells in any amount, and lining of the cysts by attenuated cuboidal or hobnail epithelium. Neoplastic tubules, variably differentiated glomeruli, striated muscle, cartilage and fat may also be found along with blastemal cells in the septa (**Fig. 3**). A macroscopically and histologically similar lesion—cystic nephroma—used to be regarded as a lesion related to cystic partially differentiated nephroblastoma, but recent molecular studies showed that they are likely separate entities since cystic partially differentiated nephroblastoma shows no association with *DICER1* mutations, which are reported in 90% of cystic nephroma. From a management perspective, however, both lesions are treated with surgery only, and both have excellent prognosis (100% survival), but it is important to distinguish them from Wilms tumor with prominent cystic component.

An important histological feature of Wilms tumor, with major therapeutic and prognostic implications, is anaplasia which is defined as the presence of large, multipolar, atypical mitotic figures, marked nuclear enlargement and hyperchromasia (**Fig. 4**). Anaplastic tumors are generally aneuploid. Anaplasia is found in 5%–8% of Wilms tumors, and the patients are usually older than those with non-anaplastic tumors. Anaplasia never occurs in the first 6 months of life, it is exceptionally rare in the first year of life, and only 5% of patients with anaplastic tumors are under 2 years of age. Anaplasia may occur in any of the histological components of the tumor, but it is critical for its diagnosis that all three criteria are fulfilled. A rhabdomyoblastic stromal component in a tumor without anaplasia may show considerable cellular pleomorphism, but if atypical mitoses are absent, this is not regarded as genuine anaplasia. Anaplasia is further subclassified as focal and diffuse. Focal anaplasia is localized, usually as a sharply demarcated focus (or two to three small foci) showing the features mentioned above. All other cases with anaplasia should be considered as diffuse anaplasia, including when multiple foci of anaplasia are found or focal anaplasia with marked nuclear

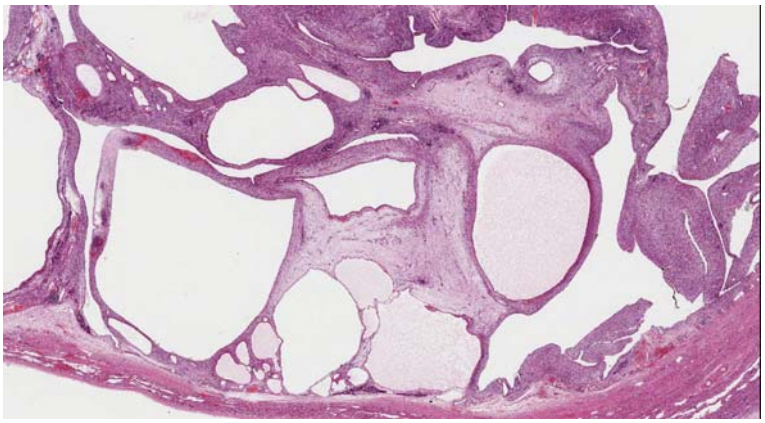

Fig. 3 Cystic partially differentiated nephroblastoma—composed entirely of cysts and septa which contain some immature tubules and foci of blastema.

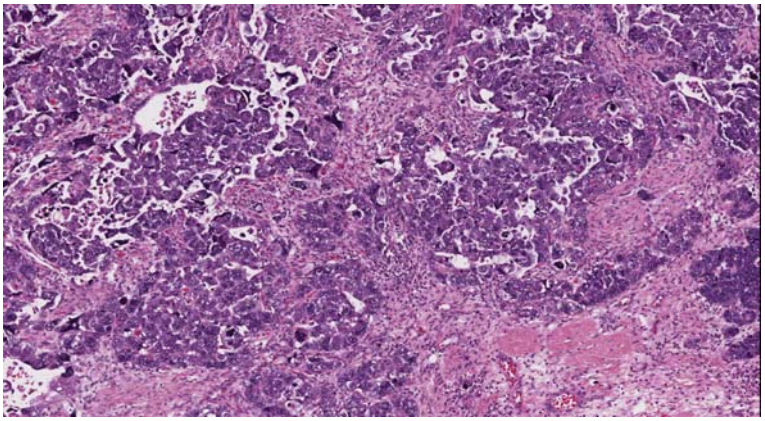

Fig. 4 Wilms tumor with diffuse anaplasia showing atypical mitoses, enlarged, pleomorphic, and hyperchromatic nuclei.

enlargement and hyperchromasia elsewhere in the tumor, when the anaplasia is seen in distant metastases diagnosed in a biopsy. Anaplastic clones are more chemotherapy-resistant than aggressive, and high stage tumors with anaplasia have a poor prognosis with only ~35% overall survival in stage 4. Anaplastic tumors often immunohistochemically express p53 (in ~80% of cases) and are *TP53* mutated, but this is also found in non-anaplastic Wilms tumors and does not distinguish between anaplastic and non-anaplastic Wilms tumors. Anaplastic Wilms tumors also show dysregulation of the *MYCN* gene, which is involved in the development of tumors with adverse outcome.

Further subclassification of Wilms tumors is based on semiquantitative assessment of different tumor components, but the criteria for subtyping differ between the two major groups which have been running renal tumor trials in the last 50 years—in the Children's Oncology Group (COG, former National Wilms Tumor Study Group), where surgery is used as the first step in treatment, followed by chemotherapy and, in higher stages, radiotherapy, Wilms tumors are classified as non-anaplastic and anaplastic types. Non-anaplastic Wilms tumors are further assigned on the basis of a predominant component (which makes more than 2/3 of the tumor) as epithelial predominant, stromal predominant or mixed (if no component makes more than 2/3 of tumor). In the International Society of Paediatric Oncology (SIOP) approach, preoperative chemotherapy is given as the first line of treatment, followed by surgery and further chemotherapy and, in higher stages, radiotherapy. Since preoperative chemotherapy often results in chemotherapy-induced changes, they are also taken into account when subclassifying tumors: if there is no viable tumor left, it is completely necrotic type. If more than 66% (2/3) of tumor is nonviable (i.e. shows chemotherapy-induced changes), it is regarded as regressive type irrespectively of the presence of remaining viable tumor components (except anaplasia). If viable tumor comprises more than 1/3 of the tumor mass, subtyping depends on the percentage of the viable components: in mixed type no component comprises more than 66% of tumor while in epithelial (or stromal) type more than 66% of the tumor is composed of epithelial (or stromal) elements, and in addition only up to 10% of blastema is allowed. When this exceeds 10% the tumor is regarded as mixed type. Blastemal type is regarded as a high risk tumor in the SIOP classification (**Table 1**).

For these reasons, it is important to bear in mind that although the terms used in COG and SIOP subtyping of Wilms tumor are similar, they do not necessarily describe the same histology and complicate a direct comparison of different studies.

Similarly, the staging criteria between the SIOP and COG differ since in the SIOP criteria chemotherapy-induced changes are taken into account for some stages (**Tables 2** and **3**).

The diagnosis is usually relatively easy in triphasic or even biphasic Wilms tumors, but their subclassification may be challenging. However, monophasic Wilms tumors may be very difficult to separate from other renal tumors with similar histological features. Pure blastemal type Wilms tumors have to be distinguished from other undifferentiated tumors such as neuroblastoma, primitive neuroectodermal tumor/Ewing sarcoma of the kidney, and desmoplastic small round cell tumor. It is particularly important to consider non-Wilms tumors in older patients and adults—Wilms tumor does occur in adults, but many of the renal tumors which in the past were labeled as adult Wilms tumors proved to be other entities. In order to reach the correct diagnosis in such cases, it is critical to perform immunohistochemical and molecular investigations looking for characteristic feature of Wilms tumors. Although blastemal components may show focal CD99 positivity, it is usually not diffuse and membranous as in Ewing sarcoma of the kidney, where genetic studies also show characteristic translocations, with t(11;22)(q24;q12) being the most common. Desmoplastic small round cell tumor shares many immunohistochemical features with blastemal type Wilms tumor, but is extremely rare and the diagnosis should only be made if genetic analysis identifies the *EWS-WT1* t(11;22)(q13;q12) translocation. Neuroblastoma usually shows elevated levels of catecholamines, and on histological examination its cells reveal nonoverlapping nuclei and coarse "salt and pepper" chromatin. Neuron-specific enolase and CD56 are positive in both tumors, but WT1 marker is negative in neuroblastoma, and chromogranin, synaptophysin and NB84a markers are negative in Wilms tumor. Rhabdoid tumor can be

Table 1 The SIOP working classification of renal tumors of childhood

	Pretreated cases[a]	*Primary nephrectomy cases*[b]
Low risk	Mesoblastic nephroma	Mesoblastic nephroma
	Cystic partially differentiated nephroblastoma	Cystic partially differentiated nephroblastoma
	Completely necrotic nephroblastoma	
Intermediate risk	Nephroblastoma—epithelial type	Non-anaplastic nephroblastoma
	Nephroblastoma—stromal type	Nephroblastoma—focal anaplasia
	Nephroblastoma—mixed type	
	Nephroblastoma—regressive type	
	Nephroblastoma—focal anaplasia	
High risk	Nephroblastoma—blastemal type	
	Nephroblastoma—diffuse anaplasia	Nephroblastoma—diffuse anaplasia
	Clear cell sarcoma of the kidney	Clear cell sarcoma of the kidney
	Rhabdoid tumor of the kidney	Rhabdoid tumor of the kidney

[a]Diagnostic criteria for cases treated with preoperative chemotherapy differ from those used for cases that are treated with primary nephrectomy.
[b]For cases treated with primary nephrectomy, the only subclassification needed is to distinguish between non-anaplastic and anaplastic types.

Table 2 SIOP staging criteria (2016) (for tumors treated with preoperatively chemotherapy)

Stage I
(a) The tumor is limited to kidney or surrounded with a fibrous (pseudo)capsule if viable tumor is outside of the normal contours of the kidney. The renal capsule or pseudocapsule may be infiltrated by the tumor but it does not reach the outer surface of the capsule.
(b) The tumor may be protruding (bulging) into the pelvic system and "dipping" into the ureter but it is not infiltrating their walls.
(c) The vessels or the soft tissues of the renal sinus are not involved.
(d) Intrarenal vessel involvement may be present.
Stage II
(a) Viable tumor is present in the perirenal fat and it is not covered by a (pseudo)capsule, but it is completely resected (resection margins "clear").
(b) Viable tumor infiltrates the soft tissues of the renal sinus.
(c) Viable tumor infiltrates blood and lymphatic vessels of the renal sinus or renal veins or is present in the perirenal tissue but it is completely resected.
(d) Viable tumor infiltrates the ureter's wall.
(e) Viable tumor infiltrates adjacent organs or vena cava but is completely resected.
Stage III
(a) Viable tumor extends to the resection margins. If there is only nonviable tumor at inked resection line, it is regarded as stage III only if viable tumor is <5 mm to the inked margin. If the viable tumor is >5 mm from the resection line and only regressive changes are found at inked margin it does not upstage the tumor (the minimal distance of 5 mm tissue without viable has to be documented with several blocks of this area).
(b) Any abdominal lymph nodes are involved with either viable or nonviable tumor.
(c) Pre- or intraoperative tumor rupture, if visible at pathological examination (irrespective of other criteria for staging).
(d) Tumor thrombus is present at resection margins of ureter, renal vein or vena cava inferior (always discuss resection margins with a surgeon).
(e) Tumor thrombus which is attached to the IVC wall is removed piecemeal by surgeon.
(f) Tumor has been biopsied (wedge/open biopsy) prior to preoperative chemotherapy or surgery.
(g) Tumor implants (viable and/or nonviable) are found anywhere in the abdomen.
(h) Tumor (viable and/or nonviable) has penetrated through the peritoneal surface.
Stage IV
Hematogenous metastases (lung, liver, bone, brain, etc.) or lymph node metastases outside the abdomino-pelvic region.
Stage V
Bilateral renal tumors at diagnosis. Each side should be substaged according to the above criteria.

Table 3 COG staging system (for tumors treated with primary surgery)

Stage I
(a) Tumor limited to the kidney and completely resected.
(b) Renal capsule intact.
(c) The tumor was not ruptured or biopsied prior to removal.
(d) Renal sinus vessels not involved.
(e) No evidence of tumor at or beyond the margins of resection.
Stage II
(a) Tumor completely resected.
(b) No evidence of tumor at or beyond the margins of resection.
(c) Tumor extends beyond the kidney, as evidenced by one of the following:
- Penetration through the renal capsule.
- Extensive invasion of the soft tissue of renal sinus.
- Blood vessels within the nephrectomy specimen outside the renal parenchyma, including those of the renal sinus, contain tumor.

Stage III
(a) Residual non-hematogenous tumor confined to the abdomen is present after surgery as evidenced by any of the following:
- Involvement of lymph nodes within the abdomen or pelvis
- Penetration through the peritoneal surface
- Tumor implants on the peritoneal surface
- Tumor present at the margins of surgical resection
- Tumor not resectable because of local infiltration into vital structures
- Biopsy of tumor prior to removal of kidney
- Tumor spillage of any degree or localization occurring before or during surgery
- Tumor removed in greater than one piece

Stage IV
(a) Hematogenous metastases (lung, liver, bone, brain, etc.)
(b) Lymph node metastases outside of the abdomino-pelvic region
Stage V
(a) Bilateral renal involvement at the time of initial diagnosis
(b) Each side should be separately staged according to the above criteria

distinguished from Wilms tumor by marker immunohistochemistry, as nuclear INI1 expression is not seen in rhabdoid tumor. Pure epithelial type Wilms tumor may be difficult to distinguish from metanephric adenoma, renal cell carcinoma, and hyperplastic perilobar nephrogenic rest. Highly differentiated epithelial type Wilms tumor may be composed of small, well differentiated, and closely packed tubules similar to metanephric adenoma, but the latter can be diagnosed by the lack of a capsule between the tumor and renal parenchyma and absent mitotic activity. The combination of CK7–, AMACR–, WT1+, and CD57+ is the typical immunohistochemical marker profile of metanephric adenoma. Histological features of renal cell carcinomas in children associated with translocations are usually distinctive and immunohistochemistry or fluorescence in situ hybridization to detect *TFE3* gene rearrangement is of huge help, but papillary renal cell carcinoma (as seen in adults) may be more difficult to diagnose. Immunohistochemistry using the epithelial markers CK7 and CD10 and cytogenetic analysis may be very helpful. In the differential diagnosis of pure stromal type Wilms tumor, clear cell sarcoma of the kidney and mesoblastic nephroma and in older children monophasic synovial sarcoma should be considered. In Wilms tumors treated with preoperative chemotherapy, the stroma may show a striking clear cell sarcoma-like appearance, and extensive sampling may be required in order to find foci with other Wilms tumor components.

The diagnosis and staging of renal tumors of childhood is challenging for a number of reasons, including their rarity, extreme morphological heterogeneity, which varies from case to case, histological patterns of certain Wilms tumor subtypes which may appear similar to other rare pediatric renal tumors, lack of objective criteria distinguishing Wilms tumor from nephrogenic rests, and the fact that assessment of the tumor and determination of the pathology stage is a multistep and time-consuming process. For all these reasons, a significant number of misdiagnosed and mis-staged cases have been identified in the previous SIOP and COG studies, and in order to ensure that the patients who are entered in the studies are treated according to their precise diagnosis and stage, rapid central pathology review has been introduced within a time-frame that assures that the treating physician will dispose of the review results.

Nephrogenic Rests

Nephrogenic rests are defined as abnormal foci of embryonic tissue persisting beyond 36 weeks of intrauterine life. They are found in 40% of kidneys with Wilms tumor and very rarely in routinely examined kidneys at autopsy. Nephrogenic rests are regarded as precursor lesions of Wilms tumor. There are two main types of nephrogenic rests—perilobar and intralobar nephrogenic rests, and they have different histological features and clinical importance. In about 5% of cases, both perilobar and intralobar nephrogenic rests are present. They are further subclassified as obsolescent, dormant, sclerosis, and hyperplastic types. Perilobar nephrogenic rests are found at the periphery of the renal lobe, they are typically multifocal and demarcated from the renal parenchyma. Histologically, they usually contain blastema and tubules (Fig. 5) and are associated with overgrowth Wilms tumor syndromes (hemihypertrophy and Beckwith–Wiedemann syndrome) and with blastemal and epithelial Wilms tumors. Intralobar nephrogenic rests are found within the renal lobe, they are poorly defined and merge with the surrounding renal parenchyma, as they are composed of stroma, blastema, and tubules (Fig. 6). They are associated with WAGR and Denis–Drash syndromes and stromal Wilms tumors. If perilobar or intralobar nephrogenic rests are hyperplastic, they may be impossible to distinguish from a Wilms tumor, since there are no histological or immunohistochemical features which provide definitive diagnosis. The vast majority of the rests do not develop into a Wilms tumor. Nephroblastomatosis is term used to describe multiple nephrogenic rests. A special type of nephroblastomatosis is diffuse hyperplastic perilobar nephroblastomatosis, in which the renal cortex is completely replaced by proliferating perilobar rests. It requires treatment as it virtually always progresses into a Wilms tumor. Similar to Wilms tumor, there are also racial differences in the prevalence of nephrogenic rests, with fewer perilobar rests seen in the Japanese and Indian population.

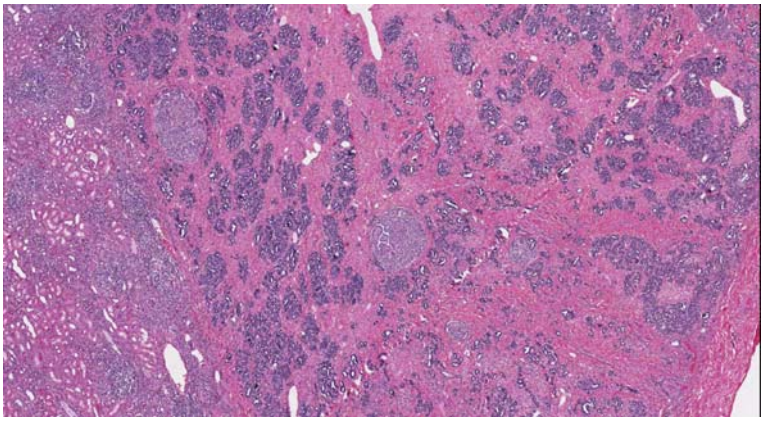

Fig. 5 Perilobar nephrogenic rests showing a mixture of sclerosing and hyperplastic (adenomatous) rests without sharp demarcation from the renal parenchyma.

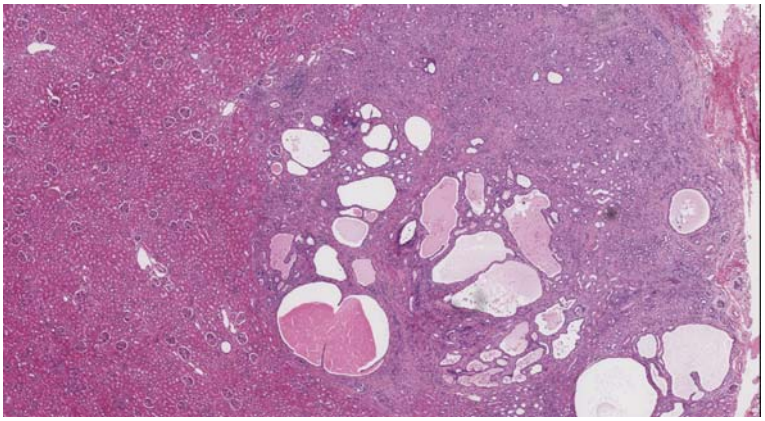

Fig. 6 Intralobar nephrogenic rest with cystically dilated tubules blending with the surrounding renal parenchyma.

Prognostic Features

The prognosis of Wilms tumors depends on a number of factors which, again, are not identical between the two big groups. In SIOP, prognostic factors include stage, histology, tumor volume, response to treatment, and (potentially) volume of blastema in postchemotherapy specimen.

An initial stage is assigned at the time of diagnosis in terms of localized, metastatic or bilateral, and this provides the basis for preoperative chemotherapy. A final stage is determined after preoperative chemotherapy, following nephrectomy, applying the staging criteria as outlined above and taking into account both chemotherapy-induced changes and viable tumor components.

Histological subtyping and risk group assignment are done following nephrectomy as in **Table 1**. Completely necrotic tumors are regarded as low risk, and no further treatment is given for stage 1, whereas other stages are treated with milder therapy. The high risk group contains, in addition to diffuse anaplasia, blastemal type Wilms tumor. Although it represents only 5%–8% of Wilms tumors, it is responsible for about 30% of events, and therefore it is treated with more aggressive postoperative therapy which has resulted in improved 5-year event-free survival from 67% to 80% (for all stages of localized disease), and for stage 1 from 71% to 96%. The last SIOP 2001 Trial showed that treatment of stage 2 and stage 3 tumors from the intermediate risk group without doxorubicin (a known cardiotoxic drug) is just as effective, which is important for avoiding late sequelae of treatment. Focal anaplasia is regarded as conferring intermediate risk and treated accordingly.

Preoperative chemotherapy usually results in decreased tumor volume, but when tumors remain large (with a volume of 500 mL or more after preoperative chemotherapy) and are not of stromal or epithelial subtype (which are known to be chemotherapy-resistant), this is regarded as a bad prognostic sign, and such tumors receive more intense postoperative treatment. Response to preoperative treatment is assessed on the basis of reduction in tumor volume, different distribution of tumor types, and clearance of metastases.

Age has no significance in treatment stratification in SIOP, although the results of previous studies showed that patients under 2 years of age with localized disease had 92% 5-year OS, compared to patients between 2 and 4 years (88% 5-year OS) and patients older than 4 years (80% 5-year OS).

The results of the SIOP 2001 Wilms tumor Trial indicated that patients could be better stratified on the basis of blastemal volume rather than the percentage of the blastemal component, and that patients with localized disease and a blastemal volume of more than 20 mL did significantly worse than those with a smaller blastemal volume. This criterion is now being prospectively assessed in the new SIOP Study (UMBRELLA 2016).

In COG, the prognostic factors are stage, histology, patient age and tumor weight, response of lung metastases, and molecular markers (loss of heterozygosity at 1p and 16q, and 1q gain).

Tumor stage has been an important risk factor since the first NWTSG Study, and over the years the criteria for staging have been modified, taking into account the results and findings from the previous studies. It is worth emphasizing that the staging criteria in COG and SIOP are not exactly the same, since in SIOP there are chemotherapy-induced changes which are taken into account for certain stages, whereas in COG tumors are staged on the basis of viable components only. The staging criteria are presented in **Table 3**.

The only histological feature impacting on treatment and with prognostic significance is anaplasia (see above), and there is a difference in treatment of focal and diffuse anaplasia. Treatment and prognosis of a tumor with focal anaplasia is intermediate between that of tumors with favorable histology and those with diffuse anaplasia.

Previous studies showed that increased age is associated with increased risk of relapse and less favorable outcome, but this is only taken into account for risk stratification of small (<550 g), stage 1, favorable histology Wilms tumors in patients younger than 2 years of age, who are treated with surgery only.

If there is no complete response of lung metastases on initial chemotherapy, this is regarded as a bad prognostic sign and treatment is intensified by adding radiotherapy of the lung while this is not given to patients with complete response.

Previous NWTSG studies showed that in a small number of patients (~5%) concurrent loss of heterozygosity for chromosomes 1p and 16q is associated with increased relative risk of relapse and death.

Recent COG and SIOP studies showed that gain of chromosome 1q is present in about 30% of Wilms tumors, and as it is associated with poor outcome it will be used as a risk stratification criterion in coming COG studies.

Management

As already mentioned, management of Wilms tumors is according to two different approaches: COG and SIOP. The COG approach is followed mainly in the North America and consists of primary surgery, followed by further treatment if necessary, including chemotherapy and advanced stages radiotherapy. The last COG trial included the following four categories: (a) very low and standard risk favorable histology; (b) higher risk favorable histology; (c) high risk (anaplastic); and (d) bilateral, multicentric, or bilaterally predisposed unilateral Wilms tumor. The assignment to treatment groups was based on the above mentioned prognostic factors. For surgical and pathological staging this is more straightforward since tumor histology is not modified by chemotherapy. Furthermore, non-Wilms tumors are not treated with potentially inappropriate preoperative chemotherapy, and patients from a very low risk group will not receive chemotherapy.

In the SIOP approach, tumors are treated with preoperative chemotherapy, followed by postoperative chemotherapy and radiotherapy, if necessary. The advantages of this approach are that tumors respond to treatment and are reduced in size, are better encapsulated, and easier to remove, which reduces the risk of pre- or intraoperative rupture and spillage. This reduces overall treatment in all stages. Preoperative chemotherapy also results in down-staging of tumors. Studies showed that of Wilms tumors primarily treated by surgery, only 62% could be completely resected (stage I–II), whereas this was 84% in patients who underwent preoperative chemotherapy. Finally, preoperative therapy provides in vivo information on treatment response, and allows identification of tumors which are chemotherapy resistant.

In the United Kingdom, the SIOP approach has been followed since 2001, but including pre-chemotherapy biopsy for the sole purpose of pre-therapy confirmation of the tumor as Wilms tumor. The percutaneous cutting needle biopsy is not associated with an increased risk of local relapse and therefore does not imply a higher stage.

These two different approaches have resulted in remarkably similar outcome, with overall survival over 90% making Wilms tumor one of the childhood cancers with excellent prognosis. In Britain, 5-year survival of children with renal cancer was 59% for those diagnosed in 1971–75 and 75% for those diagnosed in 1976–80. In population-based data from Europe and North America, 5-year survival has generally been over 85% for Wilms tumor and over 80% for all renal tumors combined. In Cuba, the 5-year survival for renal tumors diagnosed in 1988–89 was 62%. In Bangalore, India, 5-year survival for Wilms tumor in 1982–89 was only 27%. Treatment has a high success rate in specialist centers in developing countries, but overall survival is adversely affected because patients discontinue treatment.

As a result of increasing survival rates there are now substantial numbers of long-term survivors of Wilms tumor in the general population. As with other childhood cancers, one of the most serious sequelae of Wilms tumor is development of a subsequent primary neoplasm. Large studies of subsequent malignancies after Wilms tumor showed that leukemia, skin carcinoma, and solid tumors of the digestive organs, breast, thyroid, bone, and CNS are the most common second tumors. Occurrence of a subsequent malignancy has a severe effect on survival. Two-thirds of patients who developed leukemia have died, with median time from diagnosis of leukemia to death of 10 months. Age-specific mortality was increased 15-fold for subjects who developed a solid second malignancy. Risk of leukemia was highest in the most recently diagnosed patients, whereas the risk of solid tumor decreased for more recent decades of Wilms tumor diagnosis. Late causes of death among 5-year survivors are subsequent malignancies, cardiomyopathy and congestive heart disease, and end-stage renal disease.

Conclusion

The last decades have shown a remarkable progress in classification, treatment, and understanding of the pathology and molecular biology of Wilms tumor. As a rare tumor, it continues to represent a diagnostic problem and awareness of the potentially complex pathological features of this malignancy is required for accurate diagnosis, subtyping, and staging to allow appropriate treatment. Preoperative chemotherapy affects histological and staging features, and diagnostic pathologists should be familiar with these when assessing such tumors. Molecular biology markers are likely to play an even more important role for diagnosis and prognosis in the future but pathological examination continues to represents the gold standard for diagnosis, subtyping, treatment, and prognosis.

Wnt Signaling in Intestinal Stem Cells and Cancer

Rebecca L Myers, Maryam Yousefi, Christopher J Lengner, and Peter S Klein, University of Pennsylvania, Philadelphia, PA, United States

Glossary

Adenoma A benign tumor formed from glandular structures in epithelial tissue.

Carcinoma A cancer arising from epithelial tissues, such as the intestinal epithelium.

Epithelium The layer of cells that lines the surface of an organ. Epithelial cells attach to a basement membrane that separates them from connective tissue and are held together by specialized cell adhesions. Intestinal epithelial cells are a single layer of columnar cells that face the lumen of the intestinal tract, are involved in absorption of nutrients and water, and form a protective barrier.

Germline mutation A mutation that is passed from parent to offspring.

Homeostasis Maintenance of a stable equilibrium; in the case of an epithelium, generation of new cells to replace dying cells without a change in the total number of cells. If too many new cells form, this leads to neoplasia. If insufficient cells form to replace dying cells, epithelial functions fail.

Ligand A molecule that binds to a receptor to activate or inhibit signaling.

Malignant A cancer that can invade outside of its tissue of origin, leading to metastasis.

Neoplasia New cell growth out of proportion to normal tissues. This can be benign, as in adenomas, or malignant, as in cancer.

Oncogene A gene that causes cancer when activated, for example, by mutation.

Palmitoylation The covalent attachment of palmitic acid, a fatty acid, to proteins, causing the protein to localize to hydrophobic surfaces such as the plasma membrane. More generally, acylation is the attachment of fatty acids to proteins through an acyl linkage.

Somatic mutation A mutation that occurs after fertilization, that is, not a germline mutation.

Tumor suppressor gene A gene that normally prevents cancer progression and when mutated allows for cancer progression.

Wnt The name of the signaling pathway described here *and* the family of secreted proteins that serve as ligands for the Wnt pathway. "Wnt" is a portmanteau of *Wingless* (the first *Wnt* gene identified in *Drosophila*) and *Int-1*, the first *Wnt* gene discovered in mammalian cells.

Introduction

Wnt signaling regulates cell fate specification and embryonic pattern formation throughout development and maintains self-renewal of somatic stem cells in multiple tissues, including intestinal, neural, and epidermal stem cells. Unrestrained activation of canonical Wnt signaling due to loss of function mutations in pathway inhibitors or gain of function mutations in pathway activators promotes carcinogenesis. For example, loss of the tumor suppressor *Adenomatous Polyposis Coli* (*APC*) causes the inherited cancer predisposition syndrome familial adenomatous polyposis (FAP) and somatic mutations in *APC* underlie the pathogenesis of most colorectal carcinomas. This article will describe the canonical Wnt signaling pathway and then summarize the role of APC and other Wnt pathway components in the regulation of intestinal stem cells and colorectal cancer.

Canonical Wnt/β-Catenin Signaling

The canonical Wnt signaling pathway is activated by the binding of Wnts to receptors on the cell surface, leading to stabilization of the transcription activator β-catenin and culminating in the transcription of Wnt target genes (Fig. 1). This "canonical" pathway, as delineated by genetic and biochemical studies in model organisms including *Drosophila*, *Xenopus*, mice, as well as human colorectal cancer cells, is characterized by a conserved complement of intracellular signaling components that includes the Wnt coreceptors Frizzled and LRP5/6, the β-catenin destruction complex, β-catenin, and a conserved DNA binding complex that is activated by β-catenin. In the absence of Wnts, the destruction complex promotes rapid, proteasomal degradation of β-catenin. When the pathway is activated, β-catenin is stabilized, translocates to the nucleus, and activates target gene transcription. The core components of the Wnt signal transduction machinery will be introduced in more detail in the following section.

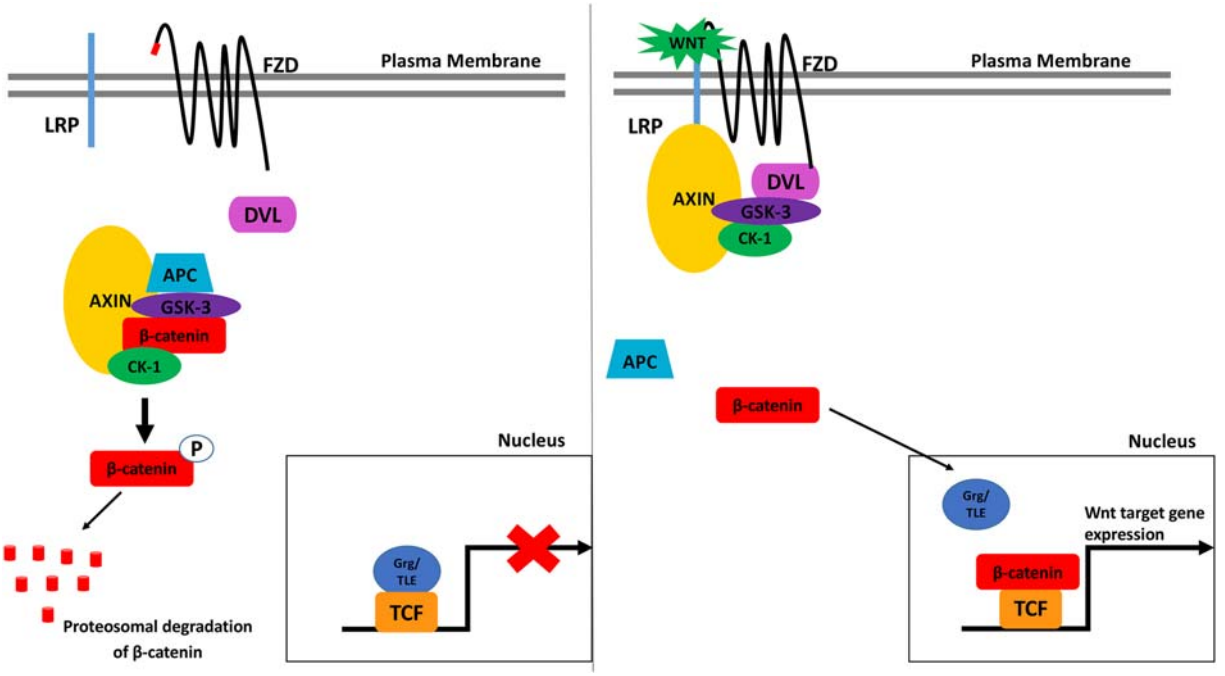

Fig. 1 The canonical Wnt signaling pathway. Panel A: In the absence of Wnts, β-catenin is targeted for destruction by a complex comprising APC, Axin, CK1α, and GSK-3. Sequential phosphorylation by CK-1α and GSK-3 marks β-catenin for ubiquitination by the βTrCP ubiquitin ligase complex and subsequent proteasomal degradation. Panel B: The pathway is activated when Wnts bind to the Fzd CRD and the extracellular domain of LRP, which results in the recruitment of the Axin complex, phosphorylation of the LRP5/6 C-terminus, and inhibition of GSK-3 mediated phosphorylation of β-catenin. Unphosphorylated β-catenin translocates into the nucleus, binds to TCF (or the related factor LEF), displaces the repressor Groucho/TLE, recruits coactivator proteins, and thereby activates transcription of downstream target genes.

Wnt Signaling Components

Wnts

The Wnt family in mammals consists of 19 secreted glycoproteins with conserved spacing of multiple cysteine residues. Wnts are posttranslationally modified, including N-linked glycosylation and palmitoylation at a unique serine residue within a highly conserved sequence motif. Palmitoylation has been proposed to play a role in secretion, receptor binding, and tethering of the ligand to extracellular surfaces. Wnt palmitoylation occurs in the endoplasmic reticulum and requires Porcupine (Porc); Wnts are then escorted to the membrane for secretion by Wntless (Wls). The significance of multiple Wnt genes is still not well understood, although they have been broadly subcategorized into "canonical" Wnts (e.g., Wnt1, Wnt3a), which activate β-catenin-dependent transcriptional programs, transform mammary cells, and induce dorsal development in *Xenopus*, and "noncanonical" Wnts (e.g., Wnt5a/b), which have diverse functions, including regulation of polarized cell movements, and appear to activate distinct intracellular signaling pathways. However, this distinction may depend more on the complement of Wnt receptors present in the receiving cell as well as potential synergistic interactions between different Wnt proteins.

The palmitoylation of Wnts markedly reduces their solubility and has limited the biochemical analysis of Wnt proteins, but a crystal structure was recently solved for *Xenopus* Wnt8 in complex with the extracellular domain of the Wnt receptor Frizzled8 (Fzd8). This structure revealed that Wnt8 binds to the Fzd extracellular domain at two sites with the palmitoyl group (site 1) partially bound to a hydrophobic groove in Fzd. This groove only buries 60% of the palmitoyl group, however, with the remainder of this hydrophobic surface apparently exposed to solvent. Unexpectedly, mutation of the acylation site reduces but does not eliminate the binding or activity of Wnt8, Wnt3a, and the *Drosophila* Wnt1 homolog wingless (wg). Furthermore, non-Wnt ligands such as Norrin, which is not acylated, and "surrogate" Wnt ligands that lack the acylation site also bind the Fzd CRD and activate signaling. The activity of Wnt proteins lacking the conserved palmitoylation site raises the possibility that acylation serves an alternative function, such as restriction of diffusion by tethering the ligand to the plasma membrane.

Frizzleds and LRP5/6

In the canonical pathway, Wnts bind to a surface receptor complex that includes Frizzled (Fzd) and the coreceptor LDL receptor-related proteins 5 or 6 (LRP5/6). There are 10 mammalian Fzds, each containing an extracellular cysteine-rich domain (CRD) that binds Wnts, 7 transmembrane domains, and an intracellular carboxy-terminal domain that is not well conserved among

the different family members. Although Fzds are topologically similar to G-protein coupled receptors, the sequence similarity is limited.

LRP5/6 are type 1 membrane receptors that are 70% identical to each other and are functionally redundant in most instances. These single transmembrane receptors contain an extracellular domain made up of four tandem β-propeller/epidermal growth factor repeats and three LDLR type A repeats. Wnts bind initially to Fzd with high affinity and then bind to the extracellular domain of LRP to form a bridge between LRP and Fzd. This interaction leads to recruitment of Disheveled, phosphorylation of the LRP5/6 by glycogen synthase kinase-3 (GSK-3) and casein kinase-1, and recruitment of the destruction complex to the intracellular plasma membrane.

Disheveled

Disheveled (Dvl, Dsh) functions downstream of Frizzled and is required for the transmission of Wnt signals. It contains a Disheveled–Axin interaction (DIX) domain that can bind to Axin or to itself and a central PDZ domain that interacts with Frizzled. When Wnts bind to Frizzled and LRP, Disheveled is recruited to Frizzled. Disheveled can then oligomerize via the DIX domain, and this has been proposed to form a docking site for the Axin complex, described below.

Axin

Axin is a cytosolic scaffold for core Wnt signaling components, including Dvl, APC, casein kinase 1α (CK1α), GSK-3, and β-catenin. The Axin complex serves two, seemingly opposing functions in the Wnt pathway. Recruitment of the Axin complex to LRP5/6 is essential for pathway activation, yet, in the absence of Wnts, the complex inhibits the pathway by facilitating the degradation of β-catenin. Thus, loss of function mutations in *Axin* activate Wnt signaling, induce dorsal axis duplication in mouse and *Xenopus* embryos (hence the name "Axin" for axis inhibitor), and promote carcinogenesis. Axin binds to APC through the N-terminal RGS domain, which bears sequence similarity to regulators of G protein signaling but lacks a key residue conserved in RGS proteins. The GSK-3 interaction domain (GID) and the CK1α binding sites are adjacent to the β-catenin interaction domain, facilitating sequential phosphorylation of β-catenin. In addition to β-catenin, GSK-3 phosphorylates Axin to regulate its stability and increase binding to APC and β-catenin. Axin also interacts with itself through a dimerization domain in the C-terminus and has been reported to interact with multiple other signaling molecules, including protein phosphatases-1 and 2A and the tuberous sclerosis complex.

Mammals have two *Axin* genes; *Axin1* and *Axin2*. *Axin1* is expressed ubiquitously and is likely the predominant form involved in basal Wnt suppression and LRP phosphorylation. *Axin2* expression (also known as *Axil* or *conductin*) is generally induced by Wnt pathway activation and is considered a feedback inhibitor of the pathway. *Axin2* also serves as a useful expression marker for pathway activation.

APC

APC is a classical tumor suppressor gene that encodes an approximately 310 kd protein. In addition to antagonizing Wnt signaling by promoting β-catenin degradation, APC regulates cell adhesion, migration, chromosome segregation, spindle assembly, apoptosis, and neuronal differentiation. APC contains multiple conserved functional domains (Fig. 2). The domains involved in Wnt signaling are located in the central part of the protein. In vertebrate APC, these include three 15-amino acid repeats and seven

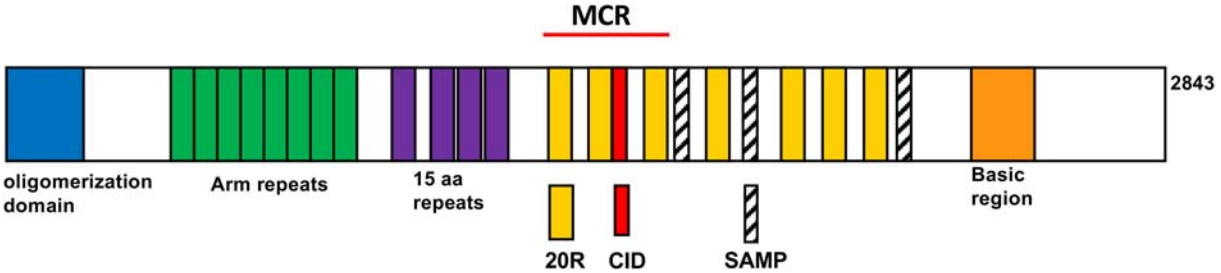

Fig. 2 APC conserved functional domains. APC contains multiple conserved functional domains involved in the regulation of pathways such as cell adhesion, migration, chromosome segregation, spindle assembly, apoptosis, and neuronal differentiation. The domains involved in Wnt signaling include (in vertebrate APC) four 15-amino acid repeats (*purple*) and seven 20-amino acid repeats (*yellow*), all of which bind to β-catenin except the second 20 amino acid repeat; three Ser-Ala-Met-Pro (SAMP) repeats (*hatched*), which bind to the RGS domain of Axin; and a β-catenin inhibitory domain (CID; *red*). Most truncating mutations in *APC* occur in the mutation cluster region (MCR), indicated here by a *solid line*. APC also contains an N-terminal oligomerization domain and a C-terminal basic region that interacts with microtubules.

20-amino acid repeats, all of which bind to β-catenin except the second 20-amino acid repeat; three Ser-Ala-Met-Pro (SAMP) repeats, which bind to the RGS domain of Axin; and a β-catenin inhibitory domain (CID). The CID and second 20-amino acid repeat are required for suppression of Wnt signaling, although neither motif binds to β-catenin. Truncating mutations in APC associated with Wnt pathway activation and carcinogenesis frequently occur in the mutation cluster region (MCR), preventing expression of these motifs. Furthermore, a fragment of APC encoding these motifs can restore normal levels of Wnt signaling and reverse APC mutant phenotypes.

However, the mechanism by which APC suppresses Wnt signaling is not well understood. Several hypotheses to explain APC's role in the destruction complex have been put forward. APC may recruit β-catenin to the destruction complex, protect β-catenin from dephosphorylation to ensure subsequent ubiquitination and degradation, act as an additional scaffold for the complex, or facilitate the transfer of phosphorylated β-catenin from the Axin scaffold to the proteasome, as APC competes with Axin for the same binding sites on β-catenin. Alternatively, APC may enhance the enzymatic activity of GSK-3 to increase phosphorylation of β-catenin; as Wnt pathway activation causes dissociation of APC from the Axin complex, this latter hypothesis can also explain how Wnt signaling reduces GSK-3 enzymatic activity and thereby reduces β-catenin phosphorylation.

Protein Kinases GSK-3α/β and CK1α

The Axin complex drives β-catenin turnover by supporting sequential phosphorylation by CK1α and GSK-3. CK1α provides a priming phosphorylation at serine-45 of β-catenin that is essential for subsequent phosphorylation by GSK-3 at threonine-41, serine-37, and serine-33. GSK-3 also phosphorylates APC and Axin; phosphorylation of Axin increases binding with β-catenin and increases the stability of Axin. Mammals have two GSK3 genes, *GSK3A* and *GSK3B* which encode the highly homologous and mostly redundant isoforms GSK-3α and GSK-β (here referred to collectively as GSK-3). Both isoforms of GSK-3 are constitutively active serine/threonine kinases that suppress Wnt signaling, glycogen synthesis, and signaling through Akt, hedgehog, Hippo, and mechanistic target of rapamycin complex-1 (mTORC1) dependent pathways. Thus, inhibition of GSK-3 activates downstream signaling in each case. For example, insulin signaling inhibits GSK-3 by a phosphatidylinositol 3-kinase (PI3K)/Akt-dependent mechanism; Akt phosphorylates GSK-3 on an N-terminal serine (serine-21 in GSK-3α and serine-9 in GSK-3β), which inhibits GSK-3 activity by creating a pseudo-substrate. Wnt signaling inhibits GSK-3 activity through a completely separate mechanism unrelated to N-terminal phosphorylation. GSK-3 involved in Wnt signaling is sequestered in the Axin complex and inaccessible to Akt. Several distinct but nonexclusive mechanisms for Wnt-mediated GSK-3 inhibition have been proposed. As above, Wnt-induced dissociation of APC from the Axin complex may reduce GSK-3 activity within the complex; alternatively, the phosphorylated C-terminus of LRP5/6 can inhibit GSK-3 directly; additionally, sequestration of Axin and GSK-3 into multivesicular bodies has been proposed to suppress GSK-3 phosphorylation of β-catenin although this is likely too slow to account for the rapid inhibition of GSK-3 by Wnts.

β-Catenin

β-Catenin, encoded by the *CTNNB1* gene, was first recognized for its role in cadherin-based adherens junctions that stabilize cell–cell contacts where the vast majority of β-catenin is sequestered (in epithelial cells). β-Catenin was subsequently shown to have an independent role in activation of transcription of Wnt target genes. β-Catenin contains 12 armadillo repeats that bind to both APC and Axin. As described above, phosphorylation of Axin-bound β-catenin by CK-1 and GSK-3 marks β-catenin for ubiquitination and proteasomal degradation. This pool of rapidly turned over β–catenin is distinct from cadherin-associated β-catenin, which has a substantially longer half-life. Wnt activation stabilizes cytosolic β-catenin, which then enters the nucleus where it binds TCF/LEF family proteins and activates transcription. β-Catenin contains both N- and C-terminal activation domains. The N-terminal activation domain binds the coactivator Pygopus through the adaptor protein Bcl9. The C-terminal activation domain, distal to the armadillo repeats, binds the histone acetyltransferase CBP or p300. β-Catenin also recruits the protein arginine methyltransferase PRMT2, which is required for Wnt signaling in *Xenopus* and colorectal cancer cell lines.

TCF/LEF

T-cell factor (TCF)/lymphoid enhancer factor transcription factors are the major nuclear mediators of the Wnt signaling pathway. They contain a conserved high mobility group (HMG) box and a basic tail which together comprise the DNA-binding domain. In the absence of β-catenin (e.g., Wnt signaling off), TCF/LEF repress transcription of Wnt target genes due to recruitment of a repressor complex that includes Groucho/transducin-like enhancer of split (TLE) and histone deacetylases. When the pathway is activated, β-catenin binds to a conserved motif near the amino terminus, displaces Groucho/TLE, and activates transcription of target genes. TCF/LEF proteins display considerable heterogeneity as a result of alternative promoters and mRNA splicing, and this allows for Wnt signals to be interpreted differently in terms of gene targeting, as well as interacting with specific repressors or activating cofactors.

Pathway Inhibitors

This section describes core components of the canonical Wnt signaling machinery, but it should be emphasized that many more factors have been implicated at each step of this signaling cascade. Although a full description is beyond the scope of this article, it should be noted that multiple Wnt pathway inhibitors and coactivators have been described. For example, the secreted factors dickkopf (dkk), frizzled related proteins (sFRPs), Wnt inhibitory factor (WIF), Notum, and sclerostin interfere with Wnt binding to the Fzd CRD or to LRP5/6, whereas R-spondin is a secreted factor that potentiates canonical Wnt signaling in intestinal stem cells through its interaction with the Lgr receptor family. In addition, several Wnt induced intracellular antagonists have been described, including Axin2 (see above), Naked cuticle (Nkd), and, in intestinal cells, the transmembrane E3 ubiquitin ligases Rnf43 and Znrf3.

Putting It Together: Activation of Wnt Signaling

In the absence of Wnts, β-catenin is targeted for destruction by a complex comprising APC, Axin, CK1, and GSK-3. Sequential phosphorylation by CK-1 and GSK-3 marks β-catenin for ubiquitination by the β-transducin repeat–containing protein (βTrCP) ubiquitin ligase complex and subsequent proteasomal degradation. The pathway is activated when Wnts bind to coreceptors Fzd and LRP which results in the recruitment of the Axin complex to LRP5/6, phosphorylation of the LRP5/6 C-terminus, and inhibition of GSK-3 mediated phosphorylation of β-catenin. Unphosphorylated β-catenin translocates into the nucleus, binds to TCF/LEF, displaces the repressor Groucho/TLE, recruits coactivator proteins, and thereby activates transcription of downstream target genes, including Axin2, cyclinD1, and many others.

Wnt Signaling and Intestinal Stem Cells

Intestinal Stem Cells

Intestinal epithelial cells are repeatedly exposed to pathogens, xenobiotics, and other toxic agents and must be able to regenerate rapidly after damage. This ability to regenerate depends on a robust intestinal stem cell (ISC) compartment that includes actively proliferating crypt base columnar (CBCs) stem cells, in which canonical Wnt signaling induces expression of *Lgr5* and mitotic self-renewal, as well as a distinct, rare population of slowly cycling ISCs lacking canonical Wnt pathway activity referred to as reserve stem cells.

$Lgr5^+$ CBCs give rise to cycling transit amplifying progenitors and all differentiated cell types in the intestinal epithelium, as shown by lineage tracing. Although genetic ablation of $Lgr5^+$ cells indicated that they are dispensable for intestinal homeostasis under basal conditions, they are essential for a robust regenerative response to genotoxic treatments such as irradiation. The expendable nature of $Lgr5^+$ CBCs during intestinal homeostasis as well as the sensitivity of CBCs to DNA damage suggested that a distinct population of intestinal epithelial cells compensate for CBC loss.

Reserve ISCs are distinct from CBCs and are indispensable for epithelial homeostasis under basal conditions. These cells were first identified by insertion of a Cre recombinase dependent reporter into the *Bmi1* gene, but cells that share characteristics of $Bmi1^+$ cells have since been identified, including those marked by insertion of CreER into *Hopx*, *mTert*, and subpopulations of much larger groups of cells marked by broadly expressed reporters inserted into *Krt19*, *Lrig1*, *Axin2*, and *Sox9*. Reserve ISCs are characterized by limited response to Wnt signals, slow cycling relative to CBCs under basal conditions, resistance to DNA damage, and a strong proliferative response to such injury. They are also referred to as "quiescent" stem cells and as '+4' cells based on their position above the crypt base, although several different cell types have been observed at this position.

Although reserve stem cells are refractory to Wnt signaling, they give rise to Wnt-responsive CBCs during intestinal homeostasis and after injury consistent with a model in which reserve stem cells reside upstream of more active and shorter-lived, Wnt-driven CBC stem cells. Interconversion between these active and dormant stem cell states, however, remains a possibility.

Wnt Signaling in ISC Homeostasis

Wnt signaling is required for crypt base proliferation, differentiation into secretory cells, and migration along the crypt-villus axis. The role of Wnt signaling in intestinal crypt biology was demonstrated in one of the earliest functional studies through disruption of the *Tcf7l2 (Tcf4)* gene, which caused loss of proliferative compartments in the intestinal epithelium of neonatal mice. Similarly, inhibition of Wnt signaling in adult intestinal epithelial cells, either by deletion of *Tcf7l2* or overexpression of the Wnt inhibitor *Dickkopf 1* (*Dkk1*), caused loss of CBCs and decreased epithelial proliferation. Conversely, CBC-specific activation of the Wnt pathway, for example, by inactivating *APC*, enhances proliferation of ISCs and leads to adenoma formation, as described in greater detail below.

The importance of Wnt signaling for maintenance of the intestinal epithelium raises questions about the source of the Wnt ligand in the ISC niche and its range of action. Paneth cells secrete Wnt3 and were hypothesized to form the CBC niche. However, genetic deletion of Paneth cells had no effect on CBCs or intestinal homeostasis under basal conditions and did not affect regeneration following radiation injury. Furthermore, selective deletion of *Wnt3* or inhibition of Wnt secretion in epithelial cells had no effect on ISC activity, suggesting a nonepithelial source of Wnt. In contrast to Paneth cell ablation, ablation of a rare population of $Foxl1^+$ subepithelial cells (termed telocytes), which express *Wnts* and other niche factors, impairs Wnt signaling and proliferation in

the ISC compartment. Furthermore, knockout of *porcupine*, which is required for Wnt processing and secretion, in *Foxl1*$^+$ telocytes blocks Wnt signaling responses in intestinal crypt cells and impairs ISC maintenance and renewal, demonstrating that *Foxl1*$^+$ telocytes are a critical source of Wnts for ISCs.

Wnt target gene expression is graded in the intestinal epithelium, declining as cells progress away from the crypt base. Although this might suggest a gradient of extracellular Wnt protein, the palmitoylation of Wnts markedly limits their solubility and likely their diffusion in the intestinal epithelium. Consistent with this, newly secreted Wnt3 in intestinal organoid cultures appears to bind only to adjacent cells, and distribution of Wnt3 away from its source was proposed to occur through cell division rather than extracellular diffusion. In *Drosophila*, a membrane tethered form of Wingless (Wg) can replace the endogenous protein in the imaginal disk; apparent action at a distance from the source of ligand was shown to be due to exposure from adjacent cells at an earlier stage of development, followed by separation of secreting and responding cells due to cell division, and, at a later stage of development, delayed activation of Wg target genes through "memory" of the prior exposure to Wg. We hypothesize that this memory could be explained by Wnt-dependent chromatin modifications conferring epigenetic memory for prior Wnt exposure, as demonstrated for Wnt responses in *Xenopus* embryos. A similar "memory" of Wnt exposure could also account for Wnt responses in cells that were once adjacent to, but are now distant from the source of Wnt in the intestinal crypt.

These studies have established the hierarchical nature of the ISC within the intestinal crypt, the complexity of the ISC niche, the importance of epithelial and mesenchymal cell interactions, and the central role of Wnt signaling (as well as other secreted factors) in intestinal epithelial homeostasis. Disruption of this complex regulatory system interferes with intestinal homeostasis. For example, the *Clostridium difficile* toxin TcdB, binds to the extracellular domain of Fzds in intestinal cells and inhibits Wnt signaling, and this has been proposed as a pathogenic mechanism for *C. difficile* colitis. In contrast, mutations that inappropriately activate Wnt signaling lead to adenoma formation and cancer, as described in the next section.

Wnt/β-Catenin Signaling in Cancer

Genetic analysis of inherited cancer predisposition syndromes together with molecular, biochemical, and developmental biology studies have established the central importance of genetic lesions that activate key signaling pathways in multiple cancers including colorectal cancers. A key to this line of investigation was the study of Familial Adenomatous Polyposis (FAP), an autosomal dominant disorder characterized by formation of numerous colonic polyps at a young age, transformation to adenocarcinoma, and multiple extracolonic neoplasms. Genetic analyses of families with FAP identified the *APC* gene on the long arm of chromosome 5 and showed that the disorder is caused by truncating mutations in *APC* followed by loss of the wild-type allele (loss of heterozygosity or LOH). Similar somatic mutations in *APC* were found in approximately 80%–90% of sporadic colon cancers.

The Wnt pathway was linked to colon cancer when it was found that APC interacts with both β-catenin and GSK-3, and additionally that truncating mutations in *APC* stabilize β-catenin protein and constitutively activate downstream Wnt signaling. *APC* is the most commonly mutated gene in sporadic colorectal cancer, and *APC* mutations are among the earliest driving mutations in the transformation to cancer. The majority of these mutations occur in the "Mutation Cluster Region" (MCR), a region spanning the central region of the protein and containing the 20 amino acid repeats, the SAMP repeats, and the CID (**Fig. 2**). These mutations are often frameshift or point mutations leading to premature termination and expression of a truncated protein lacking the SAMP repeats and other Wnt signaling motifs. Subsequent loss of the wild-type copy of APC then activates Wnt signaling. Importantly, expression of full-length *APC* can rescue colorectal cancer cells back to functioning "normal" cells in vivo even in the presence of activated *KRAS* and *p53* loss of function mutations. Furthermore, expression of an *APC* gene fragment containing the Wnt signaling motifs restores turnover of β-catenin, suppresses Wnt signaling, and rescues *Apc* loss of function phenotypes in animal models. There may be selective pressure for mutations in the MCR in colorectal cancer, as larger deletions in *APC* are uncommon, possibly because the N-terminal region of APC serves a vital function and/or that the truncated *APC* alleles achieve an intermediate level of Wnt/β-catenin signaling that is critical for neoplastic transformation.

Although *APC* mutations are found in ~80% of colon cancers, a substantial fraction of colon cancers with wild-type *APC* have gain of function mutations in *β-catenin/CTNNB1* that prevent phosphorylation and thereby stabilize the protein, providing compelling genetic support for the core roles of APC and β-catenin in Wnt signaling and colon cancer. *CTNNB1* mutations are also found in cancers that occur outside the gut, such as endometrioid ovarian cancer.

Somatic mutations in *Axin (Axin1)* and *Axin2* have also been found in sporadic cancers, including hepatocellular, colorectal, and other cancers. As reviewed elsewhere, the role of *AXIN1* loss of function mutations in HCCs is well supported, but the functional significance of *AXIN1* and *AXIN2* sequence variants in colorectal cancer remains to be established.

Constitutive activation of Wnt signaling is an essential early step in the development of colorectal cancer, but additional steps are required for malignancy. This was evident from the observations that FAP patients develop hundreds to thousands of adenomas due to LOH for *APC*, but only a few of these transform to cancer. Similarly, up to 50% of adults will develop colonic adenomas associated with LOH for *APC*, but only a fraction of these will develop cancer. Furthermore, *APC* mutations initially cause microadenomas and dysplastic aberrant crypt foci without morphological evidence of malignancy, indicating that additional steps are required for progression to cancer.

These and other observations led to the model that *APC* serves a gatekeeper function in the pathogenesis of colon cancer and that additional mutations are required in the progression to malignancy. The most common mutations include activating mutations in *KRAS* (found in 40% of sporadic CRCs), loss of the tumor suppressor *p53*, as well as mutations that either inactivate transforming

growth factor-β signaling or activate phosphatidylinositol-3 kinase (PI3K) signaling pathways. These mutations by themselves do not transform colon epithelia; for example, *p53* mutations are found in 80% of CRCs but germline mutations in *p53* do not predispose to CRC in the absence of *APC* mutations. Similarly, activating mutations in *KRAS* by themselves do not lead to CRC. A whole exome sequencing study of breast and colon tumors confirmed the high frequency of these mutations in CRC and revealed additional recurrent and potential driver mutations that occur at low frequency in CRC.

Divergence in Canonical Wnt Signaling

Studies of the "canonical" Wnt pathway have generally focused on the regulation of β-catenin stability and activation of Wnt target genes (the "Wnt/β-catenin pathway"). However, accumulating evidence suggests that the Axin/APC/GSK-3 complex is a signaling hub with β-catenin as just one of its multiple effectors (Fig. 3). Wnt signaling through Axin, APC, and GSK-3 stabilizes other proteins, determines mitotic spindle polarity in *C. elegans*, modulates transcription factors in the Hippo pathway, and activates mammalian target of rapamycin complex-1 (mTORC1) signaling. A truncating mutation in zebrafish *apc* also causes multiple β-catenin independent phenotypes.

These findings raise the possibility that β-catenin independent pathways contribute to the effects of *APC* loss in early adenoma formation. The central role of β-catenin is firmly established and further supported by the observations that overexpression of *β-catenin/CTNNB1* generates adenomas in mice and knockout prevents adenoma formation in *APC* mutant mice. However, nuclear β-catenin is observed infrequently in early FAP adenomas, sporadic human colonic polyps, or microadenomas from a rat FAP model, despite confirmed loss of heterozygosity of *APC* and increased levels of cytosolic β-catenin. Although this may indicate that β-catenin is active in the nucleus below the limit of detection by immunofluorescence, these results also raise the possibility that an increase in β-catenin following *APC* loss is not sufficient to initiate hyperproliferation and microadenoma formation.

An additional signal downstream of *APC* loss may be provided by activation of mTORC1, a nutrient sensor that regulates translation, metabolism, proliferation, and survival and is aberrantly activated in many cancers. mTORC1 is inhibited by the tuberous sclerosis complex (TSC1 and TSC2), and phosphorylation of TSC2 by GSK-3 enhances this inhibitory function. Therefore, inhibition of GSK-3 by loss of APC or upstream activation of Wnt signaling activates mTORC1. Wnt/β-catenin signaling can also increase transcription of TOR, a core component of the mTORC1 complex, and this may also contribute to increased mTORC1 activity in *APC* mutant neoplasms. Furthermore, mTORC1 activity is required for adenoma formation downstream of *APC* loss, as

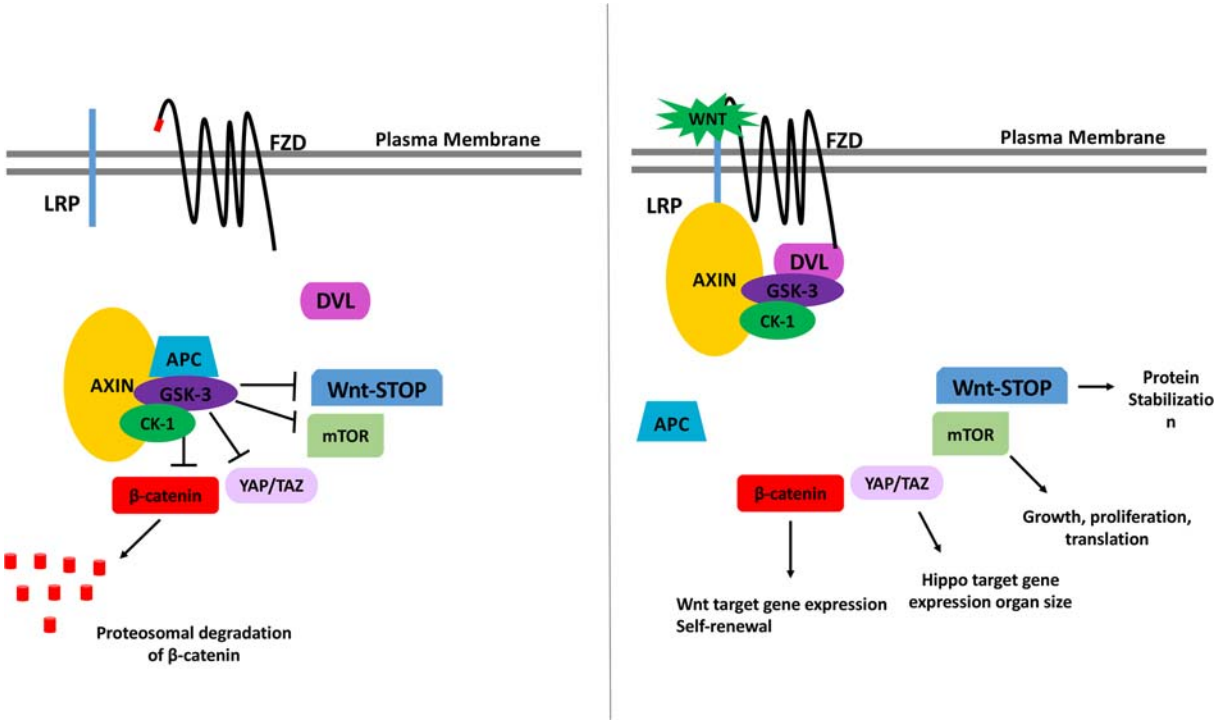

Fig. 3 The canonical Wnt signaling pathway diverges at the destruction complex to regulate β-catenin-independent pathways. In addition to stabilization of β-catenin, Wnt signaling through Axin, APC, and GSK-3 stabilizes other proteins through the Wnt-STOP pathway, modulates transcription factors in the Hippo pathway (e.g., YAP), and activates mammalian target of rapamycin complex-1 (mTORC1) signaling to regulate growth and proliferation. The "T" symbols in the left panel indicate inhibition and the *arrows* in the right panel indicate activation.

pharmacologic inhibition of mTORC1 blocks adenoma formation in *Apc* mutant mice. Thus, loss of *APC* may activate mTORC1 through β-catenin independent as well as β-catenin-dependent signaling.

The activation of mTORC1 by *APC* truncation mutations suggests an intriguing parallel between FAP and other hereditary disorders that are associated with mTORC1 activation and which cause neoplasias in multiple organs, including tuberous sclerosis, Peutz–Jeghers syndrome, and Cowden's syndrome. Tuberous sclerosis complex (TSC) is an autosomal dominant disorder associated with hamartomatous tumors of multiple organs caused by germline loss of either *TSC1* or *TSC2* which in turn activates mTORC1. Peutz–Jeghers and Cowden's syndromes similarly cause hamartomatous polyposis in multiple organ systems. Peutz–Jeghers syndrome is caused by mutations in LKB, an upstream positive regulator of TSC2, so that loss of LKB indirectly activates mTORC1. Similarly, Cowden's syndrome is caused by loss of function mutations in *PTEN*, which activate AKT and thereby also activate mTORC1. Although these syndromes are clinically and pathologically distinct, they share mTORC1 activation. This also raises the possibility that mTORC1 inhibitors currently in use clinically could be repurposed to control the extracolonic manifestations of FAP.

Hippo signaling regulates organ size through inhibition of protein kinases resulting in stabilization of the transcription factors YAP and TAZ. YAP is necessary for adenoma formation resulting from the loss of *APC* in mice and is activated in tubular adenomas of FAP patients. APC regulates other β-catenin-independent processes that may contribute to *APC* loss of function pathology, including retinoic acid synthesis, protein stability (Wnt/STOP), microtubule stability and polarity, as well as the BMP and ERK signaling pathways.

Therapeutic Targeting of the Wnt Pathway in Cancer

The Wnt pathway has been considered difficult to target with small molecule inhibitors, as the most "druggable" targets, enzymes such as GSK-3, CK1α, and ubiquitin ligase, inhibit the pathway, Indeed, GSK-3 inhibitors are used extensively to activate Wnt signaling, for example, in the culture of pluripotent stem cells, maintenance of somatic stem cells, and organoid culture. In contrast, positive regulators function mostly through protein–protein interactions (Wnt, Fzd, LRP, β-catenin), which are inherently more difficult to target with small molecules. However, a number of small molecules as well as protein-based inhibitors have been developed that target multiple steps in the pathway, from processing and secretion of Wnts to transcriptional activation by the β-catenin/TCF complex. For example, small molecules that inhibit the acyltransferase activity of Porc and thereby reduce secretion of Wnts have been tested in animal models and are in phase I clinical trials. Small molecule inhibitors of tankyrase, a poly ADP-ribose polymerase that targets Axin for degradation, inhibit Wnt signaling by increasing Axin levels to promote β-catenin turnover. Several tankyrase inhibitors have been tested in preclinical models and while significant gastrointestinal toxicity has limited their clinical use, inhibitors such as XAV939 have been useful in the laboratory for in vitro pathway analysis. PRI-724 is a small molecule inhibitor of β-catenin/CBP interaction that has been tested in preclinical models and a phase I clinical trial for pancreatic cancer, and other small molecules that interfere with β-catenin/TCF and β-catenin/Bcl9 interactions have been tested in preclinical models. Neutralizing antibodies to the Fzd CRD as well as Fzd-mimetic polypeptides have also advanced to phase I trials. An in-depth description of Wnt pathway inhibitors can be found in Krishnamurthy and Kurzrock (see Further Reading).

Conclusions

Years of research on a variety of model organisms as well as genetic and molecular investigation of human cancers have delineated the canonical Wnt signaling pathway, which is activated by secreted ligands termed Wnts resulting in the transcription of Wnt target genes. This highly conserved pathway is critical in normal development as well as stem cell homeostasis, and yet overactivation is an early step in cancer pathogenesis, as first established through characterization of mutations in *APC* and *β-catenin/CTNNB* in both hereditary and sporadic colon cancer in humans. The field is now at a point where our understanding of the pathway can be exploited for therapeutic interventions. Currently pharmacological activation of the pathway is a key tool in regenerative medicine and in the maintenance of embryonic and somatic stem cells. Conversely, inhibiting the pathway is a major goal in the treatment of colon cancer and other Wnt-driven malignancies. The Wnt pathway had traditionally been thought of as difficult to inhibit pharmacologically because most of the activating steps involve protein–protein interactions rather than more easily targeted enzymatic steps. However, numerous drugs targeting various points along the pathway are now at advanced stages of development including drugs that inhibit processing of Wnts, binding to the receptors, stability of β-catenin, or function of the Wnt-dependent transcription complex. Cancers associated with Wnt activation invariably require multiple mutations in other genes, including activating mutations in proto-oncogenes and inhibitory mutations in tumor suppressor genes, raising concern that targeting the Wnt pathway alone may not be sufficient to control an advanced malignancy. However, reexpression of *APC* in mouse intestinal tumor models ameliorates the cancer phenotype, providing hope that Wnt pathway inhibitors will have a beneficial clinical impact on the course of human malignancies.

Xeroderma Pigmentosum: When the Sun Is the Enemy

Alain Sarasin, Paris-Sud University, Villejuif, France
Carlos FM Menck, University of São Paulo, São Paulo, Brazil
Januario B Cabral-Neto, Federal University of Rio de Janeiro, Rio de Janeiro, Brazil

Glossary

Lentigines Dark spots that appear in the skin as a result of sunlight exposure.
Nucleotide excision repair (NER) Molecular pathway that acts on the removal of bulky DNA damage. Defective in most XP patients.
Translesion DNA synthesis Molecular pathway that allows the replication of a damaged DNA template. Defective in XP variant patients.
Unscheduled DNA synthesis DNA synthesis induced by NER, and not due to S-phase DNA replication.
Transcription coupled repair NER subpathway, where DNA damage is removed in actively transcribed genes.
Global Genome repair NER subpathway, where DNA damage is removed in the genome in general, independent of transcription.
Chromophores Molecules inside the cells that may absorb light with various wavelengths and generate reactive molecules, damaging many cell structures.

Introduction

Life is not easy for patients who suffer with Xeroderma Pigmentosum (XP), nor for their relatives, who take care of them. Their main enemy is outside their houses: just opening the door as sunlight hurts them. The same sunlight that provides energy and life for the living beings is what they have to avoid, living as much as possible in the dark, changing day activities to night and day, whenever this is feasible. Their skin is dry (from the Greek words *xero* and *derma*) and highly pigmented (from the Latin word *pigmentosum*), but these manifestations are restricted to the areas of the skin that are commonly exposed to sunlight. This often implies the face, which is highly affected, together with their limbs and hands. The skin of XP patients presents hyperpigmentation with lentigines and freckles, although hypopigmentation is also observed in highly exposed individuals and in black-skinned patients. Precancerous skin lesions, such as actinic keratosis, occur early in the life of unprotected patients, and they develop skin tumors (nonmelanoma and melanoma) before youth. The frequency of skin tumors was estimated 10,000-fold higher for nonmelanoma and 2000-fold for melanoma before the age of 20 years old, in XP patients compared to the general population. As many frequent tumors may appear in their faces, the surgical removal may leave rough scars, with eventual need of grafts and/or the use of prostheses. Certain areas of the face, such as mouth, tip of the tongue and eyes, may also be affected, including with the development of tumors, especially in persons with darker skin. The skin lesions are the most common clinical phenotype for XP patients, although internal tumors may also have increased prevalence (10-fold). About 20%–30% of these XP patients present developmental problems, as well as neurological degeneration and premature aging phenotypes.

The incidence of this autosomal recessive disease is low, and occurs sporadically in families. The first estimated incidence in United States was 1 case per 250,000 and in a more recent detailed study in Western Europe indicated 2.3 per million of autochthonous livebirths. The North of Africa and Japan have reported higher incidence of XP (1 per 20,000–50,000), and this was associated with the occurrence of founder-mutated alleles in high frequency. Interestingly, at least three isolated communities were described in the world with numerous XP patients, due to consanguineous marriages and closed environment.

The first clinical description of XP patients was made in 1874 in Austria, by the dermatologists Ferdinand Ritter von Hebra and Moritz Kaposi, and the clinical symptoms were associated to sunlight exposure, as an inherited disease. Later, a more severe form of XP associated with microcephaly, progressive neurological degeneration and retarded growth was also described, which was called De Sanctis-Cacchione syndrome (DSC). The molecular defect responsible for this disease was discovered in 1968, when James Cleaver detected that cells from these patients were very sensitive to ultraviolet (UV) light, and unable to perform repair synthesis (unscheduled DNA synthesis-UDS), and thus, deficient in removing UV-induced DNA lesions.

This was the first discovery of a human disease to be associated with a molecular defect in the processing of DNA. The cells from the patients were, in general, very sensitive to UV light, as they are unable to remove the UV-induced lesions on DNA. These cells are also very sensitive to and unable to repair other bulky lesions, as those induced by some human chemical carcinogens, such as aflatoxins, or some drugs used for cancer chemotherapy, such as cisplatin. This lack of DNA repair results in increased mutagenesis in cells exposed to UV, in a clear association with the clinical phenotype of increased skin tumor formation in XP patients. Clever experiments, promoting in vitro fusion of cells from two different patients, directed to the identification of genetic complementation groups, when results indicated the recovery of normal repair synthesis (UDS). These experiments led to the discovery of seven

complementation groups, called XP-A to XP-G, which were, later, confirmed by the isolation of the seven genes that, when mutated and in homozygosis in the same individual, result in the disease. The molecular roles of the proteins encoded by these genes were dissected with in vitro experiments, where the whole DNA repair pathway for lesion removal was reconstituted. Basically, these seven proteins are part of a complex repair machinery, known as Nucleotide Excision Repair (NER) that removes lesions, which distort the DNA helix (including those induced by UV).

Interestingly enough, some XP patients were reported to have cells with normal UDS and, thus, no defects in NER. They were called XP variants, or XP-V. These cells were, however, unable to replicate the DNA after UV-irradiation, although they efficiently removed the lesions. Later, the XPV protein was shown to be a DNA polymerase (Pol η) that promotes the translesion synthesis (TLS) in a damaged DNA template. Thus, cells from XP-V patients are unable to bypass correctly the UV-induced lesions, increasing mutagenesis and cancer incidence.

As commented above, 20%–30% of the XP patients have developmental and progressive neurologic degeneration symptoms, suggesting premature aging clinical phenotypes. These patients may be DSC, but also reproduce the symptoms very similar to the Cockayne syndrome (CS), and are normally called XP/CS. A defect of the recovery of RNA synthesis of UV-irradiated cells from CS patients was identified. These problems in the transcription of damaged DNA allowed the identification of two genes (*CSA* and *CSB)* that encode proteins related to the recognition of DNA lesions in actively-transcribed genes, a subpathway of NER. Cells from these XP/CS patients also present defects in the transcription of damaged DNA, but involving mutations in the *XPB*, *XPD* or *XPG* genes. Other syndromes were also related to defects in NER, such as trichothiodystrophy (TTD), cerebro-oculo-facio-skeletal syndrome (COFS) and XPF-ERCC1 progeroid (XFE) syndrome. These very rare syndromes in general involve transcription impairments, and, clinically, present symptoms related to neurological deficiencies and premature aging. Finally, a mild genetic disorder, where the patients present skin photosensitivity without neurological impairment, was described as UV-sensitive syndrome ($UV^{S}S$), which have also a defect in NER caused by mutations in *CSA* or *CSB* genes.

The Sunlight Produces DNA Damage

Although the UV component of sunlight has many health benefits to human kind, as the main source of Vitamin D in our bodies and induction of sensation of happiness, it also induces DNA damage in the skin with deleterious consequences, such as photoaging and cancer. In fact, UV is part of the spectrum of electromagnetic radiation emitted by the sun, with the following wavelength ranges: UVC (100–280 nm), UVB (280–315 nm) and UVA (315–400 nm) (**Fig. 1**A). The high-energy UVC radiation is completely absorbed by the stratospheric ozone layer, which also absorbs much of UVB. Thus, only UVA and some UVB reach the earth surface and are highly relevant with damaging impacts on human health and ecosystems. Actually, UVA corresponds to 95% of the sunlight UV that reaches humans and it penetrates deeper (compared to UVB) in the skin, up to the basal layer and the dermis (**Fig. 1**B). Therefore, although UVB is highly absorbed by DNA, UVA can also induce severe damage to this molecule, and thus both deserve attention in skin protection, especially for individuals with special sensitivity to sunlight, as the case of XP patients.

The direct absorption of UV by DNA causes covalent reactions especially in adjacent pyrimidines inducing two main types of lesion: cyclobutane pyrimidine dimer (CPD) and pyrimidine (6–4) pyrimidone photoproduct (6-4PP) (**Fig. 1**C). These lesions promote strong distortions on the double helix, and are normally repaired by NER in human cells. Thus, these lesions are considered very dangerous and may be responsible for most of the skin lesions in XP patients, which are unable to remove them. UVB (and the sunlight) irradiation of the DNA molecule induces three-fold more CPDs than 6-4PPs. UVA is little absorbed by DNA, but it was shown to also induce CPDs initially in bacteria and phage DNA, later also shown in human cells and in the human skin, demonstrating the biological relevance of these genotoxic effects by these wavelengths. Interestingly, 6-4PPs were also detected after UVA irradiation in the absence of DNA repair (which is the case for NER-deficient XP patients), promoting increased cell death in XP-A cells.

UVB and, mainly, UVA light may also damage DNA indirectly through the absorption by intermediary molecules, called chromophores, that act as photosensitizers. In fact, many chromophores are present in the human skin and UV absorption may generate organic free radicals, reactive nitrogen species and also reactive oxygen species (ROS), which may react with and damage DNA. Among the endogenous chromophores in the human skin, we find melanin and melanin precursors, porphyrins, heme, bilirubin, tryptophan, etc. The basic mechanisms of photosensitization of these molecules involve the formation of a photoexcited triplet state intermediate, which can directly interact with substrates and generate free radicals and ROS, such as the $O_2^{\bullet -}$, H_2O_2 and hydroxyl radical (•OH) via type I reaction, by energy transfer. This triplet state intermediate can also transfer energy directly to molecular oxygen, via type II reaction, producing singlet oxygen ($^1O_2$), which will react to biomolecules, including DNA. These processes generate different types of lesion, such as strand breaks, formation of base adducts and base (mainly purines) oxidation. One of the most frequent and known products of these reactions is the oxidation of guanine, producing primarily 8-oxo-7, 8-dihydroguanine (8-oxoG). Recently, the formation of $^1O_2$, and consequently 8-oxoG, was described after UVA irradiation of DNA molecule, which acts as a direct photosensitizer.

The induction of DNA damage by UVA and UVB are directly linked to the human risk to develop skin cancer, such as malignant melanoma and the nonmelanoma tumors, basal cell and squamous cell carcinomas. Thus, UV radiation was classified as a class I carcinogen by the Word Health Organization, and one of the most dangerous environmental source of cancer in humans. Thus, exposure to UV radiation depends on individuals' behavior and avoiding the sun, especially in children, is strongly recommended, particularly around noontime where the maximum of UVB is reaching the earth. However, in recent decades, the use of artificial UV

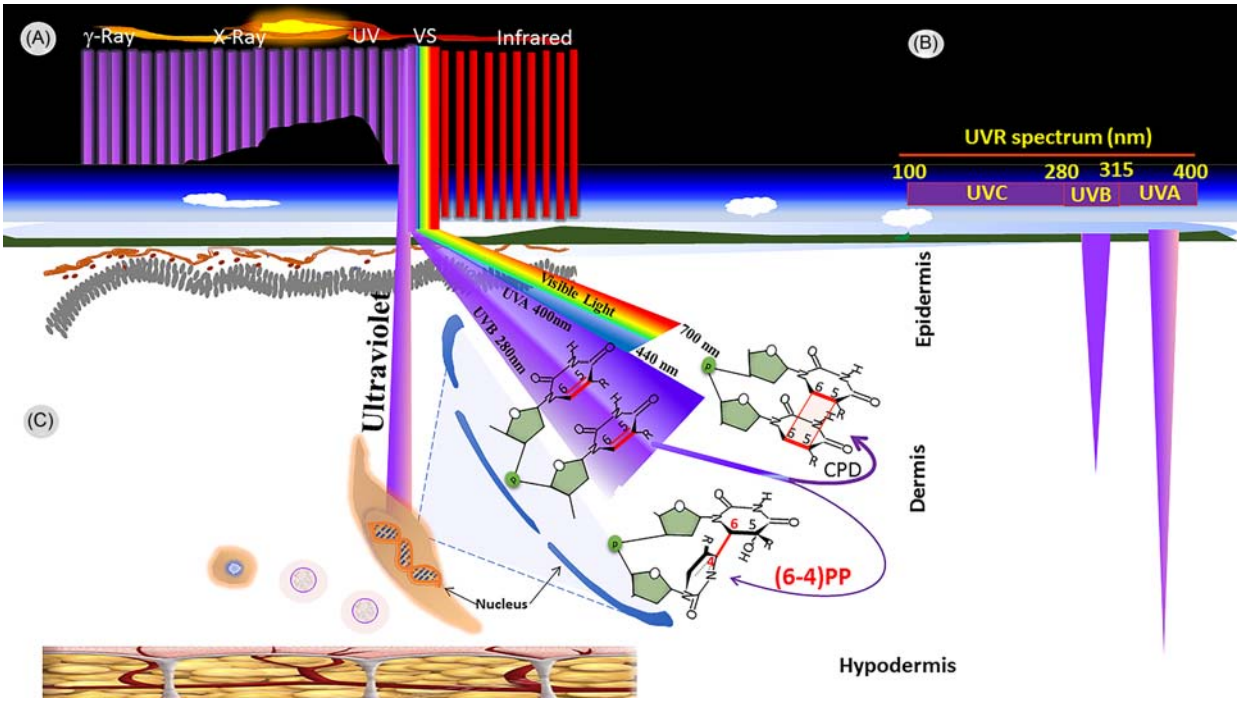

Fig. 1 *Sunlight spectrum and UV-induced DNA damage.* (A) The solar radiation, entering the atmosphere, is composed of mainly infrared light and visible light, with a smaller proportion (10%) of ultraviolet light (UV). Local factors (thickness of the ozone layer, latitude, cloud cover, elevation and season) affect the amount of UV that reaches the ground (roughly 3%). (B) This shows the electromagnetic spectrum of UV radiation at sea level and the relative amount of UVA and UVB that can penetrate differentially into the skin. On average, UVA reaches the earth in the middle of a summer's day 20 times more than UVB. UVA penetrates deeply into the dermis reaching the dermal stratum papillary. Roughly 20% of UVB reaches the epidermal stratum basal, the remainder UVB is almost completely absorbed by the epidermis. UVC are completely filtered within the atmosphere, mainly by absorption in the ozone layer. (C) Direct absorption of UV light by pyrimidine bases next to each other in the same strand can induce damage to the DNA. The most common reaction forms cis-*syn*-cyclobutane pyrimidine dimers (CPD ~ 67%–83%) and pyrimidine (6–4) pyrimidone photoproducts ((6–4) PPs) account for the rest.

radiation for skin tanning is becoming a common behavior, which is normally performed with tanning devices (sunbed). In fact, this indoor tanning is very popular especially in teenagers and women, particularly in Northern Europe and United States. The exposure to high doses of UV through these artificial sources highly increases the risk to develop skin tumors, including melanoma, especially for individuals who received their first tanning session before the age of 30. Thus, there are strong recommendations to avoid the use of sunbed and tan-seeking behavior.

The main symptoms of skin photoaging and tumors of XP patients are most probably related to the main UV photoproducts, CPDs and 6-4PPs, as the mutations observed in XP cells and tumors have signatures typical of those expected from pyrimidine dimers. Moreover, when these lesions are removed by heterologous expression of photolyases, which are specific for these lesions, the XP cells survive better after UV irradiation. These notions fit well with the NER activity of damage that causes distortions in the DNA molecule, such as the pyrimidine dimers. Interestingly, the phenotype of XP cells to UVA irradiation has been little explored, and we still do not know how lesions related to oxidative stress, for example, may affect the cells. This question deserves more investigation and the data may help to understand better how sunlight causes damage in the skin of XP patients, and will also contribute to our knowledge on the mechanisms and deleterious effects of UVA light in the skin of the population in general.

Molecular Mechanisms to Protect From Sunlight-Induced DNA Lesions That Are Deficient in XP Patients

Most of the XP patients are deficient in the ability to remove DNA damage by the NER pathway. This pathway is a very flexible and versatile type of repair that acts in structurally unrelated bulky lesion on DNA, that causes important distortions in the double helix, such as the pyrimidine dimers CPD and 6-4PP, or several chemical carcinogens or antitumoral drugs. Initial experiments detected seven complementation groups for the XP cells, which were confirmed with the cloning of seven genes (named *XPA*, *XPB/ERCC3*, *XPC*, *XPD/ERCC2*, *XPE/DDB2*, *XPF/ERCC4* and *XPG/ERCC5*) that encode the proteins XPA to XPG and participate in NER. In fact, more than 30 proteins are involved directly on this pathway, acting step by step in a concerted mode to remove the lesions from DNA and recover, without mistake, the original structure of the molecule. When the activity of one of the seven XP genes is missing due to mutations, the clinical result leads to a XP phenotype. Moreover, mutations that affect the activity of CSA or CSB proteins

result in CS, while mutations affecting the activity of TTDA/p8 cause TTD. Other more complicated syndromes have also been associated with mutations in genes that participate in the NER pathway: defects in ERCC1 and in XPF may also cause XFE, CS and COFS, and in UVSSA causes UV^{S}S. XP-C is the most common group around the world followed by XP-A and XP-D. The other groups concern a very small number of patients.

Analysis of the recovery of RNA synthesis of UV-irradiated cells from CS patients revealed that two distinct pathways are active for the removal of UV-induced DNA lesions: one, the so called Global Genome Repair (GGR) operates anywhere in the genome through the recognition of single-stranded regions within duplex DNA elicited by UV-induced photodamage, the other one, known as Transcription-Coupled Repair (TCR) is preferentially responsible for repairing damage located on the transcribed strand of actively transcribed genes.

As already pointed out, NER proteins remove DNA lesions that distort the double helix. Nevertheless, although both UV-induced DNA lesions (CPD and 6-4PP) can effectively induce distortions on DNA, CPDs are much less distortive than 6-4PPs and, by implication, much less efficiently recognized by GGR-NER recognition factors. Whereas it is fairly known that the vast majority of 6-4PPs damage are quickly repaired through GGR pathway in human cells, the repair of CPDs occurs in a much slower fashion (up to several days), mainly under the auspices of the TCR, trigged by blocked RNA polymerase II complexes. Actually, in human cells, only approximately 10% of CPDs are removed from the DNA within 4–6 h after UV irradiation, while (6–4)PP lesions are completely repaired during the same period.

The detailed NER pathway of UV-induced lesions is shown in Fig. 2. The early phase of this multiple-step process is intended to ensure the recognition of the lesions, taking into consideration not only the specific degree of distortion imputed on the double helix, relevant to the GGR's recognition factors, but also the positioning of these lesions in the genome, important to the TCR's recognizing proteins. Thus, lesions located anywhere in the genome will be quickly sensed by the XPC-Centrin2 complex, and 6-4PPs are more promptly recognized than CPD lesions. On the other hand, lesions blocking RNA polymerase II, on the transcribed strand of actively-transcribed genes, will be promptly targeted by CSA and CSB proteins. This characterizes the TCR subpathway that operates independently of the GGR subpathway. Subsequent steps of both subpathways (GGR and TCR) converge through the recruitment of the transcription factor (TFIIH). TFIIH is a multifunctional protein complex originally identified by its requirement in transcription initiation by RNA polymerase II. In addition to its role in transcription, TFIIH plays key roles in NER through its

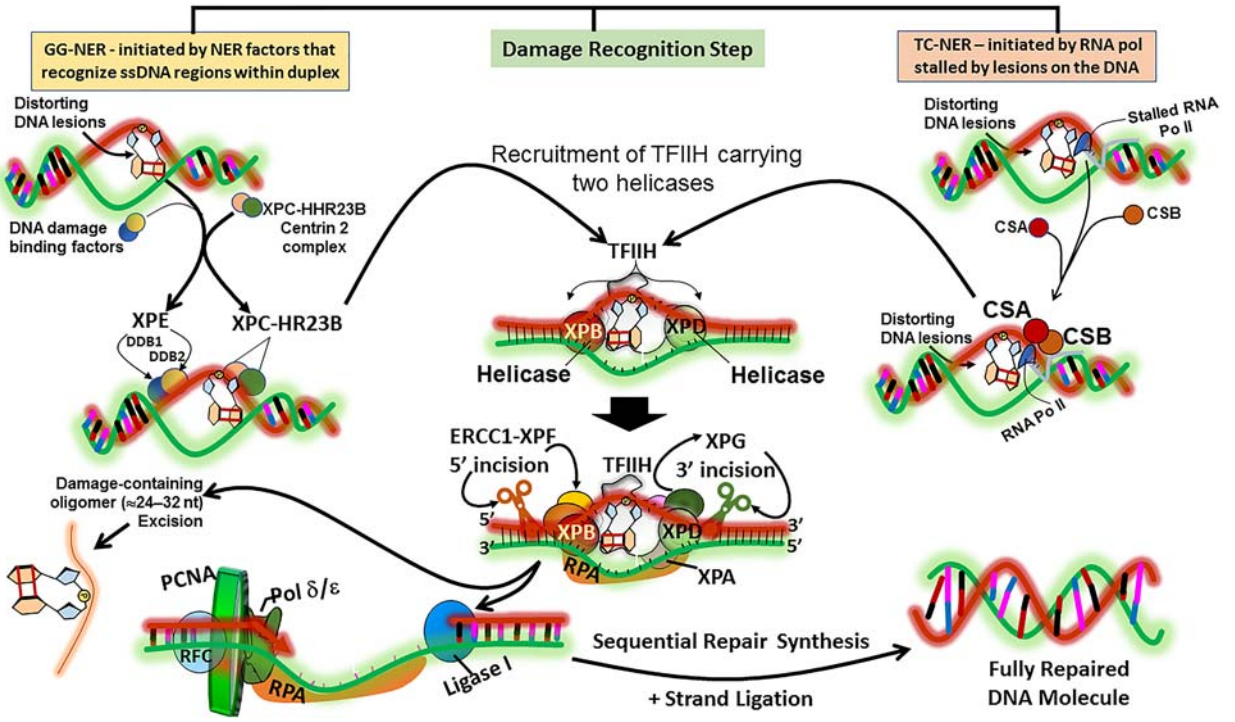

Fig. 2 *Schematic diagram showing the sequential steps of the nucleotide excision repair (NER) process in mammalian cells.* The recognition step proceeds by two independent subpathways: Global genome NER (GG-NER), in the top left-hand corner, can occur anywhere in the genome, except in transcribed strands, is initiated by NER factors (UV-DDB (XPE) and XPC-RAD23B complexes) that recognize ssDNA regions, caused by bulky adducts, within duplex DNA. Transcription-coupled repair (TC-NER), in the top right-hand corner, occurs in actively transcribed genes, due to the blockage of the RNA synthesis machinery, and is initiated by TCR-specific proteins (CSA and CSB). Subsequent steps of both pathways converge through the recruitment of the TFIIH transcription factor, harboring the DNA helicases (XPB/XPD), which induces helix opening stimulated by the XPA protein. The RPA protein stabilizes the single-stranded DNA generated by its local opening and facilitates the localization of XPF-ERCC1 and XPG endonucleases, responsible for 5′ and 3′ incisions, respectively. Finally, a new DNA fragment is synthesized by DNA polymerases epsilon or delta, and DNA ligase I completes the repair process by catalyzing the ligation of the new DNA fragment to the original sequence.

3′-5′ and 5′-3′ ATP-dependent DNA helicases subunits encoded, respectively, by the NER *XPB* and *XPD* genes. Once loaded on the damaged strand, TFIIH unwinds ~30 bp around the damaged DNA site, which become covered by RPA (Replication Protein A), the major eukaryotic single-strand DNA (ssDNA)-binding protein. The local opening of the double helix, afforded by the helicases, is stimulated by the binding of XPA protein, which together with RPA complex stabilizes the single-stranded DNA generated by its local opening and facilitates the localization of the endonucleases (XPF/ERCC1 complex and XPG protein), which cleave the DNA strand at the 5′ and 3′ sides of the lesion, respectively. The 24- to 32-base oligonucleotide containing the DNA damage is removed from DNA leaving a gap. The formed gap is then filled with the synthesis of a new DNA fragment by DNA polymerases epsilon or delta, and the final step is achieved by DNA ligase I, catalyzing the ligation of the newly-synthesized DNA to the original sequence. Thus, at the end of this process, the original DNA sequence is fully recovered in an error-free manner (**Fig. 2**).

XP-E and XP-C patients exhibit a deficient GGR mode but a fully efficient TCR. These patients have a normal development and neurology. XP-A, XP-B, XP-D, XP-F and some XP-G patients exhibit various levels of both TCR and GGR deficiencies associated with various levels of abnormal development and some neurological impairment.

Translesion Synthesis of Damaged DNA: The XP-V Syndrome

Under normal conditions, DNA damage induce a transient arrest of the cell cycle, known as DNA damage checkpoint, which, in turn, activate a plethora of biological processes, including the activation of DNA repair mechanisms to ensure that the lesions are repaired before cell division. However, when bulky DNA injuries are introduced after the cell decision toward DNA replication has already been made, the replication machinery will probably encounter unrepaired DNA lesions, which block DNA synthesis, as replicative polymerases are unlikely to copy damaged templates. By blocking the polymerases, bulky DNA lesions ends up inducing the collapse of the replication fork, then subsequent production of double-strand breaks, and, ultimately, cell death. Therefore, long-term consequences of DNA lesions include different forms of mutations and genomic instability, which, although constituting the driving forces that give rise to evolution, also significantly contribute to carcinogenesis or cell death.

Progress in the past 20 years has unraveled some of the underlying principles of DNA damage tolerance in eukaryotic cells, through which DNA lesions may be overcome during S phase and the repair of these lesions, postponed, allowing the achievement of the DNA replication and cell survival maintenance. In fact, translesion DNA synthesis (TLS), performed by specialized DNA polymerases, constitutes an extremely efficient mechanism of tolerance to ensure replication of damaged DNA template. These TLS polymerases normally have low fidelity of replication into undamaged DNA sequences, but, interestingly act effectively when copying DNA models containing lesions. A summary of the TLS process by the polymerase η is shown in **Fig. 3**.

DNA polymerases, like other enzymes, have their proper structure-function relationship for controlling the substrate access to the active site, which end-up influencing both specificity and catalytic mechanism. Given the importance and complexity of DNA replication, it is not surprising that this process depends on a myriad of factors and accessory molecules. Thus, the human genome, for instance, encodes, nothing less than 15 distinct DNA-dependent DNA polymerases, working in concert to maintain genome stability, including the replicative B-family polymerases, namely, pol alpha (Pol α), pol delta (Pol δ) and pol epsilon (Pol ε) and the specialized Y-family polymerases, pol eta (Pol η), pol iota (Pol ι), pol kappa (Pol κ) and Pol Rev1, characterized by their unique ability to efficiently replicate, not only non-B DNA structures but also particular type of DNA lesions. DNA polymerase η, for example, is proficient in distinguishing and copying past template cyclobutane dimers by incorporating dA residues opposite the lesion. This enzyme is encoded by the *POLH* gene and deficiencies in this protein are unequivocally associated with the variant form of XP: XP-V. The main clinical features of XP-V patients are associated with extreme sensitivity to sunlight and increased risk for developing skin cancer, but normal neurology. Because XP-V patients exhibit a normal NER activity, their UV-induced symptoms usually appeared between the second and the fourth decades of their life, much later than the "classical" XP. XP-V represent about 20% of XP around the world.

The most relevant characteristic for the Y-family DNA polymerases accounts for their catalytic sites, which are much larger and flexible than the replicative polymerase' catalytic sites. Thus, these polymerases contain a more spacious binding pocket at the catalytic site needed to accommodate altered template bases and nucleotide adducts setting up the proper geometry for catalysis. However, despite the high flexibility provided by an enlarged template-binding pocket, these enzymes may present some specificity to different DNA-template adducts. Thus, for instance, pol η is supposed to accurately bypass UV lesions, while pol κ can support nucleotide incorporation opposite and beyond benzopyrene-induced DNA adducts.

Overcoming Obstacles During S Phase: Main Steps

Following UV irradiation, a vastly integrated series of biochemical events takes place through a high degree of specificity of enzymes to ensure that the DNA damage response pathway follows a smooth course. Thus, the formation of bulky adduct DNA lesions, induces a p53-dependent accumulation, chromatin recruitment of DNA pol η and ubiquitination of the DNA polymerase processivity factor, the proliferating cell nuclear antigen (PCNA). Upon encountering a UV-induced DNA lesion, the error-free replicative polymerase is blocked, thereby inducing PCNA (ring) monoubiquitination (Ub). This increases the affinity for Pol η, which inserts correct nucleotides opposite and beyond the DNA damage, thereby bypassing the lesion and allowing the replicative DNA polymerase to resume DNA synthesis (**Fig. 3**).

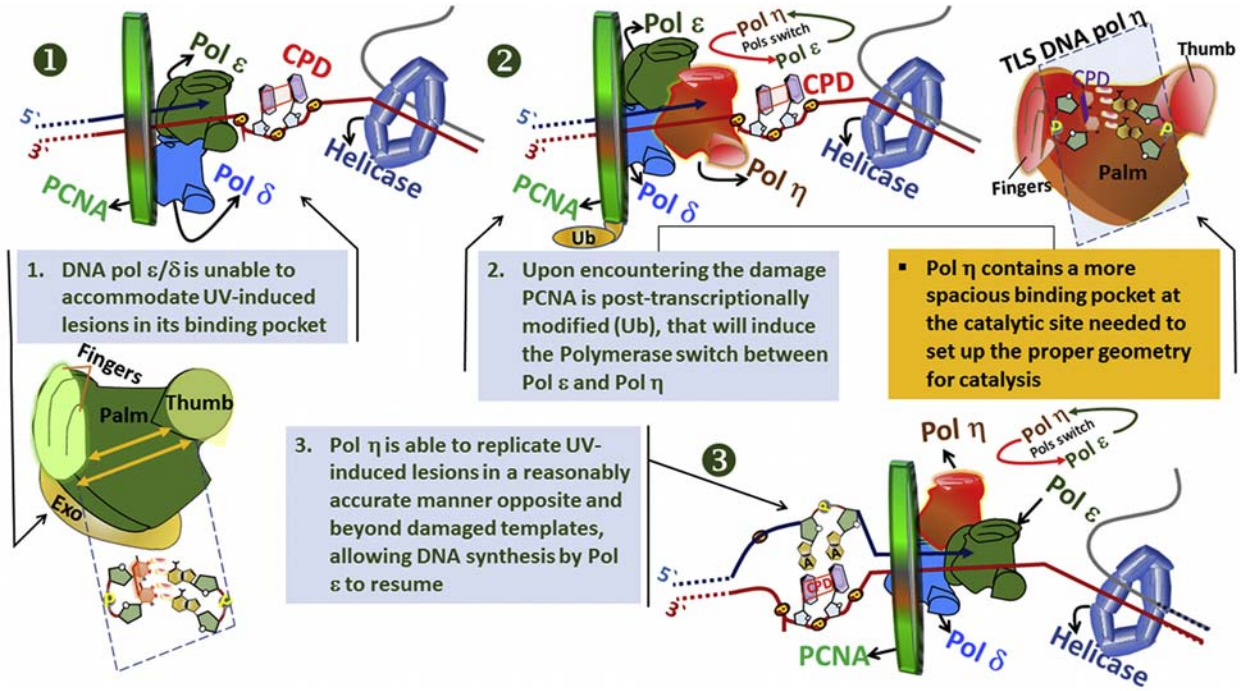

Fig. 3 *Essential steps of UV-induced translesion synthesis* (*TLS*) *process: a hallmark of XPV.* (1) Upon encountering a bulky DNA lesion, the error-free replicative polymerases (Pol epsilon/delta) stall, caused by their inability to insert a nucleotide opposite the lesion, thereby inducing (2) PCNA (ring) monoubiquitination (Ub), which increases the affinity for the specialized DNA polymerase Pol η. (3) Functional Pol η inserts correct nucleotides (A) opposite the thymidine dimers induced by UV light and allows DNA synthesis to resume with replicative polymerases. Pol η is absent in XP-V patients, whereas another error prone TLS DNA polymerases insert incorrect nucleotides opposite the lesion, thereby leading to the clinical pathological changes observed in XP-V patients, mainly sunlight-induced skin cancer.

Functional Pol η is absent in XP-V patients, therefore, mutagenesis and carcinogenesis in these XP patients, probably arise from insertion of incorrect nucleotides opposite UV-induced lesions made by other TLS DNA polymerases incapable of accurately bypass this specific kind of lesions. Indeed, sequencing XP-V skin tumors have shown that the majority of UV-induced mutations on tumor suppressor genes were located opposite Py-Py sequences.

The Psychological Approach of Xeroderma Pigmentosum

The discovery of the disease starts either by a strong sunburn of the newborn after a short exposure to sun or by the appearance of lentigines, freckles or pigmentary changes on the sun-exposed sites of the 1–3 years old child. Then, a long period of wanderings, from general practitioners to dermatologists via allergists or other specialist clinicians, starts can take several years before resumption. The exact diagnosis done by dermatologist and confirmed by molecular biologists occurs usually between the ages of 2–4 in population at risk or up to 6 years for population normally free of the disease. The diagnosis can also be made by neuro-pediatrician for some XP groups associated with neurological abnormalities.

Like most of genetically-transmitted diseases, xeroderma pigmentosum is difficult to explain and to be understood by the parents because at early age of the patient the symptoms are relatively benign. Moreover, some parents feel responsible of their child's disease and try to deny the evolution of it. Parents have to understand and to accept that the only prevention, up to now, is a complete protection of the child from UV exposure as early as possible. These protective measures include covering with UV-resistant films all windows in home, cars and school. Lamps should be everywhere checked for the absence of UV rays. When outside during daylight, XP child should be completely covered with long trousers, long sleeves and gloves as well as UV-resistant and transparent face mask (Fig. 4). For adults a broad-rimmed hat, lip balm and sunglasses are the minimum effort. It is very useful that each family acquires a UV-dosimeter enabling measurement of UVA and UVB radiations in a given place. UV is not detected by human eyes and may be present in places where people don't think about. Patients should use this dosimeter to each new place they are going to.

Parents may pretend that 70%–80% of protection should be good enough but in fact 100% is the only secure number. Even worst, when this is completely understood and that parents have fully protected their child, then a few years later XP children may develop skin cancers on exposed sites. Then the parents don't understand, at all, the arrival of skin tumors because they have fully protected their child in the last couple of years. It is, of course, necessary to explain to them in details that the appearance

Fig. 4 *Evolution of protection of XP patient in 15 years.* Around 2000, the XP patients were completely protected with thick materials and sunglasses used during skiing activities (left picture). Now the full UV-resistant and transparent facial mask with ventilated fresh air allows patients to move and play outside in a sunny day with no problem (right picture). These pictures are a gift from the French Association "Les Enfants de la Lune," with the authorization of the XP families.

of the tumors is due to the very early years of the child's life where he was not protected, independently of the recent full protection. When the family has fully integrated this situation, the future health of the child is insured. For patients without neurological abnormalities (XP-C, XP-E and XP-V), their prognosis is good if stringent protections are followed as suggested.

It is necessary that the members of the family be helped by psychologists to be able to cope with this disease. Beyond the necessary psychosocial follow up of the patient, a particular attention should be given to siblings of the XP child because usually all the family's life is centered on the patient way of living, such as only evening and night outside activities and no outside play during the day. It should be stressed that there is a risk of children with XP that might be borne to brothers and sisters of the XP proband, who might marry a member of the family or someone from the original village. Consanguinity is the highest risk to be borne with a genetic disease.

A usual question asked by XP parents concerns the arrival of a new child in the family. Of course, we explain that the probability for the next baby is 75% to be free of the disease but 25% probability to have another XP child. We and others have developed a prenatal diagnosis based on DNA repair-efficacy following UV irradiation of chorionic villus-derived cells (at 10 weeks pregnancy) or of amniocytes (13 weeks pregnancy) in affected families. When the mutation has been identified in the proband, then it is much easier and faster to sequence the fetal DNA.

Because this is a very rare disease (less than one patient for one million European autochthonous individuals), families think they are the only one in this situation and they feel completely abandoned by medical, administrative and informative authorities. One way to overcome this feeling is to organize meetings between numerous families and XP children. The American, English and French associations of XP patients have organized, for the last 15 years, summer or winter camps where XP families and children meet together and have several days of discussion, comparison and information between them and with medical or paramedical staffs. Plays organized in secure places for sun protection or at night allow the XP children and siblings to spend a very fruitful time. These camps have also been a good way for parents to better understand the disease and to have the opportunity to see some XP patients coming from some countries where children have never been protected from sunlight. The discovery of these very damaged XP patients leads to a painful situation, but a useful one, to completely understand the necessity of full UV-protection for the health of XP children.

Career prospects for XP are thwarted but psychologists should try to explain them it is possible to find a job where patients can be completely protected from sunlight. This limitation may be taking into account during the XP child studies.

Medical Treatment of XP

Photoprotection is a vital preventive measure. Patients must avoid exposure to sun but also to artificial UV irradiation. In the absence of full photoprotection, early skin cancers should be monitored as soon as possible. Physicians should be seen every 2 months and the family should also be taught how to carry out self-examinations. Repeat photographs is a valuable tool to distinguish between a benign pigmented lesion, that does not evolve, and early melanoma or between actinic keratosis (AK) and squamous cell carcinoma. Suspect lesions must systematically be biopsied.

Carcinoma in situ and AK may be treated by the local application of Imiquimod (Aldara) or 5-fluorouracil (Efudix) but complete excision is the treatment of choice for skin cancers when possible. Mohs surgery or surgery associated with histological analysis may

be particularly interesting for XP patients in order to limit the disfigurement associated with numerous cancer removals. If the open wound is too large after surgery, autologous skin grafts using patient skin not previously exposed to the sun should be used.

Systemic chemotherapy and radiation therapy could be prescribed as palliative measures for inoperable tumors. Given the DNA repair deficiency, XP cells are extremely sensitive to antitumoral treatment that damages DNA such as classical chemotherapeutic drugs. It is, therefore, highly recommended to lower the doses as a function of the mechanistic activity of the drug.

Efficient sun protection needs to prescribe regular vitamin D supplementation for XPs but also for their siblings who are usually also prevented from sun exposure. Since vitamin D is rapidly eliminated from the body, it is better to prescribe this supplementation every week or month.

In the past, oral retinoids have been used and shown to be active against skin tumors appearance. The doses used were accompanied of numerous side effects and even worst when the treatment was stopped, the tumors reappeared rapidly. In fact, a sort of rebound effect was observed with a greater number of tumors being obtained after the end of treatment, suggesting that retinoids appear to block only a late step of carcinogenesis. Finally these treatments have been discontinued in routine use.

XP patients should also avoid as much as possible any contact with environmental carcinogens such as cigarette smoke, benzene or polycyclic hydrocarbons. Also, although photodynamic therapy appears as a solution for tumor removal, this type of treatment may be performed carefully and with high surveillance, as the nontumoral tissue may be strongly affected and induce more damage than relief to the patients.

For patients with neurological abnormalities, regular measurement of the head size, assessment of deep tendon reflex, routine audiometry should help to quantify the neurological evolution of the child. A neuro-pediatrician or a neurologist should be implicated in the monitoring and management of these patients. Up to now, there is no prevention and no treatment of neurological deterioration but physical therapy and occupational therapy can help the every-day life. These neurological abnormalities are unfortunately progressive leading to severe disabilities and can result in a shortened lifespan in XP-A and XP-D patients.

Future Treatment of XP

It is necessary to explain to the XP patients and their family that there is no cure available today of their disease. Several laboratories are working on a possible gene therapy of XP. Although all the cells from XP are deficient in NER, in a first step it would be interesting to produce skin cells from an XP patient, which have been complemented or corrected for the XP mutation.

Full complementation of UV-sensitivity and DNA repair in XP-A, XP-C, and XP-D fibroblasts and keratinocytes has been obtained following transduction with recombinant retroviruses expressing the corresponding wild type DNA repair genes. Skins produced in vitro, using XP-C keratinocytes complemented with the *XPC* cDNA transduced with retrovirus, have been grafted on the back of immunodeficient mice and shown to be able to repair UV-induced DNA lesions even after several months of grafting.

As an alternative for genetic therapy of XP patients, DNA virus may carry and transduce the missing gene, with no integration in the cells' genome. This was initially performed with first generation adenovirus, which is a vector that transduces genes in different cell lines and high titers maybe achieved. Several of the NER genes (*XPA*, *XPC*, *XPD*/*ERCC2*, *XPV*/*POLH*) were shown to successfully complement XP cells in vitro: most of the cells in the culture express the transduced gene, become resistant to UV light, as control cells, and recover the ability to remove pyrimidine dimers (NER) or to bypass them (TLS). Strikingly, knockout mice for the *XPA* gene were also treated with this strategy, using AdyXPA recombinant virus. Basically, the mice received subcutaneous injection of a solution of high titer of AdyXPA, in their back, where the hair was shaved before UVB irradiation. The expression of the XPA protein was confirmed in the epidermis, dermis and hair follicle cells, clearly indicating the ability of these viruses to transduce heterologous genes in the skin. Compared to mice that did not receive the adenovirus, those transduced with AdyXPA had the skin strongly protected from the effects of UVB. Moreover, while all untreated 20 XPA mice developed tumors in their skin in the irradiated region, none of those that received the recombinant virus had any sign of tumor. These results demonstrated that recombinant adenovirus prevented the formation of skin cancer, protecting the mice from the harm of UV light, giving hope for future approaches.

However, more experiments indicated that expression of the transduced gene is limited for not more than a week, and a second application did not lead to gene expression. The simplest explanation for these results is that the first application induces an immunological response against the virus, preventing further treatment. Therefore, there is a need to search for other alternatives. The use of recombinant adeno-associated virus (rAAV) appears as a possibility to be tested. AAV are small single-stranded DNA virus, nonpathogenic for humans, inducing low levels of immunological responses, and many data have shown the heterologous expression in animals by these vectors may be maintained for a few years. Recently the European Medicines Agency approved in 2012 the use of Glybera (based on this virus) for commercialization as a pharmaceutical for the gene therapy of the lipoprotein lipase deficiency, a rare human disorder that causes severe pancreatitis. This strategy seems to work well providing good results for the first 3 years after application of the recombinant virus directly in the leg muscles of the patients. Thus the application in the skin still needs to be tested.

More recently, a full correction of the founder mutation of the XPC gene, characteristic of North African patients, has been obtained by using error-free homologous recombination (HR) between the mutated gene and a wild type XPC sequence present in a transduced plasmid (Fig. 5). The HR pathway is initiated following the induction of a double-strand break induced by a specific nuclease (Zn Finger, Meganuclease, TALEN) at a selected given sequence very close to the patient's mutation to be corrected. In this technology, the mutation is directly corrected and replaced by the normal sequence without change of the genomic position of the

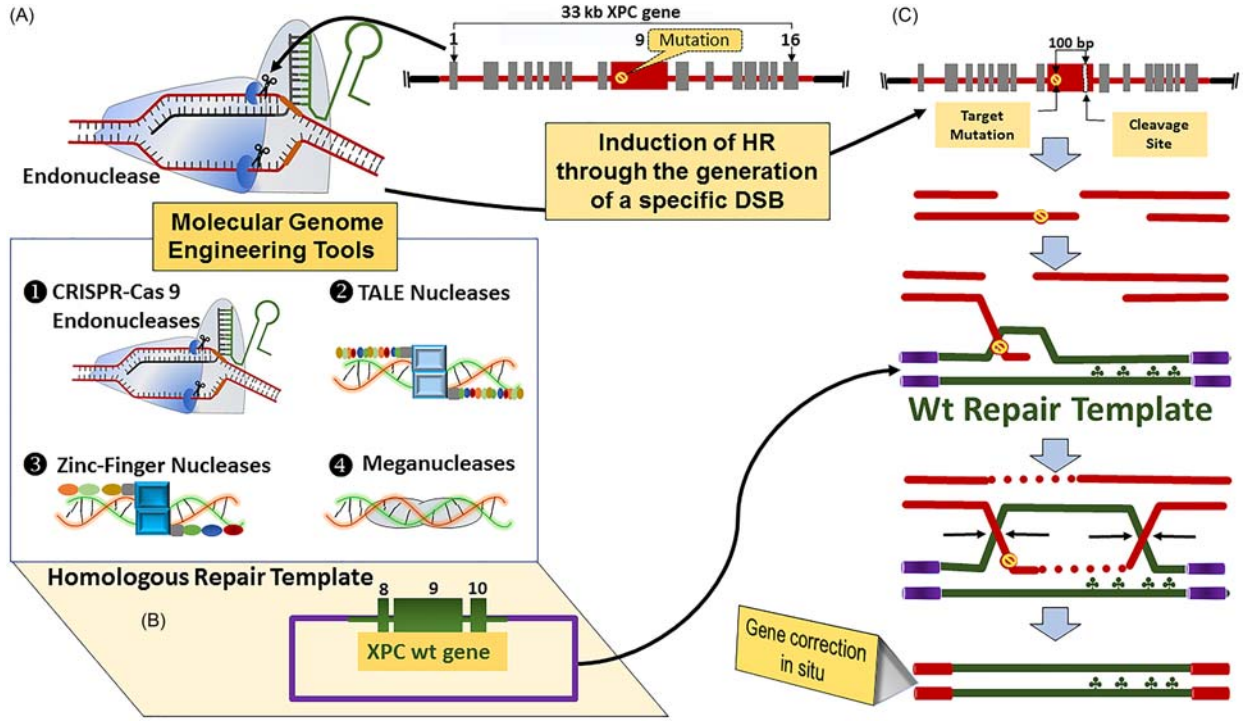

Fig. 5 *Application of high throughput molecular genome engineering tools for a genetic correction of XP cell.* (A) Genome-editing nucleases recognize and cut at specific sequences in the genome, thereby allowing either disruption of an undesirable disease-causing gene or replacement of a mutated allele sequence with a functional new copy. The main endonucleases currently used to introduce double-strand breaks (DSBs) in the genome are: (1) CRISPR-Cas9 nucleases, harboring RNA molecule (guide RNA) to base pair with the target DNA as an RNA-guided nuclease. (2) TALE nucleases, (3) Zinc-Finger nucleases and (4) Meganucleases. The last three mentioned generate sequence recognition specificity via protein-DNA interactions. (B) The presence of suitable homologous repair template (*XPC* wt gene) increases the efficiency of gene editing via homologous recombination. (C) The combination of a specific DSB and the transfection of a homologous donor DNA template corrects the mutation and restores the wt DNA sequence through homologous recombination. In this case, the mutation is fully corrected while the gene is still located at the regular place in the chromosome with its normal transcription regulation. The icons (♣) correspond to silent mutations that we have inserted in the wt *XPC* sequence harbored by the plasmid, in order to disrupt the DNA sequence recognized by the nucleases, to avoid that the plasmid be cut by the nucleases. These silent mutations are found following sequencing in the corrected final *XPC* gene indicating that the correction has been done by homologous recombination.

corrected gene, nor of its normal cellular regulation. The recent use of the CRISPR/Cas9 technology should render much easier this correction.

Adult epidermal stem cells have the capacity to renew epidermis and as already described for severely burned individuals, corrected XP keratinocytes could be used to produce in vitro epidermal sheets that can be grafted on patients such as following a large excision of skin tumors. Although still limited to research laboratories, this technology may be developed and applied to patients in the future.

Moreover from adult somatic XP cells (XP-A, XP-B, XP-C, XP-G and XPV), it has been produced induced Pluripotent Stem Cells (iPSCs) following expression of the four key factors: KLF4, cMyc, Oct3/4 and Sox2 with eventually Lin28 and sh-P53. Interestingly enough, mutations in XP genes did not compromise somatic cellular reprogramming although the XPC protein was reported as an Oct4/Sox2 coactivator. Since these cells have the potential for multilineage differentiation to the three germ layers, one can produce corrected epidermal stem cells that can be used for skin replacement via autologous transplantation. In a research view, these iPSCs can be differentiate in vitro into multiple types of cell lineages that allows researchers to specifically look after the effect of XP mutations in a given organ type. For example, neurological abnormalities in some XP groups that cannot be fully reproduced in mouse models, can be analyzed in iPSCs derived from XP-A patients differentiated into neuronal cells. Such technology should be rapidly used in the future for human therapy.

Conclusion

Xeroderma pigmentosum was first described by the Austrian dermatologist Moritz Kaposi in 1870 as a parchment skin disease. This disease has been "rediscovered" by James Cleaver in 1968 by comparison between the phenotype of XP patients and those of UV-sensitive and DNA repair-deficient bacteria. Since that time, numerous studies have revealed the complicated DNA repair processes

in mammalian cells and the role of at least 30 different proteins to allowing an efficient repair and tolerance of bulky lesions. Interestingly enough, the basic mechanism of DNA repair is similar from bacteria to plants and humans. The cloning between 1985 and 1999 of the 8 XP genes allowed medical doctors and scientists to classify the patients according to the mutated genes and to evaluate better the life expectancy of XP. Genetic counseling started to be easier for XP families.

Around the 2000s, patient associations have been very useful for helping the patients and their families allowing a better evolution for treatment, consideration in the society and interaction with other XP families and foreign patients. It is not clear up to now what will be the next step for treatment. A full protection against sun-exposure, UV-rays and maybe blue light is absolutely necessary and relatively well understood by young patients.

Gene therapy of epithelial and fibroblastic cells in order to produce in vitro XP cells corrected for their mutation is technically available now. Production of reconstituted skin in vitro is also possible and could be used to repair the disfigurement of XP faces following repetitive surgical acts. This process should, however, be carried out by private company authorized for this type of human graft. Unfortunately, the too-few numbers of patients did not guarantee the private company enough money for going into these experiments. Therefore, it is not clear if and when this type of treatment may be available for XP patients.

The use of iPSCs and embryonic stem cells that will be undoubtedly developed in the future is probably the best chance for XP treatment but several years will pass before authorized application in humans. Basic and medical researches are still necessary and the best way for hoping an efficient treatment.

Prospective Vision

As treatment of the Xeroderma Pigmentosum disease still relies mainly on the avoidance of exposure to sunlight and on early skin tumor resection, gene and cell therapy with novel techniques, such as CRISPR-Cas9 to correct the patient's mutation, appear as potential avenues, giving hope for patients and their families. Similarly, embryonic stem cells and iPSCs technology will be used in a near future not only to better understand the disease, but also to propose new therapies. But these opportunities still have long way to go. Meanwhile, the ability to perform fast DNA sequencing (by Next Generation Sequencing) provides in the last few years simple ways for the identification of mutated genes and, thus, molecular diagnosis. This small step may help to detect the disease early in patient's lives, advising the need of sun avoidance, and improving their life quality. The molecular diagnosis, including the prenatal one, may also help the families to take decisions based on genetic counseling.

INDEX

Notes

Cross-reference terms in *italics* are general cross-references, or refer to subentry terms within the main entry (the main entry is not repeated to save space). Readers are also advised to refer to each article for additional cross-references — not all of these cross-references have been included in the index cross-references.

The index is arranged in set-out style with a maximum of three levels of subheading. Major discussion of a subject is indicated by bold page numbers. Page numbers suffixed by t, f, and b refer to Tables, Figures, and Boxes respectively. *vs.* indicates a comparison.

The index entries are presented in word-by-word alphabetical sequence in which a group of letters followed by a space is filed before the same group of letters followed by a letter. For example, entries beginning 'air density' are alphabetized before 'aircraft.' Prefixes and terms in parentheses are excluded from the initial alphabetization.
