Notices
Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers may always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

EDITORS IN CHIEF

Paolo Boffetta, MD, MPH, graduated in Medicine from the University of Turin and obtained a Master in Public Health from Columbia University. He worked at the American Cancer Society, the International Agency for Research on Cancer, a specialized agency of the World Health Organization located in Lyon, France, and at the German Cancer Research Center in Heidelberg, Germany. In 2010 he moved to Icahn School of Medicine at Mount Sinai, New York, where he is Professor of Medicine, Global Health, Oncological Sciences, and Preventive Medicine, and Associate Director for Global Oncology of the Tisch Cancer Institute, a NCI-designated Cancer Center.

Dr. Boffetta also holds a full professorship at the University of Bologna and adjunct appointments at Harvard School of Public Health, Vanderbilt University, Catholic University of Rome, and University of South Carolina. Since 2017 he is Senior Advisor for Research at Vinmec Health System. His main fields of research are cancer epidemiology and cancer prevention, with emphasis on modifiable risk factors (environmental exposure and personal behaviors), gene–environment interactions, molecular epidemiology, and evidence integration. He is the initiator and coordinator of several large-scale international consortia of molecular cancer epidemiology studies, including ILCCO (lung cancer), INHANCE (head and neck cancer), PANC4 (pancreatic cancer), StoP (stomach cancer), and ILCEC (liver cancer).

Dr. Boffetta is the editor or associate editor of 5 scientific journals and member of the editorial board of 10 additional journals; he is a member of review panels of NIH and several medical research agencies in Europe. He has edited 13 books and is Editor in Chief of the new edition of Elsevier's *Encyclopedia of Cancer*. He has published over 1250 peer-reviewed publications; his publications have been quoted more than 90000 times; his h-index is 148.

Pierre Hainaut is Professor of Exceptional Class in Cancer Biology at University Grenoble-Alpes, France and Director of the Institute of Advanced Biosciences (IAB), a joint research center of Institut National de la Santé et de la Recherche Médicale (Inserm), Centre National de la Recherche Scientifique (CNRS), and University Grenoble-Alpes. He also heads the IAB research team on Molecular Biology and Biomarkers.

Pierre Hainaut holds a PhD in Biology (Zoology) from University of Liège, Belgium (1987). After postdocs in Nice (France, 1988–90), Cambridge, and York (United Kingdom, 1990–94), he joined the International Agency for Research on Cancer (IARC, World Health Organization) in 1995, where he held the post of Head of Molecular Carcinogenesis from 1999 to 2011. In 2012, he joined the International Prevention Research Institute (Lyon, France) and became Professor at the Strathclyde Institute of Pharmacy and Biomedical Science (Glasgow, United Kingdom). In 2014, he was awarded a Chair of Excellence in Translational Research from University Grenoble-Alpes (Grenoble, France).

His research focuses on *TP53* mutations and p53 protein regulation in cancer and chronic diseases. From 1994 to 2011, he has led the development of the international IARC TP53 database, a source of information on the causes and consequences of mutations affecting the *TP53* suppressor gene in cancer. His work addresses the mechanisms of *TP53* mutagenesis as well as the prognostic and predictive significance of *TP53* mutations in lung, liver, and oesophageal cancers. His studies on p53 regulation have focused on the role of environmental mutagens in *TP53* mutagenesis, on the biochemical mechanisms of p53 control by oxidation-reduction and by metabolism, and on the identification of p53 isoforms as factors acting as dominant inhibitors of p53 functions in cancers without *TP53* mutations. His current activities focus on germline *TP53* mutation and on the diversity of genetic and nongenetic factors that modulate the penetrance of the Li–Fraumeni Syndrome, as well as on the mechanisms that maintain optimal p53 protein balance in cells and tissues over lifetime. He is the author of over 450 publications and 50 book chapters. He is Editor of the Cancer Biology section of *Current Opinion in Oncology*. He has co-edited books on p53 (*25 Years of p53 Research*, 2005, 2007, *p53 in the Clinics*, Springer), a textbook on molecular epidemiology (*Molecular Epidemiology: Principle and Practice*, IARC Press, 2011) and two-volume textbook on human biobanking (*Human Biobanking, Principle and Practice*, 2017, 2018).

EDITORIAL BOARD

This page intentionally left blank

SECTION EDITORS

Fred T. Bosman MD PhD, studied Medicine at the University of Leiden (MD 1971), where he also earned his PhD degree (in cytogenetics, 1976), and trained as a pathologist. He was staff pathologist at the University of Leiden, Professor and Chair of Pathology at the Faculty of Medicine of the University of Maastricht, Faculty of Medicine of the Erasmus University in Rotterdam, Director of the University Institute of Pathology, and Professor of Pathology at the University Medical Center (CHUV) of Lausanne in Switzerland, now emeritus. He is Honorary Fellow of the Royal College of Pathologists (United Kingdom) and foreign correspondent of the Royal Netherlands Academy of Sciences.

Fred Bosman's research activities (combining diagnostic and experimental pathology) focused on the biology of digestive tract cancer, notably Barrett's esophagus and colorectal cancer, with a strong emphasis on the development of molecular diagnostics. He has written over 350 original publications and over 50 book chapters. Fred Bosman was Series co-editor of the 4th edition of the WHO Series *Classification of Human Tumours*, the international standard for tumor classification, and co-editor of the Volume on *Tumours of the Digestive Tract*.

Graham A. Colditz, MD, DrPH, FAFPHM, is an internationally recognized leader in cancer prevention. As an epidemiologist and public health expert, he has a longstanding interest in the preventable causes of chronic disease, particularly among women. He focuses his research on early life and adolescent lifestyle, growth, and breast cancer risk. He is also interested in approaches to speed translation of research findings into prevention strategies that work. Dr. Colditz developed the award-winning Your Disease Risk website (www.yourdiseaserisk.wustl.edu) which communicates tailored prevention messages to the public. He has published over 1100 peer-reviewed publications, six books and six reports for the Institute of Medicine, National Academy of Sciences. His h-index is over 220.

In October 2006, on the basis of professional achievement and commitment to public health, Dr. Colditz was elected to membership of the National Academy of Medicine, an independent body that advises the US government on issues affecting public health. In 2011, he was awarded the American Cancer Society Medal of Honor for cancer control research. In 2012 he received the AACR-American Cancer Society Award for Research Excellence in Cancer Epidemiology and Prevention. He also received awards in 2014 for cancer prevention research from ASCO and from AACR. During 2016 he served on the Implementation Science Work Group of the Blue-Ribbon Panel to advise the National Cancer Moonshot. He received the 2018 Daniel P. Schuster Award for Distinguished Work in Clinical and Translational Science, Washington University School of Medicine. He was also elected as a Fellow, American Association for the Advancement of Science

Carlo La Vecchia received his MD from the University of Milan and a Master of Science degree in Medicine (epidemiology) from Oxford University. Presently, he is Professor of Medical Statistics and Epidemiology at the Faculty of Medicine at the University of Milan. Dr. La Vecchia serves as an editor for numerous clinical and epidemiologic journals. He is among the most renowned and productive epidemiologists in the field with over 2040 peer-reviewed papers in the literature and is among the most highly cited medical researchers in the world, according to ISI HighlyCited.com, the developer and publisher of the Science Citation Index (2003, 2017, H index 153, H10 index 1543, second Italian in Clinical Medicine). Dr. La Vecchia is Adjunct Professor of Medicine at Vanderbilt Medical Center and the Vanderbilt-Ingram Cancer Center (2002-18).

Gerd. P. Pfeifer received a PhD degree in biochemistry from Goethe University in Frankfurt, Germany. After postdoctoral training, he became a faculty member at the Beckman Research Institute of the City of Hope in Duarte, California, where he spent much of his career working on cancer research. In 2014, Dr. Pfeifer joined the new Center for Epigenetics at the Van Andel Research Institute in Grand Rapids, MI, United States, as a Professor of Epigenetics. Dr. Pfeifer has authored more than 300 publications, has held an NIH MERIT award, and was elected Fellow of the American Association for the Advancement of Science in 2015. Research in Dr. Pfeifer's laboratory has been concerned with genetic and epigenetic mechanisms of human carcinogenesis, with emphasis on DNA methylation and genetic toxicology.

Marco Alessandro Pierotti graduated in 1973 in Biological Sciences at the University of Milan, Italy, and started working at the Fondazione IRCCS Istituto Nazionale dei Tumori (INT) in Milan. From 1978 to 1980 he was Visiting Investigator at the Laboratory of Chemical Cancerogenesis of the NCI-NIH Bethesda (MD, United States) and Postdoctoral Research Fellow at the Laboratory of Viral Oncology of the Memorial Sloan-Kettering Institute in New York. In 2006, Dr. Pierotti was appointed Scientific Director of the Fondazione IRCCS Istituto Nazionale dei Tumori in Milan, where, since 1970, he had already held various positions, including Director of the Department of Experimental Oncology.

Since 1988, he has been Professor of Molecular Genetics of Cancer at the Postgraduate School of Oncology, University of Milan Medical School and co-director of the Laboratory of Molecular Diagnosis at the INT. In September 2014 he resigned from his position at INT to take the position of President and CEO of Nerviano Medical Sciences (NMS) srl, one of the biggest oncological pharma companies in Europe. In April 2015 he left the company and took the position of Scientific Coordinator of the Institute of Pediatric Researches (IRP) in Padua, Italy, devoted to study molecular aspects of the main pediatric diseases with particular focus on pediatric onco-hematology. The Institute was created by a private Charity, The City of Hope Foundation of Monte Malo (Vi).

Since 2000 he is Senior Group leader of the Molecular Genetics of Cancer group at the Institute FIRC of Molecular Oncology (IFOM, Milan). Past President (2006–08) of the Italian Cancer Society, Dr. Pierotti is a member of the American Association for Cancer Research and of its Advisory Board and the Laboratory Research Awards Selection Committee. He has also been President (2006–08) of the European Association for Cancer Research (EACR) and in this role was among the founders of the European CanCer Organisation (ECCO) where he was appointed as member of the Policy Committee.

In recent years, he was the Italian Representative at the Scientific Committee of the International Agency for Research on Cancer (IARC), Lyon. From 2006 to 2014 he was Scientific Secretary of Alleanza Contro il Cancro (ACC), promoted by the Italian Ministry of Health. In 2008 he was Member of the Evaluation of the Research Program Functional and Structural Genomics for DKFZ. He was an expert for the Oncology Research Projects of the European Community and was a consultant in oncology research for the Ministries of Research of different Countries. From 2006 to 2014 he was Chair of the regional Project, The Region Lombardy Oncological Network (ROL), selected in 2014 by the EC as one of the best examples of oncological network. His appointments in the Organisation of European Cancer Institutes (OECI) started in 2007 when he took the position of Vice-President. From 2008 he was the President-elect and then the President of the Organization. Finally, in 2014 he was appointed OECI Executive Secretary.

Over the years, Dr. Pierotti has been Principal Investigator or Head of several national and international research grants, funded by both private and public bodies. His authorship includes over 470 publications that deal with various aspect of experimental oncology including studies on immunology, biochemistry, and molecular biology using both experimental and human tumors.
In addition, since its fifth edition he is the first author of the chapter on "Oncogenes" in the most reputed textbook *Cancer Medicine* (Holland-Frei). The metrics of his scientific activity is summarized by an H index of 96 and total citations of 37.256 (Google scholar June 2018).

Professor **Thomas Tursz**, born in Kraków, Poland, in 1946, died in Paris, France, on April 27 2018. He was Professor of Oncology at the Faculty of Medicine Paris-Sud since 1986 and General Director of the Institut Gustave Roussy (1994–2010). He was the leader of the French Doctoral School of Oncology which he founded in 1999, and President of the French Federation of Comprehensive Anticancer Centres (FNCLCC) from 2004 to 2010. He was highly involved in the European Organization for the Research and Treatment of Cancer (EORTC) as both Chairman of the Scientific Advisory Committee (2003–06) and Vice President of the Board (2006–09). His experience as President of the FNCLCC was crucial for the Organization of European Cancer Institutes (OECI) when he acted as President from 2002 to 2005.

His scientific interests included the biology of virus-induced tumors, as well as immunological responses including the role of thioredoxin in lymphocytes infected by Epstein–Barr virus. In the clinical research area, he conducted a number of important clinical trials in breast cancer, lung cancer, and soft-tissue sarcoma. He had a particular interest in cytokines and gene therapy, and his clinical research activities were further disseminated to the European level when he was the Chairman of the Sarcoma Group of the EORTC (1993–96).

Prof. Tursz received several prestigious awards, such as the Prix de Cancérologie from the French National League Against Cancer (1979), the Bernard Halpern Immunology Award (1983), the Rosen Oncology Award (1989), the Grand Prix in Oncology from the Academy of Medicine (1992), the Hamilton Fairley Award for clinical research (1998), and the Prix de Rayonnement Français (2001). He was the author of 350 international scientific publications. He was also an esteemed member of the Editorial Board of *Molecular Oncology* ever since its creation in 2007.

Modified from Ulrik Ringborg and Julio E. Celis. Thomas Tursz (1946–2018) in: *Molecular Oncology* (2018). Published by FEBS Press and John Wiley & Sons Ltd. https://doi.org/10.1002/1878-0261.12361

HOW TO USE THE ENCYCLOPEDIA

Structure of the Encyclopedia

All articles in the encyclopedia are arranged alphabetically as a series of entries.

There are four features to help you easily find the topic you are interested in: an alphabetical contents list, cross references, a full subject index, and contributors.

1. Alphabetical contents list: The alphabetical contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia. So that they can be easily located, entry titles generally begin with the key word or phrase indicating the topic, with any generic terms following. For example, "Multiple Myeloma: Pathology and Genetics" is the entry title rather than "Pathology and Genetics of Multiple Myeloma".
2. Cross references: Virtually all the entries in the encyclopedia have been extensively cross-referenced. The cross references which appear at the end of an entry, serve three different functions:
   i. To draw the reader's attention to related material on other entries
   ii. To indicate material that broadens and extends the scope of the article
   iii. To indicate material that covers a topic in more depth

Example
The following list of cross-references appears at the end of the entry "Carcinogen—DNA Adducts".

> ***See also:*** Cancer Risk Reduction Through Lifestyle Changes. Cell Responses to DNA Damage. Genetic Instability. Hereditary Risk of Breast and Ovarian Cancer: BRCA1 and BRCA2. Molecular Epidemiology and Cancer Risk. Role of DNA Repair in Carcinogenesis and Cancer Therapeutics.

3. Index: The index appears at the end of volume 3 and includes page numbers for quick reference to the information you are looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.
4. Contributors: At the start of each volume there is a list of the authors who contributed to all volumes.

This page intentionally left blank

SUBJECT CLASSIFICATION

Causes of Cancer

Aflatoxins
Aging and Cancer
Cancers as Ecosystems: From Cells to Population
Diabetes and Cancer
Dietary Factors and Cancer
Helicobacter Pylori-Mediated Carcinogenesis
HIV (Human Immunodeficiency Virus)
Obesity and Cancer: Epidemiological Evidence
Opisthorchis Viverrini, *Clonorchis Sinensis*, and Cholangiocarcinoma
Papillomaviruses
Physical Inactivity and Cancer
Radiation Therapy-Induced Metastasis and Secondary Malignancy
Sleep Disturbances and Misalignment in Cancer

Diagnosis and Therapy

Acute Lymphocytic Leukemia: Diagnosis and Treatment
Acute Myelogeneous Leukemia: Diagnosis and Treatment
Bladder Cancer: Pathology, Genetics, Diagnosis, and Treatment
Bone and Soft Tissue Sarcoma: From Molecular Features to Clinical Applications
Cancer Vaccines: Dendritic Cell-Based Vaccines and Related Approaches
Cholangiocarcinoma: Diagnosis and Treatment
Chromatin Dynamics and Cancer: Epigenetic Parameters and Cellular Fate
Chronic Myelogenous Leukemia: Pathology, Genetics, Diagnosis, and Treatment
Colorectal Cancer: Diagnosis and Treatment
End of Life Support
Esophageal Cancer: Diagnosis and Treatment
Glioblastoma: Biology, Diagnosis, and Treatment
Interferons: Cellular and Molecular Biology of Their Actions
Kidney Cancer: Diagnosis and Treatment
Laryngeal Cancer: Diagnosis and Treatment
Malignant Tumors of the Eye, Conjunctiva, and Orbit: Diagnosis and Therapy
Myelodysplastic Syndromes: Mechanisms, Diagnosis, and Treatment
Nasopharyngeal Carcinoma: Diagnosis and Treatment
Neuroblastoma: Diagnosis and Treatment
New Rationales and Designs for Clinical Trials in the Era of Precision Medicine
Non-Hodgkin Lymphoma: Diagnosis and Treatment
Oncology Imaging
Oral Cavity Cancer: Diagnosis and Treatment
Ovarian Cancer: Diagnosis and Treatment
Pancreatic Cancer: Diagnosis and Treatment
P-Glycoprotein-Mediated Multidrug Resistance
Pituitary Tumors: Diagnosis and Treatment

Prostate Cancer: Diagnosis and Treatment
Radiation Oncology
Squamous Cell and Basal Cell Carcinoma of the Skin: Diagnosis and Treatment
Symptom Control
Thyroid Cancer: Pathology, Genetics, Diagnosis, and Treatment
Uterine Cervix Cancer: Diagnosis and Treatment

Hallmarks of Cancer

Anoikis
Autophagy and Cancer
Cancer-Related Inflammation in Tumor Progression
Cell Adhesion During Tumorigenesis and Metastasis
Cell Responses to DNA Damage
DNA Mismatch Repair: Mechanisms and Cancer Genetics
Epithelium to Mesenchyme Transition
Genetic Instability
Glutamine Metabolism and Cancer
Induced Pluripotent Stem Cells and Yamanaka factors
Inhibitors of Lactate Transport: A Promising Approach in Cancer Drug Discovery
Lipid Metabolism
Metastatic Signatures—The Tell-Tale Signs of Metastasis
Mevalonate Pathway
Mitogen-Activated Protein Kinases (MAPK) in Cancer
Pyruvate Kinase
Role of DNA Repair in Carcinogenesis and Cancer Therapeutics
Senescence and Cellular Immortality
Telomeres, Telomerase, and Cancer
TGF-β in Cancer Progression: From Tumor Suppressor to Tumor Promotor
TP53
Tumor-Associated Macrophages
Tumors and Blood Vessel Interactions: A Changing Hallmark of Cancer
Tunneling Nanotubes (TNTs): Intratumoral Cell-to-Cell Communication

Mechanisms

Animal Models of Cancer: What We Can Learn From Mice
Ataxia Telangiectasia Syndrome
Carcinogen—DNA Adducts
Carcinogenesis: Role of Reactive Oxygen and Nitrogen Species
Chromosome Rearrangements and Translocations
Copy Number Variations in Tumors
Defective 5-Methylcytosine Oxidation in Tumorigenesis
DNA Methylation Changes in Cancer: Cataloguing
DNA Methylation Changes in Cancer: Mechanisms
Enhancers in Cancer: Genetic and Epigenetic Deregulation
Environmental Exposures and Epigenetic Perturbations
Epigenetic Therapy
Genome Wide Association Studies (GWAS)
Hereditary Risk of Breast and Ovarian Cancer: BRCA1 and BRCA2
Hormones and Cancer
Li–Fraumeni Syndrome
Lynch Syndrome
Microbiota and Colon Cancer: Orchestrating Neoplasia Through DNA Damage and Immune Dysregulation
Mod Squad: Altered Histone Modifications in Cancer
Mutational Signatures and the Etiology of Human Cancers
Mutations in Chromatin Remodeling Factors

Mutations in DNA Methyltransferases and Demethylases
Mutations in Histone Lysine Methyltransferases and Demethylases
Mutations: Driver Versus Passenger
Polyomaviruses in Human Cancer
Systems Biology Approach to Study Cancer Metabolism
TCA Cycle Aberrations and Cancer
Unprogrammed Gene Activation: A Critical Evaluation of Cancer Testis Genes
Wnt Signaling in Intestinal Stem Cells and Cancer
Xeroderma Pigmentosum: When the Sun Is the Enemy

Pathology and Genetics of Specific Cancers

Adrenal Glands Tumors: Pathology and Genetics
Anal Cancer: Pathology and Genetics
Bladder Cancer: Pathology, Genetics, Diagnosis, and Treatment
Bones and Joints Cancer: Pathology and Genetics
Breast Cancer: Pathology and Genetics
Chronic Lymphocytic Leukemia: Pathology and Genetics
Chronic Myelogenous Leukemia: Pathology, Genetics, Diagnosis, and Treatment
Colorectal Cancer: Pathology and Genetics
Endometrial Cancer: Pathology and Genetics
Esophageal Cancer: Pathology and Genetics
Eye and Orbit Cancer: Pathology and Genetics
Gastric Cancer: Pathology and Genetics
Germ Cell Tumors: Pathology and Genetics
Glioblastoma: Pathology and Genetics
Hepatocellular Carcinoma: Pathology and Genetics
Hodgkin Lymphoma: Pathology and Genetics
Integrative Molecular Tumor Classification: A Pathologist's View
Jaws Cancer: Pathology and Genetics
Larynx Cancer: Pathology and Genetics
Malignant Skin Adnexal Tumors: Pathology and Genetics
Melanoma: Pathology and Genetics
Multiple Myeloma: Pathology and Genetics
Neuroblastoma: Pathology and Genetics
Non-Hodgkin Lymphoma: Pathology and Genetics
Nonsmall-Cell Cancers of the Lung: Pathology and Genetics
Oral and Oropharyngeal Cancer: Pathology and Genetics
Ovarian Cancer: Pathology and Genetics
Pancreatic Cancer: Pathology and Genetics
Parathyroid Cancer: Pathology and Genetics
Pituitary Tumors: Pathology and Genetics
Prostate Cancer: Pathology and Genetics
Renal Cell Cancer: Pathology and Genetics
Small-Cell Cancer of the Lung: Pathology and Genetics
Thyroid Cancer: Pathology, Genetics, Diagnosis, and Treatment
Uterine Cervix Cancer: Pathology and Genetics
Wilms Tumor: Pathology and Genetics

Prevention and Control

Aspirin and Cancer
Cancer Disparities
Cancer in Populations in Transition
Cancer in Sub-Saharan Africa
Cancer in the Middle East
Cancer Risk Reduction Through Lifestyle Changes

Cancer Survival and Survivorship
Cervical Cancer: Screening, Vaccination, and Preventive Strategies
Chemoprevention of Cancer: An Overview of Promising Agents and Current Research
Chemoprevention Trials
Diet and Cancer
Environmental and Occupational Exposures
Financial Burden of Cancer Care
Hereditary Cancer Syndromes: Identification and Management
Metformin
Molecular Epidemiology and Cancer Risk
Prevention and Control: Nutrition, Obesity, and Metabolism

PREFACE

Cancer holds a special status in biology, medicine, and society. It offers formidable challenges to basic, clinical, and population science; it ranks at the top of medical research priorities and healthcare costs in most countries. The general public is continuously exposed to news of discoveries promising to defeat the disease in the near future. Indeed, ground-breaking advances are being made, from preventive vaccines to genome-guided personalized medicine, sophisticated imaging and surgical technologies, and systemic therapies aimed at awakening natural immune responses against cancer. These novel therapeutic approaches make cure a real possibility for a growing number of patients. They also launch cancer care into a new era of maintaining the disease under control for an indefinite period of time, turning it into a form of chronic disease. At the same time, evidence-based prevention and early detection strategies have opened a new window on the natural history of the disease, enabling effective intervention well ahead of diagnosis. As a result, the first two decades of this millennium have witnessed a marked decrease in the mortality and, in some instances, the incidence of cancers that have dominated the death toll in more developed countries during the second half of the 20th century.

A turning point in our understanding of cancer is the deciphering of the human genome and its spin-off endeavors aimed at exploring the genomic landscape and architecture of human cancers. These discoveries are causing a major overhaul of our vision of cancer as a dynamic, rapidly evolving, and heterogeneous disease at the individual level. Harnessing this complexity requires mastering increasingly complex sources of data at molecular, cellular, systemic, personal, environmental, and societal level, heralding the emergence of big-data science in cancer diagnosis and treatment. However, this exceptional acceleration in knowledge and solutions cannot hide the fact that cancer remains a global scourge that exerts a massive burden on humankind and societies worldwide, in particular in societies in transition and in low-resource contexts.

Today, cancer crystallizes many of the major societal challenges pertaining to lifestyles, sustainable development and environmental policies, demography and population aging, access to education and healthcare, sharing of resources and knowledge, and protection of persons and personal information. The information on cancer available at a fingertip is overwhelming in volume, complexity, veracity, and velocity. We worked on the Third Edition of Elsevier's *Encyclopedia of Cancer* with this rapidly changing background. Rather than aiming at developing a comprehensive framework encompassing all aspects, we attempted to address the literal meaning of the greek terms ἐγκύκλιος παιδεία, which means "general education". While we retained some articles from the previous edition, which, at the time of the publication, represented an exceptional achievement of Dr. J. Bertino, we largely modified the structure and the list of chapters, and the possibility of continuous update of the articles has been a great incentive for us and for the authors of the chapters. This new edition of the Encyclopedia consists of six major parts: (i) mechanisms of cancer, (ii) hallmarks of cancer, (iii) causes of cancer, (iv) cancer prevention and control, (v) diagnosis and treatment of specific cancers, and (vi) pathology and genetics of specific cancers. This repartition is necessarily artificial and is complemented by the extensive cross-references between articles. The repartition, however, reflects our effort to identify discrete topics that would best address the needs of a wide community of readers.

The primary target readership of the Encyclopedia comprises medical and other health science students, as well as non-specialized physicians and other health practitioners. Cancer researchers, oncologists, and other cancer professionals may find the articles pertaining to their specific field to be too short, over-simplistic, and perhaps obsolete; they too, however, may benefit from articles on topics other than their own. The Encyclopedia also offers an easy way to navigate across concepts and topics that should be appealing to readers from other communities, including social sciences or stakeholders in public decision-making.

We were fortunate to work with a formidable team of section editors, including Fred Bosman, Graham Colditz, Carlo La Vecchia, Gerd Pfeifer, and Marco Pierotti. An additional section editor was Professor Thomas Tursz, who passed away prematurely during the preparation of the Encyclopedia. Thomas was a great colleague and mentor, and a major figure in oncology in France and internationally. We had the privilege to involve him in the last project of his long career, and we want to dedicate this work to him. We wish to thank the many article authors, who agreed to contribute to the success of this international endeavor, and in particular Dr. Katarzyna Szymańska, who drafted several cancer-specific articles. Finally, we want to thank the staff at Elsevier, whose patience and perseverance helped us bringing the project to the final stage. All these individuals are responsible for the many strengths of the new edition of the *Encyclopedia of Cancer*, while weaknesses are mainly ours.

Paolo Boffetta
Pierre Hainaut

CONTENTS OF ALL VOLUMES

VOLUME 1

Acute Lymphocytic Leukemia: Diagnosis and Treatment 1
Katarzyna Szymańska and Sophie Park

Acute Myelogeneous Leukemia: Diagnosis and Treatment 9
Katarzyna Szymańska and Sophie Park

Adrenal Glands Tumors: Pathology and Genetics 18
Thomas G Papathomas, Thomas J Giordano, Eamonn R Maher, and Arthur S Tischler

Aflatoxins 30
Joshua W Smith and John D Groopman

Aging and Cancer 44
Mingyang Song

Anal Cancer: Pathology and Genetics 53
Fred T Bosman

Animal Models of Cancer: What We Can Learn From Mice 60
Giustina Ferone, Paul Krimpenfort, and Anton Berns

Anoikis 75
Sharan Malagobadan and Noor Hasima Nagoor

Aspirin and Cancer 85
Mangesh A Thorat

Ataxia Telangiectasia Syndrome 101
Palak R Parekh and France Carrier

Autophagy and Cancer 112
Christina G Towers and Andrew Thorburn

Bladder Cancer: Pathology, Genetics, Diagnosis, and Treatment 122
Katarzyna Szymańska, Fred T Bosman, and Pierre Hainaut

Bone and Soft Tissue Sarcoma: From Molecular Features to Clinical Applications 134
Sarah Watson and Olivier Delattre

Bones and Joints Cancer: Pathology and Genetics 153
Pancras C W Hogendoorn and Carlos E de Andrea

Breast Cancer: Pathology and Genetics 170
Amy E McCart Reed, Emarene Kalaw, Andrew Reid, and Sunil R Lakhani

Cancer Disparities 184
Ivana Kulhánová and Salvatore Vaccarella

Cancer in Populations in Transition 191
Aleyamma Mathew and Preethi S George

Cancer in Sub-Saharan Africa 212
Mariana Brandão, Ivo Julião, Carla Carrilho, Filipa Fontes, and Nuno Lunet

Cancer in the Middle East 225
Iman El Sayed

Cancer Risk Reduction Through Lifestyle Changes 243
Christina Bamia

Cancer Survival and Survivorship 250
Dana Hashim and Elisabete Weiderpass

Cancer Vaccines: Dendritic Cell-Based Vaccines and Related Approaches 260
Laurence Chaperot, Olivier Manches, and Caroline Aspord

Cancer-Related Inflammation in Tumor Progression 275
Alberto Mantovani

Cancers as Ecosystems: From Cells to Population 278
Graham A Colditz

Carcinogen—DNA Adducts 282
Annette M Krais, Rajinder Singh, and Volker M Arlt

Carcinogenesis: Role of Reactive Oxygen and Nitrogen Species 296
Jean Cadet and J Richard Wagner

Cell Adhesion During Tumorigenesis and Metastasis 307
Lubor Borsig and Heinz Läubli

Cell Responses to DNA Damage 315
Jean Y J Wang

Cervical Cancer: Screening, Vaccination, and Preventive Strategies 326
Paolo Giorgi Rossi and Francesca Carozzi

Chemoprevention of Cancer: An Overview of Promising Agents and Current Research 345
Elizabeth G Ratcliffe, Andrew D Higham, and Janusz A Jankowski

Chemoprevention Trials 352
Kunal C Kadakia, Ashley G Matusz-Fisher, and Edward S Kim

Cholangiocarcinoma: Diagnosis and Treatment 367
Katarzyna Szymańska

Chromatin Dynamics in Cancer: Epigenetic Parameters and Cellular Fate 372
Daniel Jeffery, Katrina Podsypanina, Tejas Yadav, and Geneviève Almouzni

Chromosome Rearrangements and Translocations 389
Stefan K Bohlander, Purvi M Kakadiya, and Alix Coysh

Chronic Lymphocytic Leukemia: Pathology and Genetics 405
Julio Delgado, Neus Villamor, Ferran Nadeu, and Elías Campo

Chronic Myelogenous Leukemia: Pathology, Genetics, Diagnosis, and Treatment 418
Katarzyna Szymańska and Sophie Park

Colorectal Cancer: Diagnosis and Treatment 425
Katarzyna Szymańska

Colorectal Cancer: Pathology and Genetics 428
Fred T Bosman

Copy Number Variations in Tumors 444
Tao Huang

Defective 5-Methylcytosine Oxidation in Tumorigenesis 452
Gerd P Pfeifer and Seung-Gi Jin

Diabetes and Cancer 459
Rachel Dankner

Diet and Cancer 471
Livia S A Augustin, Concetta Montagnese, Ilaria Calabrese, Giuseppe Porciello, Elvira Palumbo, Sara Vitale, and Stephanie Nishi

Dietary Factors and Cancer 501
Isabelle Romieu

DNA Methylation Changes in Cancer: Cataloguing 512
Tibor A Rauch and Gerd P Pfeifer

DNA Methylation Changes in Cancer: Mechanisms 520
Hideyuki Takeshima and Toshikazu Ushijima

DNA Mismatch Repair: Mechanisms and Cancer Genetics 530
William J Graham V, Christopher D Putnam, and Richard D Kolodner

End of Life Support 539
Kavitha J Ramchandran and Jamie Von Roenn

Endometrial Cancer: Pathology and Genetics 549
Ben Davidson

Enhancers in Cancer: Genetic and Epigenetic Deregulation 559
Kaixiang Cao and Ali Shilatifard

Environmental and Occupational Exposures 569
Harvey Checkoway

Environmental Exposures and Epigenetic Perturbations 574
Igor P Pogribny

VOLUME 2

Epigenetic Therapy 1
Richard L Bennett, Aditya Bele, Sayantan Maji, and Jonathan D Licht

Epithelium to Mesenchyme Transition 14
Laia Caja and E-Jean Tan

Esophageal Cancer: Diagnosis and Treatment 24
Katarzyna Szymańska

Esophageal Cancer: Pathology and Genetics 32
Jean-François Fléjou

Eye and Orbit Cancer: Pathology and Genetics 47
Sarah E Coupland, Santosh U Kafle, and Jakub Khzouz

Financial Burden of Cancer Care 61
Bernardo H L Goulart and Veena Shankaran

Gastric Cancer: Pathology and Genetics 77
Irene Gullo and Fátima Carneiro

Genetic Instability 99
Meiyun Guo, Lin Mei, and Christopher A Maxwell

Genome Wide Association Studies (GWAS) 110
Giuliana Restante, Elena Arrigoni, Marzia Del Re, Antonello Di Paolo, and Romano Danesi

Germ Cell Tumors: Pathology and Genetics 121
J W Oosterhuis and Leendert H J Looijenga

Glioblastoma: Biology, Diagnosis, and Treatment 154
Akanksha Sharma, Maciej M Mrugala, and Jan Buckner

Glioblastoma: Pathology and Genetics 165
Christian Hartmann and Pieter Wesseling

Glutamine Metabolism and Cancer 179
Nianli Sang, Dan He, and Shuo Qie

Helicobacter Pylori-Mediated Carcinogenesis 187
Matthew G Varga and Meira Epplein

Hepatocellular Carcinoma: Pathology and Genetics 198
Luigi M Terracciano, Salvatore Piscuoglio, and Charlotte K Y Ng

Hereditary Cancer Syndromes: Identification and Management 211
Roberta Pastorino, Alessia Tognetto, and Stefania Boccia

Hereditary Risk of Breast and Ovarian Cancer: BRCA1 and BRCA2 214
Claus Storgaard Sørensen

HIV (Human Immunodeficiency Virus) 218
Jay A Levy and JoAnn C Castelli

Hodgkin Lymphoma: Pathology and Genetics 227
Stefano A Pileri, Stefano Fiori, Vincenzo De Iuliis, and Valentina Tabanelli

Hormones and Cancer 237
Kristen D Brantley, Susan E Hankinson, and A Heather Eliassen

Induced Pluripotent Stem Cells and Yamanaka factors 254
Stina Simonsson, Rocío C Viñuelas, Leonie Hartl, Itedale N Redwan, and Joydeep Bhadury

Definition and Classification

Acute lymphocytic leukemia (also called acute lymphoblastic leukemia; ALL) is a neoplasm of immature B- or T-cells (lymphoblasts). In the most recent World Health Organization (WHO) classification of hematopoietic and lymphoid tumors, it is classified under "precursor B-cell lymphoblastic leukemia/lymphoma" and "precursor T-cell lymphoblastic leukemia/lymphoma." This

classification has replaced the French–American–British (FAB) histopathologic classification of acute leukemia, originally proposed in 1976, which classified ALL into three entities: adult, childhood, and Burkitt type ALL. The new WHO classification system takes into account not only morphological and cytochemical characteristics of the disease but also its cytogenetic and clinical diversity. All in all, the widely used term "ALL" encompasses several entities as classified by WHO, defined below.

B-lymphoblastic leukemia (B-ALL) not otherwise specified (NOS; ICD-O code: 9811/3) is a neoplasm of precursor lymphoid cells committed to the B-cell lineage, typically composed of small to medium-size blast cells with scant cytoplasm, moderately condensed to dispersed chromatin and inconspicuous nucleoli, involving bone marrow and blood. By convention, the term B-lymphoblastic lymphoma (B-LBL), which is included under the same ICD-O code, is used when a process is confined to a mass lesion with no or minimal evidence of blood and bone marrow involvement (generally defined as less than 20% of lymphoblasts in the marrow). The term B-ALL does not encompass Burkitt leukemia/lymphoma.

B-ALLs with specific recurrent genetic abnormalities associated with particular clinical and phenotypic features, and/or of prognostic significance are classified as separate entities. These are as follows:

B lymphoblastic leukemia with *t*(*9;22*)(*q34;q11.2*); *BCR-ABL1* (ICD-O code: 9812/3)
B lymphoblastic leukemia with *t*(*v;11q23*); *MLL* (also called *KMT2A* or *MLL1*) rearranged (9813/3)
B lymphoblastic leukemia with *t*(*12;21*)(*p13;q22*); *TEL-AML1* (*ETV6-RUNX1*) (9814/3)
B lymphoblastic leukemia with hyperdiploidy (9815/3)
B lymphoblastic leukemia with hypodiploidy (Hypodiploid ALL; 9816/3)
B lymphoblastic leukemia with *t*(*5;14*)(*q31;q32*); *IL3-IGH* (9817/3)
B lymphoblastic leukemia with *t*(*1;19*)(*q23;p13.3*); *E2A-PBX1* (*TCF3-PBX1*) (9818/3)
B lymphoblastic leukemia, *BCR-ABL1*-like (9819/3)

Additionally, B lymphoblastic leukemia with *iAMP21* has been depicted as a provisional entity with no separate ICD-O code (it is coded under B-ALL, NOS; ICD-O code: 9811/3).

T-lymphoblastic leukemia (T-ALL) is a neoplasm of precursor lymphoid cells with the same cellular characteristics as B-ALL but concerning precursor cells committed to the T-cell lineage.

Presentation and Diagnosis

The symptoms of ALL are usually nonspecific and may appear only weeks or even days before diagnosis. Fatigue and weakness are among the most common nonspecific symptoms. Fever, with or without night sweats, and weight loss are frequent. The cause of fever is often not found, although granulocytopenia may lead to rapidly progressing and potentially life-threatening bacterial infections. Many patients present with thrombocytopenia and/or neutropenia, easy bruising and/or bleeding (bleeding gums, epistaxis, purplish patches in the skin or petechiae), and anemia as a result of bone marrow failure and disrupted hematopoiesis. Dyspnea, chest pain, and dizziness may also occur. Bone and joint pain due to bone marrow and periosteal infiltration is frequent in children in whom it may be the only presenting symptom. Headaches, vomiting, irritability, cranial nerve palsies, seizures, papilledema, and blurred vision are manifestations of the central nervous system (CNS) involvement and/or leukemic meningitis but initial CNS involvement is uncommon.

A sensation of abdominal fullness and/or discomfort may appear due to hepatomegaly and/or splenomegaly. Hepatomegaly, splenomegaly, and lymphadenopathy at physical examination are found in about 20% of all patients and in approximately 50% of adult ALL presentations. Extramedullary infiltration may also lead to leukemia cutis (a raised, nonpruritic rash). Oliguria may occur as a result of dehydration, uric acid nephropathy, or disseminated intravascular coagulation (DIC).

The initial workup includes complete blood count (CBC) with peripheral blood smear, blood chemistry profile, liver and kidney function tests, coagulation analysis (including measurement of prothrombin time, partial thromboplastin time, and fibrinogen), and a tumor lysis syndrome panel (including measurement of serum lactate dehydrogenase (LDH), potassium, uricemia, calcium, and phosphorus). Computed tomography (CT) scans of the neck, chest, abdomen, and pelvis are recommended for detecting possible organ involvement, lymphadenopathy, and organomegaly. If any extramedullary involvement is suspected, a positron emission tomography (PET)/CT is used for diagnosis.

The leukocyte count in ALL patients may be elevated (majority of cases), normal, or decreased. T-ALL patients typically present with a high leukocyte count and often with a large mediastinal mass or other tissue mass. Circulating blast cells are present in virtually all cases. However, the percentage may be very low in some patients.

ALL diagnosis is based on a hematopathological evaluation of bone marrow aspirate and biopsy material, with a demonstration of at least 20% of bone marrow lymphoblasts confirming a definitive ALL diagnosis. According to the guidelines of the US National Comprehensive Cancer Network (NCCN), the diagnostic workup should include a morphologic assessment of Wright/Giemsa-stained bone marrow aspirate smears and of hematoxylin-and-eosin-stained bone marrow core biopsy and clot sections, a comprehensive immunophenotyping using flow cytometry, and a baseline characterization of the leukemic clone(s) (see "**Pathology and Genetics**" section for more) to facilitate subsequent analysis of the minimal residual disease (MRD). For the latter, cytogenetic testing by fluorescence in situ hybridization (FISH) with a panel of the acute leukemia probes and reverse-transcriptase polymerase chain reaction (RT-PCR) for *BCR-ABL1* fusions (and other fusions in case of *BCR-ABL1* negativity), including determining the transcript size, are commonly used. In cases of aneuploidy, array comparative genomic hybridization (CGH) may also be useful.

Epidemiology and Risk Factors

Burden

ALL is mainly a childhood disease, with 75% of cases diagnosed in children under 6 years of age. It is also the most common form of childhood leukemia, accounting for 75%–80% of all childhood leukemia cases, while it accounts for only 20% of cases in adults. The estimated annual incidence worldwide is 1–4.8 cases per 100,000 population. In the United States, the age-adjusted incidence rate of all ALL is 1.58 per 100,000 population per year, with approximately 5970 new cases and 1440 deaths estimated in 2017. The prevalence of specific B-ALL types and of T-ALL is summarized in **Table 1**.

Etiology and Risk Factors

The etiology of both B- and T-ALL is not well known. However, some environmental exposures have been associated with an increased risk. Radiation is a well-documented leukemogenic factor in humans, with a direct relationship between cumulative radiation dose and the incidence of some leukemia types. ALL may develop following exposure to ionizing radiation as well as radiotherapy. Also chemotherapy has been associated with an increased risk of developing the disease. Moreover, some chemicals, like benzene and toluene, contribute to the risk of acute leukemias, including ALL, likely by mutating or ablating the bone marrow stem cells. Acute leukemia usually develops 1–5 years after exposure and is often preceded by bone marrow hypoplasia, dysplasia, and pancytopenia. Age over 70 years is also a known risk factor for ALL.

Moreover, several hereditary conditions are associated with an increased risk of ALL, in particular Down syndrome but also less frequent disorders: neurofibromatosis type 1, Bloom syndrome, Klinefelter syndrome, Schwachman–Diamond syndrome, Fanconi anemia, and ataxia telangiectasia.

Genome-wide association studies have identified several single nucleotide polymorphisms (SNPs) associated with an increased risk of B-ALL, including in *GATA2*, *ARID5B*, *IKZF1*, *CEBPE*, and *CDKN2A*. In true familial ALL cases, even though rare, mutations in *PAX5*, *ETV6*, and *TP53* have been described.

Pathology and Genetics

In smear preparations, B-ALL lymphoblasts present variably, from small blasts with scant cytoplasm, condensed nuclear chromatin and indistinct nucleoli to larger cells with moderate amounts of light-blue to bluish-grey cytoplasm, sometimes vacuolated, dispersed chromatin and multiple variably prominent nucleoli. Nuclei are round or convoluted. Coarse azurophilic granules are present in some lymphoblasts in about 10% of cases. In bone marrow specimens, B-ALL lymphoblasts have a relatively uniform appearance, with round or oval, indented or convoluted nuclei. Nuclei range from inconspicuous to prominent, the chromatin is finely dispersed and the number of mitotic figures varies. Lymphoblasts in B-ALLs with specific genetic abnormalities usually do not have any specific morphological or cytochemical features that would allow a more specific diagnosis. Also T-ALL lymphoblasts are morphologically indistinguishable from B-ALL lymphoblasts.

B-ALL lymphoblasts are nearly always positive for the B-cell markers CD19, cCD79a, and cCD22. None of these molecules on its own is a specific diagnostic marker but their combination or high intensity strongly supports the B-ALL diagnosis. In most cases, the expression of CD10, surface CD22, CD24, PAX5, and terminal deoxynucleotidyl transferase (TdT) is also found. The myeloid-associated markers CD13 and CD33 may be expressed and this does not exclude the B-ALL diagnosis. The PAX5 expression is

Table 1 The prevalence of different acute lymphoblastic leukemia (ALL) entities

Entity	*Epidemiology*
B-ALL with *t*(*9*;*22*)(*q34*;*q11.2*); *BCR-ABL1*	More common in adults (25% of all adult ALLs) than in children (2%–4%)
B-ALL with *t*(*v*;*11q23*); *MLL* rearranged	The most common leukemia in infants under 1 year of age; less common in older children; incidence increases with age into adulthood
B-ALL with *t*(*12*;*21*)(*p13*;*q22*); *TEL-AML1* (*ETV6-RUNX1*)	Common in children (25% of all B-ALLs in children) but not seen in infants; incidence decreases with age (this entity is uncommon in adults)
B-ALL with hyperdiploidy	Common in children (25% of all B-ALLs in children) but not seen in infants; incidence decreases with age; accounts for 7%–8% of adult B-ALL cases
B-ALL with hypodiploidy	1%–5% of cases, both adults and children (nearly-haploid ALL likely in children only)
B-ALL with *t*(*5*;*14*)(*q31*;*q32*); *IL3-IGH*	Less than 1% of all ALL cases, both adults and children
B-ALL with *t*(*1*;*19*)(*q23*;*p13.3*); *E2A-PBX1* (*TCF3-PBX1*)	About 6% of childhood B-ALL cases, uncommon in adults
B-ALL, *BCR-ABL1*-like	10%–25% of all ALL cases; incidence increases with age
B-ALL with *iAMP21*	About 2% of ALL cases in children; no data on the incidence in adults
T-ALL	About 15% of childhood ALL cases (more common in adolescents than in younger children) and 25% of adult ALL cases; more common in males than in females

B-ALL, B-lymphoblastic leukemia; *T-ALL*, T-lymphoblastic leukemia.

considered to be the most specific and sensitive marker for the B-cell lineage in tissue sections but it is also expressed in some variants of acute myeloid leukemia. The expression profile of cell surface markers within the B-cell lineage varies with the B-cell differentiation (maturation stage). The immunophenotypes characterizing B-ALLs with specific recurrent genetic aberrations are summarized in **Table 2**.

T-ALL lymphoblasts are usually positive for TdT and variably express CD1a, CD2–CD5, CD7, and CD8, with CD3 (cytoplasmic) and CD7 being positive most frequently. Only CD3, however, is specific for the T-lineage. CD4/CD8 coexpression is common but it is not specific to T-ALL. TdT expression combined with that of CD34, CD1a, and CD99 may help to establish the precursor nature of T-lymphoblasts. CD52 may be expressed in 30%–50% of adult T-ALL cases. One or both of the myeloid markers may also be expressed but, like for B-ALL, this does not exclude the T-ALL diagnosis. Moreover, many markers characteristic for premature T-cells (e.g., CD2 or CD7) may also be expressed by immature natural killer (NK) cells. Therefore, it may be very difficult to distinguish the true NK-cell ALL (which is rare) and T-ALL associated with the expression of immature T-cell markers.

Clonal rearrangements of the *immunoglobulin heavy* locus (*IGH*) gene and rearrangements of the *T-cell receptor* (*TCR*) gene are found in both B-ALL and T-ALL, albeit at different frequencies. In B-ALL, *IGH* clonal rearrangements are found in nearly all cases and *TCR* rearrangements in up to 70% of cases, whereas in T-ALL, clonal *TCR* rearrangements are seen in most cases and simultaneous *IGH* rearrangements in about 20%.

Moreover, cytogenetic abnormalities are seen in a majority of B-ALL cases, many of them defining specific entities with unique phenotypic and prognostic features (**Table 2**). In addition to those "classifying" aberrations, deletions of chromosome 6q, 9p, and 12p are frequent in B-ALL but they do not seem to impact prognosis. Some other abnormalities observed in B-ALL may emerge as having some clinical utility. For example, the rare *(17;19)(q22;p13.3)* translocation is associated with a very poor prognosis but there are too few cases to validate this alteration as a prognostic marker and classify these B-ALL cases as a separate entity.

In T-ALL, abnormal karyotype is found in 50%–70% of cases. The most common recurrent cytogenetic abnormality involves the *alpha* and *delta TCR* loci (14q11.2) as well as the *beta* (7q34) and *gamma* locus (7p14.1), with a multitude of partner genes, most common of them being the *TLX1* (also called *HOX11*; 10q24.3) and *TLX3* (*HOX11L2*; 5q35.1) transcription factors. The most prevalent deletions are those of chromosome 9p, encompassing the locus of the *CDKN2A* gene.

Alterations at a gene level are also found in ALL. In particular, a large number of recurrent genetic alterations (copy number alterations and specific intragenic mutations) are found in B-ALL. Many of them, such as those in the *PAX5* gene, are found in most of the subtypes, suggesting that they play a fundamental role in leukemogenesis. Others, like those in *RAS* and *IKFZ1*, tend to be associated with specific subtypes (**Table 2**). In T-ALL, the most frequently mutated gene is *NOTCH1* which encodes a protein critical for early T-cell development (mutated in 50% of cases). In 30% of cases, mutations in *FBXW7*, a negative regulator of *NOTCH1*, are found. According to data in the Cosmic database, the genes that are most frequently mutated in ALL are the following: *IKFZ1* (35% of cases), *ABL1* (21%), *NRAS* (10%), *TP53* (10%), *CDKN2A*, *PAX5*, and *KMT2D* (9% each). However, the data do not distinguish between B-ALL and T-ALL, which—given remarkable differences between the subtypes—is a serious limitation.

Management and Therapy

The introduction of new therapies has resulted in a dramatic improvement of cure rates, in particular in B-ALL patients. ALL has a relatively good prognosis in children (5-year survival rates up to 89%). However, the prognosis for adults remains less favorable, especially for those of older age.

Risk assessment in ALL is an essential part of treatment planning and the criteria, widely debated, have been evolving. Patient age, initial white blood cells (WBC) count, disease subtype, presence of CNS disease, and rapidity of response to induction therapy are recognized as important factors in assessing prognosis. For years, clinicians used to stratify children, adolescents, and young adults (AYA) with ALL into two groups: standard risk and high risk, based mainly on age, WBC count, and disease subtype. The Children's Oncology Group (COG) has refined risk assessment criteria, creating four groups: very high, high, standard, and low risk. The very high risk category comprises all B-ALL patients with the *t(9;22)* translocation (Ph-positive ALL) and/or presence of the BCR-ABL1 fusion protein, B-ALL patients with hypodiploidy (defined as less than 44 chromosomes), *BCR-ABL1*-like, or *iAMP21* subtype, and those with *KMT2A* alterations or failure to achieve remission with induction therapy, regardless of age and WBC count. About 4% of nonadult B-ALL patients fall into this category. Risk stratification for T-ALL has been more difficult and this entity is frequently categorized as very high risk. However, newer treatments have resulted in improved outcomes also for T-ALL patients. According to the current NCCN guidelines, the initial risk stratification of all ALL patients should be based on the presence of the *t(9;22)* chromosomal translocation and/or BCR-ABL fusion protein (Ph-positive versus Ph-negative). Further stratification may be based on patient age, WBC count, comorbidities, and the presence of minimal residual disease (MRD).

The treatment of ALL is extremely complex, with treatment regimens, selection of drugs, doses, and schedules which differ according to the age group of patients (children, AYA, or older adults), risk stratification, and ALL subtype. However, all treatment protocols follow the same basic principles, with three main treatment phases: induction, consolidation, and maintenance. CNS prophylactic and/or therapeutic treatment is also a mandatory element of ALL management.

The goal of the induction therapy, the first phase of the ALL treatment, is to reduce tumor burden by clearing as many leukemic cells as possible from the bone marrow, that is to induce remission. Most inductions regimens are based on a combination of vincristine, anthracycline (e.g., daunorubicin or doxorubicin, in particular for higher risk patients), and a corticosteroid (e.g.,

Table 2 The genetic and immunophenotypic profiles of different B-lymphoblastic leukemia (B-ALL) entities as well as their clinical significance

Entity	*Genetic profile*	*Immunophenotype*	*Prognosis and predictive factors*
B-ALL with *t*(*9*;*22*)(*q34*;*q11.2*); *BCR-ABL1*	The *t(9;22)* translocation resulting from fusion of *BCR* at 22q11.2 and *ABL1* at 9q34.1, with production of a BCR-ABL1 fusion protein (p190 BCR-ABL1 in most childhood cases and in about half of adult cases); the resulting aberrant chromosome 22 harboring the fusion *BCR-ALB1* gene locus is called Philadelphia (Ph) chromosome	Typically positive for CD10, CD19, and TdT, and negative for CD117 (KIT); CD25 expression highly associated with this entity, especially in adults; myeloid-associated markers CD13 and CD33 frequently expressed; T-cell precursor phenotype in rare cases	The worst prognosis of all types, particularly in adults; patients potentially responsive to tyrosine kinase inhibitors (e.g. imatinib), so prognosis may change with the introduction of targeted therapies
B-ALL with *t*(*v*;*11q23*); *MLL* rearranged	Fusions of the *KMT2A* (*MLL*) gene with multiple genes (over 100 identified fusion partners), the most common partner being *AFF1* (*AFF4*; 4q21), followed by *MLLT1* (19p13.3), and *MLLT3* (9p21.3); none of these fusions is specific to this entity; frequent overexpression of *FTL3*; very few additional mutations in infants, usually in the RAS pathway	Typically positive for CD19 and CD15, and negative for CD10 and CD24; the NG2 homolog usually expressed and relatively specific	*KMT2A-FFA1* translocation associated with a very poor prognosis, particularly in infants under the age of 6 months
B-ALL with *t*(*12*;*21*)(*p13*;*q22*); *TEL-AML1* (*ETV6-RUNX1*)	The *ETV6-RUNX1* translocation with production of the fusion protein (a putative negative regulator of the transcription factor RUNX1), likely an early event in the leukemogenesis	Positive for CD10 and CD19, and usually also for CD34; characteristic nearly complete absence of CD9, CD20, and CD66c (relatively specific); myeloid-associated markers, especially CD13, frequently expressed	Very favorable prognosis (cure in $>$90% of childhood cases); relapses later than for other B-ALL types
B-ALL with hyperdiploidy	Increased chromosome number (usually without structural aberrations), most commonly extra copies of chromosome 21, X, 14, and 4; the least common: chromosome 2 and 3	Positive for CD10 and CD19, and other typical B-ALL markers; most cases positive for CD34 and negative for CD45	Very favorable prognosis in children (cure in $>$90% of cases); not enough data for adults; trisomies may have more significance as prognostic factors than the actual number of chromosomes; simultaneous trisomy of chromosome 4 and 10 being associated with the best prognosis
B-ALL with hypodiploidy	Loss of one or more chromosomes and nonspecific structural aberrations in the other chromosomes (rare in near-haploid cases)	Typically positive for CD10 and CD19 but no other distinct features	Poor prognosis (likely even without MRD); the worst prognosis for nearly-haploid cases suggested by some studies
B-ALL with *t*(*5*;*14*)(*q31*;*q32*); *IL3-IGH*	A functional rearrangement between *IL3* (chromosome 5) and *IDH* (chromosome 14) leading to constitutional overexpression of IL3 and eosinophilia	Typically positive for CD10 and CD19; even small numbers of blasts expressing these two markers in a patient with eosinophilia strongly suggests this diagnosis	No data

(Continued)

Table 2 The genetic and immunophenotypic profiles of different B-lymphoblastic leukemia (B-ALL) entities as well as their clinical significance—cont'd

Entity	*Genetic profile*	*Immunophenotype*	*Prognosis and predictive factors*
B-ALL with *t*(*1*;*19*)(*q23*;*p13.3*); *E2A-PBX1* (*TCF3-PBX1*)	*TCF3-PBX* translocation with production of the fusion protein (oncogenic); the fusion gene is located on chromosome 19, may be associated with loss of chromosome 1 (unbalanced translocation); an alternative *TCF3* translocation involving the *HLF* gene (chromosome 17) in rare cases	Typically positive for CD10, CD19, and cytoplasmic mu heavy chain (pre-B phenotype); typical strong expression of CD9 with lack or very limited expression of CD34 (with these features, this diagnosis may be suspected even if cytoplasmic mu is undetermined)	The *TCF3* translocation associated with very poor prognosis; possibly an increased risk of CNS relapses in patients with this entity
B-ALL, *BCR-ABL1*-like	Various chromosomal rearrangements of multiple genes with various partners; *CRLF2* rearrangements in approximately half of the cases; the tyrosine kinase-type translocations often involve *ABL1* with partners other than *BCR*, as well as other kinases; additionally frequent deletions and point mutations in other genes, particularly *IKZF1* (not specific to this entity) and *CDKNA2A*/*B*; mutations in *JAK1* or *JAK2* found in about a half of cases with *CRLF2* rearrangements	Typically positive for CD10 and CD19; very high levels of the translocated *CRLF2* gene product (detectable by flow cytometry) in a subset of cases with these translocations	Overall poor prognosis; this may be due to an increased risk of MRD (controversial); children resistant to induction therapy usually have a translocation involving *PDGFRB* (most often with *EBF1*) and are very responsive to ABL-class tyrosine kinase inhibitors (e.g. imatinib or dasatinib); patients with *JAK* mutations or translocations may be candidates for treatment with JAK inhibitors (to be tested)
B-ALL with *iAMP21*	Intrachromosomal amplification of chromosome 21 (*iAMP21*) detectable with FISH probes recognizing the *ETV6-RUNX1* translocation; multiple other chromosomal abnormalities (most commonly involving chromosome X and 7) in 80% of cases; deletions of *RB1* and *ETV6 as well as CRLF2* rearrangements more frequent than in other ALLs	Unknown	Unclear

CNS, central nervous system; *FISH*, fluorescence in situ hybridization; *MRD*, minimal residual disease; *t*, translocation; *TdT*, terminal deoxynucleotidyl transferase.

dexamethasone or prednisone) with or without L-asparaginase and/or cyclophosphamide, given over the course of 4–6 weeks. An alternative is the so-called Hyper-CVAD regimen which alternates cycles of hyperfractionated cyclophosphamide, vincristine, doxorubicin (adriamycin), and dexamethasone with those of high-dose methotrexate and cytarabine.

Most children achieve complete remission (CR) within 4 weeks of the induction therapy. If CR is not achieved within 6 weeks, alternative treatments are started. In adults, a regimen based on a combination vincristine/prednisone/anthracycline is associated with 75% CR rates. Dexamethasone has been shown to give better outcomes compared to prednisone. It has a better penetration into the CNS, which explains its efficacy in preventing CNS relapse. However, it is associated with severe toxicities and its advantage for the overall survival has yet to be demonstrated.

CNS prophylaxis after induction chemotherapy aims at preventing CNS disease or early CNS relapse. The CNS is the initial site of ALL relapse in more than half of children unless prophylaxis is given and it is also a frequent site of relapse in adults. The goal of CNS prophylaxis and/or treatment is to clear leukemic cells within sites that cannot be easily accessed with systemic chemotherapy because of the blood–brain barrier. Different regimens of CNS-directed therapy exist. Many authorities recommend intrathecal methotrexate, often combined with cranial irradiation. Triple intrathecal therapy (methotrexate, hydrocortisone, cytarabine), with or without high-dose systemic chemotherapy (e.g., methotrexate or cytarabine), may substitute for cranial irradiation which can lead to late intellectual disabilities when used in children. For adults, prophylactic intrathecal chemotherapy alone is considered sufficient. CNS prophylaxis is typically administered to all patients throughout the entire course of ALL therapy.

The consolidation treatment aims at eliminating any leukemic cells remaining after induction therapy, further eradicating residual disease. The postremission induction phase of treatment may also be referred to as intensification therapy. It typically involves an intensive multidrug regimen. A variety of regimens are used in different centers and trials, although frequently containing similar drug combinations to those that were used during the induction treatment. High-dose methotrexate, cytarabine, 6-mercaptopurine (6-MP), cyclophosphamide, vincristine, corticosteroids, and L-asparaginase are frequently incorporated into consolidation/intensification regimens. For treatment of younger children, adjusted doses and frequencies are used.

Maintenance therapy aims to prevent disease relapse after postremission induction and consolidation therapy. Most regimens are based on daily 6-MP and weekly methotrexate, typically with a periodic addition of vincristine and corticosteroids, for 2–3 years. Of note, the efficacy of the maintenance therapy is determined by the metabolism of 6-MP. In particular, the efficacy of the active metabolite production is modified by polymorphisms in thiopurine methyltransferase (TMPT). Genotyping TMPT allows to anticipate decreased bioavailability or increased toxicity of 6-MP and adjust the dose. The optimal duration of the maintenance therapy is not clearly defined and the therapy is frequently stopped due to associated toxic effects.

The emergence of targeted drugs offers hope for more effective treatments of ALL. In particular, adding tyrosine kinase inhibitors (TKIs) to the induction treatment regimens of Ph-positive ALL patients has significantly improved their prognosis. Imatinib (also called imatinib mesylate; brand name: Gleevec®, Novartis Pharmaceuticals), an inhibitor of the BCR-ABL tyrosine kinase, has been approved by the US Food and Drug Administration (FDA) for treatment of relapsed or refractory Ph-positive ALL adult patients and of all untreated Ph-positive pediatric patients. Dasatanib, a second-generation TKI which inhibits both the BCR-ABL tyrosine kinase and kinases of the Src family, seems to be even more effective than imatinib due to its capacity to inhibit several TK-related signaling pathways. It has also been shown to maintain activity against cells harboring several (but not all) *ABL* domain mutations which confer resistance to imatinib. Furthermore, it has a better penetration of the blood–brain barrier and so it may prove useful in the CNS prophylaxis. Dasatinib (under the brand name of SPRYCEL, Bristol-Myers Squibb Co) has been approved by FDA for treatment of pediatric patients with Ph-positive chronic myeloid leukemia and it is being extensively trialed (phase II and III) for treatment of ALL. Single-agent TKI therapy in Ph-positive ALL patients has been shown to yield improved response to induction therapy as compared to chemotherapy. However, the remission-free periods are relatively short for both imatinib and dasatinib alone. TKIs have been shown to provide most benefit, with significantly improved disease-free and overall survival rates, when combined with corticosteroids. Patients with CD20-positive B-ALL benefit from the addition of rituximab, an anti-CD20 monoclonal antibody, to standard ALL chemotherapy regimens. All these agents may be incorporated as part of the induction, consolidation, and/or maintenance therapy in the initial treatment of ALL, or in regimens for treating relapsed and/or refractory disease.

Allogeneic hematopoietic stem cell transplantation (HSCT) used to be considered the standard of care in AYA and adults with Ph-positive ALL, and for relapsing ALL patients. However, with the advent of BCR-ABL-targeted TKIs, its role has been questioned. Still, it may offer some benefit to specific groups of Ph-positive patients who relapse after initial remission.

Treatment of relapsed ALL remains a challenge. Combining standard chemotherapy regimens with emerging targeted drugs offers much hope to this effect. In particular, mitoxantrone (Novantrone®, Immunex Corporation; an anthracycline derivative), cytarabine, fludarabine/cytarabine/granulocyte colony-stimulating factor/idarubicin (FLAG-IDA), methotrexate/asparaginase (CAPIZZI), and blinatumomab (a monoclonal antibody against CD19 and CD3) have been shown to provide benefit to patients with CD19-positive ALL, while inotuzumab ozagamicin (FDA-approved since August 2017) has been shown to be useful in patients with CD22-postiive disease. Several first-, second-, and third-generation TKIs are being currently tested in clinical trials and their approval for treatment of relapsed/refractory ALL, and in particular for *BCR-ABL1*-like ALL, is likely just a matter of time. However, as of now, bone marrow transplant remains the only cure for relapsed/refractory ALL.

For patients who are not eligible for transplant, generation of chimeric antigen receptor T-cells (CAR-T) targeting specific molecules on the surface of cancer cells may be a solution. In August 2017, FDA approved the anti-CD10 CAR-T therapeutic agent tisagencleucel (KYMRIAH®, Novartis Pharmaceuticals) for treatment of refractory or relapsed B-ALL patients (at least second relapse) below 25 years of age. However, CAR-T therapy is associated with severe potentially fatal toxicities (like cytokine release syndrome, B-cell aplasia, and cerebral edema) and its use should be preceded by a specific risk evaluation. FDA also requires a special

certification for centers administering this therapy. For relapsed or refractory T-ALL, nelarabine, a purine nucleoside analog, is currently an approved treatment.

Assessing the response to treatment also remains a challenging issue. Complete remission (CR) is defined as the absence of circulating blasts and extramedullary disease. However, patients who achieved CR according to morphological assessment can potentially harbor leukemic cells in the bone marrow, giving rise to a low-level disease which is not detectable by conventional cytomorphological techniques (minimal residual disease, MRD). Many trials have confirmed that MRD is the strongest prognostic factor in both children and adults. Therefore, applying reliable sensitive methods to detect MRD is of utmost importance for further treatment planning and monitoring of treatment response at all stages following the induction therapy. MRD can be detected by multicolor flow cytometry or sensitive molecular techniques targeting characteristic genetic or chromosomal aberrations, like RT-PCR or next-generation sequencing.

Definition and Classification

Acute myelogenous leukemia (AML), also called acute myeloid leukemia and acute nonlymphocytic leukemia, is a heterogeneous hematological malignancy characterized by clonal expansion of myeloid blasts in the peripheral blood, bone marrow, and/or other tissues. The term encompasses a number of entities whose basic characteristics are summarized in Table 1.

Of note, the current classification of acute leukemia is the 2016 classification by the World Health Organization (WHO). It has replaced the French–American–British (FAB) histopathologic classification of acute leukemia, originally proposed in 1976, and it takes into account not only morphological and cytochemical characteristics of the disease but also its cytogenetic and clinical diversity. However, the "historical" names of some leukemia types referring to FAB categories have persisted and they are frequently used in clinical practice and related publications. These names are listed among synonyms in Table 1. Moreover, the WHO classification has lowered the diagnostic threshold of blasts which defines AML to 20% (compared to 30% in the FAB classification) and it also allows the AML diagnosis regardless of the blast count in patients with abnormal hematopoiesis and specific cytogenetic abnormalities.

Table 1 Classification and defining characteristics of acute myeloid leukemia (AML) entities

Entity name [synonyms]	*ICD-O code*	*Defining characteristics other than cytogenetic/genetic abnormalities reflected in the name of the entity*
AML with balanced translocations/inversions		
AML with *t(8;21)(q22;q22); RUNX1-RUNX1T1* [FAB M2, *t(8;21)(q22;q22);* FAB M2, *AML1(CBF-alpha)/ETO*]	9869/3	Generally shows maturation in the neutrophil lineage; Bone marrow and peripheral blood show large myeloblasts with abundant basophilic cytoplasm, often containing azurophilic granules; Classified as AML regardless of the blast count
AML with abnormal marrow eosinophils [AML, *t(16;16)(p 13;q 11)*; AML, *CBF-beta/MYH11;* acute myelomonocytic leukemia with abnormal eosinophils; FAB M4Eo; AML, *inv(16)(p13;q22)*]	9871/3	Usually shows monocytic and granulocytic differentiation and characteristically abnormal eosinophil component in the bone marrow; Classified as AML regardless of the blast count
Acute promyelocytic leukemia (APL) with *PML-RAR*-alpha [acute promyelocytic leukemia, *t(15;17)(q22;q11-12)*; acute promyelocytic leukemia, NOS; FAB M3; AML, *PML/RAR*-alpha; AML with *t(15:17)(g22;q11-12)*]	9866/3	Predomination of abnormal promyelocytes; Two types exist: hypergranular and microgranular (hypogranular); Classified as AML regardless of the blast count
AML with *t(9;11) (p22;q23); MLLT3-MLL*	9897/3	Usually associated with monocytic features; It is controversial whether cases with blast count $<20\%$ should be classified as AML
AML with *t(6;9)(p23;q34); DEK-NUP214*	9865/3	At least 20% of peripheral blood or bone marrow blasts with or without monocytic features; often associated with basophilia and multilineage dysplasia
AML with *inv(3)(q21q26.2) or t(3;3)(q21;q26.2); RPN1-EVI1* [AML with *inv(3)(q21q26.2) or t(3;3)(q21;q26.2); GATA2-MECOM*]	9869/3	At least 20% of peripheral blood or bone marrow blasts; often associated with normal or elevated platelet counts and showing increased dysplastic megakaryocytes with unilobed or bilobed nuclei and multilineage dysplasia in the bone marrow
AML (megakaryoblastic) with *t(1;22)(p13;q13); RBM15-MKL1*	9911/3	Usually shows maturation in the megakaryocyte lineage; It is controversial whether cases with blast count $<20\%$ should be classified as AML
AML with *BCR-ABL1*	9912/3 (provisional entity)	De novo AML in patients with no evidence of chronic myeloid leukemia that do not meet the criteria for other AML types
AML with gene mutations		
AML with mutated *NPM1*	9877/3	Frequently monocytic or monomyelocytic features
AML with biallelic mutations of *CEBPA*	9878/3	Usually meets the criteria for AML with maturation or for AML without maturation; myelomonocytic or monoblastic features in some cases
AML with mutated *RUNX1*	9879/3 (provisional entity)	None; cases that fulfil the criteria for any other AML type, should not be classified in this category
Other AMLs		
AML with myelodysplasia-related changes [AML with multilineage dysplasia; AML with prior myelodysplastic syndrome; AML without prior myelodysplastic syndrome]	9895/3	At least 20% peripheral blood or bone marrow blasts with morphological features of myelodysplasia, or a prior history of a myelodysplastic syndrome (MDS) or myelodysplastic/myeloproliferative neoplasm, or MDS-related cytogenetic abnormalities, and absence of the specific genetic abnormalities of AML with recurrent genetic abnormalities; patients should not have a history of prior cytotoxic or radiation therapy for an unrelated disease; cases assigned to this category for one or more of the following reasons: AML arising from previous MDS or myelodysplastic/myeloproliferative neoplasm, AML with an MDS-related cytogenetic abnormality, or AML with multilineage dysplasia

Therapy-related AML (t-AML), NOS [therapy-related AML, alkylating agent related; therapy-related AML, epipodophyllotoxin-related]	9920/3	t-AML is part of a category grouping all therapy-related myeloid neoplasms (under one ICD-O code) and is distinguished from other subentities in this category by the number of blasts; cases which progressed to AML from myeloproliferative neoplasms or MDS are excluded from this category (categorized as "secondary AML")
AML, NOS [acute nonlymphocytic leukemia; acute granulocytic leukemia; acute myelogenous leukemia; acute myelocytic leukemia]	9861/3	AML which does not fulfil the criteria for any of the entities listed above; Includes several subtypes, classified/coded separately because they require different diagnostic criteria (below)
Acute myeloblastic leukemia [AML with minimal differentiation; FAB M0]	9872/3	AML with no morphological or cytochemical evidence of myeloid differentiation; the myeloid nature of the blasts is shown by immunophenotyping
AML without maturation [FAB M1]	9873/3	High percentage of bone marrow blasts without significant evidence of maturation to more mature neutrophils; nucleated bone marrow cells comprise $<10\%$ of maturing cells of the granulocytic lineage; the myeloid nature of the blasts is demonstrated by MPO or Sudan black B (SBB; 3% or more of blasts) positivity and/or the presence of Auer rods
AML with maturation [FAB M2, NOS]	9874/3	At least 20% blasts in the bone marrow or peripheral blood and evidence of maturation ($\geq 10\%$ maturing cells of the granulocytic lineage); cells of monocyte lineage comprise $<20\%$ of bone marrow cells
Acute myelomonocytic leukemia [FAB M4]	9867/3	Proliferation of both neutrophil and monocyte precursors; peripheral blood or bone marrow has $\geq 20\%$ blasts (including promonocytes); neutrophils and their precursors, and monocytes and their precursors, each comprise at least 20% of bone marrow cells; the threshold of 20% distinguishes this entity from cases of AML with or without maturation in which some monocytes may be present
Acute monocytic and monoblastic leukemia [FAB M5]	9891/3	At least 20% of blasts (including promonocytes) in peripheral blood or bone marrow, and 80% or more of the leukaemic cells being of monocytic lineage, including monoblasts, promonocytes and monocytes; a minor neutrophil component ($<20\%$) may be present; Acute monoblastic leukemia and acute monocytic leukemia are distinguished by the relative proportions of monoblasts and promonocytes (most of the monocytic cells are monoblasts (typically $>80\%$) in the first case, and promonocytes or monocytes in the latter)
Pure erythroid leukemia [acute erythroid leukemia; erythroleukemia; FAB M6; Di Guglielmo disease]	9840/3	Neoplastic proliferation of immature cells (undifferentiated or proerythroblastic in appearance) committed exclusively to the erythroid lineage ($\geq 80\%$ of bone marrow cells) with no evidence of a significant myeloblastic component
Acute megakaryoblastic leukemia [megakaryocytic leukemia; FAB M7]	9910/3	At least 20% of blasts of which at least 50% are of megakaryocyte lineage; this category excludes cases of AML with myelodysplasia-related changes, AML with *t(1;22)(p13;q13)*, *inv(3)(q21q26.2)*, *t(3;3)* (*q21;q26.2*), and Down syndrome-related cases
Acute basophilic leukemia	9870/3	AML with the primary differentiation to basophils
Acute panmyelosis with myelofibrosis (APMF) [malignant myelosclerosis; acute myelofibrosis; acute myelosclerosis, NOS; acute panmyelosis, NOS]	9931/3	Acute panmyeloid proliferation with increased blasts (at least 20%) and accompanying fibrosis of the bone marrow that does not meet the criteria for any other AML
AML associated with Down Syndrome	9898/3	Most frequently acute megakaryoblastic leukemia, often following a prolonged MDS-like phase

inv, inversion; *MDS*, myeslodysplastic syndrome; *t*, translocation.

Table 2 Prevalence of different acute myleoid leukemia (AML) entities

Entity	*Prevalence*
AML with balanced translocations/inversions	
AML with *t(8;21)(q22;q22); RUNX1-RUNX1T1*	1%–5% of all AML cases, mostly in younger patients
AML with abnormal marrow eosinophils	5%–8% of younger AML cases; less among older adults
Acute promyelocytic leukaemia (APL) with *PML-RAR*-alpha	5%–8% of younger AML cases; less frequent among elderly patients; most patients are middle-aged adults
AML with *t(9;11) (p22;q23); MLLT3-MLL*	More common in children (9%–12% of pediatric cases compared to 2% of adult cases)
AML with *t(6;9)(p23;q34); DEK-NUP214*	0.7%–1.8% of AML cases, both childhood (median age: 13 years) and adult
AML with *inv(3)(q21q26.2) or t(3;3)(q21;q26.2); RPN1-EVI1*	1%–2% of AML cases, occurs mostly in adults
AML (megakaryoblastic) with *t(1;22)(p13;q13); RBM15-MKL1*	Less than 1% of AML cases; most common in infants, predominantly female
AML with *BCR-ABL1*	Less than 1% of all AML cases and less than 1% of all *BCR-ABL1*-positive acute and chronic leukemias; mostly in adults, possibly with a male predominance
AML with gene mutations	
AML with mutated *NPM1*	2%–8% of childhood AML and 27%–35% of adult AML cases (45%–64% of cases with a normal karyotype), with a female predominance
AML with biallelic mutations of *CEBPA*	4%–9% of childhood AML cases, probably less in adults
AML with mutated *RUNX1*	4%–16% of all AML cases; more frequent in Fanconi anemia and congenital neutropenia patients
Other AMLs	
AML with myelodysplasia-related changes	24%–36% of all AML cases; occurs mainly in elderly patients, rare in children
Therapy-related AML (t-AML), NOS	10%–20% of all AML, MDS, and MDS/MPN cases taken together; 80%–95% of cases develop t-AML following previous treatment of a malignancy, either solid (most commonly breast cancer), or hematological (most commonly non-Hodgkin lymphoma); the risk associated with alkylating agents or radiotherapy increases with age
Acute myeloblastic leukemia	Less than 5% of all AML cases; occurs mostly in infants and older adults
AML without maturation	5%–10% of AML cases; most patients are adults (mean age: 46 years)
AML with maturation	10% of AML cases; occurs in all age groups, with 25% of patients under the age of 25 and 40% over 60
Acute myelomonocytic leukemia	5%–10% of AML cases; more common in older individuals (median age: 50 years)
Acute monocytic and monoblastic leukemia	Less than 5% of AML cases; acute monocytic leukemia is more common in adults, with the male-to-female ratio of 1.8:1, whereas acute monoblastic leukemia is more common in young individuals
Pure erythroid leukemia	Extremely rare; occurs in all age groups
Acute megakaryoblastic leukemia	Less than 5% of AML cases, both childhood and adult
Acute basophilic leukaemia	Very rare
Acute panmyelosis with myelofibrosis (APMF)	Rare; occurs mostly in adults
AML associated with Down Syndrome	20%–30% of pediatric AML cases; about 1%–2% of children with Down syndrome develop AML, mostly under 5 years of age

MDS, myelodysplastic syndrome; *MDS/MPN*, myelodysplastic/myeloproliferative neoplasm.

Epidemiology and Risk Factors

Burden

AML is the most common adult leukemia (90% of all AML cases) and the first cause of leukemia-associated death. An estimated 19,520 new cases will be diagnosed and 10,670 people will die of the disease in the United States in 2018. As over a half of the cases are diagnosed in older adults (mean age at diagnosis in the United States: 67 years; 54% of cases diagnosed in individuals over 65 years of age), the incidence of AML seems to be rising with aging of the population. However, some AML subtypes are more common in children. The prevalence of particular AML subtypes is summarized in Table 2.

Etiology and Risk Factors

The environmental factors that are well known to increase the risk of developing AML include prolonged exposure to petrochemicals, solvents (like benzene or toluene), pesticides, and ionizing radiation. The chemicals probably contribute to the risk of AML by mutating or ablating the bone marrow stem cells. The disease usually develops 1–5 years after exposure and is often preceded by bone marrow hypoplasia, dysplasia, and pancytopenia.

Another risk factor for developing AML is radiation which is a well-documented leukemogenic factor in humans, with a direct relationship between cumulative radiation dose and the incidence of some leukemia types. AML may develop following exposure to ionizing radiation as well as radiotherapy.

Also chemotherapy used for treatment of certain primary tumors (including breast and gynecological cancers, and lymphomas) has been associated with an increased risk of developing AML. In particular, alkylating agents (e.g. cyclophosphamide) and topoisomerase II inhibitors (e.g. doxorubicin) have been clearly shown to be leukemogenic agents. Treatment with antimetabolites, such as the purine analog fludarabine, has also been associated with therapy-related AML in patients with lymphoproliferative disorders, especially when administered in combination with alkylating agents.

Finally, several hereditary conditions are also associated with an increased risk of MDS and AML. These include Fanconi anemia, congenital dyskeratosis, Diamond–Blackfan anemia, Shwachman–Diamond syndrome, and the Down syndrome (individuals with the Down syndrome usually develop acute megakaryoblastic leukemia). Moreover, recent genomic analyses of families with multiple cases of MDS or AML have identified several genes which confer inherited risk for MDS and/or AML as the primary malignancy, including *RUNX1*, *ANKRD26*, *DDX41*, *ETV6*, *GATA2*, and *SRP72*.

Presentation and Diagnosis

AML patients present with signs and symptoms resulting from bone marrow failure or organ infiltration with leukemic cells, or both, many of them nonspecific. The time course is variable. In some cases, in particular in younger individuals, acute symptoms develop within a few days to up to 2 weeks, whereas others may experience symptoms that last for months. A longer course may suggest an antecedent hematological disorder, such as MDS.

Fatigue and weakness are among the most common nonspecific symptoms and are related to anemia, neutropenia, and thrombocytopenia resulting from bone marrow failure. Other symptoms of anemia include dyspnea upon exercise, dizziness, and—in patients with coronary artery disease—anginal chest pain. Myocardial infarction may actually be the first presenting symptom in older AML patients. Physical signs of anemia, including pallor and a cardiac flow murmur, are frequent in all AML patients. Many patients have decreased neutrophil levels (neutropenia) despite an increased total white blood cell (WBC) count. Patients generally present with fever which may occur without an apparent infection. However, a history of upper respiratory infection symptoms that have not improved despite empiric treatment with oral antibiotics is common. Thrombocytopenia and coagulopathy resulting from disseminated intravascular coagulation (DIC) are also frequent. This manifests as easy bruising and/or bleeding, including bleeding gums, petechiae (particularly on the lower extremities) and multiple ecchymoses, and may also lead to potentially life-threatening bleeding in the lungs, gastrointestinal tract, and central nervous system.

AML manifestations may as well result from organ infiltration by leukemic cells, the most common infiltration sites being the spleen, liver, gums, and skin. A sensation of abdominal fullness and/or discomfort, and early satiety may appear due to hepatomegaly and/or splenomegaly. Lymphadenopathy on physical examination is less common. Gingivitis and swollen gums due to gum infiltration and also neutropenia often lead AML patients to present at their dentist's first. Organ infiltration occurs most commonly in patients with the monocytic subtypes of AML. Skin rashes due to infiltration of the skin with leukemic cells (leukemia cutis) may occasionally appear.

Patients with markedly elevated WBC counts can present with symptoms of leukostasis, such as respiratory distress and altered mental status. Leukostasis is a medical emergency that calls for immediate intervention. Patients with a high leukemic cell burden may present with bone pain caused by increased pressure in the bone marrow.

Headaches, vomiting, irritability, cranial nerve palsies, seizures, papilledema, and blurred vision are manifestations of central nervous system (CNS) involvement and/or leukemic meningitis. However, initial CNS involvement, like other extramedullary presentations, is uncommon in most AML subtypes.

Rapidly distinguishing AML from other, less urgent, hematological conditions is a major challenge. The initial workup includes complete blood count (CBC) with peripheral blood smear and a differential, blood chemistry profile, liver and kidney function tests, coagulation analysis (including measurement of prothrombin time, partial thromboplastin time, and fibrinogen), and a tumor lysis syndrome panel (including measurement of serum lactate dehydrogenase (LDH), potassium, serum uric acid, calcium, and phosphorus). The leukocyte count in AML patients may be elevated (majority of cases), normal, or decreased. Circulating blasts are present in nearly all cases, however their proportion may be very low in some patients.

The AML diagnosis is made based on the presence of at least 20% of leukemic blasts in the bone marrow or peripheral blood (with the exception of a few subentities; see **Table 1** for definitions). Myeloblasts, monoblasts, and megakaryoblasts are included in the blast count. In AML with monocytic or myelomonocytic differentiation, monoblasts and promonocytes, but not abnormal monocytes, are counted as blast equivalents. The accurate AML diagnosis requires multidisciplinary studies using immunochemistry and/or cytochemistry as well as molecular genetics. Flow cytometry immunophenotyping of bone marrow or peripheral blood samples can be used to help distinguish AML from acute lymphocytic leukemia (ALL) and further classify the AML subtype. The most commonly used diagnostic AML immunomarkers include precursor markers of the myeloid lineage (CD34, CD117 (c-KIT), CD33, CD13, and HLA-DR), granulocytic markers (CD65 and cytoplasmic MPO), monocytic markers (CD14, CD36, and CD64), megakaryocytic markers (CD41 and CD61), and erythroid markers (glycophorin A and CD36).

Cytogenetic analysis of the bone marrow (karyotype), with or without fluorescence in situ hybridization (FISH), is necessary for risk stratification and to guide therapy. A comprehensive analysis of several molecular markers for risk assessment and prognostication, and for confirming diagnosis of an AML with genetic abnormalities in some cases, is also an important element of the initial workup (see also the section "Genetics and Prognostic Biomarkers"). Circulating blasts form peripheral blood can be used to detect molecular abnormalities in patients with blast counts over 1000/mcL.

If an extramedullary involvement is suspected, positron emission tomography with computed tomography (PET/CT) is recommended. Patients presenting with signs or symptoms suggesting the central nervous system (CNS) involvement should be evaluated using proper imaging techniques, like CT or magnetic resonance imaging (MRI), followed by a lumbar puncture if no CNS mass or lesion is detected by imaging. However, CNS involvement is uncommon in AML patients.

Genetics and Prognostic Biomarkers

Like most sporadic human malignancies, AML is a complex disease, characterized by multiple somatically acquired driver mutations, coexisting competing clones, and molecular evolution over time. However, AML genomes seem to have fewer mutations than those of many other adult cancers. A comprehensive genomic analysis of 200 AML samples by the Cancer Genome Atlas (TCGA) Research Network has concluded that adult AML genomes contain a median of only one somatic copy-number variant and an average of less than one gene fusion event (generally caused by translocations). The study identified 23 significantly mutated genes, including genes that had been well established as being relevant to AML pathogenesis (e.g., *DNMT3A*, *FLT3*, *NPM1*, *IDH1*, *IDH2*, and *CEBPA*), along with genes that have only recently been implicated in AML pathogenesis, such as *U2AF1*, *EZH2*, *SMC1A*, and *SMC3*. *FLT3* mutations were identified in 28% of samples and an additional 31% were found to have mutations in genes encoding other kinases, phosphatases, or *RAS* family proteins. However, most of these genes were mutated in only one to three samples (with the exception of *KIT*, *KRAS*, *NRAS*, and *PTPN11*). In total, 59% of samples had a mutation in a gene encoding a signaling protein. A recent analysis of mutational patterns in 1540 AML samples has segregated AML cases into nonoverlapping classes, each with a distinct clinical phenotype and outcome. Beyond known disease classes, three additional heterogeneous classes emerged: AML with mutations in chromatin and RNA-splicing regulators, AML with *TP53* mutations and/or chromosomal aneuploidies, and, provisionally, AML with *IDH2* mutations. Recent studies in large population-based cohorts have identified recurrent mutations in epigenetic regulators (*DNMT3A*, *ASXL1*, *TET2*) and—less frequently—in splicing factor genes (*SF3B1*, *SRSF2*), associated with clonal hematopoietic expansion in elderly seemingly healthy subjects. The most common chromosomal and genetic alterations found in AML are summarized in Fig. 1.

Genetic abnormalities have been shown to be powerful prognostic factors in AML. However, the prognostic value of most of them is context-dependent, which calls for comprehensive analyses of genetic profiles in AML patients. Current guidelines, in

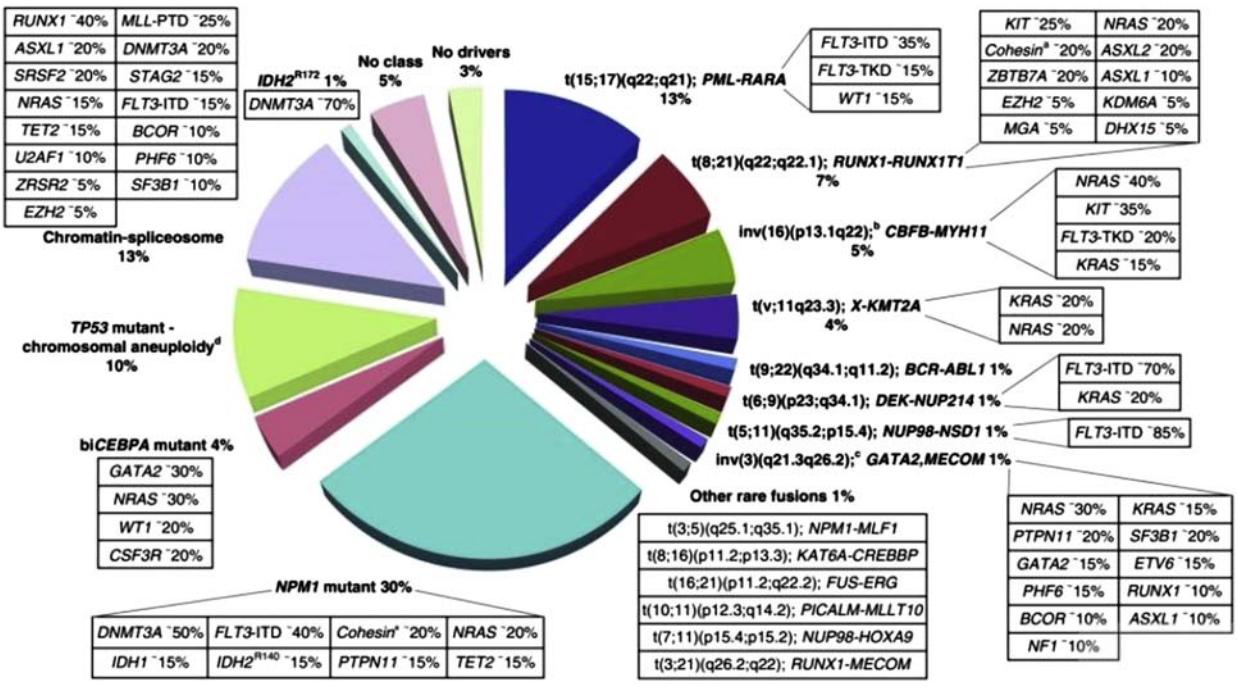

Fig. 1 Molecular classes of AML and concurrent gene mutations in adult patients up to the age of ~65 years. For each AML class denoted in the pie chart, frequent cooccurring mutations are shown in the respective boxes. Data on the frequency of genetic lesions are compiled from the databases of the British Medical Research Council (MRC), the German–Austrian AML Study Group (AML SG), and from a few selected studies; a: indicates cohesin genes including *RAD21* (~10%), *SMC1A* (~5%), and *SMC3* (~5%); b: *inv(16)(p13.1q22)* or *t(16;16)(p13.1; q22)*; *CBFB-MYH11*; c: *inv(3)(q21.3q26.2)* or *t(3;3)(q21.3;q26.2)*; *GATA2*, *MECOM*(*EV11*); and d: *TP53* mutations (found in ~45% of this class), and complex karyotypes (~70%). addition to routine screening for cytogenetic abnormalities, recommend screening for mutations in *NPM1*, *CEBPA*, *RUNX1*, and *FLT3* (both for internal tandem duplications (ITDs) together with the mutant–to–wild-type allelic ratios, and for tyrosine kinase domain mutations at codons D835 and I836) as well as in *TP53* and *ASXL1* within the diagnostic workup, even though in many countries these results are not yet used to guide treatment decisions. With the ongoing research, other genes/genetic alterations should soon extend that list. **Table 3** lists the currently established prognostic AML biomarkers.

Management and Therapy

Treatment options for acute myeloid leukemia (AML) traditionally comprise a backbone of anthracyclines and aracytine, and stem cell transplantation. However, the cure rates of standard chemotherapy regimens could be improved and so including AML patients in clinical trials as the main therapeutic option is highly recommended.

AML treatment is divided into the induction phase aiming at achieving remission and the postremission phase consisting of the consolidation therapy aiming at "consolidating" remission, that is obtaining durable disease control. Except for the APL subtype, maintenance therapy is not included in current regimens as the available data do not support the notion that it gives any additional benefit.

A standard induction treatment consists of infusional cytarabine (arabinosylcytosine, ara-C) and an anthracycline (daunorubicin or idarubicin) or anthracenedione (mitoxantrone). A complete remission (CR) is usually achieved in about 1 month of treatment. In adult patients with *FLT3*-mutated AML, adding midostaurin (Rydapt), an orally administered multitargeted kinase inhibitor to the standard cytarabine and daunorubicin induction regimen has been shown to improve survival. Midostaurin and its major active metabolites inhibit the activity of wild-type FLT3, *FLT3*-mutant kinases (ITD and TKD), KIT (wild type and D816V mutant), PDGFR-alpha/beta, VEGFR2, and members of the serine/threonine kinase protein kinase C (PKC) family. In April 2017, it was approved for treatment of newly diagnosed adult AML patients by the US Food and Drug Administration (FDA). Moeover, it has been suggested that adding purine analogs, such as cladribine or fludarabine, to the backbone induction regimen may improve patient outcomes. Purine analogs increase intracellular uptake of cytarabine by promoting the accumulation of cytarabine triphosphate (ara-CTP) in leukemia blasts. However, the results are still preliminary and using these agents is not a number one recommendation in any of the current clinical guidelines. The use of high-dose cytarabine (HiDAC) combined with an anthracycline for induction therapy remains controversial. The US National Comprehensive Cancer Network (NCCN) recommends this option as the first choice only for patients under 45 years of age.

The induction therapy is associated with severe toxicities, including—among others—tumor lysis syndrome, cardiac abnormalities, and pancytopenia. As patients who do not receive postremission therapy usually relapse within 6–9 months, it is important that patients complete the induction therapy in a condition to tolerate subsequent more aggressive treatments of the consolidation therapy. Therefore, treating patients over 60 years of age is controversial as they often cannot tolerate the toxicities of the intensive induction therapy. Moreover, they frequently develop AML with adverse prognostic features. Those older adults who are candidates for intensive induction therapy may be treated with standard infusional cytarabine and anthracycline or—in case of cardiac or other contraindications—with alternative nonanthracycline and lower intensity regimens, such as those with hypomethylating agents (e.g. 5-azacytidine or decitabine), or with the purine analog clofarabine. However, clinical trials are the most recommended option.

A successful induction therapy should clear all visible signs of leukemia in the bone marrow and restore normal hematopoiesis in patients with a de novo AML. The response to the induction therapy is evaluated based on a bone marrow aspirate and a biopsy. In case of residual disease, additional standard-dose cytarabine with anthracycline (and midostaurin in *FLT3*-mutant cases) may be considered.

Postremission consolidation therapy aims to reduce the number of residual abnormal cells to a level which can be contained by immune surveillance. Most patients below 60 years of age are evaluated for allogeneic hematopoietic stem cell transplantation (HSCT), except for patients with favorable cytogenetic and molecular markers and those with significant comorbidities who are offered further chemotherapy. HiDAC therapy is standard for patients under 60 with favorable prognosis (in particular AML with *CEBPA* mutations). One cycle of HiDAC may also be a reasonable option for older patients.

Gemtuzumab ozogamicin (GO; Mylotarg), a monoclonal antibody against CD33 conjugated with a toxin (calicheamicin) offers hope for targeted treatment of CD33-positive AML. In September 2017, this drug was approved by FDA for treatment of adults with newly diagnosed CD33-positive AML and for treating relapsed or refractory CD33-positive AML in patients older than 2 years.

Patients with relapsed AML have an extremely bad prognosis. Most of them respond poorly to salvage therapies (e.g. patients with an initial CR duration of less than 1 year or with no initial CR have a 14% complete response rate to the initial salvage therapy) and should be referred to investigational therapies (clinical trials) whenever possible. If that is not possible, standard regimens with high-dose cytarabine or with hypomethylators are the remaining options. These include cladribine combined with high doses of ara-C, with granulocyte colony-stimulating factor and mitoxantrone (CLAG-M), and mitoxantrone/etoposide/intermediate-dose cytarabine (MEC). If remission is obtained, an allogeneic transplantation should follow in these patients whenever feasible.

A number of novel targeted therapeutics that emerge give hope for the treatment of relapsed and refractory AML. A monotherapy with venetoclax (VEN), a selective BCL2 inhibitor, has been shown to have an activity in relapsed and refractory AML, and also efficacy in lower intensity combinations for treatment-naive elderly AML patients. Different venetoclax regimens are currently tested in several phase II and III clinical trials. A very promising class of targeted therapeutics are inhibitors of IDH1 and IDH2. Mutations in genes encoding these two enzymes are key events in AML pathogenesis, leading to accumulation of the oncometabolite (*R*)-2-hydroxyglutarate (2HG) and a block in cell differentiation. In view of recent genomic data, AML with *IDH2* mutations is likely to be classified as a separate entity. In August 2017, an oral inhibitor of mutant IDH2, enasidenib (IDHIFA, Celgene Corp.) was approved by FDA for treatment of relapsed or refractory *IDH2*-mutant AML. Enasidenib is also tested for treatment of newly diagnosed AML patients in combination with the induction and consolidation therapy, or with azacitidine in patients who are not candidates for intensive chemotherapy. Other IDH inhibitors, like AG-120 or FT-2102 (both IDH1 inhibitors), are in clinical development. Another class of targeted molecular therapeutics are agents that restore the function of mutant p53 protein. Among those, the small molecule PRIMA-1 and its methylated derivative PRIMA-1(MET; APR-246) can restore the wild-type conformation of the mutant p53 protein and thus restore its normal function, which results in apoptosis of tumor cells. The safety and efficacy of APR-246 is currently tested in a phase Ib/II clinical trial and it is actually the first compound targeting mutant p53 which has entered into a clinical trial.

Acute promyelocytic leukemia (APL) is a particularly aggressive AML subtype with distinctive clinical features and its management substantially differs form that for the other AML subtypes. APL is commonly associated with coagulopathy due to DIC and fibrinolysis. Therefore, aggressive supportive care is an important component of the APL treatment. This diagnosis used to be associated with a particularly poor prognosis. However, incorporation of all-*trans*-retinoic acid (ATRA) and precise risk stratification based on WBC count into the management strategies have resulted in dramatically improved outcomes. ATRA has the capacity to induce differentiation in APL blasts and thus reverse the coagulopathy which is the major cause of death during APL induction therapy. Patients with suspected APL are put on the ATRA therapy immediately, without waiting for a cytogenetically confirmed diagnosis, as this disease is rapidly fatal, usually due to early hemorrhage. If the APL diagnosis is not confirmed, the ATRA therapy is discontinued and patients are switched to standard AML induction therapy.

Following the APL diagnosis, patients are stratified according to their WBC count. Low-risk patients (WBC below 10×10^9/L) receive "chemo-free therapy," for example ATRA plus arsenic trioxide (ATO) until remission. ATO has been shown to be a potent inducer of apoptosis in APL cells. For higher risk patients, alternative regimens include ATRA with daunorubicin and cytarabine, or ATRA with idarubicin. Combining ATRA with an anthracycline for induction therapy has been shown to give CR rates exceeding 90%. Consolidation therapy for APL is most often ATRA with ATO for 4 weeks out of 8 weeks for 4 cycles, followed by ATRA 2 weeks on, 2 weeks off for 7 cycles. Other regimens using various combinations of ATRA, ATO and chemotherapy are also used. High-risk patients (WBC above 10×10^9/L) receive induction therapy with ATRA plus chemotherapy (daunorubicin and cytarabine or idarubicin) with or without ATO. Consolidation therapy consists of combinations of ATRA, ATO, and chemotherapy.

Following consolidation therapy, patients are assessed for molecular remission based on the analysis of bone marrow samples. Patients who have achieved CR are usually put on a maintenance regimen of ATRA with 6-mercaptopurine and methotrexate. In patients who do not achieve CR following the complete induction plus consolidation treatment and in relapsed patients, subsequent treatment with ATO is recommended, either as a single agent or in combination with chemotherapy. However, the optimal consolidation strategy following ATO-based treatment of patients with relapsed APL remains to be defined.

A serious complication associated with ATRA and ATO therapy is the APL differentiation syndrome (APLDS; also called the retinoic acid syndrome). It results from rapid differentiation of leukemic promyelocytic cells into mature polynuclear cells and is characterized by fever, weight gain, pleural and pericardial effusions, respiratory distress, episodic hypotension, and acute renal failure. This syndrome occurs in about 25% of patients treated with ATRA alone. However, concurrent administration of chemotherapy

(idarubicin and cytarabine) seems to reduce the APLDS incidence. Moreover, corticosteroids (dexamethasone) can be effective both as prophylaxis and therapy.

Assessing the response to treatment remains a challenging issue in the management of both APL and other AML subtypes. Complete remission (CR) is defined as the absence of circulating blasts and of extramedullary disease. However, patients who achieved CR according to morphological assessment can potentially harbor leukemic cells in the bone marrow, giving rise to low-level disease which is not detectable by conventional cytomorphological techniques (minimal residual disease, MRD). Many trials have confirmed that MRD is the strongest prognostic factor. Therefore, applying reliable sensitive methods to detect MRD is of utmost importance for further treatment planning and monitoring of treatment response at all stages following the induction therapy. MRD can be detected by multicolor flow cytometry or sensitive molecular techniques targeting characteristic genetic or chromosomal aberrations, like RT-PCR or next-generation sequencing. The current clinical guidelines have not incorporated MRD detection into postremission monitoring strategies, except for APL. However, including it in the guidelines for all AML subtypes is only a matter of time.

Pheochromocytoma and Paraganglioma

Definitions

Pheochromocytomas and paragangliomas (PPGLs) are neurally derived neoplasms arising from the adrenal medulla and extra-adrenal paraganglia respectively.

Paraganglia are anatomically dispersed neuroendocrine organs which are divided into two groups. The first group, known as "sympathetic" or "sympathoadrenal" paraganglia, is normally distributed along the prevertebral and paravertebral sympathetic chains, and along sympathetic nerve branches that innervate retroperitoneal and pelvic organs. The second group, known as "parasympathetic" or "head and neck" paraganglia, is associated with supradiaphragmatic branches of the vagus and glossopharyngeal nerves, predominantly in the middle ear and carotid bodies. The adrenal medulla is a sympathetic paraganglion and, by definition, pheochromocytoma is an intraadrenal sympathetic paraganglioma. Older literature frequently refers to sympathetic paragangliomas as extra-adrenal pheochromocytomas. However, current nomenclature reserves the name pheochromocytoma for tumors in the adrenal.

Sympathetic paragangliomas are almost always biochemically functional, that is, capable of catecholamine synthesis, and usually are also clinically functional, as defined by signs and symptoms of catecholamine excess. Pheochromocytomas are biochemically distinctive in that they often produce epinephrine, which is very rare in other paragangliomas. Parasympathetic paragangliomas are primarily located in the head and neck, and are usually clinically nonfunctional. A subset of these clinically silent tumors produces small quantities of norepinephrine and/or dopamine, but many do not express tyrosine hydroxylase which is required for catecholamine synthesis, and therefore they are also biochemically silent.

Burden

Paraganglionic tumors occur in patients of any age, but mainly in the fourth to fifth decades of life with approximately equal sex distribution. Hereditary disease commonly manifests before the age of 40 years. The annual incidence of pheochromocytoma is estimated at 0.4–9.5 cases per million population and that of head and neck paragangliomas at 1 case per 30,000–100,000 population. The prevalence of PPGL in hypertensive adults is approximately 0.1%–0.6% and higher in pediatric population (0.5%–2%). There is a higher prevalence of hereditary, extra-adrenal, multifocal, noradrenergic, and metastatic PPGLs in children than in adults.

Risk Factors

Hereditary susceptibility is the main causative factor for PPGLs, while chronic hypoxic states, that is, high altitude environment and cyanotic heart disease, are implicated as additional risk factors for head and neck PGLs. Prolonged hypoxic conditions have been suggested to contribute to development of sympathetic paragangliomas.

Pathology

The first histological description and histochemical contribution to diagnosis of pheochromocytoma was performed by pathologist Max Schottelius, who was acknowledged but not listed as an author of the classic 1886 paper by his clinical colleague Felix Fränkel. Paraganglionic tumors usually exhibit the classic histoarchitecture of an alveolar "Zellballen" pattern, comprising nests of polygonal neoplastic cells with peripheral sustentacular cells, separated by a delicate fibrovascular framework. Variations in architecture, unusual histological features and/or degenerative changes can be present, confounding the diagnosis. Unusual sites of occurrence, co-occurrence with other neuroendocrine tumors particularly in syndromic settings, and nonendocrine tumors in various anatomic sites might pose additional diagnostic challenges. Immunohistochemistry (IHC) is accordingly utilized as a valuable aid to diagnosis in challenging cases: PPGLs express generic neuroendocrine markers, that is, chromogranin A, synaptophysin and CD56, as well as specific paraganglionic markers, such as catecholamine-synthesizing enzymes, such as tyrosine hydroxylase and dopamine beta-hydroxylase, while usually negative for keratins, CEA and calcitonin. S100 and/or GFAP highlight the sustentacular cell population.

Molecular Pathology and Genetics

Genetic Profile

Pheochromocytomas and paragangliomas carry the highest degree of heritability among all human neoplasms. Approximately 40% of PPGL patients carry a causal germline mutation, while at least 30% of the remaining "sporadic" cases harbor a somatic mutation in a predisposing gene. Consequently, the American Society of Clinical Oncology recommends offering genetic testing to all PPGL-affected patients and the Endocrine Society has published clinical practice guidelines concerning genetic assessment by accredited laboratories. In the recent WHO Classification of Tumours of Endocrine Organs, 17 hereditary PPGL susceptibility genes are mentioned, that is, *VHL*, *RET*, *NF1*, *SDHD*, *SDHAF2*, *SDHC*, *SDHB*, *SDHA*, *TMEM127*, *MAX*, *EPAS1/HIF2A*, *PHD1/EGLN2*, *PHD2/EGLN1*, *FH*, *MDH2*, *KIF1B*, and *MEN1*.

The catalogue of genes implicated in PPGL pathogenesis is continuously expanding, including many genes of low mutational frequency. Tumor-suppressor genes and oncogenes reported at the germline and/or somatic level, in addition to the aforementioned ones, now include: *IDH1*, *IDH3B*, *GOT2*, *SLC25A11*, *HRAS*, *BRAF*, *CSDE1*, *IRP1*, *ARNT*, *SETD2*, *FGFR1*, *IGF1*, *EZH2*, *H3F3A*, *CDKN2A*, *CDKN2C*, *GNAS*, *TP53*, *BAP1*, *MSH2*, *ATRX*, *MET*, *MERTK*, *KMT2D*, *KMT2B*, *JMJD1C*, *STAG2*, *PALB2*, *STAT3*, *CREBBP*, *EP300*, *WHSC1L1*, *SMARCA4*, *SMARCA5*, *SMARCAL*, *SMARCE1*, and *ARID1B*. Mutations in *IDH1*, *HRAS*, *BRAF*, *CSDE1*, *IRP1*, *ARNT*, *SETD2*, *FGFR1*, *TP53*, *ATRX*, *CDKN2A*, *CDKN2C*, *GNAS*, *STAG2*, *PALB2*, *STAT3*, *CREBBP*, *EP300*, *WHSC1L1*, *SMARCA4*, *SMARCA5*, *SMARCAL*, *SMARCE1*, and *ARID1B* have been reported thus far at the somatic level only, *HRAS* and *BRAF* mutations displaying a mean frequency of about 9% in sporadic paraganglionic tumors. *NF1* inactivation is more common at the somatic level in contrast to the *SDHx* mutations, which are exceedingly rare in the absence of germline mutations. *NF1*, *HRAS*, *EPAS1/HIF2A*, *ATRX*, *VHL*, *RET*, and *CSDE1* are frequent somatically mutated genes.

In addition to low mutation frequency of significant genes, PPGLs have a low mutational load and some mutations are mutually exclusive. As an example, somatic *HRAS* mutations have not been detected in cases with known PPGL susceptibility gene mutations. In contrast, other somatic variants do co-occur with germline mutations. These include *ATRX* with *SDHx/VHL/RET/NF1/FH* mutations, *CDKN2C* with *RET* mutations, *NF1* with *EZH2* mutation, *EPAS1/HIF2A* with *IGF1* mutation, *KDM2B/TP53* with *SDHB* mutation, *KIF1Bb/MET* with *NF1* mutation and *VHL* with *SDHA* mutation. In this context, a subset of aggressive SDH-deficient extra-adrenal PGLs is enriched for mutations in non-coding functional genomic regions, such as the promoter of the telomerase reverse transcriptase (*TERT*) gene. At the somatic level, co-occurrence of mutations in PPGL susceptibility genes, that is, *RET/VHL/MAX/MET* co-occurring with *NF1* mutation, has been reported. In the era of massively parallel sequencing of PPGL patients, potential cases of double germline mutations or *M*ultilocus *I*nherited *N*eoplasia *A*lleles *S*yndrome (MINAS) were found, for example, germline *PTEN* and *SDHC* mutations in a patient suffering from multifocal papillary thyroid carcinoma and carotid PGLs. These findings, along with the fact that PPGLs of different genetic backgrounds share overlapping territories of genomic gain or loss, suggest that co-segregation of susceptibility mutations might play a pathogenetic role, in keeping with other paradigms of molecular tumourigenesis.

Integrative genomic analysis has provided strong concordance between the mutation status of the well-known PPGL susceptibility genes and multiomics data, adding further to the initial transcription profile-based PPGL classification into a pseudohypoxic cluster 1 (*VHL*, *SDH-x*, *FH*, *MDH2*, *EPAS1/HIF2A*, *PHD1/EGLN2*, *PHD2/EGLN1*) and a kinase receptor-signaling cluster 2 (*RET*, *NF1*, *TMEM127*, *MAX*, *KIF1B*). The close link between gene-expression subtypes of PPGL and tumor genotype has been subsequently confirmed with *HIF2A*-mutated PGLs displaying a characteristic expression signature within the pseudohypoxic cluster. A consensus clustering analysis of multi-omics data classified paraganglionic tumors into five molecular subgroups with distinct driver mutations, copy number changes, DNA methylation aberrations, miRNA dysregulations, expression signatures, and clinical characteristics. The following clusters emerged: (1) cluster C1A comprising *SDHx*- and *FH*-mutated tumors; (2) cluster C1B comprising *VHL*-mutated tumors; (3) cluster C2A comprising tumors containing *RET*, *NF1*, *TMEM127*, *MAX*, *HRAS* mutations; (4) cluster C2B comprising tumors containing *MET* mutations; and (5) cluster C2C. Clusters C2B and C2C were enriched in sporadic tumors.

A Cancer Genome Atlas project (TCGA) study classified PPGLs by comprehensive integrated analysis into four molecularly defined groups: (1) pseudohypoxia subtype, (2) kinase signaling subtype, (3) Wnt-altered subtype, driven by *MAML3* and *CSDE1*, and (4) a cortical admixture subtype possibly representing adrenal cortical contamination of PCCs belonging to other groups. An important discovery in the TCGA study was the presence of fusion genes in PPGLs, involving *MAML3*, *BRAF*, *NGFR*, and *NF1*, adding to the diversity of mechanisms that influence PPGL pathogenesis through a broad range of biological pathways. In addition to germline/somatic mutations, these include postzygotic mosaicism, epigenetic alterations (e.g., extensive genome methylation in *SDHx*-mutated tumors), fusions as well as large and recurrent structural alterations/copy number changes (1p/3q, 11p, 11q, 6q, 17p, 22 losses; 9q, 17q, 19p13.3, and 20q gains).

Genetic Susceptibility

Germline mutations in almost all PPGL susceptibility genes lead to an autosomal dominant pattern of inheritance. In those familial cases associated with *SDHD*, *SDHAF2*, and *MAX* mutations, there is a parent-of-origin expression phenotype, with paraganglioma development almost always dependent on inheritance via the paternal line. However, PCC-affected patients have inherited the *SDHD* mutation via the maternal line. The Hensen model, the Muller threshold model and the Baysal methylated boundary

element model have been proposed to explain the mechanism underlying the paternal transmission of *SDHD* and/or *SDHAF2* mutations.

Gain-of-function mutations in the *RET* proto-oncogene and *EPAS1* do not require a second hit, in contrast to tumor suppressor genes characterized by inactivation or loss of the wild-type allele in the tumors. Nonetheless, double *RET* mutations at the somatic/germline level, duplication of the mutated *RET* allele, double *EPAS1* mutations at the somatic and/or somatic/germline level as well as somatic *EPAS1* mutation co-occurring with *EPAS1* locus amplification have been documented in paraganglionic tumors. Most *EPAS1* mutations associated with PPGL are somatic/mosaic. This expands the spectrum of endocrine syndromes that can involve mosaicism, including neurofibromatosis type 1 (NF1) and McCune-Albright syndrome. Although mosaicism is caused by a postzygotic de novo mutational event, usually resulting in somatic mosaicism, the mutation can potentially also be present in germinal cells (germline mosaicism) and therefore be transmitted to the offspring. This possibility creates genetic counseling implications. Postzygotic mutation in the histone 3.3 encoding gene (*H3F3A*) was recently linked to a new paraganglioma syndrome, encompassing paraganglionic tumors and aggressive giant cell tumor of bone, and without a family history of pheochromocytoma or paraganglioma.

Another nonhereditary genetic disorder, possibly characterized by mosaicism, is the Carney Triad, a syndrome of tumors affecting at least five organs, that is, GIST in the stomach, pulmonary chondroma, PCC/PGL of adrenal medulla/extra-adrenal paraganglia, adrenal cortical adenoma and leiomyoma of the esophagus. Although approximately 10% of Carney Triad patients harbor germline variants in the *SDHA*, *SDHB* or *SDHC* genes, most cases display SDH down-regulation through site-specific aberrant DNA hypermethylation of the *SDHC* gene promoter. Germline and/or somatic mosaicism for *SDHC* promoter methylation has been documented in GIST-affected patients as well as in patients suffering from PGLs and adrenocortical adenoma and/or PCCs and GIST. Although it remains speculative whether these might represent Carney Triad cases with incomplete phenotypic expression, epigenetic changes should be taken into consideration in the evaluation of PPGL-affected patients. Of note, *SDHC* epimutations have been documented exclusively in females.

Awareness of syndromic associations (**Table 1**) and genotype-phenotype correlations, provides clues to occult hereditary disease, which has important implications both for the patients and their families in terms of genetic testing and counselling, active surveillance programs and management. Specific tumor combinations, that is, PPGLs and enteropancreatic neuroendocrine tumors, pituitary adenomas, adrenocortical adenomas, renal tumors, gastrointestinal stromal tumors (GISTs) or peripheral neuroblastic tumors (**Table 2**) should raise a suspicion of occult hereditary disease. Although these neoplasms and/or related conditions such as polycythemia do arise within different genetic syndromes, it remains elusive whether particular dysregulated pathways, for example, defects in oxygen sensing pathways for polycythemia, and/or inherently susceptible tissues explain distinctive combinations of findings associated with different genotypes.

MEN2- and TMEM127-related adrenal gland pathology is characterized by bilateral and/or multicentric micro- and macro-PCCs, different from this seen in VHL with a thick vascular capsule, small- to medium-sized tumor cells with amphophilic clear cytoplasm and numerous interspersed small vessels. The qualification of micro-PCCs to nodular adrenomedullary hyperplasia has been recently expanded in the MAX-deficient state. Worth mentioning is also SDH-deficient GIST with its particular gastric location (predilection for the distal stomach/antrum), common multifocality, a multinodular/plexiform growth pattern, epithelioid cytomorphology, either pure or combined with a spindle-cell component, SDHB and/or SDHA immunonegativity, metastatic potential, a relatively indolent clinical course, even in the presence of metastatic disease (often to lymph nodes), and insensitivity to imatinib. Finally, pathological features of SDH- and FH-deficient renal cell carcinoma (RCC) merit to be mentioned. SDH-deficient RCC exhibits uniform low-grade cytology, cytoplasmic vacuoles, eosinophilic or flocculent cytoplasm, focal cystic change, solid to lobulated growth with peripherally entrapped renal tubules and absence of immunoreactivity for SDHB and/or SDHA. FH-deficient RCC exhibit predominantly papillary morphology combined with additional architectural patterns, and at least focal presence of eosinophilic macronucleoli with perinucleolar halos, reminiscent of viral inclusions, and display loss of FH expression and aberrant S-(2-succinyl) cysteine (2SC) immunoreactivity.

In parallel with recent advances in molecular genetics, IHC has emerged as a screening tool for inferring the presence of mutations in patients presenting with tumors associated with hereditary cancer predisposition syndromes. Since IHC detects a phenotype rather than a genotype, it should ideally be regarded as a preliminary screen to triage patients for optimal genetic testing. In particular, IHC has been shown to complement morphological or clinical suspicion of hereditary PPGL predisposition syndromes.

Currently, three panels of IHC staining are in use: (i) IHC staining for SDHB/SDHA/SDHD to evaluate SDH deficiency (**Fig. 1**) (ii) staining for FH and 2SC to evaluate FH deficiency; and (iii) staining for MAX to evaluate MAX deficiency. Loss of SDHB protein expression is seen in PPGLs either harboring a germline mutation in any of the *SDHx* genes (**Fig. 2**) or with somatic hypermethylation of the promoter region of *SDHC* gene, whereas loss of both SDHB and SDHA immunoreactivity is exhibited only in the context of an *SDHA* mutation. Loss of FH expression and 2SC overexpression in cases containing germline *FH* mutations, while immunohistochemical expression of MAX is negative in cases harboring *MAX* truncating mutations.

SDHB/SDHA IHC has been integrated either in genetic testing algorithms along with other parameters, that is, tumor location and biochemical/secretory phenotype, or in genetic testing strategies encompassing massively parallel sequencing (NGS panels) and copy number variation (CNV) analysis. In the presence of syndromic presentation and/or known familial variant, targeted sequencing is accordingly recommended. Despite the availability of genetic testing of PPGLs at an ever-decreasing cost, IHC still remains an important integrated component of algorithms to guide either subsequent Sanger sequencing or biological validation of variants of uncertain significance (VUS) identified by massive parallel sequencing. Correct immunohistochemical evaluation is critical, given that false-positive or false-negative interpretation can result in failure to identify PCC/PGL affected individuals at

Table 1 Clinical presentations of pheochromocytoma and paraganglioma associated with germline mutations and somatic mosaicism

Gene	*Mutation rate (%)*[a]	*Predominant tumor site*	*Tumor number*	*Nonparaganglionic tumors and other related features*
VHL	7	PCC > PGL	Multiple	Retinal and CNS hemangioblastoma, clear cell RCC and renal cysts, pancreatic neuroendocrine tumor and pancreatic cyst, endolymphatic sac tumors, papillary cystadenoma of the epididymis/broad ligament and mesosalpinx
RET[b]	6	PCC > PGL	Multiple	Medullary thyroid carcinoma, multiglandular parathyroid disease, marfanoid habitus, mucocutaneous neuromas, gastrointestinal ganglioneuromatosis, cutaneous lichen amyloidosis
NF1	3	PCC > PGL	Single	Neurofibroma, malignant peripheral nerve sheath tumor, gastrointestinal stromal tumor, optic nerve and other brain stem glioma, neuroendocrine tumor (somatostatinoma) of the periampullary duodenum, cafe-au-lait spots and axillary or inguinal freckling, Lisch nodules, dysplasia of sphenoid bone or long bones, kyphoscoliosis, cerebral arteriopathy, pulmonary artery stenosis, learning disabilities
SDHA	1–3	PGL >> PCC > PGL/PCC	Single > multiple	Gastrointestinal stromal tumor, pituitary adenoma, SDH-deficient RCC, melanoma?
SDHB	6–8	PGL > PCC	Multiple	Gastrointestinal stromal tumor, SDH-deficient RCC, pituitary adenoma
SDHC	1–2	PGL > PCC	Multiple	Gastrointestinal stromal tumor, SDH-deficient RCC, pituitary adenoma
SDHD	5–6	PGL > PCC	Multiple	Gastrointestinal stromal tumor, SDH-deficient RCC, pituitary adenoma, pancreatic neuroendocrine tumor?
SDHAF2	0.1	PGL > PCC	Multiple	None reported
FH	1	PCC > PGL	Single	Hereditary leiomyomatosis and RCC (HLRCC) phenotypic manifestations including cutaneous and uterine leiomyomas and/or leiomyosarcomas? and FH-deficient RCC encompassing papillary RCC Type 2, tubulo-papillary RCC and/or tubulocystic RCC with poorly differentiated foci, and collecting duct RCC; and leydig cell tumor of the testis?
MDH2	<1	PGL?	?	?[c]
TMEM127	2	PCC > PGL > PCC/PGL	Multiple	Clear cell RCC
MAX	1	PCC > PGL	Multiple	Pituitary adenoma, Renal oncocytoma? RCC?
KIF1B (*s* > *g*)	<1	PCC?	?	Neuroblastoma? ganglioneuroma? Lung and colorectal adenocarcinomas? Endometrial carcinoma? Leiomyosarcoma?
EPAS1/HIF2a[b] (*s* and *s/m* >> *g*)[d]	1	PGL > PCC >> PGL/PCC	Multiple > single	Polycythemia with markedly elevated EPO levels, duodenal somatostatinoma, hamangioblastoma, ocular manifestations, that is, dilated capillaries, retinal neovascularization and fibrosis overlying the optic disc
H3F3A (m)	<0.1	PCC/PGL	?	Giant cell tumor of the bone; recurrent/metastatic forms
PHD1/EGLN2	<1	PCC/PGL	?	Polycythemia with borderline or mildly elevated EPO levels
PHD2/EGLN1	<1	PGL∼PCC	?	Polycythemia with borderline or mildly elevated EPO levels?
BAP1	<1?	PGL?	?	Uveal melanoma, malignant mesothelioma, cutaneous melanoma, atypical spitz tumors/naevi, basal cell carcinoma, RCC
MEN1	<1?	PCC > PGL	Single	Parathyroid adenoma/hyperplasia, entero-pancreatic neuroendocrine tumor (gastrinoma > nonfunctioning/ PPoma > Insulinoma > Glucagonoma/VIPoma), pituitary adenoma (prolactinoma > somatotrophinoma > corticotrophinoma/ nonfunctioning), adrenal cortical tumor, brochopulmonary neuroendocrine tumor, thymic neuroendocrine tumor, gastric neuroendocrine tumor, angiofibromas, collagenomas, lipomas, meningiomas
MET[b] (*s* > *g*)[d]	<1?	PCC > PGL	?	Germline *MET* mutations are associated with Hereditary Papillary RCC[e]
MERTK[b] (*g*∼s)?	<1?	PCC/PGL	?	Medullary thyroid carcinoma?

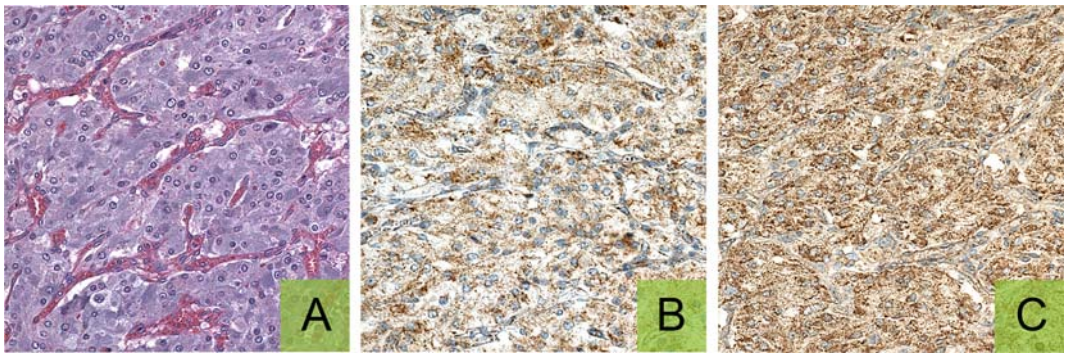

Fig. 1 Sporadic pheochromocytoma (A; H&E) with wild type SDH showing identical patterns of granular cytoplasmic staining for SDHB (B) and SDHA (C) corresponding to the mitochondrial localization of the enzyme. For proper interpretation, staining should be granular and of the same intensity as in endothelial cells, which serve as an essential endogenous control.

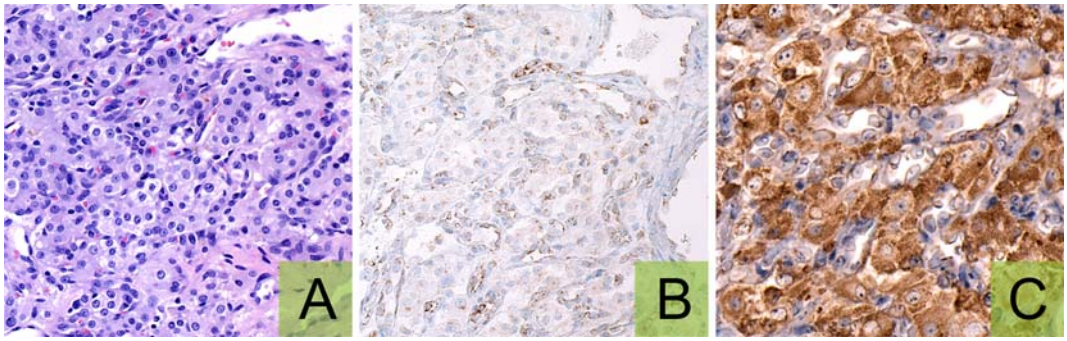

Fig. 2 Extra-adrenal paraganglioma (A; H&E) arising in the context of germline *SDHB* mutation. Granular cytoplasmic staining for SDHB (B) is maintained in endothelial cells and lost in tumor cells. Note that some tumor cells show a faint blush of non-granular background stain.

increased risk for other than endocrine-related neoplasia (e.g., GIST and/or RCC), incorrect interpretation of the pathogenicity of genetic VUS and inappropriate genetic testing.

In order for clinical practice to keep pace with the rate of discovery as well as to advance the diagnosis and optimize PPGL-affected patient care, a comprehensive reporting template has been proposed taking into consideration clinicopathologic correlations and SDHB/SDHA IHC. A simpler pathology reporting template based on current established evidence for clinical relevance of each of the pathology parameters is being developed under the auspices of the International Collaboration on Cancer Reporting (http://www.iccr-cancer.org/) and major pathology societies.

Microenvironment Including Immune Response

The antitumor immune response has been largely unexplored in PPGLs. In an attempt to evaluate prevalence and clinico-pathologic significance of programmed cell death (PD) ligands expression in PPGLs, evidence has emerged, supporting differential regulation of PD-L1 and PD-L2, the latter having a more predominant role in shaping the immune-tolerogenic environment given a preferential co-expression of immune-inflammatory genes in association only with PD-L2.

Experimental studies have shown that the microenvironment, as represented by primary cancer-activated fibroblasts, plays a pivotal role in enhancing collective migration/invasion in spheroids of mouse Pheo *SDHB*-silenced cells.

Staging and Grading

Staging

TNM staging of tumors of the adrenal medulla and extra-adrenal paraganglia (PPGLs), has been recently introduced in the American Joint Committee on Cancer (AJCC) staging manual, 8th edition. Stage 1 and stage 2 are defined as strictly localized pheochromocytomas with a size of <5 cm or ≥ 5 cm in greatest dimension, respectively. Stage 2 includes sympathetic paragangliomas of any size, but without invasion into surrounding tissue. Stage 3 tumors are characterized by infiltration into surrounding tissue (e.g., liver, pancreas, spleen, kidney) or positive regional lymph nodes. Stage 4 is restricted to patients with distant metastasis to bone (M1a), to only distant lymph nodes/liver or lung (M1b) or to bone plus multiple other sites (M1c). According to this staging system, parasympathetic paragangliomas are not staged as they are regarded as largely benign.

Grading

Currently, no histologic grading system is widely utilized or endorsed. The Pheochromocytoma of the Adrenal Gland Scaled Score (PASS) scoring system has been proposed for stratifying risk of metastasis only for pheochromocytomas and based on histological features, while the GAPP (Grading of Adrenal Pheochromocytoma and Paraganglioma) system has been proposed for predicting metastatic disease for both pheochromocytomas and paragangliomas and is based on histologic and non-histologic parameters.

Prognostic and Predictive Biomarkers

In contrast to the WHO 2004 classification of endocrine neoplasia which defined malignancy by development of metastatic disease, current thinking as stated in the WHO 2017 classification assumes metastatic potential in all PPGLs and adopts an approach based on risk stratification. At present, the major risk factors are *tumor location*, *size*, *genotype*, and *biochemical phenotype*, all of which are interrelated. Local invasion, even if extensive, is a poor predictor of metastasis when considered alone, but is one of several putative adverse features in proposed grading systems. The overall risk of metastasis in PPGLs is approximately 10%–15%. In decreasing order of frequency, around 40% of extra-adrenal sympathetic PGLs, 5%–10% of pheochromocytomas and 4%–6% of head and

neck PGLs metastasize. In order to differentiate between metastases and multiple primary tumors, the diagnosis of metastasis requires the presence of tumor at anatomic sites devoid of normal paraganglionic tissue, that is, nodes, bone, liver, and lung. Rarely, mostly solitary primary paragangliomas occur in lung or near the hilum of the liver.

Although metastases can develop decades after resection of a primary tumor, 35%–40% of patients whose tumors are destined to metastasize have synchronous metastases at initial presentation and 65% of patients develop metachronous metastases at a median of 5.5 years. The clinical course of patients with metastatic PPGL is heterogeneous with metastases not necessarily signifying a poor short-term prognosis, in accordance with variable mortality rates. R a p i d disease progression has been associated with male sex, older patient age at initial diagnosis, synchronous metastases, tumor size >5 cm, elevated dopamine and unresectability of primary tumor. Noradrenergic and/or dopaminergic biochemical phenotype appears to be related to metastatic potential, while distant metastases seem to be associated with overall survival rate. In particular, patients with bone metastases only have better survival than liver and/or lung metastatic disease regardless of co-existence of skeletal metastases.

In support of a close link between prognosis and genetic profile, up to 55% of pediatric and/or adult PPGL patients with metastatic disease have been reported to be germline *SDHB* mutation carriers. Despite the fact that children show a higher prevalence of metastatic PPGLs, *SDHB*-mutated children survive longer than adult patients with germline *SDHB* mutations. Lower survival rates have been documented in the latter compared with apparently sporadic counterparts further adding to the concept that SDHB status is predictive of patient outcome.

The enrichment of Krebs cycle-related gene mutations, i.e. succinate dehydrogenase subunits (*SDHA/B/C/D*) and assembly factor (*SDHAF2*), fumarate hydratase (*FH*), malate dehydrogenase 2 (*MDH2*), isocitrate dehydrogenases (*IDH1/IDH3B*), as well as mitochondrial genetic defects i.e. mitochondrial 2-oxoglutarate/malate carrier (*SLC25A11*) or glutamic-oxaloacetic transaminase 2 (*GOT2*), highlights a link between metabolism and downstream signaling pathways involved in PPGL tumorigenesis. Based on metabolic profiling, genotype-specific differences were illustrated in PPGLs with a specific succinate-glutamate signature of *SDH*-mutated PGLs and/or ratios of succinate:fumarate and other metabolites proposed as a method to identify patients for testing of *SDHx* mutations and to validate VUS with prognostic implications. In this context, it has been shown that mass spectrometric profiling can identify PPGLs with metastatic potential based on differential expression of specific asparagine-linked glycan (N-glycan) structures.

Recent TCGA analysis revealed differences in mutations and mRNA expression between metastatic and non-metastatic PPGLs and MAML3 fusion gene was found to correlate with metastatic potential. A significantly higher mutation density was detected in malignant than in benign tumors. Structural *TERT* rearrangements underlying *TERT* activation were documented in metastatic pheochromocytomas, in the absence of *TERT* promoter mutations or promoter DNA methylation. As histological and/or multiparameter scoring systems are not currently endorsed, biomarkers emerging from transcriptomic profiling and/or DNA methylation analysis hold promise for stratifying PPGL patients according to risk of developing metastasis.

Adrenal Cortical Carcinoma

Definition

Adrenal cortical carcinoma (ACC) is a malignant epithelial neoplasm arising from the mesodermal-derived cortex of the adrenal gland.

Burden

ACC is a rare endocrine malignancy with an annual incidence of 0.5–2.0 cases per 1 million population. ACC is even more uncommon in the pediatric population, except in geographic regions with a high prevalence of founder mutations which account for a high incidence, e.g. *TP53* p.R337H mutation in Southern Brazil with a penetrance of adrenal cortical tumors estimated approximately at 10%. The median age at diagnosis is in the fifth and six decades with a female preponderance and a F:M ratio ranging from 1.5:1–2.5:1. A bimodal distribution has been suggested with a second incidence peak during childhood and a striking female predominance observed at a young age (3:1), but not in children ≥ 10 years old (1:1). Differences in age of onset (≤ 5 years and/or >5 years) and hormonal secretion pattern of pediatric adrenocortical tumors might be *tissue* (fetal or transient embryonic adrenal cortex)- and/or *genotype* (germline *TP53* mutation)-dependent, possibly reflecting perturbations of sex- and age-specific developmental processes in the adrenal cortex.

Risk Factors

Hereditary susceptibility is the main causative factor (see *Genetic Susceptibility*). Subsets of ACC exhibit mutation signature 1, featuring C > T substitution in a CG context and resembling the age- and DNA-mismatch repair-deficiency signatures. They also exhibit mutation signature 2, featuring A > T substitution in a CG context and resembling the smoking signature. The latter is in accordance with data derived from the 1986 National Mortality Followback Survey suggesting heavy cigarette smoking as a risk factor in men. The same study supported a role of using oral contraceptives before the age of 25 as risk factor in women. This is consistent with clinical data indicating that proliferation and/or secretion of adrenocortical neoplasms might be affected by the

hormonal context of pregnancy. It is also supported by experimental evidence: a growth-inhibitory effect of selective estrogen receptor modulators on human adrenocortical cell line H295R and on human tumors xenografted in athymic nude mice.

Pathology

For a diagnosis of malignancy (i.e., the ability to invade adjacent structures and metastasize) of an adrenal cortical neoplasm, multiparametric histopathological scoring systems are used, including parameters such as cell type, tumor architecture, tumor cell invasion, and cellular proliferation. These systems include the Weiss scoring system, Hough scoring system, van Slooten scoring system, Weiss revisited index and/or diagnostic algorithms, including the stepwise discriminate diagnostic system and the "reticulin" diagnostic algorithm. The latter defines malignancy in a two-step process, the presence of a disrupted reticulin framework constituting the first step of this diagnostic approach, and subsequent identification of at least 1 out of 3 parameters: a high mitotic rate ($>5/50$ HPFs), necrosis, and venous invasion. Both the "reticulin" algorithm and the Helsinki score, a novel model for prediction of metastases in ACCs based on mitotic index ($>5/50$ HPFs), necrosis and Ki67 labeling index, have been subsequently validated.

The Weiss system is the most popular among all multifactorial scoring systems, comprising nine histologic parameters, that is, *high nuclear grade*, *mitotic rate* (>5 mitotic figures/50 HPFs), *atypical mitoses*, *<25% clear cells*, *diffuse architecture*, *tumor necrosis*, *capsular invasion*, *venous invasion*, and *sinusoidal invasion*, with presence of ≥ 3 indicating malignant behaviour. Nevertheless, no particular system is currently endorsed in the 2017 WHO classification. Various limitations of the Weiss system include lack of reproducibility of several criteria, borderline tumors with a Weiss score of 2 or 3, oncocytic and myxoid variants of adrenocortical neoplasms, and pediatric adrenocortical tumors, which are frequently overdiagnosed as malignant given the presence of impressively atypical histologic features. With regard to the latter, a specialized classification system has been proposed by Wieneke et al., while the Lin-Weiss-Bisceglia system has been established for oncocytic adrenocortical neoplasms given the inherent presence of three definitional criteria and overdiagnosis of malignancy if Weiss system is applied.

On a large ACC series, assessment of the most frequent diagnostic pitfalls resulted in a disagreement level as high as 9% of referral cases. Misclassification of metastatic and/or primary intra-adrenal tumors (PCC, ACA, and soft tissue neoplasm) as ACCs and vice versa accounted for such discrepancies, which significantly modified clinical management. An immunohistochemically determined Ki67 proliferation index $>5\%$ and/or over-expression of IGF2 with a characteristic juxtanuclear (Golgi) dot-like pattern are useful for accurate classification of adrenocortical neoplasms. From a differential diagnostic perspective, ACCs usually exhibit reactivity for steroidogenic factor-1 (SF-1), Melan-A, inhibin-α, calretinin and synaptophysin, while they are negative for cytokeratins, EMA, CEA, PAX-8, HMB-45 and chromogranin-A. Hence, this immunohistochemical panel can exclude *intraadrenal tumors*, for example, PCC and primary soft-tissue neoplasms, *metastatic tumors*, for example, lung/breast/colorectal adenocarcinomas, urothelial carcinomas and melanomas, and *adrenal gland involvement by other malignancies*, for example, renal cell carcinoma, hepatocellular carcinoma and retroperitoneal sarcomas.

Despite these advances, some adrenocortical neoplasms defy classification into benign and malignant categories. In such cases, the diagnosis germ of *adrenocortical neoplasm of uncertain/undetermined malignant potential* can be used.

Molecular Pathology and Genetics

Genetic Profile

Driver-gene mutations and activation of key cellular signaling pathways they control appear to suffice for adrenal tumorigenesis. By adapting methods from molecular evolution to the study of cancer genomes, it has been shown that positive selection outweighs negative selection during cancer development, while the number of driver mutations increases, but not linearly, with increasing mutation burden. Multistep tumorigenesis within ACCs was further corroborated by data emerging from pan-genomic analysis of TCGA based on variant allele fractions, genotype and LOH patterns and from a comprehensive genomic analysis of pediatric adrenocortical tumors based on timing of copy-neutral-LOH patterns and the temporal order of somatic single nucleotide variations (SNV). The former displayed widespread chromosomal loss with whole genome doubling (WGD) as important genomic event in ACC progression, while the latter highlighted copy-neutral-LOH of chromosomes 11/17 as early driver events with subsequent SNV acquisition in these regions.

Whether ACCs arise de novo or as result of an adenoma-to-carcinoma sequence is still not settled, although clinicopathologic and molecular evidence in support of a progression model is accumulating. Molecular evidence in support of stepwise progression derives from isolated reports, single nucleotide polymorphism (SNP) array profiling, comparative genomic hybridization, X-chromosome inactivation pattern analysis and microsatellite allelotyping. Nevertheless, this sequence is currently regarded as exceptionally rare with an extremely low progression rate given molecular and/or epidemiological data.

In the pediatric context, a similar model was also proposed for *TP53*-associated adrenocortical tumors, arising from a simpler genomic background and progressing to acquire complex genomic aberrations. Given shared molecular attributes in pediatric adrenal cortical tumors, that is, germline *TP53* mutations, chromosome 11p15 abnormalities, and IGF2 overexpression, it has been recently proposed that adrenocortical adenomas, tumors of undetermined histology and ACCs represent a spectrum of the same disease.

The comprehensive TCGA study has recently provided detailed insight in molecular events in ACC oncogenesis. ACC displayed a heterogeneous somatic mutation density with a median of 0.9 per Mb, which is higher than all genitourinary malignancies, with

the exception of urothelial carcinoma of the bladder. Significantly mutated genes were *TP53*, *CTNNB1*, *MEN1*, *PRKAR1A*, and *RPL22*. The catalogue of known ACC driver genes was expanded to include *TERF2*, *CCNE1*, and *NF1*. A low frequency of gene fusions was found without recurrent events. Copy number alterations were significant with WGD as hallmark mechanism for disease progression. Expression level of telomerase reverse transcriptase (*TERT*) was high but telomere length decreased, highlighting the role of telomerase reactivation and telomere maintenance. Finally, *p53 apoptosis/Rb1 cell-cycle* pathway and *Wnt/β-catenin* pathway as well as *PKA subnetwork* were significantly modified. Despite the relative lack of targetable hotspot mutations, a subset of ACCs demonstrated approximately 50 potentially actionable alterations, encompassing mutations and copy-number changes.

The TCGA study was based on a near-global ACC sample and in continuity with previous efforts on adult and pediatric adrenocortical cancer from Europe, North America and Brazil. This confirmed (i) highly prevalent IGF2 over-expression; (ii) high frequency of *TP53* mutations, which are dominant in the pediatric setting; (iii) high frequency of diverse defects resulting in deregulation of the *Wnt/β-catenin* pathway, that is, *CTNNB1* point mutations, homozygous deletion of Wnt repressors *ZNRF3/KREMEN1* and/or deactivating *APC/MEN1* alterations; (iv) evidence for epigenetic deregulation, for example, alterations of chromatin remodeling (*ATRX/DAXX*) and histone modification (*MLL/MLL2/MLL4*) genes; and (v) significant copy number changes with recurrent focal involvement of the *ZNRF3* and/or *TERT* loci. Along these lines, *TERT* promoter mutations were also detected in a small subset of ACCs in accordance with previously published data. In addition, the TCGA study expanded the transcriptomics classification and refined the multi-omics classification of two distinct molecular entities C1A/C1B driven by different oncogenic alterations into three molecular Cluster of Cluster (CoC) subtypes I/II/III with distinct clinical outcomes based on integrated analysis of DNA copy number, mRNA expression, DNA methylation and miRNA expression.

The occurrence of genome near-haploidisation with or without subsequent *endo*-reduplication has been demonstrated in thyroid, parathyroid and adrenocortical tumors with oncocytic features and without any associations with mitochondrial (mt) DNA mutations. In another study, the 4977 bp mtDNA "common deletion" was detected in approximately 50% of oncocytic adrenocortical neoplasms and with a relatively high degree of intercellular and intracellular heteroplasmy. A subset of sarcomatoid ACC was shown to be monoclonal in origin with dysregulation of *Wnt/β-catenin signaling* pathway and mutational *TP53* inactivation as frequent genetic events. In this context, SF1 immunonegativity and/or loss of expression of steroidogenic enzymes provided further evidence of a dedifferentiation process in this ACC variant.

Molecular diagnostic markers that differentiate ACCs from adenomas have been stemming from gene expression, microRNA and DNA methylation profiling analyses. Further studies are warranted in order to validate and define the level of diagnostic accuracy for such molecular tests especially in borderline adrenocortical tumors.

Genetic Susceptibility

Hereditary transmission of ACCs is uncommon: most tumors are sporadic. Nonetheless, the spectrum of genes associated with familial cancer susceptibility syndromes encompasses *TP53* (Li-Fraumeni syndrome), *IGF2/CDKN1C/H19* locus alterations on 11p15 (Beckwith-Wiedemann syndrome), mismatch repair (MMR) genes, that is, *MSH2*, *MSH6*, *MLH1*, *PMS2* (Lynch syndrome), *APC* (Familial Adenomatous Polyposis syndrome), *NF1* (Neurofibromatosis type 1), *MEN1* (Multiple Endocrine Neoplasia type 1), and *PRKAR1A* (Carney Complex). Pathogenic *MUTYH* mutations were also present in ACC patients of two series analyzed by whole-exome sequencing and with the corresponding tumors displaying loss of the wild-type *MUTYH* allele. Germline *MUTYH* mutations are associated with MUTYH-associated polyposis and of interest is that mostly benign adrenal lesions are relatively frequent in patients with polyposis, that is, Familial Adenomatous Polyposis, Attenuated Familial Adenomatous Polyposis and/or MUTYH-Associated Polyposis, who undergo abdominal imaging.

Exceedingly rare examples of ACCs have been reported arising in patients with germline *SDHC/SDHA* mutations (PGL3/PGL5), *FH* (Hereditary Leiomyomatosis and Renal Cell Cancer), *BRCA2 (*BRCA2 hereditary breast and ovarian cancer syndrome*)* and in the context of Werner syndrome, a rare genetic disease caused by pathogenic *WRN* mutations and often accompanied by various types of malignancy. However, ACC is not considered component of the tumor spectrum of the aforementioned syndromes, while evidence for biallelic inactivation in the tumor was documented only in two cases, that is, *SDHC* and *BRCA2*.

Adrenal cortical carcinoma is a core malignancy of the classical tumor spectrum of Li-Fraumeni syndrome with germline *TP53* mutations accounting for 50%–80% of ACC cases in the pediatric population. Nonetheless, only 4%–6% of carriers develop adrenal cortical tumors, indicative of co-operating genetic alterations in the tumorigenic process. Hotspot *TP53* p.R337H mutation exerts founder effect and was found in one out of 375 individuals within a total population of ~100 million in Southern and Southeastern Brazil. Those carriers exhibit variable tumor susceptibility ranging from isolated pediatric ACC cases to Li-Fraumeni or Li-Fraumeni-like syndromes.

Genotype-phenotype correlations were reported in the setting of this pleiotropic hereditary cancer syndrome with a proposed clinical gradient of germline *TP53* mutations: (i) dominant-negative missense mutations as the most severe aberrations significantly associated with early tumor onset and representing the main germline alterations in carriers who develop childhood cancers apart from ACC; (ii) nondominant-negative missense mutations which define an intermediate class with regard to clinical severity; and (iii) loss of function mutations, that is, nonsense mutations, frameshift mutations, or genomic rearrangements, as the less severe aberrations associated with later tumor onset, and mainly detected in pedigrees characterized by cancers occurring in adults. Gene alterations other than dominant-negative missense mutations were detected in the majority of pediatric ACCs; with the low-penetrant *TP53* p.R158H mutation as the predominant mutation in childhood ACC and adult tumors.

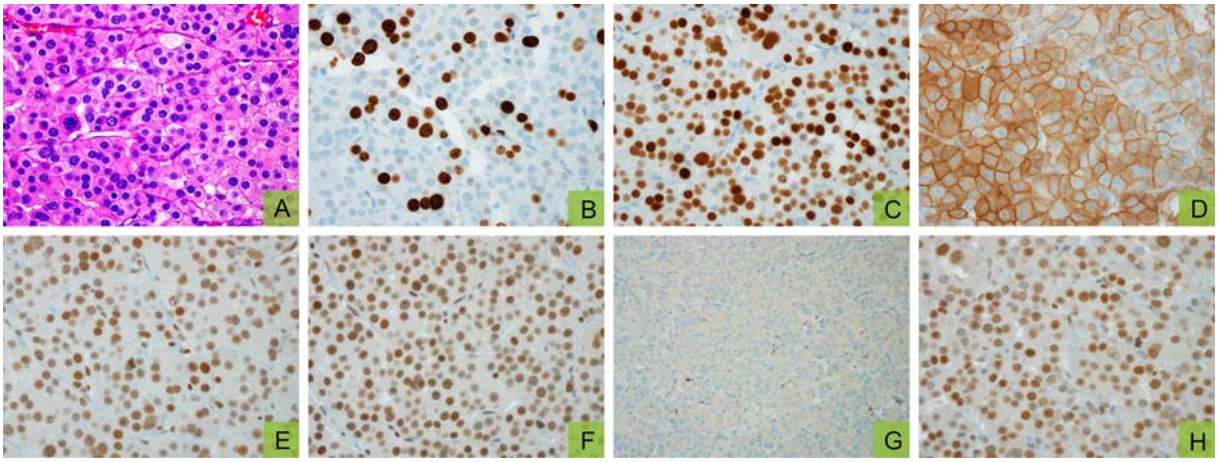

Fig. 3 Immunohistochemistry stains of a mismatch repair (MMR)-deficient adrenocortical carcinoma (A; H/E stain) including the proliferation marker Ki67 (B), p53 (C), beta-catenin (D), and the MMR panel of four markers, that is, MLH1 (E), MSH2 (F), MSH6 (G) and PMS2 (H). This tumor displays nuclear p53 and membranous beta-catenin immunoreactivity with Ki67 labeling index estimated at 22% by manual counting. As in this case a germline MSH6 mutation had been identified. MSH6 nuclear staining is absent, while nuclear immunoreactivity for MLH1, MSH2 and PMS2 is retained.

Analysis of the International Agency for Research on Cancer (IARC) TP53 database to re-evaluate age and variant-dependent tumor patterns showed that pathogenic *TP53* variants in the germline have different consequences according to cell, tissue, context and age. This indicates *variable penetrance* according to age, sex and mutation type and *temporal tumor patterns* displaying distinct phases. At 0–15 years, 22% of all malignancies includes ACC, rhabdomyosarcoma, choroid plexus carcinoma, and medulloblastoma. At 16–50 years this is 51%, encompassing breast cancer, osteosarcoma, soft tissue sarcomas, leukemia, astrocytoma and glioblastoma, colorectal and lung cancer. At 51–80 years this is 27%, comprising prostate and pancreatic cancer.

In the adult population, germline *TP53* mutations and *MMR* gene mutations account for 3%–7% and 3% of ACC cases respectively. Of note is that the prevalence of Lynch syndrome among patients with ACC is comparable to that in colorectal and endometrial cancer. Irrespective of family history and/or restriction of age at diagnosis, it is recommended that all patients with newly diagnosed ACC shall be offered genetic counseling and assessed for inherited predisposition, i.e. germline testing for *TP53* mutations and/or immunohistochemical analysis for MMR deficiency (**Fig. 3**) and subsequent molecular genetic testing for germline *MMR* gene mutations and/or *EPCAM* deletion. Given that MMR-deficient ACCs were found to be microsatellite stable, microsatellite instability analysis might not be needed as a complementary test to the IHC screening.

Microenvironment Including Immune Response

Adrenocortical carcinomas are regarded as relatively pure tumors with low fractions of tumor infiltrated stromal cells and lymphocytes in cortisol-secreting tumors; the latter mainly attributable to suppressive action exerted by glucocorticosteroids.

Staging and Grading

Staging

TNM staging of adrenal cortical carcinoma, as introduced in the 8th edition of AJCC staging manual, is consistent with the European Network for the Study of Adrenal Tumors (ENSAT) staging system. Accordingly, stage 1 and stage 2 are defined as strictly localized tumors with a size of ≤ 5 cm or > 5 cm, respectively. Stage 3 tumors are characterized by infiltration into surrounding tissue or invading adjacent organs, that is, kidney, diaphragm, pancreas, liver or great vessels (renal vein or vena cava), or positive regional lymph nodes. Stage 4 is restricted to patients with distant metastasis.

In the pediatric population, the staging system for ACCs (**Table 3**) is based on a modification of the work of Sandrini et al. by investigators from Children's Oncology Group (COG) and relies on the clinical data from the International Pediatric Adrenocortical Tumour Registry.

Grading

The mitotic rate has been incorporated in all multiparametric systems and/or diagnostic algorithms for evaluating the biological behaviour and also included in the grading of ACCs, further adding to the prognostic value of proliferative activity (see *Prognostic*

and Predictive Biomarkers). Proliferation grading of ACCs is based on mitotic rate, that is, low grade ≤ 20 mitoses per 50 high-power fields and high grade > 20 mitoses per 50 high-power fields.

The TCGA study measured adrenal cortical differentiation using a single metric, namely Adrenocortical Differentiation Score (ADS), based on 25 genes, which are of importance for adrenal function, i.e. cholesterol transporters, steroidogenic enzymes and their transcriptional regulator SF1, and with very high expression levels in the adult adrenal cortex. Of interest, higher ADS values were noted in functional tumors, but without any association with histopathological parameters, that is, Weiss score.

Prognostic and Predictive Biomarkers

The prognosis of ACC is poor, but heterogeneous, with a 5-year overall survival rate varying between 37% and 47%. The resection status and the proliferation marker Ki67 constitute the most relevant prognostic parameters in both localized and advanced ACCs. Modified ENSAT stages (stages IVa, IVb, or IVc) along with G R A S parameters [Grade (Weiss > 6 and/or Ki67 $\geq 20\%$), resection status, age ≥ 50 years and tumor- or hormone-related symptoms] correlated with overall survival in stage III–IV ACCs. Clinically relevant hypercortisolism has an adverse effect on survival in patients with completely resected ACC. Surgical margin status has an impact on long-term outcome, roughly two-thirds of ACC patients experience disease recurrence. Patients with combined locoregional and distant recurrence have worse survival than those with distant-only or locoregional-only recurrence.

Some studies confirmed Ki67 as a powerful tool for prognostic stratification, and it has been integrated into a model for prediction of metastatic disease. However, preanalytical variation, lack of standardized assessment methods and significant levels of interobserver variation pose important challenges. This is reflected in the variable threshold (10%–30%) used to incorporate the parameter into treatment flow charts to guide therapy decision making. In the pediatric setting, Ki67 proliferation marker has recently emerged as a strong prognostic indicator with Ki67 LI $\geq 15\%$ independently associated with poor prognosis.

In an effort to refine prognostic prediction in ACC, it has been recently shown that combined assessment of Ki67 LI and VAV2 expression improved patient stratification to low-risk and high-risk groups. VAV2 is a guanine nucleotide exchange factor for small GTPases that control the cytoskeleton, and that is driven by increased expression of the gene encoding SF-1 (also known as *NR5A1*) in ACC. SF1 is a marker of adrenal cortical derivation, but also of biological aggressiveness as reflected in immunohistochemical marker staining patterns. Other proliferation-based (immunohistochemical) scoring methods and/or routine histology, that is, assessment of mitotic activity, angioinvasion, and Weiss score, can provide valuable aid in determining prognosis.

In addition to the aforementioned methods, -omics derived parameters seem very promising to recognize aggressive behaviour in adrenocortical cancer. Two distinct molecular groups have been identified: the C1A subgroup with poor outcome, characterized by numerous mutations as well as alterations of DNA methylation, and the C1B subgroup with good prognosis, exhibiting specific deregulation of two microRNA clusters. Furthermore, three ACC subtypes have been identified with distinct clinical outcome, based solely on integrated multi-platform molecular profiling: Cluster of Cluster (CoC) I/II/III. CoC I ACCs showed better outcome, significantly unregulated genes in immune-mediated pathways and lower Ki67 expression levels, whereas CoC III tumors showed dismal outcome, significant disregulation of genes in mitotic pathways and higher Ki67 defined proliferative activity. CoC II ACCs had more heterogeneous outcome.

A recent TCGA study showed that high mutation density and a specific copy-number phenotype, characterized by a high number of chromosomal breaks and frequent loss of 1p (with 1q intact), are associated with aggressive disease. Whole genome doubling, associated with *TERT* expression along with telomere shortening, predict dismal outcome in ACC. This is consistent with recent immunohistochemical data suggesting a better prognosis of ACCs with loss of expression of the telomere regulator DAXX.

Methylation profiles support a correlation between CpG island hypermethylation and poor survival. Tumor DNA methylation has recently emerged as independently prognostic for disease-free survival (along with stage) and overall survival (along with stage and Ki67 proliferative index) in ACC. miRNA expression signatures (high levels of miR-483-5p and/or low levels of miR-195) have been reported to predict worse overall survival. Expression of TOP2A, EZH2 and BARD1, identified through gene expression studies, might provide additional prognostic information. Overexpression of histone methyltransferase EZH2, a result of deregulated *P53/RB/E2F* pathway activity, has been associated with increased proliferation and poor prognosis.

With regard to pediatric adrenocortical cancer, recent National Cancer Data Base (NCDB) and European Cooperative Study Group on Pediatric Rare Tumors (EXPeRT) studies showed that age ≥ 4 years, tumor size ≥ 10.0 cm in diameter, extension of primary disease into adjacent structures, metastatic disease, and margin status were significantly associated with poor long-term survival. Furthermore, distant metastatic disease and large tumor volume > 200 cm^3 were the main unfavorable prognostic factors. Of note, a cut-off ≥ 10.0 cm in tumor diameter, corresponding to a tumor volume of 524 cm^3, was found to be of prognostic relevance, consistent with data generated by the Surveillance, Epidemiology, and End Results (SEER) program study on pediatric ACC. This challenges the 200 cm^3 threshold currently used in the COG modification of the Sanrini et al. staging system.

In pediatric cases, concomitant germline *TP53* and somatic *ATRX* mutations as well as associated genomic aberrations, such as massive structural variations and/or frequent background mutations, are associated with a dismal outcome. Such cases showed high tumor weight and advanced disease (COG stage III/IV). Glucose transporter 1 (GLUT1) was found to be more strongly expressed in clinically malignant pediatric adrenocortical tumors and associated with shorter overall and disease-free survival. Of note, metabolic reprogramming towards a hyperglycolytic and acid-resistant phenotype is also found in adult cases, with GLUT1 emerging as a stage-independent predictor of outcome. Accordingly, ACC patients with a high metabolic tumor volume, total lesion glycolysis and maximum standardized uptake value by 18F-FDG PET/CT prior to treatment, had worse overall survival.

Human cytochrome P450 2W1 (CYP2W1), ribonucleotide reductase large subunit 1 (RRM1) and sterol-O-acyl-transferase 1 (SOAT1) might represent predictive markers for the response to mitotane. This agent confers adrenal-specific cytotoxicity and down-regulates steroidogenesis. However, mitotane is significantly toxic. Topoisomerase II alpha (TOP2A) and thymidylate synthase (TS) were not found predictive of mitotane efficacy in ACC patients. These markers await further validation in prospective studies.

Aflatoxins

Joshua W Smith and John D Groopman, Johns Hopkins University, Baltimore, MD, United States

Introduction

As one of the most potent naturally occurring known carcinogens, aflatoxins represent a special case in the study of cancer etiology (Squire, 1981). Research spanning more than five decades has created a detailed corpus of histological, biochemical, and molecular toxicology, which comprehensively and convincingly characterizes the carcinogenic mechanisms following aflatoxin exposure (Kensler et al., 2011; Wogan et al., 2012). These efforts have produced a suite of non- and minimally-invasive biomarkers, the use of which have allowed the mechanistic relation of aflatoxin exposures to internal dose, DNA adduct formation, and a signature carcinogenic mutation in the tumor suppressor p53. Harnessing these tools, epidemiological studies have consistently demonstrated a significantly increased risk of hepatocellular carcinoma (HCC) from dietary aflatoxin exposure (Liu et al., 2012) and, most dramatically, a synergistic increase in risk for those also chronically infected with hepatitis B virus (HBV) (Wild et al., 2009). Consequently, out of total global HCC incidence (nearly 800,000 new cases per year (Ferlay et al., 2015)), it is estimated that approximately one quarter is attributable to aflatoxin exposure, either alone or in combination with chronic viral hepatitis (Liu et al., 2010, 2012). The International Agency for Research on Cancer (IARC) declared aflatoxins, as a group, to be human carcinogens in 1987 (International Agency for Research on Cancer, 1987), a classification that has been confirmed in each of three subsequent reviews (International Agency for Research on Cancer, 1993, 2002, 2012). Concordantly, cancer prevention efforts have benefitted from the same half-century of molecular toxicology that enabled the determination of aflatoxins' carcinogenicity. Biomarkers of aflatoxin exposure, with their mechanistically defined relationships to HCC development, unshackled scientists from the necessity to directly link exposures to cancer outcomes, greatly reducing the time and resources required to test novel preventative measures. As a result, a wide array of promising primary and secondary prevention strategies have been identified (Groopman et al., 2008; International Agency for Research on Cancer, 2015), some of which have now been associated with reductions in HCC mortality (Chen et al., 2013). The goals of this chapter are not only to describe the carcinogenic effects of aflatoxin exposure and to recount major discoveries in aflatoxin research, but also to highlight throughout the strength and breadth of this body of literature.

Sources of Aflatoxin Exposure

Aflatoxins are secondary metabolites produced by members of the fungal genus *Aspergillus*, which contains approximately 250 known species (Klich, 2007). However, less than a dozen are known to produce aflatoxins (International Agency for Research on Cancer, 2002; Klich, 2007; Bennett et al., 2003) and only *A. flavus* and *A. parasiticus* are truly relevant to human health through contamination of the food supply. *A. flavus* is found in soils across the globe, but is more common in tropical and sub-tropical climates between latitudes 35 degrees north and south of the equator (Klich, 2007; Abbas et al., 2009; Council for Agricultural Science and Technology, 2003). Regardless, due to globalized trade, dietary aflatoxins are a worldwide concern. A major distinction between these two aflatoxigenic species are their profiles of toxin production—while *A. parasiticus* produces both the B and G series of aflatoxins, *A. flavus* produces only B toxins (Dorner et al., 1984; Klich et al., 1988).

Many factors can influence the crop colonization, growth, and toxin production of *Aspergillus* species, notably heat, humidity, pest or environmental host stressors, and post-harvest practices (Abbas et al., 2009; Pitt et al., 2013; Diener et al., 1987). Maize, groundnuts, cottonseed, and tree nuts represent the most common sources of food supply contamination worldwide, as these crops are preferred by *Aspergillus* for colonization pre-harvest, while also being susceptible to contamination due to improper drying and storage conditions post-harvest. However, although other crops like wheat, sorghum, and rice are much less susceptible to pre-harvest colonization, poor post-harvest handling can also encourage aflatoxin contamination in these stored commodities and levels of contamination vary widely (International Agency for Research on Cancer, 2002; Council for Agricultural Science and Technology, 2003).

Aflatoxin Discovery and Structural Elucidation

The aflatoxins were first discovered as a result of their role in the acute intoxication and death of many thousand British poultry in 1960 (Blount, 1961). The toxic outbreaks were linked to moldy groundnut meal used in animal feed (Blount, 1961) and crude extracts revealed the presence of a potent substance produced by *A. flavus*, which was able to recapitulate the lethal and histological effects of the original toxic feed (Sargeant et al., 1961). The carcinogenic potential of the as-yet-unidentified agent was quickly suspected, however, as liver tumors were found in rats fed the toxic groundnut meal (Lancaster et al., 1961). Crude extracts were revealed to contain at least two primary constituents (van der Zijden et al., 1962; De Iongh et al., 1962), which, given their mycological source and intense blue or green fluorescence, were designated as aflatoxin (*A. flavus* toxin) B and G, respectively (Nesbitt et al., 1962). Büchi, Wogan, and colleagues proposed the structures of AFB_1 and AFG_1 in 1963 (Asao et al., 1963), followed by

a longer report 2 years later (Asao et al., 1965), in which they identified the structures of AFB_2 and AFG_2. In 1967, Büchi's group produced the first total synthesis of AFB_1 (Büchi et al., 1967). The structures of the naturally occurring aflatoxins are shown in Fig. 1.

Aflatoxin Metabolism and Molecular Mechanisms of Carcinogenicity

Human exposure to aflatoxins occurs through the diet, however, these parent compounds are not carcinogenic per se. Rather, as procarcinogens, they must first be transformed in vivo to their carcinogenic derivative (Smith et al., 2016; Rendic et al., 2012). The ultimate carcinogenic metabolite of AFB_1, AFB_1-*exo*-8,9-epoxide, is produced in the liver through oxidation of AFB_1 by cytochrome P450 (CYP) enzymes. If not conjugated by GSTs, the AFB_1-*exo*-8,9-epoxide intercalates with DNA, facilitating electrophilic attack on guanine residues at the N^7 position, leading to mutagenesis.

Structure–Activity Relationships Driving Aflatoxin Carcinogenicity

Mixtures of the four naturally occurring aflatoxins (AFB_1, AFG_1, AFB_2, and AFG_2) represent the relevant form of aflatoxin exposure for humans and have been classified by IARC as a Group 1 carcinogen, indicating sufficient evidence for carcinogenicity in humans (Ostry et al., 2017). However, while carcinogenic as mixed species (Carnaghan, 1967; Norred et al., 1983), in their purified forms, these four aflatoxins are not equally potent. In bacterial mutagenicity assays, with AFB_1 as the reference, AFG_1 is 3% as potent, and both AFB_2 and AFG_2 retain $<1\%$ activity (Wong et al., 1976). In general, carcinogenesis studies agree both with this order and the relative decrements in potency, to the point where AFG_2 is essentially non-toxic (Wogan et al., 1971, 1974a; Bailey et al., 1988; Ayres et al., 1971; Butler et al., 1969). AFB_1, by far the most carcinogenic of the group, displays a dose–response in carcinogenicity in rats down to 1 ppb in the diet ($\sim$0.2 μg/kg bw) with long-term dietary exposure (Wogan et al., 1974a), while very large studies in trout suggest that it may retain carcinogenic potency well below the 1 ppb level (Williams et al., 2009). Single large doses of purified AFB_1 cause substantial rates of hepatocarcinogenesis in rats (Carnaghan, 1967), while even a single 15 minute exposure to 0.5 ppm AFB_1 is carcinogenic in trout (Bailey et al., 1988).

Appreciation of critical structural differences between these similar compounds reveals structure–activity relationships responsible for their differing carcinogenicities. As shown in Fig. 1, all four naturally occurring aflatoxins share a common structural feature—the methoxylated difuranocoumarin backbone. Very strong biochemical evidence supports the 8,9-*exo*-epoxide (Fig. 2) as the ultimately carcinogenic DNA-adducting metabolite of AFB_1 (Swenson et al., 1973, 1974, 1977) and its generation depends on the oxidation potential of the 8,9 carbon–carbon bond of the outermost furan ring (Guengerich et al., 1998) (or the 9,10 bond in G series aflatoxins). A blunt illustration of this requirement is provided by synthetic analogues entirely lacking the furofuran moiety (e.g., 5,7-dimethoxycyclopentenone coumarins)—these agents are completely inactive as liver carcinogens in the trout (Ayres et al., 1971) or at high doses in the rat (Wogan et al., 1971). Comparison of AFB_2 and AFB_1 provides a more relevant perspective. Saturation of the 8,9 double bond in AFB_1 significantly reduces the carcinogenicity of AFB_2: doses of AFB_2 115-fold greater than that of AFB_1 induced fewer tumors in rats (Wogan et al., 1971), while equivalent doses of AFB_1 and AFB_2 in trout induced liver tumors at drastically different rates (78% vs. 5%) (Ayres et al., 1971). Molecular evidence supports these studies, showing that administration of radiolabeled AFB_2 to rats results in hepatic DNA adduct formation at levels approximately 1% that of an equivalent dose of radiolabeled AFB_1 (Swenson et al., 1977).

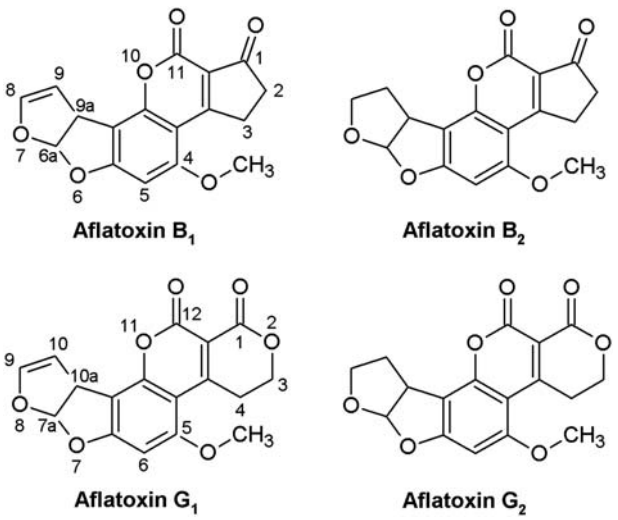

Fig. 1 Structures of the naturally occurring aflatoxins.

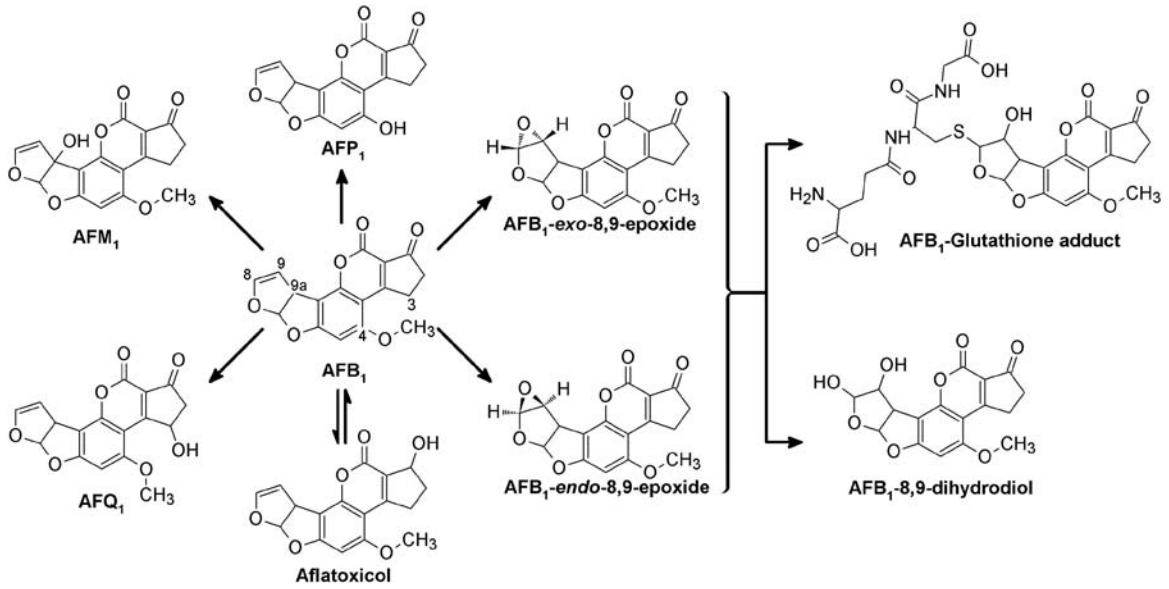

Fig. 2 AFB_1 metabolism.

Oxidation of AFB_1 by cytochrome P450s produces two stereoisomers: the AFB_1-8,9-*exo*- and AFB_1-8,9-*endo*-epoxides (Guengerich et al., 1998; Dohnal et al., 2014). However, the *exo* epoxide is $\sim 10^3$ times as mutagenic as the *endo* (Iyer et al., 1994; Ueng et al., 1995), which exhibits negligible reactivity towards double-stranded DNA (Iyer et al., 1994). Intercalation of the 8,9-epoxide into DNA dramatically enhances adduction—single-stranded DNA is 6.5-fold less reactive with the epoxide than is double-stranded DNA (Johnson et al., 1997a), while adduction to free deoxyguanosine is 2000-fold less efficient (Brown et al., 2009). While both the *exo*- and *endo*-epoxides intercalate into double-stranded DNA (Gopalakrishnan et al., 1989, 1990), structural differences result in differing rates of adduct formation. After intercalation, the oxirane moiety of the *exo*-epoxide faces away from the guanine N^7, providing optimal orientation for S_N2 attack (Iyer et al., 1994). In contrast, the position of the *endo*-epoxide precludes the reaction, and consequently, adduction. Secondly, calculations from molecular modeling suggest that steric hindrance from solvating water molecules during the reaction with guanine is systematically greater in the *endo* configuration than the *exo* (Okajima et al., 2000; Bren et al., 2007). These mechanisms likely explain why the *exo*-epoxide is a highly potent carcinogen, while the *endo* isomer is non-toxic.

Finally, additional structural differences between aflatoxin species affects their intercalation into DNA and, thus, carcinogenic potency. Compared to the cyclopentenone ring of AFB_1 and AFB_2, the lactone substituent of the G series aflatoxins is less planar (Cheung et al., 1964); as a result, AFG_1 and AFG_2 intercalate into DNA with an affinity approximately one order of magnitude lower than AFB_1 and AFB_2 (Raney et al., 1990). AFB_1-8,9-epoxide forms more guanine adducts than its equivalent AFG_1 epoxide at equivalent concentrations, and, accordingly, AFG_1 has been shown to be less carcinogenic than AFB_1 in both rats (Wogan et al., 1971) and trout (Ayres et al., 1971).

To summarize, saturation of the furofuran ring is the largest determinant of carcinogenic activity and separates the relatively nontoxic AFB_2 and AFG_2 from the carcinogenic AFB_1 and AFG_1. Further refinement in potency is provided by substitution of the cyclopentenone ring for a lactone ring, resulting in the reduced intercalation efficiency and DNA adduction of AFG_1 compared to AFB_1.

Aflatoxin Metabolism

Phase I activation

As with procarcinogen metabolism more generally (Rendic et al., 2012), the P450s are the major players in aflatoxin oxidation (Guengerich et al., 1998; Dohnal et al., 2014). Multiple CYPs have been shown to activate AFB_1 (Pelkonen et al., 1997; Aoyama et al., 1990), but CYP3A4 appears to be the enzyme of greatest relevance for AFB_1 epoxidation in humans (Guengerich et al., 1998; Dohnal et al., 2014; Ueng et al., 1995; Shimada et al., 1989); one report in human liver microsomes suggests that CYP3A4 accounts for 79%–95% of total AFB_1-8,9-epoxide formation (Kamdem et al., 2006). This has been somewhat controversial, though, as some epidemiological data suggests that polymorphisms in CYP1A2 modify HCC risk (Chen et al., 2006), and experimental reports suggested CYP1A2 as the dominant enzymatic source of AFB_1 epoxidation, rather than 3A4 (Gallagher et al., 1994, 1996). However, CYP1A2 hepatic protein content is 10–25 times lower than CYP3A4 and, even granting the former an advantage in reaction rate, 1A2 is likely far outstripped by 3A4 in total AFB_1 epoxidation capacity (Kamdem et al., 2006). Moreover, while CYP3A4 produces only the mutagenic AFB_1-8,9-*exo*-epoxide but not the non-toxic *endo*-epoxide, CYP1A2-derived AFB_1 epoxides are split roughly equally between the *exo* and *endo* stereoisomers (Ueng et al., 1995). Finally, higher contribution of other CYP enzymes to

AFB_1 epoxidation has been shown to depend on concurrently low CYP3A4 activity (Kamdem et al., 2006; Wojnowski et al., 2004).

Genetic differences may impact AFB_1 epoxidation and risk of carcinogenesis. Several reports have demonstrated very high inter-individual variation in hepatic P450 protein content—up to 57-fold in CYP3A4 (Kamdem et al., 2006; Doi et al., 2002; Kirby et al., 1993). Accordingly, microsomal AFB_1 epoxide formation exhibits high variability (Kamdem et al., 2006) and correlates with CYP3A4 expression (68). Male rats fed AFB_1 demonstrated two- to threefold higher hepatic microsomal P450 content and AFB_1-DNA adduct formation than AFB_1-fed female rats, but castration of males lowered these values to those in females, while testosterone administration in castrated males rescued values to those of intact males (Gurtoo et al., 1976). A similar result was shown with hypophysectomy (Swenson et al., 1977; Goodall et al., 1969), while testosterone administration to female rats resulted in a phenotype very similar to that of intact males (Gurtoo et al., 1976). In the analysis of human hepatic microsomes by Kamdem et al., males exhibited a median rate of aflatoxin epoxidation nearly 50% higher than females (Kamdem et al., 2006). These mechanisms may explain, at least in part, the epidemiological evidence showing that men are at two- to threefold higher risk of HCC incidence than women (Petrick et al., 2016).

Once formed, the 8,9-*exo*-epoxide is highly unstable in solution ($t_{½} \approx 1$ s), rapidly undergoing hydrolysis to the 8,9-dihydrodiol (Johnson et al., 1996) (**Fig. 2**). Hydrolysis of the carcinogenic *exo*-epoxide is catalyzed enzymatically by epoxide hydrolase, but in vitro evidence suggests that only supra-physiological expression of the enzyme would be able to provide added protection from genotoxicity (Johnson et al., 1997b). Despite this, epidemiological studies have revealed elevated AFB_1 adduct levels (McGlynn et al., 1995; Dash et al., 2007) or an increased risk of HCC in individuals carrying mutant alleles of the enzyme (McGlynn et al., 1995; Tiemersma et al., 2001). An alternate possibility is that epoxide hydrolase status may impact HCC risk independently from aflatoxin metabolism (Tiemersma et al., 2001; Rahat et al., 2012).

Major metabolites of AFB_1

AFB_1 is also detoxified through conversion to less-potent metabolites (**Fig. 2**). CYP3A4 indeed produces the AFB_1-8,9-*exo*-epoxide, but also catalyzes hydroxylation of the cyclopentenone ring to yield aflatoxin Q_1 (AFQ_1). The yield for each of these products is vastly different, with production of AFQ_1 being up to 8-fold greater than the epoxide (Ueng et al., 1995; Wang et al., 1998). Similarly, another major metabolite, AFM_1, is produced though 9a-hydroxylation by CYP1A2, at a ratio of up to 5:1 AFM_1:epoxide (Ueng et al., 1995). Additionally, AFB_1 can be demethylated to aflatoxin P_1 (AFP_1) (Dalezios et al., 1971, 1973) or subjected to ketoreduction at the cyclopentenone ring to form aflatoxicol. Notably, these major detoxification products (AFM_1, AFQ_1, AFP_1, and aflatoxicol) all retain the crucial 8,9 double bond and thus themselves can be epoxidized at this site, capable of DNA adduct formation (Bujons et al., 1995; Neal et al., 1998; Eaton et al., 1988; Essigmann et al., 1980). However, it appears that very little epoxidation occurs relative to AFB_1 (Neal et al., 1998; Eaton et al., 1988), limiting their mutagenicity. Indeed, while AFM_1 is carcinogenic in its own right (International Agency for Research on Cancer, 2002; Hsieh et al., 1984; Cullen et al., 1987; Wogan et al., 1974b), AFM_1, AFQ_1, and AFP_1 are all at least 10 times less potent than AFB_1 (Wong et al., 1976). An exception is aflatoxicol, which retains ~20%–50% the potency of its parent (Wong et al., 1976; Garner et al., 1972). Interestingly, although the epoxide of aflatoxicol can form DNA adducts in vitro, aflatoxicol-DNA adducts are undetectable after dietary aflatoxicol treatment in vivo, while AFB_1 adducts are readily observed (Bailey et al., 1994). This, as well as the high potency of aflatoxicol relative to the other major AFB_1 metabolites, can be explained by the in vivo conversion of aflatoxicol back to AFB_1 (Salhab et al., 1976). In total, nearly 90% of cytochrome P450 oxidation products may be diverted away from epoxidation during initial metabolism of AFB_1 (Kamdem et al., 2006).

Phase II conjugation

Phase II detoxification involves the conjugation of phase I-activated electrophiles to endogenous nucleophiles, to create polar metabolites that may be safely passed in the urine or excreted through biliary secretion into feces. In general, most of this work is performed through hepatic glucuronidation by UDP-glucuronosyl transferases (UGT) or adduction to glutathione by glutathione S-transferase (GST) enzymes (Rendic et al., 2012). As discussed above, the bulk of ingested AFB_1 is converted to its hydroxylated metabolites (AFM_1, AFQ_1, AFP_1), which are subsequently glucuronidated or sulfonated and excreted (Dalezios et al., 1973; Wei et al., 1985a, b; Wogan et al., 1967; Raj et al., 1984). However, as for the carcinogenic epoxide, GST-dependent conjugation to glutathione (**Fig. 2**) appears to be the most critical phase II detoxification pathway (Appleton et al., 1982; Monroe et al., 1988; Lotlikar et al., 1980; Raj et al., 1986), as well as a significant source of variation for between- and within-species aflatoxin sensitivity (Dohnal et al., 2014; Hayes et al., 1991). With the exceptions of GSTM1 and GST1, most human GST isoforms do not conjugate the AFB_1 epoxide well, or at all (Raney et al., 1992; Johnson et al., 1997c). However, primary hepatocytes from GSTM1-positive subjects—but not GSTM1-null—have been shown to be competent in glutathione conjugation of AFB_1-8,9-epoxide (Langouët et al., 1995; Gross-Steinmeyer et al., 2010), GSTM1-null individuals were more likely than GSTM1-positive to have elevated AFB_1 adduct levels (McGlynn et al., 1995), and GSTM1 expression and GST conjugating activity have been shown to be lower in liver tumors than neighboring normal tissue (Kirby et al., 1993). Accordingly, GST polymorphisms—especially in GSTM1—have been shown to increase HCC risk in numerous epidemiological studies, particularly in the context of high aflatoxin exposure (Sun et al., 2001; Kirk et al., 2005a; Long et al., 2006; Shen et al., 2014).

Due to metabolic differences throughout the aflatoxin detoxification pathway (Dohnal et al., 2014), animal species exhibit substantial variability in sensitivity to aflatoxin (Newberne et al., 1969). However, the capacity to detoxify the AFB_1-epoxide through conjugation to glutathione appears to be the largest determinant of a species' sensitivity to aflatoxins, and thus the

most crucial of the metabolic idiosyncrasies between clades. Beginning with the paper from Degen et al. (1981), many reports have characterized the divergent susceptibilities of adult rats (sensitive) and mice (resistant) to be the result of a striking difference in AFB_1-epoxide detoxification capacity (Monroe et al., 1987, 1988; O'Brien et al., 1983). Subsequent interspecies comparisons revealed that the significant kinetic advantage of murine hepatic cytosolic fractions over those from rats (7–50-fold) and humans (300–3500-fold) (Raney et al., 1992; Slone et al., 1995) was not simply due to greater enzymatic abundance, but that reaction rates for purified mouse GSTs were orders of magnitude greater than their rat and human homologues (Raney et al., 1992; Johnson et al., 1997c; Buetler et al., 1992). However, differences in GST expression may impact aflatoxin sensitivity *within* a species—relative to male rats, female rats are more resistant to aflatoxin-induced DNA adduction (Gurtoo et al., 1976), apparently due to 10-fold higher expression of GSTA5 (Hayes et al., 1994) and greater epoxide detoxification (Degen et al., 1981). Additionally, temporal shifts in aflatoxin metabolism may dramatically impact the sensitivity of an organism throughout its development. While adult mice are resistant to aflatoxin-induced carcinogenesis, infant mice have long been known to be much more sensitive (Vesselinovitch et al., 1972). Recent work has shown that prenatal/neonatal AFB_1 exposure induced 20 times more mutations than exposures during adulthood (Chen et al., 2010; Chawanthayatham et al., 2015). Moreover, Shupe et al. have shown that murine hepatic GST content rose fivefold from 4 days postnatal to the end of the first year of life, while DNA adducts from AFB_1 gavage decreased 13-fold over the same period (Shupe et al., 2004).

Targeting Nrf2 for chemoprotective modulation of aflatoxin metabolism

Nuclear factor erythroid 2 like 2 (Nrf2) is a crucial regulator of the endogenous antioxidant response, which protects cells from oxidative damage by reactive oxygen species and electrophiles (Suzuki et al., 2015). This is accomplished through binding of Nrf2 to the antioxidant response element (ARE) motif within the promoter regions of phase II detoxifying enzymes, including GSTs (Itoh et al., 1997; Nguyen et al., 2000; Kensler et al., 2007). Indeed, loss of *Nrf2* in rodents increases sensitivity to chemical carcinogenesis (Ramos-Gomez et al., 2001; Taguchi et al., 2016), while stabilization of Nrf2 through disruption of its negative regulator, Keap1, results in increased expression of cytoprotective Nrf2-target genes (Thimmulappa et al., 2002; McWalter et al., 2004; Yates et al., 2007). Mice lacking the Nrf2 target GSTA3 (Jowsey et al., 2003) are rendered hypersensitive to dietary AFB_1 treatments, with AFB_1-DNA adducts accumulating to levels >100-fold greater than in wild-type mice (Kensler et al., 2014; Ilic et al., 2010). However, neither simultaneous deletion of Keap1 nor pharmacological activation of Nrf2 was able to rescue adduct levels in $GSTA3^{-/-}$ mice back to control levels, despite the presence of an active Nrf2 signaling pathway (Kensler et al., 2014).

Similar approaches have been used to identify chemopreventative strategies for translation to at-risk human populations. Studies with oltipraz, a dithiolthione previously studied as an antischistosomal agent, have demonstrated it to be an inducer of GST expression and activity (Davidson et al., 1990; Kensler et al., 1985, 1987; Primiano et al., 1995), an inhibitor of AFB_1-DNA adduct formation (Kensler et al., 1985, 1987), and protective against AFB_1-induced hepatocarcinogenesis (Kensler et al., 1997). While oltipraz does appear to be a modulator of cytochrome P450-dependent AFB_1 oxidation (Langouët et al., 1995; Kensler et al., 1985, 1987), DNA adduction by AFB_1 was inversely and highly correlated with induction of GST activity (Kensler et al., 1985, 1987), suggesting this to be the predominant effect on AFB_1 metabolism. Another inducer of carcinogen detoxification, 1-[2-cyano-3-,12-dioxooleana-1,9(11)-dien-28-oyl]imidazole (CDDO-Im), has been shown to exhibit exceptional chemoprotective effects in animals exposed to AFB_1. Demonstrating that CDDO-Im acts through Nrf2, Taguchi et al. reported that in wild-type rats—but not Nrf2-knockouts—CDDO-Im potently induced Nrf2, GSTA3, and GSTA5, while reducing hepatic AFB_1-DNA adducts (Taguchi et al., 2016). Others have shown that CDDO-Im dose-dependently induced GST expression and inhibited hepatic AFB_1-DNA adduct formation (Yates et al., 2006), while another report revealed complete protection against AFB_1-induced hepatocarcinogenesis with simultaneous administration of CDDO-Im (Johnson et al., 2014). Finally, natural agents, such as the isothiocyanate sulforaphane, are able to provide protection against aflatoxin exposure through the same Nrf2-dependent mechanism (Kensler et al., 2013; Wakabayashi et al., 2004). Although not as potently as CDDO-Im, sulforaphane induces phase II detoxification genes (Hu et al., 2004) in an Nrf2-dependent manner (Thimmulappa et al., 2002) and inhibits the formation of mutagenic AFB_1-DNA adducts (Fiala et al., 2011).

DNA Adduct Formation

Prior to DNA adduction, the AFB_1-8,9-*exo*-epoxide must remain stable long enough to enter the nucleus and interact with DNA after formation in the endoplasmic reticulum by P450s. Given the rapid solvolysis of the AFB_1-*exo*-epoxide in aqueous solution (Johnson et al., 1996), a pertinent consideration is a comparison of the rate of epoxide hydrolysis with its anticipated rate of encounter with DNA. Based on estimates of diffusion rate and distance within the cell, Johnson et al. have calculated the epoxide's rate of interaction with DNA to be roughly 10^{11}-times greater than its spontaneous degradation (Johnson et al., 1997a). As described above in the section "Structure–activity relationships driving aflatoxin carcinogenicity", intercalation of the AFB_1-8, 9-*exo*-epoxide into double-stranded DNA facilitates S_N2 attack on the N^7 position of guanine residues; specifically, Kobertz et al. have shown that this intercalation must occur to the 5′ side of guanine (Kobertz et al., 1997). The AFB_1-N^7-guanine adduct (N^7-guanine; **Fig. 3**) was first identified in vitro by Wogan and colleagues (Essigmann et al., 1977), followed by their demonstration of its dose-dependent formation in vivo (Croy et al., 1978). Due to its positively charged imidazole ring, the N^7-guanine DNA adduct is unstable and susceptible to either spontaneous depurination or base-catalyzed hydrolysis and imidazole ring-opening (**Fig. 3**). In the former case, this produces an apurinic (AP) site and the free AFB_1-N^7-guanine adduct, which is excreted and can be detected in the urine (Bennett

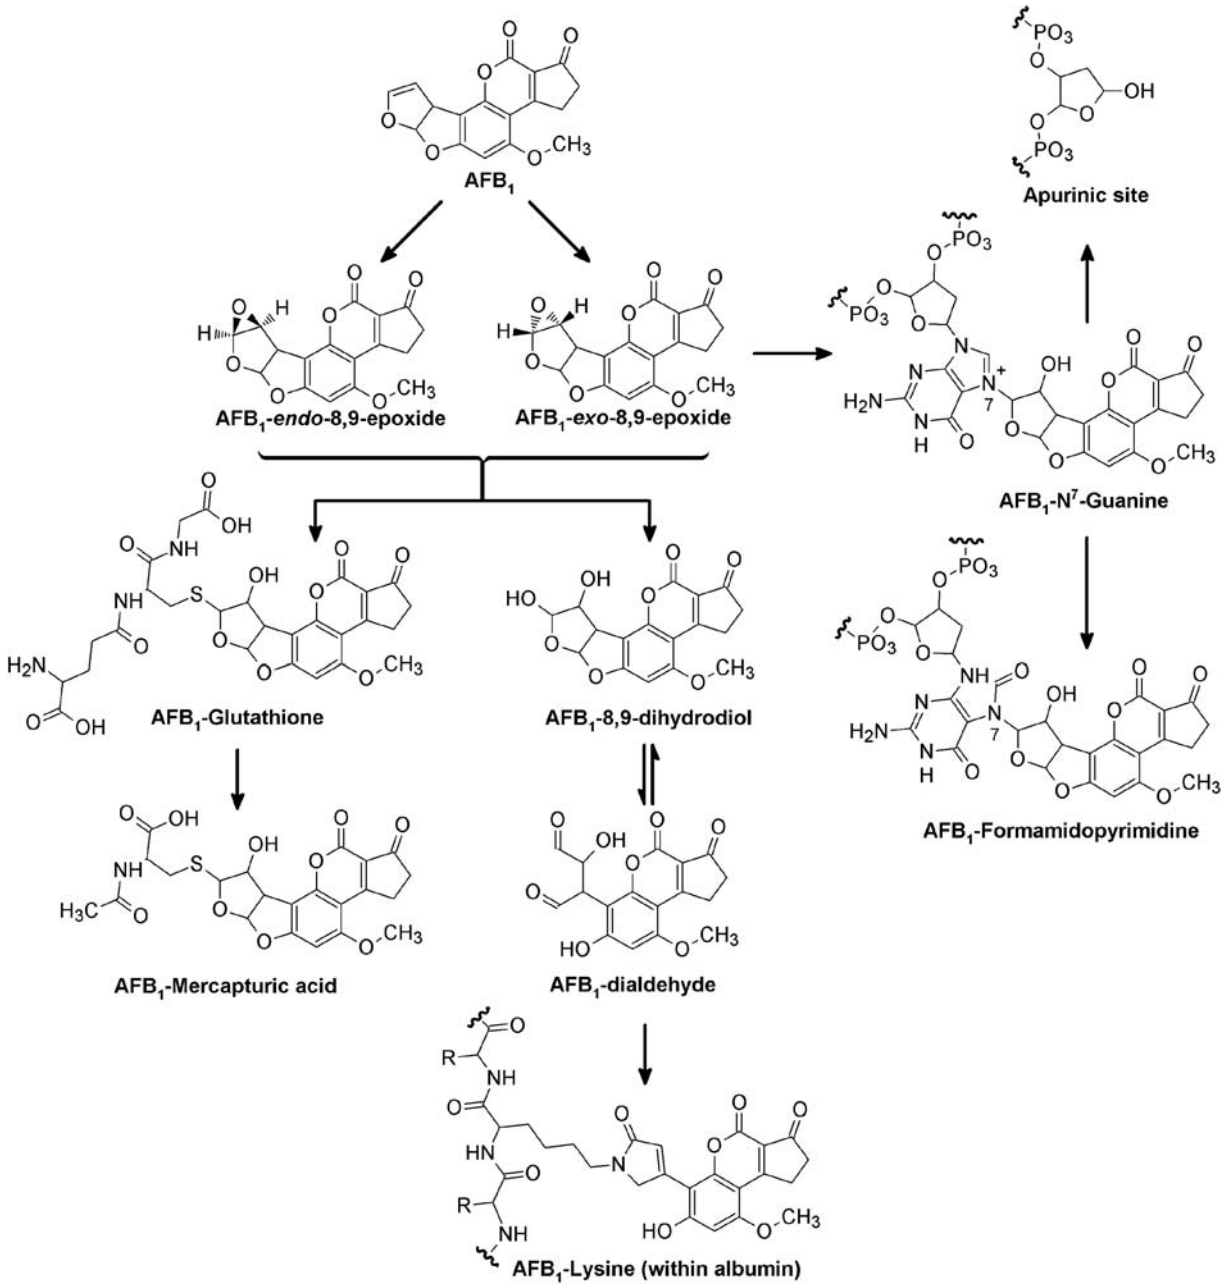

Fig. 3 Formation of major AFB_1 adducts.

et al., 1981). Spontaneous depurination is not uncommon in mammalian cells in general (Loeb et al., 1986) and dose–response experiments in rats suggest that approximately 30% of the initial AFB_1-N^7-guanine DNA adducts may be depurinated and excreted within 48 hours of initial dosing (Bennett et al., 1981). Regarding base-catalyzed ring-opening, hydrolysis of the AFB_1-N^7-guanine imidazole ring results in formation of an AFB_1-formamidopyrimidine (FAPyr) adduct that is much more stable than the initial N^7-guanine lesion. This accounts for the observed temporal shifts in adduct profiles in AFB_1-perfused livers or single AFB_1 doses in vivo. Two hours after dosing, N^7-guanine adducts represent $>80\%$ of total AFB_1 adducts (at a rate of ~ 10 AFB_1-N^7-guanine per 10^{11} nucleotides), while FAPyr adducts (~ 1 per 10^{11}) account for less than 10% (Essigmann et al., 1980; Croy et al., 1981a, b). However, the chemical instability of the N^7-guanine DNA adduct and the persistence of the FAPyr adduct results in the predominance of FAPyr at 24 hours and a reversal of the initial profile by 48–72 hours (Croy et al., 1981a; Hertzog et al., 1980). This shift is delayed with repeated AFB_1 exposure—for example, dosing to rats over 14 days (Croy et al., 1981a)—but eventually results in an accumulation of FAPyr at $\sim 80\%$ of total DNA adducts.

Adduct Repair in DNA

Enzymatic repair of AFB_1 lesions in DNA is carried out through both nucleotide excision repair (NER) and base excision repair (BER) mechanisms. Typically, NER is considered to act on a variety of bulky, helix-distorting lesions, with BER utilized for small lesions, such as AP sites (Bedard et al., 2006). However, both NER and BER have been shown to contribute to N^7-guanine and FAPyr adduct repair. In human fibroblasts treated with AFB_1, deficiency of the NER gene *XPA* resulted in lower efficiency of N^7-guanine adduct repair (Leadon et al., 1981) and higher rates of mutation frequency (Levy et al., 1992), while AFB_1-dosed $Xpa^{-/-}$ mice had greater hepatic carcinoma incidence and multiplicity than similarly treated wild-type controls (Takahashi et al., 2002). While the FAPyr adduct has been shown to be repaired by NER mechanisms in bacteria (Alekseyev et al., 2004), this adduct is persistent in mammals (Croy et al., 1981a; Hertzog et al., 1980), independently from NER status (Leadon et al., 1981). However, the FAPyr adduct appears to be less helix-distorting than the N^7-guanine adduct and prokaryotic NER mechanisms are less sensitive to helix distortion than their mammalian homologues (Bedard et al., 2006). Thus, poor recognition of FAPyr adducts by mammalian NER mechanisms may increase its persistence and explain differences between assays performed in prokaryotic and eukaryotic systems. Several BER enzymes are capable of DNA glycosylase activity at guanine formamidopyrimidine adducts, allowing for specific excision of these mutagenic lesions (Dizdaroglu et al., 2008). One of these, *Neil1*, has recently been shown to catalyze excision of the AFB_1-FAPyr adduct (Vartanian et al., 2017), while AFB_1-treated newborn mice deficient in *Neil1* exhibit more FAPyr adducts 48 hours post-dosing and are more susceptible to HCC than wild-type animals (Vartanian et al., 2017).

In humans, epidemiological evidence suggests that defects in adduct repair may increase AFB_1-related HCC risk. Polymorphisms of several DNA repair genes (XRCC1, XRCC3, XRCC4, XRCC7, ERCC2, XPC) have been shown to increase HCC risk (Kirk et al., 2005a; Long et al., 2006, 2008, 2013; Yao et al., 2014), especially in individuals with high AFB_1 exposure (Long et al., 2006, 2008, 2013; Yao et al., 2014). In particular, ERCC2 and XPC are involved in NER, while XRCC1 is involved in BER.

Mutagenesis

AFB_1 exposure induces G → T transversion mutations in humans and animal models (Hsu et al., 1991; Bressac et al., 1991a; Smela et al., 2001; Chawanthayatham et al., 2017). While the AP, N^7-guanine, and FAPyr adducts all result from AFB_1 exposure, they may not contribute equally to the resulting mutational spectra. AP sites are well-known to be mutagenic, as they induce incorporation of non-complementary bases opposite to the adducted base (Loeb et al., 1986). Given the origination of AFB_1-induced AP sites from adducted guanine residues and a predominance of AP→T mutations (Bailey et al., 1996), AP sites may logically contribute to AFB_1 mutations. However, although most AFB_1-induced mutations occur at the site of adduction, a minor fraction (7%–13%) occur at the residue 5′ to the adducted guanine (Bailey et al., 1996). Although these mutations can be caused by intercalation of the bulky N^7-guanine or FAPyr adducts, they cannot result from AP sites, which only form mutations at the lesioned base (Smela et al., 2001; Bailey et al., 1996). Furthermore, while N^7-guanine and FAPyr adducts exhibit the same mutagenic profiles (>80% G→T, 10% G→A, <5% G→C, <5% deletion), the FAPyr is at least twice as mutagenic as the N^7-guanine adduct (Lin et al., 2014a, b; Smela et al., 2002). Thus, combined with observed differences in stability and repair, the FAPyr adduct is likely responsible for the majority of AFB_1 mutagenesis.

In 1991, two reports in the same issue of Nature reported the presence of a G→T transversion hotspot at the third position of codon 249 (5′-CGG **AGG** CCC-3′) of the human *TP53* gene (Hsu et al., 1991; Bressac et al., 1991a), resulting in the non-synonymous substitution of arginine with serine (R249S) within the p53 protein (Li et al., 1993). Experiments in vitro have shown that AFB_1 causally induces this R249S mutation (Aguilar et al., 1993) and epidemiological evidence strongly supports a role of aflatoxin exposure in its occurrence in human HCC (Chawanthayatham et al., 2017; Villar et al., 2011; Stern et al., 2001; Qi et al., 2015; Zhang et al., 2006; Lunn et al., 1997; Xie et al., 1994; Unsal et al., 1994; Szymańska et al., 2009; Kirk et al., 2005b; Shimizu et al., 1999). While the R249S mutation is found in only 3%–7% of HCCs in general (TCGA Research Network, 2017; Wellcome Trust Sanger Institute, 2017), its prevalence rises to 30%–60% in HCC cases with documented or likely AFB_1 exposure (Villar et al., 2011; Stern et al., 2001; Qi et al., 2015; Xie et al., 1994; Unsal et al., 1994; Szymańska et al., 2004, 2009; Kirk et al., 2005b; Shimizu et al., 1999; Jackson et al., 2001; Coursaget et al., 1993). Indeed, it is rarely seen in liver tumors diagnosed in Europe or North America, where aflatoxin exposure is typically very low (Unsal et al., 1994; Wong et al., 2000; Bressac et al., 1991b); exceptions are often migrants from high-exposure regions (Amaddeo et al., 2015). The emergence of this mutation as a prototypical AFB_1 hotspot can be linked to two factors: the contextual preference of AFB_1 adduction within nucleotide sequences and disruption of p53 protein function. First, a study which systematically investigated the sequence context of AFB_1 adduction found a preference for guanines in GC-rich regions, particularly when flanked by other guanines (5′-GGG-3′) or with guanine or cytosine at the 5′ position—for example, GGX, CGX (Benasutti et al., 1988). These in vitro predictions align with the observed hotspot mutation in codon 249 of human *TP53* (GGC), as well as the predominating genome-wide mutational spectra (CGC; G→T) seen in AFB_1-treated rodents (Chawanthayatham et al., 2017; Woo et al., 2011; Wattanawaraporn et al., 2012) and humans with R249S-mutant HCC (Chawanthayatham et al., 2017). Secondly, the arginine → serine missense alteration of mutant R249S p53 substantially disrupts its DNA-binding and promoter transactivation activity, leading to loss of cell cycle and apoptotic control (Gouas et al., 2009). However, its mechanism of selection in vivo (e.g., dominant negative) remains unclear and a subject of investigation.

Carcinogenicity of Aflatoxins: Evidence in Humans

IARC has conducted several systematic reviews of the available data, which most recently in 2012 reaffirmed the carcinogenicity of aflatoxins to humans (International Agency for Research on Cancer, 1987, 1993, 2002, 2012). This section will not replicate those reports, but rather highlight the validation and implementation of molecular biomarkers to establish aflatoxins' carcinogenicity.

Before the availability of biomarkers of internal and biologically effective dose, epidemiological studies relied on estimates of dietary AFB_1 exposure, acquired through food contamination surveys. However, substantial imprecision in such estimates can arise from heterogeneity in the spatial distribution of contamination within sampled food items (on the order of 10^3), errors in actual *vs.* assumed food consumption, and unappreciated temporal or geographical variation in contamination, due to unaccounted ecological factors. Nonetheless, such studies have provided circumstantial support for an association between AFB_1 intake and HCC risk. In a cohort of nearly 8000 men in Guangxi, China, HCC rates among four communities correlated with estimates of dietary aflatoxin contamination (Yeh et al., 1989). In an ecological study in high- and low-incidence regions of China, although 85% of corn samples in the high-incidence region were contaminated with AFB_1, only 5% of samples in the low-incidence community had detectable levels (Li et al., 2001). While these and other data were suggestive of the carcinogenic effects that had long been observed in animal models, the limitations of the ecological approach persist. This necessitated the development, validation, and implementation of minimally-invasive biomarkers of aflatoxin exposure, internal dose, and biologically effective dose.

Aflatoxins and Cancer Risk: Assessment with Biomarkers of Exposure

Measurement of AFB_1 or its metabolites in the urine has long been an approach for the subject-level assessment of aflatoxin exposure, continuing into the present day. Analytical techniques have advanced since early studies with radiolabeled tracers in animals (Dalezios et al., 1973; Wogan et al., 1967), and a breakthrough was the development of high-affinity monoclonal antibodies recognizing aflatoxins (Groopman et al., 1984), which could be implemented in immunoassays (Hatch et al., 1993; Zhu et al., 1987) or affinity columns for aflatoxin purification prior to analytical HPLC (Groopman et al., 1985, 1992a).

Using these approaches, studies have shown that 24-hour urinary AFM_1 excretion is highly correlated with AFB_1 dose in animals (Groopman et al., 1992a) and AFB_1 intake in humans (Zhu et al., 1987; Groopman et al., 1992b). In contrast, AFB_1 exposure does not show a linear relationship with urinary AFP_1 excretion (Groopman et al., 1992a, b) and correlations with total urinary aflatoxin excretion are inconsistent, likely due to variation in AFP_1 production (Groopman et al., 1992b, c). Thus, urinary AFM_1 is a valid biomarker of short-term ($\sim$24 hour) dietary AFB_1 exposure. With this validated tool in hand, Ross et al. were the first to report an increased risk of HCC with subject-level estimates of aflatoxin exposure (Ross et al., 1992), a finding which has subsequently been replicated several times (Hatch et al., 1993; Qian et al., 1994; Sun et al., 1999; Wu et al., 2009; Wang et al., 1996). Finally, in settings of pre-existing aflatoxin exposure, modulation of urinary AFM_1 excretion has been used as a biomarker of efficacy in chemoprevention trials (Scholl et al., 1996; Wang et al., 1999), or interventions utilizing enteric adsorbents to reduce AFB_1 uptake in the intestine (Mitchell et al., 2013).

Aflatoxins and Cancer Risk: Assessment with Biomarkers of Internal Dose

Similarly to urinary metabolites, levels of urinary AFB_1-mercapturic acid (AFB_1-NAC)—the ultimate product of AFB_1-glutathione conjugation and excretion—reflects recent aflatoxin exposures. However, unlike AFM_1 or other oxidative metabolites (AFP_1, AFQ_1), AFB_1-NAC links aflatoxin exposure with the production and detoxification of the toxic AFB_1-8,9-*exo*-epoxide (Degen et al., 1978; Moss et al., 1983, 1985). Similarly, the AFB_1-albumin (AFB_1-alb) adduct (**Fig. 3**) is formed downstream from the AFB_1-epoxide: solvolysis of the epoxide results in the AFB_1-8,9-dihydrodiol, which exists in equilibrium with AFB_1-dialdehyde (Johnson et al., 1996). This dialdehyde does not adduct DNA or participate in GST-mediated conjugation, but can react with lysine residues within proteins (Guengerich et al., 2002), notably in serum albumin (Sabbioni et al., 1987, 1990). Enhanced reduction of the dialdehyde by aldo-ketoreductases (Guengerich et al., 2001) results in lower AFB_1-alb adduct levels, but has no impact on carcinogenesis (Roebuck et al., 2009). Thus, like AFB_1-NAC, AFB_1-alb is a biomarker of internal dose, as it integrates dietary exposure with metabolic production of the mutagenic epoxide; unlike AFB_1-NAC, it does not reflect activity of the predominant phase II detoxification pathway (GST conjugation). Despite this difference, both are highly correlated with AFB_1 exposure (Sabbioni et al., 1990; Scholl et al., 1997, 2006; Wild et al., 1990, 1992) and hepatic DNA adduct formation (Scholl et al., 1997; Wild et al., 1986, 1996). Rather, the most substantial difference lies in the temporal window each provides to investigators. While urinary biomarkers reflect only the most recent exposure/dose, the half-life of albumin in circulation is $\sim$3 days in the rat, $\sim$21 days in humans, and is unaffected by AFB_1 adduction (Sabbioni et al., 2017)—meaning that previous exposures may be quantifiable for several months in humans. Additionally, this long-term indicator of internal dose represents a "smoothed" estimate of habitual aflatoxin exposure (Wild et al., 1992), while levels of dietary contamination may vary significantly (e.g., daily or between wet and dry seasons (Wild et al., 2000; Gong et al., 2004)).

Both of these biomarkers of internal dose have been used to interrogate cancer risk in humans. AFB_1-NAC was detectable in 24 of 27 HCC cases from Guangxi, China (Wang et al., 2001), while oltipraz (Wang et al., 1999) and green tea polyphenols (Tang et al., 2008) have been shown to increase urinary AFB_1-NAC excretion in secondary prevention trials. Several reports from a Taiwanese case-control study (Hatch et al., 1993) have demonstrated a significantly elevated risk of HCC with detectable (Chen et al.,

1996) or elevated (Wu et al., 2009) AFB_1-alb levels, while secondary prevention trials with enterosorbent clay (Pollock et al., 2016) and post-harvest crop processing and storage (Turner et al., 2005) have shown benefits in mitigating existing AFB_1 exposure.

Aflatoxins and Cancer Risk: Assessment with Biomarkers of Biologically Effective Dose

Spontaneous depurination of the unstable N^7-guanine adduct leads to its dose-dependent appearance in the urine of rodents (Bennett et al., 1981; Groopman et al., 1992a; Walton et al., 2001), in proportion to the initial mutagenic N^7-guanine adduct burden in the liver (Bennett et al., 1981; Groopman et al., 1992a). In humans, although direct validation of urinary N^7-guanine to hepatic adducts is not possible, urinary N^7-guanine excretion in humans very closely reflects dietary AFB_1 intake (Groopman et al., 1992b, 1992c). While also present in the urine, the urinary N^7-guanine adduct does not reflect the same 24-hour window of aflatoxin exposure as do AFM_1 and AFB_1-NAC. A single dose of AFB_1 produces an initial burden of N^7-guanine adducts, of which 30%–50% may depurinate in a biphasic decay and appear as urinary N^7-guanine over the first 48 hours (Bennett et al., 1981; Hertzog et al., 1980). Of course, AFB_1 exposure in humans is rarely in the form of a single bolus and multiple-dosing regimens in animals demonstrate that repeated exposure can result in a sustained release of N^7-guanine adducts for many days (Croy et al., 1981a). Thus, although the N^7-guanine biomarker appears in the urine and certainly reflects a narrower window of exposure (days) than does AFB_1-alb (weeks-months), it exhibits different kinetics than the other aflatoxin biomarkers measured in the urine compartment.

Ross et al. reported associations between HCC risk and subject-level aflatoxin exposure in two papers from a case-control study in China in the late 1980s (Ross et al., 1992; Qian et al., 1994). In addition to finding elevated risk with detectable urinary AFM_1, detectable urinary N^7-guanine was also associated with increased HCC risk, and to an even stronger degree: nearly fivefold in the initial report (95% CI 1.5–16.3) and more than ninefold in their follow-up paper (95% CI 2.1–11.8). Additionally, in the second report (Qian et al., 1994), the HCC risk estimates associated with detectable urinary AFM_1, AFP_1, AFB_1, or AFQ_1 all increased when detected simultaneously with the N^7-guanine adduct. Similar patterns have been reported in a Taiwanese case-control study (Yu et al., 1997). As with other aflatoxin biomarkers, N^7-guanine levels have been used in intervention and prevention trials, revealing associations with broccoli-sprout glucosinolates (Kensler et al., 2005) and reduced N^7-guanine adduct formation with the use of chlorophyllin as an orally administered enterosorbent (Egner et al., 2001).

Aflatoxins and Cancer Risk: Assessment with Biomarkers of Early Biologic Effect

The use of circulating tumor DNA as a biomarker of early carcinogenic events or tumor emergence has been of great interest for some time (Christie et al., 2016; Jahr et al., 2001). Given the high penetrance of the R249S mutation in AFB_1-induced HCC, as well as the great importance of p53 as a tumor suppressor, detection of this mutation in circulating DNA from pre-neoplastic lesions or early carcinomas became an attractive biomarker target. Kirk et al. (2000) tested plasma from Gambian controls or patients diagnosed with HCC or cirrhosis; using restriction endonuclease digestion, they found the R249S mutation in only 3/53 controls and 2/13 cirrhotic patients, but in 19/53 HCCs (36%; OR 16.4, 95% CI 3.0–90.5). Moreover, they were not able to detect the R249S biomarker in any of the 10 European controls or 50 European HCC cases. Other publications followed, with most utilizing the short oligonucleotide mass analysis (SOMA) technique (Laken et al., 1998; Qian et al., 2002). Jackson and colleagues detected the R249S mutation first in 10/25 HCC tumors from China (validated with DNA sequencing) and subsequently in 11/20 tumors from a second Chinese cohort (Jackson et al., 2001). In the second cohort, paired plasma for 6/11 mutant tumors tested positive for the circulating R249S mutation, while 0/10 plasma samples from healthy American controls did. A study in Gambian HCCs reported similar rates of tumoral R249S mutation, with greater concordance (89%) between paired tumor-plasma dyads (Szymańska et al., 2004). A later study of HCC in Qidong, initiated after aflatoxin exposure had likely begin to decrease (Chen et al., 2013), found ~60% prevalence of both tumoral and plasma R249S mutations, despite low levels of serum AFB_1-alb adducts (Szymańska et al., 2009)—thus demonstrating the ability to reveal significant past exposures not captured temporally with other aflatoxin biomarkers. Others have demonstrated relative quantitation of plasma R249S levels, enabling its use as a continuous HCC risk variable (Lleonart et al., 2005); for example, while only 2% of controls had R249S levels $>10^3$ copies per mL, 26% of HCC cases did (OR 62, 95% CI 4.7–820). Subsequent studies have found increased HCC risk with either higher relative levels of plasma R249s (Kirk et al., 2005b; Villar et al., 2012) or R249S detection (Kirk et al., 2005b; Jackson et al., 2003).

Chemical–Viral Interactions

A crucial and consistent factor impacting the role of AFB_1 in HCC risk has been the interaction between concurrent chronic HBV infection and AFB_1 exposure. This relationship has been noted since the earliest AFB_1 biomarker studies—while Ross and colleagues reported a substantially increased HCC risk overall with any detectable urinary N^7-guanine adduct (RR 4.9, 95% CI 1.5–16.3), stratification by HBV surface antigen (HBsAg) status revealed a crucial interaction (Ross et al., 1992). Detectable urinary N^7-guanine conferred no significant HCC risk in HBsAg-negative individuals (RR 1.9, 95% CI 0.5–7.5), but a 60-fold increased risk (95% CI, 6.4–561.8)—greater than multiplicative—with concurrent HBsAg-positive status. This remarkable finding was replicated in their follow-up report: while detectable urinary aflatoxin biomarkers now significantly elevated HCC risk in HBsAg-negative individuals (likely due to improved power from additional cases and controls), aflatoxin exposure in HBsAg-positive participants was still associated with a nearly 60-fold increased risk (Qian et al., 1994). While some recent studies have not returned the same magnitude of

synergy as earlier reports, this may be partly due to improved HBV vaccination in some regions (Chang et al., 2009; Sun et al., 2013; Qu et al., 2014), declining aflatoxin exposure in others (Chen et al., 2013; Sun et al., 2013), and may explain some findings of additive, rather than synergistic, interaction (Wu et al., 2009). Regardless, the existence of a chemical-viral interaction appears to hold a firm consensus, regardless of the biomarker used for estimating aflatoxin exposure (Lunn et al., 1997; Kirk et al., 2005b; Yeh et al., 1989; Wang et al., 1996). Indeed, much of the impact of aflatoxin exposure on HCC incidence must be viewed in context with HBV infection. Reduced aflatoxin exposure, rather than HBV vaccination, likely accounts for the attenuation of HCC mortality in Qidong, China over the past 30 years; however, the great majority of this effect (83%) was attributable to reducing aflatoxin exposure in HBV-infected individuals (Chen et al., 2013). Similarly, while a recent systematic review and meta-analysis reported that 17% of worldwide HCC risk could be attributed to aflatoxin, this was higher in HBV-infected (21%) than HBV-uninfected individuals (9%), with odds ratios of 73.0 (95% CI 36.0–148.3) for concurrent exposure and 6.4 (95% CI 3.7–10.9) for aflatoxin alone (Liu et al., 2012).

Several mechanisms have been proposed to explain this striking interaction between HBV and aflatoxin exposure. First, mutations in the HBV HBx gene are predictive of HCC development (Kuang et al., 2004; Muñoz et al., 2011) and HBx protein—particularly mutant HBx—physically interacts with (Gouas et al., 2010; Iyer et al., 2011) and inhibits p53 (Iyer et al., 2011), disrupting genome surveillance. Additionally, coexpression of HBx and R249S mutants has been shown to increase proliferation and aneuploidy in immortalized hepatocytes (Jiang et al., 2010). Second, HBV infection may exacerbate AFB_1-induced mutagenesis and inhibit adduct repair. HBx protein and the HBV large envelope protein have been shown to induce CYP3A4 expression, potentially leading to greater AFB_1 epoxidation and adduct formation (Niu et al., 2013; Kirby et al., 1994). Moreover, HBx appears to reduce NER through both p53-dependent and -independent mechanisms (Jia et al., 1999), with one study demonstrating specific impairment of AFB_1-adduct repair (Groisman et al., 1999). Unsurprisingly, epidemiological evidence suggests that *TP53* R249S mutations co-occur with HBx genomic integration and mutation in HCC (Ortiz-Cuaran et al., 2013; Kuang et al., 2005; Gouas et al., 2012).

Summary and Outlook

In closing, the half-century of investigation into the toxicology and molecular biology of aflatoxin exposure now represents a classic and voluminous case study in chemical carcinogenesis. Few agents have been so thoroughly characterized through basic research; fewer still provide molecular epidemiologists with as wide of an array of tools with which to investigate. While much has been revealed, work in many subfields remains ongoing—from characterization of the epigenetic impacts of AFB_1-induced hepatocarcinogenesis (Livingstone et al., 2017), to the role of AFB_1 in carcinogenesis at other organ sites (Noguier et al., 2015; Koshiol et al., 2017; Carvajal et al., 2012), to predictions of elevated and shifting aflatoxin exposures as a result of impending climate change (Medina et al., 2014; Battilani et al., 2016). Work from many investigators has identified effective, culturally competent, and cost-effective strategies for the primary and secondary prevention of aflatoxin exposure (Groopman et al., 2008). Given that the burden of aflatoxin exposure will continue to fall on many of the world's most vulnerable populations (International Agency for Research on Cancer, 2015; Wu et al., 2012), efforts to implement these strategies will likely (and rightly) become a priority.

Aging and Cancer

Mingyang Song, Harvard Medical School, Boston, MA, United States; Massachusetts General Hospital, Boston, MA, United States; and Harvard T.H. Chan School of Public Health, Boston, MA, United States

Glossary

Aerobic glycolysis Refers to a metabolic phenomenon commonly observed in cancer cells that convert glucose to lactate in the presence of oxygen.

Autophagy Is a major intracellular self-degradative process that delivers cytoplasmic materials to the lysosome for degradation.

Cellular senescence Also known as replicative senescence, refers to the essentially irreversible arrest of cell proliferation (growth) that occurs when cells experience potentially oncogenic stress.

Clonal hematopoiesis Refers to a common aging-related phenomenon in which hematopoietic stem cells (HSCs) or other early blood cell progenitors carrying recurrent somatic mutations contribute to the formation of a genetically distinct subpopulation of blood cells.

Inflammasomes Are innate immune system receptors and sensors that regulate the activation of caspase-1 and induce inflammation in response to infectious microbes and molecules derived from host proteins.

Loss of heterozygosity Is a gross chromosomal event that results in loss of the entire gene and the surrounding chromosomal region.

Oxidative stress Refers to an imbalance between the production of reactive oxygen species and the ability of the body to counteract or detoxify their harmful effects through neutralization by antioxidants.

Progeroid syndromes Refer to a group of rare genetic disorders which mimic physiological aging, such as Werner syndrome, Hutchinson–Gilford progeria syndrome, trichothiodystrophy syndrome, and Cockayne syndrome.

Reactive oxygen species (ROS) Refer to a number of reactive molecules and free radicals derived from incomplete reaction of oxygen in mitochondria.

Warburg effect Is the enhanced conversion of glucose to lactate observed in tumor cells, even in the presence of normal levels of oxygen.

Incidence of most cancers increases over age (Fig. 1). In the United States, 50% of all malignancies occur in individuals over the age of 65, which represent 12% of the population. With the current aging rate, it is estimated that 70% of all cancers will occur in the elderly by 2030. Despite the evident age-dependent pattern of cancer incidence, the relationship between the biology of aging and cancer is far from clear. According to the widely accepted multi-step model of cancer, cancer is the end-result of various sequential mutations and successive cellular changes. Therefore, it has been debated whether aging has any causal effect on cancer independent of the prolonged exposure time to carcinogens due to aging. However, emerging evidence from studies of genetic and dietary manipulations indicates that cancer may be reduced by chronic downregulation of pro-aging pathways. On the other hand, although several mechanisms are well known to be shared between aging and cancer, the molecular and cellular hypotheses posited to

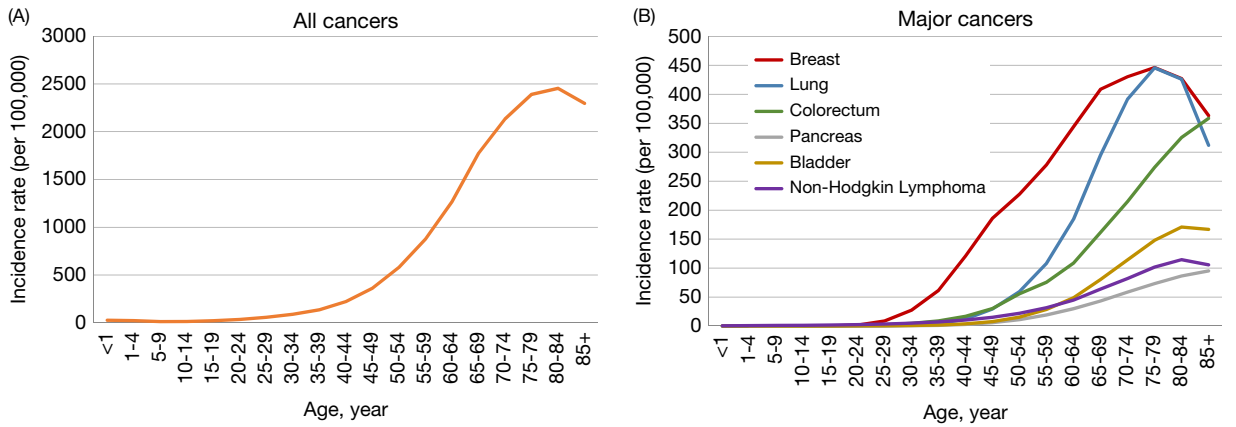

Fig. 1 The incidence of all cancers (A) and cancers of major sites (B) according to age at diagnosis. Except for gender-specific cancers, data from males and females are combined. Data are from the United States Cancer Statistics (1999–2013), Wide-ranging Online Data for Epidemiologic Research (WONDER) database (https://wonder.cdc.gov/cancer-v2013.HTML).

explain a causal relationship between the two processes remain largely untested. These controversies and unknowns are not surprising because the nascent field of geroscience is only beginning to inform oncology of the biological links between cancer and aging. Herein, I aim to summarize recent advances in aging biology that are relevant to cancer, and highlight the crucial questions that need to be addressed to not only gain a better understanding about the aging–cancer link, but also to facilitate translation of the findings from the biology of aging into the clinic for cancer prevention and treatment.

Endocrine, Genetic and Dietary Regulations of Aging Linked to Cancer

The original hypothesis of organismal longevity posits that aging is the natural result of slow, inexorable degradations in functionality of the cells, tissues, and organs of the animal. However, research over the past few decades has unveiled the surprising plasticity of aging that is at least in part regulated by genetic and nutritional signals. Hundreds of genes, particularly those involved in stress response and nutrient sensing, have been shown to modulate the aging process in model organisms. Caloric restriction has been shown to significantly increase lifespan (by up to 50%) in many species, from yeast to primates. Importantly, studies using longevity mutants and treatments have demonstrated that slowed or accelerated aging in rodents has an effect on cancer incidence, suggesting that aging process may contribute to cancer development independently of increased exposure to carcinogens due to aging.

Growth Hormone (GR)-Insulin/Insulin-Like Growth Factor (IGF-1) Signaling

Growth hormone, which is produced by the anterior pituitary, stimulates production of its secondary mediator, IGF-1, by many cell types. The intracellular signaling pathway of IGF-1 is shared by that elicited by insulin, which is produced by beta cells of the pancreatic islets in response to increased glucose concentration in the blood. The GR-insulin/IGF-1 pathway is the first identified and the most conserved aging-controlling pathway in evolution. It was first linked to life span in *Caenorhabditis elegans*, where mutations in *daf-2*, a known regulatory gene encoding an insulin/IGF-1 receptor ortholog, were found to more than double the life span of the animal. Subsequent studies identified other life-extending mutations in the phosphatidylinositol 3-kinase (PI(3)Kf)/AKT/PDK kinase cascade, a key downstream pathway of the insulin/IGF-1 signaling that regulates various cellular functions such as cell growth, proliferation, differentiation, motility, survival, and intracellular trafficking. These mutations influence lifespan through changes in the activity of numerous transcription factors, including a FOXO family transcription factor DAF-16, the heat-shock transcription factor HSF-1, and a Nrf-like xenobiotic-response factor SKN-1. These transcription factors, in turn, upregulate or downregulate diverse genes that act cumulatively to influence lifespan.

Importantly, insulin/IGF-1 pathway and its signaling cascade, which involves PI3K, AKT, mTOR, and AMPK, have been implicated in cancer development and progression (Fig. 2). Insulin may promote cancer directly as a mitogen on susceptible cells through insulin receptors, or indirectly by decreasing IGF-1 binding proteins and thereby increasing levels of bioactive IGF-1. High levels of circulating insulin and IGF-1 have been associated with increased risk of cancer at several sites, including colorectum, endometrium, pancreas, breast, prostate, and ovary. Hyperinsulinemia and insulin resistance have been suggested as key mediators underlying the link between obesity, sedentary lifestyle, diabetes, and increased cancer risk. On the other hand, small molecules that suppress the insulin/IGF-1 pathway by targeting downstream effectors, including mTOR inhibitors (e.g., rapamycin and resveratrol) and AMPK activators (e.g., anti-diabetic drug metformin), have been shown to possess life-extending properties and are being tested as promising cancer-preventive and therapeutic agents. In fact, rapamycin has been approved by the FDA for treatment of pancreatic cancer. Metformin use have been associated with lower incidence and mortality of cancer in numerous studies. A recent phase III trial reported that low-dose administration of metformin for 1 year to patients without diabetes reduced the recurrence of colorectal adenoma, a precursor lesion for colorectal cancer. These findings provide further support for the critical role of the insulin/IGF-1 pathway in the link between aging and cancer, and open new avenues for cancer prevention and treatment.

Life-Extending/Shortening Genetic Alterations and Cancer

There is clear evidence that a single gene mutation can extend longevity in rodents and mammals. As such, studies have examined the impact on cancer development of manipulations in crucial aging-related genes. Findings indicate that compared with wild-type mice, mutant mice with disrupted GH and IGF-1 signaling are long-lived and tend to have lower cancer incidence and often longer cancer latency. For example, Ames dwarf mice, which are GH-deficient and have significantly extended lifespans due to a recessive mutation at pituitary transcription factor 1 (*Pit-1*), show a delayed occurrence of fatal neoplastic diseases and lower severity of lung adenocarcinoma compared with wild-type littermates. Similar findings have been reported in the growth hormone receptor/binding protein (GHR/BP) knockout mice, which live approximately 40%–55% longer than their normal siblings due to defective GH–IGF-1 signaling. These GHR/BP knockout mice are less frequently tumor-bearing, develop fewer different tumors, and also show a significantly lower incidence of fatal neoplastic lesions than wild-type controls.

In line with the animal evidence, humans with GHR mutations which result in GHR deficiency (GHRD) are protected against cancer. In a prospective cohort study of 99 individuals with GHRD, no cancer death was observed compared with a proportion of 20% due to cancer among all deaths in relatives without GHRD. Further in vitro studies indicated that treating human mammary epithelial cells with serum of GHRD subjects led to a spectrum of changes commonly observed in life-extending model organisms, including decreased DNA breaks, increased apoptosis, downregulation of oncogenes, and upregulation of mediators of cellular

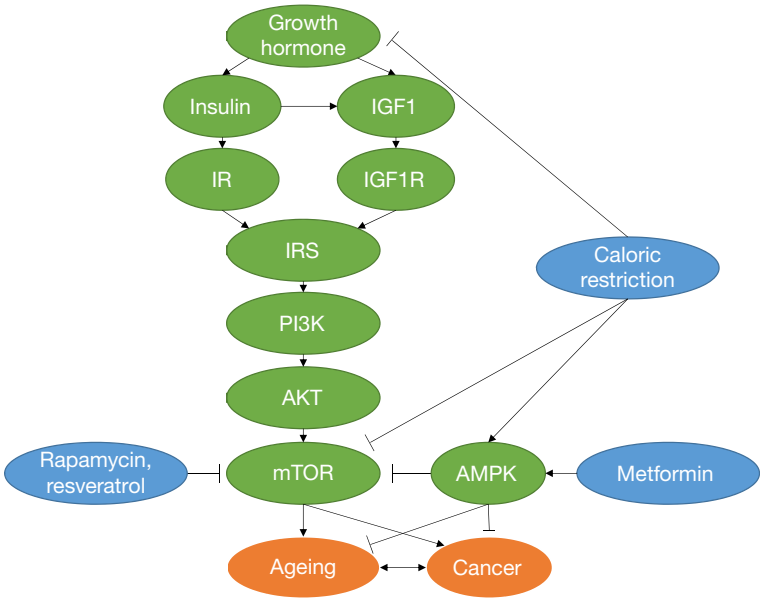

Fig. 2 Growth hormone-insulin/IGF-1 pathway in aging and cancer. Growth hormone stimulates production of IGF-1, and blocks the activity of inulin that can lead to high insulin levels which in turn increase bioactive IGF-1 levels by decreasing IGF-1 binding proteins. Insulin and IGF-1 bind to their receptors and activate, via insulin receptor substrate (IRS), the downstream signaling cascade, which involves PI3K, AKT, and mTOR, to promote aging and cancer development. On the other hand, as a conserved sensor of energy status, AMPK negatively regulates mTOR and has both life-extending and anti-tumorigenic activities. Rapamycin and resveratrol are inhibitors of mTOR and have been shown to protect against aging and carcinogenesis. Caloric restriction can inhibit mTOR signaling both directly and indirectly through activation of AMPK pathway. Metformin, which is used for treatment of diabetes, activates AMPK and inhibits cell growth in an AMPK-dependent manner. AKT, protein kinase B; AMPK, AMP-activated protein kinase; IGF1R, IGF1 receptor; IR, insulin receptor; mTOR, mechanistic target of rapamycin; PI3K, phosphoinositide 3-kinase.

protection against oxidative stress. Taken together with the aforementioned pro-cancer effect of GH-insulin/IGF-1 signaling, these findings support the overlapping effects of endocrine regulations on aging and cancer processes, and suggest that cellular changes that lead to longevity may preferentially antagonize tumor cell growth.

On the other hand, increased cancer predisposition has been observed in patients with Werner syndrome who develop a variety of signs of aging at a relatively young age due to defects in DNA repair. The cells of Werner syndrome show significant chromosomal abnormalities, increased frequency of deleterious mutations, and accumulation of DNA double-strand breaks, although the relevance of this and other progeroid syndromes to normal aging remains unresolved due, in part, to the fact that they recapitulate only some aspects of aging. The fact that disruption of DNA repair results in signs of premature aging and cancer predisposition indicates that genomic instability may be an important overlapping mechanism for aging and cancer (see section "**Genomic Instability**").

Caloric Restriction, Aging and Cancer

In addition to genetic mutations, dietary manipulations have a substantial impact on aging and cancer. The most widely studied life-extending intervention is calorific restriction, a reduction of 10%–40% in caloric intake of a nutritious diet without inducing malnutrition. Although most studies of this phenomenon have been conducted in rodents and lower animals, data accumulating from rhesus monkeys suggest that calorific restriction may also be relevant for primates, including humans. So far, three controlled intervention trials of calorific restriction have been reported in rhesus monkeys, the studies at the Wisconsin National Primate Research Center (WNPRC, $n = 76$), the National Institute on Aging (NIA, $n = 121$), and the University of Maryland Obesity, Diabetes and Aging Animal Resource Center (ODAAR, $n = 117$). The WNPRC study reported that 30% calorific restriction initiated in adult rhesus monkeys (7–14 years, average lifespan of ~27 years in captivity) lowered the incidence of aging-related deaths (13% in the intervention group vs. 37% in controls), and delayed the onset of age-associated pathologies, including the incidence of cancer, diabetes, cardiovascular disease, and brain atrophy. The ODAAR study included 8 dietary-restricted and 109 ad libitum-fed monkeys. After approximately 25 years of follow-up, control monkeys experienced a 2.6-fold increased risk of death (median survival = 25 years) than the calorically restricted monkeys of the same age (median survival = 30 years). In contrast, the NIA study did not observe any significant difference in survival between control and caloric restriction monkeys. Differences in study design, husbandry, and diet composition have been suggested to at least partly explain the discrepant findings. In particular, because the control monkeys in the NIA study were fed according to regulated portioning rather than ad libitum, they may have effectively undergone and benefited from caloric restriction. Despite the divergence, however, the NIA study also observed a markedly reduced incidence of cancer in monkeys that received caloric restriction at young age compared with controls, supporting the anti-cancer effect of caloric restriction.

Interestingly, the effects of caloric restriction are not uniform, with tumors from different tissues responding to restriction to different degrees, and a fraction of tumors originating in the same tissues showing resistance to caloric restriction. Functional studies have identified the activation status of the PI3K pathway as a molecular signature that largely predicts the sensitivity of a tumor to dietary restriction. As a downstream mediator of the insulin/IGF-1 signaling pathway, PI3K is recruited to the cell membrane, where its activity, which is antagonized by the PTEN tumor suppressor, leads to the recruitment and activation of AKT that in turn phosphorylates and regulates several targets that enhance cellular growth and inhibit apoptosis. While dietary restriction does not affect a PTEN-null mouse model of prostate and lung cancer, it significantly decreases tumor burden in a mouse model of lung cancer lacking constitutive PI3K signaling.

The benefit of caloric restriction has also been indicated in the first randomized trial in humans, the Comprehensive Assessment of the Long Term Effects of Reducing Intake of Energy (CALERIE) study. The study found that 6 months of caloric restriction improved two well-established biomarkers of longevity (reduced fasting insulin levels and body temperature), although serum dehydroepiandrosterone sulfate (DHEAS), another longevity marker, did not show slowed decline in the intervention group. These favorable effects have led to a longer-term trial, the CALERIE-2 study, which aims to test the anti-aging effect over a 2-year period of 25% caloric reduction in energy intake from baseline in nonobese adults. Feasibility of sustained caloric restriction is indicated by the fact that 82% participants completed the CALERIE-2 protocol. While no change was observed in the two primary outcomes (resting metabolic rate and core body temperature) and IGF-1 levels, a diversity of benefits were detected in support of potential anti-aging and anti-cancer effects, including persistent weight loss, reduced fat mass, increased levels of serum IGF binding protein-1, improvements in cardiometabolic risk factors (including whole-body and regional adiposity, lipid profile, blood pressure, and glucose control), adaptive decreases in daily energy expenditure, and decreases in markers of thyroid axis and inflammation (circulating triiodothyronine and tumor necrosis factor-alpha). Another two studies with 1- and 6-year caloric restriction also found no reduction in IGF-1 levels, unless it is combined with protein restriction. However, given the short duration and limited size, these trials are unable to examine the effect of caloric restriction on cancer outcomes.

Fasting and Cancer

Increasing data have suggested the potential of another dietary intervention, fasting, in cancer prevention and treatment. Different from caloric restriction, in which meal frequency is maintained, fasting is achieved by no or minimal intake of food and caloric beverages for periods that typically range from 12 h to 3 weeks. Natural experiments of religious groups that incorporate periods of fasting into their rituals indicate the benefits of fasting. For example, Muslims who fast from dawn until dusk during the month of Ramadan showed favorable physiological changes analogous to those observed in caloric restriction, including improved lipid profile, better glucose control, and decreased oxidative stress. Experimental studies have tested different fasting methods, including intermittent fasting, which typically has cycles lasting 24 h and one to a few days apart, prolonged fasting, whose cycles last two or more days and are at least 1 week apart, and very low calorie/low protein fasting-mimicking diets (FMDs), which are developed to minimize the burden of prolonged fasting. Overall, these fasting methods have been shown to retard aging and extend lifespan in rodent models, possibly by reducing IGF-1 levels and increasing insulin sensitivity and cellular stress resistance, although the magnitude of the effects on longevity depends upon the species of rodents and age at regimen initiation.

As for cancer, fasting has shown positive effects in cancer prevention and treatment. Fasting for 1 day per week delayed spontaneous tumorigenesis in p53-deficient mice, alternate day fasting in mice caused a major decline in the incidence of lymphomas, and FMD started at middle age reduced tumor incidence, delayed their onset, and caused a major reduction in the number of tumorigenic lesions. However, it has been observed that fasting-induced cell death and/or atrophy in a wide range of tissues is accompanied by a period of abnormally high cellular proliferation in these tissues, driven in part by the replenishment of growth factors during refeeding. When combined with carcinogens during refeeding, this increased proliferative activity can actually increase carcinogenesis and/or precancerous lesions in tissues including liver and colon. These findings highlight the need for an in-depth understanding of the mechanisms of action of fasting for the purpose of cancer prevention. A recent randomized controlled trial reported that compared to individuals on an unrestricted diet, those who consumed the FMD for 5 consecutive days per month for 3 months demonstrated favorable changes in a diversity of metabolic and inflammatory markers, many of which have been associated with lower cancer risk, such as lower body mass index, IGF-1, and C-reactive protein. However, because the FMD contains a generally healthy dietary pattern (plant-based, low in sugars and protein but high in unsaturated fats) beyond fasting, it is unknown whether the observed beneficial effects are driven by dietary components or fasting itself.

On the other hand, in the treatment of cancer, fasting has shown more consistent and positive effects. Prolonged fasting for 2–3 days protect normal cells while simultaneously sensitizing malignant cells to high-dose chemotherapy. This differential stress resistance (DSR) may be related to reduction of IGF-1, downregulation of proto-oncogene signals, and profound metabolic shift by fasting that promotes an anti-Warburg effect in cancer cells and results in oxidative damage and apoptosis. Multiple cycles of prolonged fasting have been shown to be as effective as chemotherapeutic agents in delaying progression of different tumors, abate the immunosuppression and mortality caused by these drugs, and augment their effectiveness in the treatment of some cancers in mice. Combination of chemotherapy and FMD enhance $CD8^+$ T cell-dependent killing of cancer cells and enrich lymphoid progenitor cells to suppress tumor progression. These data collectively indicate the potential of fasting as an adjuvant strategy in cancer chemo- and immunotherapy. It may have superior feasibility over chronic caloric restriction, because the latter generally induces weight loss and may not be feasible for cancer patients receiving chemotherapy, surgery or immunity-based treatments who are at risk for losing weight and becoming frail and cachectic.

Mechanistic Links Between Aging and Cancer

Unlike disease that typically develops within a certain time window, aging is a process lasting across the entire lifespan and starting, theoretically, immediately after birth. Therefore, from a mechanistic perspective, it is difficult to disentangle the causes and consequences of aging, especially given the possibility that the two sets may overlap (e.g., genetic damage accumulates over aging while at the same time may result in accelerated aging). It becomes even more difficult when one attempts to link to cancer, and to tease out the shared mechanisms that contribute to both aging and cancer processes from aging-induced molecular alterations that in turn affect cancer risk. However, such separation is less important from the standpoint of cancer prevention, which can be achieved by targeting any of the pathways regardless their temporal relationships with aging.

Recently, López-Otín et al. proposed nine hallmarks that are generally considered to contribute to the aging process with experimental evidence that aggravation and amelioration of these hallmarks accelerate and retard aging, respectively. Not surprisingly, all of the hallmarks are intrinsically connected to the hallmarks of cancer that were first proposed by Hanahan and Weinberg in 2000 and then updated in 2011 (Fig. 3). These connections operate at various levels of biological processes, ranging from genetic, epigenetic, to metabolic alterations, and encompassing both cell-autonomous mechanisms and changes in the intercellular communications. Such multilevel interconnections reinforce the idea that cancer and aging may represent two different manifestations of the same underlying process, namely the accumulation of cellular damage.

Herein, I summarize the major cellular and molecular hallmarks of aging that are relevant to cancer, and highlights the mechanistic connections between aging and cancer processes.

Genomic Instability

The integrity and stability of DNA are continuously challenged by exogenous physical, chemical, and biological agents, as well endogenous threats, including reactive oxygen species (ROS), DNA replication errors, and spontaneous hydrolytic reactions. To counteract DNA damage, organisms have evolved a complex network of protective mechanisms, including the DNA repair system, and mechanisms for maintaining the appropriate length and functionality of telomeres and ensuring the integrity of mitochondrial DNA. Given the massive data on the predominant role of telomere shortening and mitochondrial dysfunction in aging and cancer, they will be discussed in separate sessions in more details, and this session will be focused on nuclear DNA damage responses.

Several forms of DNA damage, including somatic mutations and chromosomal aberrations, accumulate with aging. A causal role for deficiencies of DNA repair mechanisms in aging and cancer is suggested by the development of premature aging and increased cancer risk of Werner syndrome patients who demonstrate a variety of mutations in the WRN gene that is important for the reinitiation of stalled replication forks to reduce replication errors. Experimental evidence in animal models also indicates that artificial reinforcement of nuclear DNA repair mechanisms may delay aging and suppress tumor development. Recent large-scale

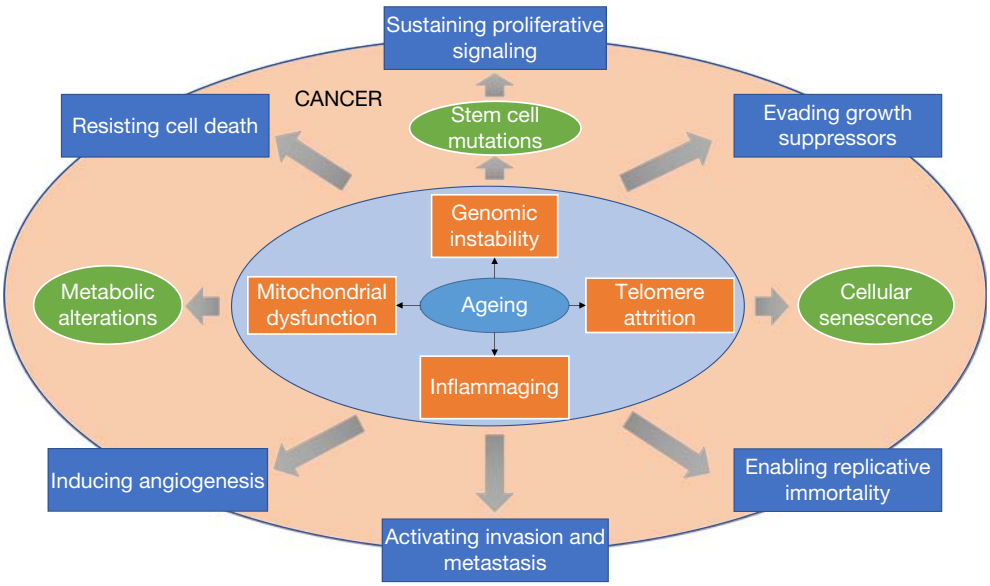

Fig. 3 Links between the major hallmarks of aging and cancer. The aging process is characterized by genomic instability, mitochondrial dysfunction, telomere attrition, inflammaging, stem cell mutations, and dysregulated nutrient sensing, which can contribute to carcinogenesis by affecting multiple hallmarks of cancer, including (1) increased production of growth factors and induction of somatic mutations to sustain chronic proliferation; (2) inhibition of tumor suppressor genes to facilitate evasion of growth suppressors; (3) attenuation of apoptosis and induction of autophagy to resist cell death; (4) alteration of telomere length and telomerase activity to enable replicative immortality of cells; and (5) disruption of tissue microenvironment to induce angiogenesis.

studies have begun to quantify the accumulation of mutations and chromosomal anomalies in human: one study using whole-exome sequencing data from blood DNA of 17,182 individuals found that detectable somatic mutations were very rare in persons younger than 40 years of age, but rose appreciably in frequency with age (9.5% among persons 70–79 years, and 18.4% among those of 90–108 years). Furthermore, the study found that persons with detectable mutations had a markedly increased risk of hematologic cancer. Similarly, a comprehensive assessment of somatic mutations in various tumor types found a strong positive correlation between the number of mutations and age of diagnosis for a wide range of solid tumors that are characterized by certain mutational signatures with prominence of C > T substitutions at NpCpG trinucleotides. These data together support the possibility that mutations may alter key genes and transcriptional pathways, resulting in dysfunctional cells that, if not eliminated by apoptosis or senescence, may jeopardize tissue and organismal homeostasis, therefore leading to accelerated aging and higher cancer risk. However, to what extent and through what mechanisms accumulation of mutations contributes to the aging process and drives the evolution of normal cells into cancer cells still remains an open question. Recent data point to a critical role of the decline in functional capacity and genetic integrity of adult tissue stem cells in the impairment in the tissue maintenance and the increase in cancer formation during aging.

Aging is associated with clonal dominance of mutant stem and progenitor cells. For example, the number of somatic mutations in hematopoietic stem cells increases exponentially with age, contributing to their clonal expansion, a phenomenon termed "clonal hematopoiesis." Importantly, most such clonal expansions appear to involve "driver mutations," which increase the selective growth advantage of the cells containing them, and thus represent an early event in the development of hematologic cancers. Similar aging-related accumulation of clonal crypt-dominance has also been reported in intestinal stem cells (ISCs) harboring chromosomal gains and losses. A recent study uncovered two mechanisms of genome instability in adult *Drosophila* ISC: first, frequent loss of heterozygosity (LOH) driven by mitotic homologous recombination results in genetic mosaicism, a phenomenon of the occurrence of more than one genetically diverse cell population in an organism arising from a single fertilized egg, which may contribute to tumor formation by facilitating expansion of positively selected variant clones with greater fitness; second, somatic deletion of DNA sequences and large chromosomal rearrangements led to spontaneous inactivation of the X-linked tumor suppressor *Notch* that in turn drove neoplasia in 10% of aged wild-type males. In addition to these cell-intrinsic mechanisms, there is increasing evidence that aging-associated defects in the cell-extrinsic factors, including the stem cell niches, systemic environment, and immune surveillance, may also affect the selection of mutant stem cells during aging, which can be potentially modifiable by environmental exposures, such as diet.

Linking the genetic and stem cell models of cancer, recent studies proposed that accumulation of random mutations through stem cell divisions, the so-called "bad luck," is a major determinant of the variation in cancer risk across tissues, on the basis of the observed high correlation between the number of stem cell divisions of a given tissue and the lifetime risk of cancer in that tissue. While these studies present a novel, quantitative assessment of the potential stochastic effects of DNA replication on cancer development, the proposed hypothesis does not appear to be consistent with the empirical data on genome-wide mutation patterns in human adult stem cells (ASCs). A recent study sequenced clonal organoid cultures derived from primary multipotent cells of human donors, and observed that the annual mutation rate in ASCs was in the same range for all assessed tissues, despite the markedly dissimilar cancer incidence in these tissues. For example, cancer incidence in the colon is approximately 10 times higher than that in the small intestine, but ASCs from both tissues accumulated about 36 mutations per year with very similar mutation spectra. Another limitation of the "bad luck" hypothesis is that it fails to account for potential modification in the number and replication rate of stem cells by host and extrinsic factors. For example, tall persons tend to have higher number of stem cells and height has been linked to increased risk of cancer in various tissues. Therefore, the estimated stochastic effects may be at least partly attributable to height, which is a trait determined by both genetic and early-life exposures. Finally, the hypothesis proposed in the original study did not clearly distinguish the variation in cancer risk across tissues versus the cancer risk variability across individuals/populations, which are two completely different concepts, thereby creating confusion and leading some to question the preventability of cancer.

In summary, there is extensive evidence that genetic instability is a shared mechanism for aging and cancer. Growing data implicate the particularly important role of DNA damage in stem cells in this mechanism. However, it remains to be determined how genetic mutations in stem and other cells drive aging and carcinogenesis, and whether and to what extent these pathways may be modified to slow aging and reduce cancer risk.

Telomere

Telomeres are repetitive sequences at the ends of chromosomes that protect the end of the chromosome from deterioration or from fusion with neighboring chromosomes. Telomeres shorten with cell division and limit proliferative capacity of in vitro-cultured cells, by activating DNA damage response pathways that cause cells to undergo irreversible growth arrest, the so-called replicative or cellular senescence or Hayflick limit. A causal role for telomere shortening in organismal aging has been established in genetically modified animal models that exhibited decreased or increased lifespans with shortened or lengthened telomeres, respectively. In contrast, the role of telomere length in cancer development has been inconclusive, with supporting evidence for both pro- and anti-cancer effects of telomere shortening.

On the one hand, cellular senescence and apoptosis induced by telomere shortening have been shown to act as a tumor suppressor mechanism by limiting the proliferation of preneoplastic cells and blocking their further malignant transformation. Furthermore, human cancer cells have been found to acquire mechanisms to maintain telomeres, either through expressing high levels of telomerase, a specialized DNA polymerase that elongates telomeres, or through alternative lengthening of telomeres

(ALT) by homologous recombination between telomeres. Mice deficient in telomerase activity show resistance to cancer induced by a variety of genetic defects or carcinogenic treatments. On the other hand, telomere shortening and the resulting telomere dysfunction have been suggested to contribute to cancer susceptibility by increasing the risk of chromosomal aberrations caused by breakage-fusion-bridge cycles, and initiating clonal drift in stem cell pools and promoting clonal dominance of mutant stem cells during tissue aging. Moreover, in addition to suppressing tumorigenesis, replicative senescence may facilitate cancer development by rendering more fertile grounds in old tissues. Studies have shown that senescent cells can disrupt the tissue microenvironment and promote tumorigenesis through production of proinflammatory cytokines, extracellular matrix components, vascular endothelial growth factor, and other cancer-promoting factors.

In parallel with the mixed mechanistic data, epidemiologic studies have also yielded inconsistent findings for the relationship between leukocyte telomere length and cancer incidence. Early retrospective case-control studies generally reported a positive association between telomere shortening and cancer risk. However, this association may, at least in part, be due to reverse causation, where shorten telomere may be a consequence rather than cause of the presence of malignant disease, because leukocyte DNA was obtained from cancer cases after diagnosis. In support of this explanation, prospective studies tended to report weak or null associations of longer telomeres with higher overall and site-specific risk of cancer, with some exceptions. These contradictory findings may also result from confounding effect, because shorter leukocyte telomeres are correlated with numerous cancer risk factors, including older age, male sex, smoking, higher body mass index, and physical inactivity. These complex confounding patterns pose great challenge for observational studies to elucidate the causality of telomere length in cancer development. To overcome this difficulty, a recent study applied the Mendelian randomization approach to study the effect of genetically determined telomere length on incidence of various noncommunicable diseases using summary data from published large-scale GWAS studies. Because of the independent assortment of alleles during gamete formation, which is analogous to the randomized assignment in intervention trials, the Mendelian randomization approach ensures that the association of genetic variants with disease outcome is unconfounded by other common factors. Sixteen single nucleotide polymorphisms corresponding to 10 independent genomic regions were used as the instrumental variables that collectively account for 2%–3% of the variation in leukocyte length. Genetically increased telomere length was associated with a modestly increased risk of overall cancer, and a positive association was found for 9 of 22 primary cancers, suggesting the predominance of tumor-suppressing activities of telomere shortening. However, the magnitudes of the association were found to be highly variable across cancer types with approximately sixfold difference. The associations tended to be stronger for cancers arising from the tissue sites that have lower rates of stem cell division, such as glioma, neuroblastoma, and serous ovarian cancer, whereas for other cancer sites with high tissue turnover rates the associations were largely null (e.g., colorectal and pancreatic cancer). This variation may explain the mixed findings in previous studies when overall cancer risk is the outcome, and mirrors the aforementioned pleiotropic effects on cancer risk of telomere shortening and associated cellular senescence, suggesting the importance of tissue-dependent mechanisms underlying the telomere-cancer relationship.

In summary, in contrast with the well-established role of telomere shortening in aging, the relationship of telomere length with cancer risk is complex and remains controversial. Telomere shortening may possess both cancer-suppressive and predisposing effects, and the collective impact on cancer development is probably tissue-specific, as a function of the regeneration rate of the tissue and the contribution of cell-extrinsic factors to tumorigenesis in that tissue.

Mitochondrial Dysfunction

Mitochondria are complex organelles that perform many roles beyond energy production, including the generation of reactive oxygen species (ROS), redox molecules and metabolites, regulation of cell signaling and cell death, and biosynthetic metabolism. Many of these functions are critical regulators of aging and cancer. The importance of mitochondrial dysfunction in aging is indicated by the mitochondrial free radical theory, which proposes that increased production of ROS resulting from the progressive mitochondrial dysfunction that occurs with aging causes further mitochondrial deterioration and global cellular damage, resulting in overall loss of organismal fitness over time. However, intense re-evaluation of this hypothesis over the past two decades has led to revelation of a neutral or even positive effect of ROS on aging. For example, increased ROS in the mitochondria may prolong lifespan in yeast and *C. elegans*. Genetic manipulations in mice that increase mitochondrial ROS and oxidative damage do not accelerate aging, and mice with increased antioxidant defenses do not present an extended lifespan. Moreover, ROS are shown to be required to increase replicative lifespan of human fibroblasts under hypoxia. In support of these observations, mechanistic studies have indicated that ROS can facilitates cellular adaptation to endogenous and exogenous stimuli of stress through multiple physiological mechanisms, including increase in adaptation to hypoxia by activation of hypoxia-inducible factor (HIF), regulation of autophagy by induction of autophagic cell death, maintenance of normal innate and adaptive immune functions, and regulation of stem cell differentiation. Therefore, ROS have been regarded as a stress-elicited survival signal that can activate compensatory homeostatic responses. Recognition of the dual function of ROS in promoting both cell damage and cell adaptation significantly expands the original mitochondrial free radical theory of aging and suggests that the balance of the ROS levels in different environmental conditions may be crucial for organismal survival.

Similar complex picture exists for the relationship between ROS and cancer development. Historically, high levels of ROS were believed to promote cancer development and metastasis by increasing oxidation of macro-molecules, such as lipids, proteins, and DNA; inducing genomic instability; regulating oncogenic signaling pathways; and promoting inflammatory responses. This led to great enthusiasm in testing the chemopreventive effect of dietary antioxidants in several large clinical trials. However, these studies have produced inconsistent results, and some studies indicated that antioxidants might even increase lung cancer risk among

smokers. Based on the insufficient evidence regarding the balance of benefits and harms for antioxidant multivitamins, the U.S. Preventive Services Task Force recommends against their use for the prevention of cardiovascular disease and cancer. Similar to the dual effect in aging, ROS in moderate concentrations may be essential for the body's stress defense system to clear damaged cells, including those that are precancerous and cancerous, and protect against cancer development. Recent data indicate that enhanced ROS detoxification may mediate the pro-tumor activity of oncogenes such as K-RAS and B-RAF by activation of NRF2-mediated transcription of endogenous antioxidant genes. Moreover, dietary supplementation with antioxidants such as *N*-acetyl-cysteine and vitamin E markedly increased tumor progression by reducing P53 expression in mouse models of lung cancer, and promoted metastasis in mice with endogenous malignant melanoma. These findings suggest the importance of the balance of ROS and the endogenous antioxidant system, and warn against the use of antioxidant supplements that may disrupt this balance among high-risk individuals who have either precancerous lesions or established tumors.

In addition to oxidative stress regulation, mitochondrial dysfunction may contribute to tumorigenesis through other mechanisms. As a central hub for both catabolic and anabolic metabolism, mitochondria drive metabolic reprogramming of cancer cells to support macromolecule synthesis and bioenergetic demand through multiple mechanisms, including limiting its respirational uptake of pyruvate to support aerobic glycolysis during Warburg metabolism, mitochondrial localization of the tumor suppressor sirtuin to promote consumption of glutamine for nucleotide and amino acid synthesis, and production of citrate to support lipogenesis. Furthermore, metabolites generated by mitochondrial metabolic pathways, the so-called oncometabolites, can promote tumor initiation and growth by influencing both nuclear gene transcription via chromatin modification and cytosolic signaling pathways. In addition to oncometabolites, other components released from mitochondria, such as cytochrome *c*, may influence cell behavior through altering the pro- and anti-apoptotic balance. Finally, due to the extremely dynamic morphology, mitochondria may promote K-Ras-dependent cellular transformation, and cancer cell growth and migration through the balance between fusion and fission events.

Given the complex role of mitochondria in cancer, studies have attempted to examine how abnormalities in mitochondrial DNA may impact tumorigenesis. Mitochondria contain multiple copies of a circular 16kB genome that are maternally inherited and encode the electron transport chain machineries, mitochondrial rRNAs, and tRNAs. Somatic mutations in mitochondrial DNA may induce mitochondrial dysfunction that contributes to cancer development through multiple pathways, including regulation of apoptosis in aging cells and some cancer cells, activation of mitochondria-to-nucleus retrograde signaling to modulate the expression of nuclear genes involved in metabolic reprogramming, and facilitation of cells to adapt to altered environments, and development of resistance to chemotherapeutic agents, and promotion of metastatic properties of cancer cells. Although numerous epidemiologic studies have linked germline and somatic mutations in mitochondrial DNA to cancer risk, the results remain inconsistent. Differences in mtDNA copy number are also implicated in tumorigenesis. However, both an increase and a decrease in copy numbers have been associated with increased risk of cancer, even for the same type of cancer. These controversial findings may not be surprising given the multiplicity of mitochondrial genomes, which allows for the coexistence of mutant and wild-type genomes within the same cell, a phenomenon known as "heteroplasmy."

In summary, the original mitochondrial free radical theory of aging is now considered to be too simplistic. ROS possess a diversity of physiological activities in organismal homeostasis. Besides ROS, mitochondrial dysfunction may influence tumorigenesis through alterations in several pathways related to their bioenergetic, biosynthetic and signaling functions. Despite these data, however, human data relating mitochondrial DNA mutations and copy number changes to cancer risk remains inconclusive. Further large-scale studies are needed, especially by accounting for potential metabolic heterogeneity across tumor subtypes.

Inflammaging

In addition to cell-autonomous alterations, aging also involves a global reduction in the capacity to cope with a variety of stressors and a concomitant progressive increase in proinflammatory status, which is referred to as "inflammaging." Inflammaging may result from various causes, including the accumulation of proinflammatory tissue damage, the failure of the immune system to effectively clear pathogens and dysfunctional host cells (known as "immunosenescence"), increased production of proinflammatory cytokines by senescent cells (see "Telomere"), enhanced activation of NF-κB signaling pathway by persistent stress, and a decline in autophagic capacity that impairs cellular housekeeping. These alterations stimulate intracellular danger-sensing multiprotein platforms called inflammasomes, which subsequently activate inflammatory pathways and contribute to the pathogenesis of numerous aging-related diseases, including cancer. In fact, chronic, low-grade inflammation has been established as an enabling characteristic that contributes to multiple hallmark capabilities of cancer by supplying bioactive molecules to the tumor microenvironment, including growth factors that sustain cell proliferation, survival factors that limit cell death, proangiogenic factors, and extracellular matrix-modifying enzymes that facilitate angiogenesis, invasion, and metastasis.

Despite these well-established mechanistic links, the influence of age-acquired immunodeficiency on the incidence of cancer remains an open question. Compared to younger individuals, older persons have markedly lower frequency of naive $CD8^+$ T cells and a slightly lower frequency of naïve $CD4^+$ T cells in the peripheral blood, possibly due to the conversion of naïve cells to memory cells over a lifetime of exposures to immune challenges. However, the functional consequences for carcinogenesis of this age-associated decline in circulating immune cells remain to be determined. On the other hand, differences between older and younger people for other immune compartments, such as B cells, NK cells, and dendritic cells, are subtler. Furthermore, the malignancies associated with profound immunodeficiency, such as in patients with AIDS or organ transplantation, are mostly

virus-induced (e.g., lymphoma, Kaposi's sarcoma, and leukemia) and not the common malignancies that inflict the elderly population. In addition, if it is true that aging-associated immunosenescence reduces the ability of T cells to recognize and control tumor growth, immunotherapy would be expected to be less effective in older patients. However, existing, albeit still limited, evidence indicates similar response rate in the elderly and younger patients in the treatment of advanced melanoma with anti-CTLA-4 antibodies.

In summary, although substantial data support the role of aging in chronic inflammation and the tumor-promoting effect of inflammation, it remains unresolved whether and how functional decline in the immune system during the aging process may affect carcinogenesis. Addressing this question has great implications for cancer prevention and treatment in the elderly population, especially in the context of the recent demonstration that cancer immunotherapy extends survival of patients with advanced cancers.

Prospective Vision

Studies of genetic and dietary manipulations indicate that alterations in the aging process may influence cancer development independently of changes in duration of exposure to carcinogenic factors. These influences can be broadly categorized into the seed effect, which is characterized by the increased susceptibility of aging cells to carcinogens (e.g., due to genomic instability and metabolic dysfunction), and the soil effect, which is mediated by systemic and micronevironmental conditions favoring tumor development (e.g., immunosenescence and tumor-permissive inflammation). However, the detailed biological underpinnings of the interplay between aging and cancer are intrinsically complex and remain largely unknown. Some aging processes may possess both pro- and anti-cancer activities, possibly in a tissue-specific manner. Because most of the available evidence is based on animal models, further human studies are urgently needed to better understand the collective impacts of the aging process on cancer development in a specific tissue. These studies may employ either novel high-throughput sequencing technologies or new interventional approaches to examine the functional consequences of aging-related alterations on carcinogenesis. In addition to mechanistic investigations, more translational research is also needed to address how findings from the biology of aging can be translated into effective strategies for cancer prevention and treatment. As the aging population is leading to an unprecedented increase in cancer burden across the world, understanding the links between aging and cancer is more important than ever. Systematic, in-depth research in this area will undoubtedly lead to improved knowledge about the fundamental biology of cancer and development of novel preventive and therapeutic strategies.

Anal Cancer: Pathology and Genetics

Fred T Bosman, Institute of Pathology, University of Lausanne Medical Center (CHUV), Lausanne, Switzerland

Nomenclature

AIN Anal intraepithelial neoplasia
AJCC American Joint Committee on Cancer
Apocrine Type of gland in anal mucosa
ASIN Anal squamous intraepithelial carcinoma
CDKN2A Cyclin-dependent kinase inhibitor 2A, gene encoding p16 protein
CDX2 Gene encoding homeobox protein CDX-2
Eccrine Type of gland in anal mucosa
EGFR Epidermal growth factor receptor
GCDFP15 Gross cystic disease fluid protein 15
GIST Gastrointestinal stromal tumor
HER2 Human epidermal growth factor receptor 2
HIV Human immunodeficiency virus
HPV-16 Human papilloma virus type 16
HSIL High grade squamous in situ lesion
KIT Proto-oncogene c-Kit
Koilocytic HPV induced squamous epithelial abnormality
LSIL Low grade squamous in situ lesion
Morphotype Histological type of a neoplastic lesion
MRP1 Multidrug resistance-associated protein 1
PD-L1 Programmed death-ligand 1
PI3K/ATK/mTOR pathway Intracellular signaling pathway important in regulating the cell cycle
SOX 2 Sex determining region Y-box 2, gene encoding a transcription factor
TP53 Gene encoding p53, tumor associated gene

Definitions

The complex anatomy and histology of the anal canal, which comprises of several distinct zones, has led to different terminologies used in different disciplines. The term "anal canal" has been in use for more than a century but the definition anatomists use (the structure between the dentate line and the perianal skin) is not used by surgeons (for whom the definition is the structure between the rectum and the perianal skin, which makes it to extend about 2 cm. above the dentate line). In a clinical context the latter definition is mostly used, which results in an anal canal with three zones: an upper part covered by rectal mucosa, a transitional zone covered by a simple "transitional" epithelium and the longest part down to the perianal skin, covered by a non-keratinizing squamous epithelium. Intestinal type adenocarcinomas in the upper zone are to be considered as rectal carcinomas and staged as such. Tumors of the anal mucosa proper can be glandular, transitional or squamous and are all staged as anal cancers. Cancers in the perianal skin (squamous cell carcinoma, Bowen's disease, basal cell carcinoma, Paget's disease) are to be considered as skin cancers and staged as such.

Anal Squamous Cell Carcinoma

Burden

Anal cancers are uncommon and represent around 2% of large bowel malignancies. The incidence in the general population is estimated at between 0.8 and 1.4 cases per 100,000 people-years. Life time anal cancer risk is approximately 0.2%. The incidence has doubled in the last 25 years. The most frequent tumor of the anal canal is squamous cell carcinoma (SCC), the incidence of which is increasing significantly, notably in high risk groups such as males with male sexual partners, immunodeficient patients due to HIV or to immunosuppressive therapy and women with a history of HPV associated cervical squamous intra-epithelial lesions. The incidence in these high risk groups goes up to 35 cases per 100,000 people-years (males with male sexual partners) and even to more than 100 cases per 100,000 people-years (HIV infected patients).

Risk Factors

For the development of anal cancer multiple risk factors have been identified: HPV infection (notably with HPV-16), immunosuppression, long term use of steroid drugs, anal sexual intercourse, HIV infection and smoking. Anal squamous cell carcinoma develops from a premalignant precursor lesion, anal intraepithelial neoplasia (AIN).

Pathology

Anal intraepithelial neoplasia

The terminology of this condition has been somewhat confusing. The WHO classification of 2010 proposes the term anal squamous intraepithelial carcinoma (ASIN). The American Joint Committee on Cancer (AJCC) has recommended using low grade squamous in situ lesion (LSIL) and high grade squamous in situ lesion (HSIL), in analogy to the terminology used for in situ neoplastic lesions of the uterine cervix. Oncogenic HPV genotypes (16, 18, 31, 33) are found in 90% of AIN and play a major etiological role. Immunosuppressed patients (HIV infected patients and immunosuppressed organ transplant recipients) are at high risk for HPV infection and AIN development because of incapacity of the immune system to clear the HPV infection. Ultimately, the oncogenic HPV genome is integrated into the genome of premalignant cells and AIN and the lesion then progresses to squamous cell carcinoma. The HPV oncoprotein E7 binds to retinoblastoma protein (pRb), which makes the transcriptional factor E2F constitutionally active. This induces overexpression of CDKN2A (also known as p16), a cyclin-dependent kinase involved in regulation of the cell cycle. Expression of p16 is frequently used as surrogate marker for HPV infection.

AIN are characterized by squamous epithelium with varying degrees of architectural and cytonuclear atypia (Fig. 1). Architectural atypia includes loss of stratification. Keratinization may be found and superficial cells often show koilocytic changes. Cytonuclear atypia includes nuclear pleomorphism and hyperchromasia as well as increased mitotic activity, often even high up in the epithelium. AIN is graded as AIN-L (synonymous with LSIL) or AIN-H (synonymous with HSIL). When in doubt immunohistochemical staining for CDKN2A (p16) is recommended as AIN-H is almost invariably CDKN2A positive.

Bowenoid papulosis is a peculiar multifocal form of AIN. Clinicians recognize BP as multiple, small, well-demarcated, gray-brown, red, pink, or skin-colored papillomatous papules in the perianal area (but they also occur on the glans penis or foreskin in males and in the vulva in females). The disease almost always has a benign course in spite of the histopathologic features of high grade AIN. As in AIN, oncogenic HPV types (mostly HPV 16) are responsible for the development of this condition. Rare cases of Bowenoid papulosis have been reported to progress to squamous cell carcinoma. Given its similarity to AIN, it is primarily considered as a clinical entity and the diagnostic term is discouraged for histopathological classification.

Anal squamous cell carcinoma

Anal squamous cell carcinoma may present as a bleeding, painful mass. More rarely a change in bowel habits is the presenting symptom. On examination, a raised or even polypoid mass may be seen but some lesions are flat. Examination of inguinal lymph nodes is important, as these are the sites of potential metastases. Lymph node metastases are associated with decreased success of local treatment, risk of disease progression and poor prognosis.

Most anal carcinomas are SCC's. In the past several morphological subtypes were recognized (keratinizing, large cell non-keratinizing, small-cell non-keratinizing, basaloid). It has become clear, however, that subtypes have no real clinical significance

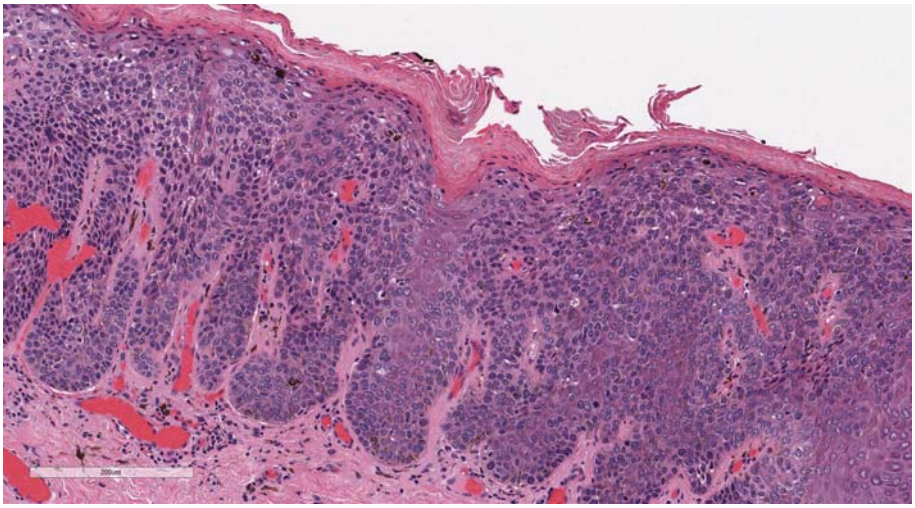

Fig. 1 High grade anal intraepithelial neoplasia (AIN 3). Note irregular epithelial architecture and cytonuclear atypia throughout the epithelium. Epithelial surface is slightly parakeratotic.

and moreover most anal SCC show several different morphotypes. As a result, presently all are diagnosed as SCC. The only variant with different characteristics is verrucous carcinoma, which will be discussed separately.

Histologically different patterns may be encountered. When fields of large eosinophilic cells are seen with distinct cell borders and variable nuclear atypia, associated with keratinization in the center of the field, this is recognized as keratinizing SCC. Depending on the degree of cytonuclear atypia the carcinoma can be graded as well, moderately or poorly differentiated (Fig. 2A). Poorly differentiated SCC may present more spindle shaped highly atypical cells. Rather often, anal SCC will contain circumscribed fields of smaller basophilic cells with relatively little cytoplasm and with palisading arrangement of the cell nuclei at the border of these fields (Fig. 2B). For this morphology the term basaloid has been introduced (Fig. 2C). For carcinomas in which this morphotype dominates the term basaloid carcinoma has been used (but also the misnomer "cloacogenic"). As the pure morphotype is rare and tumors with such morphology do not behave differently from those with conventional keratinizing morphology, they should be diagnosed as SCC with as further characterization "basaloid type." This has to be differentiated from peri-anal basal cell carcinoma which shows overlapping morphological characteristics. Histological differentiation is facilitated by immunohistochemical staining for CDKN2A (also known as p16) or SOX2, which are both almost invariably expressed in BSCC but not in basal cell carcinoma. CDKN2A is a marker for infection with HPV.

Molecular Pathology and Genetics

In more than 80% of anal SCC HPV DNA can be detected. In anogenital condylomata acuminata this is usually HPV-6 or -11 but these subtypes do not carry any risk for the development of cancer. Cancer risk is most frequently associated with infection with HPV-16 and -18. Anal SCC often shows loss of function p53. This can be caused by deletion of the TP53 locus on chromosome 17p or by a *TP53* point-mutation. More typically in anal SCC loss of p53 function is caused by sequestering of p53 by the HPV E6 protein. HPV E7 protein binds to pRb, the protein encoded by the Rb gene. The combination of p53 and pRb loss leads to inability of the cell to respond to DNA damage by cell cycle arrest and apoptosis. As a result, lesional cells continue to accumulate gene mutations, which contributes to progression of the lesion.

As anal SCC is rather chemotherapy resistant, several studies have addressed the question which mechanisms might be responsible. It was found that most anal SCC express multi-drug resistance-associated protein 1 (MRP1), which is associated with resistance to chemotherapy due to drug efflux. Furthermore, expression has been found of excision repair cross-complementing gene 1, which may confer resistance to platinum-based chemotherapy, and of thymidylate synthase, which is leads to fluoropyrimidine resistance. Several studies have explored signaling pathways involved in anal SCC in search for plausible targets for targeted therapy. In most anal SCC, immunohistochemistry has shown EGFR to be expressed, which suggests that anti-EGFR therapy might be considered even though this has proven a poor marker for response to anti-EGFR therapy. The limited experience with this approach to anal SCC treatment has provided encouraging results, however. Dysregulation of the PI3K/ATK/mTOR pathway has been identified in more than half of anal squamous cell carcinomas. AKT has been found activated in anal SCC and studies in mouse models suggest that mTOR is also involved. Both would provide a plausible therapy target. Finally, in a small subset of anal SCC HER2 amplification was found, which suggests that HER2-targeting agents might be considered as treatment.

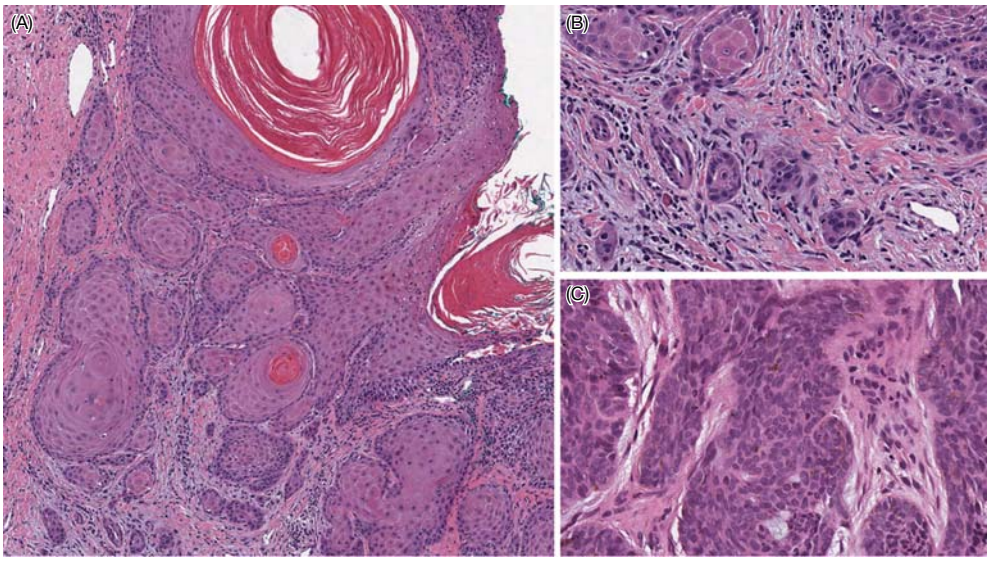

Fig. 2 Characteristic histology of squamous cell carcinoma and basaloid carcinoma. (A) Well differentiated squamous cell carcinoma. Note keratin "plugs" as evidence of squamous differentiation. (B) Higher magnification of invasion front of (A). Note small groups of cells invading into the surrounding mesenchymal stroma. (C) Area of basaloid differentiation, characterized by the presence of compact well circumscribed nests of cells with basophilic nuclei and little cytoplasm.

Microenvironment Including Immune Response

Few studies have explored the host response to anal SCC. In a recent study expression of PD-L1 was found in about half of a cohort of anal SCC, independent from HIV status. This suggests that checkpoint blocking immunotherapy might be considered, even in HIV positive patients. First results with such treatment are encouraging.

Staging and Grading

T-stage is determined mostly by size, 5 cm being the threshold between T stages 2 and 3. In T-stage 4 the tumor has invaded adjacent organs. Lymph node status has major prognostic implications. Anal SCC proper (location in the anal canal above the dentate line) metastasize to lymph nodes along the pelvic and ultimately femoral veins. Perianal squamous cell carcinoma first metastasizes to inguinal lymph nodes. Abundant lymph node metastases may inverse lymph flow, resulting in retrograde patterns of metastases also involving inguinal lymph nodes in cases of anal carcinoma. Tumor grade is conventional in well, moderately well and poorly differentiated. Grading is not optimally reproducible and prognostic significance is limited.

Prognostic and Predictive Biomarkers

Tumor budding and the presence of tumor infiltrating lymphocytes has been found of prognostic significance. Positive HIV status tends to be associated with poor prognosis. Prognostic significance has been reported for expression of p53 and cyclinA.

Verrucous Carcinoma

Definition

Verrucous carcinoma is also known as giant condyloma acuminatum or Buschke–Löwenstein tumor. It is a highly differentiated squamous cell carcinoma with a verrucous architecture, cytologically bland and blunt, pushing margins. Verrucous carcinomas grow slowly and have a very low tendency to metastasize. However, they can be locally destructive of underlying and adjacent tissues. Transformation to a more malignant form of squamous cell carcinoma occurs in about half the cases when the lesion is incompletely resected, but over a prolonged period of time (about 5 years).

Burden

Verrucous carcinoma occurs at any age but most frequently between the age of 30 and 60 and slightly more frequently in males than in females.

Risk Factors

Epidemiological studies have associated sexual promiscuity, poor personal hygiene, immune deficiency associated with HIV infection or immunosuppressive treatment, prolonged steroid use, diabetes and alcohol abuse with an increased risk for developing verrucous carcinoma. The disease is caused by HPV infection, mostly types 6 and 11.

Pathology

Verrucous carcinomas are large, slowly growing, exophytic cauliflower-like lesions in the anus or perianal region (Fig. 3). Histology shows acanthosis and papillomatosis but bland cytological characteristics. The epithelium shows orderly maturation and mostly only mild dysplasia. Mitotic activity is confined to the basal layer of the epithelium (Fig. 3, inset). Characteristically, invasion is pushing and blunt, and vascular or perineural invasion are absent. The lesions are low grade by definition. When a usual squamous cell carcinoma has developed, this is graded separately. Verrucous carcinoma does not metastasize unless usual squamous cell carcinoma has developed.

Staging

Verrucous carcinoma is staged as anal squamous cell carcinoma.

Extramammary Paget's Disease

Definition

Extramammary Paget's disease (EMPD) is an intraepidermal adenocarcinoma occurring in areas rich in apocrine glands. In most cases the lesion is entirely intra-epidermal but occasionally extension into the underlying dermis is seen. Perianal Paget's disease

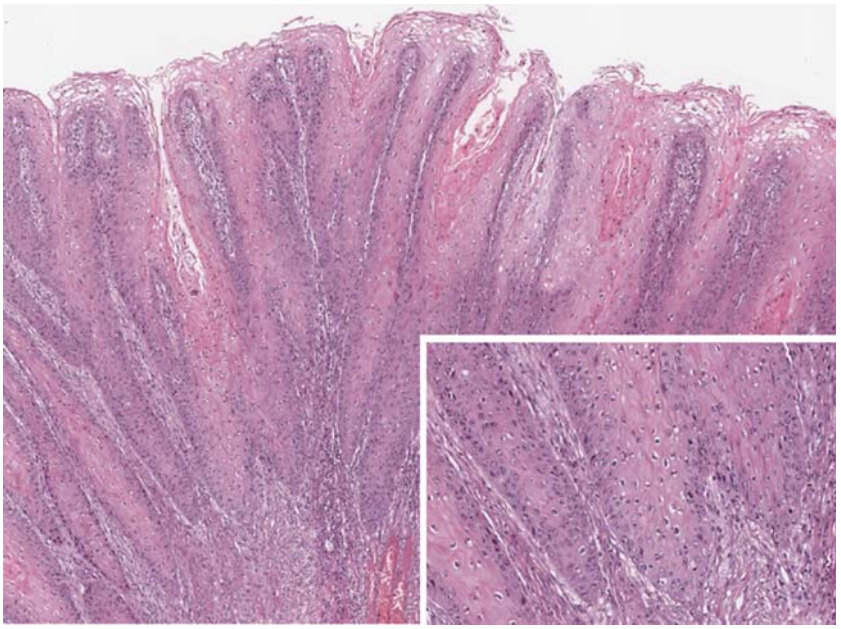

Fig. 3 Histology of a verrucous carcinoma. Insert: high magnification of the basal layers. Note bland nuclear morphology and lack of invasive growth.

is called primary when it is not associated with an underlying anal or rectal adenocarcinoma. Secondary Paget-like extension can occur in cases of distal rectal or anal adenocarcinomas.

Burden

EMPD generally occurs between the ages of 50 and 80 years, most frequently in Caucasians and more in females than in males (female/male ratio 1.4:1). EMPD occurs in the (*peri*)anal region but also in the vulva, axillae, on the penis or scrotum, on eyelids, around the umbilicus and in groins.

Risk Factors

The pathogenesis of EMPD is controversial. Most likely it develops from neoplastic changes in apocrine and eccrine skin adnexa, but often such changes are not found. Alternatively, EMPD might develop from pluripotent squamous epithelial stem cells within the epidermis, or so-called Toker cells, clear cells which are found in areolar or vulvar epidermis.

Pathology

EMPD can be primary or secondary. EMPD (or intraepidermal EMPD) is primary when neoplastic cells are found exclusively in the epidermis. The cells, however, have the capacity to become invasive into the dermis, gain access to lymph vessels and metastasize to lymph nodes and distant organs. EMPD is called secondary, when neoplastic cells have spread into the anal mucosa from an adenocarcinoma in an underlying gland or from a primary cancer in the genitourinary or gastrointestinal tract. EMPD cells have characteristic morphological features: they are large with abundant pale cytoplasm and vesicular pleomorphic nuclei. Infiltration is typically by single cells or small cell clusters (Fig. 4). In case of an underlying adenocarcinoma, deeper layers of the lesion may show glandular structures. The differential diagnosis with anal melanoma, underlying visceral carcinoma or squamous cell carcinoma in situ can be difficult. In such cases immunohistochemical markers are useful. Cells in primary EMPD often express cytokeratin 7 but not cytokeratin 20. They tend to be GCDFP15 positive but CDX2 negative. In contrast, secondary EMPD is often cytokeratin 7 negative but cytokeratin 20 positive while GCDFP15 negative. They also express CDX2.

Anal Melanoma

Definition

Primary anorectal melanoma is very rare; metastasis of a primary melanoma elsewhere to the digestive tract is much more common. The diagnosis is made by exclusion. The anus is the most common site in the digestive tract and most arise at or close to the dentate line.

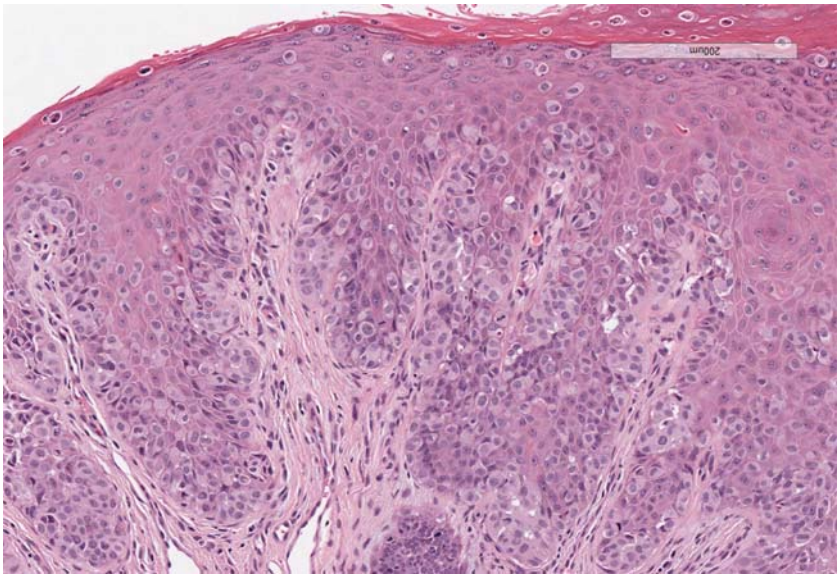

Fig. 4 Extramammary Paget's disease. Note the presence of individual cells and cell nests with slightly paler cytoplasm, mounting almost up to the surface in a slightly parakeratotic squamous epithelium.

Burden

Anorectal malignant melanoma accounts for 1% to 3% of all anal tumors and 0.3% of all melanoma. Most occur in the 5th to 6th decade in Caucasian patients with an equal frequency in men and women. After cutaneous and ocular melanoma, anorectal melanoma is the third most common melanoma location.

Risk Factors

Etiology and predisposing conditions are unknown.

Pathology

Anal melanoma is most commonly found at or close to the dentate line. Less than half of the tumors is pigmented. When small, anal melanoma presents as sessile papules. Most cases, however, are diagnosed at an advanced stage and then appear as bulky masses deeply infiltrating in underlying tissues.

Microscopically anal melanoma is composed of sheets and clusters of cells with large pleomorphic nuclei (Fig. 5) with prominent nucleoli and occasionally nuclear pseudo-inclusions. Most often the tumor cells appear epithelioid, but spindle cells also

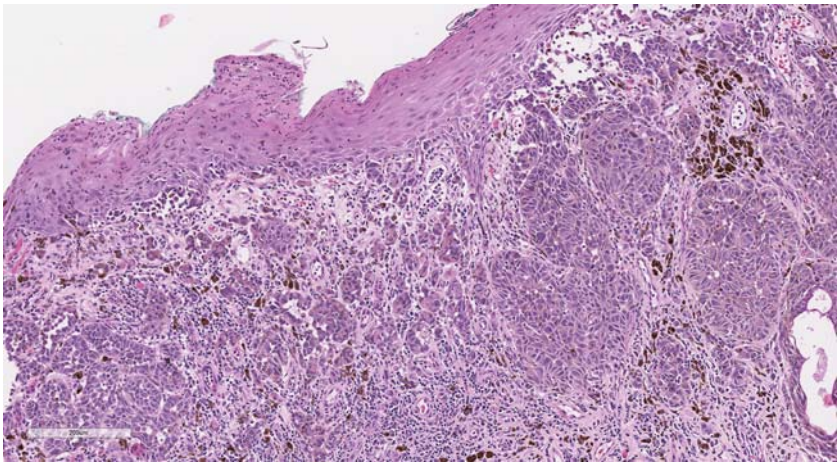

Fig. 5 Anal melanoma. Nests of pleomorphic largely amelanotic tumor cells diffusely proliferate in the subepithelial stroma and focally invade the squamous epithelial mucosa. The pigmented cells are melanin laden macrophages.

occur. Often pagetoid spread of tumor cells in the overlying epithelium is noted. Wide surgical resection is necessary as anal melanoma tends to infiltrate adjacent structure profusely. Regional lymph node metastases (including to inguinal lymph nodes) are frequent.

Amelanotic melanoma can be difficult to differentiate from gastro-intestinal stromal tumor (GIST). Both tumors express c-Kit and immunohistochemical staining for CD117 may lead to confusion.

Molecular Pathology and Genetics

Melanomas often harbor *KIT* or *BRAF* mutations and respond to tyrosine kinase inhibitors such as imatinib or BRAF inhibitors such as vemurafenib.

Animal Models of Cancer: What We Can Learn From Mice

Giustina Ferone, Paul Krimpenfort, and Anton Berns, Oncode Institute, Division of Molecular Genetics, The Netherlands Cancer Institute, Amsterdam, The Netherlands

Glossary

Allograft Transplantation of organ or tissues from one individual to another of the same species with a different genotype. For example, transplantation of mouse cell lines in recipient mice.

Cre/LoxP system Cre/LoxP system used to spatiotemporal control the activation of gene modifications by implementing enzymes (Cre recombinases) able to mediate recombination of DNA sequences flanked by Loxp sites, previously introduced in the germline of a desired organism.

Engraftment Successful incorporation of transplanted material into the body of the recipient organism.

Immunosurveillance A process by which the immune system of immunocompetent individuals is able to initially detects and suppress neoplastic cells.

Translational oncology A process by which basic knowledge of oncological processes is used to achieve clinically relevant advancements.

Transposons A DNA sequence able to change its position in the genome. Therefore, transposable elements can create gene modifications by their insertion in or near genes.

Tumor microenvironment Environment created by the interaction between tumoral cells and their niche composed of immune cells, stromal cells, and normal cells.

Xenograft Transplantation of organ or tissues from one individual to another of different species. For example, transplantation of human cell lines or tumor material in recipient mice.

Introduction: The Mouse as Experimental Model

A range of animal models are being exploited to experimentally address fundamental biological processes and the choice of which species is most suitable depends on the type of biological question. For instance, the genetics of pattern formation is studied primarily in Drosophila, neural system development in *C. elegans* and physiology in rats whereas experiments addressing complex cognitive function are performed in monkeys. The mouse serves as the most preferred species for studying mammalian development, and (human) diseases with emphasis on genetic diseases that are either inherited or somatically acquired as is almost always the case for cancer. The mouse has several features making it an ideal experimental model: it is a relatively cheap and very efficient breeding mammal with large litters and short gestation time; its (embryonal) development, physiology and metabolism shares many similarities with humans. Initially, in the prerecombinant DNA era, cancer modeling "in vivo" involved the exposure of mice and other rodents to cancer-causing agents such as chemical compounds, radiation and pathogens such as viruses. On this basis, mouse models have been established for many tumor types. This approach has been taken to test the carcinogenic nature of all kinds of environmental agents. With the advent of sophisticated gene modification technologies, the use of genetically engineered mouse models (GEMMs) started to increasingly dominate the cancer modeling arena permitting the fundamental study of causality at the molecular level. An enormous body of knowledge on cancer related genes has been acquired from studies using GEMMs and this expertise is now employed for building accurate models of human cancers to study the onset and progression of cancer in vivo and for the preclinical evaluation of therapeutic intervention protocols.

We provide here a comprehensive yet selective description of the various preclinical mouse models, outlining their suitability for possible applications and their drawbacks.

Modeling Cancer in the Mouse

Both in vitro cell line testing and mouse modeling are being used to facilitate the process of anticancer drug discovery. Without doubt, in vivo tumor models constitute the best tool when it comes to comprehensively mimic the genetics, the morphology, and ultimately the intimate crosstalk between cancer cells and their local and systemic environment including immune cell infiltrations. However, they have a range of drawbacks as well and the different systems have their own specific advantages and disadvantages (Table 1). Cell line tests in vitro and mouse models are complementary and both needed, depending on the question to be answered. That being said, in this article we will focus on mouse models. Currently, there are different mouse

Table 1 Characteristics of cancer-related mouse models

	External agent induced models	*Cell transplantation models*	*PDX*	*GEMMs*	*Transplanted organoids models*
Pros	• De novo tumor development • Multistep process of tumorigenesis • Immunocompetent mice • Can be combined with GEMMs	• Low cost and synchronous tumor growth • Rapid preclinical evaluation of drug candidates • Easy monitoring	• Bypass the potential artifacts of in vitro cultures • Orthotopic PDX models more predictive of human therapeutic response • Extensively characterized tumor collections • Coclinical trials to guide treatment decisions	• De novo tumor development • Multistep process of tumorigenesis • Genetic lesions can be locally and temporally controlled • Synchronous tumor growth • Immunocompetent mice	• Rapid preclinical evaluation of drug candidates • Reproducible tumor growth • Multistep process of tumorigenesis • Can be made for almost every tumor type • Synchronous tumor growth • Immunocompetent host (if from mouse)
Cons	• Not all forms of cancer are recapitulated • Latency and penetrance not homogeneous in the cohort	• Mutation load of most established mouse cell lines is limited • Immune compromised host for human cell lines • Risk of genetic and phenotypic drift and clonal selection during vitro culturing	• Severely immune compromised recipient • Variable engraftment rates • Undergo selective pressure, diverging from the primary tumor after multiple passages • Logistics • High costs	• Time consuming strategies for stem cells manipulation • Time consuming backcrossing to the desired background • High costs	• Immune compromised host for human organoids • Culture reagents expensive • Heterogeneity might be lost.

model categories that are being used in different areas of cancer research (Fig. 1). We conveniently divide them in the following five categories:

1. External agent-induced tumor models.
2. Cell line-derived mouse cancer models (allograft, xenograft).
3. Patient-derived xenografts (PDX).
4. Genetically engineered mouse models (GEMMs).
5. Transplantable organoids models.

External Agent-Induced Models

Cancer is a genetic disease. However, the contribution of inherited genetic lesions to the development of the majority of cancers is relatively modest and most cancer-causing mutations are somatically acquired through spontaneous events or environmental exposure. Carcinogen exposure has been linked to higher risk of developing cancer already for over 200 years when the incidence of nasal polyps was found higher in users of sniff and scrotal cancer in chimney sweepers exposed to polycyclic aromatic hydrocarbons (PAHs). Reducing the exposure to PAHs diminished the cancer risk. Other noteworthy examples are the association of lung cancer to tobacco consumption, bladder cancer to exposure to aromatic amines and mesothelioma to asbestos. Therefore, cancer is for a substantial part an environmental disease connected to the exposure to compounds that can induce DNA mutations.

For this reason, external agent-induced mouse cancer models are valuable for mimicking some human tumors, particularly those that are caused by environmental exposure. Several distinct carcinogens can be used to induce tumors through a defined multistep process. Pioneer studies have been carried out by locally applying ultraviolet light to develop skin tumors such as squamous cell carcinoma. Another well-established protocol encompasses the combination of the carcinogen 7,12-dimethylbenz[*a*]anthracene (DMBA), also known as the initiator, and 12-O-tetradecaboylphorbol-13-acetate (TPA), known as the promoter for causing papillomas which may evolve into squamous cell carcinoma (Fig. 1A). This treatment recapitulates the multistep process of tumorigenesis, and the topical application of the carcinogen followed by the promoter enables the formation of local tumors which can be easily monitored. There are other efficient procedures not only to induce skin tumors, but also breast (by a combination of progesterone receptor stimulation and DMBA) and colon cancer (combining the proinflammatory agent dextran sodium sulfate, DSS, and the DNA damaging agent azoxymethane, AOM), as well as lung cancer (urethane). Unlike skin tumors, the other tumor types are more difficult to monitor and require micro-CT or ultrasound imaging.

Since 1970, these models have been used by the US National Cancer Institute to test the carcinogenic potential of many compounds in the so-called Carcinogenesis Bioassay Program, this in order to assess safe exposure levels. Mouse models of chemical carcinogenesis are currently used in experimental cancer research, as well as translational research in particular for chemoprevention or early detection of cancer.

A number of inbred mouse strains spontaneously develop cancer at high incidence or following environmental exposure. They have been used to study the properties of spontaneous cancers, to identify cancer genes and to assess the effects of carcinogens and drugs. However, these models only develop a limited subset of tumors, show variable penetrance and latency, and do not accurately reflect the common types of human cancers.

More recently, chemical carcinogens have been combined with GEMMs which allow study of the complex interaction between genotype and environmental exposure to cancer development. This approach can yield new insights in areas of cancer research that have been gaining more attention over the last 10 years such as the epigenetic basis of cancer, cancer prevention, the systems biology of cancer, and the effects of inflammation and the immune system on cancer development (Table 2).

Cell Line-Derived Mouse Models

From 1950 onwards, researchers have used human cancer cell lines. In spite of their limitation in mimicking the complexity of human tumors, they represent a very useful tool for biochemical analysis and a wide variety of screening approaches. Evidently, cell lines are more convenient to define the critical drivers of transformation and evaluate the therapeutic efficacy of candidate anticancer agents (e.g., EGFR inhibitors). A logical next step is to assess to what extent the in vitro behavior of tumor cells has its corollary in vivo.

Cell line transplantation models exploit in vitro established tumor cell lines. Low cost, and synchronous tumor growth make cell lines attractive for the rapid identification and validation of cancer-related genes and preclinical evaluation of drug candidates. Consequently, cell line transplantation models serve as the work horse in both basic and translational oncology. Eighty-two percentage of articles published in 2016 that include the use of mouse cancer models are based on cell line transplantation according to Gengenbacher and colleagues in a recent analysis published in Nature Reviews in 2017.

Transplantable cell lines can be established from mouse (allograft) or human (xenograft) tumors. Xenograft studies have to be performed in immunodeficient mouse strains, such as athymic nude mice, severe combined immunodeficiency (SCID), non-obese diabetic (NOD)-SCID, and recombination-activating gene 2 (*R*ag2)-common-gamma chain knockout mice and combinations thereof. The more severely immunocompromised the host, the higher the probability that human tumor cells will efficiently engraft.

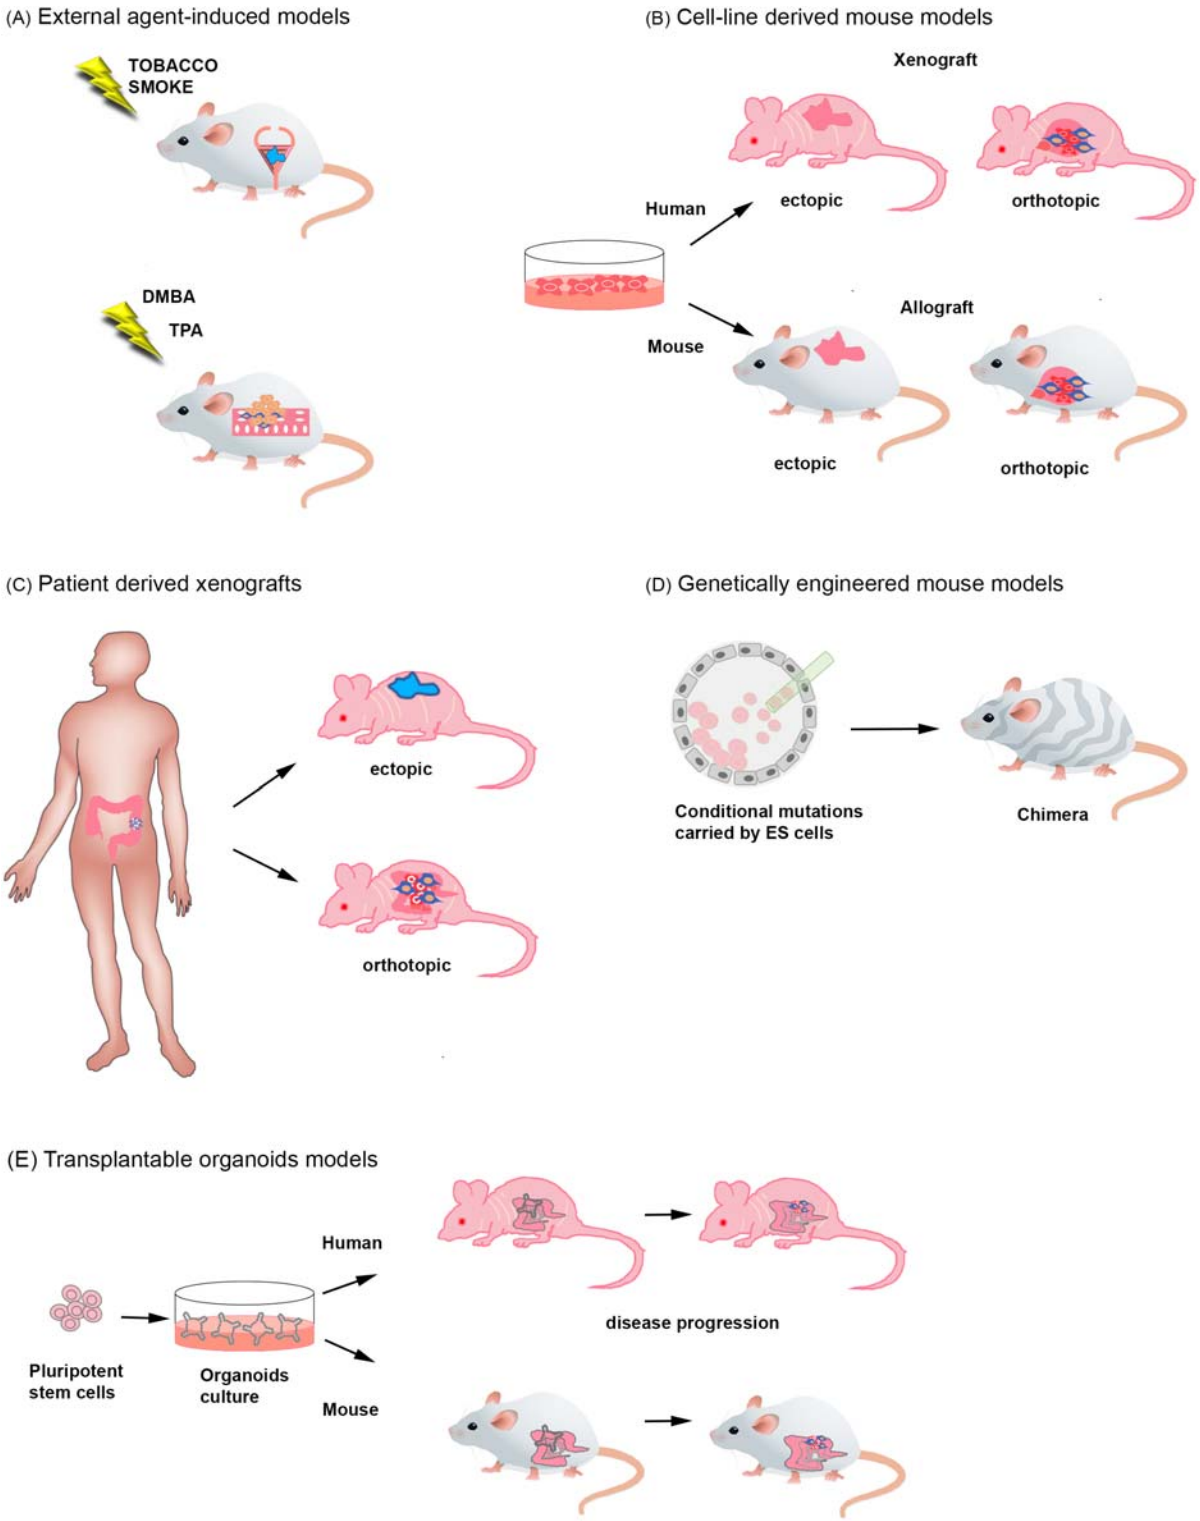

Fig. 1 Categories of cancer-related mouse models. (A) Cancer can be induced in mice by exposure to external agents such as carcinogens contained in tobacco smoke or DMBA/TPA which can cause bladder and skin tumors respectively. (B) Cell lines of human origin (xenograft) can be transplanted either ectopically (different site of original tumor) or orthotopically (same site of original tumor) into immunocompromised mice. Mouse cell lines (allograft) can be transplanted into immunocompetent mice either ectopically or orthotopically. (C) Patient derived xenografts are directly transplanted into recipient immunocompromised mice either ectopically or orthotopically, without undergoing in vitro culturing. (D) Genetical engineered mouse models are generated by in vitro modification of embryonic stem (ES) cells that are subsequently injected into the blastocyst of recipient mice to generate chimeric mice. If the mutant ES cells contribute to the germline of chimeric mice, the genetic modification will be stably transmitted to the progeny. (E) Three-dimensional organoids of either human or mouse origin can be established in vitro by culturing pluripotent stem cells or tumor initiating cells. Human organoids can only be propagated into immunocompromised mice (either ectopically or orthotopically), whereas mouse organoids can also be transplanted into immunocompetent hosts. In both cases it is possible to follow the multistep process of tumorigenesis, from the formation of initial lesions, to disease progression (metastasis).

Table 2 The utility of mouse models on different areas of cancer research

	External agent induced models	*Cell transplantation models*	*PDX*	*GEMMs*	*Transplanted organoids models*
Prevention	• Testing agents that reduce DNA damage • Testing inhibitory strategies of tumor outgrowth	• Testing inhibitors of colonization (e.g., upon IV injection)	• Not suitable	• Testing inhibitory strategies of tumor outgrowth	• Testing inhibitors of colonization
Drug development	• Not suitable	• For validation	• Limited combinations (coclinical trials, Avatar)	• For validation	• Limited combination (coclinical, Avatar)
Metastasis	• Primary tumor too difficult to resect due to multifocal growth • Latency too long for spontaneous metastasis • Asynchronous formation in multiple organs • Few models develop spontaneous metastasis • No certain correlation genotype-phenotype	• Primary tumor is easy to remove because implanted in one site • Orthotopic models have a higher incidence of metastasis • Lung and liver metastasis over-represented in subcutaneous or tail vein injection tumor models • Highly metastatic variant can be selected	• Can be directly derived from patient metastasis • If not directly derived from metastasis, primary tumor is easy to remove because implanted in one site • Orthotopic models have a higher incidence of metastasis • In ectopic models, metastatic spread is affected by the way of injection • No possible to study interaction with Immune system unless using humanized mice	• Primary tumor too difficult to resect due to multifocal growth • Latency too long for spontaneous metastasis • Asynchronous formation in multiple organs • Few models develop spontaneous metastasis	• Suitable for some tumor types

Mouse or human cell lines can be inoculated ectopically (in a tissue different from the original primary tumor site), orthotopically (the cognate location of the original tumor), or systemically (via intravenous injection) to facilitate colonization of multiple sites. Orthotopic models are best suited to mimic the interaction of tumor cells with their natural microenvironment (Fig. 1B).

Mouse allograft may be superior to human xenograft models because of species compatibility and option to use syngeneic mice with an intact immune system allowing studies of the in vivo interaction between tumor cells and the immune system. However, the collection of mouse cell lines is relatively modest compared to the panel of human cell lines. Many of these cell lines were established from tumors induced by chemical mutagenesis.

Fortunately, the number of cell lines derived from tumors induced in GEMMs is steadily expanding. In contrast to many of the human tumor cell lines, they harbor relatively few mutations. Since immunogenicity appears to correlate with mutational load these cell lines are less suitable for immunotherapeutic studies. However, this can be overcome by equipping these cell lines with defined antigens that are recognized as foreign by the immune system.

Human xenograft cell lines might be more predictive of response to therapeutic compounds specifically targeting tumor cells. Although cost-effective and convenient to propagate and utilize in xenograft experiments, these long-term propagated cell lines suffer from the way they have been derived. The long-term culturing of cells often results in the selection of clones that have a high proliferation rate and are adapted to artificial culture conditions. This selection often profoundly affects their phenotypic characteristics, causes further genetic drift and skews their response to many anticancer agents, one of the reasons why cell lines and allo- or xenograft models are not very reliable predictors for drug responses in humans.

To overcome this limitation, researchers are increasingly switching to organoid models that can be propagated more stably in vitro under specific culture condition or to PDX models. In the latter case, the tumor is excised from the patient and immediately implanted into a recipient mouse. Thereby, the artificial culturing step and in vitro selection is eliminated (see following section). A further refinement constitutes humanized mouse models that are engineered such that (parts of) a human immune system can be cografted in the mouse and its interaction with the xenografted tumor assessed.

Patient-Derived Xenografts

Patient-derived xenografts (PDXs) are obtained by transplantation of human tumor material directly into recipient immune-deficient mice (Fig. 1C). Hence, compared to cell line-derived mouse models, they bypass the potential artifacts of in vitro culture.

In order to establish a PDX model, efficient engraftment of primary tumor tissues is needed. This requires an even more severely immunocompromised recipient than used for most cell line transplantation studies. NOD-SCID mice with IL-2Rγ mutations (NSG or NOG mice) have enhanced immunodeficiency and permit engraftment of most human cancers.

Once they have given rise to a sizable tumor, tumor cells or tumor fragments are transplanted into secondary recipients for further expansion. The expanded tumors can then be harvested and cryopreserved or transplanted into tertiary recipients for specific studies. Tumor transplantation routes are similar as described above with orthotopic implantation usually being the most challenging. However, the advantage of the latter is that the natural local interaction of the implanted tumor with its microenvironment is preserved. Therefore, orthotopic PDX models are believed to be more predictive of human response to therapeutic intervention.

Currently, there are many collections of PDXs covering a range of human tumor types. They are often well characterized in terms of genomic, transcriptomic, and proteomic features, metastatic behavior, treatment response to a variety of standard treatments and experimental therapeutics.

Several studies have shown that PDXs largely retain the biological characteristics, the genetic mutations, the gene expression profile, the histopathology, and the therapeutic response of the original tumor. Remarkable overlap between PDXs and patients' response to anticancer drugs has been shown in, for example, in colorectal and pancreatic adenocarcinoma PDXs models, whose response to cetuximab and gemcitabine, respectively, closely resembled those of the corresponding patients enrolled in clinical trials.

This has led to an increased application of PDXs in personalized medicine, where so called "Avatar PDX models" are employed in coclinical trials to guide treatment decisions for patients from which they were derived.

Despite these advantages of PDX models, sometimes poor engraftment rates, slow growth, and high costs as well as logistic difficulties have limited their application as recorded over 2016, at least in academia. According to Gengenbacher and colleagues, PDX models were employed in only 7% of cancer-related studies in 2016.

In addition, a recent study argues against the common belief that PDXs model are better than cell-line transplantation models in terms of genomic stability. According to this study PDXs models are exposed to very different selection pressures as compared to the primary tumors in the donor patient: some copy number alterations which are barely detectable in human tumors were found to be selected for whereas prominent lesions were irreversibly lost. Moreover, PDX models share a number of drawbacks with human cell line-derived models. They cannot be xenografted into immunocompetent mice and PDXs as such are therefore not suitable to study the role of the immune system in immunosurveillance which is believed a critical component of tumor–host interactions.

Oncoimmunology research generally has been performed in mouse models lacking human cells, defining an area of cancer research where the use of human material was limited. However, the recent development of Humanized PDX models offers new inroads for studying tumor–host interactions.

Humanized PDXs are based on the coengraftment of patient tumor with hematopoietic stem cells (HPSC) from the same patient. Successful coengraftment depends on the mouse strain used and the isolation of HPSC (usually CD34 expressing cells). Mouse strains which better support the engraftment of the human immune system are NSG and NOG mice. These mice strains

can be further optimized to support growth of human innate immune effector cells through the replacement of four endogenous mouse cytokines, important for innate immune cell development with their human counterparts (e.g., interleukin-3 (IL-3), granulocyte–macrophage colony-stimulating factor (GM-CSF), M-CSF and thrombopoietin). Variations on this theme constitutes the cografting of tumor cells and human B or T cells tuned to recognize specific antigens or epitopes expressed or presented by the tumor cells.

GEMMs as a Cancer Model

Genetic modification technologies

In the 1970s of last century recombinant DNA technology caused a revolution in biological science. This made it possible to molecularly characterize the genetic events underlying the development of cancer both in humans and in (experimental) animals. For example, the role of viruses involved in the onset of cancers in different species such as the mouse and chicken, could now be studied at the genetic level and a substantial range of oncogenes were identified through this route. Moreover, human oncogenes were uncovered by the molecular analysis of genetic events such as translocations in hematopoietic malignancies. In all these cases solid validation of the oncogenic capacity of these genes required their introduction and expression in an in vivo system, that is, a transgenic animal, preferably a mammal. To achieve this, the initial approach was to genetically manipulate embryos in an early as possible stage. The mouse had been widely used in embryological research for a long time and isolation, culture and handling of mouse preimplantation embryos and their subsequent transfer into fosters were already common practice. Therefore, the first attempts to genetically manipulate the mammalian genome were performed in the mouse. The first successful experiment introducing foreign DNA into all cells of a mouse was reported in 1971 even before recombinant DNA technology was available. In this experiment SV40 DNA isolated from viral suspensions was injected into the cavity of mouse blastocysts, which resulted in life-born pups carrying the SV40 DNA in their genome. A few years later retroviral infection of preimplantation murine embryos was described as an efficient method for the introduction of foreign genetic information into the genome of the mouse. However, the value of these approaches to analyze the biological significance of the transferred genetic information, for example, in validating the candidacy of identified oncogenes in vivo, was limited because the genes embedded in proviral genomes integrated in preimplantation stages were in most cases not expressed due to methylation triggered by their proviral backbone.

The most effective and relatively straightforward method to generate transgenic mice was reported in 1981 and was based on the direct injection of purified DNA molecules in the pronucleus of zygotes that were subsequently transferred into the oviduct of pseudopregnant fosters (**Fig. 2**A). Usually, multiple copies of the injected DNA are incorporated randomly in the host genome and transmitted to all daughter cells and consequently present in all cells of the developing animal. This method yielded very high success rates and remained for a long period the standard for the production of transgenic mice, although for some of the most-used laboratory mouse strains (e.g., C57Bl6) its efficiency was rather low. This was mainly due to limited responses to super-ovulation procedures and poor in vitro development of the injected zygotes. Furthermore, proper tissue specific expression of transgene constructs was often a matter of trial and error and the tissue-specific expression levels could vary substantially between independent transgenic mice depending on copy number and integration site. This variation can also be quite informative as it permits assessment of the expression level on the phenotype.

Overexpression of putative oncogenes has been observed in many human tumors and the oncogenicity of many of these has been validated in transgenic mice. Subsequently, such strains were shown to be instrumental in identifying new collaborating oncogenes in screening approaches using insertional mutagenesis with replication competent murine leukemia viruses. Also, the effects of the combinations of oncogenes could be easily studied in vivo by crossbreeding mice overexpressing these oncogenes.

Whereas transgenesis enables study of the effects of overexpression of individual genes in an intact animal, the normal function of genes cannot be properly addressed by this approach. For this, gene inactivation in a living animal is necessary. While the number of transgenic mouse strains did rapidly grow during the 1980s, at the same time researchers in embryology put quite some effort on the isolation of embryonic stem cells from the inner cell mass (ICM) of blastocysts and on the conditions to culture and manipulate these cells with the aim to retain their totipotency. An essential criterion for this is that ES cells introduced into developing preimplantation embryos contribute to the germ line of the resulting chimeric mouse (**Fig. 1**D and **2**B). These efforts finally resulted in robust procedures enabling the generation of ES cell clones carrying targeted modifications in defined endogenous genes. The basis of these procedures is homologous recombination of DNA fragments carrying a desired modification with the cognate gene of interest in ES cells resulting in the desired modification in the target gene. Homologous recombination in ES cells is very efficient and this ensures that targeted insertion is much more frequent than random insertion facilitating the identification of correctly modified ES cell clones. Initially, the application of these procedures focused on the simple inactivation of endogenous genes in ES cells, which were subsequently used to produce chimeric mice that transmitted the knockout gene to their offspring. In the area of cancer research knockout strains have been invaluable for the validation of tumor suppressor genes and for assessment of their normal functions.

Genetic modification via the ES cell route is much more labor-intense and time-consuming than transgenesis via pronuclear injection. However, since all the steps in the procedure including the check for the desired genetic alterations can be performed in vitro, only those ES cells that contain the desired genetic changes will be used to generate a mutant mouse strain and thus, the modifications in the ultimate animal are exactly known which is not the case in transgenic animals generated via pronuclear injection.

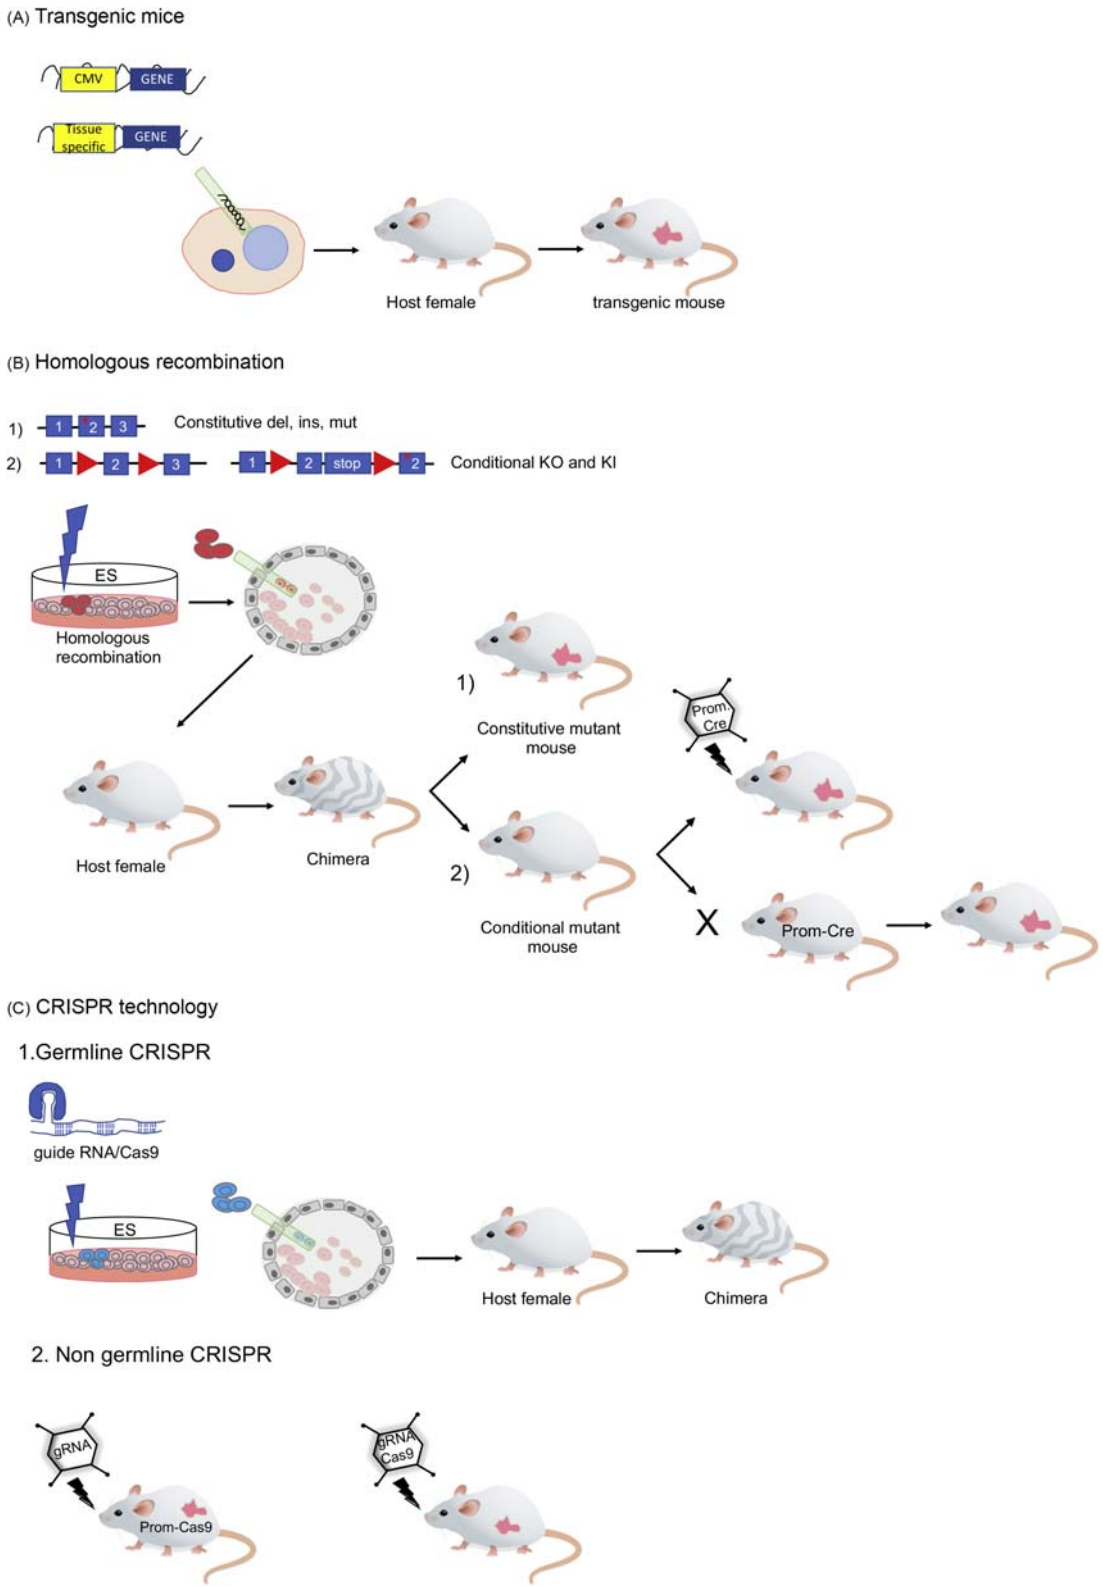

Fig. 2 Approaches to generate cancer mouse models by genetic modifications. (A) Transgenic mice are generated by introducing purified DNA (plasmid) carrying the transgene, into the male pronucleus of a fertilized egg. This approach can only be used to over-express gene product. The transgene can be constitutively expressed (CMV promoter) or can be driven by a tissue specific promoter. (B) Knock out of tumor suppressor genes or knock in of mutation in oncogenes can be achieved by specifically targeting the homologous genes in ES cells. Targeting vector carrying either constitutive deletion, insertion or mutations (1) or conditional modification (e.g., by using Cre/LoxP system) (2), flanked by arms of homology with the endogenous gene locus, to be electroporated into ES cells in order to modify the genome by homologous recombination. Mutant ES cell clones are subsequently injected into the blastocyst of pseudopregnant females. If the mutant ES cells contribute to the germline of the derived chimeric mice, the mutation will be stably transmitted to the progeny. If the mutation introduced is conditional, its activation can be can be spatiotemporally controlled by injection of recombinant viruses carrying Cre recombinase under specific promoters. The activation of the mutation can also be controlled by crossing the mouse model with other mice carrying Cre recombinase under the control of tissue specific promoters. In case the Cre is fused to a hormone binding domain additional temporal control is possible by administering the corresponding hormone.

In addition, the ES cell route allows the introduction of more complicated modifications in a single ES cell clone before generating animals from that specific clone. This is especially relevant when multiple manipulation steps are needed, for example, in case of creating conditional mutant genes that are required for the local and temporal induction of gene modifications (Fig. 2B).

Conditional gene modification, both activating and inactivating, constitutes a significant advance in the modeling of human cancer development in mice. Along with the control over the activation of gene mutations, a range of reporter systems were developed to visualize, either histochemically or via in vivo imaging, the cells in which the gene mutation had materialized (see below). This enabled the imaging of tumor progression in live animals and also permitted measuring the response to therapeutic intervention.

ES cell manipulation also enables transgenesis in a much more controlled fashion, for example, by targeting gene constructs to endogenous regulatory sequences such as promoters to impose authentic tissue-specific expression. These include oncogenes and constructs encoding reporters for lineage tracing and or recombinases instrumental for effectuating the conditional genetic mutations.

However, despite the enormous progress that has been made over the last decades, the ES cell technology also had its limitations. First, competent ES cells could be isolated only from a limited number of mouse strains (primarily 129) and these strains do not belong to the mouse strains most used in research. In many cases the chimeric mice generated from the modified ES cell clones were bred to the standard mouse strains. As a consequence, the experimental cohorts consisted of mice with variable genetic backgrounds, which can complicate interpretation of the results especially in the case of cancer research. To a large extent this problem can be solved by repeated backcrossing to the desired background, but this procedure is expensive and time consuming and even then, a subset of the genes contributed by the ES cell background will remain part of the backcross line due to linkage with the modified locus or loci. However, recent advances in the culture conditions have made it possible to isolate, culture and modify germline-competent ES cells from virtually any background. As a result, now experiments can be performed in ES cells from any desired strain. Moreover, ES cells can be derived from existing (compound) mouse (cancer) models in order to introduce additional modifications and analyze their effects using the original mouse model as reference. This procedure can tremendously speed up assessing the effects of additional genetic lesions in mice with the same background. As a short cut, using a series of differently modified ES cell clones with an identical genetic background, highly chimeric mice can be generated that directly serve as experimental cohorts which makes study of the effects of additional mutations even faster.

Recently, new revolutionizing genome-editing technologies have become available that are based on engineered nucleases or "gene scissors" such as zinc finger nucleases (ZFN), the transcription activator-like effector nucleases (TALEN) and the CRISPR guided Cas nucleases to precisely target endogenous sequences (Fig. 2C). They offer an accurate, inexpensive and efficient way of modifying genes in living cells including ES cells and even zygotes. The engineering includes inactivation, replacing or inserting distinct DNA fragment but also controlled activation and inactivation as well as introducing chromatin modifications. ZFNs and TALENs are chimeric nucleases composed of programmable, sequence-specific DNA-binding modules linked to a nonspecific DNA cleavage domain. CRISPR/Cas nuclease specificity is based on RNA-guided (gRNA) DNA endonucleases. From a practical standpoint, CRISPR/Cas is now by far the most preferred system as each ZFN or TALEN nuclease must be constructed de novo, whereas the specificity of the Cas9 nuclease component is determined by a small guide RNA that can be easily adapted. In addition, CRSPR/Cas is very flexible as it allows the modification of multiple endogenous loci at the same time. Importantly, it also can be applied somatically. Especially for modeling cancer in vivo this is of significant importance. The set-up of proper experimental cohorts can be simplified by applying CRSPR/Cas gene editing through viral or other gene transfer methods directly into somatic tissues of mice from any background strain (Fig. 2C).

Transplanted Organoid Models

First created at the Hubrecht Institute by Hans Clevers and his team in 2009, organoids represent 3D in vitro cultures of tissue stem cells that retain their identity by the use of specific growth media. In order to obtain these 3D cultures, they isolated fragments of the small intestine enriched for pluripotent stem cells and cultures those cells in matrigel supplemented with the growth factors also supplied by their natural niche. This enabled the cells to self-organize and recapitulate the original tissue organization resulting in miniguts in a dish. Organoids can be generated from both mice and humans and can be used to study developmental processes but also to understand the molecular basis of many diseases, including cancer (Fig. 1E).

In 2013, a biobank of genetically diverse human tumor organoids for use in preclinical drug testing has been established by Clever's team and his colleague Johannes Bos, in collaboration with scientists from the Hubrecht Institute, University Medical Center Utrecht, Netherlands Cancer Institute and Wellcome Trust Sanger Institute.

Organoid cultures are established from patients' tumor samples and used to test the response to single drugs or drug combinations. In this way also the underlying mechanisms of drug sensitivity or drug resistance can be explored.

Genome-editing tools like the CRISPR/Cas system, can be used in organoids to identify genes that have a causal role in the development of distinct tumors, that are critical for their survival, or instrumental in resistance to specific drug regimens. Organoid cultures appear relatively genetically stable over time.

Another major advantage is that organoids cultures can be made from almost any tumor, including the ones for which cell lines are lacking, such as prostate, and pancreas. Moreover, they can be used in xenograft studies. Neoplastic organoids have been orthotopically transplanted in mice, fully mimicking the tumorigenic process by forming early-grade neoplasms that progress to locally invasive and metastatic carcinomas.

Transplanted organoids can be used for genomic and proteomic profiling, and for revealing genes and pathways altered during tumor progression.

Recently, a protocol to swiftly create a mouse model of CRC by organoid transplantation into an immunocompetent mouse recipient has been described. The model recapitulates the entire adenoma–adenocarcinoma–metastasis axis in vivo and shows that Wnt pathway activation is crucial for tumor progression. The study also shows preliminary results how to generate a rapid transplantable model from patient-derived human CRC organoids.

Establishing organoids cultures and engrafting them is a routine once protocols for their generation and maintenance have been established. However, the costs of cell culture reagents is high and can therefore be a limiting factor.

The Utility of Mouse Models for Different Areas of Cancer Research

Metastasis

Although metastasis is the major cause of cancer-related deaths, accounting for 90% of cases, studies with preclinical models are still primarily focusing on primary tumor growth.

Metastatic dissemination appears more difficult to model. However, understanding in detail the factors driving metastatic spread and gaining insight into newly acquired vulnerabilities of metastasizing cells is important for designing better intervention strategies. Mouse models in which the whole sequence of events—acquiring migratory capacity, intravasation of tumor cells into the circulation, extravasation into the distal organ, and colonization of the foreign site—can be effectively studied are therefore receiving increasing attention.

GEMMs are the eligible cancer model when it comes to mimic the early stages of tumor initiation and progression, but only a subset gives rise to metastatic growth as observed in humans. The lifespan of GEMM tumor models is often limited by multifocal tumor development, and therefore provide less opportunity for lesions to give rise to metastases. Resection of multiple primary tumors in order to enable the growth of metastasis is in many cases not possible. Limiting the number of target cells in which the oncogenic lesions are induced, for example, by using low titer viral vector infections carrying Cre or Cas9 is one way to increase the probability of inducing fewer primary lesions and metastasis to occur. Nevertheless, there are several GEMMs that spontaneously develop metastasis and have been used as model system of metastasis; this is the case for a breast mouse model in which *Her2* is expressed under the control of Mouse Mammary Tumor Virus (MMTV) and a model of pancreatic islet carcinoma in which SV40 T antigen (Tag) is expressed under the control of the rat insulin promoter (RIP–Tag). These models develop metastasis to lung or other organs. The same holds for small cell lung cancer models that show metastasis to multiple organs.

In the case of pancreatic islet carcinoma, antiangiogenic therapy caused regression of the primary tumor but in parallel elicited progression to a higher malignancy state facilitating the growth of distant metastasis. Besides the relatively few GEMMs that spontaneously develop metastasis, other approaches involving non-autochthonous models have been proven suitable to dissect the process of metastasis. Both cell line- and tumor-xenotransplantation models have been successfully used for this. Despite the disadvantages of transplantation models, tumors can be grafted into a single site, making it relatively easy to surgically remove the primary tumors, allowing the monitoring of the metastatic growth of cells spread to distant sites.

In this regard, orthotopic transplantation models appear the better approach because they have a higher incidence of metastasis compared to ectopic models. Moreover, cells from the primary tumors then can follow their natural routes to spread to distant organs, better mimicking what likely happens in human. Subcutaneous or tail vein injection tumor models are still used but metastatic spread is strongly skewed by this way of inoculation leading to overrepresentation of metastatic growth in lung and liver. Metastatic models have been made more effective by selection of cell variants with a higher metastatic potential as compared to the parental cell lines they originated from. Genetic and/or expression profile differences between the variants and the parental lines then can point to the genes that facilitate metastasis.

Breast and melanoma cell lines either from human patients or GEMMs, are relatively simple to orthotopically transplant compared to cell lines from cancer types, such as lung or prostate. The metastatic process can be best monitored by introducing reporter constructs such as luciferase into the cells. Highly metastatic variants of melanoma cell lines have been derived from the WM-239 human melanoma through in vivo selection involving orthotopic grafting of primary tumor, followed by its resection and isolation of lung metastasis several months later. The resulting highly metastatic variant appeared able to cause metastasis in 4 weeks compared to 4–6 months for the parental cell line. The same approach has also been used to isolate highly metastatic variants of the MDA-MB-231 breast cancer cell line.

Considering mouse models currently available to study cancer, metastatic models using a combination of orthotopic tumor transplantation and surgical resection of the primary tumor, offer the best perspectives as they permit study of all phases of the metastatic process.

Drug Development

Next to their use in the study of tumor development and progression, mouse models play an important role in drug validation as they are "the" preclinical "in vivo" intermediate between "in vitro" testing and clinical trials.

Since 1995, prescreening of new agents was primarily performed by using three cell lines: MCF-7 breast cancer, NCI-H460 large-cell lung cancer and SF268 glioblastoma cancer. Only if a drug would inhibit the proliferation of at least one of these cell lines, it

would proceed to be tested on a panel of 60 cancer cell lines representative of 9 different cancer subtypes. This panel has been used to test 70,000 compounds, including a range of chemotherapeutic agents.

The advances in our insights into the molecular mechanisms driving tumor initiation and progression promoted a shift from random testing to more focused strategies targeting tumor drivers found to be activated in the tumor cells under study. This has resulted in remarkable clinical responses in tumors such as chronic myelogenous leukemia (using inhibitors of BCR-ABL), melanoma (using inhibitors of $BRAF^{V600E}$), and lung adenocarcinomas carrying mutations in EGFR (using EGFR inhibitors).

Nevertheless, long-term clinical remissions for investigational drugs remain rare. The average number of anticancer drugs approved by the US Food and Drug Administration (FDA) per year has declined since 1990s. There is clearly a divergence between R&D costs and the approval of new drugs. Many of the drugs fail during evaluation in clinical trials. An important reason behind this failure is the poor predictive value of standard in vivo preclinical models. As discussed above, xenotransplantation of human cell lines is the simplest procedure to perform drug screenings but not the most realistic one due to the fact that established cell lines are in general not robust predictors of response. Nevertheless, drug screenings using a collection of cell lines combined with xenograft models for a single type of cancer, adequately representing its diversity, is a rational and useful first approach. However, a follow up with more sophisticated testing in GEMMs can have substantial added value as it might bring out tumor features that have been lost in the cell culture adapted, often fast dividing cells used to identify the specific drug sensitivity whereas those "lost features" might be critical for its response to the drug in question.

The suitability of GEMM tumor models for drug screening will depend on a number of parameters: (1) mice should carry a corresponding set of mutations that drives the cognate human tumor and express these in the appropriate target cell; (2) The histopathology should be as similar as possible; (3) tumor development should preferentially proceed through the same, or similar, "preneoplastic" stages.

Even if all these criteria are met: a mouse model remains a model. In this regard PDX models are more suitable than GEMMs when it comes to examine therapeutic responses to drugs (see section "**Patient-Derived Xenografts**" for more details). Nevertheless, the use of GEMMs has increased exponentially in the last decade, thanks to new genome editing technologies (see section "**GEMMs as a Cancer Model**" for more details). Collectively, murine models are critical for drug development, but to the testing trajectory really useful a rational approach is required beginning with target discovery and drug response measurements which can be performed in in vitro, confirmed by genetic approaches in GEMMs, followed by toxicology and pharmacology studies conducted in simple cell-line transplantation models, progressing with PDXs for target validation, and establishing treatments regimen.

One of the advantages of mouse models is that the underlying mechanisms resulting in drug resistance of tumors can be more easily studied. One route to identify drug resistance related mechanisms using "in vivo" material takes advantage of the comparison of resistant tumors with the nonresistant primary tumors. This comparison, which might include WGS, expression and chromatin profiling, might reveal putative resistance genes that can be validated in the same model. Drug resistance mechanisms can also be tackled in GEMMs using the extensive amatory of genetic tools. Screening experiments with shRNA and CRISPR/Cas libraries on tumor cells treated with drugs targeting specific pathway have clearly shown the utility of this concept "in vitro". Screening strategies for drug resistance directly in "in vivo" models can be based on activation of transposon systems, shRNA or CRISPR/Cas9 libraries as used "in vitro". Screening experiments in vitro and in vivo have shown benefits of strategies based on drug combinations targeting multiple pathways or multiple targets in what is considered the "same" pathway, this all depending on the specific tumor subtype and resistance mechanisms that were identified. Also, the specific drug scheduling can be a critical parameter for efficacy. Rigorous "in vivo" validation entails next to the use of transplanted cell lines, tumors in GEMMs in which the cognate pathways are mutated, organoid-based tumors and/or PDXs. This knowledge can be subsequently used to design hopefully more effective clinical trials.

Prevention

Cancer prevention is not only intended as a series of actions taken in order to limit the exposure to environmental agents which have been shown to have a causal role in cancer (primary prevention) but also to limit cancer cell outgrowth or minimize the adverse consequences that result from exposure to tumor-inducing agents. This requires a precise understanding of the genetic and epigenetic factors that promote cancer, and how environmental components such as diet, hormones and drugs affect them (secondary prevention).

Mouse models are particularly suited to investigate aspects of cancer prevention that are difficult to study in humans, such as identifying factors or interventions that prevent the outgrowth of preneoplastic and early tumor lesions. Genetic context and environmental conditions can be precisely defined in mice, which is difficult to accomplish in humans. Mouse model suitable for prevention studies should meet a number of criteria:

1. Tumors should originate de novo in their natural microenvironment and in the context of an intact immune system, which applies to GEMMs, some nongermline GEMMs and carcinogen-induced models, but excludes most non-autochthonous models.
2. Tumor development should reproduce the stages of disease progression from preneoplastic to more malignant lesions; again, this criterion is only met by autochthonous models.
3. Genetic and/or environmental factors employed to cause the cancer should have relevance for the human cancers. For example, loss of function of *Pten* represents the driver genetic alteration of prostate cancer in both human and many GEMMs. Similarly, carcinogens from tobacco smoke are responsible for bladder cancer in both human and mouse models.

4. The histological and molecular features of mouse tumors should resemble their human counterparts; again, this has been recently demonstrated for bladder cancer. Additionally, cells-of-origin should be the same in human and mouse; tumor penetrance should be high in the cohort of mice and latency not excessively long.

There are successful studies performed with GEMMs and carcinogen induced models that have proven the value of cancer prevention models. Examples are experiments carried out in mouse models of colon cancer, in which loss of function mutations introduced in the APC gene either by chemical exposure or by gene manipulation, enabled investigation of chemopreventive agents, such as COX inhibitors. GEMMs can be instrumental for the identification of early detection biomarkers considering the easy access to body fluids and tumors from the earliest stages of cancer initiation to the latest stages of cancer progression. Indeed, putative biomarkers for early detection of ovarian, colon and lung cancer have been already identified by using GEMMs.

Ultimately, a combination of GEMMs, outbred strains and carcinogen induced models will be of great help in understanding the interaction between environmental exposure, the genetic background, and specific oncogenic lesions in the initiation and progression of cancer.

Distinct Cancer-Related Questions (Basic and Translational Medicine Related)/Applications

Identification of Cancer Genes and Their Contribution to Cancer Initiation and Progression

The developments of high-throughput genome sequencing and subsequent analyses using advanced bioinformatic tools have made it possible to profile entire cancer genomes and identify recurrent amplified or repressed gene loci in cancer. The often high complexity of human cancer genomes and the concomitant large number of genetic alterations can make it hard to distinguish "driver" from the "passenger" mutations. Even if recurrent in a subset of patients, a distinct genetic alteration might turn out to be only secondary to tumor formation or occur very late in the multistep process of tumorigenesis thereby contributing only to a limited extent to tumor development. Hence, targeting such alterations will unlikely result in a robust clinical response unless these mutations have created new vulnerabilities or represent drivers of convergent tumor evolution. Here, mouse models can swiftly provide answers (**Table 3**). They enable the validation of candidate cancer genes; they also allow the discovery of new genes and pathway involved in tumorigenesis. In this way the contribution of defined genetic lesions to the process of initiation and progression of human cancer can be assesses.

The "in vivo" identification of (new) driver mutations can be based on several strategies: (1) chemical mutagenesis (e.g., using DMBA) followed by deep sequencing of independent tumors enabling the identification of recurrent mutations indicative of their causality. (2) Infection with replication-competent retroviruses leading to enhanced expression of cancer promoting genes at the site of proviral integration. However, the use of retroviruses has been limited to a small number of tissues with the hematopoietic system and mammary tissue as the most pronounced examples. (3) Activation of transposons, for example, Piggy Bag and Sleeping Beauty, which integrate more or less randomly into the host genome. Transposons have been modified to enable both activation and inactivation of genes near or at the site of integration. As such the use of transposons can enable the identification of tumor driver genes by genome analysis similar to the retroviral tagging approach. To apply this "in vivo", mice need to be transgenically equipped with inducible transposon systems whereas for retroviral infection wildtype mice can be used. However, the transposon system can be spatiotemporally activated (e.g., by using Cre-ERT/LoxP and Dox systems), enabling identification of drivers in cancers arising in many different tissues. (4) Currently, genome wide CRISPR/Cas gene editing (see above) is being widely used "in vitro" in defined cancer cell lines to find genes involved in transformation, migration, metastatic capacity, drug response etc. In principle these screening strategies could also be applied to find new driver mutations "in vivo". However, since tumor development requires multiple modifications in the same cell, CRISPR/Cas screens using retroviral libraries will be challenging in a wildtype background since the likelihood of tagging multiple relevant genes in one cell is low. In a way CRISPR/Cas screens in wildtype mice might resemble chemical carcinogenesis except that it permits cell-type specific targeting which is impossible with carcinogens.

Table 3 The utility of mouse models on different cancer related applications

	External agent induced models	*Cell transplantation models*	*PDX*	*GEMMs*	*Transplanted organoids models*
Cancer gene identification	• Suitable	• Suitable	• Suitable	• Suitable	• Suitable if target is known
Allele variation	• Suitable	• Not suitable	• Not suitable	• Suitable	• Not suitable
Cell of origin and/or tumor propagating cell	• Not suitable	• Can be used to define tumor propagation capability of specific isolated cell populations	• Not suitable	• Lineage tracing experiments require previous genetic manipulation to introduce Cre/Lox sites	• Suitable for identifying tumor initiating cells
Immune therapy	• Suitable to test immunosurveillance	• Useful in syngeneic setting	• Not suitable unless humanized systems are applied	• Suitable if engineered with appropriate neoantigens	• Not suitable unless humanized systems are applied

Transposon systems are also attractive for identifying tumor progression events by including these "mutagens" in established tumor models. This can lead to accelerated primary tumor development, metastatic spread as well as drug resistance, the latter when inapplied a therapeutic intervention setting.

An attractive bioinformatic-oriented strategy to identify new drivers is based on the molecular comparison of murine cancers generated by combinations of gene modifications with their human counterparts in which the same genes are affected. This comparison includes deep sequencing analyses, expression profiling and the characterization of copy number variation and epigenetic landscape changes in syntenic regions. These comparisons have provided candidate genes that could be subsequently validated in the relevant mouse model (e.g., Nfib and p73 in SCLC).

Allele Variation: Predisposition

Most mouse tumor models have been generated, by whatever technology, in a single genetic background. After validation, subsequent studies of tumorigenesis are usually performed in the same mouse strain. However, it has been known for a long time that the genetic background can strongly influence tumor development. Taking advantage of the many available mouse strains (e.g., mice of the Collaborative Cross) it is possible to identify tumor susceptibility loci and the responsible gene(s). Subsequent cognate human cancers carrying the same somatic driver mutations can be analyzed for the presence of susceptibility conferring alleles of the same gene(s) (**Table 3**).

Cell of Origin and Tumor Propagating Cells

Although the combination of mutations is critical for the tumor phenotype, increasing evidence also points to the cell-of-origin as an important factor in determining tumor characteristics; moreover, the cell-of-origin and the resulting cancer initiating cell can play an important role not only in tumor initiation but also in tumor maintenance and metastasis. Since tumor initiating cell might also be more resistant to treatment their eradication by specific targeted therapies is crucial to avoid tumor relapse.

Cells in a tissue have very different capabilities to give rise to tumors. Some cells, even if targeted by a specific tumor-associated set of mutations will just be resistant to transformation. Moreover, tissue cell subpopulations capable to generate a tumor, will likely produce neoplasms with unique morphology, location, grade of differentiation and hence aggressiveness. Genetic lineage-tracing experiments concomitant with the conditional expression of oncogenes and/or the deletion of tumor suppressor genes in defined cell lineages of mouse models, have been instrumental in defining the cell-of-origin of different human tumors. To achieve the activation of genetic lesions in a subset of cells, Cre or other recombinases are targeted to the desired subset of cells by topical delivery of viral vectors equipped with cell-type-specific promoters driving a recombinase (or Cas9) or by activation of an inducible Cre/Cas9 inserted in a distinct genetic locus with defined expression characteristics (see section "Genetic modification technologies").

Before designing lineage-tracing experiments, it is important to know the hierarchy of stem and progenitor cells in a given tissue, their location and marker profile. Genetic lineage-tracing experiments conducted in wildtype mice carrying a conditional reporter gene (β-galactosidase or a GFP) whose expression can be activated in a particular cell lineage using the aforementioned tools, have greatly contributed to our understanding of the cellular hierarchy of normal tissues under physiological conditions.

Using cell-type specific (in)activation of oncogenes and tumor suppressor genes the cell-of-origin of tumors can be assessed. For example, neuroendocrine cells in lung are the most effective cell lineage to initiate SCLC upon *p53* and *Rb* deletion as shown by Sutherland et al. by using intratracheal delivery of cell-type restricted adenoviral vectors carrying Cre recombinase driven from different promoters, specific for different lung cell subpopulations. The same approach has been used to define the cell-of-origin of lung adenocarcinoma (LADC) and lung squamous cell carcinoma (LSCC). Interestingly, in $Sox2^{Col1A1\,+/-}$;$Pten^{fl/fl}$;$Cdkn2ab^{fl/fl}$ mice, LSCC could be initiated by the same set of genetic lesions in different subsets of lung cells, although with a different efficiency. Accordingly, tumor arising from different cells had different locations.

The tumor propagating cell might retain markers of the cell-of-origin not shared by the bulk of the tumor cells. Tumors can be collected from specific GEMMs or directly from cancer patients and the desired subsets of cells isolated using cell surface markers or fluorescence reporters by activated cell sorting (**Table 3**) . Once sorted, subsets of cells are transplanted into immunocompromised mice. If the cell fraction is able to cause tumor growth and recapitulates the original tumor morphology in serial transplantations, it is considered to harbor the tumor-initiating cell. The ultimate proof can be provided by showing that a single cell has this capacity (as shown for breast cancer and leukemia).

For example, only brain tumor cells positive for the CD133 cell surface marker, were capable of tumor initiation in a severely immunodeficient NOD-SCID mouse graft model. The tumor which was a phenocopy of the patient's tumor, could be serially transplanted, whereas injection of different dilutions of cells negative for CD133 did not cause tumor growth.

Similarly, cells isolated from LSCC of $Lkb1^{fl/fl}$;$Pten^{fl/fl}$ mice positive for $SCA1^{+}NGFR^{+}$ were enriched for tumor-propagating capacity and could be serially transplanted in orthotopic assays carried out in immunocompromised mice.

Immunotherapy (Tumor–Host Interaction; Microenvironment)

Escaping from immune surveillance is now considered as a critical feature for tumor development. Indeed, the immune system plays a role in detecting and eliminating tumor cells from the host. However, there are still many unanswered questions regarding the interaction between the innate and adaptive immune system and tumors arising in an immunocompetent host. Tumors more

likely develop when the innate and/or adaptive immune response is impaired or repressed. This hypothesis has been tested in a variety of mouse models that were deficient in one or more components of the innate or adaptive immune system. For example, the elimination of interferon (IFN)-γ gene resulted in an increased incidence and growth of spontaneous and chemically-induced tumors. However, immune cells can also support tumor growth.

Syngeneic allograft models are used the most in immune-oncology research (Table 3). The immune system can directly influence preclinical tumor monitoring that utilizes reporter genes such as GFP or Luciferase as the reporter proteins are can be recognized as foreign. To make mice tolerant to these possibly immunogenic proteins, "glowing head" mice have been used, in which low levels of GFP or Luciferase are locally expressed by using a transgene expressed in the anterior pituitary gland where these proteins cause immune tolerance because of their expression early in life. As compared to GEMMs, allografts have the advantage to be a simple low-cost model. Furthermore, tumor growth is largely synchronous permitting the investigator to easily follow immune responses over time. However, they often lack specific immunophenotypes such as chronic inflammation which is very often seen in human cancers. Moreover, they mostly arise in a site different from the original tumor (usually subcutaneously) which lacks the natural microenvironment of the original tumor. In spite of these limitations, transplantable models have been critical for three revolutionary discoveries of cancer immunotherapy: (1) the utility of Immune checkpoint blockers (ICBs) to enhance an immune response against tumor cells; (2) the contribution of immunogenic cell death (ICD) to most of the currently used anticancer chemotherapeutic agents (CT26 colon carcinomas respond much more efficiently to chemotherapy when grafted in BALB/c mice with an intact immune system).

Consequently, anticancer therapies using a combination of ICD inducers and ICBs are more effective.

For studying the natural interplay between tumor–host, carcinogen-induced tumor models are more realistic because they carry many mutations, are genetically more diverse and heterogeneous, and tumors arise at their natural site. Carcinogens-induced tumor models can also be used to assess the contribution of the immune system to conventional therapies. Unfortunately, such experiments are cumbersome because tumors take considerable time to establish and can be quite heterogeneous, making it difficult to interpret the results. GEMMs accurately reflect human tumors and are genetically defined but as is the case for carcinogens-induced tumor models, the tumor latency can also be quite long, and monitoring can be challenging dependent on the tumor site. Furthermore, they carry few new mutations. Therefore, these tumors will unlikely express any neoantigens the immune system might react to. It required additional genetic manipulations in order to express defined neoantigens in the tumor. Although much can be learned from autochthonous mouse models, at the same time there remain ample differences between mouse and human and therefore it is important to also aim for humanized models so that the features unique to the human immune system can be studied.

Summary/Prospective Vision

Mouse tumor models have come a long way. The capacity to genetically manipulate the genomes of the mouse have not only resulted in cancer models, it has also provided insight in the function of genes critical for development and maintenance of mammalian organism. Next to their significance for the overwhelming body of fundamental knowledge on cancer development mouse models have been essential for elucidating how the immune system works. With the currently exploding interest in its role in cancer this has not always been appreciated but is now probably their most relevant contribution for the cancer field. This has only been possible by transgenic and knockout studies in the mouse in which the function of genes involved in immune responses was assessed. Undoubtedly, mouse models will remain invaluable to further evaluate the many the modulators that influence immune responses. Mouse cancer models mimicking the cognate human tumors have been similarly instrumental for our understanding of the role of oncogenes and tumor suppressor genes and many other modulating factors that influence tumor development. With the current armature of genetic tools, one can easily generate a wide diversity of mouse models carrying multiple distinct lesions thus permitting to mimic human tumors very closely. Organoids, PDXs and Humanized mouse models will gain in importance and create the conditions in which these models become more predictive with regard to treatment responses. Moreover, the mouse is the system of choice to explore tumor susceptibility genes that only start to have sizable effects when combined with distinct somatic lesions that occur by accident or as a result of environmental exposures. Finally, mouse models in which we can monitor early lesions will be invaluable to develop early detection and rational primary and secondary prevention measures. Therefore, mouse models will be around for the foreseeable future and continue to make contributions to our knowledge that cannot be acquired otherwise.

Anoikis

Sharan Malagobadan and Noor Hasima Nagoor, University of Malaya, Kuala Lumpur, Malaysia

What Is Anoikis?

Anoikis is the name given to the induction of apoptosis in cells upon loss of attachment to the extracellular matrix (ECM) and neighboring cells. The relationship between cell adhesion and apoptosis was first elucidated and defined by Steven M. Frisch and Hunter Francis in 1994. In their finding, cell death upon detachment was observed in epithelial cell lines but not in fibroblasts. This phenomenon was then introduced as 'anoikis,' a term derived from the Greek words that mean homelessness. Anoikis plays a fundamental role in preventing inappropriate translocation and attachment of cells, which can lead to abnormal growth in an ectopic environment. Anoikis is largely regulated by interaction with the ECM and nearby cells, although some cellular stress events such as autophagy and hypoxia are also known to be involved in some circumstances.

An example of how anoikis is required for normal cellular function can be seen in the turnover of enterocytes. Enterocytes are epithelial cells lining the small intestine, responsible for the absorption of nutrients in the digestive system. These cells have a short life span of approximately 3–5 days, and they are constantly renewed from a pool of precursor cells, migrating towards the apex of villus in the small intestine and eventually dying. As such, enterocyte cell death has been demonstrated to take place through the induction of anoikis when they are detached from the ECM of the villus and lose signaling from the cell adhesion molecules (CAM).

ECM is a mesh of various molecules, such as proteoglycans and proteins, that serve as a scaffold to accommodate cell localization and attachment. The composition of ECM shows variation across tissue types, which determines their roles and cell type specificity for adhesion. Components of the ECM are known to be produced and excreted into the ECM by several types of cells, mainly fibroblasts. Examples of such components are collagen, fibronectin, hyaluronic acid, and laminin. Each of these molecules is capable of various functions, such as assisting cell attachment, ligating numerous receptors, and even storing growth factors within the ECM.

In addition to providing structural support, ECM also participates in wound healing through active remodeling of its structure, which is mediated by fibroblasts. Epithelial-to-mesenchymal transition (EMT) is also induced as a result, enabling repopulation of cells to replace the injured tissue. While this process is strictly regulated in normal cells, cancer cells often abuse the dynamic nature of ECM to induce EMT to gain a more aggressive phenotype during metastasis. As such, the preservation of normal functions and integrity of the ECM is essential in maintaining proper tissue homeostasis.

Aberrantly induced anoikis has been shown to be responsible for various diseases, such as aneurysm and chronic vascular diseases. Normally in these situations, it is not the properties of the cells themselves that causes anoikis, but rather the changes in the ECM, such as degradation or modification of ECM proteins by proteases. For example, plasmin mediated proteolysis of fibronectin in the ECM was observed to cause smooth cell anoikis, whereas methylglyoxal mediated modification of type IV collagen was found to cause endothelial cell anoikis. In the absence of survival signaling from binding to these ECM ligands, cell detachment ensues and anoikis is subsequently initiated. While such diseases occur due to the gratuitous activation of anoikis, the biggest threat posed by anoikis malfunction happens when it is suppressed during carcinogenesis, contributing to invasion and metastasis of cancer cells.

The interaction between cells and the ECM is facilitated by the focal adhesion. Focal adhesion is an intricate assembly made up of integrins, a type of CAM, and various adaptor proteins. The function of focal adhesion is in forming the connection between ligands found in the ECM and the actin cytoskeleton. Furthermore, the intracellular portion of the focal adhesion also associates with various kinases, such as the focal adhesion kinase (FAK), to initiate signaling pathways. As such, focal adhesion serves as the bridge between the extracellular signals and the intracellular events related to cell attachment, motility, and apoptosis.

Like cell–ECM interaction that provides signals inhibiting anoikis, cell–cell interaction also generates similar signaling, occurring through another CAM known as cadherin. A notable member of the cadherin family pertinent to anoikis is E-cadherin, which can be found expressed in epithelial cells. This receptor is ligated by other E-cadherins from neighboring cells and its activation is necessary for various survival signaling pathways. Additionally, E-cadherin is also connected to the actin filaments through α-catenin, providing a link between cell–cell interaction and intracellular cytoskeletal dynamics.

When cells are detached and anoikis is induced, cell death takes place through the apoptotic pathways. This means that anoikis could occur through both intrinsic and extrinsic apoptotic pathways. Loss of attachment causes changes in the cytoskeletal dynamics, initiating the intrinsic pathway to cause permeabilization of outer mitochondrial membrane through the actions of apoptotic regulators. Meanwhile, similar activation of extrinsic pathway can also occur during anoikis through the upregulation of ligands for the tumor necrosis factor receptor (TNFR) family. Regardless of the route taken, both intrinsic and extrinsic apoptotic pathways lead to the eventual activation of caspases, which causes cell death. Additionally, caspase-independent cell death has also been established as a possibility in anoikis through a mitochondrial protein, Bit1. Taken together, the apoptotic regulators involved in these pathways are important players in anoikis execution. However, it is the upstream signaling factors related to cell adhesion that gives anoikis its additional distinction from the basic apoptosis process, which will be discussed in the next subtopic.

Regulation of Anoikis

Signaling pathways and major players governing anoikis sensitivity and resistance have been well documented over the years. As previously mentioned, the information regarding cellular attachment to the ECM and neighboring cells are relayed by a number of cell surface proteins. Since the anoikis network connects the cytoskeletal system with the apoptotic machinery, various signaling pathways associated with survival and apoptosis have been shown to function downstream of receptors and integrins.

One of such receptors is the epidermal growth factor receptor (EGFR). EGFR belongs to the ErbB receptor family and is often found mutated to be constitutively active in cancer. In an active homodimeric or heterodimeric form when ligated, EGFR transduces signals to initiate key pathways regulating anoikis, such as the MAPK/ERK and PI3K/Akt pathways. The initiation of these pathways results in activation of downstream effectors promoting survival and inhibiting anoikis. Additionally, activation of MAP/ERK signaling pathway by EGFR also results in the phosphorylation and degradation of the proapoptotic protein Bim, further enhancing the anti-anoikis effect of activated EGFR. Due to the prevalent nature of EGFR in preventing cancer cell apoptosis, inhibition of EGFR as a therapeutic approach has shown success in clinical settings, such as through the use of erlotinib, a receptor tyrosine kinase inhibitor. Interestingly, cancer cells have shown the ability to overcome such inhibition through the formation of an EGFR heterodimer with insulin growth factor 1 receptor (IGF1R), conferring drug resistance and enabling cell survival. IGF1R is another cell surface receptor well known to suppress anoikis. As a hormone receptor, IGF1R plays a crucial role in body growth and development. As for its regulation of anoikis, ligation of IGF1R prevents anoikis from being induced mainly through the activation of PI3K/Akt pathway.

Findings from a large number of studies on anchorage-independent growth provide a consensus on the major role played by MAPK/ERK and PI3K/Akt pathways in preventing anoikis. Conforming to that, tropomysin receptor kinase B (TrkB) adds to the list of cell surface receptors regulating anoikis through both pathways. Studies across multiple cancer cell lines have proven TrkB to not only suppress anoikis by activating these pathways, but also induce epithelial-to-mesenchymal transition (EMT) to further reinforce anoikis resistance in cancer cells. Despite playing an important role in human neural tissues, tropomysin receptor kinase (Trk) family was first identified to be oncogenic in colon cancer few decades ago. However, it was only recently that the Trk family gained necessary attention as a promising target in cancer therapy, thanks to emerging studies revealing the prominent involvement of Trk gene fusions in various cancer types. As such, an inhibitor targeting abnormally expressed Trk receptors named larotrectinib is currently in clinical trial with positive response so far.

In addition to kinase receptors, it is worth emphasizing the regulation of anoikis by another type of receptor, the E-cadherin. E-cadherin is a well-established transmembrane glycoprotein that mediates cell–cell interaction, enabling cell adhesion. E-cadherin has been found to interact with β-catenin to suppress the Wnt/β-catenin pathway and subsequently the transcription of various genes promoting EMT and anoikis resistance. As such, inactivation or functional loss of E-cadherin is often correlated with increased plasticity of cancer cells due to the acquisition of a mesenchymal phenotype. Arguably, E-cadherin is the most important transmembrane receptor when it comes to maintaining anoikis sensitivity, and its role goes beyond just regulating the Wnt/β-catenin pathway, as is better explained in the next subtopic.

While E-cadherin is responsible for cell–cell interaction, integrins are receptors responsible for cell–ECM interaction. Integrins exist on the cell surface as heterodimers, with varying combination of one α- and one β-subunits. As a result, a total of 24 combinations of integrin pairs can occur, and each of these combinations can be found in a varying distribution across different cell types with unique ligand specificity. Some components of the ECM, such as collagen and fibronectin, act as ligands and activate the integrins upon binding. Accordingly, activated integrins transduce signals from the ECM to the cytoplasm, controlling a wide array of cellular events including anoikis. Among the ways this is achieved is through the activation of FAK/Src pathway and other effectors such as integrin linked kinase (ILK) and transcriptional factors STAT3 and c-Myc, causing the activation of PI3K/Akt pathway and inhibition of anoikis.

Lastly, the topic of anoikis related signaling pathways will not be complete without the mention of Hippo pathway. Hippo pathway gained prominence when it was discovered to play a critical role in determining and retaining organ sizes. This pathway is activated by a complex network of transmembrane proteins, which results in the initiation of a kinase cascade. Cell detachment and even cytoskeletal perturbation have been found to cause the activation of Hippo pathway in normal cells, and consequently, anoikis. The notable key component of this pathway relevant to anoikis is the Yes-associated protein (YAP), whose function is inhibited through phosphorylation and sequestration by Hippo pathway kinases and various other regulators such as E-cadherin and α-catenin. When no longer inhibited, the oncogenic transcriptional regulator YAP is activated and promotes the expression of genes related to proliferation and anoikis resistance, making Hippo pathway an important regulatory system for maintaining anoikis.

New studies on anoikis regulation continue to shed light on other signaling pathways and novel proteins requiring further investigation. Regardless, the aforementioned receptors and pathways make up a significant part of the signaling cascades that converge to form a multifaceted network regulating anoikis (**Fig. 1**).

Interplay between EMT and Anoikis in Cancer

EMT is characterized by the loss of epithelial markers, such as E-cadherin and α-catenin, and gain of mesenchymal markers, such as N-cadherin, vimentin, and fibronectin. Functional loss of epithelial markers results in the dedifferentiation of cells, enabling them

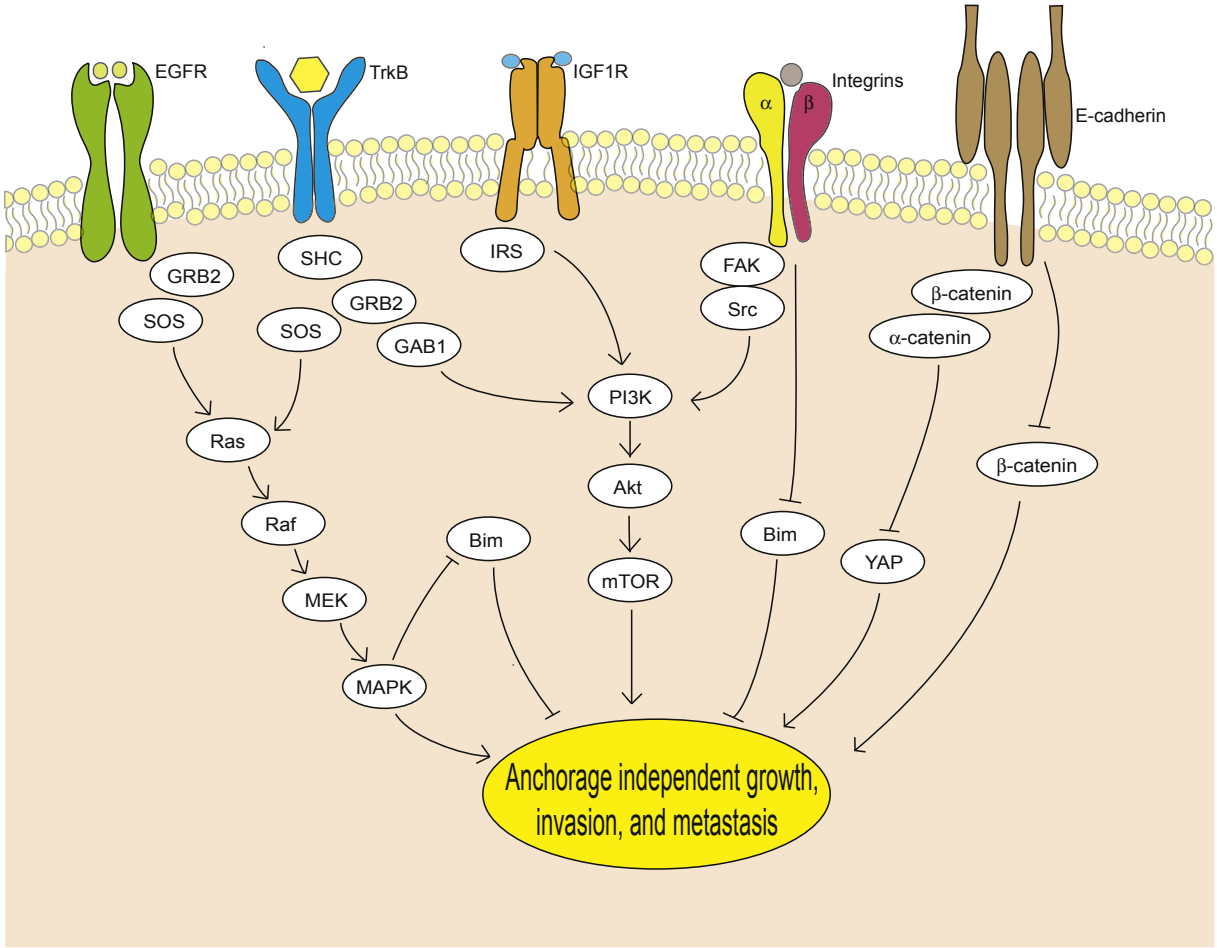

Fig. 1 An overview of signaling pathways regulating anoikis. Major pathways involved are the PI3K/Akt, MAPK/ERK, and Hippo pathways, composing the core of survival signaling originating from receptors mediating cell–ECM and cell–cell interactions. Examples of such receptors with validated roles in regulating anoikis are EGFR, TrkB, IGF1R, integrins, and E-cadherin.

to adopt a mesenchymal phenotype marked by increased cell motility and invasiveness. EMT is a reversible process that plays a pivotal role during embryogenesis and wound healing. This is potentially followed by the reversal of EMT, which is aptly termed mesenchymal-to-epithelial transition (MET). Consequently, the cells can undergo differentiation to return to their former epithelial state.

As expected, this dynamic process requires the cells to overcome various regulatory checkpoints such as anoikis, which would otherwise restrict movement and changes in the differentiated epithelial cells. In cancer cells, EMT similarly occurs during tumorigenesis as they begin to metastasize. Cancer cells also undergo MET, which seeds the growth of secondary tumors and colonization of distant organs, as the disseminated cells reassume their original state. Regardless of the use of the word epithelial, this process is not exclusive to epithelial cancer, as similar genetic signature for EMT has been noted in other cancer types such as sarcoma.

Despite the various mutations accumulated during tumor progression, cancer cells still need to overcome anoikis to begin the process of metastasis. As such, EMT enables yet another way for cancer cells to acquire anoikis resistance. This ability of EMT to repress anoikis lies in the regulation of major receptors mediating cell–cell interaction. In normal cells, these receptors provide pro-survival signaling when in correct attachment with the neighboring cells. Alteration of these receptors enables the bypass of this regulatory system and essentially, anoikis. To understand the tight interconnection between EMT and anoikis, one must first look at the important role played by E-cadherin, whose removal marks the beginning of EMT.

In addition to facilitating cell–cell contact through its extracellular domain, E-cadherin also regulates various signaling pathways through its cytoplasmic domain, which is largely responsible for its role in suppressing EMT. As previously mentioned, one such pathway is induced by β-catenin. B-catenin, which interacts with the cytoplasmic domain of E-cadherin, is kept sequestered away from the nucleus. In the absence of E-cadherin, the Wnt/β-catenin signaling pathway is activated, resulting in the translocation of β-catenin into the nucleus and activation of mesenchymal markers such as Snail, Twist, and ZEB1, endowing cancer cells with mesenchymal motility. Another protein that is regulated by E-cadherin is PTEN, a well-established tumor suppressor protein often found inactivated in cancer. Through the activation of E-cadherin, PTEN expression is upregulated and kept stable, allowing it to

suppress the pro-survival PI3K/Akt pathway signaling pathway by dephosphorylating PIP_3, a positive regulator of this pathway. Ankyrin-G also joins the list of E-cadherin interacting proteins, which was shown to activate a tumor suppressor protein promoting anoikis called P14ARF through inhibition of its transcriptional repressor TBX2. However, the anoikis inducing nature of P14ARF has been put into question, as a study recently unraveled the paradoxical nature of P14ARF inhibiting anoikis, suggesting that it may play a cancer type dependent role. These are just some examples of how E-cadherin positively regulates anoikis, highlighting the necessity of its removal during tumorigenesis.

Activation of EMT can also occur through TGF-β signaling pathway, during which numerous transcriptional repressors of E-cadherin are upregulated, such as Twist, ZEB1, ZEB2, Snail, and Slug, resulting in the abrogation of E-cadherin expression. Concomitantly, transient E-cadherin silencing has also shown to upregulate Twist and ZEB1 expression, suggesting that there exists a feedback loop between these transcription factors and E-cadherin. In addition to repressing E-cadherin expression, some of these transcription factors have also shown to change integrins expression in cancer cells, such as Snail and ZEB2, thus inducing EMT from multiple angles.

Next, in view of the important role played by integrins in mediating cell–ECM interactions, it comes as no surprise that cancer cells alter the integrin repertoire on the cell surface to favor metastasis inducing signaling pathways. Such changes in integrin expression in common cancer types have been listed and elegantly reviewed by Koistinen and Heino. In one of their examples, a study found breast adenocarcinoma to have significant downregulation of integrin $\alpha2\beta1$ compared to normal mammary epithelial cells. In a subsequent study, $\alpha2\beta1$ when ectopically expressed was able to diminish the malignancy of breast cancer cells by reducing its motility and invasiveness. This does not necessarily define it as a tumor suppressor across cancer types, as oncogenic function of $\alpha2\beta1$ has been exhibited in other cancer types as well.

As for an example of integrin upregulated in cancer, $\alpha5\beta1$ is of particular interest in the context of EMT and anoikis. $\alpha5\beta1$ is often found highly expressed, such as in prostate cancer and glioma, and correlated with poor prognosis in cancer patients. Experimental studies have uncovered the specific mechanisms by which these integrins can affect EMT, which starts with the ligation of $\alpha5\beta1$. This leads to the activation of FAK/Src and ILK pathways, both of which result in a cascade of signaling pathways repressing E-cadherin and activating EMT promoting transcription factors. Additionally, one of the products of these transcription factors, fibronectin, is produced and excreted into the ECM. Fibronectin, an extracellular mesenchymal marker, can act as a ligand to activate similar motility related integrins, fueling a feedback loop and further augmenting the integrin mediated pro-EMT signaling pathways.

Through the suppression of E-cadherin and manipulation of integrins during EMT, cancer cells are able to proceed with initiation of metastasis and become more invasive. This is also aided by mesenchymal markers which allow the restructuring of cytoskeletal dynamics to enable increased proliferation and motility. In further clarifying the intricate cross talk between EMT and anoikis, a study was performed to elucidate the role of several genes known to be upregulated during EMT in an ovarian cancer cell line. Interestingly, loss of function studies on each of these genes revealed that they did not have significant effect on anoikis regulation, with a notable exception of SYDE1, a Rho family GTPase.

Transient silencing of SYDE1 enabled both the recovery of E-cadherin expression and an increase in anoikis sensitivity, although the role played by SYDE1 in regulating anoikis remains elusive due to the limited number of studies investigating its function. Even more curious was the finding that ZEB1 silencing increased the expression of E-cadherin without any effect on anoikis. In keeping with that, other ZEB1 overexpression studies showed downregulation of E-cadherin but without an increase in anoikis resistance. Taken together, these suggest that although EMT is tightly linked to anoikis, varying the expression of E-cadherin alone is insufficient to cause changes in anoikis sensitivity.

In brief, inhibition of EMT has been consistently linked with increased anoikis sensitivity in a wide array of cancer types. As EMT precedes metastasis, inhibiting EMT as a therapeutic approach has been extensively studied. Such studies have yielded potential therapeutic molecules capable of suppressing EMT and inducing anoikis in various cancer cell lines. In addition, promising EMT targeting candidates have also been advanced to the clinical trial stages. Unfortunately, despite being advanced from development stages, they are yet to translate into successful clinical applications as many of these drugs fail to show efficacy in cancer patients.

Regulation of Anoikis by Autophagy in Cancer

Considering how anoikis involves the activation of apoptotic pathways, it is inevitable for a bevy of cellular processes related to cell survival and death to be affected by anoikis as well. As it has been previously established, anoikis occurs upon loss of ECM attachment. However, removal from the ECM does not result in imminent cell death, as studies have shown that another process, namely autophagy, is capable of interfering prior to initiation of anoikis. In this scenario, autophagy delays the activation of anoikis, providing the detached cells a small window of opportunity to promptly recover proper attachment with the ECM and neighboring cells.

Autophagy is a process in which cytosolic component are degraded as a tradeoff to enable survival in the event of cellular stress. Although there are different types of ways autophagy is achieved, the eventual outcomes are usually controlled degradation and turnover of cellular proteins and organelles, which increase the survival rate. The connection between anoikis and autophagy is primarily modulated by regulators of both processes, which link the cytoskeleton to the intrinsic apoptotic pathway. Two BH3-only family members crucial for anoikis, Bim and Bmf, are apoptotic activators notable for regulating autophagy. In their interaction with the cytoskeletal complex in normal attached cells, both proteins are found in an inactivated form, with Bim being associated

with dynein light chain 1 (DLC1), and Bmf with dynein light chain 2 (DLC2) of the cellular microtubule. This association enables Bim and Bmf to sequester Beclin-1, a pro-autophagy regulator and prevent its functional activation. Ultimately, cell detachment from the ECM translates to disturbance of the cytoskeletal architecture, which in turn releases Beclin-1 from this inhibition and enables the initiation of autophagy.

Unsurprisingly, the short gap that occurs after detachment afforded by autophagy is effectively exploited by cancer cells to continuously survive while metastasizing. Indeed, studies have shown that inhibiting autophagy limits cancer cells survival in suspension, whereas inducing autophagy results in increased survival and resistance towards anoikis. The complexity of how cancer cells achieve this is evident from findings of numerous studies, each highlighting unique key players and signaling pathways. Among the identified mechanisms are the activations of protein kinase A (PKA), transcriptional factor ATF4, HGF/c-Met pathway, and autophagy regulators such as ATG3.

In addition, cancer cells are also known to manipulate cellular stress as another method of utilizing autophagy to evade anoikis. For example, PERK, a transmembrane protein kinase found in the endoplasmic reticulum, is responsible for mediating stress response by suppressing protein translation. As an oncogene, PERK has found to be upregulated in a variety of cancer types and inhibition of PERK has shown to impair aggressive cancer phenotypes. As for its specific role in impeding anoikis, PERK was shown to promote cell survival after ECM detachment by inducing autophagy regulators through the activation of AMP-activated protein kinase (AMPK). Taken together, these studies suggest that cancers cells take advantage of the readily available loophole of autophagy to escape the anoikis barrier and become metastatic.

Nevertheless, the nature of autophagy is not as linear as being cytoprotectant in cancer cells during tumorigenesis. Studies have also brought to light the contrasting role played by autophagy in cancer cells, in which activation of autophagy was found to have a tumor suppressive role instead. One of the early studies investigating the function of Beclin-1 found it to be downregulated in breast cancer cells. When overexpressed, Beclin-1 was able to inhibit tumorigenesis in vitro and in vivo, through the activation of autophagy and subsequently apoptosis. Other studies corroborated the tumor suppressive function of autophagy. Separate studies on breast cancer cells revealed autophagy to promote cell death through the inhibition of IP3R and the degradation of Notch1 intracellular domain. Furthermore, several compounds have been shown to induce autophagy and apoptosis concurrently, such as fluvastatin in lung cancer metastasis and genistein in pancreatic cancer cells.

Autophagic cell death in cancer cells is also apparent in studies on several FDA-approved anticancer drugs. For example, tamoxifen treatment was found to involve the activation of autophagy in inducing cell death in luminal and triple-negative breast cancer, whereas gemcitabine was found to potentiate cell death through autophagy in pancreatic cancer. Interestingly, a study recently uncovered that autophagy induced by gemcitabine can also play an opposing role of promoting survival in bladder cancer cells through the activation of nuclear protein HMGB1, once again stressing the convoluted relationship between autophagy and cell death. Although anoikis induced cell death was also found to be upregulated in some of these instances in which autophagy promoted cell death, number of similar examples is limited, presumably due to the emphasis of such studies being mostly on cancer cell proliferation and tumor regression, and not on anoikis resistance. As such, it remains unclear if targeting the anoikis-autophagy interaction will work as an effective strategy in treating cancer, as more studies are needed to delineate the context dependent role played by autophagy.

Hypoxia and Anoikis

The highly proliferative nature of cancer cells presents a challenge in terms of oxygen delivery, which often serves as a limiting factor for tumor size. Cancer cells overcome this restriction by forming additional blood vessels through the process of angiogenesis. In the event of reduced oxygen availability, also known as hypoxia, hypoxia-inducible factors (HIF) are activated, which promote the expression of genes enabling adaptation to the stress. HIF, such as HIF-1, are heterodimeric transcription factors whose expression is kept low by the molecular oxygen sensor PHD2.

Although hypoxia in cancer mainly concerns cell embedded within the tumor, activation of HIF has results that extend beyond angiogenesis, as it can also negatively regulate anoikis. First of such regulation is by the induction of EMT through several mechanisms, such as activation of TGF-β signaling pathway and upregulation of EMT transcription factors. The link between hypoxia and EMT is by the virtue of HIF's regenerative role in stimulating wound repair. However, this can be opportunistically appropriated by cancer cells to increase motility and escape the hypoxic environment. Consequently, anoikis resistance is also concurrently acquired due to the induction of EMT. In addition, hypoxia is also correlated with autophagy, where autophagy inducers such as BNIP3 have been shown to be upregulated upon the activation of HIF-1α, a subunit of HIF-1. The outcome of this is the involvement of autophagy during hypoxia in cancer cells, which can play a protective role against anoikis.

Interestingly, hypoxia can be triggered even in the absence of oxygen deprivation through alternate methods. For example, constitutive activation of CAM such as EGFR and another ErbB family receptor, ErbB2, can stabilize and elevate HIF-1 expression, which otherwise would be immediately degraded in normoxic conditions. Since such receptors are often upregulated during anchorage-independent growth, activation of HIF provides another pathway for cancer cells to evade apoptosis while in suspension. Conversely, silencing of HIF-1 has shown to inhibit anti-anoikis signaling pathways such as PI3K/Akt pathway, further confirming the negative regulation of anoikis by HIF. Taken together, the connection between HIF and anoikis demonstrates how even cellular stress such as lack of oxygen can be exploited to benefit the growth and survival of cancer cells through the suppression of anoikis.

Regulation of Anoikis in Cancer by Non-coding RNA

Non-coding RNA (ncRNA) refers to sequence of transcribed RNA that is not translated into protein. Although some are regarded as 'junk RNA,' the highly abundant ncRNAs have shown to be functionally prolific. Next, we will look at how anoikis is regulated by some of these ncRNAs, namely microRNA (miRNA), long non-coding RNA (lncRNA), and small nucleolar RNA (snoRNA).

miRNA

Recent studies continue to reveal the complexity of anoikis regulation by elucidating more novel ways cancer cells regulate anoikis related genes. This brings us to miRNA, a short strand of RNA molecules approximately 22 nucleotides in size. The miRNAs regulate gene expression post-transcriptionally, which means that it interacts with mRNA causing either its degradation or translational impairment. The interaction between a miRNA and its target mRNA depends on sequence complementarity between both RNA molecules. Unlike in plant cells where nearly perfect complementarity is needed, miRNAs in mammalian cells only require a minimum base pairing at its seed region spanning 6 nucleotides with the 3′ UTR of the mRNA.

miRNA mediated gene silencing is based on RNA interference. A miRNA begins as a transcript of pri-miRNA in the nucleus, which gets processed into pre-miRNA before being exported to the cytoplasm. There, the final processing is carried out by the enzyme Dicer, producing a mature miRNA. In the cytoplasm, a miRNA will get loaded into an RNA Induced Silencing Complex (RISC). This enzyme complex containing the catalytic protein argonaute is directed to a target mRNA, which binds to the complementary miRNA. Consequently, the mRNA will be either cleaved or unavailable for translation. Regardless, the outcome of this miRNA-mRNA interaction is the downregulation of the miRNA target gene.

Dysregulation of miRNAs have been well observed not only in cancer, but also in numerous other diseases such as atherosclerosis and cystic fibrosis. In cancer, various miRNAs have been established to play clear oncogenic and tumor suppressive roles, although many of them have cancer specific functions. It is not uncommon for miRNAs to play oncogenic role in one cancer type and an opposing tumor suppressive role in another. With that in mind, miRNAs that regulate key cancer phenotypes such as anoikis, EMT, and autophagy have been extensively studied and reviewed.

Interestingly, some miRNAs have consistently shown up in studies investigating such processes, such as the miR-200 family. This miRNA group, consisting of miR-200a, miR-200b, miR-200c, miR-141, and miR-429, has shown definite roles as tumor suppressive miRNAs by regulating both EMT and anoikis in a variety of cancer types. From such miRNAs, certain pathways have been found to be frequently targeted through various target genes, which are the PI3K/Akt, Wnt/β-catenin, and TGF-β signaling pathways, thus underlining the significance of these pathways in regulating anoikis and EMT.

In addition to regulating itself with miRNAs, cancer cells are also able to utilize miRNAs to control other cells. This is owing to its ability to produce exosomes, the purpose of which is to either dispose tumor suppressive miRNAs or influence neighboring cells with oncogenic miRNAs. However, there are more evidences to support the latter function than the former. Through exosomal excretion, cancer cells are able to transfer oncogenic miRNAs extracellularly, in addition to proteins required for miRNA processing, through exosomes which then get absorbed by nearby cells. Once absorbed, these exosomal miRNAs can carry out their usual function in a new cell, despite originating elsewhere. This is especially useful for cancer cells that have acquired resistance to anoikis, as they are now able to impart similar characteristic to adjacent anoikis sensitive cells through exosomal miRNAs. Indeed, exosomes sourced from cancer cells have been shown to induce anoikis resistance among even normal cells upon exposure.

As previously established, since only a short stretch of complementary sequence is needed in a target mRNA, a single miRNA can target and downregulate multiple genes while numerous miRNAs can target a single gene, which creates a complicated network of post-transcriptional regulation. Herein lies miRNA's advantage for therapeutics, as it is capable of regulating multiple signaling pathways at once, making it more forceful compared to using a target specific siRNA. However, it is important to note that there are limited circumstances when the use of miRNA based therapeutics has definite advantages in clinical application. In the context of anoikis resistance, potent miRNAs must first be found, whose manipulation will result in little to no side effects to normal cells, as is the case for any ideal anticancer drug. This will require extensive studies to determine the specific roles played by the chosen miRNAs, which is complicated due to their confounding functional characteristics. This is due to the contradictory role miRNAs play in different cell types and thus will require extensive studies to elucidate and narrow down potential miRNA candidates.

On the other hand, miRNA based prognostic is less ambiguous in nature and deserves more attention for development. Clear correlation has been demonstrated between serum level of oncogenic miRNAs conferring anoikis resistance and predicted outcome for cancer patients. As such, miRNA based prognostics can be developed through the monitoring of changes in serum miRNA throughout cancer treatment. Since this prognostic method is noninvasive with immediate results as compared to other biopsies, pairing it with existing treatment regimens will allow evaluation and prediction of the effectiveness of such treatments earlier in individual patients. This will also enable necessary treatment modifications to be implemented sooner due to the relative ease of miRNA based prognostics. For this to be practical, however, probable miRNA biomarkers need to be examined and established for specific cancer types. Personalized medicine still has far to go, and miRNA based therapeutics, and prognostics has a lot to offer to push it forward.

lncRNA

Another type of ncRNA known to control anoikis is lncRNA. lncRNA is characterized by a size of more than 200 nucleotides and is significantly more tissue specific when compared to mRNA. Initially dismissed as non-functional, lncRNAs are now found to control

various protein expression machineries through a range of approaches, including epigenetic mechanisms such as methylation of DNA and modification of histone. In addition, lncRNAs are also able to control gene expression at both transcriptional and post-transcriptional levels. This makes lncRNAs highly versatile by modulating gene expression at numerous stages, unlike miRNAs that only perform post-transcriptional gene regulation. Interestingly, recent studies on lncRNA have unearthed another novel translational role for lncRNAs that were previously thought to be non-coding, as a small number of them were found to encode for functional micropeptides. As such, the broad functions played by lncRNA have made it a subject of increasing importance in studying dysregulation of genes in cancer cells.

Naturally, with diverse mode of action and abundant expression, lncRNAs have been shown to regulate anoikis in various cancer types. Studies have revealed several prominent lncRNAs such as the metastasis associated lung adenocarcinoma transcript 1 (MALAT1), HOX transcript antisense RNA (HOTAIR), and highly upregulated in liver cancer (HULC) with validated roles in suppressing anoikis in cancer. MALAT1 and HOTAIR were found to modulate anoikis sensitivity through the downregulation of their target genes, while HULC has been shown to inhibit anoikis and induce protective autophagy in various cancer cell lines. These are just few examples, for there are many other lncRNAs that have also been implicated in regulating related processes such as invasion and metastasis, highlighting its compelling role in dysregulation of genes in cancer cells.

In addition, lncRNA is also demonstrated to interact with miRNA, which further complicates lncRNAs' regulatory network. This relationship between lncRNA and miRNA can take place through one of two ways. The first interaction is by the binding of lncRNAs to complementary miRNAs, which can cause either their degradation or simply the inhibition of the miRNAs' function. In this case, lncRNA acts as a negative regulator of miRNA. Another interaction is one in which the lncRNA acts as a source of miRNA, wherein functional miRNAs can be spliced out of the lncRNAs. As such, sequestering or inhibiting tumor suppressive miRNA through the regulation of associated lncRNAs can also effectively serve as a strategy to evade anoikis in cancer cells.

Despite its abundance, lncRNA is only now being extensively studied and understood due to its complex nature. So far, numerous lncRNAs have been experimentally identified to be correlated with specific cancer types, acting as either oncogenes or tumor suppressor genes. As such, it can be expected that future studies may continue to unravel more novel ways lncRNAs regulate anoikis in cancer cells and how it can be beneficial for cancer treatments.

snoRNA

Similar to other ncRNAs, snoRNAs have also been found dysregulated in cancer and implicated in the regulation of anoikis. It is approximately 60–300 nt in size and can be categorized into two types, which are the box C/D and box H/ACA snoRNAs. This classification is based on the presence of conserved sequence motifs in the snoRNA and its respective functions. Box C/D snoRNAs carry out methylation whereas Box H/ACA carry out pseudouridylation of ribosomal RNA (rRNA). Although snoRNA's function is mainly associated with modification of rRNA, it has also been found performing other roles such as regulation of mRNA by interacting with snRNA. Interestingly, snoRNA has also been described to act as miRNA (sno-miRNA), albeit in relatively limited circumstances.

While recent studies have uncovered an increasing number of snoRNA that are dysregulated in cancer cells, specific role of such snoRNAs' in regulating anoikis remains largely unknown as of now. This does not imply that snoRNAs play a minimal role in regulating anoikis, as many of these studies have found connection between snoRNA expression and anoikis related pathways such as the PI3K/Akt pathway to influence cancer cell proliferation and similar processes.

As such, the most prominent snoRNA known to regulate anoikis is small nucleolar RNA 42 (SNORA42), a box H/ACA snoRNA. SNORA42 was initially identified as an oncogene when it was found to be highly expressed in non-small cell lung cancer (NSCLC). Since then, more recent studies conducted in NSCLC and colorectal cancer (CRC) revealed poor prognosis among patients expressing high level of SNORA42. Meanwhile, overexpression studies in CRC showed that SNORA42 was able to increase anoikis resistance. There are several suggestions to explain the function of SNORA42 as an oncogene, such as through upregulation of stem cell genes and inhibition of p53-dependent apoptosis. However, this is still being investigated and the exact mechanism has yet to be determined. With studies revealing the increasingly important roles of snoRNAs, future findings may reveal more snoRNAs like SNORA42 and how manipulation of such ncRNAs may prove beneficial in cancer therapeutics.

Circulating Tumor Cells and Anoikis

So far, we have seen the molecular perspective of how anoikis is regulated and how various cellular mechanisms can intervene to potentiate anoikis resistance in cancer cells, generating potent seeds for metastasis. Next, we will look at what happens when these modifications are acquired as the cancer cells enter the blood stream to form circulating tumor cells (CTCs).

CTCs are anoikis resistant cancer cells that have escaped the original tumor formation site and entered the circulatory system. Naturally, entering the circulatory system exposes the cancer cells to selective pressure, allowing only those with resistance to anoikis to remain and survive as CTCs. Although many CTCs are cells that have undergone EMT and intravasation into the blood vessels, some of these cells may have detached merely due to inflammation or sheer force. As such, CTCs do not inherently possess the competency to seed a secondary tumor right away. In fact, the formation of a secondary tumor by CTCs has been acknowledged to be an improbable event and a bottleneck step in metastasis. While anoikis resistance enables CTCs survival in suspension, stem cell characteristics are further needed for the final stages of metastasis, which brings us to cancer stem cells (CSCs).

As implied by its name, CSCs are cancer cells that portray similar characteristics as stem cells, such as self-renewal and ability to form tumorspheres. These cells can further undergo changes such as EMT, endowing them with even more plasticity to become important drivers for metastasis. Not surprisingly, CSCs make up a large subset of CTCs. Indeed, numerous studies on metastasis have proven CTCs to be highly heterogeneous, with subgroups of varying degree of pathogenicity. The interplay between CTCs and CSCs suggests that CTCs may play an important role in survival in suspension and invasiveness, whereas CSCs may be responsible for the establishment of the metastases upon extravasation.

Examination of spheroid cultures in vitro revealed a constitutive activation of EGFR to transduce MAPK/ERK signaling pathway among others, providing protection from anoikis in the absence of ECM. Furthermore, CTCs analysis also revealed increase in mesenchymal markers and decrease in epithelial markers, consistent with the findings that CTCs undergo EMT in addition to being anoikis resistant. Such changes are warranted as CTCs attempt to survive in an anchorage-independent environment within the circulatory system. As such, CTCs presents a major problem for cancer patients as conventional radiotherapy does not work against these cells. To make things worse, chemotherapy is not as effective either as CTCs in suspension do not rapidly replicate, as the emphasis is placed on survival instead.

These issues necessitate individual attention to CTCs, which may reveal vital information for effective cancer treatments that otherwise would have gone overlooked. To illustrate this point, consider the following scenario of gastric cancer treatment and the molecular classification of the tumor cells. Recent studies have shown the existence of CTCs exhibiting HER2 positive phenotype in gastric cancer patients, despite the primary tumor biopsy showing HER2 negative phenotype. Preliminary findings showed that these patients benefited from combined treatment using trastuzumab, a cancer drug targeting HER2 overexpressing cancer cells. As such, it is indisputable that this potential treatment strategy would not have been discovered if not for the analysis of CTC population.

Even though platforms exist for the isolation and enrichment of CTCs for analytical purpose, sporadic molecular characteristic of CTCs and difficulties in obtaining enough CTCs from liquid biopsy hinder its application as prognostic biomarkers. Furthermore, while a long list of markers has been identified to classify CTCs, it is not exhaustive and continues to be updated and changed thanks to recent studies revealing more details on the heterogeneity of CTCs. Presently, there are many strategies for detection of CTCs based on sizes or molecular features, though they are mostly either time consuming or insufficiently sensitive to analyze the whole representative of CTCs. Additionally, indirect approximation of CTCs through the analysis of serum miRNAs have also been demonstrated and suggested as an alternative to CTCs detection. Regardless, the increased attention that CTCs have gotten over the past few years have resulted in emergence of newer methods requiring shorter time and lesser samples, paving way for another option for personalized cancer treatment. If such newer methods can be reliably accomplished, characterization of CTCs derived from patients will definitely contribute to better decision making in treating cancer metastasis.

Tackling Anoikis Resistance in Treating Cancer

Understandably, the pivotal role anoikis resistance plays in enabling CTCs' existence and survival has made targeting anoikis network in cancer treatment a necessary approach. In addition to existing cancer drugs, many new compounds have been experimentally shown to sensitize cancer cells to anoikis and reduce its malignancy. The following are examples of such compounds (Table 1).

Table 1 Summary of example compounds known to regulate anoikis in preclinical and clinical stages

Type of drug	*Name*	*Mechanism for regulating anoikis*
Inhibitors	Dasatinib	Suppression of SFK
	Erlotinib	Inhibition of EGFR
	Lapatinib	Inhibition of EGFR
	Sorafenib	Inhibition of MAP/ERK pathway
Repurposed drugs	Disulfiram	Activation of calpain and increase of intracellular zinc level
	Metformin	Activation of AMPK
Antibiotics	Anisomycin	Inhibition of apoptosis regulator FLIP
	Rapamycin	Inhibition of PI3K/Akt pathway
	Renieramycin M	Inhibition of PI3K/Akt and MAP/ERK pathways
	Salinomycin	Suppression of STAT3
miRNA based drug	MRG106	Inhibition of pro-EMT miR-155
Natural compounds	*Morus alba* leaf lectin	Inhibition of FAK
	Sambucus sieboldiana lectin	Suppression of MGAT5 mediated anoikis resistance
	Apigenin	Suppression of FAK and MAP/ERK pathway
	Moscatilin	Inhibition of PI3K/Akt and MAP/ERK pathways
	Geraniin	Inhibition of TGF-β signaling pathway
	Gigantol	Inhibition of PI3K/Akt and MAP/ERK pathways

Inhibitors

Owing to the myriad of enzymes involved downstream of receptors regulating anoikis, it should come as no surprise that many FDA-approved cancer drugs belong to the inhibitor class compound and work very well in abrogating anoikis resistance in cancer cells. Examples of inhibitors that reduced anchorage-independent growth in cancer cell cultures are dasatinib, erlotinib, lapatinib, and sorafenib. Dasatinib and sorafenib are multi-kinase inhibitors that have shown the ability to induce anoikis by suppressing Src family kinases (SFK) and MAP/ERK signaling pathway respectively. Meanwhile, erlotinib and lapatinib similarly promote anoikis but by inhibiting the EGFR instead. Intriguingly, some of these drugs have also shown increased efficacy when used in combination, such as lapatinib and sorafenib in human glioblastoma, by activating various cell death mechanisms including both extrinsic and intrinsic apoptotic pathways.

Repurposed Drugs

While new drugs continue to be developed, existing drugs for other conditions are finding new niche in cancer treatment. As these drugs are already FDA approved in terms of safety for human use, they face significantly less hurdle in re-entering the market as anticancer drugs. One of such drugs that has shown efficacy in treating anoikis resistance in cancer cells is disulfiram (DSF). Used to treat a completely unrelated indication of alcohol dependence, DSF has also shown potency as an anticancer agent. Remarkably, epidemiology survey has shown reduced occurrence of breast and prostate cancer within a Danish DSF user sample population. The ability of DSF to induce anoikis in cancer cells has been attributed to activation of calpain in a copper dependent manner. In addition, DSF has also been experimentally shown to act as an ionophore, increasing the intracellular level of zinc to sensitize breast cancer cells to anoikis. This isn't surprising, given that the value of zinc as an anticancer agent has been well studied, especially as a promoter of anoikis through the inhibition of PI3K/Akt pathway.

Another similar drug with pro-anoikis property is metformin. Metformin is a type 2 diabetes medication that has been found to have an increasing number of potential uses, including against cancer. Several studies investigating the anticancer effect mediated by metformin found evidence that it induces anoikis in numerous cancer cell lines mainly through the activation of AMPK. These studies have also shown that metformin can work against cancer cells both by itself and as an adjuvant. Similar to DSF, metformin use has also been associated with overall reduced incidence of various types of cancer, highlighting its latent benefits and the necessity to repurpose such drugs in the battle against cancer.

Antibiotics

In line with the discussion on repurposed drugs, it is worth noting another group of compounds, antibiotics, that has shown efficacy in promoting anoikis among cancer cells. Various antibiotics have exhibited success in treating anoikis resistance in cancer cells, such as anisomycin, rapamycin, renieramycin M, and salinomycin. The ways these antibiotics are able to induce anoikis are numerous, such as impeding the formation of tumorspheres, suppressing pro-survival signaling pathways, and inhibiting anoikis suppressor proteins. Despite demonstrating promising results in vitro, studies on antibiotics use to treat cancer have been mostly preclinical, although a small scale clinical study has been carried out with salinomycin. Presently, salinomycin has been subjected to extensive studies in the context of cancer treatment, with specific emphasis on the underlying mechanisms enabling its effects against cancer cells. In fact, a proprietary formulation of salinomycin (VS-507) which worked against CSCs by targeting the Wnt pathway was under development by Verastem Inc. in 2012. However, no updates have since been heard about VS-507, and it is assumed to no longer be in development. Notably, salinomycin's toxicity primarily affected cancer cells with stem cell properties. As such, the practicality of developing antibiotic based drugs as a standalone appears questionable for now. Use of antibiotics as chemotherapeutic drugs for cancer is fascinating, especially considering that antibiotics are often deemed necessary for patients undergoing chemotherapy due to their weakened immune system and predisposition to infections. Although antibiotics use has been reported to have some success in improving cancer patients' survival, whether this is due to staving off infections or the therapeutic effect on cancer cells or a combination of both is yet to be established.

miRNAs

Many miRNAs regulating anoikis have been well studied and characterized. However, passing the preclinical stages appears to be the biggest barrier, as only a handful of miRNAs are currently in the drug development pipeline. As of now, the most prominent miRNA based therapeutic is miravirsen, a miR-122 inhibitor developed for treatment of Hepatitis C by Santaris Pharma. Interestingly, miravirsen is not the only experimental drug to use this strategy, as RG-101 from Regulus Therapeutics works similarly by targeting miR-122 in the liver, but with a structural difference in the inhibitor. How this difference translates to different safety and efficacy in human application is yet to be conclusively determined, as both drugs are currently in different stages of clinical trial, each with its own pros and cons. Meanwhile, development of miRNA based cancer therapeutics is not as fortunate, as MRX34, a mimic of tumor suppressor miR-34 in Phase 1 was recently halted after five immune-related patient deaths were reported. Although MRX34 is not the only anticancer miRNA based drug in the development pipeline, it was the first miRNA mimic to advance into Phase 1 and showed promising results prior to these serious adverse events, causing a huge setback for such drugs. Regardless, there are still few miRNA based cancer drugs in clinical stages, among which is MRG106. An antagonist of miR-155, MRG106 can be

considered to be significant in promoting anoikis in cancer. MRG106 was developed for cutaneous T-cell lymphoma and targets miR-155, a known oncogenic miRNA which suppresses anoikis by inducing EMT. Depending on its success in clinical trials, we may see more of such miRNA based drugs in the future, as there is a long list of miRNAs with potential for becoming anticancer drugs.

Natural Compounds

Natural compounds and their derivatives represent an emerging class of potential cancer drug candidates, whose popularity is credited to the relatively low toxicity towards normal cells, easy availability, and low cost. Originally prevalent for traditional uses, various plants around the world are now being realized as sources harboring valuable natural compounds with therapeutic potential. Indeed, many FDA-approved drugs such as vinblastine and paclitaxel are derivatives that exist today thanks to the discoveries of potent anticancer property of natural compounds found in plants. That being the case, many new natural compounds have been revealed to promote anoikis in cancer cells. Lectin from *Morus alba* leaf and *Sambucus sieboldiana*, apigenin, moscatilin, geraniin, and gigantol are just some examples of natural compounds that were recently discovered to induce anoikis in vitro in different cancer types. While more research is needed before these discoveries can be translated into viable anticancer drugs, the very abundance of such compounds increases the probability of similar compounds being found and developed past the preclinical stages.

Conclusion

The critical role played by anoikis in maintenance of tissue homeostasis makes it an important barrier to overcome among cancer cells attempting to metastasize. We have seen how resistance to anoikis is often acquired through various approaches, such as through manipulation of receptors regulating anoikis and dysregulation of various types of ncRNAs. Accordingly, anoikis resistance poses a big threat to conventional treatment, as they endow cancer cells with unique properties distinguishing them from the original tumor. Indeed, adoption of anoikis resistance is usually correlated with poor prognosis in patients regardless of cancer types. As such, targeting anoikis resistant cancer cells plays a key role in determining whether a cancer treatment will be effective, as we have seen how CTCs can be markedly different from majority of cancer cell population in a tumor.

Studies on anoikis manipulation in cancer cells have begun to gain momentum and more novel ways cancer cells can be made sensitive to anoikis are being revealed. Unless specifically targeted, these anoikis resistant cells may continue to fuel metastasis or remain dormant in circulation during treatment, possibly resulting in recurrence in cancer patients. As cancer therapeutics gradually incorporates a more personalized strategy, it is imperative that anoikis resistance is taken into consideration for a wholesome approach in treating cancer.

Historical Perspective

Aspirin is a drug that has reinvented itself a few times over the 20th and early 21st century. Although medicinal acetylsalicylic acid (ASA), that is Aspirin was first synthesized at Bayer AG in 1897, (Mahdi et al., 2006; Sneader, 2000) salicylates from the bark of willow tree have been used for their medicinal purposes for millennia before that. Felix Hoffmann is widely credited for the synthesis of ASA; however, the historical account is controversial with Arthur Eichengrün's claim that Hoffmann did so under Eichengrün's instructions. (Sneader, 2000; Eichengrün, 1949) For the first several decades of its use, Aspirin was used for its analgesic, antipyretic, and anti-inflammatory properties. Early reports of Aspirin's effect on myocardial infarction started appearing in medical literature in 1950s and 1960s, and soon cardiovascular trials, beginning with the UK Medical Research Council I (MRC-I) trial were launched (Elwood, 2006; Miner and Hoffhines, 2007). The mechanism of Aspirin action for all these effects however remained elusive for 70 odd years until John Vane (Vane and Botting, 2003; Vane, 1971) demonstrated in 1971 that Aspirin inhibits prostaglandin synthesis and he was jointly awarded Nobel Prize in 1982 for this important contribution. The mechanistic understanding of Aspirin's antiplatelet effects combined with the positive results (Lewis et al., 1983; Elwood et al., 1974) of randomized controlled trials (RCTs) led to increasing use of Aspirin as an antithrombotic agent in prevention of cardiovascular disease (CVD) from 1980s (Elwood, 2006; Miner and Hoffhines, 2007). With this widened use and new clinical trials (Steering Committee of the Physicians' Health Study Research G, 1988; Steering Committee of the Physicians' Health Study Research Group, 1989) came the first hints of Aspirin's beneficial effects on cancer and precancerous lesions (Kune et al., 1988; Gann et al., 1993; Logan et al., 1993; Rosenberg et al., 1991; Thun et al., 1991, 1992, 1993; Suh et al., 1993). Aspirin's effects on cancer incidence and mortality have subsequently been a subject of a very large number of observational studies and analyses from randomized trials (Algra and Rothwell, 2012; Bosetti et al., 2012; Cuzick et al., 2009, 2015; Flossmann and Rothwell, 2007; Rothwell et al., 2010, 2011, 2012a; Thorat, 2016; Thorat and Cuzick, 2013). These data collectively confirm that Aspirin has beneficial effects in reducing incidence and mortality of certain cancers (Cuzick et al., 2009, 2015; Thorat, 2016; Thorat and Cuzick, 2013).

Evidence for Effects on Cancer

Peculiarities of Aspirin's Effects on Cancer

A very large body of evidence now supports Aspirin's beneficial effect on cancer and this evidence is discussed below in detail. It is, however, important to recognize specific features or peculiarities of Aspirin's effects on cancer (**Box 1**).

Aspirin's effects on cancer are site-specific and the evidence for Aspirin's benefit is most clear and consistent for three gastrointestinal (GI) cancers, namely colorectal cancer (CRC), esophageal cancer, and gastric cancer. The magnitude of benefit is also the largest for these three GI cancers. The evidence for Aspirin's effect is somewhat less clear for the cancers of the breast, prostate, and lung; the magnitude of benefit is also much smaller than that observed for GI cancers (Cuzick et al., 2015; Thorat, 2016; Thorat and Cuzick, 2013). Although some studies report effects on other major cancer types including hepatocellular (Petrick et al., 2015; Sahasrabuddhe et al., 2012), pancreatic, endometrial (Burn et al., 2011; Zhang et al., 2016a), ovarian (Zhang et al., 2016b; Trabert et al., 2014; Baandrup et al., 2013; Ni et al., 2013), and hematopoietic tumors, this limited evidence is not consistent across study types and does not show unequivocally clear effect (Rothwell et al., 2011, 2012a; Cook et al., 2013; Jacobs et al., 2012).

Box 1 Peculiarities of Aspirin's effects on cancer

- **Site-specificity:** The effects of large magnitude seen on three GI cancers (colorectal, esophageal, and gastric); smaller effects on breast, prostate, and lung cancers.
- **Duration of use:** Effects are clearer in those who have used Aspirin for 5 years or more.
- **Lag in beneficial effects:** Effects become apparent only after 3 (for cancer incidence) to 5 years (for cancer mortality).
- **Carry-over of beneficial effects:** Effects then continue even after use is stopped; effects on mortality continue for up to at least 20 years as observed in trials with long-term follow-up, effects on incidence continue for at least up to 5 years.
- **Mechanisms of action:** The magnitude of effect on cancer mortality is larger than that on incidence suggesting that the beneficial effects on cancer mortality are mediated through different/additional mechanisms of action.

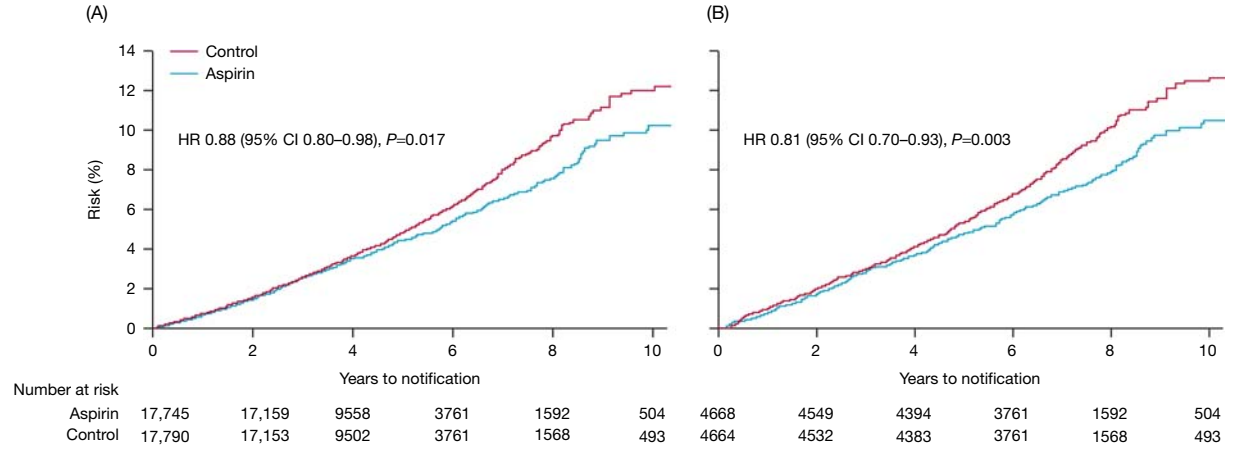

Fig. 1 Aspirin's effects are clearer in those who have used it for 5 years or more—Hazard ratio (HR) of 0.88 in all trials versus HR of 0.81 in trials with scheduled treatment duration of at least 5 years. Pooled analysis of effect of allocation to Aspirin on incidence of cancer during six randomized trials of daily low-dose (75–100 mg daily) Aspirin versus placebo in primary prevention of vascular events. (A) All patients. (B) All patients with scheduled duration of trial treatment of at least 5 years. HR = hazard ratio. Reprinted from: Rothwell, P.M., Price, J.F., Fowkes, F.G., Zanchetti, A., Roncaglioni, M.C., Tognoni, G., et al. (2012) Short-term effects of daily aspirin on cancer incidence, mortality, and non-vascular death: Analysis of the time course of risks and benefits in 51 randomised controlled trials. *Lancet* **379**(9826), 1602–1612. Copyright (2012), with permission from Elsevier.

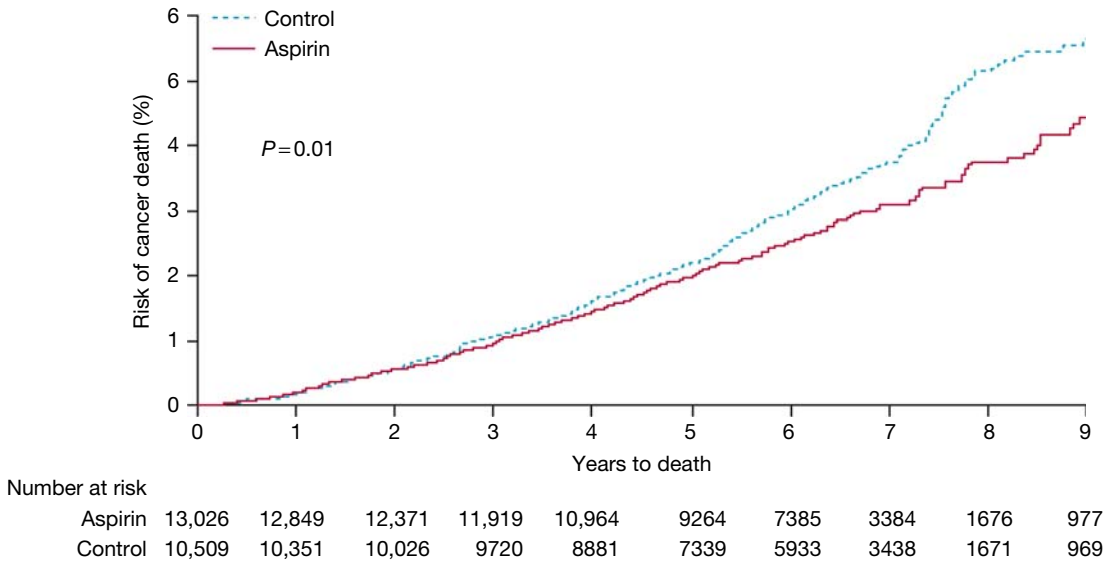
The duration of Aspirin use is important as the beneficial effects are much clearer with at least 5 years of Aspirin use (**Fig. 1**). The pooled analyses of clinical trials by Rothwell et al. (2011) show that the effect sizes are larger for the trials where scheduled treatment duration was 5 years or longer. Beneficial effects of Aspirin with a much shorter duration of 2 years of use have been reported in the CAPP2 trial, a randomized trial in Lynch syndrome carriers (Burn et al., 2011). The CAPP2 trial reported a 63% reduction in CRC incidence among those completing 2 years of treatment (Burn et al., 2011). However, this was a trial in high-risk individuals taking higher than standard doses of Aspirin (600 mg/day). The current body of evidence suggests that for an average-risk individual taking low-dose Aspirin, at least 5 years of use is necessary for modification of their cancer risk.

It is now also clear from the pooled analyses of a large number of clinical trials performed by Rothwell et al. (2011, 2012a) that Aspirin's beneficial effects on cancer are not apparent immediately and there is a lag of approximately 3 years for its effects on cancer incidence to become apparent and a lag of approximately 5 years for its effects on cancer deaths to become apparent (**Fig. 2**). The lag period for Aspirin's effects on cancer deaths can be observed from the lack of separation of Kaplan–Meier survival plots for first 5 years in **Fig. 2**. In the Women's Health Study (WHS), which used low-dose Aspirin (100 mg /day) on alternate days, the beneficial effects on CRC incidence were clearly observed only in the post-trial follow-up period as these emerged after 10 years (Cook et al., 2013). It is therefore unsurprising that the meta-analyses (Seshasai et al., 2012; Sutcliffe et al., 2013) with a short overall follow-up of 5–6 years have failed to observe a significant effect of Aspirin on cancer deaths and all-cause deaths. The apparent lack of effect with short follow-up was clearly demonstrated in analyses by Rothwell et al. (2011, 2012a), the Kaplan–Meier survival plots overlap each other in the first panel in **Fig. 3**.

Similarly, the beneficial effects continue for several years after cessation of Aspirin use (**Fig. 3**). This carry-over period lasts for at least 5 years for effects on cancer incidence and at least 10 years for effects on cancer deaths. In the pooled analyses by Rothwell et al. (2011, 2012a), the effects on cancer deaths remained constant until the end of follow-up period of at least 20 years when treatment duration in all these trials was < 10 years. **Fig. 3** shows that the Kaplan–Meier survival plots remain separated at 20 years in the trials



Number at risk

Aspirin	13,026	12,849	12,371	11,919	10,964	9264	7385	3384	1676	977
Control	10,509	10,351	10,026	9720	8881	7339	5933	3438	1671	969

Fig. 2 Lag in Aspirin's effect on cancer deaths—the separation of Kaplan–Meier survival plots starts at 5 years of follow-up. Effect of allocation to Aspirin versus control on risk of death due to cancer during the trial treatment periods in a pooled analysis of the 23,535 patients in seven trials. Reprinted from: Rothwell, P.M., Fowkes, F.G., Belch, J.F., Ogawa, H., Warlow, C.P., Meade, T.W. (2011). Effect of daily aspirin on long-term risk of death due to cancer: Analysis of individual patient data from randomised trials. *Lancet* **377**(9759), 31–41. Copyright (2011), with permission from Elsevier.

with long-term follow-up. In the WHS (Cook et al., 2013), the effects on CRC appeared only in the posttreatment period, but continued for the entire posttrial follow-up period with the total median follow-up being 18 years.

The overall evidence from observational studies, randomized trials, and meta-analyses of these studies (summarized in **Table 1** for major cancer sites) shows that the beneficial effects of Aspirin on overall cancer mortality are larger in magnitude than effects on cancer incidence (Cuzick et al., 2015; Rothwell et al., 2011, 2012a,b; Thorat and Cuzick, 2013). This suggests that in addition to modifying the process of carcinogenesis to reduce cancer incidence, Aspirin also affects other processes like cancer progression and cancer dissemination or metastasis. Therefore, at least two different, and possibly several mechanisms of action drive Aspirin's effect on cancer (discussed later).

Aspirin's Effects on Different Cancers

Colorectal cancer

A very large body of evidence shows that regular Aspirin use is associated with a reduction in CRC incidence and mortality (Thun et al., 1993; Algra and Rothwell, 2012; Bosetti et al., 2012; Rothwell et al., 2010, 2011, 2012a; Burn et al., 2011; Cook et al., 2013; Jacobs et al., 2012; Chan et al., 2007a, 2008; Ratnasinghe et al., 2004; Rothwell, 2013; Cao et al., 2016; Chubak et al., 2015). Pooled results of case-control studies (Algra and Rothwell, 2012; Bosetti et al., 2012) show almost 40% reduction in CRC incidence whereas the pooled analyses of cohort studies show a smaller effect size with approximately 20% reduction (**Table 1**). The overall reduction in CRC incidence observed in pooled analyses of randomized trials (Rothwell et al., 2010) is approximately 25%, with 38% reduction in trials with scheduled treatment duration of 5 years or more. In the WHS (Cook et al., 2005, 2013), no effect was observed for the first 10 years of the trial, and 42% reduction in CRC incidence was observed in the posttrial period with 100 mg alternate day Aspirin use.

The pooled analyses of cohort studies (Thun et al., 1993; Jacobs et al., 2012; Ratnasinghe et al., 2004) show that the magnitude of Aspirin's effect on CRC death is larger than that on CRC incidence with approximately 35% reduction in CRC deaths observed. The pooled analyses of RCTs also report similarly larger effect on CRC deaths, with almost 50% reduction observed in trials with scheduled treatment duration of 5 years or more (Rothwell et al., 2010). A semi-quantitative summary of Aspirin's effects on CRC incidence and deaths is given in **Table 2**.

Larger reductions have also been observed in individuals at high risk of colorectal cancer such as those with Lynch syndrome (Burn et al., 2011). A 63% reduction in CRC incidence was observed among those completing 2 years of 600 mg daily Aspirin in the CAPP2 trial (Burn et al., 2011). Similarly, reduction in the colorectal adenoma risk or recurrence risk of adenoma with Aspirin use has been observed (Cole et al., 2009; Veettil et al., 2017; Zhao et al., 2016).

Esophageal cancer

Pooled analyses of case-control studies (Algra and Rothwell, 2012; Bosetti et al., 2012) show almost 45% reduction in the incidence of esophageal cancer with Aspirin use whereas approximately 25% reduction is observed in cohort studies (**Table 1**). The effects do

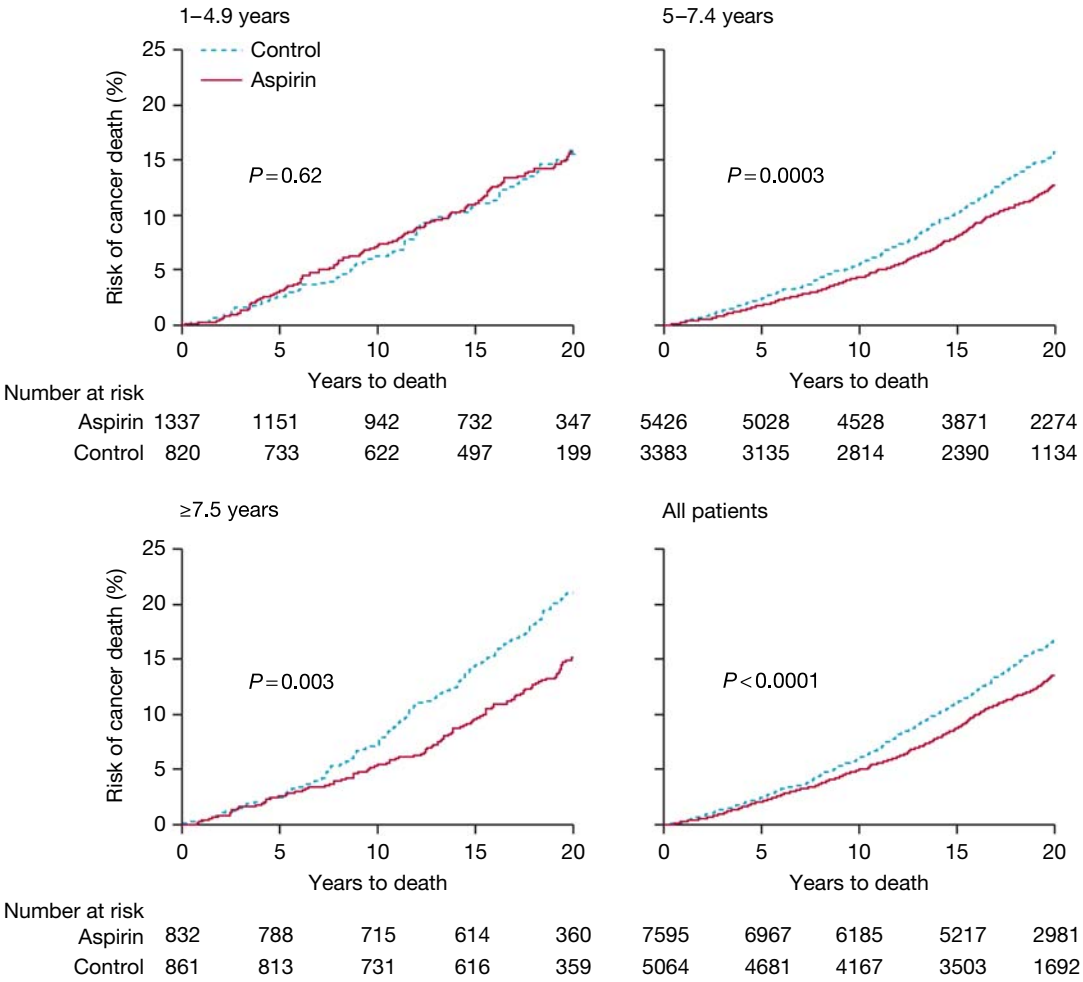


Fig. 3 Carry-over of Aspirin's beneficial effect on cancer deaths—the Kaplan–Meier survival plots remain separated at 20 years of follow-up. Effect of allocation to Aspirin versus control on 20-year risk of death due to any solid cancer stratified by scheduled duration of trial treatment in three trials with long-term follow-up. ‡Number of lethal prostate cancers, that is any metastatic prostate cancer or prostate cancer death.

Table 2 A semi-quantitative summary of site-specific effects of Aspirin on cancer incidence and mortality (reductions in percentages)

	Incidence	*Mortality*
Cancer site	*Reduction*	*Reduction*
Colorectal cancer	30%–35%	35%–40%
Esophageal cancer	25%–30%	45%–50%
Gastric cancer	25%–30%	30%–35%
Lung cancer	0%–5%	10%–15%
Breast cancer	5%–10%	0%–5%
Prostate cancer	5%–10%	10%–15%

not differ by histology; similar reductions have been reported for squamous cell esophageal cancers (39%) and adenocarcinomas (36%) including gastric cardia (Bosetti et al., 2012). The benefit of Aspirin in reducing esophageal cancer deaths has been approximately 40% in cohort studies and almost 60% in RCTs (Rothwell et al., 2011), although the latter is based on a relatively smaller number of events.

Gastric cancer

Similarly larger effect sizes in case-control studies than cohort studies (Algra and Rothwell, 2012; Bosetti et al., 2012), a reduction of approximately 40% and 25% respectively, have also been seen for incidence of gastric cancer (**Table 1**). More recent meta-analyses also demonstrate similar significant reductions (Huang et al., 2017). Nonsignificant 31% reduction in gastric cancer deaths ($P = 0.11$), mostly contributed by a delayed (after 10 years) reduction of 58% ($P = 0.007$), has been observed in RCTs (Rothwell et al., 2011). Cohort studies show a 41% reduction in gastric cancer mortality (Thun et al., 1993; Ratnasinghe et al., 2004).

Breast cancer

No effect on breast cancer incidence was seen in the first analysis of WHS (Cook et al., 2005), or after a longer 17.5-year follow-up (Cook et al., 2013). However, approximately 18% reduction in breast cancer incidence in case-control studies and approximately 10% reduction in cohort studies (Algra and Rothwell, 2012; Bosetti et al., 2012) has been reported (**Table 1**). More recent meta-analyses of cohort studies (Lu et al., 2017), case-control and cohort studies (Zhong et al., 2015a), and all types of studies including RCTs (Luo et al., 2012) show a reduction in breast cancer incidence to the tune of 10%. Similar small reductions in breast cancer mortality of 5% in a case-control study (Chan et al., 2007a) and 14% in cohort studies have also been observed (Thun et al., 1993; Ratnasinghe et al., 2004). Meta-analyses of observational studies (Zhong et al., 2015b) showed almost 20% reduction in breast cancer mortality in sensitivity analyses carried out to control heterogeneity. Results from RCTs (Algra and Rothwell, 2012) are unreliable due to a small number of events ($n = 23$).

Lung cancer

Pooled analyses of case-control studies show approximately 20% reduction in the incidence of lung cancer, but no reduction was observed in cohort studies (Algra and Rothwell, 2012; Bosetti et al., 2012). More recent meta-analyses (Hochmuth et al., 2016; Xu et al., 2012; Jiang et al., 2015) report similar reductions; however, a meta-analysis by McCormack and colleagues reported benefit only in men (McCormack et al., 2011), a finding also reported by Jiang et al. (2015).

Similar trends for the reduction in lung cancer mortality, that is approximately 10% reduction (nonsignificant) in case-control studies and no overall effect in cohort studies (Thun et al., 1993; Jacobs et al., 2012; Ratnasinghe et al., 2004) have been reported. However, data from the first and second National Health and Nutrition Examination Study studies (Ratnasinghe et al., 2004) show a significant 31% reduction in lung cancer deaths among men and no effect in women. Similar reduction of 29% has also been reported in pooled analyses of RCTs (Rothwell et al., 2011).

Prostate cancer

The effect of Aspirin on prostate cancer incidence is also small like that on breast cancer incidence. Several meta-analyses have now pooled data from various observational studies and RCTs to generate estimates of Aspirin's effect on prostate cancer incidence, incidence of advanced prostate cancer, and prostate cancer deaths; these have been summarized in **Table 3**. In general, case-control studies report a larger reduction in prostate cancer incidence, as compared with cohort studies (Algra and Rothwell, 2012; Bosetti et al., 2012) and an overall reduction of 5%–10% in prostate cancer incidence in all users is reported in observational studies. A larger benefit, a reduction of 8%–18%, is seen with Aspirin use of 5 years or more and a larger effect is also seen on advanced prostate cancer, incidence of which is reduced by 12%–19%. The reductions observed in RCTs are larger, above 20%, but statistically not significant. Prostate cancer deaths are reduced by 11%–12% in observational studies and by almost 20% in RCTs; the latter benefit is however statistically not significant.

Table 3 Summary of meta-analyses evaluating effects of Aspirin on prostate cancer incidence and mortality

Author	*Year*	*Studies included*			*Total prostate cancer incidence*	
		Case control (n)	Cohort (n)	RCTs (n)	All users	Longer duration

[a]Metastatic prostate cancer; Risk estimates are relative risks (RR) for meta-analyses of observation studies and Hazard ratios (HR) for meta-analyses of RCTs.

Aspirin as an Adjuvant Treatment

The potential role of Aspirin in cancer treatment has been discussed in detail elsewhere (Langley et al., 2011) and more recent studies provide further evidence to support evaluation of Aspirin as an adjuvant treatment. It is clear from the larger effect sizes of Aspirin's benefit on cancer deaths than cancer incidence that it prevents cancer progression or metastasis after the cancer has developed. Aspirin's effects in reducing cancer recurrence risk have particularly been reported for breast cancer and CRC. A meta-analysis of observational studies (Huang et al., 2015) reported improved breast cancer survival with postdiagnostic Aspirin use (Holmes et al., 2010). A recent cohort study (Cronin-Fenton et al., 2016) based on the Danish Breast Cancer Cooperative Group registry however reported that only prediagnostic Aspirin use reduced the risk of recurrence. Prediagnosis (Coghill et al., 2011) or postdiagnosis (Bastiaannet et al., 2012; McCowan et al., 2013; Goh et al., 2014) Aspirin use is associated with an improved CRC survival (Ng et al., 2015), particularly in CRC with *PIK3CA* mutation (Liao et al., 2012; Domingo et al., 2013) or COX-2 overexpression (Chan et al., 2007b) or wild-type BRAF tumors (Frouws et al., 2017), although lack of such association has also been reported (Murphy et al., 2017). Several trials (**Table 4**) are currently investigating the adjuvant role of Aspirin in treatment of cancers, for example, ASCOLT trial (Ali et al., 2011) in CRC, the ABC trial (Chen et al., 2017) in breast cancer and ADD-Aspirin trial (Langley et al., 2011; Coyle et al., 2016) in a range of cancers including colorectal, gastro-esophageal, breast, and prostate cancer. Several other trials are being planned, for example, AIDA and SAKK 41/13 trials in CRC, latter in patients with *PIK3CA* mutation.

Aspirin as Preventive Therapy in General Population

Benefit–Harm Analyses

Aspirin has now been used for secondary prevention of CVD for >3 decades but its role in primary prevention of CVD has remained controversial (Baigent et al., 2009; Preventive Services, 2009). However, data from pooled analyses of trials by Rothwell et al. (2011, 2012a) demonstrated that the main significant benefit of Aspirin in general population is reduction in cancer deaths and not reduction in vascular deaths. Therefore, it is necessary to consider Aspirin's effects on all diseases including cancer and CVD when considering its role as preventive therapy in general population. We carried out first such comprehensive analyses (Cuzick et al., 2015) using actual population level data (Thorat and Cuzick, 2015) to model Aspirin's benefits and harms. Instead of numerically equating minor (e.g., nosebleed) and major (e.g., hemorrhagic stroke) harms, these analyses, for the first time took severity of harms into account (Cuzick et al., 2015). Furthermore, as another first, these analyses also employed a modeling approach (similar to a Markov model) that took in to account peculiarities of Aspirin's effects like lag and carryover of benefits (Thorat, 2016) (**Fig. 4**).

Our benefit–harm analyses (Cuzick et al., 2015) show a net benefit for average-risk individuals aged 50–65 years taking Aspirin for 10 years. In such individuals, there would be a relative reduction of between 7% (women) and 9% (men) in the number of cancer, myocardial infarction, or stroke events over a 15-year period and an overall 4% relative reduction in all deaths over a 20-year period; the main benefits being driven through reduction in cancer incidence (**Fig. 5**) and cancer deaths (**Fig. 6**). These

Table 4 Ongoing trials of Aspirin

Trial name	*Comparison*	*Sample size*	*Participants*
Target population: general population			
ASPREE (NCT01038583)	100 mg Aspirin versus Placebo	19,000	People over 65 years of age
ARRIVE (NCT00501059)	100 mg Aspirin versus Placebo	12,551	Individuals with 10-year CHD risk of approx. 10%–20%
ACCEPT-D (ISRCTN48110081)	100 mg Aspirin versus None	5170	Individuals with type one or type two diabetes with no clinical evidence of vascular disease and receiving statins—Simvastatin (starting dose 20 mg/d)
ASCEND (NCT00135226)	2 × 2 Factorial design A. 100 mg Aspirin versus placebo B. 1 g of omega-3-Ethyl Esters versus placebo	15,480	Patients with diabetes who are not known to have occlusive arterial disease
Target population: High-risk individuals			
CaPP3 (NCT02497820)	600 mg versus 300 mg versus 100 mg of enteric coated Aspirin	3000	Carriers of a germline pathological mismatch repair gene defect, Lynch Syndrome
AspECT (NCT00357682)	2 × 2 Factorial design (A) 300 mg Aspirin versus none (B) 20 versus 80 mg Esomeprazole	2513	Patients with Barrett's metaplasia
Target population: Cancer patients – adjuvant setting			
ADD-Aspirin (ISRCTN74358648)	Aspirin 300 mg versus 100 mg versus placebo	Total: 9920 Breast (3100), Colorectal (2600), Gastro-esophageal (2100), Prostate (2120)	Adjuvant treatment after primary therapy in nonmetastatic breast, colorectal*, gastro-esophageal, and prostate cancers
ASCOLT (NCT00565708)	200 mg Aspirin versus Placebo	1200	Patients with Dukes' C or high risk Dukes' B colorectal cancer.
APREMEC (NCT02607072)	Aspirin 200 mg versus 100 mg versus placebo	3000	Stages I–III colorectal cancer completely removed with R0 resection margin
ASPIRIN (NCT02301286)	80 mg Aspirin versus Placebo	1588	Stage II and III colon cancer patients of 45 years of age and older
ALASCCA (NCT02647099)	160 mg Aspirin versus Placebo	816 Patients screened – 3900	Stages I–III colorectal cancer with *PIK3CA* mutation (exon 9 and 20) or with mutations in other PI3K pathway genes PIK3CA (other than exon 9 and 20), PIK3R1 or PTEN
SAKK 41/13 (NCT02467582)	100 mg Aspirin versus Placebo	185	Stages II–III completely resected (R0) colon cancer with *PIK3CA* mutation (exon 9 and 20); rectal cancer excluded
The ABC Trial (NCT02927249)	300 mg Aspirin versus Placebo	2936	Early stage node-positive HER2 negative breast cancer patients
Target population: cancer patients—primary therapy setting			
PROVENT (ISRCTN91422391)	3 × 2 Factorial design (A) Aspirin 300 mg versus 100 mg versus placebo (B) Vitamin D3: 4000 IU/d versus placebo	Feasibility phase	Men on active surveillance for prostate cancer

*Includes fully resected metastatic colorectal cancer.

main analyses assumed beneficial effects on six cancers discussed above; however, sensitivity analyses assuming effects on only three GI cancers (esophageal, gastric, and colorectal) or CRC alone [Supplement in Cuzick et al. (2015)] also show net benefit with Aspirin use. The absolute benefit of Aspirin in an individual is dependent on sex and age at which Aspirin use is started since the baseline risks differ by age and sex. These analyses (Cuzick et al., 2015) show that 1 death would be prevented if 47 men aged 65 or 213 women aged 50 took Aspirin for 10 years, a much larger absolute benefit in older men since the baseline cancer and CVD risks are much higher in older men as compared with younger women. We also estimated that the net benefit could be further improved by reducing the risk of some of the harms like peptic ulcer or GI bleeding by almost a third through eradication of *Helicobacter pylori* infection (Thorat and Cuzick, 2015) which is still substantially prevalent in older cohorts of men and women in the developed world.

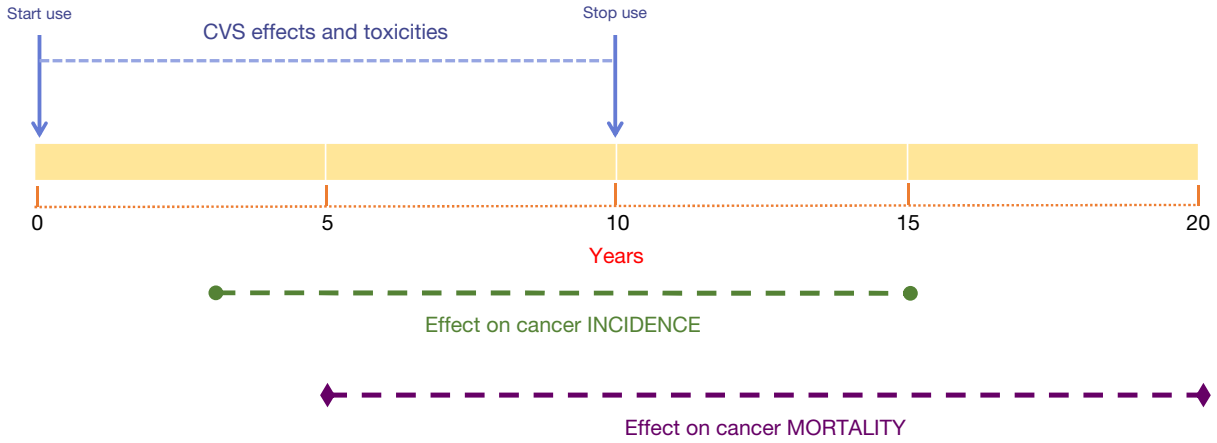

Fig. 4 Aspirin's effects in general population—Modeling to account for lag and carryover effects.

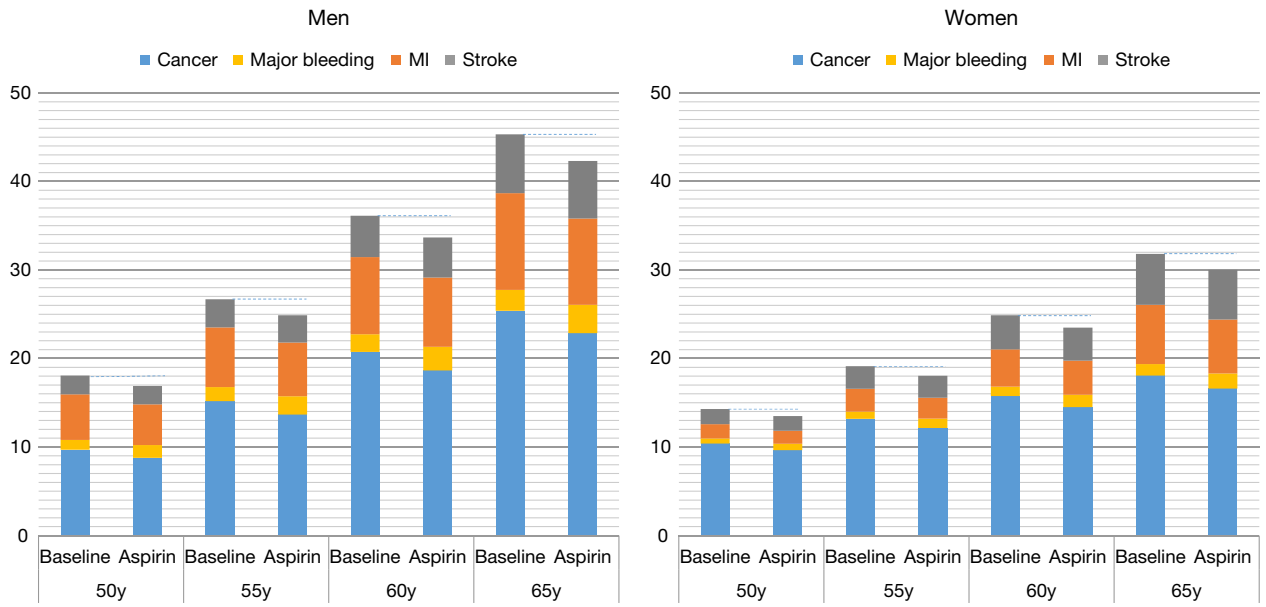

Fig. 5 Aspirin's effects in general population—reduction in incidence of major events over a 15-year period with 10 years of Aspirin use. *Y*-axis—events in a proportion (%) of individuals with or without Aspirin; *MI*—Myocardial infarction.

Health Economics

Full economic evaluation of Aspirin as a preventive therapy in general population remains to be done. Our benefit–harm analyses (Cuzick et al., 2015) assuming effects on only three GI cancers (esophageal, gastric, and colorectal) show that if everyone in the UK aged 50–64 (UK population year 2013) took Aspirin for 10 years, every year, approximately 5900 GI cancers and 4000 heart attacks or strokes will be prevented whereas approximately 2800 extra major bleeding events will be caused. Aspirin will also prevent approximately 3500 deaths every year. Aspirin, being a generic medicine, is available at a low cost of £3/per year per person (Joint Formulary Committee, 2016). Using economic costs of cancer and CVD reported in the British Heart Foundation report (British Heart Foundation, 2013), we estimate that such Aspirin use will result in a net healthcare cost savings of at least £76 million every year. Bupa report (Macdonald, 2011) estimated the average per cancer treatment cost to be £30,000, which is expected to increase to £40,000 by year 2021 (Choices, 2011). Calculations using these higher per cancer costs show that Aspirin use will potentially save the UK National Health Service up to £157 million every year and these annual savings could increase to £216 million by the year 2021. A thorough economic evaluation of Aspirin as a preventive therapy in general population is a research priority but these estimates demonstrate that with ever increasing cancer care costs in the healthcare systems in the developed world, Aspirin has a potential to be a highly cost-effective preventive intervention in the general population.

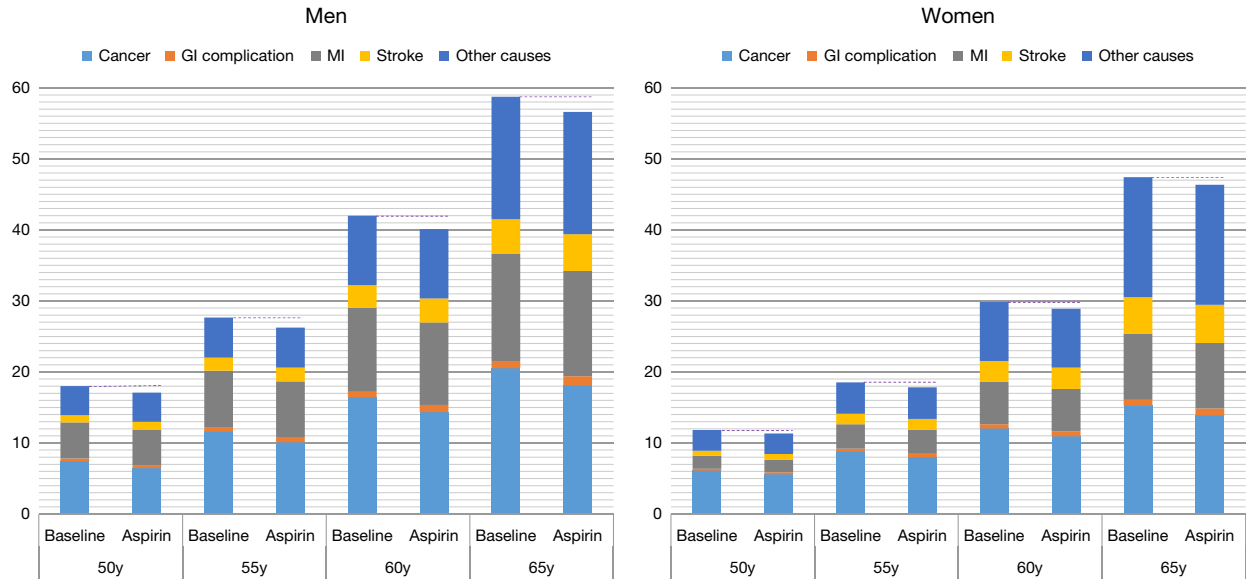

Fig. 6 Aspirin's effects in general population—reduction in deaths over a 20-year period with 10 years of Aspirin use. *Y*-axis—events in a proportion (%) of individuals with or without Aspirin; *MI*—Myocardial infarction; *GI*—Gastrointestinal.

Guidelines

Uncertainty regarding Aspirin's benefits for the primary prevention of CVD (Baigent et al., 2009), and oligo-dimensional approach (Thorat, 2016) taken by various guideline producing organizations resulted in divergent recommendations (Vandvik et al., 2012; Force, 2007, 2009; Perk et al., 2012). However, after our comprehensive analyses, the U.S. Preventive Services Task Force (USPSTF) also adopted a similar approach and resultantly, their recommendations (Bibbins-Domingo and Force, 2016) changed in favor of Aspirin use as a preventive therapy. The USPSTF now recommends initiating low-dose Aspirin use for the primary prevention of CVD and CRC in adults aged 50–59 years who have a 10% or greater 10-year CVD risk (Bibbins-Domingo and Force, 2016). There are currently no recommendations regarding Aspirin as an adjuvant therapy in cancer as it is a subject of active investigation.

GI Cancer Prevention—Aspirin and Screening

A recent systematic review by Emilsson and colleagues (2017) reported that Aspirin was more effective than Fecal Occult Blood Test (FOBT) screening [RR 0.36; 95% predictive interval (PrI) 0.22–0.59] and flexible sigmoidoscopy (FlexiSig) screening (RR 0.37; 95% PrI 0.22–0.62) in preventing new diagnosis of cancer or death from cancer in the proximal colon. Overall, Aspirin was equally effective as FOBT and FlexiSig screening in reducing CRC incidence and mortality. Authors concluded that a randomized comparative effectiveness trial of Aspirin versus screening is warranted (Emilsson et al., 2017). However, FlexiSig, although highly effective for CRC screening, has poor sensitivity for proximal colon lesions (Lin et al., 2016). Aspirin, on the other hand, has much greater effect on incidence of proximal CRC, and mortality from proximal CRC (Rothwell et al., 2010). Therefore, FlexiSig screening and Aspirin as a preventive therapy could prove complementary to each other. Furthermore, an observational study (Brenner et al., 2010) has shown that Aspirin increases sensitivity of Fecal Immunochemical Test. Therefore, even this method of CRC screening and Aspirin could prove complementary to each other in preventing CRC mortality. In summary, instead of evaluating comparative effectiveness of Aspirin versus screening as Emilsson and colleagues (2017) suggest, research to evaluate combined impact of these two methods of CRC prevention and research to facilitate adoption of such combined approach is required.

Mechanisms of Aspirin Action

Aspirin's effects on CVD and cancer are very clear from epidemiological data; however, the mechanisms underpinning these effects barring the antiplatelet mechanism are far from clear. Aspirin's pharmacological effects range from antiplatelet action at low doses to antiinflammatory action at high doses and several new mechanisms of action continue to be discovered.

Prostanoid Synthesis

Enzyme Prostaglandin H Synthase (PGHS) or Cyclooxygenase metabolizes arachidonic acid to synthesize prostanoids which are tissue-specific lipid compounds involved in signaling. Prostanoids include Prostaglandin (PG) D_2, E_2, $F_{2\alpha}$, Thromboxane A_2

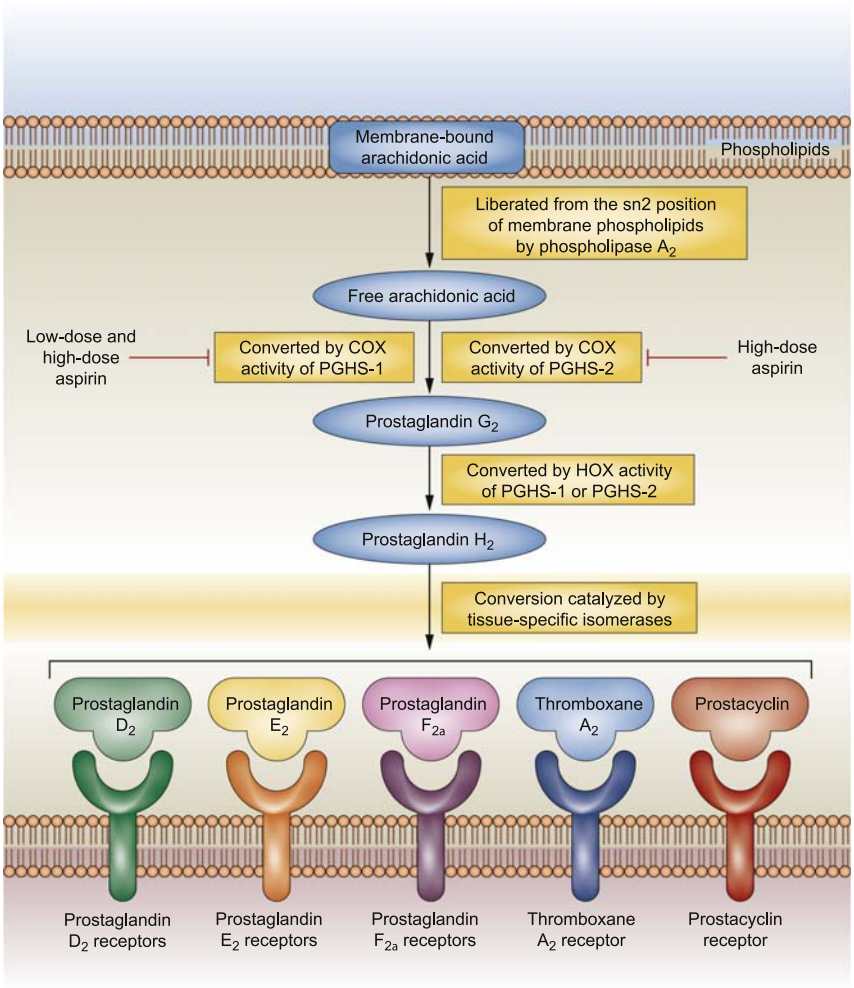

Fig. 7 Prostanoid synthesis. Reprinted from: Thun, M.J., Jacobs, E.J., Patrono, C. (2012). The role of aspirin in cancer prevention. *Nature Reviews. Clinical Oncology* **9**(5), 259-267. Copyright (2012), with permission from Macmillan Publishers Limited.

(TXA_2), and prostacyclin (PGI_2). PGHS has two major isoforms, COX-1 and COX-2. COX-1 is constitutively expressed in most tissues while COX-2 expression is tissue-specific, for example vascular endothelium, brain, and kidney (Fig. 7).

Aspirin irreversibly inactivates both COX-1 and COX-2. However, the level of inhibition of activity is dependent on bioavailability of Aspirin in the target tissue and de novo enzyme synthesis that leads to recovery of COX activity (Pedersen and FitzGerald, 1984).

Antiplatelet Action

Mature platelets only express COX-1. Platelet COX-1 is involved in synthesis of TXA_2, which has a central role in platelet aggregation. Vascular endothelium, on the other hand, expresses COX-2 involved in PGI_2 synthesis (Patrono et al., 2005). Aspirin inhibits both COX-1 in platelets and COX-2 in vascular endothelium. While enzymatic activity in vascular endothelium (COX-2) recovers through de novo enzyme synthesis, COX-1 activity in platelets does not recover since mature platelets lack nuclei and therefore cannot synthesize COX-1 enzyme (Pedersen and FitzGerald, 1984). Furthermore, platelets also pass through portal circulation where Aspirin concentration is much higher than that in systemic circulation (Zhou et al., 2011). The net result is inactivation of platelets in systemic circulation even at low doses of Aspirin whereas vascular endothelial function continues as normal at low doses. Therefore, doses as low as 30 mg Aspirin per day have very transient and minimal effects on nonplatelet targets but result in significant cardio-protective antiplatelet effects.

Antiinflammatory Action

Aspirin has a very short half-life of 15–20 min as it is metabolized rapidly during its first-pass through liver and also by plasma esterases (Zhou et al., 2011). As a result, achieving and maintaining sustained COX-1 and COX-2 enzyme inhibition in nucleated

cells that are capable of de novo enzyme synthesis requires frequent dosing (3–4 times per day) and a large cumulative dose (around 2000 mg per day). At these doses, Aspirin has effect on nucleated cells driving inflammatory response resulting in its antiinflammatory action. Sustained inhibition of prostanoid synthesis is necessary for this action, but several other mechanisms including inhibition of protein kinase IkB kinase β (IKKβ) in the NF-kB pathway (Yuan et al., 2001) and Aspirin-triggered 15-epi-lipoxins (Serhan, 2005) are also involved.

Analgesic Action

Analgesic effects of Aspirin appear to be dose-dependent (McQuay and Moore, 2007) and these are also thought to be mediated through several mechanisms (Smith, 2012).

Anticancer Action

Aspirin has a larger effect on cancer deaths than that on cancer incidence. This means that apart from carcinogenesis, it also affects cancer progression and metastasis. While the effects of Aspirin on cancer are clear, the mechanisms are not clear yet. The most accepted among several hypotheses is that anticancer action is mediated through COX-2 inhibition (Chan et al., 2012; Thun et al., 2002). This hypothesis however cannot explain unequivocal anticancer effects of Aspirin that occur at low dose (Rothwell et al., 2010, 2011, 2012a). On the other hand, as proposed by Thun and colleagues (2012), Aspirin may prevent platelet-mediated COX-2 induction and downstream signaling at the site of intestinal mucosal injury and hence increase apoptosis, reduce proliferation and angiogenesis. While this hypothesis of abrogation of platelet-mediated COX-2 induction preventing carcinogenesis remains to be proven, a recent study by Patrignani and colleagues (2017) has demonstrated that low-dose Aspirin is capable of acetylating COX-1 enzyme in colorectal mucosa and thereby reducing PGE_2 synthesis as well as phosphorylation of S6 despite of low bioavailability due to rapid first-pass metabolism. Therefore, it is possible that Aspirin acts through both COX-1 and COX-2 mediated pathways in preventing carcinogenesis at low doses. Furthermore, low-dose Aspirin's ($\leq$100 mg/day) antiplatelet effect may reduce direct interaction of platelets with cancer cells, the so-called platelet chaperoning (Rothwell et al., 2012b), and thus prevent metastasis (Gasic et al., 1968, 1972). These mechanisms are compatible with low-dose Aspirin's effects in preventing carcinogenesis as well as cancer metastasis.

Several other mechanisms of Aspirin action have been proposed, although these require higher drug concentrations than those achieved by low-dose Aspirin (Shaw and Cantley, 2012). Additional potential mechanisms of Aspirin action, many previously listed by us (Thorat and Cuzick, 2013), include inhibition of NF-kB (Chan et al., 2007b), induction of polyamine catabolism (Hubner et al., 2008), inhibition of mTOR signaling (Din et al., 2012) and activation of AMP-activated protein kinase (Din et al., 2012; Hawley et al., 2012), effects on PI3-kinase pathway (Liao et al., 2012), particularly in *PIK3CA*-mutants (Zumwalt et al., 2017) or its cross-talk with COX-2 (Kaur and Sanyal, 2010; Uddin et al., 2010) and induction of apoptosis through other pathways (Dikshit et al., 2006; Lu et al., 2008). Although Aspirin's anticancer effects at a low dose are clear, the relationship between Aspirin's dose and its anticancer effects is not clearly understood (discussed below). It is possible that different mechanisms are activated at different doses and higher Aspirin doses may confer greater anticancer benefit.

Ongoing Trials

Several trials (**Table 4**) are already underway or due to start evaluating Aspirin in general population, or high-risk individuals or as a cancer treatment. >50,000 individuals have been recruited in the trials in general population and these are expected to report their first results by year 2020. Approximately 8000 high-risk individuals will also have been recruited in Aspirin trials over next few years. Approximately 20,000 cancer patients will also enter Aspirin trials in the next few years. Data from these approximately 80,000 Aspirin trial participants will help us understand Aspirin's effects and mechanisms in a much better manner; however, a word of caution is due at this stage. Aspirin's effects on cancer are not apparent for at least first few years and therefore, early trial reports with short follow-up need to be carefully interpreted. Furthermore, all trials should be followed up for a sufficiently long period, preferably for at least 10 years after cessation of treatment.

Research Priorities

We have previously identified duration of Aspirin use and optimum dose as important research questions (Cuzick et al., 2015; Thorat and Cuzick, 2013, 2015) for most effective use of Aspirin for prophylaxis in general population.

Aspirin needs to be consumed for at least 5 years to derive anticancer benefit and the benefits continue for several years after cessation of Aspirin use. While it seems prudent to stop Aspirin use by age of 70 years to minimize bleeding harms which rise sharply after 70 (Thorat and Cuzick, 2015), the optimum duration of Aspirin use and upper age of stopping is not clear and therefore an important research question.

As mentioned above, the relationship between Aspirin dose and anticancer effect is also not clear. An indirect comparison of RCTs shows that increasing dose does not confer a greater reduction in cancers (Rothwell et al., 2010) or adenomas (Baron

et al., 2003). However, observational studies (Chan et al., 2008; Friis et al., 2003) have reported that reductions in advanced adenomas are greater with the higher dose (Cole et al., 2009) and significant effects of Aspirin with doses above 300 mg. Furthermore, CAPP2 trial used 600 mg Aspirin dose in high-risk individuals and reported a much larger effect on CRC than in other RCTs (Burn et al., 2011). CAPP3 trial (**Table 4**) is hence evaluating different Aspirin doses, but in high-risk individuals. Since it is possible that different mechanisms get activated at different dose levels of Aspirin, a particular dose may confer greatest anticancer benefit. The linearity of relationship between Aspirin's harms and dose is also not clearly established (Thorat and Cuzick, 2015). Therefore, identifying optimum dose of Aspirin at which its net benefit is the highest is an important research priority.

All the ongoing trials in general population setting are using low dose of Aspirin and none of these is evaluating duration of Aspirin use. Furthermore, all of the trials except ASPREE are in individuals at a risk higher than average. Therefore, dose and duration of Aspirin use in average-risk general population still remain important research questions that need to be addressed in a trial in an average-risk general population.

Lastly, mechanisms underpinning Aspirin benefit are poorly understood and a greater understanding of these mechanisms will not only allow us to use this drug in a more effective manner but also lead to the development of additional cancer therapy options. Bio-specimens from the participants in ongoing and future trials will help greatly in this quest. The need for effective use of bio-specimens from Aspirin trials and long-term follow-up of these trials cannot be overemphasized.

Conclusions

Aspirin has a range of beneficial effects on cancer and it reduces incidence and mortality from three GI cancers, namely colorectal, esophageal, and stomach as well as from lung, breast, and prostate cancer although the effects of these non-GI cancers are less clear and the magnitude of benefit is much smaller. Aspirin's effects on cancer are not immediately apparent but continue for several years after cessation of use. Aspirin, taken as preventive therapy for at least 5 years by men and women aged 50–70 years from developed world, will provide net health benefits primarily its effects on cancer. Aspirin also has a potential role as an adjuvant treatment in cancer and this is currently being evaluated in several trials. Further research to determine optimum dose and duration of Aspirin use and to elucidate its mechanisms of action is needed.

Ataxia Telangiectasia Syndrome☆

Palak R Parekh, University of Maryland, Baltimore, MD, United States
France Carrier, University of Maryland, Baltimore, MD, United States

Glossary

Ataxia The loss of muscular coordination.
Autosomal Any chromosome except X and Y.
Homozygote An individual carrying two of the same allele (one from each parent) in a particular loci.
Linear energy transfer (LET) The energy absorbed by the medium through which an ionizing particle is traveling per unit length of the track of the particle, usually expressed in keV μ^{-1}.
Recessive The allele phenotype that is obscured in a heterozygote individual by the dominant allele.
Telangiectasia The dilatation of peripheral blood vessels.
Tumor suppressor A gene product preventing the transformation of normal cells to tumor cells.

Clinical Aspects

Clinical Symptoms

AT disease was first reported by Syllaba and Hellner in 1928 and described by Boder& Sedgwick later on. Its prevalence is not restricted to any geographical region or ethnic group (Hoche et al., 2012); having an incidence rate of 1–2.5 in 100 000 (Palau and Espinos, 2006). Two symptoms, cerebellar ataxia and oculocutaneous telangiectasia, are considered the minimal criteria for a positive diagnosis of the ataxia telangiectasia disease. The ataxia, due to primary neuronal degeneration, progresses steadily and typically results in the patient's confinement to a wheelchair by early adolescence. Telangiectasia in or around the eyes usually develops between 3 and 6 years of age and later spreads in a symmetrical pattern to the eyelids, face, ears, and neck, and in particular sunlight-exposed and friction areas of the skin. Apart from neurodegeneration and vasodilations (ocular and dermal telangiectasia), AT shows a number of other clinical manifestations like pulmonary infections, predisposition to cancer- lymphoma or leukemia, insulin-resistant diabetes, immunodeficiency, radiation sensitivity, sterility (gonadal dysfunction), mild hepatitis, growth retardation and premature aging (Ambrose and Gatti, 2013). The high secretion of alpha-fetoprotein is a hallmark of AT disease, often used as one of the diagnostic parameter to confirm the disease. The life span of AT patients is less than 20–30 years though an exception was reported for a 48 years old AT patient harboring ATM deleterious variants that were not null mutations (Davis et al., 2013). The major AT clinical conditions are described below (**Figure 1**).

Neurodegeneration

Neurodegeneration is the most prominent feature of the AT disease that manifest as early as 6 to 18 months of age and progress steadily over time (McKinnon, 2012). Children with AT learn to walk at a normal age but start showing truncal swaying, abnormal gait, muscle hypotonia and dyssynergia early on. All these symptoms lead to patients' dependency on a wheel chair before the end of the first decade of life. Based on the various neuropathological anomalies, AT can be classified as a primary neuronal degeneration. Primary neuronal degeneration is a progressive disease characterized by the premature death of neurons in the absence of pathological evidence of a specific cause. The neurological abnormalities in AT include progressive cerebellar ataxia, dysarthric (slurring) speech, movements of the extremities, peculiar eye movements called oculomotor dyspraxia, hyporeflexia or areflexia, and apparent arrest of cognitive development. The uncontrolled jerk movements and tremors become evident at later stage (after 12 years of age) (Carrier and Fornace, 2002) (McKinnon, 2012). At the autopsy, a marked atrophy of the cerebellar cortex primarily due to degeneration of the Purkinje and granular cells and, to a lesser extent, of basket cells is also observed. Eventually, the posterior and lateral columns of the spinal cord degenerate and the anterior horn cells are lost. There are exceptions to this phenotype since in some cases of AT, patients showed atypical slow progression lacking the characteristic early onset of an abnormal gait (Carrillo et al., 2009). Those milder forms of AT are often associated with ATM mutations that retain some low levels of ATM protein kinase activity and consequently functionality.

☆*Change History:* April 2015. Parekh and Carrier updated the text in the cellular and molecular sections to reflect the newly described ATM functions in the cytosol and they added the new ATM targets associated with neurodegeneration. Moreover the use of human neuronal stem cells to study the molecular mechanisms of neurodegeneration in AT are presented in the Future Directions. A revised Figure 2 and a new Figure 3 have been added to reflect these changes. This article is an update of Palak R. Parekh, France Carrier, Ataxia Telangiectasia Syndrome, In Encyclopedia of Cancer (Second Edition) edited by Joseph R. Bertino, Academic Press, 2002, Pages 153–164.

Cancer predisposition

The risk of developing malignancy in AT patients is about 1200-fold greater than that of an age-matched control population. The incidence of new cancer from age 10 on is estimated to be 1 in 10 patients each year. Cancer is therefore observed several years after the initial neurologic disorders have started to take their toll on the AT patients. The vast majority of the AT malignancies, more than 85%, are acute lymphocytic lymphoma or leukemia. Other cancer predispositions have also been noticed in at least 38% of the patients; carcinomas of the breast, stomach, liver, pancreas, ovary, oral cavity, and salivary gland have been reported. Early studies have suggested an increased cancer predisposition in AT heterozygotes. The cancer most often associated with single gene carriers of this disease is breast cancer. Carriers of ATM mutations have a 2–7-fold increased risk of developing breast cancer. The increased risk is presumably associated with loss of heterozygosity, sporadic loss of the normal ATM allele resulting in either total loss of or a large reduction in functional ATM protein. The risk of AT heterozygotes to develop breast cancer has been calculated at 11% by age 50 and at 30% by age 70. Since heterozygote cells in culture also show some sensitivity to radiation, it is possible that doses of radiation too small to produce any cancer risk in noncarriers induce cancer in heterozygotes.

Immunodeficiency & lung disease

The most consistent abnormality of the AT immune system is that invariably the thymus fails to develop normally, resembling an embryonic stage of development, and sometimes is even totally absent. Defects in both cellular or humoral immune system can occur. Because of immunodeficiency, frequent sinopulmonary infections are common mainly due to ataxia and swallowing difficulties. Severe recurrent lung infections are often the major cause of death in the affected patients. Recent studies with improved diagnosis of the lungs without using radiation, have found that whether AT patients show pulmonary infection symptoms or not, they have abnormal lungs (Montella et al., 2013). Immunodeficiency also leads to non-Hodgkin lymphoma. The basic reason for these above varied patho-physiological condition is disturbed B and T cells homeostasis (Driessen et al., 2013). Humoral immunodeficiencies are found in most patients: 80% have IgG_2 deficiency, 60% have IgA deficiency, and approximately 50% have IgE deficiency. Despite the frequency of these humoral immunodeficiencies, deficiencies of IgM, IgG_1, and IgG_3 are uncommon. As will be discussed below, the majority of the AT cancers are acute lymphocytic lymphoma or leukemia, but it is interesting that acute or chronic myeloid leukemia are completely absent. The combined immunodeficiency in AT patients is reminiscent of the phenotypes found in a mutant mouse model named severe combined immunodeficient mutation (SCID). Cells from these mice are deficient in a recombination process utilized in both DNA double-strand break repair and lymphoid variable (diversity)-joining [V(D)J] recombination. The resulting phenotype is therefore manifested in both cellular hypersensitivity to ionizing radiation and a lack of B- and T-cell immunity. The DNA-dependent kinase p350, a strong candidate for the murine SCID defect, is, however, normal in SV40-transformed AT cells (GM 5849). This indicates that even though AT and the SCID mice share similar phenotypes, the affected mechanisms that regulate them are most likely different.

Tissue radiosensitization

A universal characteristic of all AT patients is their hypersensitivity to radiation. The marked hypersensitivity is seen in both patients and cells derived from their normal tissue. Sensitivity of AT fibroblasts to ionizing radiation was first investigated in the mid-1970s due to reported fatal radiation burns in AT patients receiving radiotherapy for malignancies. Other severe reactions caused by the administration of standard radiotherapy to AT patients include ulcerative dermatitis, severe esophagatis, dysphagia, and deep tissue necrosis. It is estimated that the 1- to 9-mGy dose of radiation received in a diagnostic exposure is sufficient to increase considerably the risk of breast cancer in AT heterozygote women while a dose of 100–200 mGy is required to see a similar effect in normal individuals.

Genetics and frequency

Ataxia telangiectasia is a rare disease with a birth frequency any where between 1 in 80 000 to 1 in 300 000. The gene frequency of the AT allele has been estimated at 0.007 based on the assumption that AT is due to a mutation in both alleles of the AT gene. People that are heterozygote for the AT gene have been estimated at 1.4% of the U.S. white population. The genetics of this disease is fairly homogenous; linkage studies of 176 families from various parts of the world localize the major AT locus to the region between S1819(A4) and S1818(A2) at chromosome 11q22.3 (Gatti et al., 1988) in all but 7 families. In addition to the United States, cases of ataxia telangiectasia have been reported throughout Europe, Japan, China, Africa, the Middle East, India, and South and Central America. The frequency of the disease in the U.S. black population is similar to the proportion of black individuals in the general population, but the cancer rates in black AT patients in the United States are considerably higher than those in white patients. The differences between the two ethnic groups might reflect differences between the AT alleles or other genetic or environmental factors.

Cellular Aspects

Cellular Radiosensitization

The basis for AT cells radiosensitivity is still not completely understood but may be due to a slower rate of repair of DNA double strand breaks or to the continued existence of residual breaks (see **Repair Parameters** below). Although there is no gross defect in DNA repair of DSBs in AT cells, residual breaks persist even longer than in cells deficient for Non-Homologous End joining repair (Lavin, 2008). The chromatin environment rather than the nature of the DNA lesions seems to underlie the capacity to repair the small fraction of breaks remaining in heterochromatin. In fact, ATM can phosphorylate the transcriptional corepressor Kruppel-associated box (KRAB)-associated protein-1 (KAP1) which facilitates entry of the DNA-repair machinery into heterochromatin. The absence of a functional ATM could thus reduce the capacity to repair a fraction of DNA DSBs and increase radiosensitivity. Nonetheless, in Purkinje cells, a primary target for neurodegeneration in AT, the chromatin is mostly of the euchromatic type while granule neurons are more heterochromatic (Kriaucionis and Heintz, 2009). Accessibility of the DNA-repair machinery to DNA DSBs is thus probably not sufficient to carry the radiosensitivity phenomenon. Radiosensitivity in AT cells is exhibited by both a loss of colony formation ability and a higher frequency of chromosomal damage within individual cells. Although several abnormalities have been reported in cells from obligate AT heterozygotes, no clear effect on the capacity to stop DNA synthesis following irradiation (radiation-resistant DNA synthesis) has been demonstrated so far. Several studies indicate that radiosensitivity levels measured in AT heterozygotes by cell survival, chromosome aberrations, production of micronuclei, or flow cytometry are intermediate in between that of controls and AT homozygotes. However, others have pointed out that when larger scale blind evaluations were performed, sufficient overlap between heterozygotes and normal cells was obtained so that no assays could really distinguish between the two groups. Radiation sensitivity is defined by the steepness of a slope obtained from a survival curve when cells are

exposed to graded doses of IR. The slope is proportional to $1/D_0$, where D_0 is the dose required to reduce cell survival to 37%. Normal human fibroblasts have typical D_0 values ranging from 1.2 to 1.4 Gy. AT cells, on the other hand, have D_0 values around 0.7 Gy. At 10% survival (D_{10}), AT cells are about twice as sensitive as normal cells. AT cells are also hypersensitive to certain radiometric chemicals, inhibitors of DNA topoisomerases, and restriction endonucleases. Some variability exists between the different AT cell lines, but AT cells in general are sensitive to compounds that induce DNA strand breaks most probably via free radical attack. The hypersensitivity of AT cells to the X-ray type of DNA-damaging agent is specific since AT cells are not hypersensitive to 254 nm UV radiation. However, damage from densely ionizing radiation [α-particles, high linear energy transfer (LET)], which causes more extensive local damage to DNA, is less effective on AT cells, relative to normal, than damage from sparsely ionizing radiation (X-rays, low LET). Radiosensitivity of AT cell lines is considerably greater than that of cell lines from other neurodegenerative diseases such as Huntington and Alzheimer diseases. This is even more clearly illustrated with cells from AT heterozygotes that have no clinical evidence of neurological abnormalities but are more radiosensitive than cells from patients with other radiosensitive diseases demonstrating significant neuronal degeneration.

Cell Cycle

Exposure of normal mammalian cells to DNA-damaging agents, particularly IR, results in transient inhibition or delay of their progression through the cell cycle at a number of different checkpoints, including G_1, S, and G_2. It is thought that these delays allow cells time to repair their DNA and avoid the passage of defective genetic information to the next generation. The importance of these checkpoints for the maintenance of cellular integrity is obvious in that the G_1/S checkpoint precedes DNA replication and that the G_2/M checkpoint precedes the segregation of chromosomes. It is now well established that a wild-type phenotype for the tumor suppressor p53 is necessary to observe a normal G_1 delay following IR. The involvement of p53 in such a critical point in the life of a cell is another indication of the importance of these delays since p53 mutations or mutations in cellular pathways regulating p53 functions are found in the majority of human cancer cells. Anomalies in the progression of the AT cells through the cell cycle following exposure to IR have been described in virtually all of these cell cycle checkpoints. The first observation of a defect in the AT cell cycle checkpoints described their inability to stop DNA synthesis following irradiation and most likely referred to the S phase checkpoint since the DNA synthesis was measured 40 min after irradiation. The radioresistance to DNA synthesis allows the AT cells to proceed through S phase unchecked which results in a reduced mitotic delay and various cellular aberrations. However, increasing evidence suggests that the inability to stop the DNA synthesis cannot be responsible for the hypersensitivity as it was first thought. The two phenomena, radioresistant DNA synthesis and sensitivity to cell killing are dissociated in cell hybrids between AT lines and a normal line. In AT heterozygote, neither the radioresistant DNA synthesis nor the shortened mitotic delay is observed. Unlike the arrest in G_1 after IR, the IR-induced S phase arrest seems to be independent of p53.

The correlation between p53 and a normal G_1 arrest is also reflected in the increased levels of the p53 protein. In AT homozygous, the G_1 delay and the normal increased p53 levels are not observed following a 1-hr exposure to 2 Gy of IR. The abnormal G_2 block in AT cells following ionizing radiation is more complex since although cells already in G_2 fail to arrest at the G_2-M checkpoint, cells irradiated in the G_1/S phase arrest when they reach G_2. This observation may reflect differences in the type of DNA damage that is produced in G_2 versus G_1. Furthermore, there may be distinct protein complexes (defective in AT) involved in processing and/or repair of one type of DNA lesion versus another. A correlation has been suggested between the number of cells arrested in G_2 and radiosensitivity, but in AT it seems that the number of cells arrested in G_2 correlates with an adverse prognostic indicator. The isolation of the AT gene has allowed a better understanding of the molecular basis of the defective checkpoints. This is described in more detail below (Section **Molecular Aspects**).

Cytogenetics

Two types of basal (uninduced) cytogenetic abnormalities are seen in cells from AT patients: (i) an excess of 'spontaneous' chromosome breaks (e.g., gaps, fragments) and rearrangements distributed randomly among the chromosomes, and (ii) clonal abnormalities usually involving chromosome 7 or 14. The incidence of these spontaneous changes varies among different patients and also within the same patient as a function of donor age and cell types, that is, fibroblasts versus lymphoblast. The chromosomal translocations and inversions almost exclusively involve these six breakpoints: three T-cell receptor complexes, 7q35, 7q14, and 14q11, and three B-cell receptor complexes, 22q12, 14q32, and 2p12. All these sites are sites of gene rearrangements, implicating perhaps a common recombinase. These specific translocations are also observed in normal lymphocytes but at a lower frequency. Chromosomal aberrations also occur in fibroblasts but they are nonspecific and almost never involve the six sites mentioned earlier. The AT gene(s) site, 11q23 (Gatti et al., 1988), is never compromised in the chromosomal breakpoints, suggesting that this type of aberration is a consequence rather than a cause of the AT phenotype. Abnormalities in chromosome 14 are also associated with Burkitt lymphoma, Hodgkins disease, and various leukemia, indicating that this chromosome may contain a locus predisposing to lymphoproliferative malignancies. The proximity of the chromosomes 7 and 14 to some immunoglobin genes might be an indication that cytogenetic anomalies play a role in the immunodeficiency observed in AT. The type of aberrations produced in AT lines by radiation differs from that in control lines. In the mitosis following irradiation in the G_0 early G_1 stage of the cell cycle, AT cells show both chromosome and chromatid aberrations while only chromosomal aberrations are observed in normal lines. The reason for this particular response is still unclear, but it implies that some single-strand breaks persist for excessive periods in AT.

Repair Parameters

The increased sensitivity of AT to ionizing radiation derives most likely from an inability to recover from DNA breakage in the normal manner. Subtle defects in the ability to process DNA breaks such as accuracy of strand rejoining and persisting residual breaks may affect the ability to recover from DNA breakage. Conflicting reports in the literature have been published on the capacity of AT cells to repair their damaged DNA. This early confusion may have resulted from the differences in the sensitivity of the various techniques used. For example, cytogenetic experiments utilizing comparison of the breakage and rejoining of prematurely condensed chromosomes (pcc) indicated that after a dose of 6.0 Gy, both AT and normal cells had the same initial frequency of breaks and the same rate for rejoining of the breaks, but the fraction of breaks that did not rejoin was five to six times greater in the AT cells. It should be noted that the frequency of such events is orders of magnitude less than IR-induced DNA strand breaks. Fornace and Little, and subsequently others, using filter elution assays from the early 1980s, found no convincing differences between AT and normal lines in the ability to repair DNA strand breaks. Another technique, the pulse field gel electrophoresis, which detects double-stranded breaks in genomic DNA after low doses of γ-irradiation, indicated that the residual amount of unrepaired double-strand breaks in normal cells was 1.4% while it was 5.2 and 2.1% in AT cells and AT heterozygotes, respectively. There is also evidence of misrejoining of double-strand breaks in damaged plasmids. Interestingly, the cellular aberrations found in the next mitosis following the treatment of AT cells in G_1 with IR or electroporated restriction enzymes commonly involve only one chromatid. This suggests that AT cells have a defect in the repair of double strand breaks. However, the levels or activity of repair enzymes such as 5,6 dihydroxydihydrothymine, apurinic-site specific endonuclease, and ADP-ribose transferase are normal in AT. It seems therefore that a search for a specific DNA repair defect might not be the most likely way to find an explanation for the AT phenotype. In fact, it has been suggested that AT main defects might reside in the signaling of DNA repair. In this regard, phosphorylation of several key regulators of DNA repair has been described in an AT dependent manner (see Section **Molecular Aspects**). In addition, as mentioned above, the chromatin environment and the accessibility of the repair machinery to the heterochromatin rather than the nature of the DNA lesions seem to underlie the capacity of AT cells to repair residual DNA breaks.

Molecular Aspects

The AT Gene

Cloning of the AT gene in 1995 opened the door to numerous molecular studies that had been awaited for quite some times. Because roughly 97% of tested AT families link to chromosome 11, the concept that a common multimeric molecule, with different subunits of the molecule being affected in different patients, could lead to the indistinguishable AT phenotype became plausible. Early linkage analysis clearly localized the AT gene to a 3 cM region of chromosome 11q22-23. Subsequently, a more precise analysis involving 176 AT families localized the AT gene(s) within a 500-kb interval flanked by S1819 and S1818. There are several functional genes that have already been mapped to chromosome 11q22-23; many of these genes have remained together for over 80 million years of evolution. There is also a number of diseases associated with this region, one of which, tuberous sclerosis, confers radiation hypersensitivity. Long-range cloning of the AT locus ultimately led to the isolation of a major transcript of approximately 13 kb predicting a product of 3056 amino acids. The carboxy terminal region of this protein shows considerable similarity to several yeast, *Drosophila*, and mammalian phosphatidylinositol-3′ (PI-3) kinases that are involved in mitogenic signal transduction, meiotic recombination, cell cycle control, or DNA damage detection. The pleiotropic nature of the AT phenotype is therefore well served by this protein. This gene product, named ATM (AT mutated), is a serine/threonine protein kinase sharing the substrate recognition motif Ser/Thr-Gln-Glu of the phosphatidylinositol 3-kinase-like (PIKK) family of protein kinases. The ATM protein is predominantly found in the nucleus of proliferating cells but a variable amount (~10-20%) has also been observed in the cytoplasmic fraction of differentiated cells such as cerebellar neurons. ATM probably interacts with other proteins to facilitate its entry into the nucleus since there are no obvious nuclear localization signals in ATM primary sequence. ATM could thus possibly play different roles depending on its presence or absence in a given cellular compartment. ATM kinase activity is rapidly enhanced following treatment with agents that cause DNA double strand breaks (DSB) but is insensitive to other types of DNA damaging agents such as UV radiation and alkylating agents. It is now believed that the initial signal triggering ATM activation following IR is probably relaxation of higher order chromatin structure following DSB. In the absence of cellular stress, ATM exists as an inactive non-covalently associated dimer but converts to an active monomer following autophosphorylation on Ser 1981 upon DNA damage in the presence of Mre11/Rad50/Nbs1 (MRN) complex. A number of other phosphorylation sites and additional post-translational modifications such as acetylation have also been reported. However, ATM can also be activated by cellular stress in the absence of DSB such as hypoxia and brief exposure to oxidative stress. These recent findings support a broader role for ATM in not only responding to genotoxic stress but also maintaining cellular homeostasis (Shiloh and Ziv, 2013). Several laboratories using slightly different strategies have developed *ATM* knockout mice. All animals exhibit most of the noncentral nervous system features such as growth retardation, mild neurological dysfunction, male and female infertility, immunodeficiency, radiosensitivity, and predilection for thymic lymphoma. Nonetheless, none of the animals reproduced the neurodegeneration changes observed in AT patients, even though one laboratory showed evidence of neuron degeneration in the cerebellar cortex of 2-month-old *ATM* −/− mice. Mutations of the *ATM* gene, mainly characterized by premature truncation of the protein product, have been found in all AT patients regardless of the phenotype severity. This indicates that *ATM* is probably the sole gene responsible for the AT disorder. Most AT patients are

compound heterozygotes and have two different *ATM* mutations. More than 600 mutations have been described so far; a current list of *ATM* mutation can be found on the internet (http://www.hgmd.cf.ac.uk/ac/gene.php?gene=ATM).

The ATM Substrates

ATM substrates that could be linked to neurodegeneration have been elusive until recently. A new study by (Chan et al., 2014) demonstrated that the transcription factor myocyte enhancer factor 2D (MEF2D), which plays a critical role in promoting survival of cerebellar granule cells, is phosphorylated by ATM in response to DNA damage. Phosphorylated MEF2D activates the pro-survival Bcl-xL gene. This offers an alternative explanation for the role of ATM in neurodegeneration since it is estimated that only about 10% of DSB repair are mediated by ATM. Nonetheless, phosphorylation of MEF2D by ATM has only been confirmed in Atm knockout mice and not in AT-patients yet. However, given that ATM kinase is activated by agents that cause DSB, there are numerous reports on ATM substrates involved in (1) cell cycle checkpoint (2) stress response, or (3) DSB repair, all aspects of the cellular response to genotoxic stress. Specific substrates involved in these cellular functions are described below.

Cell cycle checkpoint

Key regulators of all phases of the cell cycle have been identified as ATM substrates. The tumor suppressor p53 was the first cell cycle regulator identified and is among the best characterized substrates. In normal human hematopoietic and other cells, increases in the levels of the tumor suppressor p53 correlate with a transient G_1 arrest after irradiation. Cells that are mutant for p53 show no G_1 arrest but retain the G_2 arrest found typically after irradiation. In AT cells, the G_1 arrest and the p53 response is delayed. The suboptimal p53 activation is also reflected in the lower induction levels of the proteins Gadd45, MDM2, and $p21^{WAF1/CIP1}$, which are encoded by three p53 downstream effector genes. Moreover, the DNA-binding activity of p53 is also abnormal following IR in AT, and failure to inhibit cyclin/cdk complexes by IR, an activity associated with $p21^{WAF1/CIP1}$ induction, has also been reported. However, the defective p53 activation might be specific to IR since induction of p53 by other DNA damaging agents appeared relatively normal in AT. Disruption of p53 function in normal fibroblasts (**Figure. 2**) results in increased spontaneous recombination rates and loss of the p53-dependent G_1/S cell cycle checkpoint. These two phenomena, also present in AT, indicate that an abnormal p53 response might contribute to the AT phenotype. In addition to these effects, a role for p53 in the mediation of the molecular abnormalities in AT has been demonstrated by insertion of mutant p53 protein, or viral protein known to degrade p53, in AT fibroblasts. Disruption of functional p53 in AT, results in increased resistance to streptonigrin and IR due to suppression of the apoptotic response. ATM regulates p53 activation and stabilization by a number of different mechanisms. First, ATM phosphorylates p53 directly on Ser15 and other residues and increases its transcriptional activity. Second, ATM activates the checkpoint kinase 2 (chk2) by phosphorylating it on Thr68, which allows it to phosphorylate p53 on Ser20 and increases p53 stability by interfering with binding to the mouse double minutes 2 (MDM2) protein. MDM2 is the main mediator of the proteoasome-mediated degradation of p53, where it functions as the E3 ligase in p53 ubiquitination process. A third mechanism used by ATM to regulate p53 action is to phosphorylate MDM2 directly on Ser395, which prevents p53 export out of the nucleus, a necessary step in p53

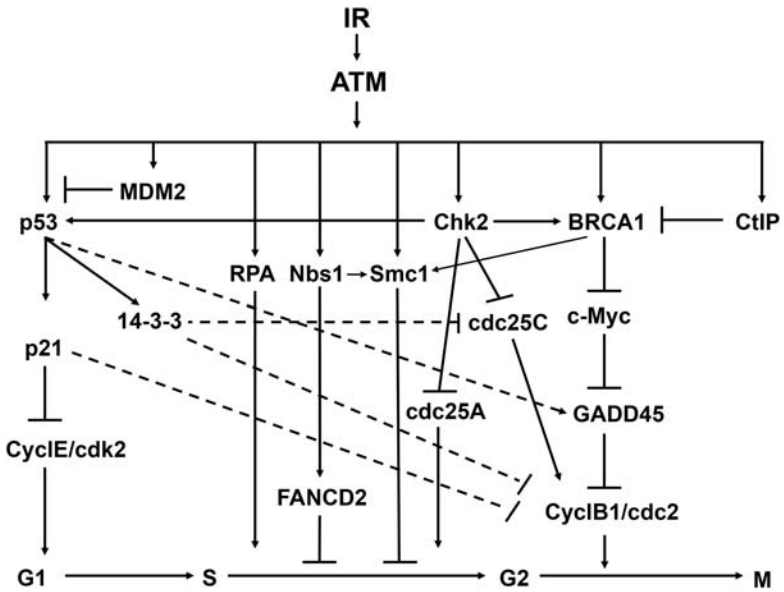

Figure 2 The AT gene product normally plays a role in the activation of several cellular responses following ionizing radiation. ATM activates key regulators of every phase of the cell cycle. Positive regulations are indicated by arrows while negative regulations are indicated by blunt arrows. Dashed lines indicate G2 regulation mediated by p53 when cells enter G2 with damaged DNA or are arrested in S phase (see details in the text).

degradation. Several other indirect mechanisms including other post translation modification such as acetylation, dephosphosphorylation and deubiquitylation were recently reviewed (Shiloh and Ziv, 2013).

Activation of chk2 by ATM provides also a mechanism for ATM's control of the G_2/M checkpoint. The activated chk2 can phosphorylate and inactivate the cdc25C phosphatase. This phosphatase is responsible for dephosphorylation and activation of cdc2, the kinase controlling entry into mitosis. ATM can also regulate the G_2/M checkpoint through the breast cancer susceptibility gene 1 (BRCA1). Similar to p53 regulation, ATM regulation of BRCA1 also involves several mechanisms. First, ATM phosphorylates BRCA1 directly on Ser1423 and Ser1525, chk2 in response to ATM phophorylates BRCA1 on another serine, Ser988, and, finally, ATM phosphorylates and inactivates CtIP, a negative regulator of BRCA1. The precise mechanism by which BRCA1 regulates the G_2/M checkpoint is still not completely understood, but current findings indicate a role as co-repressor. BRCA1 does not physically interact with DNA but rather associates with the proto-oncogene c-Myc and represses its transactivation. Among the different genes regulated by c-Myc is the growth arrest and DNA damage inducible gene *GADD45*.The expression of *GADD45* can be repressed by c-Myc through a C/EBP element within the *GADD45* promoter. Gadd45 binds to cdc2 and disrupts the cyclinB1/cdc2 complex, which results in the inhibition of the kinase activity and prevents cell cycle progression beyond G_2. By phosphorylating BRCA1, ATM may thus control the G_2/M checkpoint by allowing BRCA1 to relieve the transcriptional repression imposed by c-Myc on the *GADD45* promoter. ATM can also control G_2 arrest through p53 when cells enter G_2 with damaged DNA or are arrested in S phase. Under these conditions, p53 inhibits cdc2 simultaneously by three transcriptional targets, GADD45, p21, and 14-3-3 sigma. The p21 protein may contribute to G_2 arrest by several mechanisms including direct binding to CyclinB1/cdc2 and inhibition of CAK, the kinase phosphorylating cdc2. The 14-3-3 protein is a direct substrate of p53 and binds to Cyclin B1/cdc2 as well as Cdc25 and sequesters them in the cytoplasm.

The role of ATM in the regulation of the S-phase checkpoint is complex and involves the phosphorylation of several key regulators. Hyperphosphorylation of the replication protein A (RPA) following IR is reduced and delayed in AT cells. RPA is a three-subunit protein complex involved in the initiation and elongation stages of DNA replication and in repair. It seems that in AT cells, the underphosphorylation of RPA sub-unit, p34, is not due to the absence of RPA kinases but rather to a slower phosphorylation rate. This delay might be mediated by another kinase sharing similar substrate specificity such as DNA-PK or the ATM-related kinase ATR. On the other hand, the delay might be caused by reduced accessibility of RPA to repair sites. This might imply that there is a defect in AT chromatin structure. The evidences supporting this possibility are discussed below (repair parameters). Whether phosphorylation of RPA by ATM in response to IR is required for the S phase checkpoint is still not clear since over-expression of the ATM kinase domain is sufficient to restore the radioresistant DNA synthesis (RDS) defect without correcting the RPA phosphorylation status. Another important substrate of ATM for the S-phase checkpoint is the Nbs1 protein also known as nibrin or p95. Nbs1 is part of a large nuclease complex also containing Mre11 and Rad50 that is involved in repair of DSB generated at stalled replication forks. The nbs1 gene is mutated in the Nijmegen breakage syndrome (NBS), a syndrome sharing a variety of phenotypic abnormalities with ATM. Nbs1 is phosphorylated on Ser278, Ser343, Ser397, and Ser615 by ATM. Mutation of either Ser278 or Ser343 is sufficient to abrogate an S-phase checkpoint induced by IR. ATM binds directly to Nbs1; this interaction is enhanced upon DNA damage but ATM phosphorylation of Nbs1 does not affect Nbs1 binding to Mre11. However, ATM, the NBS proteins, and BRCA1 are part of a super complex named BASC (BRCA1-associated genome surveillance complex) that is thought to function as a sensor for DNA damage. Phosphorylated Nbs1 acts as an adaptor for the ATM-dependent phosphorylation of other substrates such as the structural maintenance of chromosomes protein Smc1. ATM phosphorylates Smc1 on Ser957 and Ser966 *in vivo* and *in vitro* following IR. Optimal phosphorylation of Smc1 by ATM requires Nbs1 and BRCA1, but the reasons for this requirement are not clearly understood yet. It is possible that Nbs1 and BRAC1 are used as scaffold proteins to enhance ATM activity on Smc1. Mutations of the Smc1 protein at the ATM phosphorylation sites are sufficient to abrogate the IR-induced S-phase cell cycle checkpoint. As mentioned above, phosphorylation of chk2 by ATM provides a mechanism for ATM to control both G_1 and G_2 checkpoint. Phosphorylation of chk2 by ATM can also control the S-phase checkpoint through phosphorylation of the cdc25A phosphatase. Chk2 phosphosrylates Ser123 on cdc25A in response to IR in an ATM dependent manner. Phosphorylation of cdc25A triggers its degradation, which prevents dephosphorylation of cdk2 and arrest the cells in S phase. ATM can also control the S phase checkpoint through direct phosphorylation of the Fanconi Anaemia complementation group D2 (FANCD2) protein on Ser222. Moreover, biallelic disruption of *FANCD2* results in IR hypersensitivity.

Stress response

Another class of substrates that are phosphorylated by ATM includes several important stress responsive proteins. ATM phosphorylates the non-receptor nuclear tyrosine kinase c-Abl on Ser465 in response to IR. This phosphorylation activates c-Abl which then phosphorylates its substrates such as the C-terminal repeated domain (CTD) of RNA polymerase II and the Jun N-terminal kinase (JNK), among others. JNK is a member of a subgroup of stress activated kinases known as the MAPKs that are activated by several cellular stresses including DNA damage. JNK stimulates the transcriptional activity of the AP-1 transcription factors such as c-*jun*. In AT cells, activation of the JNK pathway by IR is defective, but activation by UV radiation and protein synthesis inhibitors is intact. The inhibitor proteins known as IκB are also phosphorylated by ATM. IκB interacts with the transcription factor NFκB and prevent it from translocating to the nucleus by masking NFκB nuclear localization domain. Phosphorylation of IκB leads to its degradation and release of the NFκB to the nucleus where it can transactivate its downstream effector genes. NFκB is involved in the regulation of immunoglobulin genes and is a member of a gene family involved in lymphomagenesis. Moreover, NFκB is constitutively expressed at high levels in neurons, suggesting a possible link to central nervous symptoms in AT. The molecular mechanisms underlying ATM mediated IκB degradation are currently emerging as a complex interdependency between ATM activation and IKK, the kinase

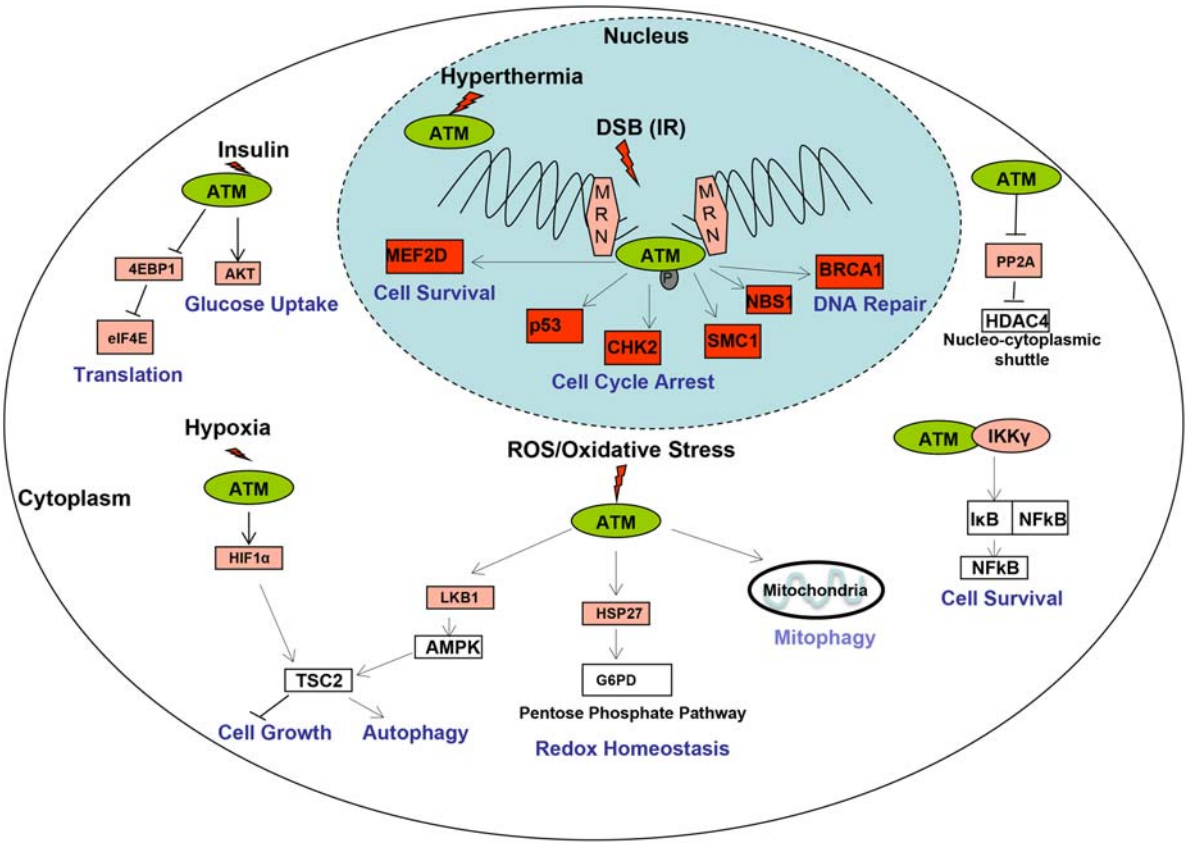

Figure 3 ATM; a master regulator of cellular homeostasis. Involvement of ATM inregulating cellular response to a variety of stimuli- DNA double strand break (DSB), inducing irradiation or chemicals, oxidative stress, hypoxia, hyperthermia, metabolic, signaling (Insulin). ATM acts as a major signal transducer in response to DSB formation, in the nucleus, leading to cell cycle arrest, DNA repair or apoptosis. In the cytoplasm it, acts predominantly on maintaining metabolic, oxidative and growth homeostasis.

regulating IkB degradation. In response to genotoxic stress, ATM autophosphorylation on Ser1981 results on phosphorylation of IKKγ, triggering a sumoylation-for-ubiquitination exchange on IKKγ. The ubiquitinated IKKγ-ATM complex is then exported from the nucleus to the cytosol where ATM associates with and causes the activation of IKK (Figure 3).

DSB repair

In addition to the Nbs1 protein, ATM also participates in the activation of other important proteins involved in DSB repair. The RAD51 protein is an indirect substrate of ATM; it is phosphorylated by c-Abl in an ATM dependent manner following IR exposure. Phosphorylation of RAD51 increases the interaction of RAD51 with RAD52, a complex mediating homologous recombinational repair (McKinnon, 2012).

Defect in Recombination and Chromatin Modification

A defect(s) in some form of DNA recombination in AT has been suggested based on the presence of spontaneously occurring chromosome translocations involving breakpoints in T-cell receptor (TCR) genes. Interestingly, the 70-fold increased frequency of TCR hybrid genes in AT lymphocytes does not affect the productivity nor the structure of the recombined TCR. This suggested that unlike the case with scid mice, the recombination process in AT cells is qualitatively normal. Using recombination vectors it has been shown that spontaneous intrachromosomal recombination rates are 30–200 times higher in AT fibroblasts line compared to normal cells, whereas extrachromosomal recombination frequencies are near normal. This indicates that the abnormality is specific to the AT chromosomal integrity and is not related to viral or plasmid DNA. The hyperrecombination rate is also particular to the AT phenotype and is not a consequence of defective DNA repair since cells from xeroderma pigmentosum patients, which are defective in excision repair, do not show abnormal recombination rates. The increased recombination rate is therefore an integral component of the AT phenotype and might contribute to genetic instability and an increased risk of cancer.

The defects in recombination may be linked to an ATM direct interaction with DNA and chromatin. ATM binds to meiotic chromosomes and is part of the recombination nodules, the structures thought to mediate chromatid exchanges. Fragmentation of meiotic chromosomes occurs at these sites in ATM deficient mice and may explain the infertility of these animals. A defective

chromatin structure in AT has been suggested as a possible reason for the higher rate of conversion of DNA double-strand breaks into chromosomes breaks. This was suggested based on apparent alterations of nucleosomal periodicity near the telomere chromatin. Moreover, a defective chromatin structure was also postulated to explain the inability of AT cells to stop DNA synthesis following exposure to IR. It is presumed that the defective chromatin structure could reduce accessibility of RPA to repair sites. The fact that in ATM deficient mice RPA remains attached to the ends of abnormal chromosomes fragments formed at the sites of the recombination nodules supports this possibility. There are several lines of evidence indicating that ATM could modulate the chromatin structure. First, transient dephosphorylation of histone H1, but not histone H3, following IR is ATM-dependent. Dephosphorylation of histone H1 is believed to increase chromatin decondensation. The exact pathways leading to H1 dephosphorylation have not been elucidated yet. Second, ATM rapidly interacts with the histone deacetylase HDAC1, both *in vivo* and *in vitro*. The amount of HDAC1 activity associated with ATM increases after IR. Histones deacetylation also decreases chromatin decondensation, which in turn affects radiosensitivity (Carrier, 2013). A third line of evidence comes from ATM capacity to phosphorylate the histone H2A variant H2AX in response to DSB. Phosphorylation of H2AX at Ser139 is rapid (within 1–3 min) and specific to the sites of DNA damage. In yeast, H2AX phosphorylation causes chromatin decondensation, while in mammals it mediates the recruitment of repair or damage signaling factors such as BRCA1, Nbs1, RAD50, and RAD51 to the sites of DNA damage. H2AX phosphorylation following IR is severely compromised in *ATM* −/− cells but phosphorylation of H2AX can be restored by ectopic expression of ATM in these cells. In fact, ATM mutations associated with different AT phenotypes have been linked to diverse degrees of chromatin condensation and reorganization with the more severe phenotype presenting the most decondensed chromatin and consequently alteration of gene expression.

Abnormal Apoptosis

The control of the cell number in each lineage is determined by a balance between cell proliferation and cell death. The process regulating cell proliferation is highly regulated with numerous checks and balances. The regulation of cell death is now appearing to be as complex as cell proliferation. Differentiated cells have the ability to carry out their own death through the activation of an internal suicide program called apoptosis. The apoptotic process is usually turned on to eliminate cells that have developed improperly, have been produced in excess, or have sustained irreparable damage to their DNA. Apoptotic cell death is different from necrotic cell death which is a pathological form of death resulting from acute cellular injury. The difference between these two forms of death can be observed morphologically. Cells dying from necrosis will swell rapidly and lyse which will result in the leakage of cytoplasmic contents and the induction of an inflammatory response. An apoptotic cell undergoes a controlled autodigestion with the maintenance of the plasma membrane integrity and therefore no inflammatory response. In mouse, ATM is essential for IR-induced apoptosis in the developing nervous system. ATM-mediated apoptosis in the nervous system also required p53 and the pro-apoptotic effector Bax. The apoptotic response in ATM null mice is defective but the precise role of ATM in apoptosis is still debated. The conflicting results often reported in the literature may be associated with the cell types, the different apoptotic stimuli, or even the cellular states (proliferative vs quiescent) of the cells used by the investigators. Interestingly, AT fibroblasts are unusually sensitive to drugs that also produce internucleosomal DNA cleavage, characteristic of apoptosis. Widespread apoptosis was detectable in four A-T fibroblast lines, AT22IJE, AT4BVI, AT5BIVA, and AT2SFSV but not in two control lines. Apoptosis began 24 hr after exposure to X-rays or streptonigrin (radiomimetic agent) and peaked 72 to 96 hr following treatment. No apoptotic differences were detected between AT and control fibroblasts following exposure to 30 J m^{-2} of UV irradiation. Streptonigrin also induced widespread apoptotis in AT lymphoblasts but not in control lymphoblasts. The interval between exposure of cells to apoptotic agents and the induction of apoptosis can be short, being detected in some instances as soon as 4 hr after exposure. The significant delay in AT to trigger the apoptosis machinery might be due to a defect in the same pathway responsible for the loss of G_1 delay since p53 is required for radiation-induced apoptosis. Current evidence, however, suggests that c-Abl may rather link ATM to p73, a member of the growing p53-like family that is not induced by DNA damage but plays a role in damage-induced apoptosis. In response to ATM phosphorylation, c-Abl phosphorylates and activates p73. As mentioned above, one of the AT gene domains shares homology with PI-3 kinase. PI-3 kinase is required for the prevention of apoptosis in rat pheochromocytoma cells by nerve growth factor. This facet of the AT gene might correlate with the increased nerve cell death in AT and the increased apoptosis in cultured AT cells exposed to DNA-damaging agents.

Future Directions

Since the cloning of the ATM gene, tremendous efforts have been directed at delineating ATM functions in cell cycle regulation, sensing of DNA damage, and initiation of DNA repair mechanisms. The predominantly nuclear localization of the protein is in good agreement with these important cellular functions. However, it is now becoming evident that ATM probably plays other important roles in cellular homeostasis that may be mediated by the small pool of cytoplasmic protein (Shiloh and Ziv, 2013). For example, ATM could react with Reactive Oxygen Species (ROS) in the cytosol and affect the redox state of a cell. Several lines of evidence are supporting a role for ATM in the oxidative stress response. For instance, increased levels of ROS have been detected in the cerebellum of *ATM* deficient mice. The absence of *ATM* may thus result in oxidative damage and cause the degeneration of cerebellar neurons. In fact, ATM has now been described as a redox sensor in addition to its role as a sensor of DSBs. Recent reports indicate that ATM can be oxidized and activated by the formation of covalent dimers through disulfide bonds between two

monomers. This activation process is different and independent of the MRN/DNA complex (Guo et al., 2010). In addition, other evidences have demonstrated a role for ATM in the production of gluthathione by the pentose phosphate pathway (PPP) and the maintenance of redox homeostasis. ATM helps in glucose 6-phosphate dehydrogenase activation through phosphorylation of heat shock protein 27 which in the end produces NADPH (Cosentino et al., 2011) (Ambrose and Gatti, 2013).

The variety of symptoms and the presence of ATM in the cytoplasm indicate that certain ATM substrates are likely to be involved in mechanisms other than the ones related to the DNA damage response. Substrates found in the cytosol, such as the translational regulatory protein 4E-BP-1, are good examples of this possibility. ATM phosphorylates this regulatory protein in response to insulin stimulation. There is also evidence that ATM may be linked to growth factor mediated pathways such as the insulin-like growth factor-1 receptor (IGF-1R). Transcriptional expression of IGF-1R appears to be ATM-dependent. Evidence is now accumulating to suggest that ATM is actually involved in the development of insulin resistance through down regulation of AKT activity. Cytoplasmic ATM is not only a major upstream activator of AKT in response to insulin but can also regulate the transport of GLUT-4 to the surface of cells and modulate insulin-mediated glucose uptake (Halaby et al., 2008). This function could explain the insulin resistance condition in some AT patients.

The most challenging AT symptom that remains to be alleviated is progressive neurodegeneration. Although a number of factors have been implicated in the neurodegenerative phenotype of AT, the unavailability of a human model system able to recapitulate the neurological disease has prevented the identification of a causative factor. In order to compensate for this deficiency, human neuronal stem cells (hNSCs) have been used to gain insight into the molecular mechanisms of neurodegeneration in AT. hNSCs can be induced to differentiate into the three major central nervous system (CNS) cell types, neurons, astrocytes and oligodendrocytes. Upon differentiation, ATM-proficient and ATM-deficient ihNSCs (immortalized with v-myc) yield a similar number of neurons expressing the MAP2 and β-Tubulin III markers but ATM deficient ihNSCs consistently yield attenuated levels of neurons exhibiting a GABAergic phenotype (Carlessi et al., 2013). This finding is consistent with pathological and clinical findings showing a GABA deficiency in the cerebellum of AT patients, and amelioration of the ataxia manifestation by treatment with a GABA-analog. Neurodegeneration can also be studied with human somatic cells that are reprogrammed into induced pluripotent stem cells (iPSCs). Human iPSCs re-programmed from AT fibroblasts and capable of generating a variety of functional neurons have been generated. In spite of numerous advantages, these stem cell models have obvious limitations including the inability to generate Purkinje neurons, a primary target underlying the ataxia phenotype in AT. Nonetheless, stem cells are more and more in demand and under study specifically for regenerative medicine purpose and particularly for neurological disorders. Transplantation of neuronal stem cells in the brain of AT patients will have to await further investigations on the techniques to be used and a better understanding of possible unintended side effects since transplantation of fetal neuronal stem cells in the brain of one AT patient resulted in uncontrolled growth in his spinal cord and brain (Amariglio et al., 2009).

As mentioned above, clues regarding ATM participation in preventing neurodegeneration may be provided by the cytoplasmic localization of a fraction of ATM in normal neurons. In addition to its role as a redox sensor ATM can also interact with the synaptic proteins VAMP2 and Synapsin-1 in the cytoplasm of neurons. Moreover, neurodegeneration in AT has been linked to the translocation of the histone deacetylase HDAC4 from the cytoplasm to the nucleus with consequent suppression of neuronal gene expression. To remain in the nucleus HDAC4 must be dephosphorylated by the protein phosphatase 2A (PP2A), which is down regulated by ATM phosphorylation. As a consequence, PP2A activity is enhanced in AT cells and contributes to neurodegeneration. It thus appears that the neurodegenerative phenotype in AT is linked to, at least in part, an impaired ATM cytoplasmic activity that is distinct from its nuclear activity. ATM could also affect cerebellar degeneration through regulation of Ligase III levels and mitochondria homeostasis in the brain (Sharma et al., 2014). Reduced levels of Ligase III impede mitochondria DNA repair and could contribute to mitochondria ROS production and cerebellar degeneration.

Targeting *ATM* or smaller part of the gene to the Purkinje cells will be a difficult challenge but the development of strategies to generate hNSC that can differentiate into Purkinje cells or the identification of substrates specific to Purkinje cells will surely help direct these efforts. The emerging role of ATM in the cytoplasm as well as its functions in post-mitotic cells indicate that this multitask protein kinase is complex and versatile. The mechanisms that regulate its transitions from one function to another will probably include some post translational modifications affecting its structural characteristic and consequently its substrate preferences and interacting partners. Structural studies will allow a better understanding of the different ATM domains involved in these interactions and will likely result into the development of drugs that can specifically target a given pathway. Identification of the ATM gene was a major breakthrough and its studies will provide tools to better understand several fundamental cellular mechanisms that have implications far beyond the AT syndrome.

Autophagy and Cancer

Christina G Towers and Andrew Thorburn, University of Colorado School of Medicine, Aurora, CO, United States

Glossary

Macroautophagy The cellular degradation process by which cytoplasmic content is delivered to the lysosome via double membrane vesicles (autophagosomes) for degradation by lysosomal hydrolases.

Microautophagy Direct invagination of the lysosome to engulf and degrade cytoplasmic material.

CMA (chaperone mediated autophagy) The targeted delivery and degradation of proteins containing a KFERQ motif by the lysosome.

Mitophagy A form of selective macroautophagy that specifically degrades damaged mitochondria.

Lysosome A cellular organelle that maintains an acidic pH and contains degradative enzymes that can function at a low pH to degrade proteins and other cellular material into amino acid and other macromolecular building blocks that can be recycled.

ATG genes Genes that encode the regulators of autophagy. ATG proteins function in various complexes to cause the initiation, elongation, and fusion steps of autophagy.

Autophagic flux The formation and degradation (via fusion with the lysosome) of autophagosomes.

LAP (LC3-associated phagocytosis) A form of noncanonical autophagy used by phagocytic cells that utilizes parts of the autophagic machinery but is autophagosome-independent, and plays important roles in immunity.

Introduction

The award of the 2016 Nobel Prize for Medicine or Physiology to Yoshinori Ohsumi for his work uncovering the mechanisms of autophagy highlighted the recognition in recent years that autophagy is critically important in biology and many diseases including cancer. The term "autophagy," literally translated as "eating oneself," describes three mechanistically distinct processes by which cellular material is delivered to the lysosome for degradation by the lysosomal hydrolases. The resulting macromolecular precursors (amino acids, fatty acids etc.) are then recycled to make new macromolecules or used to fuel metabolic pathways. In addition, it has recently become apparent that the machinery that controls autophagy is also involved in nondegradative processes, for example in cellular secretion and in controlling signal transduction pathways.

The three types of autophagy that have been described are macroautophagy, chaperone mediated autophagy (CMA) and microautophagy. Macroautophagy involves the formation of double membrane vesicles called autophagosomes, which engulf proteins and other cellular material including organelles and parts of organelles. Autophagosomes go on to fuse with lysosomes in order to expose the engulfed material to the lysosomal hydrolases, which digest the contents of the autophagosome. CMA is the process by which specific proteins that contain the pentapeptide amino acid motif, KFERQ, are directly delivered to the lysosome. The KFERQ motif is recognized by the cytosolic chaperone protein hsc70, targeting the KFERQ-containing protein to the lysosomal surface, where the lysosome-associated membrane protein 2A (LAMP-2A) acts as a receptor to mediate translocation of the targeted protein into the lumen of the lysosome. One important difference between macroautophagy and CMA is that CMA only delivers proteins to the lysosome while macroautophagy delivers proteins as well as other cellular components. Additionally, CMA only delivers specific KFERQ motif-containing, proteins, while macroautophagy, although often selective for specific substrate proteins can, in principle, cause the turnover of any protein by the lysosome. Microautophagy traps cellular material in the lysosome by direct invagination of the lysosomal membrane. Hereafter, in this article when we say "autophagy" we will refer to macroautophagy, which is by far the best understood type with CMA being less well studied and microautophagy even less so.

Christian de Duve, who shared the 1974 Nobel Prize for his discoveries of the lysosome and peroxisome, first coined the term "autophagy" in the early 1960s. However, there was little work on this process until the late 1990s when genetic studies in yeast by Professor Ohsumi (and also other investigators especially Daniel Klionsky and Michael Thumm) led to the identification of genes (now called *ATG* genes) that control autophagy. This identification of autophagy regulators opened up the field for further study and it was rapidly discovered that other organisms had orthologs of the yeast genes and that in many cases the ATG proteins encoded by these genes had equivalent functions in mammals and other organisms. The discovery of the ATGs also allowed the development of better methods to study and measure autophagy and, since the early 2000's, there has been an explosion of interest in autophagy research in many areas of biomedicine and in normal biology. Thus, we now know that autophagy is important in regulating metabolism and homeostasis, it controls longevity, and is involved in infectious, metabolic, cardiovascular and neurodegenerative diseases as well as cancer.

Autophagy is affected by diverse physiological and pathological stimuli and is often affected positively or negatively by drugs that were developed for other purposes. For example, nutrient deprivation and starvation, hypoxia, hypothermia and rewarming, glucose deprivation, redox stress and many other stressful stimuli have all been shown to induce autophagy. A high

proportion of approved drugs including many anticancer drugs with different mechanisms of action including DNA damaging agents, antimetabolites kinase inhibitors, proteasome inhibitors, epigenetic modifiers and apoptosis targeted drugs like the BH3 mimetics also induce autophagy. Conversely some other anticancer drugs including microtubule-targeted agents can inhibit autophagy. Normal physiological processes such as exercise also activate autophagy. Many such stimuli will apply in cancer patients where, for example, nutrient deprivation and hypoxia of tumors is common and, perhaps more importantly, variable in many patients. Given the broad physiological stimuli that tumors are exposed to, combined with the fact that many anticancer drugs affect autophagy, it is impossible to avoid variations in autophagy impacting tumor behavior. This highlights the importance in obtaining a comprehensive understanding of the effects of autophagy on cancer cell behavior and also opens up an opportunity to deliberately manipulate autophagy to improve cancer treatment.

Regulation and Cellular Functions for Autophagy

Signaling Pathways and ATG Proteins That Control Autophagy

The process of autophagosome formation is highly regulated and complex involving multiple different protein complexes that contain ATG proteins and other regulators and only a brief and simplified summary is provided here. For more details please see the Further Reading section of this article.

Not surprisingly given that autophagy is affected by a large number of different stimuli, numerous signaling pathways regulate autophagy. However, the majority of these pathways converge on the mTOR/PI3 Kinase pathway where the mechanistic target of rapamycin (mTOR and specifically the mTORC1 complex) serves as a master negative regulator that controls autophagy (**Fig. 1**). This function might be expected since mTORC1 coordinates cellular growth and metabolism in response to diverse environmental signals including nutrients and growth factors. Thus by simultaneously promoting anabolic pathways while suppressing catabolic pathways like autophagy, coordinated cellular growth can occur. A key early step in the way that mTORC1 regulates autophagy is to control the activity of pair of protein kinases, ULK1 and ULK2, which form a complex with several other autophagy regulators including ATG13, FIP200 and ATG101. When nutrients are plentiful, mTORC1 phosphorylates ULK1. This prevents activation of ULK1 by AMPK, which itself is a key mediator of amino acid signaling. Thus relative levels of mTORC1 and AMPK activity control ULK1 activity to regulate autophagy and mTOR inhibitors like rapamycin are potent autophagy inducers.

Such posttranscriptional signaling largely explains how acute changes in autophagy—for example, an increase in the rate of formation of autophagosomes in response to acute amino acid starvation, are controlled. In addition transcriptional regulation of multiple components of the autophagy pathway (and also of lysosomal proteins) occurs. This is achieved through members of the TFEB/MITF and FOXO families of transcription factors, along with a number of epigenetic modifiers including BRD4 and repressors of gene expression. These transcriptional regulators directly regulate multiple *ATG* genes in a coordinated manner to allow a more sustained regulation of relative autophagy levels. This allows some cells to have a higher or lower level of sustained autophagy compared with other cells. Transcriptional regulation of autophagy is also coordinated with the mTOR pathway. For example, TFEB is a direct target of mTORC1 and its phosphorylation leads to sequestration of the transcription factor in the cytoplasm, thus preventing it from activating its target genes in the nucleus. By targeting both long term transcriptional control of the autophagy regulators and directly controlling the kinase complex that initiates formation of autophagosomes, coordinated control of the pathway is possible. In cancer these effects are thought to be especially important. For example in pancreas cancer, elevated activity of the MITF family leads to sustained increase in autophagy, that is critical for allowing tumor cell survival and pancreas tumor growth.

The ULK complex controls another complex that includes a protein called Beclin1 (BECN1), which is the mammalian ortholog of the yeast Atg6 protein. The BECN1 complex, which serves to initiate nucleation of the vesicle that will become the autophagosome, also contains a class III phosphatidyl inositol kinase, VPS34 as well as other regulators including AMBRA, RUBICON and UVRAG. Activation of the BECN1 complex increases VPS34 activity to phosphorylate phosphatidylinositol to form phosphatidylinositol (3)-phosphate (PtdINs(3)P) and this is critical for autophagy as well as other trafficking events including endocytosis.

The next steps in autophagosome generation involve protein conjugation systems that are conceptually similar to the systems that conjugate proteins with small peptides like ubiquitin. Two conjugation events take place. In the first, a small protein, ATG12, is conjugated to ATG5. This is catalyzed by an E1-like activating enzyme, ATG7, which works together with ATG10 (the E2 conjugating enzyme) to create the ATG12-ATG5 conjugate. The ATG12-ATG5 conjugate noncovalently interacts with another protein, ATG16, to create a complex that has an E3 like activity that together with the E2 enzyme ATG3 and ATG7 again serving as the E1, catalyzes another conjugation event that adds phosphatidylethanolamine (PE) to members of the MAP1LC3 and GABARAP families of proteins. These proteins are homologs of yeast Atg8. The most commonly studied of these proteins is MAP1LC3B (often referred to as LC3). PE conjugation occurs after proteolytic cleavage of LC3 by one of four members (A–D) of the ATG4 family of proteases. The LC3 conjugation event to create LC3-PE, which is usually referred to as LC3-II, is important for formation of autophagosomes (though perhaps not completely necessary since cells that have deletion of many of the above ATGs can still make autophagosome like vesicles). This event is also important in a practical sense because the conjugated LC3-II form runs faster on polyacrylamide gels than the unconjugated LC3-I protein and forms foci in cells. These easily detected changes in LC3 serve as the primary way that autophagosomes are quantified. Thus the conjugation events that drive autophagosome formation involve the same E1 enzyme (ATG7), different E2s (ATG10 and ATG3) and create a protein–protein conjugate (ATG12-ATG5) and a protein–lipid conjugate (ATG8/LC3/GABARAPs-PE). Researchers can target these molecules (most commonly ATG7 or ATG5) as a way to inhibit autophagy

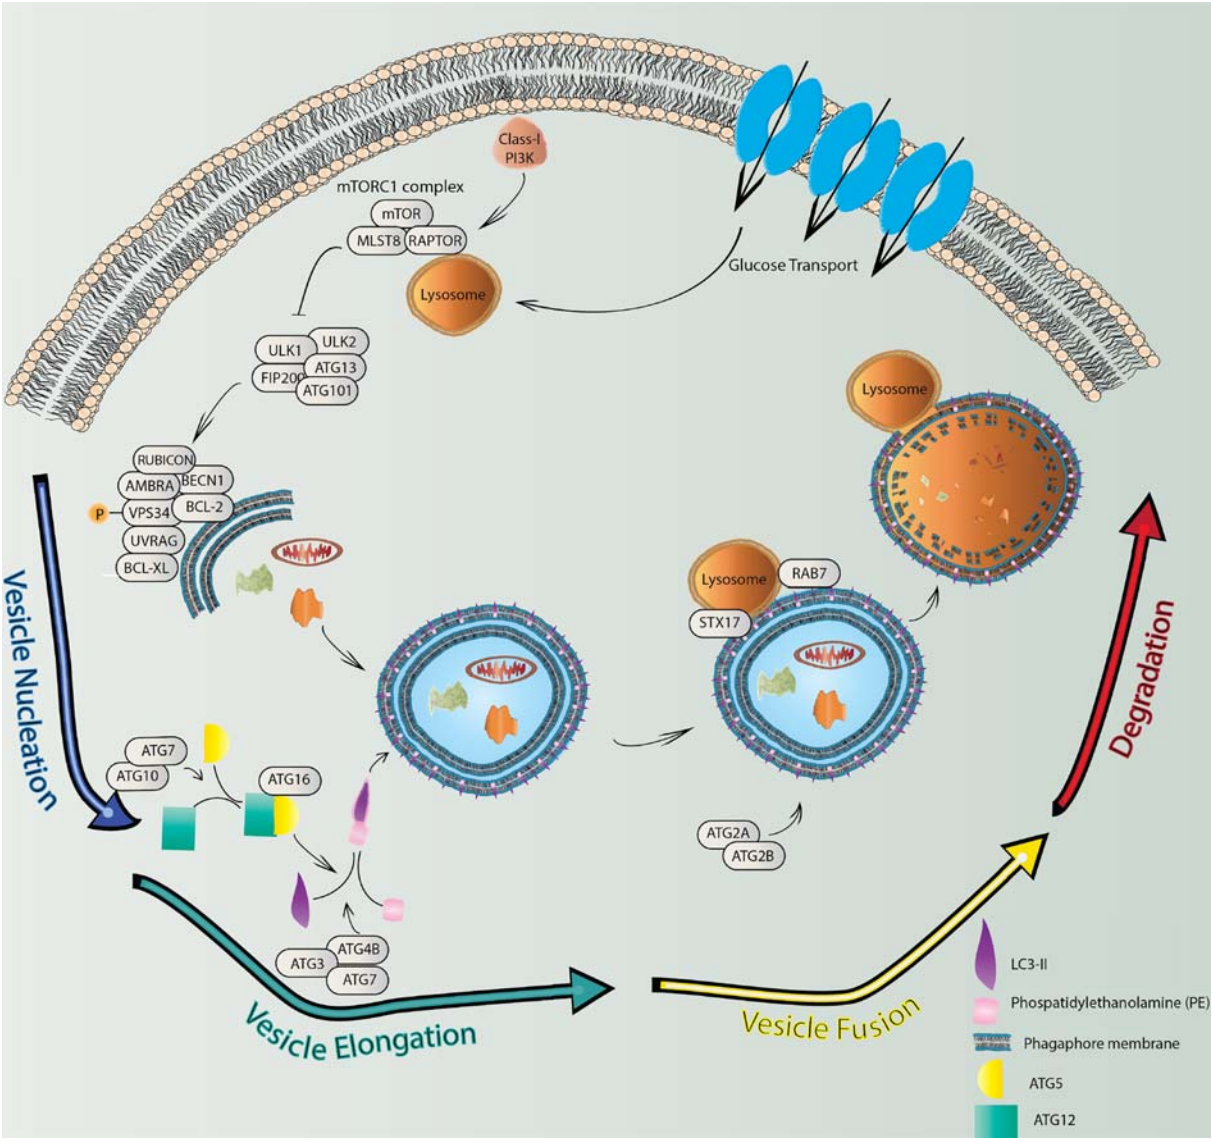

Fig. 1 A schematic of the autophagy pathway and the key proteins involved in the induction and nucleation of autophagosomes as well as the fusion of autophagosomes with lysosomes.

and there have been many preclinical animal studies to assess tumor development and progression following deletion of one or other of these genes in a particular tumor type.

Following the conjugation events, the autophagosome marked with LC3-II then closes. This step involves the RAB5 GTPase, and also requires two other proteins ATG2A and ATG2B, which if deleted, prevent closure. LC3-marked intact autophagosomes with their cargo that is destined for degradation then fuse with lysosomes. This requires another small GTPase, RAB7. Eventually the LC3-II protein that is on the inside of the autophagosomal membrane is degraded along with the rest of the cargo while LC3-II on the outside is cleaved by ATG4B releasing the LC3-I protein for re-use in another round of conjugation to PE to make new autophagosomes. Lysosome fusion also requires the snare protein, STX17, as well as proteins on the lysosome itself, especially LAMP2. Fusion also requires a fully functional lysosome that maintains an acidic pH. This means that drugs that affect the lysosome such as the antimalarials chloroquine, hydroxychloroquine or quinacrine as well as the V-ATPase inhibitor Bafilomycin A1, can function as autophagy inhibitors by preventing fusion of lysosomes to autophagosomes.

From the cancer biology perspective, there are a number of important issues that should be noted. First, the multistep nature of the autophagy pathway means that there are many potential opportunities for manipulation of this process. Such manipulations can be done both genetically by using shRNA, gene knockouts or dominant negative mutants to inactivate or block the activity of specific ATG proteins or many of the same proteins can be targeted pharmacologically. Thus selective inhibitors of the protein kinases (ULK1 and ULK2) as well as the lipid kinase VPS34 have been tested for antitumor effects, as have inhibitors of the protease ATG4B and the E1 conjugating ATG7 protein. At the current time however, the only drugs that have been used in people to inhibit

autophagy are the lysosomal inhibitors chloroquine and hydroxychloroquine. It is also possible to manipulate autophagy by interfering with the complexes themselves. For example, a cell permeable peptide that disrupts a negative regulator of the BECN1 complex has been used to activate autophagy. The BECN1 complex also contains antiapoptotic proteins including BCL2 and BCL-XL. These proteins interact with BECN1 via a BH3 domain. This is the same type of domain that controls BCL family activity at the mitochondria during mitochondrial outer membrane permeabilization (MOMP) to regulate the rate-limiting step in canonical apoptosis. The discovery of this interaction led to the suggestion that BH3 mimetics (e.g., Venetoclax), which are drugs that were designed to disrupt BH3 protein interactions to push tumor cells closer to their apoptotic threshold, could also disrupt the BECN1 complex and induce autophagy. Specific details of the mechanism are incomplete and while it is generally agreed that BH3 mimetics activate autophagy, the idea that they do so by disrupting the BECN1–BCL2 interaction has been challenged. Even if the details of the BH3 mimetics have been questioned however, the important point is that there are multiple potential strategies by which autophagy may be inhibited or induced and these include both interference with enzymatic activities and altering protein complexes; both strategies are conducive to selective pharmacological interventions.

Thus there are many potential ways by which autophagy could be manipulated and this brings up a second important point: the various potential interventions to block autophagy can do so at different steps in the process (Fig. 2). This is important because while blocking autophagy at any step should be similar in terms of its ability to prevent degradation of cargo, stopping the autophagy process before formation of autophagosomes may have different effects than blocking after formation of autophagosomes but before fusion with the lysosome when the autophagosome is serving as a signaling hub (see below for further discussion).

Selective and Nonselective Autophagy

Ultimately, the function of autophagy is to degrade cellular material. This is often described as nonselective, implying that the material that is engulfed by autophagosomes and degraded by the lysosomal hydrolases is completely random. This idea is incorrect. While there undoubtedly is random capture of cytosolic proteins in autophagosomes with their level in the autophagosome being determined simply by their cytosolic concentration, many proteins are specifically targeted for autophagic degradation or specifically excluded from autophagic degradation. Thus, although a large proportion of the proteome can be degraded by autophagy, autophagy is often quite specific. Global proteomic analysis suggests that short-lived proteins tend to be degraded by the proteasome while longer-lived proteins tend to be degraded by autophagy. Moreover some proteins and protein complexes seem to be especially resistant to autophagic turnover (e.g., the ribosome). Specific proteins can also be targeted for autophagic degradation and this can be regulated by external stimuli. A good example is ferritin, which binds iron. Ferritin must be degraded in the lysosome (a process that has been named ferritinophagy) for iron to be released. Thus under iron-deficient conditions, ferritin is specifically targeted to autophagosomes to be degraded. This is achieved by an adaptor protein called NCOA4, which binds to ferritin under iron-deficient conditions targeting it for recognition by the developing autophagosome. Oncogenic signals can also cause specific proteins to be degraded by autophagy. For example, the nuclear lamin B1 protein is selectively targeted to autophagosomes in RAS-transformed tumor cells. There are likely many other cases where specific proteins are targeted for autophagic degradation but identifying such proteins is technically difficult and to date most cases of selective autophagy of particular proteins have been identified by chance or by taking a very targeted candidate approach.

Autophagy also targets protein complexes (e.g., toxic aggregated proteins including those associated with glutamine expansion diseases like Huntington's disease and other neurodegenerative diseases), specific organelles (mitochondria, peroxisomes,

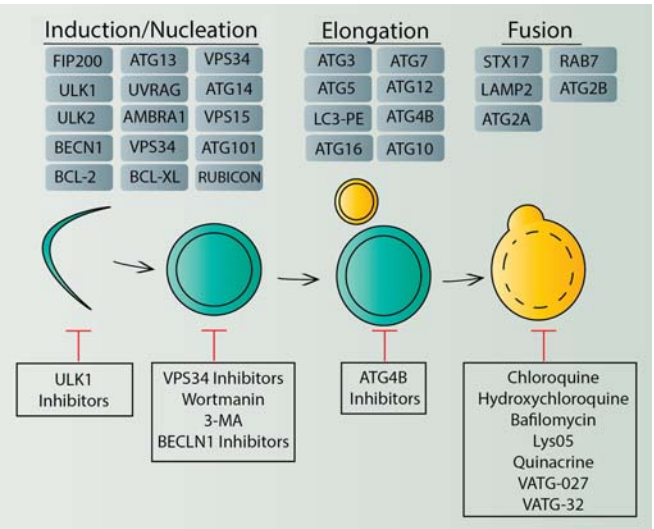

Fig. 2 The autophagy pathway can be targeted at multiple steps, either pharmacologically or genetically.

lysosomes and portions of the endoplasmic reticulum) and other organisms (bacteria and viruses). Many of these selective forms of autophagy have specific names (e.g., mitophagy refers to degradation of mitochondria while pexophagy is the degradation of peroxisomes). Specificity is achieved by particular cargo receptors that recognize the cargo and direct it to the forming autophagosome ensuring that the target in question is preferentially engulfed in autophagosomes. The best-characterized autophagy cargo receptor is SQSTM1 commonly known as p62, which binds ubiquitinated molecules to shuttle them to autophagosomes. It is likely that many other cargo receptors exist, and for example, the TRIM family of proteins can regulate different cargo targeting events. One focus of current research in cancer and other diseases is to try to understand and eventually find ways to enhance or inhibit specific forms of selective autophagy rather than affecting the process as a whole.

Measuring and Manipulating Autophagy

The most common way to measure autophagy is to assess levels of LC3-II. This is done either by western blotting, taking advantage of the faster mobility of the PE-conjugated protein in polyacrylamide gels, or by counting LC3 foci after immunostaining or, sometimes in laboratory studies, after exogenous expression of a fluorescent version of LC3. A common misunderstanding in the autophagy literature is that an increase in LC3-II levels by these measures must be associated with an increase in autophagy. The problem is that autophagy is a dynamic process whereby autophagosomes are formed (i.e., increasing LC3-II) but then fuse with lysosomes resulting in degradation and a decrease of LC3-II. This formation then degradation of autophagosomes is termed autophagic flux and a true increase in autophagy actually means an increase in the flux. The practical problem is that increased autophagic flux could lead to more LC3-II, less LC3-II or the same amount of LC3-II depending on the relative rates of formation, fusion, and degradation of the autophagosomes. In the literature there are many studies where misinterpretation of such experiments has occurred and in some cases incorrect conclusions have been made (e.g., on whether autophagy has been induced or inhibited).

As with any dynamic process involving turnover of biological molecules, in order to assess whether it is increased or not, one must block flux through the system. In the laboratory the most common way to definitively test if there is truly an effect on autophagy is to block the lysosome with chloroquine or Bafilomycin A1. When fusion is prevented, LC3-II should accumulate and, if there is also a stimulus-dependent increase in autophagosome formation (i.e., increased autophagy), this will be manifested by further accumulation of LC3-II and more LC3 foci. Autophagic flux is also measured using LC3 or other autophagosome-targeted proteins with fluorescent markers that change based on the acidity of their environment, thus allowing one to follow fusion with the acidic lysosomes by fluorescence microscopy or flow cytometry. An important unsolved problem in the field is that while such assays can be easily performed in cell culture experiments, it is much harder to do this kind of experiment in a living animal. It is even harder still to do such measurements in tissue samples such as might be available from clinical specimens. This means that there are many situations (e.g., when examining biopsy samples obtained as part of a clinical study) where these approaches to measure autophagy are not feasible. Alternative methods to measure autophagic flux have therefore been proposed. The levels of p62/SQSTM1 can be measured, which as noted above is an important cargo receptor for a number of selective autophagy substrates. An increase in p62 can be suggestive of autophagy inhibition while a decrease in p62 is interpreted as an increase in autophagy. A problem here is that p62 is also regulated in other ways. For example it is transcriptionally activated by many stimuli. At this time we have no truly specific marker whose levels alone are indicative only of the amount of autophagy that is taking place.

Functions for Autophagy: Controlling Metabolism and Cell Death

Two of the main related functions of autophagy that impinge on cancer are to control cellular metabolism and cell death. One way that autophagy controls metabolism is by providing breakdown products when macromolecular autophagy substrates are degraded by lysosomal hydrolases. These products are then used for biosynthesis or energy generation. For example, amino acids can feed into the TCA cycle to generate ATP through oxidative phosphorylation. This use of internally generated nutrients and metabolic precursors by the cell is especially important when external nutrients are not available, for example, during starvation. Not surprisingly, adult mice that are suddenly made completely defective in autophagy (by inducible knockout of the *Atg7* gene) display marked changes in metabolism and are very sensitive to starvation. Autophagy is also important in regulating the overall types of metabolism that cells rely on. For example, autophagy has been shown to promote glycolysis in RAS-transformed cancer cells. Autophagic degradation of specific substrates, for example, lipid droplets (a process that is called lipophagy) also affects cellular metabolism. Autophagic turnover of specific organelles (especially mitochondria) that themselves control metabolic pathways also impacts the overall metabolic state of the cell and organism. In cancer biology, another important aspect of autophagy's ability to control metabolism arises because autophagy in one cell can affect the behavior of another cell. One such non cell-autonomous effect occurs when autophagy in pancreatic stellate cells feeds amino acids (particularly alanine) to neighboring pancreatic cancer cells to promote metabolism in the tumor cells that is necessary for tumor cell growth.

Another frequently studied function for autophagy related to cancer is its ability to control cell death with both pro-death and antideath functions having been identified. Indeed autophagy-dependent cell death (sometime called autophagic cell death or Type 2 programmed cell death) is one of the currently defined versions of programmed cell death along with apoptosis (Type 1 programed cell death) and various types of programmed necrosis (Type 3 programmed cell death) such as necroptosis. Autophagy-dependent cell death is also important during normal development as has been best demonstrated in *Drosophila*. In the cancer literature there are many examples where autophagy has been proposed to promote tumor cell killing by anticancer

drugs. In most cases, this conclusion is based on two observations. First, the drug induces autophagy that is then followed by cell death. Second, inhibition of autophagy by knockdown of ATGs and/or the use of pharmacological inhibitors of autophagy reduces the number of tumor cells that are killed. One problem with such studies is that autophagy regulators may be able to regulate cell death/apoptosis by autophagy-independent mechanisms. For example both ATG5 and ATG12 can regulate mitochondrial apoptosis in ways that do not involve the process of autophagy itself. If the cell death mechanism that is being studied requires multiple different ATG proteins, then it is more likely that this is indeed a type of death that requires autophagy. In that event it is also important to determine if this is a case of autophagy itself killing the cell (i.e., true autophagic cell death) or a case of autophagy promoting another form of death such as apoptosis.

Such effects can be highly specific. For example, it has been shown that even in the same population of tumor cells, autophagy is able to specifically promote or inhibit two very similar apoptotic stimuli (the death receptor ligands Fas Ligand/CD95 Ligand and tumor necrosis factor-related apoptosis inducing ligand, TRAIL). In this case, the ability to promote or inhibit apoptosis was achieved through selective degradation of specific proteins. Thus autophagy sensitizes cancer cells to Fas Ligand because autophagy degrades a negative regulator of the Fas Receptor (the protein phosphatase PTPN13). Because the substrate protein that is being degraded only affects one apoptotic stimulus, this mechanism serves to make autophagy-mediated promotion of apoptosis highly stimulus-specific. Such effects can also be cell type-specific because only cells that express PTPN13 showed autophagy-dependent apoptosis by Fas Ligand. The important point is that by targeting specific proteins for autophagic degradation, it is possible for autophagy to display very specific effects on apoptosis. Other specific autophagy substrates that negatively control apoptosis may exist.

Conversely, the ability of autophagy to protect against apoptosis is more general and it is this activity that allows autophagy inhibitors to function as sensitizers to other anticancer drugs. Indeed this is the basis for numerous clinical trials based on preclinical studies where autophagy inhibitors have been shown to promote tumor cell apoptosis by other anticancer agents. Recently it was shown that one of the main mechanisms by which this occurs is through autophagy regulating a core component of the apoptosis machinery that controls release of mitochondrial proteins such as cytochrome *c* during apoptosis. Autophagy targets the protein PUMA/BBC3, but does so indirectly, as autophagy controls the basal transcription rate of the *PUMA* gene by degrading an upstream transcription factor. Thus when autophagy is low, basal PUMA levels are higher and this serves to prime a cell to undergo mitochondrial apoptosis more easily. Interestingly, in this case the ability of chloroquine to sensitize to conventional cytotoxic cancer drugs like etoposide or doxorubicin is achieved through this mechanism via just one transcription factor binding site in the human genome.

Nondegradative Functions for ATG Proteins and Autophagosomal Structures

Another important source of confusion in autophagy research comes from the fact that the ATG proteins that control autophagy have other biological effects that are autophagy-independent. Many of these other functions have important implications for cancer. For example ATG7 regulates the tumor suppressor p53 through autophagy-independent mechanisms. Similarly BECN1 controls cytokinesis, while as noted above, ATG12 and ATG5 control apoptosis and ATG5 also controls MAP kinase signaling. These kinds of effect usually involve a single autophagy regulator having an effect that other ATGs do not. It is therefore imperative to test multiple ATGs, particularly from different parts of the pathway when assessing the role of autophagy in a given system, as results from knock down/knock out of a single protein may not be due to autophagy related functions.

In other cases, we know that there are distinct autophagy-related processes that involve many of the ATGs but are not true autophagy. For example a type of phagocytosis called LC3-associated phagocytosis (LAP) involves most of the ATG proteins that are required for autophagy. LAP can be distinguished from autophagy by its dependence on a component of the Beclin complex called RUBICON, which is a negative regulator of autophagy but a positive regulator of LAP.

Our mechanistic understanding of autophagy-independent roles for ATG proteins and the autophagy machinery lags behind our understanding of how degradative functions of autophagy elicit biological effects. Studies with the FIP200 protein provide a model for how we can know whether the cancer-promoting effects of a protein that works in both autophagy and other cell pathways is autophagy-dependent. FIP200 is required for autophagy induction as part of the ULK1 complex where it binds to ATG13. It is also an important component of focal adhesions where it regulates focal adhesion kinase activity to alter integrin signaling. FIP200 knockout mice are embryonic lethal but this is due to FIP200's autophagy-independent effects as shown by the generation of a mouse with point mutations in FIP200 that ablate only its autophagy-dependent functions by disrupting ATG13 binding without affecting its other roles; these mice survive longer than the FIP200 knockouts and have a similar phenotype to *Atg5* or *Atg7* knockout mice that are deficient in autophagy but not in integrin signaling. In contrast, the same mutant protein was used to show that FIP200's ability to regulate breast tumor growth is in fact dependent on its autophagy function.

In other cases, evidence suggests that the roles of an autophagy regulator that are important for cancer cell behavior may be via functions that are independent of autophagic degradation. For example, the autophagy machinery regulates cellular secretion of cytokines and other molecules and this activity, independent of the degradative functions of autophagy can explain why interference with ATGs prevents breast tumor cell motility and invasion. The important issue as regards cancer is that although the ATGs that regulate autophagy can have important cancer specific functions, these may or may not be due to autophagy and it is necessary to understand the molecular mechanisms on a case-by-case basis to understand how the cancer phenotype that is of interest is controlled.

Autophagosomes and autophagosome-like structures can also serve as signaling hubs or scaffolds. At this time, the full range of signaling pathways that may be affected by autophagosomal scaffolding are incompletely understood. However we do know that two distinct types of cell death—apoptosis and necroptosis—can be regulated by association of signaling molecules on the

autophagosome. These physical associations activate either caspases to induce apoptosis or regulate the necroptosome, which is a protein kinase complex that controls necroptosis. Such mechanisms also demonstrate an important concept mentioned above—autophagy inhibition can have varying effects, depending on which stage of the pathway is inhibited. Thus, in a particular type of cancer (prostate tumor cells with loss of the tumor suppressor gene *MAP3K7*, which encodes the protein kinase TAK1) TRAIL kills cancer cells by necroptosis rather than apoptosis. In this case, necroptosis is caused by recruitment of components of the necroptosome to autophagosomes via the p62 adaptor protein mentioned above. However, because the underlying mechanism is autophagosomal scaffolding rather than autophagosomal degradation, interventions to inhibit autophagy that prevent formation of the scaffold can have opposing effects compared with those that prevent degradation of the scaffold. Thus inhibition of ATG5, ATG7 or the lipid kinase VPS34 that are all needed for formation of autophagosomes inhibit tumor cell necroptosis while inhibition of the lysosome to prevent autophagosome fusion increases tumor cell necroptosis. This establishes the concept that it may not just be important whether or not one inhibits autophagy, but exactly how autophagy is inhibited may determine usefulness in cancer treatment.

Roles of Autophagy in Cancer Development and Progression

Autophagy as an Inhibitor of Cancer Initiation and Development

The first note-worthy connection of autophagy to cancer came when Beth Levine's laboratory identified Beclin 1 as the human homolog of yeast Atg6 based on its ability to interact with the oncogene BCL2. This work also suggested that Beclin 1, which is often deleted in human tumors, could function as a tumor suppressor. The importance of the *BECN1* gene in human cancer has been challenged however because in humans it is located next to the well known tumor suppressor *BRCA1;* this has led to the suggestion that the genomic loss that is often seen in human tumors is actually just a consequence of this proximity rather than an indication that Beclin 1 itself is important for suppressing tumors. However, inactivation of one copy of the *Beclin 1* gene in mice is sufficient on its own to cause cancer showing that in mice at least *Beclin 1* can function as a bona fide tumor suppressor. Pro-tumorigenic effects of genetic deletion of other autophagy regulators in mice including *AMBRA-1*, *Bif-1*, and *Atg4c* and deletion of *Atg5* and *Atg7* have also been shown to induce tumor formation. Interesting puzzles have also arisen from these studies. For example in mosaic *Atg5* −/− animals, tumors (which tended to remain small and not progress) were seen only in the liver despite the fact that autophagy deficient cells occurred in other tissues in the animal as well.

Many cancer risk factors including aging, chronic inflammation and obesity are associated with reduced autophagy. Although such an association suggests that defective autophagy contributes to the increase in cancer risk, it is often difficult to rigorously demonstrate that such associations are causal. However, the current consensus is that although we have much to learn regarding the underlying mechanisms, autophagy can prevent tumor initiation (**Fig. 3**). This ability involves multiple mechanisms. Tumor suppressor activity is due at least in part to autophagy's ability to remove old and damaged organelles such as mitochondria and peroxisomes, which could generate genotoxic reactive oxidative species (ROS). Autophagy also removes damaged proteins that would otherwise cause increased endoplasmic reticulum (ER) stress. These effects in turn result in autophagy being able to reduce genomic mutations and other cell damage. Autophagy has also been implicated in causing tumor cell senescence, which can block tumor progression.

Autophagy's ability to remove specific intracellular material also plays a role in its ability to protect against cancer. A good example is that cancer-causing infectious agents such as *Helicobacter pylori* can be eliminated by a selective form of autophagy called xenophagy. Autophagy's ability to control p62 levels also affects cancer initiation because p62 can act as a pro-tumorigenic protein. In addition to targeting specific substrates for autophagy, p62 is an important signaling molecule that regulates NFκB and the transcription factor NF-E2-related factor-2 (NRF2), which is a transcriptional regulator of antioxidant genes. p62 is also critical in chronic inflammatory states that promote cancer development including pancreatitis and liver inflammation. One study directly implicates p62 as the critical mediator of autophagy's role in regulating cancer development as liver tumor development caused by deletion of the *Atg7* gene is reduced by simultaneous deletion of the *p62* gene.

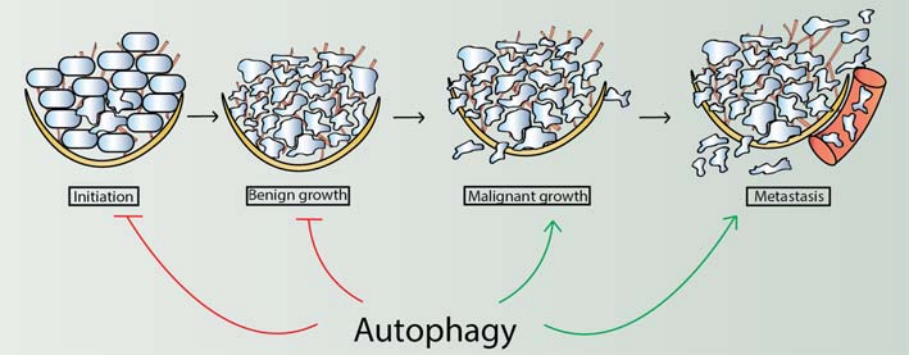

Fig. 3 Autophagy plays a complex role in tumor development where it can be tumor suppressive during early stages of disease progression but is tumor promotional at later stages.

Autophagy as a Promoter of Cancer Progression and Metastasis

Most current evidence suggests that after tumors have formed, the primary role of autophagy is to promote cancer progression. In several mouse models, it has been demonstrated that loss of autophagy regulators (often, but not exclusively through deletion of either *Atg5* or *Atg7* genes) in established tumors can reduce tumor growth and enhance cancer cell death. In lung tumors it has also been shown that deletion of essential autophagy genes can lead to a switch from more aggressive adenocarcinomas to less aggressive tumor types—specifically oncocytomas, which are notable for being associated with elevated levels of damaged mitochondria due to a lack of mitophagy.

In most of the animal studies that have examined the effect of inactivating autophagy regulators on tumor behavior, the autophagy gene knockout has taken place simultaneously with the genetic mutation that drives tumor development. This makes it hard to determine if there are different roles for autophagy at different steps in the tumor evolution. These studies also poorly model the effects of a clinical intervention as most patients are not treated until after they present with an established tumor.

To tackle this issue, more complicated animal models have been used where autophagy inhibition occurs subsequent to tumor development. In one study, this allowed the effects of complete whole body autophagy inhibition by *Atg7* knockout to be determined before or after KRAS-driven lung cancers developed. This approach models a scenario where a perfect autophagy inhibitor that affects all cells in the body and directly targets the autophagy machinery is administered. The effects were dramatic and clearly demonstrate that complete autophagy inhibition in an animal is uniformly lethal but with differing kinetics. Some mice died within a few days while the others died after a 2–3 month period. The first group died due to *Streptococcus* infection, consistent with a known role for xenophagy in eliminating pathogenic *Streptococcus* from cells. The remaining mice all died within a few months due to neurodegeneration. Again, this might have been expected because autophagy protects against aggregated protein-induced neurotoxicity. Additionally, and also as we would expect, the *Atg7*-deleted mice were very sensitive to nutritional stress as fasting for 24 h, a stress that wildtype mice can survive with no problem, was lethal for most of the animals. These toxicities could suggest that autophagy may be too toxic to be useful for cancer therapy. However, when the authors studied the effect of total body inhibition of autophagy after tumor formation specifically during the window of time when animals were healthy prior to neurodegeneration, they discovered that the lung tumors regressed. Interestingly, the antitumor effect was significantly greater when *Atg7* was deleted in all tissues compared with the effect seen when *Atg7* was deleted only in tumor cells. This suggests that autophagy has important effects in nontumor cells that affect the behavior of the tumor cells. Thus, although autophagy is indeed critical for survival of the organism, there may be a potential therapeutic window where autophagy inhibition can eradicate tumors. Gene knockouts, which are permanent and irreversible, are not going to have the same toxicities as drugs, which could be stopped for a period of time and are unlikely to ever completely inhibit a process. Another model used inducible expression of a dominant negative mutant ATG4 molecule that blocks autophagy in a pancreas cancer mouse model. This model is important because it allows reversible inhibition of autophagy by removing the inducer that activates expression of the dominant negative and also allowed intermittent treatment that better mimics the way pharmacological inhibitors of a process are used. Important conclusions from this study were that autophagy inhibition is effective at inhibiting tumor growth (i.e., autophagy is necessary for tumor progression and maintenance) and that these effects involve both tumor cell autonomous and nonautonomous mechanisms of autophagy, raising the issue of exactly what these mechanisms are.

As with its ability to suppress tumor initiation, multiple mechanisms have been identified by which autophagy may promote tumor progression and it is likely that many different mechanisms all play a role in the final behavior of the tumor. Cancer cells are generally sensitized to apoptosis, and one important mechanism by which autophagy protects tumor cell survival is by keeping tumor cells below their apoptotic threshold. Tumor cells are often exposed to nutrient stress and hypoxia; autophagy's well-established roles in protecting cells against these stresses can promote tumor cell survival under stress. Autophagy has also been shown to be important in tumor cell motility through multiple mechanisms including autophagy-dependent secretion of cytokines, turnover of cytoskeletal proteins that are important in regulating cell motility and regulation of small GTPases of the Rho family. Autophagy has been reported to be important for maintaining cancer stem cell-like activity and for allowing dormant tumor cells to survive. All of these mechanisms could contribute to increased metastasis and there are numerous reports that metastatic cancer cells have elevated autophagy. Most of these effects are tumor cell autonomous, however, there have been several studies that show important nontumor cell autonomous functions for autophagy. The best understood example shows that autophagy in the tumor microenvironment (e.g., pancreatic stellate cells) produces amino acids that are used to feed metabolic pathways in cancer cells.

Autophagy and the Immune Response to Cancer

Another important aspect of how autophagy affects tumor progression comes from the relationships between autophagy and the cancer immune response. However, as with cell death both tumor-promoting and tumor-suppressing functions have been identified. Autophagy can stimulate antitumor immune responses through several mechanisms. The adaptive antitumor immune response requires that tumor antigens are recognized by the immune system. Autophagy is important in antigen presentation by MHC class I and II molecules to T cells. Autophagy is also important in ensuring T cell maturation and survival. Activation of an effective T cell response to tumors requires that cancer cells die via an "immunogenic" type of death that involves exposure of calreticulin on the surface of the dying cell and it releasing damaged-associated molecular patterns (DAMPs) such as HMGB1 as well as ATP. Both DAMP and ATP release are affected by autophagy in the dying cell. All these effects suggest that autophagy is necessary for creating an effective antitumor immune response. Conversely autophagy can work against other forms of immune

control of cancer, by for example, reducing the ability of natural killer (NK) cells to kill cancer cells. Emerging data on the nondegradative role of autophagosome scaffolding on the apoptotic/necroptotic switch in cell death adds new issues to consider since necroptosis is especially potent at inducing antitumor immunity.

Targeting Autophagy in Cancer Treatment

Autophagy Inhibition as an Anticancer Treatment

It is clear that autophagy has context dependent roles in cancer that often compete with each other, thus it may seem unclear whether we should try to inhibit or enhance autophagy as a cancer treatment. Despite these controversies, there are dozens of clinical studies where autophagy inhibition is being tested as a cancer treatment. Indeed, although autophagy is involved in many diseases, cancer treatment with autophagy inhibitors make up the majority of all the clinical studies where attempts to deliberately manipulate autophagy to treat disease are being pursued. In addition, because autophagy is affected by many other treatments, autophagy is inadvertently being manipulated in other cases as well—for example, when a patient is treated with an mTOR inhibitor or a microtubule inhibitor. To date, attempts to deliberately inhibit autophagy as a cancer therapy have all used the lysosomal inhibitors chloroquine or hydroxychloroquine and most of the studies have involved combination therapy where the autophagy inhibitor is combined with another anticancer drug. These studies are based on a large number of in vitro and xenograft studies that followed an initial study by Amaravadi and colleagues showing that by inhibiting autophagy, another drug can be made more effective at killing cancer cells. As noted above this usually involves direct regulation of the apoptosis machinery by autophagy. This kind of chemosensitization implies that the other drug must have some activity on its own. In addition, it has been shown that autophagy inhibition can reverse drug resistance and thus make a drug that has no activity for a given tumor cell become active. For example, acquired resistance to a kinase inhibitor that targets mutated BRAF can be reversed by autophagy inhibition. Important issues that are under investigation include determination of which drugs work best in combination with autophagy inhibitors and which patients are best candidates for these therapies.

Although the current efforts to deliberately target autophagy in clinical trials focus on autophagy inhibitors, it has also been suggested that we should try to further enhance autophagy in cancer patients. The most persuasive argument for this strategy comes from studies showing that interventions that mimic caloric restriction can enhance the antitumor immune response through mechanisms that are dependent on induced autophagy.

Clinical Experience in Targeting Autophagy

Clinical response to autophagy inhibition using hydroxychloroquine and chloroquine has varied widely (see Levy et al. in the Further Reading section for more details) with some signs of clinical improvement but many cases where there was no apparent benefit. It is important to note that many of these studies have been performed in patients with advanced disease and this may have limited the potential for any benefit to be seen. Additionally, we know from several of the clinical studies that there is inconsistent autophagy inhibition in patients at clinically achievable doses of the lysosomal inhibitors that have been used. There is also marked variation in the bioavailability of hydroxychloroquine and different tumors accumulate very different levels of the drug. Encouragingly, most of the studies have not caused serious toxicity in patients. In particular, there have been no signs in patients of the toxicities that were observed in adult mice with inducible and complete inhibition of autophagy by *Atg* gene knockout (i.e., susceptibility to bacterial infection, greatly altered metabolism and neurodegeneration). This likely reflects the fact that unlike gene knockout, chloroquine and hydroxychloroquine are not 100% effective as autophagy inhibitors. Interestingly, the toxicities that have been seen, for example, in a canine clinical trial with doxorubicin plus hydroxychloroquine or in human patients treated with BRAF inhibitor plus chloroquine, were enhancement of the toxicities for the drug that was combined with the autophagy inhibitor. This suggests that systemic autophagy inhibition might also sensitize normal tissues to the anticancer drug that was used in combination. In most of the clinical studies to date there has been no attempt to define a particular subgroup of patients that may benefit most from autophagy inhibitors. This may explain the variability and low levels of clinical benefit that have been seen—perhaps only some defined subtypes of cancer will respond. One such subgroup may be patients whose tumors harbor a BRAF mutation. For example, all the BRAF mutant pediatric brain cancer patients whose tumors had become resistant to the RAF inhibitor, Vemurafenib, that were subsequently treated with RAF inhibitor plus chloroquine experienced clinical improvement. While only a few patients have been treated with this therapy, these initial studies suggest promising results for BRAF mutant tumors.

Current Efforts to Improve Autophagy-Based Therapies

The preclinical and clinical studies outlined above suggest that our current autophagy inhibitors are not effective enough. This has led to a significant effort to make more potent and selective inhibitors. These efforts have focused on targeting other molecules (e.g., the kinases ULK1/ULK2 or VPS34) as well as making more potent lysosome inhibitors. An exciting recent advance was the discovery that dimerization of antimalarials such as quinacrine can markedly enhance their potency and specificity as autophagy inhibitors. There are many options for autophagy enhancers (e.g., mTOR inhibitors and many other drugs, but also nutraceuticals such as trehalose and even potential behavioral interventions like exercise) but they all have other effects and there is, as of yet, no available agent that can be used in patients that would be considered a specific autophagy inducer.

Another major effort is to identify useful biomarkers where autophagy based interventions will be most useful. The BRAF mutation status may be useful and certain tumor types that are especially dependent on autophagy such as pancreas cancer may respond better than other tumor types. However at this time we have no definitive biomarker that would serve as a selection method for autophagy-based treatment. Perhaps the biggest barrier to improving autophagy-based therapy is that we lack an effective method to measure changes in autophagy in clinical samples. Measuring changes in autophagy in cultured cells is often problematic even when molecular biology techniques are readily available in these systems including the ability to introduce fluorescent proteins and acutely block the lysosome to measure autophagic flux. These problems are magnified significantly when it comes to studies in vivo in laboratory animals and magnified again in clinical studies where available tissue is often limited to biopsy samples before and after treatment. At this time the field lacks a reliable way to assess differences in autophagy in small tissue samples and instead must rely on correlative and usually nonquantitative studies. As progress is made on these problems and more effective manipulators of autophagy are developed it should become more feasible to rigorously test the value of autophagy-based treatments.

Prospective Vision

In the last 20 years there has been very rapid growth in our understanding of autophagy and its roles in cancer. And, although cancer is only one of very many diseases where autophagy plays a role, efforts to translate our basic understanding of autophagy to the clinic are further advanced in cancer than they are in other diseases. However, we have many areas for improvement. We have little understanding of exactly how autophagy elicits its biological effects and numerous important questions remain. What cargos are being degraded for autophagy to have a given biological effect? What is the role of nondegradative functions of the autophagy machinery in the biology? Is it possible to selectively manipulate autophagy so that only some cargos are affected? Would this make autophagy-based treatments better? How do we reconcile the various competing effects of autophagy in cancer to maximize the benefit of any intervention? Continued progress in answering these and other questions seems assured given the high level of activity in this field.

Definition and Classification

There are five major histological types of urinary bladder cancer, including non-invasive and invasive urothelial carcinoma, as well as squamous cell carcinoma, adenocarcinoma, and small cell carcinoma.

By far the most common type is urothelial carcinoma which accounts for about 80%–90% of all bladder cancers worldwide (90% in industrialized countries). Urothelial carcinoma of the urinary bladder (ICD-O code: 8120/3; also called transitional carcinoma or transitional cell carcinoma) is a malignant neoplasm arising from the transitional epithelium lining the bladder. It may have a flat or papillary configuration. According to the TNM classification system, papillary tumors confined to the mucosa are classified as stage Ta and those invading the lamina propria as stage T1. Flat, high-grade tumors that are confined to the mucosa are classified as carcinoma in situ (CIS or Tis). For therapeutic purposes, some of the current treatment recommendations group these three tumor categories under one heading of non-muscle invasive bladder cancer (NMIBC) as opposed to muscle-invasive bladder cancer (MIBC; T2 and higher). However, the malignant potential of Cis and T1 lesions has been shown to differ from that of Ta lesions. Therefore, the term "NMIBC" may be considered to be suboptimal and should be used with caution.

Presentation and Diagnosis

Approximately 70%–75% of bladder cancer patients present with a disease confined to the mucosa (stage Ta, carcinoma in situ (CIS)) or—less often—to the lamina propria (stage T1). The most common symptom and presenting complaint is hematuria. However, the severity of symptoms depends on tumor stage and early-stage non-invasive urothelial carcinomas are often asymptomatic or associated with non-specific symptoms.

The classical clinical presentation of bladder carcinoma is painless gross hematuria. Depending on the size and the surface condition of the lesion (e.g. ulceration), increased urination frequency (nocturia) and urgency as well as dysuria may also occur. If the

cancer involves the site of implantation of the ureter(s), hydronephrosis may develop, which may be complicated by pyelonephritis. More advanced tumors may be associated with pelvic pain and urinary obstructive symptoms as well as—in case of large tumor masses—with a palpable suprapubic mass or lower extremity edema.

Urine cytology has a relatively low sensitivity for detecting bladder cancer. Therefore, a number of urine biomarker tests have been developed (see "**Biomarkers**" section). However, due to conflicting data on their accuracy and clinical utility, their use is still limited and none of them has been recommended for diagnosis or follow-up of bladder cancer patients by any official guidelines. Cystoscopy, bimanual examination, and biopsy or transurethral resection remain the highest sensitivity techniques for the diagnosis and staging of urinary bladder carcinoma. Newer magnetic resonance imaging (MRI) techniques may be useful in staging, particularly in patients with tumors in difficult locations, or to distinguish between confined tumors and extravesical fat invasion. Although lymph node size is not a reliable indicator of metastasis, lymph node enlargement is considered to be predictive of metastatic disease. Positron emission tomography (PET) imaging has been reported to be superior to computed tomography (CT) and MRI in the detection of lymph node metastases.

The most important element in pathologic evaluation of bladder cancer is recognition of the presence and extent of invasion. Invasive urothelial carcinoma shows a remarkable diversity of morphological manifestations. It can present with a wide range of architectural patterns, including variably sized nests with smooth borders, sheets, trabeculae, cords, and single cells. There is often a mixture of patterns. In most tumors, there is no specific feature that resembles normal urothelium. Some data have indicated that invasion patterns have prognostic significance, with more infiltrating cords and single cell patterns being associated with a worse prognosis.

Epidemiology and Risk Factors

Bladder Cancer Burden

Nearly 430,000 new bladder cancer cases were diagnosed worldwide in 2012 (330,380 in men and 99,413 in women), making it the 11th most common cancer in the world when considering both sexes together and the 7th most common in men. The highest age-standardized incidence rates were recorded in Turkey (15.24), followed by Hungary (14.08), Spain (13.92), and Norway (13.45). Overall, 72% of cases were diagnosed in countries with a high or very high human development index (**Fig. 1**).

Despite high recurrence rates, bladder cancer has a relatively good prognosis compared to many other cancers, if treated rapidly following diagnosis. With 165,000 deaths in 2012, it was the 13th cause of cancer-related mortality.

By the year 2030, the global bladder cancer incidence is supposed to rise by about 280,000 cases, with approximately 135,000 in less developed countries. The predicted number of deaths is nearly 280,000 (156,000 in less developed countries).

There has been a decline in bladder cancer incidence and mortality in developed countries but some rising trends have been observed in Eastern Europe and in certain countries in developmental transition. However, the trends are difficult to interpret due to much variability in diagnostics and treatment practices as well as the availability of treatments between different countries. Moreover, the reported variations may also reflect differences in the quality of data collection and cancer registration.

Etiology and Risk Factors

Men are more than four times more likely to get bladder cancer than women. Ethnicity does not seem to play a role. Recent studies have identified a number of putative genetic susceptibility loci. However, a number of conflicting results have been reported and the data remain to be clarified.

Smoking, and in particular cigarette smoking, is the leading cause of bladder cancer, with up to 40%–50% of male cases attributable to smoking. The risk of developing bladder cancer is two- to sixfold higher in smokers than never-smokers, and it is correlated with the duration and intensity of smoking, while smoking cessation reduces the risk over time. The underlying carcinogenic mechanisms have not been fully elucidated but they are clearly linked to mutagens contained in the tobacco smoke, such as aromatic amines which trigger carcinogenesis through the formation of DNA adducts. Along the same line, occupational exposure to aromatic amines has been shown to cause bladder cancer and it has been suggested that their carcinogenic effect may be synergistic with that of smoking. A number of other occupational exposures have also been linked to an increased risk of bladder cancer (**Table 1**) which has been widely recognized as an occupational disease.

Arsenic-contaminated drinking water, in particular in parts of South-East Asia and in Chile, has been proven to cause bladder cancer. There is also evidence that disinfection by-products, like chemicals generated by water chlorination, could increase the risk of the disease.

Chronic bladder inflammation is a major risk factor for developing squamous cell carcinoma of the bladder. Schistosomiasis, chronic infestation with the parasitic trematode (blood fluke) *Schistosoma haematobium*, has been associated with bladder cancer development in *S. haematobium* endemic countries, with affected individuals having a 2–15-fold increased risk of developing bladder cancer compared with non-affected subjects. Continuous mucosal irritation and chronic inflammation, associated with parasitic infestation but also with the use of indwelling catheters, can cause squamous metaplasia, dysplasia, and eventually

squamous cell carcinoma of the bladder. For this reason, patients with long-term paraplegia are also at a markedly elevated risk for this tumor type.

Pathology and Genetics

Most neoplasms of the bladder are epithelial. Epithelial neoplasms are most often of transitional epithelial (urothelial) type. However, as stated in the introduction, adenocarcinomas, squamous cell carcinomas and small cell carcinomas also occur, although much less frequently than urothelial neoplasms. Urothelial neoplasms are not limited to the bladder, they occur in the entire urinary tract (including renal pelvis and ureters).

The transitional epithelial (urothelial) tumors are rather heterogeneous in morphology and behavior. Non-invasive urothelial neoplasms are precursor lesions of invasive urothelial carcinoma. Two types of precursor lesions have been identified: papillary neoplasms and flat urothelial carcinoma in situ. Papillomas represent the benign end of the spectrum while—at the other end—high-grade papillary carcinomas are very aggressive lesions. These will be addressed extensively whereas squamous cell carcinoma will be only briefly discussed. Mixed carcinomas are composed of a mixture of cell types. Adenocarcinomas are rare; most show an intestinal phenotype. Some adenocarcinomas occur in the urachal vestige of the bladder and presumably

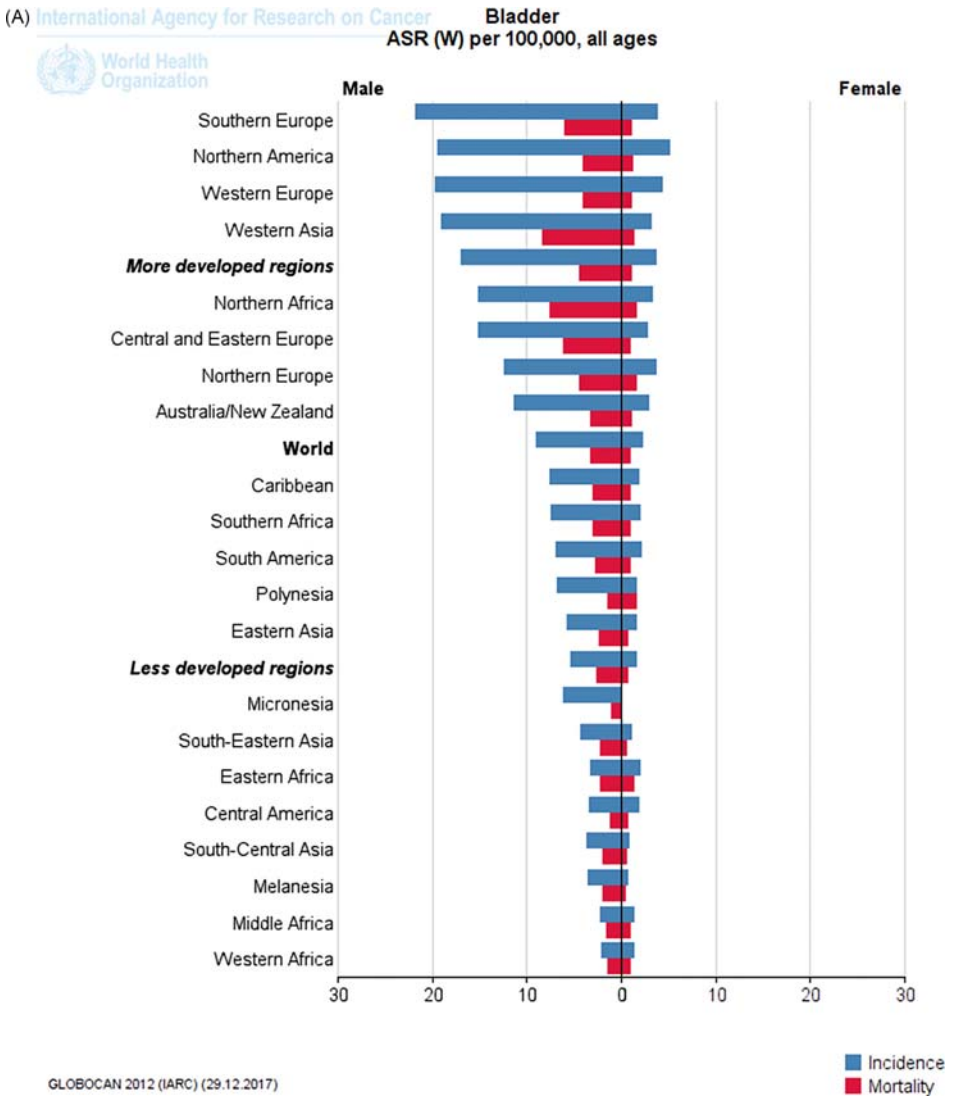

Fig. 1 Incidence and mortality of bladder cancer worldwide. (A) Age-standardized incidence and mortality rates (ASR) by gender and geographical area. (B) Incidence distribution worldwide. Fig. 1 (*continued*).

develop from areas of intestinal metaplasia. These will not be further discussed. Small cell carcinoma is rare and is similar to small cell carcinoma of the lung in morphology, biological behavior and molecular characteristics. Sarcomas are rare and will not be further discussed.

Table 1 Risk factors for urinary bladder cancer

Carcinogenic agents classified by *IARC Monographs on the evaluation of carcinogenic risks to humans* (volumes 1–120)
Agents of sufficient evidence for bladder carcinogenicity in humans
Aluminum production
4-Aminobiphenyl
Arsenic and inorganic arsenic compounds
Auramine production
Benzidine
Chlornaphazine
Cyclophosphamide
Magenta production
2-Naphthylamine
Painting
Rubber production industry
Schistosoma haematobium infection
Tobacco smoking
ortho-Toluidine
X-radiation and gamma-radiation
Agents of limited evidence for bladder carcinogenicity in humans
4-Chloro-ortho-toluidine
Coal-tar pitch
Dry cleaning
Diesel engine exhaust fumes
Hairdressers and barbers, occupational exposure
2-Mercaptobenzothiazole
Pioglitazone
Printing processes
Soot
Textile manufacturing
Tetrachloroethylene

Pathology of Non-Invasive Urothelial Neoplasms

Papilloma

Papillomas are relatively rare, representing about 1% of bladder tumors. They typically appear in young patients. Cystoscopically, papillomas are small (0.5–2.0 cm) lesions protruding with papillary fronds into the lumen of the bladder. Histologically, these are composed of a central fibrovascular stalk, covered with bland epithelial cells much like normal urothelium. Occasionally, such lesions do not extend exophytically but endophytically into the underlying stroma, but without passing through the epithelial basement membrane. These are called inverted papillomas. Papillomas are benign lesions which rarely recur or progress after endoscopic excision. Nonetheless, long-term follow-up is necessary as there are no morphological characteristics identifying those papillomas with a tendency to recur.

Papillary urothelial neoplasm of limited malignant potential (PUNLMP)

PUNLMPs mostly occur at advanced age (mean: 65 years). They are cystoscopically and histologically very similar to papilloma, but the epithelium covering the papillary fronds shows minimal atypia: it is thicker and the nuclei are slightly enlarged (Fig. 2A). PUNLMPs tend to be somewhat larger than papillomas. There is very limited proliferative activity; mitoses are rare and limited to the basal layer. PUNLMPs have a slight tendency to recur but—as a rule—the morphology does not change in recurrent lesions. Only rarely do they progress to high-grade lesions with invasive and metastatic capacity. This category has been developed to avoid a diagnosis of cancer for patients with a lesion that has a very low tendency for progression. Long-term follow-up, however, is advised.

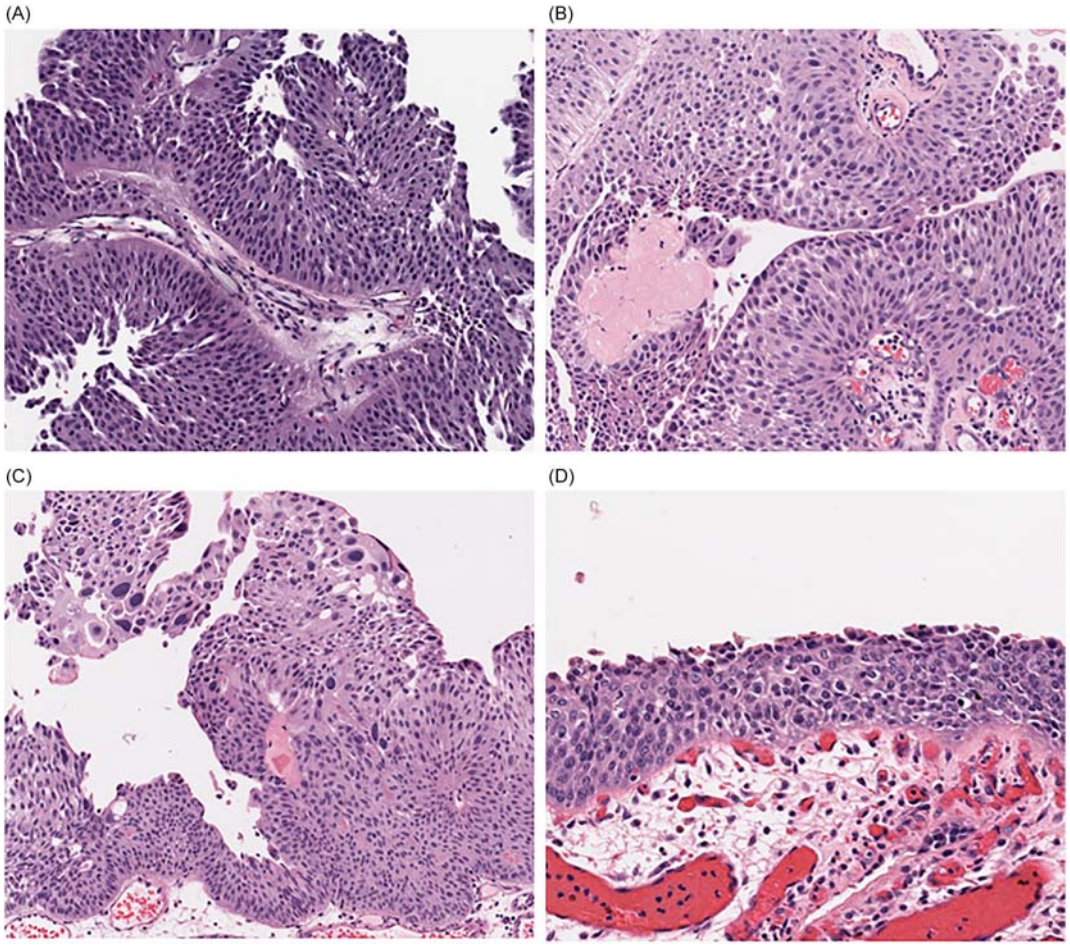

Fig. 2 Non-invasive urothelial neoplasms. (A) Papillary urothelial neoplasm of unknown malignant potential (PUNLMP). Papillary fronds are composed of a central fibrovascular core covered with normal looking urothelial cells but slightly thickened. (B) Papillary urothelial carcinoma, low-grade. Irregular papillary architecture and thickening of the epithelium. Epithelial cells show some loss of cohesion and focally of polarity. There is slight nuclear pleomorphism. (C) Papillary urothelial carcinoma, high-grade. The most important difference with low-grade papillary urothelial carcinoma is the striking nuclear pleomorphism and the presence of mitoses. There is no tendency towards invasive growth. (D) Urothelial carcinoma in situ. The mucosa is covered with an irregular urothelium with loss of epithelial stratification and cytonuclear atypia; no invasive growth. Note hyperemia and edema in the underlying lamina propria.

Low-grade papillary urothelial carcinoma

Low-grade papillary urothelial carcinomas characteristically show a rather regular architecture and limited cytonuclear atypia. The papillary fronds tend to branch. The epithelium is thickened and the epithelial cells may show some loss of polarity at higher magnification (Fig. 2B). Nuclei show some hyperchromasia and pleomorphism. Some mitotic activity is noted, not necessarily limited to the basal layer. Atypical mitoses are not found. Low-grade papillary urothelial carcinoma can recur and ultimately invade, although the latter is rare (10%).

The prognosis of papillomas, papillary urothelial neoplasms of low malignant potential, and low-grade papillary urothelial cancer is excellent, with 10-year survival rates of 98%. Even though there may be several recurrences, the tendency for progression is low.

High-grade papillary urothelial carcinoma

High-grade papillary urothelial cancers show more architectural disturbance. Papillary fronds tend to fuse, giving them a more solid appearance. The epithelium is often thickened but thickness can be quite variable. There is more striking cytonuclear atypia with loss of cell polarity, loss of cellular cohesion, nuclear hyperchromasia and pleomorphism (Fig. 2C). Mitotic activity is brisk and atypical mitoses are easily found. High-grade urothelial cancers have a much stronger tendency to progress and invade the muscular layer (80%). Once invasive, they have significant metastatic potential.

Carcinoma in situ

As stated above, invasive urothelial carcinoma has two precursor lesions, the second one being flat non-invasive urothelial carcinoma in situ (CIS). The histological term "CIS" is used for epithelial lesions that have cytonuclear characteristics of malignancy but do not invade through the epithelial basement membrane, being limited to the epithelium, hence the suffix in situ. CIS is invariably considered as high-grade. CIS tends to be multifocal and occasionally spreads diffusely over the bladder mucosa. Cystoscopically, it often appears as slightly elevated erythematous plaque but some CIS have more the aspect of an erosion.

CIS is composed of cytologically atypical cells that may occupy the full thickness of the epithelium or spread into normal urothelium in a pagetoid fashion. There is striking nuclear pleomorphism, with some nuclei 5–6 times as large as those of a lymphocyte. They tend to have one or more irregular nucleoli. Mitotic activity is significant and atypical mitoses can be found (Fig. 2D). Foci of micro-invasion are occasionally present. A lack of cohesiveness of CIS cells is responsible for shedding of the cells which may then colonize other areas of the bladder mucosa, one of the purported mechanisms of multifocality. CIS has a high tendency to progress into muscle-invasive cancer, with over 50% of cases which progress if untreated.

Molecular Carcinogenesis of Non-Invasive Urothelial Lesions

Molecular characteristics of the various non-invasive urothelial lesions are rather similar. The current working hypothesis regarding bladder carcinogenesis suggests that the initial event is a field effect, involving multiple sites in the urothelium. Supposedly, multiple oncogenic events transform stem cells in the affected areas of the urothelium into cancer stem cells. When these clonally expand, tumors are formed. Two different pathways have been singled out as affected by the initial event: the FGFR3- and p53-associated pathways which generate lesions differing in biological behavior and clinical outcome. Activating *FGFR3* mutations are associated with non-invasive lesions, while *TP53* mutations, or mutations in genes regulating p53, such as *CDKN2A*, are associated with high-grade lesions. Loss of heterozygosity of (part of) chromosome 9 is strongly associated with non-invasive lesions. Interestingly, this has been found also in normal mucosa adjacent to non-invasive lesions, supporting the field effect concept.

Pathology of Invasive Urothelial Carcinoma

Around 90% of invasive urothelial carcinomas are localized to the bladder, the remainder in the upper urinary tract. Invasive urothelial carcinomas can be unifocal or multifocal. Grossly, they may be sessile, polypoid, or ulcerative. Occasionally, invasive urothelial cancer is accompanied by papillary urothelial cancer which will be typically high-grade, or by CIS. The carcinoma usually extends into the bladder wall but, given the proximity of these structures, the adjacent prostate, seminal vesicles, ureters, or retroperitoneum may be involved. Aggressively invasive tumors with extensive necrosis may develop fistulae to rectum or vagina. Deeply invasive tumors are often metastatic to local lymph nodes (40%). Late-stage tumors show hematogenous dissemination to the liver, lungs and bone marrow.

Microscopically, urothelial carcinoma shows an astonishing array of growth and differentiation patterns. Growth pattern may be in sheets, nests, trabeculae, or single cells (Fig. 3A). As a rule, the tumor cell characteristics are those of a high-grade carcinoma, with striking nuclear pleomorphism, high mitotic activity and atypical mitoses. Often, the cytomorphology bears no resemblance to urothelium. Various divergent differentiation patterns have been recognized (squamous, glandular, trophoblastic, nested, microcystic, and micropapillary). These patterns have been associated with differences in prognosis but with the advent of molecular typing these may lose relevance.

A very important element is the presence and, if present, the extent of invasion of the carcinoma. Invasion starts with breaking through the epithelial basement membrane and migration of the invasive cells into the lamina propria (Fig. 3B). This worsens the prognosis, but invasion through the muscularis mucosae has been found to be a major prognostic determinant. In a significant proportion of biopsies, muscularis mucosa is not present and this may lead to understaging. In fact, on a small biopsy of a large

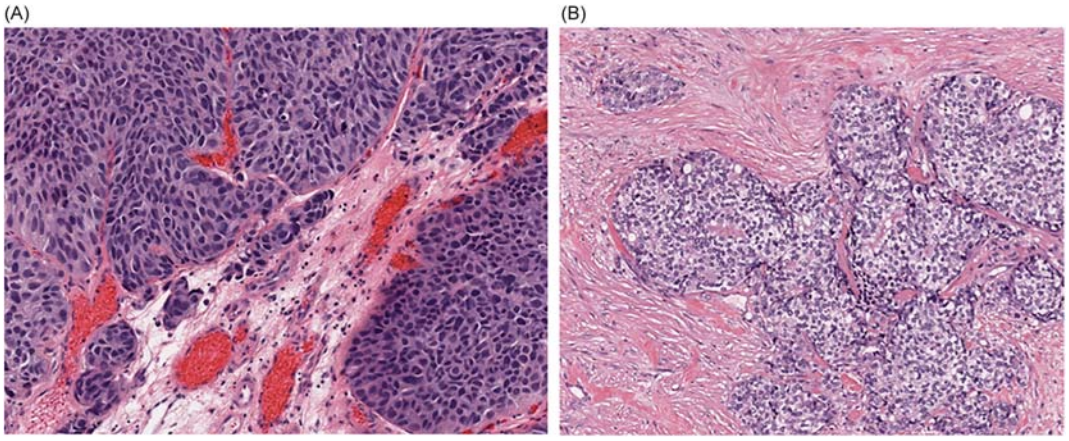

Fig. 3 Invasive urothelial carcinoma. (A) Large clusters of highly atypical urothelial cells are seen. Small clusters of carcinoma cells are found in the adjacent stroma, as evidence of invasion into the lamina propria. (B) Muscle-invasive urothelial carcinoma. Large clusters of atypical urothelial cells are surrounded by bundles of smooth muscle cells, evidence of invasion into the muscularis propria of the bladder.

lesion, the absence of invasion through the muscularis mucosae bears no significance. Only when this can be found already in the biopsy, this is significant information. Grading of invasive urothelial carcinomas is of minor importance as these are almost invariably high-grade. This is in contrast to the role the assessment of invasion plays in biopsies of non-invasive papillary urothelial carcinoma. For invasive lesions, the next step is invasion into the muscularis propria (detrusor) of the bladder wall (**Fig. 3**C). The 5-year mortality rate of patients with a detrusor muscle-invasive urothelial carcinoma is around 30%.

After resection of a urothelial carcinoma, there is a high recurrence rate, whatever the grade of the resected tumor. Tumor size, stage, grade, and multifocality or CIS in the surrounding mucosa are determinants of the risk of recurrence. Recurrence might not be the most appropriate term for this finding as studies have shown that many of the recurrent lesions are not clonally related to the original carcinoma and represent new lesions, in accordance with the field-effect concept. Some distant new lesions may share driver mutations with the original carcinoma, which can be taken as evidence of intravesical shedding and implantation of cancer cells at distant intravesical sites.

Urothelial carcinoma metastases may pose diagnostic difficulties in terms of identification of the primary tumor. The International Society of Urologic Pathology suggests that positivity for GATA3, CK20, p63, and either high molecular weight cytokeratin or CK5/6 as determined by immunohistochemistry may have some value to confirm urothelial differentiation and support differential diagnosis in the appropriate context. However, they clearly state that there is no single ideal biomarker or a panel to equivocally confirm urothelial differentiation (see also "**Biomarkers**" section).

Genetics of Urothelial Bladder Carcinoma

Unsupervised analysis of RNA-Seq data from a cohort of 1372 patients with non-muscle invasive bladder cancer (NMIBC) has led to the identification of three molecular subtypes (class 1–3) that differ by their histomolecular characteristics and by their risk of progression to MIBC. Class 1 tumors resembled the "luminal" subtype and had the best prognosis, class 2 was enriched with carcinoma in situ (CIS) and with high epithelial-to-mesenchyme transition markers, whereas class 3 tumors frequently expressed markers of bladder cancer stem cells and were more similar to "basal cell-like" subtype. T1 and high-grade tumors were more frequently seen in classes 2 and 3 than in class 1, and the majority of progression events were observed in patients with class 2 tumors. Since progression to MIBC is associated with a 50% 5-year survival, the early identification of tumors with a high risk of progression is a significant clinical challenge. Because MIBC likely arises from CIS, these findings suggest that class 2 tumors may have a genomic profile associated with an increased risk for progression. If this is validated prospectively, patients with class 2 NMIBC may benefit from definitive therapy with radical cystectomy.

A recent comprehensive analysis of 412 muscle-invasive bladder cancer (MIBC) by the Cancer Genome Atlas Research Network and collaborators has identified 58 often mutated genes as well as an overall high mutational load associated with *APOBEC*-signature mutagenesis (**Table 2**). Copy number gains occurred at loci involving *E2F3*, *PPARG*, and *MDM2*. The most commonly deleted genes were *CDKN2A* and *RB1*, whereas fusions commonly involved *FGFR3* and *PPARG*. The top most frequently mutated genes were *TP53*, *KMT2D*, *KDM6A*, *ARID1A*, *PIK3CA*, *KMT2C*, *RB1*, *EP300*, *FGFR3*, *STAG2*, and *ATM*. A classification of MIBC based on their mutagenic signatures identified four clusters (MSig1 to MSig4) characterized by *APOBEC a* and *b*, *ERCC2* and C>T at CpG sites, respectively, which were associated with overall survival. In particular, patients with MSig1 cancers (high *APOBEC* signature and high mutation burden) showed an exceptional 75% 5-year survival probability, whereas the *ERCC2* signature was more prevalent in smokers than in non-smokers.

Several groups have proposed integrative classifications of bladder cancers based on histomolecular features. An analysis of four independently published comprehensive gene expression datasets has identified several intrinsic molecular subtypes of high-grade

Table 2 Gene loci found to be most frequently altered in muscle-invasive bladder cancer in the recent Cancer Genome Atlas (TCGA) Research Network study

Pathway	*Gene (locus)*	*Alteration type*	*Estimated frequency (%)*
p53 signaling/regulation of cell division, DNA repair and apoptosis	*TP53* (17p13.1)	Point mutations	48
	E2F3 (6p22.3)	Amplifications	12
	MDM2 (12q15)	Amplifications	12
	RB1 (13q14.2)	Deletions and point mutations	17
	CDKN2A (9p21.3)	Deletions	22
	STAG2 (Xq25)	Point mutations	14
	ATM (11q22.3)	Point mutations	14
Chromatin remodeling/histone methylation	*KMT2D* (12q13.12)	Point mutations	28
	KDM6A (Xp11.3)	Point mutations	26
	KMT2C (7q36.1)	Point mutations	31
	ARID1A (1p36.11)	Point mutations	25
	EP300 (22q13.2)	Point mutations	14
PIK3CA/PTEN/Akt metabolism	*PIK3CA* (3q26.32)	Point mutations	22
	PPARG (3p25.2)	Fusions	3
		Amplifications	6
RAS-MAP-MEK signaling	*FGFR3* (4p16.3)	Fusions	2
		Point mutations	14

disease, agnostic to clinical stage or outcome. These subtypes fall into two broad classes of high-grade bladder cancer, termed "luminal" and "basal cell-like." These categories have characteristics of different stages of urothelial differentiation and have clinically meaningful differences in outcomes, with luminal subtypes having a more favorable prognosis than basal subtypes. Interestingly, these two subtypes recapitulate some of the biological characteristics of luminal and basal-like breast cancer, underscoring that common mechanistic events may underlie the development of solid tumors, beyond overlapping mutational spectra.

Pathology and Genetics of Squamous Cell Carcinoma

Squamous cell carcinoma is relatively infrequent in the Western world. It represents about 3%–7% of bladder cancers in the United States and in Europe, but in countries with endemic urinary schistosomiasis it is much more frequent. Pure squamous cell carcinoma is nearly always associated with chronic cystitis. Most squamous cell carcinomas are invasive, fungating, or ulcerative tumors. Cytonuclear characteristics vary widely, from highly differentiated keratinizing lesions to poorly differentiated tumors with only focal squamous differentiation.

Tumor staging is according to the American Joint Committee on Cancer (AJCC) TNM system. The tumor spreads by direct extension to adjacent organs or by lymphovascular invasion. Squamous cell carcinoma has a lower tendency to lymphogenous or hematogenous distant metastasis than urothelial carcinoma. It is graded as moderately or poorly differentiated, based on the criteria of extent of keratinization and nuclear morphology. Pathologic stage is the most important prognostic factor, with the overall 5-year survival of 55%–65% for pT1/pT2 tumors, dropping to 19% for pT3 and pT4 tumors. To date, there is no convincing evidence of genetic factors affecting the outcome.

Genetics of squamous cell carcinoma has been studied mostly in cases associated with Schistosoma infestation. Increased copy numbers have been found at 5p, 6p, 7p, 8q, 11q, 17q, and 20q and deletions at 3p, 4q, 5q, 8p, 13q, 17p, and 18q by comparative genomic hybridization. By immunohistochemistry, evidence has been obtained of p53 overexpression and this correlated with *TP53* mutations, base transitions at CpG dinucleotides being more frequent than in urothelial carcinomas. Furthermore, mutations of *HRAS*, and overexpression of EGFR and HER2 have been found. One study reported increased DNA methylation.

Biomarkers

Diagnostic and Monitoring Markers

For more than half a century, the detection of urothelial tumors has been dominated by cystoscopy. This rather unpleasant endoscopic examination is unavoidable for the initial workup of a patient presenting with symptoms which raise suspicion of a urothelial carcinoma. The relative frequency of precursor lesions, for which the tendency towards progression cannot be accurately assessed, has called for procedures to monitor potential future oncogenic event in the urothelium. Some claim that this causes urothelial cancer to generate the highest cost per patient of all cancers. For patients, follow-up approaches avoiding repeated cystoscopies would be a major step forward.

Urinary cytology-based diagnostics has been extensively used but its main problem is low sensitivity for detecting urothelial carcinoma, which requires repetition of the tests at relatively high frequency. In recent years, research attempts have been made

to identify and validate (cell- or protein-based) biomarkers in urine which might improve diagnostic sensitivity. Few of these biomarkers have made it into clinical use but recently developed molecular parameters hold great promise.

The most commonly used of these monitoring biomarkers are presented in Table 3.

The most established commercially available assays for detection and follow-up of bladder cancer include the Urovysion kit (Abbott) and ImmunoCyt/uCyt+ assay (Diagnocure). Urovysion is a fluorescence in situ hybridization (FISH) detection of chromosomal aberration specific to bladder cancer, designed to improve the specificity and sensitivity of cytology-based diagnostics. ImmunoCyt/uCyt+ is an immunofluorescent test using a cocktail of monoclonal antibodies against surface proteins expressed by bladder cancer cells. When used in conjunction with cytological testing, this monitoring tool has a sensitivity for the detection of bladder cancer recurrence that reaches 100%. NMP22 bladdercheck® and BTA stat/BTA TRAK have also been widely used. Moreover, the expression of different cytokeratins (CKs), intermediate filaments expressed by epithelial cells, has been used in the diagnostics of bladder cancer as markers of urothelial differentiation in a specific morphological and clinical context. A number of cytokeratin-based bladder cancer assays are commercially available, with UBC® tests and CYFRA 21-1 which are well-known and have been approved by the US Food and Drug Administration (FDA). However, their clinical utility is limited by a high rate of false positives due to other health conditions.

Overall, there are a number of either used or emerging putative diagnostic and monitoring biomarkers for bladder cancer. However, biomarker studies are frequently biased or insufficiently reported and so far, none of this plethora of putative biomarkers has been validated as an independent diagnostic or monitoring tool. Therefore, they are only recommended for use in conjunction with existing routine diagnostic methods and their results can be interpreted exclusively in the appropriate morphological and clinical context.

Prognostic and Predictive Biomarkers

Bladder cancer is a very heterogeneous disease with high recurrence rates. Therefore, reliable prognostication and risk assessment are crucial to guide treatment decisions. However, the same heterogeneity which renders the need of biomarkers so important, makes their identification extremely difficult.

Despite a number of studies on putative molecular prognostic markers, clinical features of the tumor remain the main criteria for predicting the likely course of the disease and prognostication, and thus inform treatment decisions. The simplest and most commonly used prognostic factors are the tumor grade as defined by the TNM staging system and the disease stage. Higher tumor grade and/or disease stage are associated with a higher risk of recurrence and higher progression rates, and so they prompt more aggressive treatments. The presence of associated CIS is an adverse prognostic factor. CIS progresses to invasive carcinoma in 80% of patients within 10 years of diagnosis. Also invasion of muscle, lymphatics, or perivesical fat is associated with a poor prognosis. Invasive cancer is associated with a 50% mortality rate in the first 18 months after diagnosis. Delaying cystectomy for over 12 weeks following the diagnosis of muscle invasive disease (stage T2) may hamper patient survival.

Numerous prediction tools using multiple clinical and morphological criteria have been developed, for example the nomograms by the International Bladder Cancer Nomogram Consortium. Many of them have been shown to be more accurate in predicting recurrence, disease progression, and/or survival than current staging systems. However, it is not always clear how to translate the results they provide into daily patient management decisions and therefore the adoption rate of these models for routine clinical practice is still quite low.

Among numerous putative molecular biomarkers, survivin, an anti-apoptotic protein expressed by embryonic and tumor cells but not by well-differentiated cells, holds great promise as a prognostic biomarker as its expression in bladder cancer has been associated with higher tumor grade. However, standardized detection tests with clearly defined cut-offs need to be established before any validation studies. Moreover, several new targets which are directly or indirectly linked to survivin expression, such as Nuclear factor kappa-B (NF-κB), miR-138-5p or Human HLA-F adjacent transcript 10 (FAT10), are yet to be explored. Many studies have pointed to receptor tyrosine kinases, such as FGFR3 or ERBB2 (HER2/neu) as potential prognostic and predictive biomarkers. Mutations in the *FGFR3* gene and FGFR3 overexpression have been associated with a favorable outcome in non-invasive disease. Furthermore, receptor tyrosine kinases are promising drug targets and a number of pan-FGFR inhibitors and HER2-targeted therapies are currently under clinical trials. "Molecular grade" combining *FGFR3* mutation status and Ki-67 expression has been proposed as an alternative to predict progression of non-muscle invasive bladder cancer. Ki-67 expression as detected by immunohistochemistry is a recognized measure of a tumor proliferation index. Elevated tumor proliferation index has been shown to be correlated with worse prognosis (shorter progression-free survival and disease-specific survival) in both non-invasive and invasive bladder cancer, whereas the molecular grade independently predicts disease-specific survival. Adding the molecular grade to the existing multivariable progression model increases its accuracy.

A number of putative biomarkers predicting tumor responsiveness to platinum-based therapies have been depicted by research studies. Cancers with high expression levels of ERCC1 and ERCC2, the proteins involved in the nucleotide-excision repair, have been shown to be more resistant to these therapies, whereas low ERCC1 and ERCC2 expression have correlated with responsiveness to cisplatin treatment. Multiple studies have suggested *TP53* status/p53 expression as a predictive marker for cisplatin chemosensitivity/chemoresistance, however, with conflicting results. Many other genetic alterations have also been suggested as putative prognostic and/or predictive biomarkers. However, with the emergence of large-scale genomic data which further confirm the heterogeneity of bladder cancers, it becomes clear that efficient prognostic and predictive biomarkers need to be multi-variable models which combine multiple clinical, histological and molecular parameters to reliably stratify

Table 3 Biomarkers for the detection and management of bladder cancer

Biomarker	*Characteristics and clinical utility*
Diagnostic and monitoring biomarkers[a]	
UroVysion Bladder Cancer Kit (UroVysion Kit; Abbott)	FISH-based detection of aneuploidy for chromosomes 3, 7, 17, and loss of the 9p21 locus in urine samples; designed as an aid for initial diagnosis of bladder carcinoma in patients with hematuria and for monitoring previously diagnosed patients for recurrence (FDA-approved)
ImmunoCyt/uCyt+ assay (UCyt+; Diagnocure)	Fluorescent immunohistochemistry test with three monoclonal antibodies against mucin glycoproteins found on the surface of malignant epithelial cells and a carcinoembryonic antigen expressed by bladder tumor cells; intended as a tool to monitor for bladder cancer recurrence in conjunction with standard cytology techniques to improve the sensitivity of the latter (FDA-approved)
Cytokeratins (CK)	A number of tests using different techniques exist (e.g., various UBC® tests (iDL Biotech; available both as quantitative and point-of-care assays) and CYFRA 21-1); increased CK expression is associated with urothelial differentiation and can be of added diagnostic value; not an independent biomarker due to a high rate of false positives resulting from other clinical conditions
Cytokeratin 7, 20	Expressed in bladder cancer; its immunohistochemical detection used for diagnostic purposes; not very specific
P63	Nuclear expression found in bladder cancer; its immunohistochemical detection used for diagnosis; not very specific
GATA3	Nuclear expression found in bladder cancer; its immunohistochemical detection used for diagnostic purposes; not very specific
Nuclear matrix Protein 22 (NMP22)	Overexpressed in bladder carcinoma, low sensitivity for lower-grade tumors; a quantitative sandwich ELISA test commercialized under the name NMP22 Test Kit (Maritech; FDA-approved for surveillance of non-invasive bladder cancer following surgery) a qualitative point-of-care test commercialized under the name NMP22 bladdercheck® (Alere; FDA-approved for both initial diagnosis of non-invasive bladder cancer in symptomatic and/or high-risk individuals and for monitoring for recurrence after surgery)
BTA *stat* and BTA TRAK assay	Quantitative immunoassays (FDA-approved for bladder cancer surveillance in combination with cytoscopy) which identify the bladder tumor-associated antigen (BTA; also called human complement factor H-related protein (hCFHrp)) in urine
Cxbladder tests (Cxbladder Triage, Cxbladder Detect, and Cxbladder Monitor)	Combined tests using both genetic data (five mRNA markers) and clinical data gathered during standard diagnostic procedures; Cxbladder Monitor seems to be the most promising as a follow-up test
Prognostic biomarkers	
Tumor grade and disease stage (as defined by WHO/TNM)	Higher grade and stage are associated with higher recurrence and progression rates
Presence of CIS	Associated with worse prognosis and high rates of progression to invasive disease
Ki-67 expression (as detected by immunohistochemistry)	A recognized measure of tumor cell proliferation index; high proliferation index correlates with worse prognosis (shorter progression-free survival and disease-specific survival) in both non-invasive and invasive bladder cancer
Alterations in the *FGFR3* gene	Mutations and overexpression associated with a favorable outcome in non-invasive disease
"Molecular grade": A combination of the *FGFR3* mutation status and Ki-67 expression	Proposed as an alternative to predict progression of non-muscle invasive bladder cancer; independently predicts disease-specific survival; adding the molecular grade to existing models improves their accuracy
Survivin (emerging biomarker)	Expression associated with higher grade tumors; still needs to be standardized (detection method and threshold) and validated
Predictive biomarkers	
Alterations in the *FGFR3* gene	*FGFR3*-mutant tumors may respond to pan-FGFR inhibitor treatments
ERBB2 (*HER2/neu*) expression	HER2-expessing tumors may respond to HER2-targeted therapies
ERCC1 and *2* expression (putative biomarker)	High expression levels associated with increased resistance to platinum-based therapies and low expression associated with good responsiveness

BTA, Bladder tumor-associated antigen; *CIS*, carcinoma in situ; *CK*, cytokeratin; *FDA*, US Food and Drug administration; *FISH*, fluorescence in situ hybridization.
[a]None of these biomarkers has been validated for clinical practice and none is recommended by clinical guidelines.

patients into risk groups and allow prescribing personalized therapeutic regimens. In particular, recent genomic and transcriptomic studies have identified molecularly distinct subtypes of bladder cancer that might predict therapeutic sensitivity. Clinical trials using molecularly-guided therapy selection will determine the clinical efficacy of using various predictive biomarkers to guide therapeutic decision-making.

Microenvironment and Host Response

Microenvironment of bladder cancer has been a focus of intense research for many years. Of late, this has focused on the host response to the tumor in terms of stromal reaction and immune contexture. However, urothelial carcinoma is an example of a cancer type for which therapeutic use of the host immune response has been effectively applied to treat the carcinoma or to reduce the risk of recurrence. For decades now, patients with a high risk of recurrence and/or progression of a urothelial carcinoma (CIS, papillary urothelial carcinoma high grade, multifocality, lamina propria invasive) are further treated by intravesical instillation of Bacillus Calmette-Guérin (BCG), an attenuated strain of Mycobacterium tuberculosis. These elicit an inflammatory response that also targets the carcinoma. With the emergence of immunotherapeutic modalities targeting the PD-L1/PD-1 immune checkpoint by interference with the binding of PD-L1 ligand to its two receptors, PD-1 and B7.1, in the last 5 years, interest in the immune contexture of bladder carcinoma has intensified. What was known from earlier studies is that the composition of the immune-cell infiltrate in bladder carcinoma (co)determines the response to BCG instillation: BCG failure is associated with low density of CD4+ and GATA3+ T-cells and high numbers of FOXP3+ and CD25+ regulatory T-cells (Tregs) as well as of CD68+ and CD163+ tumor-associated macrophages.

It has now been confirmed that also in bladder carcinoma clinical response to PD-L1/PD1 blocking immunotherapy is correlated with the presence of appropriate pre-existing tumor infiltrating immune cells. This has led to accelerated FDA approval of a PD-L1 blocking agent as second-line therapy for advanced bladder cancer. In initial studies, better response was associated with higher PD-L1 expression on the tumor-infiltrating leukocytes. Several studies have addressed the question of PD-L1 expression evaluated by immunohistochemistry as a biomarker for response to immunotherapy. The inhibitory molecule PD-1 is expressed after T cell activation. When this is persistent, it induces T cell dysfunction. Tumor cells as well as tumor-infiltrating immune cells can express the PD-1 ligand, PD-L1. In bladder carcinoma, PD-1 expression by tumor cells is infrequent ($<10\%$), while PD-L1 is expressed on tumor-infiltrating immune cells in about 30% of cases. This is associated with improved overall survival in metastatic disease. However, studies on the value of immunohistochemical expression of PD1/PD-L1 using different antibodies have not (yet) led to developing a convincing set of rules to guide check-point blocking immunotherapy for advanced bladder carcinoma, notably as up to 10% of patients with PD-L1-negative tumors have been shown to respond to anti-PD-L1 therapy. What is needed is a biomarker predictive of response to all drugs in the anti-PD-1/PD-L1 class. Achieving this goal will need further study.

Management and Therapy

Differentiating between non-muscle invasive tumors which have a good prognosis and aggressive muscle-invasive tumors is key to making proper management decisions (see "**Presentation and Diagnosis**" and "**Pathology and Genetics**" sections). The treatment of the tumors from the first group aims at reducing the recurrence rate and at preventing progression to a more advanced stage. The goal of therapy in patients with muscle-invasive disease is to determine whether the bladder should be removed or if it can be preserved without compromising survival, and to determine if the primary lesion can be managed independently or if the patient is at high risk for distant spread, and so requires systemic approaches to improve the likelihood of cure.

Non-muscle invasive bladder cancers (also referred to as superficial bladder tumors; the use of this term, however, is not recommended by the latest NCCN guidelines which judge it to be imprecise) which are not associated with CIS are commonly managed by transurethral resection of the bladder (TURB; also called TURBT: transurethral resection of the bladder tumor), usually segmental (partial cystectomy), and—when indicated—intravesical instillations, most often with mitomycin C. Fulguration may be effective for smaller lesions. Cystoscopy is used to follow up patients after surgery.

CIS, which has a higher malignant potential and by definition may evolve into invasive carcinoma is effectively treated by cystoscopic resection or fulguration. However, as these tumors are usually flat, they may not be visible by cystoscopy. Therefore, CIS patients receive additional treatment with intravesical Bacillus Calmette-Guerin (BCG). Induction BCG has been shown to prevent bladder cancer recurrences following TURB. Given the high risk of recurrence and progression, CIS patients need to be followed up closely with cystoscopy (every 3 months) and by routine cytology. Maintenance intravesical therapy may be considered following induction with chemotherapy or BCG. However, the efficacy of maintenance chemotherapy is controversial. Moreover, BCG toxicity inducing potentially severe local and systemic side effects is an important concern.

Invasive tumors that grow into the muscularis propria (T2 and higher) require more radical treatment. The gold standard is radical cystectomy, that is the excision of the bladder, perivesical fat, and attached peritoneum. In men, this is accompanied by removal of the entire prostate and seminal vesicles (radical cystoprostatectomy), whereas women undergo *en bloc* removal of the uterus, adnexa, and cuff of the vagina (anterior pelvic exenteration). Pelvic lymph node dissection (pelvic lymphadenectomy) is performed to stage the nodes, while extended lymphadenectomy remains controversial. Segmental resections of the bladder may be used in highly selected cases.

Radiotherapy may be an alternative to surgery for highly motivated patients who desire to retain their bladder and potency following a bladder preservation protocol. However, these multiple modality treatment protocols mandate aggressive treatments, frequent follow-up visits and close coordination of multiple subspecialties, and are therefore conducted only in selected dedicated institutions. Moreover, a salvage cystectomy is required following an attempt at bladder sparing in up to 20% of cases. Radiotherapy does not appear to improve expected survival beyond that achieved by radical surgery alone, although local recurrence is reduced.

One of the most noteworthy issues in the treatment of bladder cancer is the optimal use of perioperative chemotherapy for muscle-invasive disease in an attempt to provide the earliest possible treatment of micrometastatic disease and to facilitate definitive local therapy. Several studies have shown that neoadjuvant therapy is associated with a longer survival. The NCCN panel recommends neoadjuvant chemotherapy followed by radical cystectomy as the first-choice treatment for patients with T2, T3, and T4a bladder cancer without lymph node involvement. The neoadjuvant combination which is most common and also supported by best evidence so far is MVAC (Methotrexate, Vinblastine, Doxorubicin (Adriamycin), Cisplatin).

The data on the use of adjuvant chemotherapy are less conclusive. Adjuvant therapy with systemic cytotoxic agents for patients undergoing cystectomy has been associated with a delay in time to disease progression but there is no clear evidence for an improved survival. Therefore, neoadjuvant therapy remains the preferred option for treatment of early disease patients. Chemotherapy may be considered in case of late-stage disease and/or lymph node involvement. Different cisplatin-based combinations are used for perioperative chemotherapy, such as dose-dense MVAC (ddMVAC), gemcitabine plus cisplatin (GC), or cisplatin, methotrexate, and vinblastine (CMV).

Out of novel targeted therapies, immunotherapeutics are the future of bladder cancer treatment. In particular checkpoint inhibitors, like nivolumab (targeting PD-1) or avelumab (targeting PD-L1; both FDA-approved), have been shown to improve outcomes of patients with advanced and metastatic bladder cancer (see also "**Microenvironment and Host Response**" section).

Bone and Soft Tissue Sarcoma: From Molecular Features to Clinical Applications

Sarah Watson and Olivier Delattre, Institute Curie Hospital, Paris, France; and Inserm U830, SIREDO Oncology Center, Paris Sciences and Letters (PSL) Research University, Paris, France

Glossary

Chromosomal translocation Genetic alteration resulting from the exchange of genetic material between nonhomologous chromosomes. Translocations can be balanced or unbalanced depending on the loss of chromosomal fragments during the rearrangement, and can lead to the constitution of fusion genes.

Ewing sarcoma The second most frequent bone sarcoma after osteosarcoma. Ewing sarcoma affect mostly children and teenagers, and is predominantly found in long bones and in the pelvis. Ewing sarcoma is the first sarcoma subtype for which a specific translocation was identified.

Gene amplification Copy number increase in a restricted region of a chromosome arm containing a limited number of genes. The number of gene copies available for transcription is increased and this leads to overexpression of the gene product.

GIST Gastro intestinal stromal tumors—the most frequent subtype of sarcoma affecting exclusively the gastrointestinal tract. GIST arise from the interstitial cells of Cajal, the latter representing the smooth muscle pacemaker of the intestinal lining.

LMS Leiomyosarcoma—one of the most frequent subtype of soft tissue sarcoma. LMS derive from smooth muscle cells and that are mostly found in the uterus, the stomach, the small intestine, and the retroperitoneum.

LPS Liposarcoma—one of the most frequent subtype of soft tissue sarcoma, originating from fat tissue. The most frequent tumor locations for LPS are the retroperitoneum and other deep soft tissues. Several subtypes of LPS are observed both from pathological and molecular points of view.

MRT Malignant rhabdoid tumors—a subset of very aggressive sarcoma affecting mostly young children. Most cases of MRT develop in the kidney or in the brain, where they are referred as atypical teratoid rhabdoid tumor (AT/RT).

MSC Mesenchymal stem cells—a population of pluripotent stromal cells located in the bone marrow or in adipose tissue, which can differentiate into various cell types including osteocytes, chondrocytes, adipocytes, tenocytes, or myocytes, and which are thought to be the cell of origin of most sarcomas.

NGS Next generation sequencing—a number of different modern sequencing technologies that allow to sequence DNA and RNA in a quicker and more efficient way than the traditional Sanger sequencing. Over the last decade, NGS development has revolutionized the study of genomics and molecular biology and is currently becoming a major tool for diagnostic and theranostic strategies in cancer patients

Oncogenic mutation Genetic alteration consisting in the modification of the normal sequence of a proto-oncogene, the latter being a gene with a potential to favor cancer development. Activating oncogenic mutations are gain-of-function mutations that lead to activation of proto-oncogenes and increase cell proliferation and survival.

Small round cell sarcomas A group of highly aggressive sarcomas affecting children and adults. Small round cell sarcomas are composed of undifferentiated small round blue tumor cells of mesenchymal origin. More than 90% of these tumors are associated with the presence of a recurrent chromosomal translocation leading to the expression of a specific fusion oncogene. Famous examples include Ewing sarcoma, desmoplastic small round cell tumors, alveolar rhabdomyosarcoma, and synovial sarcoma.

Introduction

Sarcomas constitute a group of rare tumors composed of malignant cells of mesenchymal origin. These tumors are characterized by their high heterogeneity both from a clinical and biological point of view. Sarcomas can arise in children, teenagers, and adults, and develop from all kinds of tissue. Histologically, sarcomas are composed of mesenchymal tumor cells with multiple features of differentiation, leading to the pathological description of more than 50 different tumor types, and making them the most heterogeneous tumors. Over the last decades, major breakthroughs have considerably increased our understanding of sarcoma biology. Advances in cytogenetic and molecular techniques have enabled to identify specific alterations related to particular sarcoma subtypes and to decipher their oncogenic mechanisms. The understanding of sarcoma biology has led to refining the diagnostic approaches of many subtypes of tumors and to developing successful targeted therapies that have become standard of care for patients. As a result, sarcomas have become a major model in oncology by combining biological and molecular data to immediate translational and clinical applications.

From an embryologic point of view, sarcoma develop from tissues of mesodermal origin. The mesoderm is the middle layer of the three primary germ layers in the early embryo and originates from the process of gastrulation happening at 3 weeks of development. Upon the course of embryogenesis, the mesoderm develops into the paraxial mesoderm, the intermediate mesoderm, and

the lateral mesoderm. The intermediate and lateral mesoderm will ultimately develop into the primitive urothelial tract and circulatory system, respectively, while the paraxial mesoderm thus develops into somites. The somites give rise to three major structures: the dermatome, the myotome, and the sclerotome, themselves leading to the formation of connective tissues and dermis, muscles, and cartilage and bone, respectively (**Fig. 1**A).

At the cellular level, most sarcomas are thought to originate from mesenchymal stem cells (MSC). MSC are multipotent stem cells located mostly in the bone marrow that have the ability to differentiate into various cell types, including osteocytes, chondrocytes, myocytes, or adipocytes. MSC differentiation toward a defined cell type involves sequential signaling regulation and several stages regulated by the expression of specific transcription factors (**Fig. 1**B). There is a now substantial evidence that a consequent number of sarcomas is related to the transformation of MSC, as reflected by the correspondence between the differentiation capacities of MSC and the histological spectrum of sarcomas. In vitro and in vivo studies have shown that the type of sarcoma arising from transformed MSC depends on many factors, including the originating tissue of MSC, the differentiation commitment of the cells, and the targeted molecular pathway. It is now widely thought that most sarcomas derive from the inability of MSC to undergo proper differentiation into specific cell lineages, due to the emergence of oncogenic molecular alterations.

This cellular origin of sarcomas explains the histological variety and heterogeneity of sarcomas. In the last World Health Organization (WHO) classification, hundreds of different pathological subtypes of bone and soft tissue tumors are described, primarily based on their malignancy potential and differentiation characteristics. Yet, during the last decades, major advances in cytogenetics and molecular biology have led to the discovery of a broad variety of specific alterations involved in sarcoma development, and thus to the emergence of new classifications of tumors.

Genetics of Sarcomas

In clinical practice, sarcomas are commonly divided into two main groups related to the primary tumor location, with the usual separation between "bone sarcomas" and "soft tissue sarcomas." Over the last decade, a new classification has emerged, dividing tumors in two broad categories, each of them including a range of diverse sarcoma subtypes (**Table 1**). The first category comprises sarcomas with diploid karyotypes and simple and recurrent genetic alterations, most of the time translocations and simple activating or inactivating mutations. The second category includes sarcomas with complex, unbalanced karyotypes, characterized by the presence of multiple genomic aberrations within a single tumor, and heterogeneity of genomic aberrations within a given tumor subtype.

Sarcomas With Simple Genomic Profiles

Sarcomas with simple karyotypes represent 40%–50% of all sarcomas. Those tumors are characterized by the presence of recurrent and specific molecular alterations, most of the time pathognomonic of a given tumor subtype, such as chromosomal translocations, oncogenic mutations, or amplifications.

Sarcomas with recurrent chromosomal translocations

Sarcomas with recurrent chromosomal translocations account for 10%–15% of all sarcomas. In 1983, chromosomal banding on Ewing Sarcoma tumors led to the discovery of a recurrent chromosomal translocation t(11;22)(q24;q12), that later proved to drive the expression of the fusion oncogene EWSR1–FLI1 in tumor cells. Since then, numerous translocations and resulting gene fusions have been identified in various sarcoma subtypes (**Table 2**). Each translocation results in the expression of a chimeric fusion gene directly involved in the pathogenesis of the sarcoma in which it is expressed, by three main mechanisms (**Fig. 2**).

First, the most frequent mechanism consists in the expression of an aberrant chimeric transcription factor, resulting from the fusion of a gene under the control of a strong promoter which confers the expression level, with a gene carrying a DNA-binding domain and transcription factor activity. The resulting chimeric transcription factor can bind DNA and regulate its own transcription program to promote tumorigenesis. Famous examples of translocation-positive sarcoma subtypes with aberrant transcription factor activity are small round cell sarcomas (Ewing sarcoma, synovial sarcoma, alveolar rhabdomyosarcoma, or desmoplastic small round cell tumors), myxoid liposarcoma, or clear cell sarcoma. Of note, the chimeric transcription factor drives the regulation of a highly specific transcription program involved in sarcomagenesis. For example, in Ewing sarcoma, several variants of the initial *EWSR1-FLI1* fusion gene have been described. Some of them involve genes belonging to the same families as *EWSR1* and *FLI1* (TET family of proteins and ETS transcription factors, respectively). The resulting fusion genes *EWSR1-ERG*, *EWSR1-ETV1*, *EWSR1-ETV4*, *EWSR1-FEV*, *FUS-ERG*, and *FUS-FEV* are expected to keep the same functions as *EWSR1-FLI1*, and to regulate the same transcriptional programs. On the other hand, other fusions involving genes not related to the TET and ETS families have been reported, such as *CIC-DUX4* and *BCOR-CCNB3*. Those last few years, several studies have shown that those alternative chimeric transcription factors are responsible for transcriptional regulation of target genes highly different from TET–ETS fusions. The resulting tumors, previously referred to as "Ewing-like sarcoma" based on their clinical and pathological similarities, are now being considered as independent tumor entities.

Second, translocations can result in the expression of a fusion protein carrying an aberrant kinase activity, as seen in congenital fibrosarcoma and inflammatory myofibroblastic tumors. In those cases, the translocation leads to the fusion of a strongly expressed protein to the catalytic domain of a tyrosine kinase receptor. The resulting chimeric tyrosine kinase protein is thus constitutively

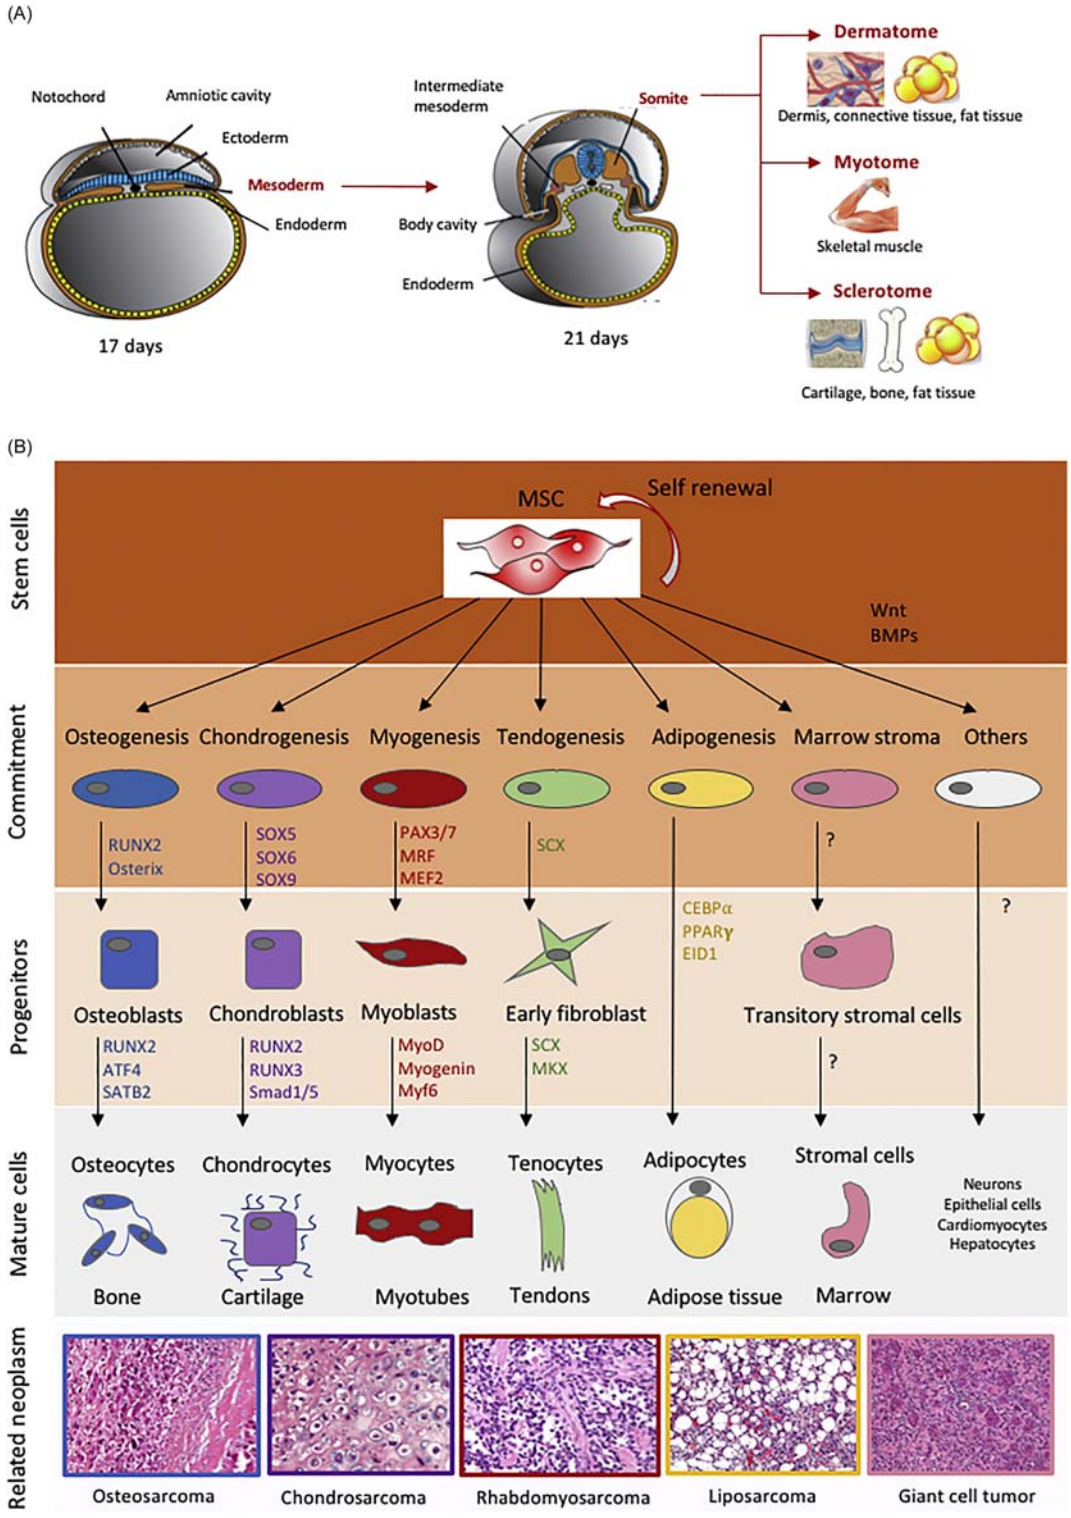

Fig. 1 Embryonal and cellular origin of sarcomas. (A) Schematic view of the embryonal development at 17 and 21 days postfertilization and the resulting derivative tissues. (B) Representation of the different steps of mesenchymal stem cells (MSC) differentiation and related sarcoma subtypes. The main transcription factors involved in each step of differentiation towards specific cell lineages are indicated.

Table 1 Molecular classification of sarcomas

	Molecular alteration	*Frequency (%)*	*Example*
Simple genomic profile	Recurrent translocation	10–15	Ewing sarcoma
	Activating mutation	15	GIST
	Inactivating mutation	5	MRT
	12q14-15 amplification	10–15	WDLPS/DDLPS
Complex genomic profile	Multiple/heterogeneous genomic aberrations	55	Leiomyosarcoma

Abbreviations: *GIST*, gastrointestinal stromal tumors; *MRT*, malignant rhabdoid tumors; *WDLPS*, well-differentiated liposarcoma; *DDLPS*, dedifferentiated liposarcoma.

Table 2 Most common translocations and gene fusions associated with specific subtypes of sarcomas

Sarcoma subtype	*Translocation*	*Main fusion genes*	*Oncogenic mechanism*	*Prevalence (%)*
Ewing sarcoma/PNET	t(11;22)(q24;q12)	EWSR1–FL1	TF	90
	t(21;22)(q22;q12)	EWSR1–ERG	TF	5
Synovial sarcoma	t(X;18)(p11;q11)	SS18–SSX1	TF	65
		SS18–SSX2	TF	35

IMT	2p23 rearrangements	Various partners-ALK	TK	60
DFSP	t(17;22)(q22;q13)	COL1A1–PDGFB	GF	>90

Abbreviations: *PNET*, primitive neuroectodermal tumor; *ARMS*, alveolar rhabdomyosarcoma; *DSCRT*, desmoplastic small round cell tumor; *ESMCS*, extraskeletal myxoid chondrosarcoma; *FMS*, fibromyxoid sarcoma; *ASPS*, alveolar soft part sarcoma; *IMT*, inflammatory myofibroblastic tumor; *DFSP*, dermatofibrosarcoma protuberans; *TF*, transcription factor; *TK*, tyrosine kinase; *GF*, growth factor.

activated in a ligand-independent mechanism and can stimulate downstream signaling pathways to promote cell proliferation and survival.

A third mechanism consists in the expression of a chimeric autocrine growth factor, as seen in dermatofibrosarcoma protuberans (DFSP) and giant cell fibroblastoma. In those tumors, the translocation results in putting platelet-derived growth factor beta (*PDGFB*) under the control of the strong *COL1A1* promoter, thus removing all elements repressing *PDGFB* transcription and leading to uncontrolled signal activation.

Translocation-positive sarcomas have become a model for oncogenesis, since their simple genomic profile has often been associated to simple oncogenic mechanisms and thus to promising therapeutic targets. Indeed, in sarcomas with chimeric tyrosine kinase receptor activity and chimeric autocrine growth factor, targeted therapies based on tyrosine kinase inhibitors have been successfully developed and have rapidly become standard of care for patients.

However, sarcomas with chimeric transcription factor activity are still a challenge for targeted therapies, since their mechanism of action is rather highly complex and not fully understood and since, at the difference of kinases, they do not present enzymatic sites that can be targeted by small molecules. For example, in synovial sarcoma, recurrent translocations between chromosomes X and 18 lead to the expression of SS18–SSX1/2 fusion protein. Both SS18 and SSX proteins lack known DNA binding motifs, yet they appear to be acting through transcriptional regulatory mechanisms. The fusion protein keeps the N-terminal domain of SS18 that is responsible for interaction with the SWI/SNF nucleosome remodeling complex, and the C-terminal domain of SSX1 or SSX2 which can interact with the polycomb repressing complex 1 (PRC1), an essential epigenetic regulator (Fig. 3A). The resulting SS18–SSX1/2 fusion proteins disrupt the assembly of the functional SWI/SNF complex by competing with normal SS18 and lead to the formation of an altered SWI/SNF complex lacking the tumor suppressor BAF47 subunit (Fig. 3B). The altered complex binds DNA on regions normally repressed by PRC1 epigenetic marks such as SOX2, activates transcription, and promotes cell proliferation.

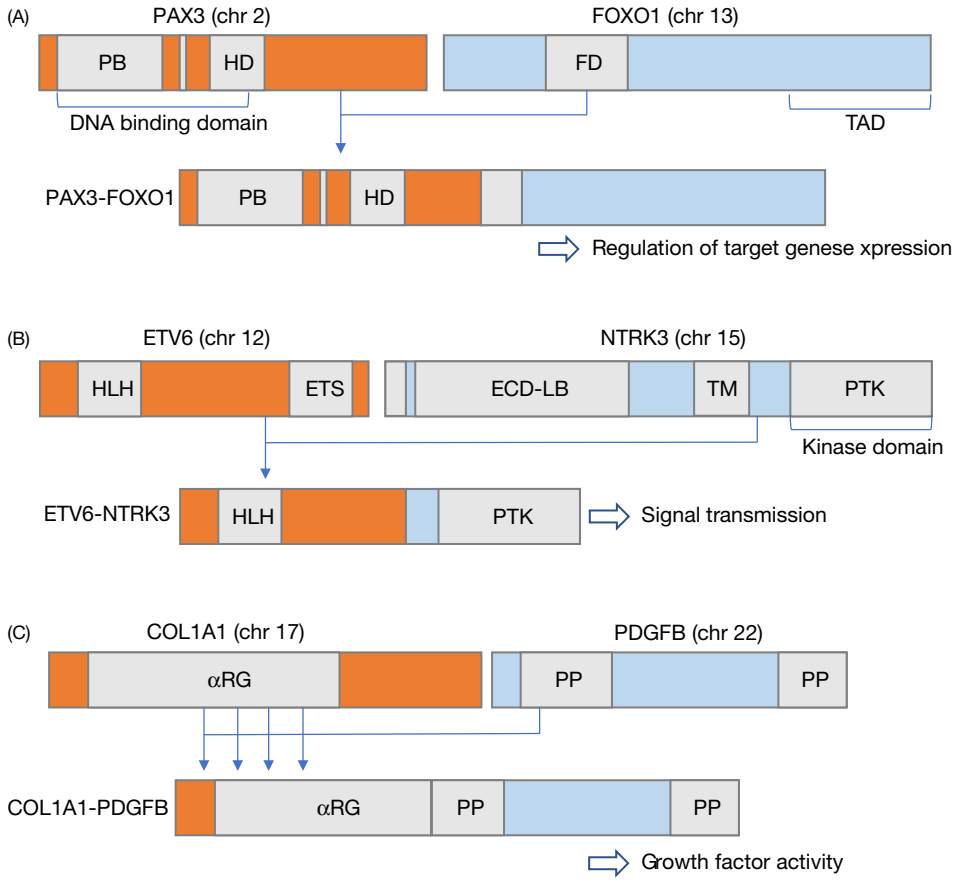

Fig. 2 Main oncogenic functions of chimeric proteins involved in sarcoma development. (A) Fusion gene encoding an aberrant transcription factor: the example of PAX3-FOXO1 in alveolar rhabdomyosarcoma. (B) Fusion gene encoding an aberrant kinase receptor: the example of ETV6–NTRK3 in congenital fibrosarcoma. (C) Fusion gene encoding an aberrant growth factor: the example of COL1A1–PDGFB in dermatofibrosarcoma protuberans. Abbreviations: *αRG*, alpha helical region; *ECD-LB*, extra cellular ligand biding domain; *FD*, fork head domain; *HD*, homeobox; *HLH*, helix loop helix; *PB*, paired box; *PP*, propeptide; *PTK*, protein kinase domain; *TAD*, transactivation domain; *TM*, transmembranous domain.

Such complex mechanisms of action for chimeric transcription factors are a hallmark of sarcomas. Thus, their simple genomic profiles do not properly reflect the level of complexity of molecular regulation at other levels. There is now growing evidence that most chimeric transcription factors in sarcoma exhibit epigenetic regulator activity. Their mechanism of action will have to be further characterized to develop successful targeted therapies.

Sarcomas with recurrent activating or inactivating mutations

Gastrointestinal stromal tumors

The presence of a specific oncogenic activating mutation is the central event in most cases of gastro intestinal stromal tumors (GIST). GIST are the most frequent mesenchymal tumors developing in the gastrointestinal tract and originate from the transformation of interstitial cells of Cajal (ICC). GIST were historically characterized by their poor prognosis, mainly due to their primary resistance to cytotoxic chemotherapy. In 1998, the discovery of recurrent activating mutations in the proto-oncogene *c-KIT* led to dramatic prognostic and therapeutic changes for GIST patients. *c-kit* encodes a type III tyrosine kinase (KIT), which is physiologically activated upon the binding of its ligand SCF. The SCF–KIT interaction is a crucial regulator of erythrocytes, germ cells, melanocytes, mast cells, and ICC growth and development, by activating major downstream pathways such as the RAS–RAF–MAPK pathway to promote cell proliferation and survival.

c-KIT mutations are found in 80%–85% of GIST and lead to constitutive activation of the receptor. *KIT* mutations in GIST are clustered in four regions, the most frequent being the one encoding the juxta-membrane domain (exon 11), and include deletions, point mutations, and amplifications. The discovery of *KIT* activating mutations led to the rapid and successful development of clinical trials evaluating the tyrosine kinase inhibitor imatinib mesylate in patients with KIT mutated GIST. Imatinib is a competitive inhibitor of BCR-ABL, KIT, ARG, PDGFRα, and PDGFRβ tyrosine kinases. With dramatic responses and prolonged survival compared to standard chemotherapy, imatinib became the most rapidly FDA-approved drug in patients with advanced GIST in 2002, only 4 years after the discovery of *c-KIT* alterations.

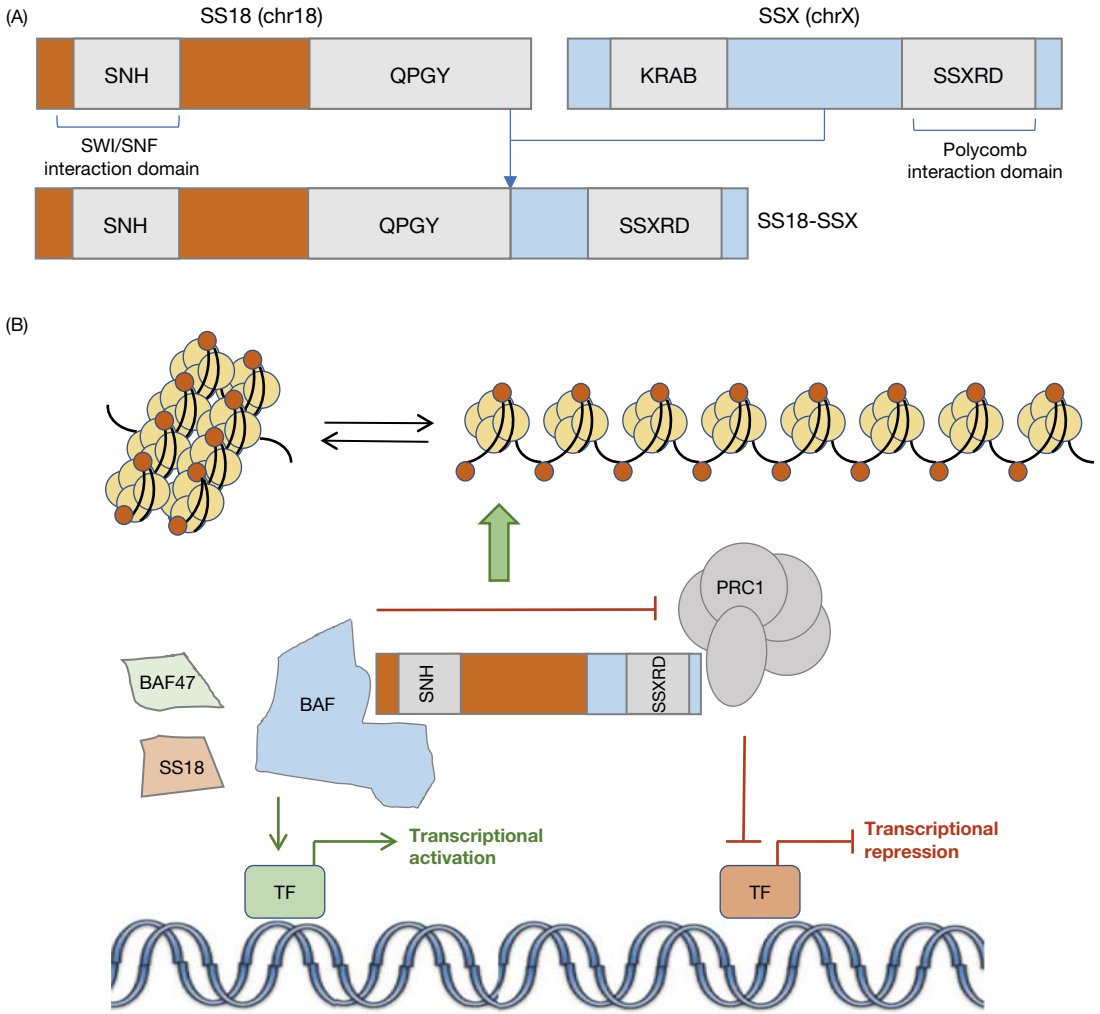

Fig. 3 Structure and oncogenic function of SS18–SSX fusion protein in synovial sarcoma. (A) Structure and main domains of SS18–SSX chimeric protein; the fusion proteins keeps the SNH SWI/SNF interaction domain of SS18 and the PRC1 interaction domain of SSX. (B) Putative molecular functions of SS18–SSX and selected protein–protein interactions; the fusion protein competes with normal SS18 for the assembly of the SWI/SNF complex, which results in an aberrant complex lacking BAF47 subunit. The fusion protein also interacts with the PRC1 complex via the SSXRD domain. The oncogenic functions of SS18–SSX protein are thus mediated by aberrant chromatin remodeling due to the disruption of the normal balance between SWI/SNF and PRC1 complexes to mediate transcription activation and repression. Abbreviations: *SNH*, SYT N-terminal homology domain; *QPGY*, glutamine, proline, glycine, and tyrosine repeat domain; *KRAB*, Krüppel associated box domain; *SSXRD*, SSX repression domain; *PRC1*, polycomb repressing complex 1; *SWI/SNF*, switch/sucrose nonfermentable complex.

In 2003, recurrent activating mutations in the gene encoding the related receptor platelet-derived growth factor receptor alpha (*PDGFRα*) were identified in 35%–40% of *KIT*-wild type GIST. Notably, *KIT* and *PDGFRα* mutations were shown to be mutually exclusive, and *KIT* and *PDGFRα*-mutated GIST to be indistinguishable with respect to activation of downstream signaling pathways and cytogenetic features. The most frequent *PDGFRα* mutations are located in the activation loop of the receptor (exon 18), and lead to the D842V amino-acid change (Fig. 4A). D842V mutation confers primary resistance to imatinib, whereas the remaining non-D842V *PDGFRα* tumors are known to be sensitive to the drug. As a result, therapeutic strategies in GIST have now become entirely guided by the detection of the primary molecular alterations, with algorithms of treatment based on the tumor genetics and the development of new drugs dedicated to specific KIT of PDGRα mutants that are resistant to conventional tyrosine kinase inhibitors.

However, approximately 10% of GIST show no detectable mutation in either *KIT* of *PDGFRα*. These correspond to three clinicopathological entities: pediatric GIST, GIST associated to neurofibromatosis type 1 (NF1), and sporadic wild-type GIST. Sporadic *BRAF* and *NRAS* mutations have been reported in a few cases of these "wild-type" GIST.

More recently, a small subset of GIST, mostly pediatric GIST and GIST associated to rare syndromes have been shown to be characterized by the intratumoral loss of function of the succinate dehydrogenase (SDH) complex. SDH-deficient GIST are exclusively located in the stomach, and they typically occur in children and young adults with a spectrum of behavior from indolent to aggressive. SDH complex is normally ubiquitously expressed. It consists of four subunits (SDHA, SDHB, SDHC, SDHD) localized in the

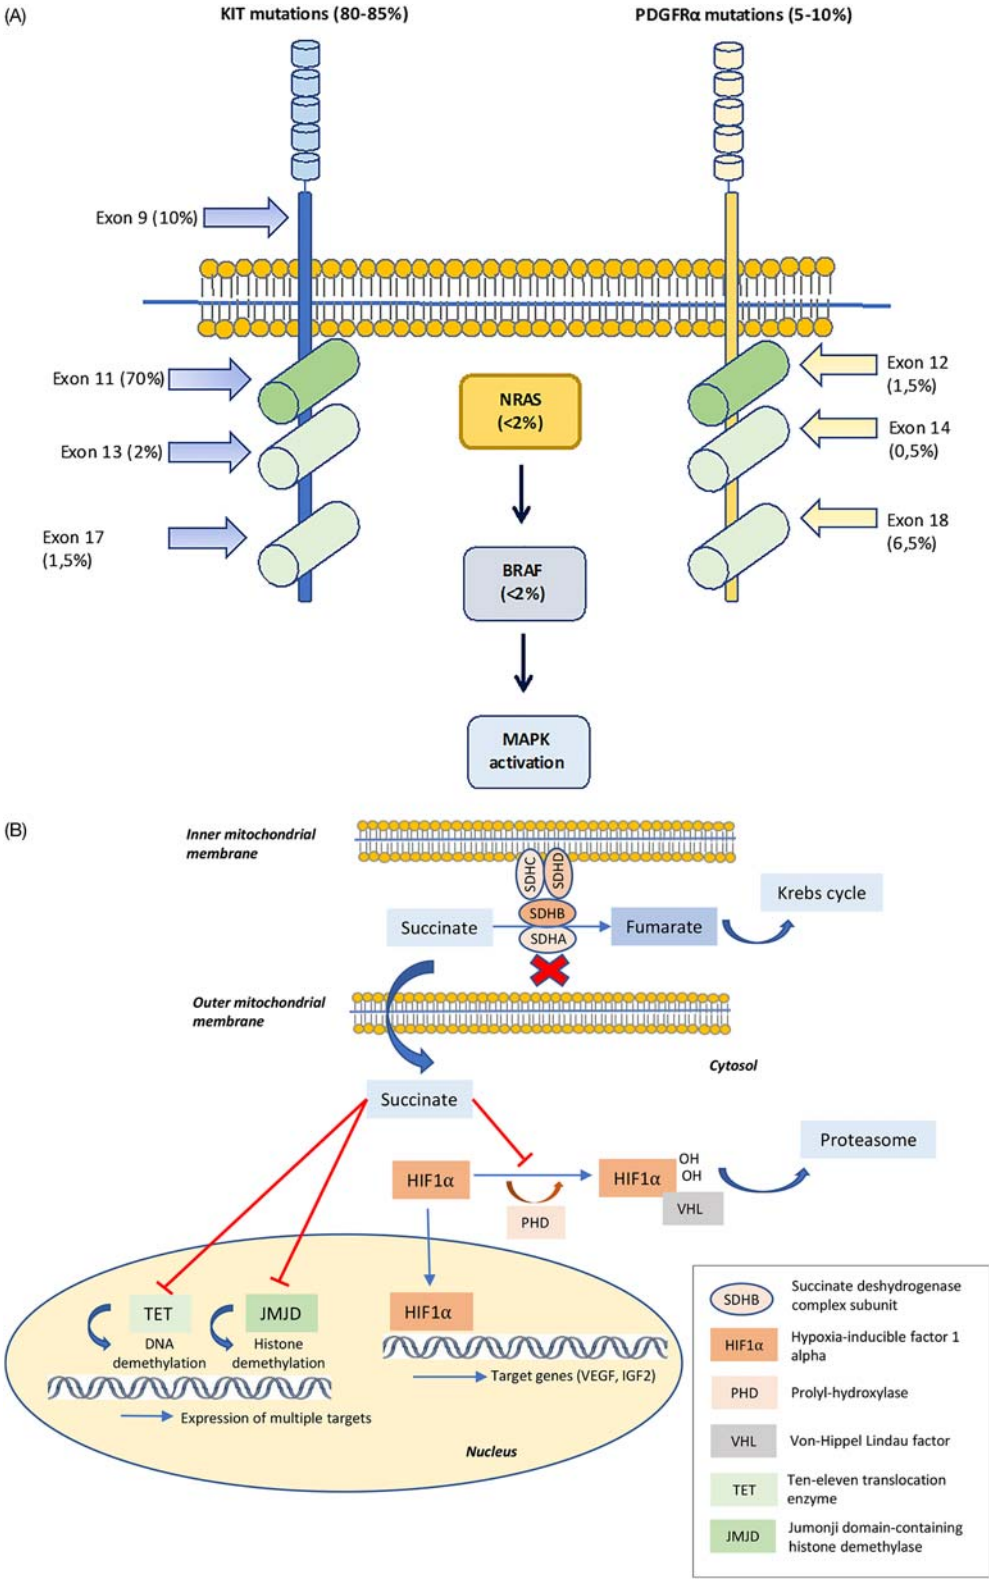

Fig. 4 Main oncogenic mutations found in gastrointestinal stromal tumors (GIST). (A) Schematic representation of c-KIT and PDGFRα receptors and downstream targets. The *arrows* show the domains most frequently mutated in GIST and the *percentages* indicate the frequency of mutations in GIST patients. (B) Representation of the SDH oncogenic pathway in patients with SDH-deficient GIST. SDH deficiency leads to the absence of transformation of succinate into fumarate in the inner mitochondrial membrane. The accumulation of succinate drives the overexpression of HIF1α through the inhibition of PHD which targets HIF1α to proteasomal degradation and results in the expression of HIFα target genes. Succinate accumulation also inhibits the DNA demethylase TET and the histone demethylase JMJD, resulting in aberrant hypermethylation profiles within tumor cells and oncogenic epigenetic changes.

inner mitochondrial membrane and acts at the interphase of the tricarboxylic acid cycle and electron transport chain, by catalyzing the transformation of succinate into fumarate (Fig. 4B). Pediatric GIST and GIST associated to hereditary paraganglioma syndromes, Carney–Stratakis syndrome, and Carney triad have been found to be SDHB deficient. SDHB deficiency is the consequence of any bi-allelic loss of function of SDH subunit, via the destabilization of the SDH complex. About half of the patients have SDH subunit gene mutations, often germline, with both alleles inactivated in the tumor cells typical of classic tumor suppressor genes. The remaining cases are not associated with *SDH*-mutations and epigenetic silencing of the *SDH* complex genes is the probable mechanism for SDH loss.

SDH loss results in the accumulation of succinate within tumor cells, which leads to the overexpression of hypoxia inducible factor 1 alpha (HIF1α) due to the inhibition of its proteasomal degradation and thus to activation of pseudohypoxia signaling and expression of target genes. Moreover, SDH-deficient tumors are characterized by a high frequency of gene methylation when compared to *KIT* or *PDGFRα* mutant GIST. This is probably the consequence of the inhibition of crucial DNA and histone demethylase enzymes caused by the accumulation of succinate within tumor cells. Both HIF1α signaling and hypermethylation are thought to be the central events in the oncogenesis of these SDH-deficient GIST.

From a practical point of view, the diagnosis of SDH-deficient GIST can be done by immunohistochemistry, with the loss of expression of SHDB subunit in tumor cells showing neither *KIT* nor *PDGFRα* mutation. Even though there is still only few data related to therapeutic strategies in SDH-deficient GIST, traditional tyrosine kinase inhibitors seem to be inactive in those tumors. New therapeutic options include alternative tyrosine kinase inhibitors and heat shock proteins (HSP) inhibitors, but still need to evaluated in clinical practice.

Malignant rhabdoid tumors

Apart from GIST, malignant rhabdoid tumor (MRT) is the most famous example of sarcoma showing a recurrent and specific mutation as main oncogenic mechanism. MRT is a rare childhood sarcoma which commonly develops in the kidney but can also arise from other soft tissues or from the brain, where it is referred as atypical teratoid rhabdoid tumor (AT/RT). MRT development was initially found to be associated to monosomy 22 and subsequently to deletions and translocations involving band 22q11.2. Early positional cloning studies managed to identify *SMARCB1* (*INI1*, *SNF5*, *BAF47*) loss as the initial oncogenic event for MRT development. *SMARCB1* functions as a classical tumor suppressor gene, with germline mutations or deletions predisposing to the disease, and somatic loss or mutation of the second allele constituting the second event. 15%–30% of *SMARCB1* germline mutations are found in MRT patients. Germline mutations or deletions can be de novo postzygotic. In such a case, related siblings are unaffected. However, these alterations can be prezygotic, mostly due to germinal mosaicism in one of the parents. In such a case, recurrence can be observed in siblings. Given the extreme aggressiveness of the disease, inherited *SMARCB1* mutation in multigeneration families associated to multiple affected siblings with MRT are extremely rare. Therefore, molecular genetic testing for a germline mutation and genetic counseling are highly recommended for MRT patients.

The majority of *SMARCB1* coding sequence mutations are point or frameshift mutations that introduce a premature stop codon and predict protein truncation. Several mutation hotspots have been described, some of them specific to AT/RT. Yet, most cases of MRT are characterized by *SMARCB1* homozygous deletions, regardless of tumor location. Copy number neutral loss of heterozygosity for most of the long arm of chromosome 22 is common, as well as more complex patterns of deletion, duplication, or translocation involving the *SMARCB1* locus.

Bi-allelic inactivation of *SMARCB1* leads to loss of expression of the protein which hence cannot be detected by immunohistochemistry in tumor cells and constitute a diagnostic tool in clinical practice.

SMARCB1 encodes a core subunit of the ATPase SWI/SNF chromatin remodeling complex, a major ubiquitous complex regulating gene expression by relieving repressive chromatin structure. The SWI/SNF complex uses ATP hydrolysis to displace nucleosomes in response to signaling and differentiation, thus regulating transcription of specific target genes. Notably, in the rare cases of MRT showing conserved expression of SMARCB1, loss of SMARCA4, another core subunit of the SWI/SNF complex, is common by bi-allelic mutations. Moreover, a new subtype of adult thoracic sarcomas characterized by SMARCA4 deficiency (SMARCA4-DTS) has recently been shown to present a transcriptional signature very close to MRT, suggesting that the loss of functional SWI/SNF complex in both cases leads to common oncogenic consequences, whatever the tissue of origin. The mechanisms by which the disruption of a functional SWI/SNF complex leads to tumor development are still being investigated, but several targets have been identified that may play a crucial role in tumor development. Among them, *CYCLIN-B1* and *c-MYC* are highly expressed in MRT, and known to be regulated by SWI/SNF and SMARCB1. Modulation of the Interferon pathway, blocking of differentiation, and increased migration have also been shown as consequences of SMARCB1 loss, and represent attractive therapeutic targets.

The most promising innovative strategy in MRT consists in the development of EZH2 inhibitors. EZH2 is the catalytic subunit of the multiprotein HMT complex known as polycomb repressing complex 2 (PRC2). PRC2 catalyzes the methylation of lysine 27 of Histone 3 (H3K27), H3K27 trimethylation marks leading to repression of gene expression. There is substantial evidence that SWI/SNF and PRC2 interact in an antagonist way to regulate gene expression at the epigenetic level. Indeed, EZH2 is highly expressed and PCR2 target genes are broadly repressed in SMARCB1-deficient tumors, which suggests an EZH2 oncogenic dependency. Moreover, in vitro and in vivo studies have shown that tumorigenesis in *SMARCB1*-deficient cells can be completely abrogated by specific codeletion of EZH2. These findings have led to the development of early clinical trials evaluating the benefit of EZH2 inhibitors such as tazemetostat in MRT patients. With promising and sustained responses observed in both SMARCB1 and SMARCA4 deficient tumors, EZH2 inhibitors are now being evaluated in larger clinical trials and could rapidly represent a new therapeutic standard for those chemo-resistant tumors.

Sarcomas with 12q13-15 amplicons

About 10%–15% of sarcomas are characterized by a simple genomic profile associated to 12q13-15 amplicons. These are mostly atypical lipomatous tumors/well-differentiated liposarcomas (ALT/WDLPS) and dedifferentiated liposarcomas (DDLPS).

ALT/WDLPS is considered a low-grade malignancy that rarely metastasizes, but needs careful follow-up because recurrence or dedifferentiation may occur. From a pathological point of view, ALT/WDLPS may be difficult to distinguish from benign lipomatous tumors, since both are composed of mature fat, variably-sized adipocytes and fibromyxoid stroma, with low cellularity and uncommon mitotic figures. On the other hand, DDLPS is a high-grade liposarcoma that arises in a background of preexisting ALT/WDLPS. Histologically, DDLPS is mostly composed of pleomorphic malignant fibrous histiocytoma-like figures, although other sarcomatous phenotypes have been described, arising by an abrupt transition from an ALT/WDLPS region.

90% of ALT/WDLPS and DDLPS have amplification of chromosome 12q13-15, which contains the oncogenes *MDM2*, *HMGA2* and *CDK4*, while additional genes located in this amplicon may also play a role in liposarcomagenesis. In most cases, the amplicon is located on neochromosomes or ring chromosomes. The 12q13-15 amplicon causes accumulation of MDM2 and CDK4 in tumor cells, so that immunohistochemical staining for these proteins can be used as a diagnostic marker for these diseases. The oncogenic role of MDM2, HMGA2, and CDK4 in liposarcoma has been widely documented both in vitro and in vivo and is as a result an active area for the development of targeted therapies. MDM2 drives the ubiquitination and degradation of the tumor suppressor P53, through a direct interaction via its RING domain. Thus, *MDM2* amplification results in reduced levels of P53 favoring transformation of progenitor cells. Competitive inhibitors of the MDM2–P53 interaction have been developed and are currently being evaluated in early phase clinical trials in patients with DDLPS. CDK4 is a protein kinase that promotes the G1/M cell cycle transition. CDK4 inhibitors have been developed and tested in patients with DDLPS. A recent Phase 2 study evaluating palbociclib, a CDK4 inhibitor, in 29 patients with refractory WDLPS and DDLPS reported a median progression-free survival of 4.7 months and only one case of partial response. This may be due to the fact that CDK4 overexpression is associated to a 12q amplicon distinct from the one containing *MDM2* and *HMGA2*, as a small subset of good prognosis WDLPS do not show increased levels of CDK4. Thus, CDK4 may be a key factor for progression, but not initiation, of liposarcoma, and targeting CDK4 alone may not be sufficient to induce tumor cell death.

Apart from the 12q13-15 amplicons, additional genomic alterations have been described in DDLPS, including 3p14-21 loss, 11q23-24 loss, and 19q13 loss. However, the mechanisms by which those alterations contribute to dedifferentiation and tumor progression are still being investigated and do not constitute current therapeutic targets.

Sarcomas With Complex Genomic Profiles

About 50%–60% of sarcomas are characterized by complex genomic profiles with multiple mutations, gene losses, and gains. This category is mainly composed of osteosarcoma, leiomyosarcoma, myxofibrosarcoma, pleomorphic liposarcoma, malignant peripheral nerve sheat tumor (MPNST), and spindle cell/pleomorphic unclassified sarcoma (previously referred as malignant fibrous histiocytoma). Some of these tumors can develop from a less aggressive sarcoma subtype, with increased genomic complexity paralleling stages of progression. Examples of such genetic evolution include the progression from neurofibroma to MPNST, of the progression from enchondroma to chondrosarcoma. However, in most cases, cytogenetically complex sarcomas arise de novo, without preexisting low-grade lesions.

Contrary to sarcoma with simple genomic profiles, these tumors present with multiple numerical and structural chromosomal aberrations that are reminiscent of epithelial tumors. Notably, some chromosomal aberrations are often unspecific and common to multiple subtypes of sarcomas. For example, broad amplifications of several chromosome arms (such as 5p) combined with deletions of the tumor suppressor genes *TP53*, *RB1*, *NF1*, *PTEN*, or *CDKN2A*/*CDKN2B* are observed in various tumor types. Inactivating mutations in the remaining allele of the deleted genes are frequent. These genetic alterations are thought to be an early event in sarcomagenesis, as the loss of function of these genes is believed to impair chromosome integrity and lead to genomic instability.

In the last few years, new molecular techniques have managed to identify prognostic signatures in cytogenetically complex sarcomas, and to point at oncogenic pathways that might be activated in specific subtypes, for example in leiomyosarcoma (LMS), osteosarcoma, and conventional chondrosarcoma.

Leiomyosarcoma

LMS is a subtype of sarcoma showing varying degree of smooth muscle differentiation, which can develop ubiquitously and represents 8%–10% of adult soft tissue sarcoma. From a cytogenetic point of view, LMS is characterized by complex karyotype alterations such as gains, losses and amplifications, often different from tumor to the other. However, some alterations are more frequent, such as loss of *RB1* and amplification of 5p13-15, while others have been associated to poor outcome and metastatic dissemination, such as loss of 1p, 2p, 13q14-q21, 10q, 16q, and gains of 17p, 8q, or 5p. At the molecular level, activation of the PI3K–AKT pathway seems to drive LMS development and maintenance, as a result of several distinct mechanisms including inactivation of PTEN. Mutations in *P53*, inactivation of *P16* and upregulation of *HIF1α* are associated with increased metastatic risk. So far, few studies have managed to identify specific alterations that may constitute attractive targets in LMS. An exception may be the amplification of myocardin (*MYOCD*), observed specifically in a subset of aggressive retroperitoneal LMS. *MYOCD* encodes a transcriptional cofactor of the serum response factor (SRF), the latter being a crucial regulator of smooth muscle differentiation, suggesting that MYOCD may be lineage-survival oncogene and could represent an attractive therapeutic target.

Osteosarcoma

Osteosarcoma is the most frequent primary bone tumor. It affects mostly children and teenagers and is thought to originate from osteoblastic cells. From a genetic point of view, the mutational landscape of osteosarcoma is highly complex, and great heterogeneity is observed between tumors. However, a hallmark of osteosarcoma is chromosome instability, with the presence of multiple aberrations in chromosome number and structure. Frequent losses of portions of chromosomes 3, 6, 9, 10, 13, 17, and 18 are observed, and lead to the loss of major tumor suppressor genes such as *RB* and *TP53*. Loss-of-function *RB* mutations are observed in up to 70% of osteosarcoma, the most common mechanisms for gene inactivation being loss-of-heterozygosity, structural rearrangements, and point mutations. *RB* inactivation leads to cell cycle progression through increased G1-to-S phase transition. Similarly, bi-allelic *TP53* mutations can be detected in almost 75% of cases of osteosarcoma. Allelic loss is the most frequent mechanism but *TP53* rearrangements and point mutations are also common. The loss of these tumor suppressor genes plays a critical role in osteosarcoma initiation and progression, as illustrated by the fact that germline *RB* and *TP53* mutations lead to osteosarcoma predisposition.

Conventional chondrosarcoma

Conventional chondrosarcoma is the most frequent subtype of chondrosarcoma and represents approximately 25% of primary bone tumors. These tumors can arise de novo or develop on preexisting benign cartilage neoplasms such as enchondromas. While enchondromas and low-grade chondrosarcomas show few cytogenetic abnormalities, high-grade chondrosarcomas are characterized by aneuploidy and complex karyotypes. A few recurrent but inconstant cytogenetic aberrations have been identified in those tumors, including 12q13-15 (containing *MDM2*) and 9p21 (containing *CDKN2A*) rearrangements, but their roles in chondrosarcoma initiation and progression still need to be clarified. The most significant advances in the understanding of conventional chondrosarcoma biology were done with the discovery of recurrent heterozygous mutations in isocitrate dehydrogenase 1 and 2 (*IDH1* and *IDH2*) in approximately 50% of cases of sporadic central and periosteal chondrosarcomas. The same mutations were detected in tumor cells of patients with Ollier disease and Maffuci syndrome, two syndromes characterized by development of multiple enchondromas, suggesting that *IDH1*/*IDH2* mutations are early events in the oncogenesis of cartilage tumors. IDH1 and IDH2 are two homodimeric enzymes localized in the cytoplasm and peroxysomes, and in the mitochondrial matrix, respectively. They catalyze a redox reaction that converts isocitrate to α-ketoglutarate (α-KG), and are thought to play a major role in the regulation of glucose, fatty acids, and glutamine metabolism, and to maintain normal cellular redox status. Mutant IDH enzymes acquire a neomorphic activity in which α-KG is converted to 2-hydroxyglutarate (2-HG), with an exclusive production of the D- enantiomeric form of the metabolite (D2HG). As a result, elevated levels of D2HG can be detected in patients with *IDH1*/*IDH2* mutated tumors. Those findings support the concept that D2HG acts as an oncometabolite to promote tumor progression, as it has been previously shown in gliomas and acute myeloid leukemias showing the same *IDH1*/*IDH2* mutations.

Apart from those examples, much work remains to be done to identify and clarify the genes involved in the genesis of complex genomic sarcomas. This will require large scale genomic studies combined with gene expression profiling and functional genetics for target discovery. Of note, even if the identification of genetic alterations in sarcomas with complex karyotypes has not yet been associated with therapeutic applications, the analysis of genomic complexity can provide key elements for predicting patients' prognosis. For example, the CINSARC (complexity index in sarcomas) expression signature, composed of 67 genes involved in mitosis and chromosome management, has been shown to be associated with genome complexity and to predict metastatic outcome in patients with nontranslocation soft tissue sarcomas. This signature has thus been proposed for improving the selection of patients that could benefit from adjuvant chemotherapy after surgery of the primary tumor.

Perspectives in Sarcoma Biology

Diagnostic and Theranostic Approaches

The increasing knowledge concerning sarcoma biology has already led to tremendous advances in both diagnostic procedures and therapeutic strategies for specific subtypes. The high specificity of the molecular alterations found in a particular sarcoma subtype, especially for sarcomas with a simple genomic profile, has led to the development of dedicated molecular diagnostic techniques, that have proven to be an essential complement to standard pathological approaches. The current molecular dismantling of bone and soft tissue sarcomas is associated to major evolutions in the diagnostic techniques, that are currently shifting from research approaches to mandatory translational and theranostic tools for direct use in clinical practice.

Historical and traditional diagnostic methods

The detection of specific molecular abnormalities has progressively become key diagnostic markers to define sarcoma entities, due to their high specificity and prevalence within a given tumor subtype. Over the last decades, diagnostic methods have been developed and validated to detect these alterations, whether at the DNA, RNA, or protein level, and are commonly used in clinical practice in complement to standard pathological analyses.

Immunohistochemical (IHC) staining is widely used to assess for the presence or absence of a given protein within tumor cells. IHC is a good technique for detecting some fusion proteins in translocation-associated sarcomas, when a portion of a protein is overexpressed as a result of the gene fusion. For example, the diagnosis of alveolar soft part sarcoma and inflammatory myofibroblastic tumor can be done by IHC staining withTFE3 and ALK antibodies, respectively. However, all fusion proteins cannot be

detected by IHC, due to the lack of specificity of some antibodies, such as FLI1 antibodies for Ewing sarcoma, or when the fusion leads to protein truncation and loss of reactive epitopes. IHC staining is also a good technique for detecting inactivating mutations resulting in protein loss, such as the loss of SMARCB1 in MRT (Fig. 5A) or the loss of the SDHB unit in SDH-deficient GIST. Overexpression of MDM2 and CDK4 in sarcomas with 12q13-15 amplicon can also be highlighted by IHC, but IHC specificity and sensitivity in these cases is less efficient than alternative methods.

Fluorescence in situ hybridization (FISH) has long been the most frequently used technique to show gene rearrangements such as translocations and amplifications. FISH consists in the detection of a specific DNA target by a dedicated fluorescent probe in the nuclei of interphase cells. Break-apart probes specific for *EWSR1*, *SS18*, *DDIT3*, *FOXO1A*, *TLS*, *ETV6*, or *ALK* are commercially available are frequently used to detect rearrangements of corresponding genes in translocation-associated sarcoma (Fig. 5B). However, this technique does not enable to identify the second gene partner involved in the translocation. The definitive diagnosis of a specific sarcoma subtype may thus need additional investigations, for example in case of a rearrangement of *EWSR1* possibly related to Ewing sarcoma, clear cell sarcoma, desmoplastic small round cell tumor, and myxoid liposarcoma. FISH is currently the most frequently used molecular approach to detect MDM2 amplifications. The combination of MDM2 probes and probes specific for the centromeric region of chromosome 12 is highly sensitive and specific for detecting 12q13-15 amplicons in WDLPS and DDLPS (Fig. 5C).

Reverse transcription-polymerase chain reaction (RT-PCR) is the gold standard approach for detecting fusion transcripts in translocation-associated sarcomas. Contrary to IHC and FISH that can be routinely performed on formalin fixed paraffin-embedded tissues, RT-PCR is more suitable with RNA extracted from frozen tissue, and requires strictly controlled laboratory conditions for primer design, RNA extraction, and reduced risk of PCR contamination. It enables to detect known fusion transcript with high sensitivity and specificity which enables the detection of circulating tumor cells. Using quantitative or real-time RT-PCR (qRT-PCR) enables to improve both the sensitivity and specificity compared to standard RT-PCR, and is more appropriate for daily diagnosis (Fig. 5D and E).

Last, the detection of KIT and PDGFRα mutations in GIST is usually done by Sanger sequencing of PCR amplified-exons on tumor DNA extracted from paraffin-embedded or frozen tissue.

Thus, all those usual techniques enable to detect specific molecular abnormalities with high sensitivity and have been widely used during the last decades for sarcoma diagnosis. However, these techniques are targeted towards known and previously characterized alterations, and do not enable a broad screen of multiple gene fusions, or to detect new abnormalities and to established unbiased tumor molecular profiling. During the last few years, new unbiased genetic and molecular techniques have been developed and are becoming key tools both for diagnosis, prognosis and therapeutic strategies.

Next generation sequencing for genetic and molecular characterization of sarcomas

Next generation sequencing (NGS), also known as high-throughput sequencing, refers to a group of new sequencing technologies that have been developed over the last decades. These techniques enable to produce millions of sequences in one run and in a cheaper way than conventional sequencing. NGS allows to get away from cloning and genomic bank constitution, and enables to sequence isolated nucleic acid molecules.

Transcriptome analysis by RNA sequencing (RNAseq)

RNAseq is a recently developed approach that uses NGS for transcriptome profiling. It consists of converting a population of RNA (total or isolated) into a bank of cDNA fragments with adaptors attached at one or both ends. cDNA are then sequenced in a high throughput manner to get sequences from either one end (single-end sequencing) or both ends (pair-end sequencing). The reads can then be aligned to a reference genome or reference transcripts to produce a transcriptional map, both at the qualitative (structure of the transcriptome) and quantitative (level of expression of each transcript) levels.

RNAseq is a highly suitable technique for the identification of fusion events, especially to detect fusion genes coding for chimeric proteins. Indeed, using transcriptome enables to focus on the fusion genes that are expressed, and thus more likely to be functional and/or involved in the disease, and RNAseq enables to identify fusion genes resulting from nongenomic events, such as trans-splicing or read-through. Pair-end sequencing facilitates the detection of novel rearrangements and fusion genes compared to single-end sequencing. A chimeric gene can be identified when a mate pair spans the fusion junction, or if the mate pairs encompass the fusion junction, and additional evidence of a fusion transcript can be detected due to the quantitative aspect of RNAseq. Concerning data analysis, several algorithms of gene fusion detection have been developed in the last decade, which enable to predict the statistical probability of the detected fusion events. In sarcomas, RNAseq has proven to be a highly efficient technique to detect fusion transcripts in translocation-associated tumors (Fig. 6A,B). Moreover, since RNAseq is not limited to detecting transcripts corresponding to known genomic sequences, this technique has enabled to discover new fusion genes corresponding to new sarcoma subtypes, such as *BCOR-CCNB3* fusion in a group of tumors previously referred to as "Ewing-like sarcomas."

The quantitative aspect of RNAseq has also made it an attractive method to study global gene expression profiles. Several supervised and unsupervised bioinformatics techniques have been developed, some the most famous being hierarchical clustering (Fig. 6C) and principal component analysis, that enable to group or divide samples based on their expression profiles. Over the last decade, this has enabled to provide a wide description of multiple sarcoma subtypes, and to establish new biological convergences between previously unrelated subtypes. For example, RNAseq has enable to discover a new group of aggressive thoracic sarcomas characterized by deficiency in SMARCA4, the ATPase subunit of the SWI/SNF complex. Transcriptomic profiling has

(B) Fluorescent in situ hybridization (FISH) for translocation-associated sarcomas. *Left panel*: representation of the *SS18* broken-apart probes used for the detection of *SS18* rearrangements. *Right panel*: example of FISH with the *SS18* broken-apart probe in a case of synovial sarcoma with *SS18-SSX1* fusion. The detection of two distinct *red* and *green* signals shows the rearrangement of *SS18* gene within tumor cells. (C) FISH for sarcomas with *MDM2* amplification. *Left panel*: representation of *MDM2* and chromosome 12 centromeric (CCP12) probes used for the detection of *MDM2* amplification. *Right panel*: example of *MDM2* amplification detected by FISH in a case of well-differentiated liposarcoma. The detection of multiple red signals shows the presence of the *MDM2* amplification within tumor cells. (D) Reverse-transcription polymerase chain reaction (RT-PCR) for the diagnosis of fusion-positive sarcomas. Line 1, ladder; line 2, negative control; line 3, positive control for SS18–SSX1 fusion transcript; lines 4–6, three samples of synovial sarcoma showing the presence of the SS18–SSX1 specific amplicon. (E) Quantitative RT-PCR for the diagnosis of fusion-positive sarcomas. The panel shows the amplification of a specific SS18–SSX1 amplicon in two synovial sarcomas specimens, whereas the amplicon is not detected in the negative control. The cycle at which the amplicon is detected gives a quantitative aspect of the expression level of the fusion transcript.

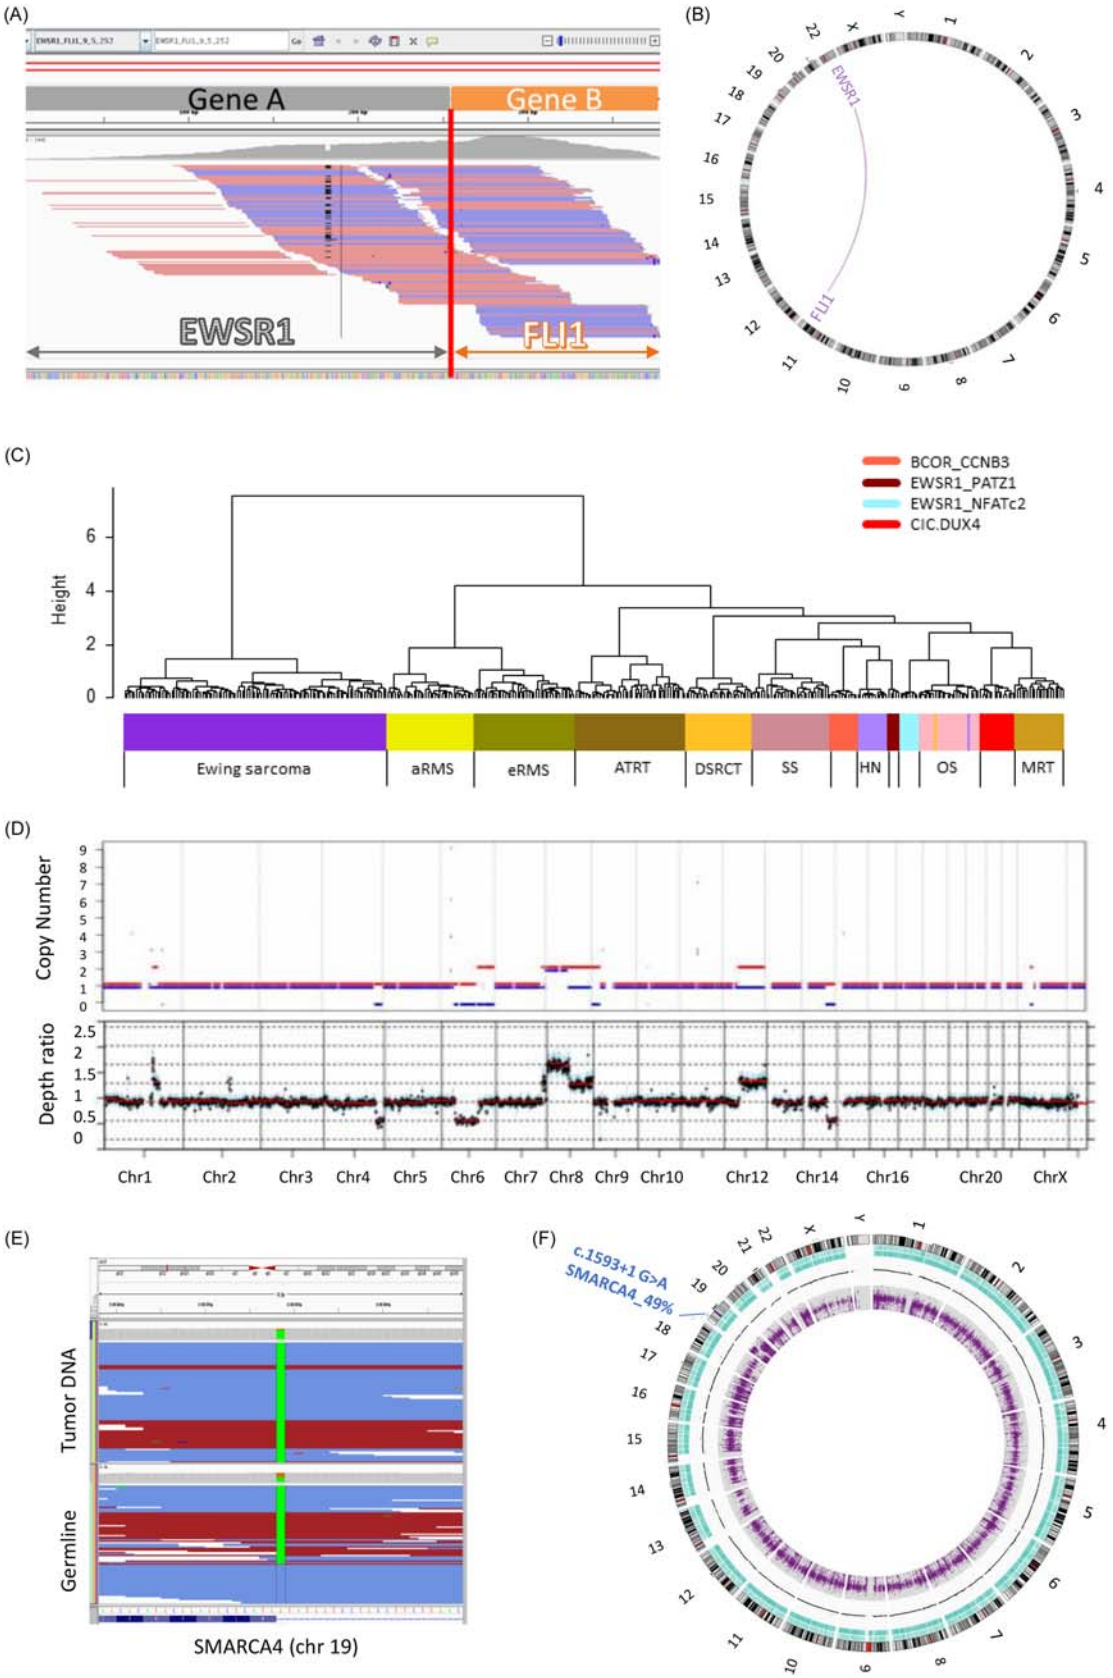

Fig. 6 Next generation sequencing for sarcoma diagnosis and theranostics. RNAseq is the gold standard NGS method for detection of previously known and/or new gene fusions. (A) Example of the detection of an EWSR1–FLI1 fusion transcript by RNAseq in a case of Ewing sarcoma. (B)

revealed that those tumors were biologically related to the other SWI/SNF-deficient MRT and small cell carcinoma of the ovary, hypercalcemic type (SCCOHT), but distinct from SMARCA4-mutated lung carcinoma.

Whole-exome and whole-genome sequencing

Apart from transcriptome sequencing, both whole-exome (WES) and whole-genome sequencing (WGS) are becoming key NGS approaches to study sarcoma genomics. WES captures and then deeply sequences all protein-coding exons of the human genome, while WGS is an unbiased technique that provide sequencing of all accessible genomic regions. Both techniques enable to detect point mutations, small insertions and deletions (indels), and copy number variations (**Fig. 6D–F**), while WGS can also simultaneously capture genome structure and intergenic variations.

Although those techniques are not currently used in clinical practice, they have already enabled to provide a genomic description of specific sarcoma subtypes and to detect previously unknown mutations that may play a major role in sarcomagenesis. For example, WES on series of matched tumor and germline samples of Ewing sarcoma patients enabled to detect recurrent mutations in the *STAG2* gene in approximately 20% of patients, the latter being associated with poor prognosis and suggesting a role of STAG2 loss-of-function in tumor progression.

In summary, NGS techniques are becoming major tools to study sarcomagenesis. Although not currently routinely used in clinics, NGS approaches have already enabled to detect previously unknown alterations in multiple sarcoma subtypes, including fusion genes and mutations, and thus to add new diversity and complexity to the usual tumor classification. Chromatin-immunoprecipitation coupled to sequencing (ChIP-seq) data are also being generated, and will facilitate target genes discovery in sarcomas with chimeric transcription factors. The current pathological classification of sarcomas is thus currently being entirely refined with the increasing number of biological data emerging from those approaches. Undoubtedly, NGS techniques combined to pathological analyses will soon become gold standard approaches for sarcoma diagnosis and classification.

Circulating-tumor DNA for sarcoma prognosis and follow-up

Circulating-tumor DNA (ctDNA) refers to fragments of DNA derived from tumor cells and circulating in the blood together with cell-free DNA from other sources. Although the mechanism leading to ctDNA release have not been fully characterized so far, it is believed that most ctDNA fragments originate from tumor cells necrosis or apoptosis. With an average size of 167 bp, ctDNA constitutes a major noninvasive genomic reservoir of tumor clones and gives a dynamic representation of tumor genomic diversity. As a result, several methods have been developed to capture and analyze ctDNA for specific molecular tumor alterations, including allele-specific PCR, droplet digital PCR (ddPCR) or targeted NGS, and are successfully used in several cancer types to monitor genomic alterations in a dynamic way.

Due to the low incidence of sarcomas, only few studies have evaluated the potential of ctDNA for genomic profiling and follow-up of patients. Some studies have suggested that ctDNA was not as frequent in sarcomas (especially soft tissue sarcomas) as in epithelial cancers. However, successful ctDNA monitoring has been reported in several subtypes of bone and soft tissue sarcomas.

Indeed, the presence of a specific gene fusion can be detected in ctDNA with a high level of sensitivity for translocation-associated sarcomas. For example, a study carried out on 20 patients with Ewing sarcoma undergoing multiple ctDNA assessments before and during multimodal treatment, revealed that *EWSR1* gene rearrangements could be detected in ctDNA in 90% of patients. Notably, ctDNA levels were correlated to tumor volume both in patients with localized or metastatic disease, and the kinetics of *EWSR1*fusion sequence copy number in the plasma correlated to response to initial chemotherapy or tumor recurrence. Similarly, successful detection and monitoring of *EWSR1-WT1* fusion gene in ctDNA of patients with desmoplastic small round cell tumors has been reported. Thus, ctDNA appears to be particularly appropriated for the follow-up of patients with fusion-positive sarcomas and by extension with karyotypically-simple sarcomas, due to the high specificity of the molecular alterations and to their expression in all tumor clones.

Apart from gene fusions, other genomic alterations have been successfully detected in ctDNA from sarcomas patients. These include *IDH1* mutations in conventional chondrosarcoma, *MYOD1* mutations in spindle cell rhabdomyosarcoma, *H3F3A* mutations in giant cell tumor of bone, or *KRAS* and *NF1* mutations in high-grade malignant spindle cell sarcoma. On the contrary,

Representation of the gene fusion detected by RNAseq in a CIRCOS representation. CIRCOS enables to give a circular representation of the transcriptomic finding, with the line indicating the fusion between genes located on separate chromosomes, the latter being distributed along the main circle. RNAseq also enables to establish transcriptional signatures and to compare the expression profiles of a pool of different samples thanks to unsupervised clustering methods. (C) Clustering of a cohort of pediatric sarcomas, showing the distinction of multiple tumor subtypes based on their expression profiles. In particular this figures shows that the tumors previously referred to as "Ewing-like sarcoma" such as CIC-DUX4 and BCOR-CCNB3 fusion-positive sarcomas, constitute distinct tumor entities clearly apart from classical Ewing sarcoma. Whole-exome-sequencing enables to establish copy number profiles on tumor DNA. (D) Copy number profiling by WES of a case of undifferentiated sarcoma showing gain of losses of multiple chromosomal fragments. WES also enables to look for mutations both in somatic and germline DNA. (E) Example of detection of a bi-allelic SMARCA4 inactivating mutation in a case of malignant rhabdoid tumor; the same mutation is found at the hemizygous level in matched germline DNA. (F) CIRCOS representation of the genomic data obtained by WES of the SMARCA4-mutated tumor presented in (E). Mutations are indicated along the outer circle, *while* copy number variations are plotted along the inner circles. Abbreviations: *aRMS*, alveolar rhabdomyosarcoma; *eRMS*, embryonal rhabdomyosarcoma; *ATRT*, atypical teratoid rhabdoid tumor; *DSRCT*, desmoplastic small round cell tumor; *SS*, synovial sarcoma; *HN*, HEY1-NCOA2 fusion-positive sarcoma; *OS*, osteosarcoma; *MRT*, malignant rhabdoid tumor. Courtesy from Gaëlle Pierron for CIRCOS plots.

for other tumors carrying well characterized mutations such as *CTNNB1* mutations in desmoid-like fibromatosis or *GNAS* mutations in fibrous dysplasia and intramuscular myxoma, no ctDNA could be detected. The absence of ctDNA detection in those cases could be due to the low aggressive potential of those tumors which do not metastasize. Indeed, there is growing evidence that ctDNA amount is directly correlated to tumor grade and metastatic potential in sarcoma patients. For example, in a recent study on patients with conventional chondrosarcoma harboring *IDH1* mutations, mutant *IDH1* ctDNA could be detected in all dedifferentiated and grade III tumors, but much more inconstantly in grade II and low-grade cases.

Concerning patients with cytogenetically complex sarcomas carrying multiple genomic aberrations in common genes such as *TP53*, RB1 pathway or Hedgehog pathway, numerous gene loci are commonly involved in these alterations, which will require the development of complex assays for ctDNA detection. In those patients, ctDNA will probably lead to a better understanding of tumor biology, with the possibility to follow multiple genomic alterations in the blood and thus to better explain their role in sarcoma development and progression.

To sum-up, ctDNA will probably become a major tool for genomic characterization, prognostic classification and follow-up of high-grade sarcoma patients undergoing multimodal treatment. Due to the low incidence of sarcomas, the inclusion of patients in systematic clinical trials will facilitate the evaluation of the impact of ctDNA assessment both for prognostic and therapeutic impacts.

Predisposition to sarcomas and genetic counseling

Although most cases of sarcoma arise sporadically with somatically-restricted genetic alterations, a proportion of tumors are integrated within well-defined heritable cancer predisposition syndromes. Since the 1880s and the first characterization by Heinrich Von Recklinghausen of the multiple neurofibromas affecting patients with neurofibromatosis type 1 (NF1) syndrome, multiple cancer predisposition syndromes have been described that can favor sarcoma development (**Table 3**). Although the first characterizations of those syndromes relied only on careful clinical observation and annotation, the tremendous advances in genetics and molecular biology have enabled to refine their description and to give insight into the biological mechanisms of sarcomagenesis for several tumor subtypes.

For example, Li–Fraumeni syndrome was first described in 1969 with the description of early onset cancers transmitted in an autosomal dominant way in a few families. More than 20 years later, germline inactivating mutations in the tumor suppressor gene *TP53* were identified as the responsible genetic aberrations. Since then, reports of large cohorts of LFS patients have enabled to widely refine the clinical and genetic characteristics of the syndrome and have led to the identification of several mutational subtypes with different clinical implications. Even if those inherited syndromes are rare, a key issue is that using common clinical criteria leads to cancer diagnosis before syndrome diagnosis, with no opportunity for preventive intervention. Thus, the complete familial medical history should be carefully examined in case of early onset sarcoma, and genetic counseling should be largely proposed in case of evocative history.

Apart from those rare inherited syndromes, several recent studies have reported a high frequency of germline mutations in cancer predisposition genes in patients with sporadic sarcomas. In a large case-control study involving 1162 sarcoma probands and 6545 Caucasian controls, an excess of potentially pathogenic germline variants was detected by targeted exome-sequencing in 55% of sarcomas patients. The most frequent mutated genes were *TP53*, *ATM*, *ATR*, *BRCA2*, and *ERCC2*, and 25% of probands carried variants with potential therapeutic significance. The excess risk was suggested to lie in both classic monogenic and previously unrecognized polygenic rare variations. Of note, the cumulative burden of multiple variants was associated with earlier age at sarcoma diagnosis. This still needs to be further confirmed in new studies but points out the attention that is required for possible genetic predisposition in sarcoma patients.

Thus, the frequency of putatively pathogenic germline variations in cancer genes may be particularly high in sarcoma patients, even in apparently sporadic cases. If recognized risk management strategies have been successfully validated for hereditary syndromes, there is now evidence that genetic counseling should be proposed more widely for sarcoma patients, and that sarcoma families carrying high-risk genetic variants might also benefit from dedicated surveillance and prevention strategies.

Therapeutic Perspectives in Sarcomas

Despite the tremendous advances in the understanding of sarcoma biology and the molecular dismantling of numerous sarcoma subtypes, those progress have not yet been associated to dramatic changes in the therapeutic strategies for most sarcoma patients. Indeed, apart from tumors for which an aberrant tyrosine kinase activity can be successfully targeted with specific tyrosine kinase inhibitors such as GIST or DFSP, most sarcomas are currently still being treated with unspecific multimodal therapeutic strategies including wide surgery, radiation therapy, and cytotoxic chemotherapy. However, new therapeutic strategies relying on biological data are emerging, both for sarcomas with simple and complex cytogenetic profiles.

Targeting gene expression reprogramming in sarcoma

There is now substantial evidence that some sarcoma subtypes are associated to a specific transcriptional signature due to the reprogramming of normal gene expression, particularly in the case of chimeric proteins with transcription factor activity. Targeting this aberrant transcriptional program represents a key therapeutic challenge, since contrary to chimeric tyrosine kinase receptors, transcription factors are not easily targetable. This is due notably to the fact that transcription factors usually lack ligand-binding domains or substrate-binding enzymatic pocket that constitute excellent opportunities for drug development. Moreover, the surface

Table 3 Main inherited syndromes associated with increased risk of sarcoma

Syndrome	*Gene*	*Transmission*	*Main clinical features*	*Associated sarcoma*
Li-Fraumeni	P53	AD	Early onset of multiple cancers including breast cancer, CNS tumors, adrenocortical carcinomas, leukemia	Osteosarcoma, RMS, LMS and others high-grade STS
Hereditary retinoblastoma	RB1	AD	Retinoblastoma before 5 years, often bilateral	Osteosarcoma and other high-grade STS
Neurofibromatosis type 1	NF1	AD	Café-au-lait spots, neurofibromas, optic gliomas, iris harmarthomas, skeletal defects	MPNST, RMS, GIST
Constitutional mismatch repair deficiency syndrome	MLH1, MSH2, MSH6, PMS2	AR	Predisposition to hematological and CNS malignancies, gastrointestinal tumors	Embryonal RMS
Familial adenomatous polyposis	APC	AD	Multiple colic adenomatous polyps, colic cancer before 40 years, osteoma, hepatoblastoma	Desmoid tumor
Carney-Stratakis	SDHB, SDHC	AD	GIST and paraganglioma	GIST
Familial GIST	KIT, PDGFRα	AD	ICC hyperplasia	Multifocal GIST
Familial rhabdoid predisposition syndrome	SMARCB1	AD	MRT and CNS tumors	MRT
Tuberous sclerosis	TSC1, TSC2	AD	Hamartomas, angiomyolipomas, renal cysts, RCC, angiofibromas	PEComa, chordoma
Hereditary leiomyomatosis and renal cancer	FH	AD	Type 2 papillary RCC, cutaneous and uterine leiomyoma	Uterine LMS
DICER1 syndrome	DICER	AD	Pleuropulmonary blastoma, cystic nephroma, ovarian sex cord-stromal tumors, thyroid neoplasia	Embryonal RMS
Gorlin syndrome	PTCH	AD	Basal cell carcinoma, odontogenic keratocyst, ovarian and heart fibroma, skeletal defects	Embryonal RMS
Bloom	RECQL3	AR	Short stature, sun sensitivity, skin changes	Embryonal RMS, osteosarcoma
Rothmund-Thomson syndrome II	RECQL4	AR	Poikiloderma, telangiestasias, congenital bone defects, cataract, hypogonadism	Osteosarcoma
Beckwith-Wiedeman	CDKN1C, IGF2, H19, KCNQ1OT1	AD, sporadic	Overgrowth syndrome, hepatoblastoma, Wilms tumor	Embryonal RMS
Costello	HRAS	AD	Rasopathy: Faciocutaneoskeletal syndrome, mental retardation	Embryonal RMS

Abbreviations: *AD*, autosomal dominant; *AR*, autosomal recessive; *RMS*, rhabdomyosarcoma; *LMS*, leiomyosarcoma; *STS*, soft-tissue sarcoma; *MPNST*, malignant peripheral nerve sheat tumor; *GIST*, gastrointestinal stromal tumors; *PEComa*, perivascular epitheliod cell tumor; *RCC*, renal cell carcinoma; *ICC*, interstitial cells of Cajal; *MRT*, malignant rhabdoid tumor; *CNS*, central nervous system.

of protein–protein and protein–DNA interactions is generally large for transcription factors and difficult to target, which creates issues for the development of small inhibitory molecules. However, several new therapeutic strategies are currently being developed for interfering with transcription factors' activity in sarcomas (**Fig. 7**).

Targeting transcription factors

Trabectedin is a marine-derived alkaloid initially isolated from the Caribean tunicate *Ecteinascidia turbinata*. Trabectedin binds covalently to DNA minor groove triplets, whereas another part of the molecule protrudes out of the DNA helix and interacts with the transcriptional machinery in a gene and promoter-dependent way. Although objective response rates to trabectedin in advanced anthracycline-resistant soft tissue sarcomas do not exceed 10%, a significantly higher proportion of responses have been reported in myxoid liposarcoma (MLPS) patients. MLPS accounts for 30%–35% of liposarcomas and is characterized by characteristic translocations resulting in the expression of a chimeric transcription factor, most of the time FUS-DDIT3 and less frequently EWSR1-DDIT3. Recent studies have shown that trabectedin blocks the trans-activating functions of FUS-DDIT3 by displacing the oncogenic fusion protein from its target promoters, which enables to induce adipogenic differentiation of MLPS cells both in experimental in vitro and in vivo models and in patient's biopsies. Trabectedin has also been shown to modulate the transcription program driven by EWSR1–FLI1 fusion and thus increase the susceptibility of Ewing sarcoma cells to topo-isomerase I poisons such as irinotecan. However, no significant response to trabectedin in Ewing sarcoma patients could be observed in a pivotal Phase II study, probably due to pharmacokinetic and pharmacodynamic issues. New drugs such as lurbinectedin, a second-generation trabectedin

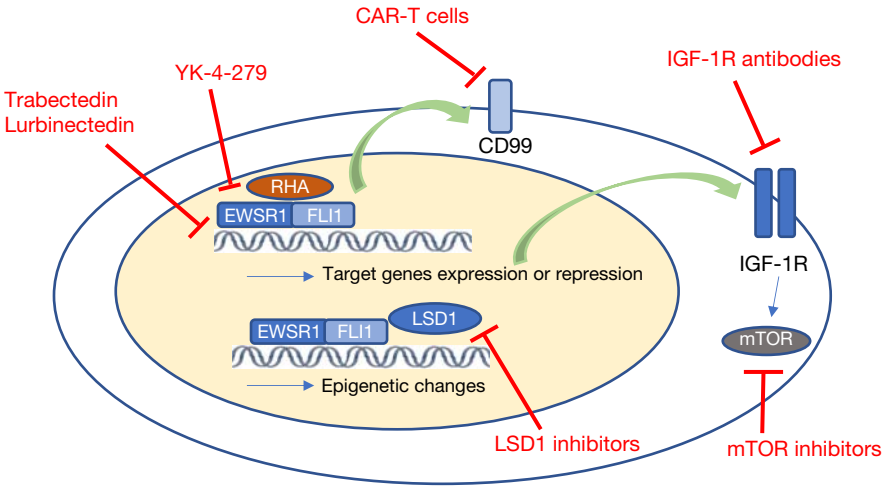

Fig. 7 Targeting transcriptional reprogramming in sarcomas: the example of Ewing sarcoma. Schematic representation of the therapeutic strategies aiming at modulating EWSR1–FLI1 transcription factor activity. EWSR1–FLI1 binding to the DNA helix can be directly targeted with the cytotoxic agents trabectedin and lurbinectedin, whereas its interaction with RNA helicase A (RHA), a major component of the transcription factor machinery, can be targeted with the small molecule YK-4-279. Epigenetic cofactors of EWSR1–FLI1 include the lysine-specific demethylase 1 (LSD1), which can be targeted with specific LSD1 inhibitors. Downstream targets of EWSR1–FLI1 such as the IGF1-R pathway also constitute therapeutic opportunities, as shown by the activity of IGF-1R inhibitors in Ewing sarcoma. Last, other EWSR1–FLI1 downstream targets such as the CD99 transmembranous protein can be targeted with immunomodulating agents, including chimeric antigen receptor gene-modified T cells (CAR-T cells) and specific antibodies.

analogue with a more favorable pharmacokinetic profile, are currently being developed and evaluated in Ewing sarcoma and other sarcoma subtypes with aberrant transcription factor activity.

Other approaches to directly target chimeric transcription factors include the development of small inhibitory molecules that interfere with the transcription machinery. For example, YK-4-279 is a small molecule which has been shown to block in vitro and in vivo the interaction between EWSR1–FLI1 and the RNA helicase A, a major component of EWSR1–FLI1 transcriptional complex, resulting in tumor growth inhibition.

Targeting epigenetic cofactors of transcription factors

Epigenetics refers to the heritable changes in gene expression that do not involve the DNA sequence, such as DNA methylation and histone modifications, and the understanding of its misregulation in cancer has significantly advanced over the last decade. There is now substantial evidenced that the oncogenic activity of chimeric transcription factors in sarcomas requires epigenetic cofactors.

For example, EWSR1–FLI1 activity depends upon histone deacetylases (HDAC) for both direct and indirect target gene repression, and treatment of Ewing sarcoma cells with the HDAC inhibitor vorinostat impairs the regulation of EWSR1–FLI1 target genes and reduces cell viability and transforming capacities in vitro. More recently, the lysine-specific demethylase 1 (LSD1) has become a major attractive target in several sarcoma subtypes including Ewing sarcoma, alveolar rhabdomyosarcoma and synovial sarcoma. More precisely, EWSR1–FLI1 mediated transcriptional regulation has been shown to require direct binding to an epigenetic complex containing LSD1. Several studies have reported that LSD1 inhibitors such as HCI-2509 upregulated EWSR1–FLI1-repressed targets and vice versa, and decreased cell viability in vitro. Moreover, LSD1 inhibition showed single-agent efficacy across multiple xenograft models for Ewing sarcoma. Several LSD1 inhibitors are thus currently being tested in early phase clinical studies including advanced Ewing sarcoma patients.

Apart from LSD1 inhibitors and HDAC inhibitors, other molecules targeting epigenetic cofactors such as BET bromodomain inhibitor and EZH2 inhibitors are currently being evaluated in sarcoma patients. Although the use of such therapeutic strategies shows promise, no reliable marker to predict clinical activity or either primary or acquired resistance has been identified so far.

Targeting downstream pathways of transcription factors

Another approach for modulating transcription reprogramming in sarcomas with aberrant transcription factor activity consists in the identification and targeting of downstream regulated pathways. This approach is highly complex due to the fact that transcription factors often regulate numerous different targets involved in various oncogenic processes. Thus, therapeutic strategies will necessarily require drug combinations for effective success in patients. For example, the insulin-like growth factor receptor 1 (IGF-1R) pathway has long been identified as an attractive downstream target of EWSR1–FLI1 chimera in Ewing sarcoma.

The IGF-1R pathway is part of a complex insulin network mostly involved in the regulation of growth, differentiation and development at the cellular, organ and organismal levels. Upon binding of the ligands IGF-1 and IGF-2, IGF-1R auto-phosphorylates which leads to subsequent activation of phosphoinositide 3-kinase (PI3K) and mitogen-activated protein kinases (MAPK) pathways. EWSR1–FLI1 regulates IGF1 and the IGF1-R pathway has long been known to be activated in Ewing sarcoma cell lines

and tumor tissues. Moreover, IGF-1 and IGF-2 bioavailability in the peripheral tissues is mostly regulated by IGF-binding proteins (IGFBP1-6), a group of proteins that bound the ligands in the circulation. More precisely, EWSR1–FLI1 fusion protein has been shown to directly bind the IGFBP3 promoter, thereby repressing its activity and leading to increased IGF-1R signaling.

These findings have led to evaluate several IGF-1R inhibitors in Ewing sarcoma patients, including monoclonal antibodies and tyrosine kinase inhibitors. The first early phase clinical trials evaluating anti-IGF-1R antibodies in advanced Ewing sarcoma patients have evidenced between 10% and 15% of objective tumor responses and approximately 25% of patients with stable disease, sometimes durable up to more than 2 years. Combining IGF-1R antibodies with the mTOR inhibitor temsirolimus resulted in higher antitumor activity with 35% of objective response. This example illustrates the relevance of targeting downstream molecular pathways in sarcomas with aberrant transcriptional programs. The successful development of such new therapeutic strategies will however require concomitant translational studies to prospectively identify potential responders.

Targeting metabolic regulators

The discovery of recurrent mutations in genes involved in metabolism regulation both in SDH-deficient GIST and IDH1/2-mutated chondrosarcoma has highlighted the role of metabolism balance in sarcomagenesis. Although SDH complex and IDH enzymes belong to different pathways, they are both involved in the regulation of glucose and fatty acid metabolism and in the maintenance of cellular redox status. Moreover, both loss of function of SDH and activating mutations of IDH1/2 result in the abnormal accumulation of a metabolic product within the cytoplasm, which is thought to act as an oncogene to promote tumor development.

Strikingly, aberrant hypermethylation patterns are observed in SDH-deficient GIST as well as in IDH1/2-mutated chondrosarcomas, suggesting that metabolic products can interfere with epigenetic cofactors to modulate gene expression. Since these mutations are thought to be early events in tumor biology, they thus represent attractive therapeutic targets.

Several selective inhibitors of the mutant forms of IDH1 and IDH2 have been developed over the last few years and have shown impressive clinical efficacy in IDH-mutated acute myeloid leukemia. For patients with solid tumors, no data are yet available in chondrosarcoma patients, but IDH inhibition has already proven to be efficient in a few IDH-mutated glioma patients. The results of ongoing clinical trials involving chondrosarcoma patients are thus eagerly expected.

Whether similar oncogenic mechanisms also occur in other sarcomas subtypes remains to be further investigated, but several studies have already highlighted abnormal metabolic regulation in both sarcomas with simple and complex genomic profiles. However, if those abnormalities are playing a key role in tumor initiation and progression or constitute only a stigmata of cancer cell activity needs to be elucidated.

Immunomodulating agents for sarcoma treatment

In the late 1800s, spontaneous sporadic remissions in sarcoma patients after severe infections were reported by William Coley, inspiring future generations of physicians and immunologist to use the immune system for cancer cure. Over a century later, new approaches of immunotherapy have become a cornerstone of cancer treatment, with more than a thousand clinical trials evaluating immunomodulating agents currently accruing on clinicaltrial.gov. In sarcoma patients, several types of immunomodulating strategies approaches are currently being developed.

The recent development of monoclonal antibodies targeting immune checkpoint blockers such as CTLA4 and the PD-1/PDL-1 axis has changed the landscape of immunotherapy, with major and sustained responses in nonsmall cell lung cancer, melanoma, urothelial cancer or head and neck carcinoma. Thus, these agents have rapidly been tested in several early phase clinical trials including sarcoma patients. SARC028 was a Phase II study evaluating the efficacy of the PD-1 antibody pembrolizumab in 80 patients with bone and soft tissue sarcoma (STS). The response rate was 19% in patients with STS, with an additional 40% of patients with stable disease. Whereas no activity could be observed in patients with LMS, most cases or tumor response were observed in patients with high-grade undifferentiated pleomorphic sarcomas and DDLPS. For bone sarcomas, only 5% of response were observed and concerned isolated patients with dedifferentiated chondrosarcoma and osteosarcoma. Since then, several studies have confirmed that monotherapy with immune checkpoint blockers should not be proposed to unselected sarcoma patients due to lack of efficacy and absence of predictive biomarker of response.

PDL-1 expression has been proposed as a predictive biomarker of efficacy of immune checkpoint blockers for several tumor types. In sarcoma, PDL-1 expression ranges from 12% to 65% depending on tumor subtypes and the type of antibody used for the analysis. In a large cohort of more than 320 patients with STS, only 20% of tumors expressed PDL-1, but 98% of PDL-1 expressing tumors showed CD8+ T cell infiltrates, supporting an immunosuppressive signature. Other immune infiltrates including Treg and tumor-associated macrophages (TAM) have been reported in sarcomas, but, so far, the role of those infiltrates to dictate prognosis and response to immune checkpoint blockers is still unknown.

Apart from immune checkpoint blockers, other immunomodulating agents are being developed and evaluated in distinct sarcoma subtypes. Vaccination strategies with tumor specific antigens and adoptive T cell therapy are currently being evaluated and constitute attractive approaches for sarcomas with simple genomic profile. Engineered TCR therapies such as specific chimeric antigen receptor gene-modified T cells (CAR T cells) directed against the ganglioside GD2 are also being evaluated in early phase trials in patients with Ewing sarcoma and osteosarcomas.

In conclusion, the use of immunomodulating agents in clinical practice in sarcoma patients is still at its infancy, and understanding the molecular features predicting the efficacy of modern immunotherapy approaches is mandatory to detect patients that could benefit from these therapeutic strategies. Since sarcomas are rare tumors, enrollment of patients with advanced disease in dedicated clinical trials will accelerate the optimal use of these new agents.

Introduction

Secondary bone tumors (e.g., metastasis presenting as bone tumors without at that time a known primary tumor) and plasmacytoma outnumber by far primary bone tumors except at children's age. Here we focus on primary bone tumors.

Many different types of primary tumors and tumor-like lesions have been described in bones. These lesions vary widely in their clinical behaviour and pathological features. Benign and malignant lesions may present at virtually any age, though there is a certain predilection period per tumor type. Most bone tumors are rare and often asymptomatic and indolent. Therefore, their true incidence is unknown.

Bone sarcomas account for only 0.2% of all neoplasms. Their incidence rates are age-related with a first peak occurring during the second decade of life, in which age group osteosarcoma and Ewing sarcoma are most frequent, and a second peak occurring in patients >60 years of age, when chondrosarcoma is the most frequently encountered bone sarcoma.

Bone sarcomas have a very specific spatial distribution in the long bones. Most bone sarcomas present around the knee (up to 56% under the age of 20 years), followed by the pelvis. Most patients experience pain and/or swelling, and therefore symptoms are not very specific. All patients with suspected bone tumors should be discussed in multidisciplinary team meetings including the radiologist and pathologist involved in the diagnosis and the (orthopedic) surgeon and oncologist involved in treatment. Radiographic imaging is of utmost importance in diagnosing bone tumors. Good image quality of the entire lesion in at least two directions is essential to assess the nature of the process. Key-factors for making a relevant judgment and differential diagnosis include: location of the lesion in the bone as a whole, localisation in the affected part of the bone, destruction pattern, matrix mineralization, cortical damage, periosteal reaction and soft tissue extension.

Some lesions develop primarily in the metaphysis (e.g., osteosarcoma and giant cell tumor of bone), others have a mostly epi- (e.g., chondroblastoma) or diaphysial (e.g., Ewing sarcoma) origin (Fig. 1). Moreover, lesions can originate centrally (e.g.,

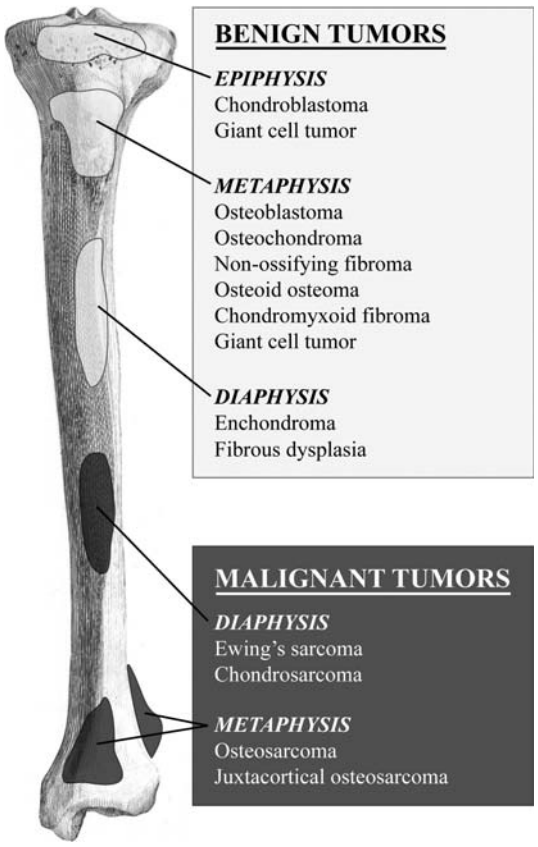

Fig. 1 Common location of bone tumors. Adapted from Fletcher, C. D. M., Bridge, J. A., Hogendoorn, P. C. W., et al. (2013). *WHO classification of tumors of soft tissue and bone*. Lyon, France: IARC Press.

enchondroma), eccentric (e.g., aneurysmal bone cyst), cortical (e.g. osteoid osteoma) or juxtacortical (e.g., parosteal/periosteal osteosarcoma). Multifocality is observed for enchondromas, osteochondromas, fibrous dysplasia, vascular tumors, Langerhans cell histiocytosis, multiple myeloma and metastases. The presence or absence of matrix (bone, cartilage) formation by the tumor assists in further characterization. Furthermore, the destruction pattern of a lesion (e.g., geographical, mottled-permeative) and the appearance of tumor margins (e.g., smooth, lobular, sharp, blunt, sclerotic) are important. The presence and amount of cortical damage (e.g., scalloping, irregular destruction or thickening) play a role in the interpretation. Presence or absence of a periosteal reaction (e.g., multi- or single layered, interrupted or not, Codman triangles and spiculation) further reduce the differential diagnosis.

As a rule, a reliable histological diagnosis cannot be made without adequate radiographical information and correlation, emphasizing the importance of multidisciplinary team meetings to establish a final diagnosis. One should always start with studying a conventional radiograph in two planes, which can be followed by MRI or CT to further define the extent of the lesion. Imaging should always be performed before the biopsy, because of the significant artifacts a biopsy results in on especially MR imaging.

While most bone sarcomas arise de novo, they can also develop within other conditions, such as Paget's disease of bone, or in preexisting benign lesions such as enchondromas and osteochondromas. Also, bone sarcomas can occur within hereditary syndromes such as Li-Fraumeni or retinoblastoma (osteosarcoma).

Classification of Bone Tumors

The current classification of bone tumors is based on the WHO consensus in which the differentiation of the tumor cells and the extracellular matrix that is being formed are important factors: (i) chondrogenic tumors (forming cartilaginous matrix), (ii) osteogenic tumors (forming osteoid), and (iii) osteoclastic giant cell rich tumors. In addition, fibrogenic, fibrohistiocytic, hematopoietic, notochordal, vascular, myogenic and lipogenic tumors are found, based on their line of differentiation. There are tumors of undefined neoplastic nature (e.g., fibrous dysplasia or aneurysmal bone cyst) and miscellaneous tumors (e.g., Ewing sarcoma, adamantinoma, and undifferentiated pleomorphic sarcoma of bone). At the current WHO classification attempts were made to harmonize the nomenclature with tumors of the soft tissues in those cases were appropriate. Immunohistochemistry plays a limited role in diagnosing primary bone tumors, while molecular diagnostics can be helpful in a subset of tumors.

The Fourth edition of the WHO classification of tumors of soft tissue and bone classifies bone tumors into four categories (similar to its soft tissue counterparts): benign, intermediate locally aggressive, intermediate rarely metastasizing and malignant. Benign tumors have a limited capacity for local recurrence, and if they do, recurrence will be nondestructive. Intermediate locally aggressive bone tumors, such as atypical cartilaginous tumor (previously called chondrosarcoma grade I), often recur locally, and display an infiltrative locally destructive growth pattern, although they do not have an evident potential to metastasize. They require wide excision, or application of a local adjuvant (e.g., phenol or cryotherapy) for local control. Intermediate—rarely metastasizing bone tumors, such as giant cell tumors of bone, bear in addition to their locally aggressive behaviour, a very small risk ($< 2\%$) of distant (lung) metastases. Such behaviour cannot be predicted on histological features. Malignant bone sarcomas carry a significant risk of distant metastases, ranging from 20% to 100% depending on the histotype and grade.

Osteogenic Tumors

Osteogenic tumors are characterized by the direct formation of osteoid or bone by the tumor cells. Bone formation by the tumor cells should be distinguished from metaplastic or reactive bone produced in nonosteogenic tumors or lesions (e.g., clear cell chondrosarcoma), or from growth plate like endochondral ossification (e.g., in osteochondroma, or fracture callus). Malignant transformation of benign bone forming lesions is extremely rare.

Osteoma

Osteoma is a benign tumor composed of compact mature bone arising on the surface of the bone. When developing in the medullary cavity, it is known as enostosis. Osteoma typically occurs in bones formed by membranous ossification, such as calvarial, facial, and jawbones, with a predilection for the paranasal sinuses. Osteoma is rare outside the skull, affecting predominantly adults between the ages of 30 and 50 years. Outside the craniofacial skeleton, parosteal osteosarcoma should be considered in the differential diagnosis. Multiple osteomas are found in the settings of the autosomal dominantly inherited Gardner syndrome (characterized by polyposis coli, osteomas/enostosis, impacted supernumerary teeth, odontomas, desmoid-type fibromatosis, epidermoid- and dermoid cysts). Gardner syndrome is a variant of familial adenomatous polyposis, caused by heterozygous mutation in the *APC* gene.

Osteoma is usually asymptomatic and does not require treatment because the lesions is slow growing and pursues an indolent clinical course. In the paranasal sinuses, it can cause obstruction or local swelling.

Radiologically, osteoma generally appears as a sharply marginated ossified mass projecting from a bony surface. Histologically, lamellar mature bone is seen, varying from compact to more trabecular. The trabeculae are lined by active or inactive osteoblasts within a well-vascularized moderately cellular fibrous stroma. If complicated by inflammation, usually due to an obstruction sinusitis, bone remodeling and a less mature bone can be found.

Osteoid Osteoma

Osteoid osteoma is a benign bone-forming tumor defined by small size (<2 cm), limited growth potential and disproportionate pain (Fig. 2A and B). Characteristically, patients with osteoid osteoma complain of localized and progressive pain that, generally, is worse at night. The lesion is thought to produce arachidonic acid and, as a result of this, non-steroidal anti-inflammatory drugs (NSAIDs) often relieve the pain. Although every bone can be affected, osteoid osteoma is more often found in the metaphysis or shaft of long bones and the cortex, particularly of the proximal femur.

Imaging studies are usually diagnostic. Osteoid osteoma is seen as dense cortical sclerosis surrounding a radiolucent nidus. The lesion is usually <1 cm, and per definition <2 cm (Fig. 2A). For lesions larger than 2 cm, osteoblastoma should be considered. Macroscopically, the nidus is seen as a small, red, granular, and softer area surrounded by sclerotic tissue. The interface between the nidus and the surrounding bone is very sharp. Histologically, the nidus is see as closely packed irregular trabeculae of woven bone, lined by active osteoblasts and occasional small, osteoclast-like giant cells (Fig. 2B). The stroma is loose, well-vascularized, and contains active fibroblasts, osteoblasts and osteoclast-like giant cells. The prognosis is excellent and recurrences are uncommon. In very rare circumstances lesions have been reported to disappear without surgical therapy.

Osteoblastoma

Osteoblastoma is a benign bone-forming lesion (>2 cm) characterized by woven bone spicules bordered by prominent osteoblasts. It is rare, accounting for about 1% of all bone tumors and is more common in males. While osteoid osteoma is most common at the long bones, osteoblastoma preferentially affects the posterior elements of the spine and sacrum. In the appendicular sites, the proximal femur, distal femur and proximal tibia are the most common site. In the spine, osteoblastomas and osteoid osteoma have similar symptoms, such as back pain, scoliosis and nerve root compression. However, in osteoblastoma the pain is usually not worse at night and is less likely to be relieved with NSAIDs.

Radiologically, osteoblastomas are lytic and well-circumscribed lesions, >2 cm (generally 3–10 cm). In those cases with secondary ABC, the lesions are generally much larger. Osteoblastoma is highly vascularized and appears red or red-brown at macroscopy with a pushing border. Histologically at high magnification, osteoblastoma is identical to osteoid osteoma, comprising interconnected trabeculae of woven bone, and distinction is made based on size (Fig. 3). The trabeculae are randomly arranged, lined by a prominent, single layer of osteoblasts. Osteoblasts may have mitosis, but they are usually not atypical. A highly vascularized stroma is present between the trabeculae. Diffusely scattered osteoclast-type, multinucleated giant cells are often observed. Epithelioid osteoblastoma (previously known as aggressive osteoblastoma) have large, plump osteoblasts with a larger nucleus containing a prominent nucleolus, accompanied by mitoses, causing confusion with osteosarcoma. Distinction can be made by careful examination of the interface between the lesion and pre-existing bone, which is not infiltrated in case of osteoblastoma. There is no evidence that epithelioid osteoblastoma has a worse prognosis than the conventional osteoblastoma.

Osteoblastoma has a higher rate of recurrence as compared to osteoid osteoma and requires surgical management. Genetically, recurrent chromosome 22 deletions affecting Wnt/Beta-Catenin signaling are found in osteoblastoma. Although these are not the hallmark of osteoblastoma, genetic analyses can be useful especially in case of a differential diagnosis between epithelioid osteoblastoma and osteosarcoma.

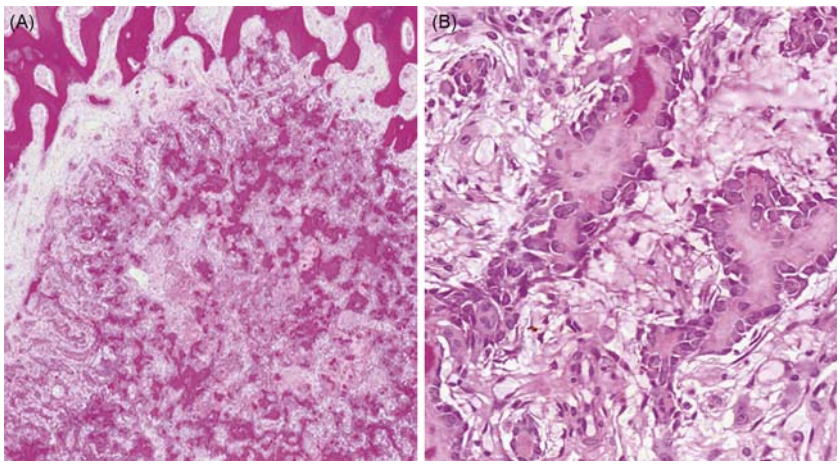

Fig. 2 Osteoid osteoma. (A) The lesion is characterized by a small nidus (<2 cm) (*right*) surrounded by reactive bone formation and fibrovascular tissue. (B) The nidus is composed of closely packed irregular trabeculae of woven bone, lined by active osteoblasts.

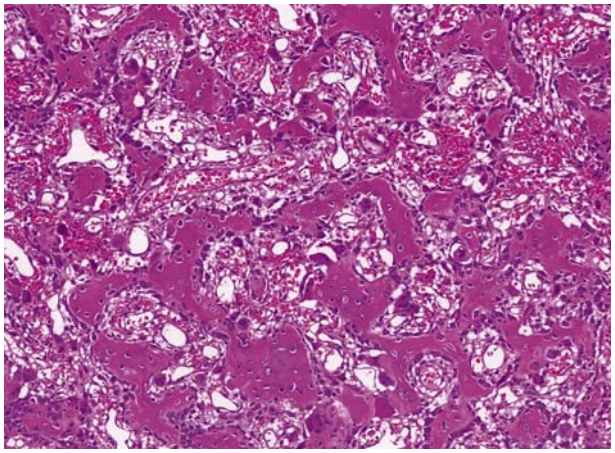

Fig. 3 Osteoblastoma. Interconnected trabeculae of woven bone lined by a prominent, single layer of osteoblasts.

Osteosarcoma

Osteosarcoma is a collective name for a group of sarcomas in which the hallmark is the production of osteoid directly by the malignant tumor cells. In addition to osteoid, the malignant cells may also produce cartilage and collagen. Osteosarcoma can be subdivided according to the site of origin (intra-osseous, surface or soft tissue), grade of malignancy, and differentiation (e.g., fibroblastic, chondroblastic etc.)

Low-Grade Central Osteosarcoma

Low-grade central osteosarcoma is defined as a low-grade malignant bone-forming neoplasm that arises within the medullary cavity of bone. It is rare and accounts for ~1%–2% of all osteosarcomas. In general, it is located in long bones, predominantly in the distal femur and proximal tibia. Radiologically, a large lytic lesion with focal aggressive features may be seen. Low-grade central osteosarcoma is histologically composed of an abundant hypocellular to moderately cellular fibrous tissue proliferation with variable amounts of osteoid production. The spindle-shaped tumor cells show little mitotic activity and slight cellular and nuclear atypia and are arranged in fascicles or interlacing bundles. Osteoclastic giant cells as well as foci of cartilage can be seen. In the majority of low-grade central osteosarcomas, some degree of cortical disruption and/or periosteal reaction and soft tissue extension is observed, which is helpful in the distinction from its mimics (e.g., fibrous dysplasia and desmoplastic fibroma). Moreover, low-grade central osteosarcoma may permeate surrounding cortical and/or cancellous bone, which is not seen in benign bone tumors.

Low-grade central osteosarcomas have a simple genetic profile with supernumerary ring chromosomes comprising amplification of chromosome 12q13–15, including the cyclin-dependent kinase 4 (CDK4) and murine double-minute type 2 (MDM2) gene region. Immunohistochemical expression of MDM2 and CDK4 is useful to differentiate low-grade osteosarcomas from benign fibrous and fibro-osseous lesions including fibrous dysplasia. Additionally, the overall lack of chromosomal aberrations and the low frequency of *TP53* mutations differentiate low-grade central osteosarcoma from the other osteosarcoma subtypes.

Low-grade central osteosarcoma has generally a good prognosis when resected with adequate margins, although progression to high grade osteosarcoma may occur (in 10%–36%).

Parosteal Osteosarcoma (Low-Grade)

Parosteal osteosarcoma is a rare, low-grade, bone-forming lesion that arises at the surface of a long bone. It accounts for ~4% of all osteosarcomas. Around 70% of parosteal osteosarcomas are found at the distal posterior femur. The tumor often presents with a long history of a localized, slow-growing, painless mass, in young adults, with a slight female predominance. The radiological presentation can be very typical with a heavily mineralized mass attached to the cortex of the femur, tibia or humerus. Parosteal osteosarcoma is histologically very similar to low-grade central osteosarcoma, being composed of a moderate cellular to cellular fibrous stroma with formation of long, thin and irregular bone trabeculae that are rather evenly spaced, parallel oriented and show ramifications (Fig. 4). The structure varies from fine lamellar to woven. The fibroblast-like cells are usually arranged in long, parallel oriented fascicles and have a rather uniform nucleus with coarse granular chromatin. Mitotic activity is low. Cartilaginous differentiation can be seen in ~50% of the tumors, either as nodules or as a cap-like arrangement (Fig. 4).

Similar to low-grade central osteosarcoma, >85% of parosteal osteosarcomas contain supernumerary ring chromosomes involving amplification of the 12q13–15 region, and immunohistochemistry or FISH detecting MDM2 or CDK4 amplification may be helpful in the diagnosis.

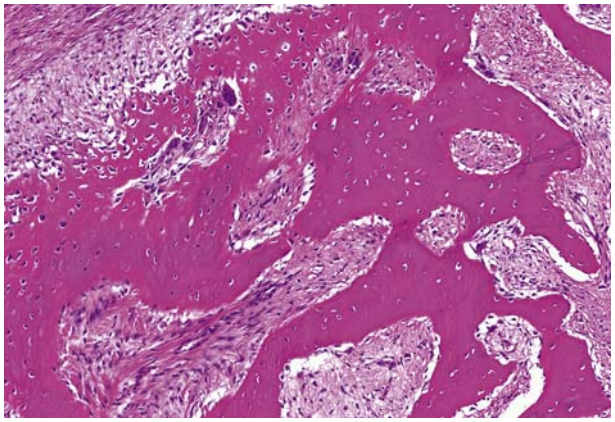

Fig. 4 Parosteal osteosarcoma. The lesion is characterized by a fibrous stroma with formation of long, thin and irregular bone trabeculae.

Progression to a high-grade sarcoma (dedifferentiation) occurs in ~15%–25% of the tumors. These areas resemble conventional osteosarcoma or high-grade spindle cell sarcoma/undifferentiated pleomorphic sarcoma. Dedifferentiation may occur at the time of diagnosis (synchronous) or at recurrence (metachronous), and worsens the prognosis.

Periosteal Osteosarcoma (Intermediate Grade)

Periosteal osteosarcoma is an intermediate grade, malignant, cartilage and bone forming neoplasm arising at the surface of bone. It accounts for < 2% of all osteosarcomas. Periosteal osteosarcoma is predominantly located in the diaphysis or diaphysis/metaphysis. It is usually seen as a sessile, anterior, medial lesion, which may almost wrap around the circumference of the bone, especially the distal femur and proximal tibia. Symptoms of pain and swelling are usually of short duration. Radiologically, the lesion is predominantly radiolucent but often contains focal areas of mineralization in the soft tissue component. There are spicules of reactive bone oriented perpendicular to the underlying bone cortex, which may be focally eroded or thickened. Invasion in the underlying medullary cavity is highly unusual. Histologically nodules of atypical cartilage predominate, occasionally with myxoid changes, separated by malignant spindle-shaped tumor cells (Fig. 5). Lace-like and woven bone is formed by the tumor cells and intermixed with cartilaginous elements and can sometimes be difficult to recognize. In addition, reactive periosteal bone formation, extending as spicules from the base of the tumor to its outer edge (periosteal surface), can be found in between lobules of tumor, but may be destroyed by tumor growth. It can be difficult to differentiate periosteal osteosarcoma from periosteal chondrosarcoma. Periosteal chondrosarcoma has a better prognosis. In periosteal chondrosarcoma, the cartilage is usually more lobular and well differentiated, while osteoid deposition by spindle cells is absent. Moreover, periosteal chondrosarcoma may contain *IDH* mutations, while for periosteal osteosarcoma no consistent genetic alterations have been reported. Reported overall 5- and 10-years survival is 89% and 83% respectively, and local recurrence is associated with an increased risk of metastases.

Conventional Osteosarcoma

Conventional osteosarcoma is a high-grade, intra-osseous, malignant neoplasm in which the neoplastic cells produce bone. It accounts for > 90% of all osteosarcomas. Conventional osteosarcomas usually arise de novo as primary bone tumors. Secondary

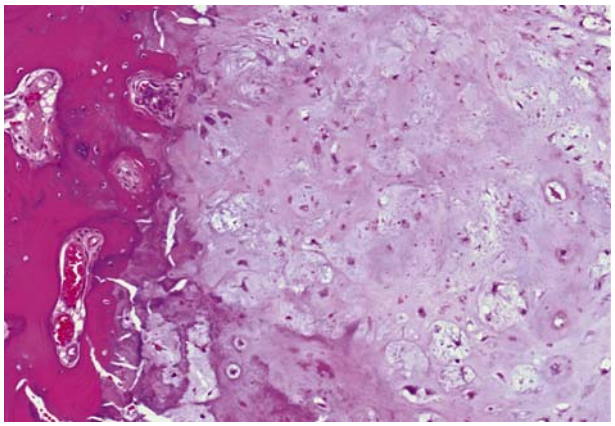

Fig. 5 Periosteal osteosarcoma. The lesion comprises of nodules of atypical cartilage, occasionally with myxoid changes, separated by malignant spindle-shaped tumor cells.

osteosarcomas are mainly associated with Paget's disease of bone or irradiation. Osteosarcoma has a bimodal age distribution, predominantly affecting adolescents and young adults (mean age is about 17 years), with a second peak in patients over 40 years of age. Its etiology is unknown and no benign precursor lesion has been identified. An increased incidence of primary osteosarcoma associated with several genetic syndromes (e.g., Li-Fraumeni, hereditary retinoblastoma, and Rothmund-Thomson). Osteosarcoma is characterized by deep pain that developed over a period of weeks to a few months. Osteosarcoma may affect any bone, but the vast majority is found in the metaphysis of long bones (**Fig. 6**A).

Radiologically, osteosarcoma presents as a lytic and/or sclerotic mass. Tumor expansion causes cortical infiltration and invasion of surrounding tissues. The neoplasm is usually located on the metaphysis and extends into the diaphysis; the epiphysis is generally spared or minimally involved. There is elevation of the periosteum with a prominent periosteal reaction. A characteristic radiological feature is the Codman's triangle that is produced when the tumor breaks through the periosteum.

Histologically, osteosarcoma is highly heterogeneous and has many different histological subtypes (see below), all of which share the diagnostic hallmark of deposition of osteoid by malignant tumor cells with a permeative growth pattern and erosion of preexisting bone trabeculae (**Fig. 6**B and C). Osteoid is un-mineralized bone matrix that is eosinophilic, dense, homogeneous and becomes bone as result of mineralization. No minimal amount of osteoid is required to establish the diagnosis of osteosarcoma. Conventional osteosarcomas are high-grade tumors containing pleomorphic neoplastic cells with large, abnormal, hyperchromatic nuclei. Mitotic activity is high and there can be numerous atypical mitotic figures. The histological heterogeneity of conventional osteosarcoma might be associated with its multipotent cell of origin, which is most likely the mesenchymal stem cell along its path of differentiation to the osteoblastic lineage. The immunohistochemical profile of osteosarcoma is however nonspecific. The tumor cells can express osteocalcin, osteonectin, S100, actin, CD99, keratin, EMA, and desmin, which could cause diagnostic confusion. SATB2 and DMP1 have recently been described as markers for bone-forming tumors as they demonstrate osteoblastic differentiation, which may be of help in cases with limited osteoid deposition and to distinguish hyalinised stroma closely mimicking osteoid.

Osteosarcoma is a highly genomically unstable tumor with as a consequence a complex, aneuploid karyotype. Chromothripsis, involving shattering of the chromosomes caused by a single event followed by their random re-assembly is a common phenomenon. Recurrent amplifications and DNA copy number gains and losses have been reported, such as deletion and LOH of *3q13* (including the *LSAMP* gene), amplification of *6p12–21* (containing the *RUNX2* and *VEGFA* genes), amplification and gain of 8q, and deregulation of the *RB* and p*53* pathway. However, thus far no single specific molecular marker is available to diagnose osteosarcoma.

Conventional osteosarcomas are usually treated with multimodal treatment including neoadjuvant chemotherapy. The histological response to chemotherapy is one of the most important prognosticators of overall and disease-free survival. For evaluating the response it is important to examine a full cross section through the largest tumor diameter, which can be divided in parts and as such fully submitted to microscopy. A good response is defined as $>90\%$ tumor necrosis and is strongly associated with improved survival in primary conventional osteosarcoma.

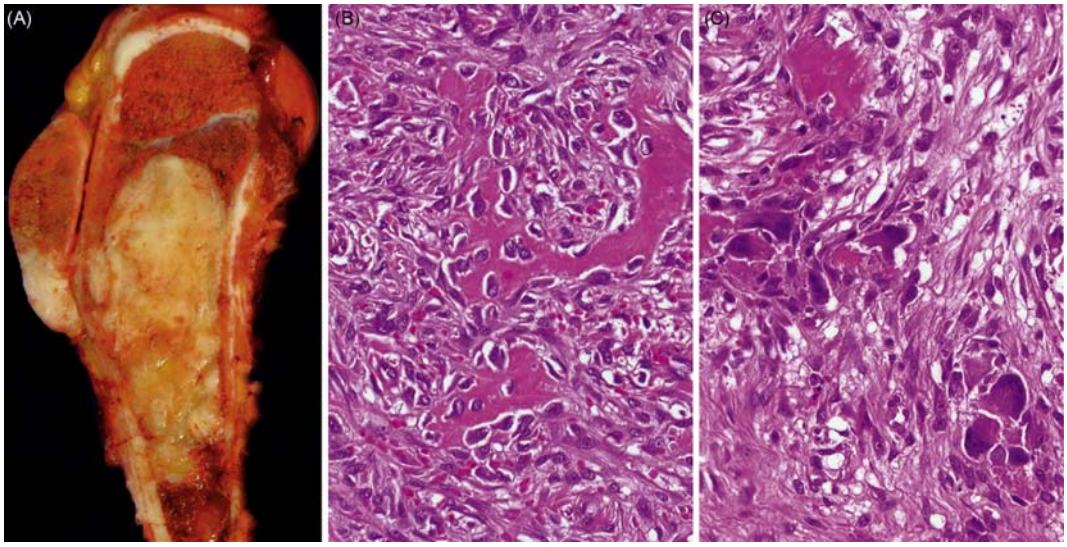

Fig. 6 High-grade conventional osteosarcoma. (A) Gross specimen of conventional osteosarcoma. Note that the epiphyseal plate acts as a relative barrier. (B) Deposition of osteoid by neoplastic tumor cells. (C) Hyperchromatic, pleomorphic tumor cells that produce osteoid.

Conventional Osteosarcoma, Histological Subtypes and Variants

O*steoblastic osteosarcoma* is the most common subtype in which neoplastic bone is the principal matrix component. The matrix varies from fine, lace-like osteoid to compact bone. The amount of matrix mineralization is variable. When the amount of compact bone is extensive, the neoplasm is subclassified as the sclerosing type. *Sclerosing osteosarcoma* is a high-grade sarcoma in which increase of tumor matrix is associated with a decrease of atypia ("normalization" of cells), giving the wrong impression of low grade malignant or even benign.

In *chondroblastic osteosarcoma* a significant amount of neoplastic cartilage is identified, which is usually hyaline and high-grade. Myxoid changes may be seen, particularly in tumors arising in jaw bones. In contrast to chondrosarcoma, the cartilage in chondroblastic osteosarcoma usually displays severe nuclear atypia. Moreover, in addition to the different clinical and radiological presentation, IDH mutation analysis can be helpful in distinguishing chondroblastic osteosarcoma from chondrosarcoma.

In *fibroblastic osteosarcoma* the neoplastic cells are purely spindle shaped, with only small foci of matrix.

Telangiectatic osteosarcoma is characterized by large spaces filled with blood, often with septations. Radiographically, the tumor is purely lytic with extensive bone destruction and soft tissue extension. Histologically, large vascular spaces separated by septa of fibrous tissue containing areas of hemorrhage and necrosis are seen. The neoplastic cells, some of which produce osteoid matrix or bone, are pleomorphic and show significant nuclear hyperchromasia and can be seen within the septa or in the lining of the cystic spaces. Osteoid can be hard to identify. Atypical mitoses are often seen. Numerous osteoclast-like giant cells are present within the tumor. Some of the blood-filled or empty cystic spaces closely resemble aneurysmal bone cyst.

Small cell osteosarcoma is composed of small cells with a variable degree of osteoid production. The small cells have round to oval nuclei and scant cytoplasm. Mitotic figures are often identified. A hemangiopericytoma-like vascular pattern may be found. Osteoid production is the key to the diagnosis and is found among sheet or nests of tumor cells. It has a lace-like pattern and should be distinguished from fibrin deposits that can be seen in Ewing sarcoma, which is the main differential diagnosis. CD99 can also be positive in small cell osteosarcoma, while FLI1 is negative which may help in the distinction. EWSR1 rearrangements are absent.

Chondrogenic Tumors

Osteochondroma

Osteochondroma is a benign cartilage capped bony projection arising on the external surface of bone containing a marrow cavity that is continuous with that of the underlying bone. The base of osteochondroma can be broad (sessile) or small (pedunculated). The lesion is entirely surrounded by perichondrium (Fig. 7A). Osteochondromas are the most common cartilage tumor, and found on the femur (21%), humerus (17%), and tibia (11%). Osteochondromas develop and increase in size during the first decade of life, and stop growing when growth plates close during puberty. The osteochondromas are often asymptomatic. They can be sporadic (solitary) or found in the setting of hereditary syndrome multiple osteochondromas (previously called hereditary multiple exostoses). Multiple osteochondromas is an autosomal dominant condition caused by mutations in *EXT1* or *EXT2*. Radiologically, the osteochondroma is typically found at the transition of the metaphysis to the diaphysis, projected away from the joint, the osteochondroma stalk is in continuity with the cortex of the underlying bone.

Histologically, three layers are seen: perichondrium, cartilage and bone. Chondrocytes are often arranged in columns, as is normally observed in the growth plate (Fig. 7B). Endochondral ossification is seen at the cartilage-bone interface. Cellularity is variable depending on the age of the patient. Binucleated cells, calcification, necrosis, nodularity and cystic changes can be seen. Malignant

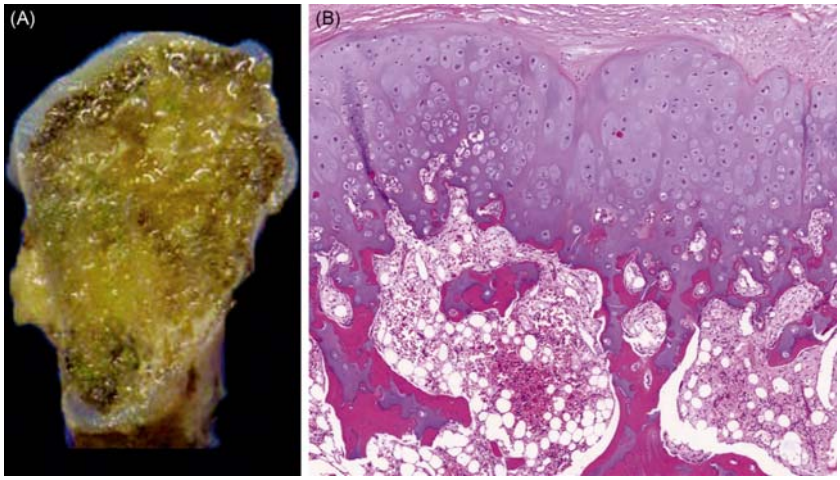

Fig. 7 Osteochondroma. (A) Gross specimen of osteochondroma. The tumor is formed by a stalk of medullary bone covered by a smooth, pale, blue-gray cartilage cap that has a thickness of <1 cm. (B) Three layers are seen: perichondrium, cartilage, and bone.

transformation to secondary peripheral chondrosarcoma occurs in 1%–5%. There are no accepted histological criteria to distinguish osteochondroma from low-grade secondary peripheral chondrosarcoma; the radiological and gross macroscopic documentation of the thickness of the cartilaginous cap is extremely important as a cartilage cap exceeding 1.5–2 cm in adults is suggestive of malignancy.

Enchondroma

Enchondroma is a benign hyaline cartilage neoplasm of medullary bone. Most tumors are solitary, however, they occasionally involve more than one bone or site in a single bone. Enchondromas are relatively common and have a wide age range. They are found in the long bones, and 50% of all cases are located in the bones of the hands and feet (Fig. 8A). Chondrosarcomas are only rarely seen at this location. The size of the enchondroma is often <3 cm. Radiologically, matrix mineralization in the form of "popcorn" calcifications is often seen. The edge of the lesion is most often lobular and sharp.

Histologically, enchondroma are lobular, relatively cell-poor hyaline cartilage, often surrounded by a zone of reactive bone formation (encasement). The chondrocytes have nuclei with condensed chromatin (Fig. 8B). Binucleated cells are infrequent and mitoses are absent. Occasionally degenerative features, such as necrosis or calcifications are found. The distinction between an enchondroma and atypical cartilaginous tumor/chondrosarcoma grade 1 can be difficult at radiology. Moreover, also on histology they are difficult to distinguish causing a large degree of interobserver variation. Mucomyxoid matrix degeneration and entrapment of preexisting host bone are most predictive of atypical cartilaginous tumor/chondrosarcoma grade I. Immunohistochemistry or molecular diagnostics cannot help in the differential diagnosis. Malignant transformation of enchondromas is rare ($<1\%$).

Multiple enchondromas are seen in the setting of non-hereditary Ollier disease (multiple enchondromas with a unilateral predominance) and Maffucci syndrome (multiple enchondromas combined with (spindle cell) hemangiomas), caused by somatic mosaic mutations in the *IDH1* or *IDH2* genes. In these conditions the risk on malignant transformation is increased to 18%–46%, depending on the extent and localisation of the lesions.

Periosteal Chondroma

Periosteal chondroma is a rare benign, small (<5 cm) hyaline cartilage neoplasm of bone surface that arises from the periosteum. Periosteal chondroma is often located at the fingers or proximal humerus.

Histologically, they display a mixture of low- and highly cellular areas. Myxoid changes of the matrix and nuclear pleomorphism can be seen. Some of these features would lead to a diagnosis of chondrosarcoma if it were located outside the periosteal area. The distinction between a periosteal chondroma and a periosteal chondrosarcoma is mainly based on the presence of cortical destruction in case of a periosteal chondrosarcoma. Furthermore, periosteal chondrosarcomas are usually >5 cm in size[4]. $\sim$70% of periosteal chondromas harbor mutations in *IDH1*.

Synovial Chondromatosis

Synovial chondromatosis is a rare benign neoplasm presenting as multiple hyaline cartilage nodules in the subsynovial tissue. The lesion is monoarticular, with the knee most often affected. There is a male predominance, with an average age of 41 years. At radiography, the presence of opaque bodies and/or stippled calcification is found. At macroscopy multiple gray-white nodules are seen. Histologically, nodules are seen surrounded by a thin layer of synovial tissue. Characteristically, the nodules are formed by chondrocytes that cluster together in nests. The cartilage is hypercellular with plump hyperchromatic nuclei, with numerous binucleate cells. Inflammation and ossification can be found.

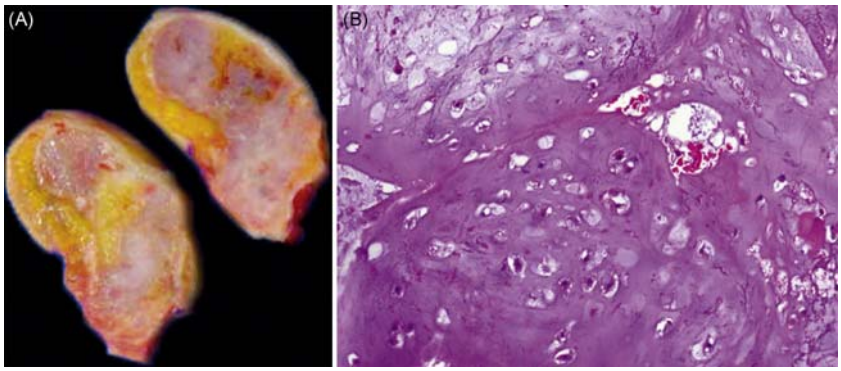

Fig. 8 Enchondroma. (A) Gross specimen of enchondroma. (B) The lesion consists of lobular, relatively cell-poor hyaline cartilage.

Chondromyxoid Fibroma

Chondromyxoid fibroma is a very rare benign cartilaginous neoplasm composed of lobules of spindle shaped or stellate cells with abundant myxoid or chondroid intercellular material. The lesions can affect any bone. Patients are adolescents or young adults.

Radiologically, the lesion is eccentric, oval, and radiolucent in the metaphysis. Histologically, the periphery of the lobules is more cellular, with spindle shaped or round cells, mixed with multinucleated giant cells. The centre of the lobules has more stellate cells found in a mucomyxoid matrix. Nuclear enlargement and hyperchromasia can be found. Mitoses are unusual but can be seen. The cells in chondromyxoid fibroma express S100, and the cells at the periphery of the lobules are myofibroblastic expressing MSA and SMA.

Genetically, chondromyxoid fibroma is characterized by upregulation of GRM1 through gene fusion and promoter swapping. This upregulation is due to genomic rearrangements that place GRM1 under the influence of a strong promoter.

Chondroblastoma

Chondroblastoma is a rare benign, chondroid-producing neoplasm composed of chondroblast-like cells usually arising in the epiphyses of skeletally immature patients.

At radiography chondroblastoma is an eccentric radiolucent lesion, with sharp sclerotic margin and areas of calcification, characteristically located in the epiphysis of the long bones. Histologically the tumor is highly cellular with relatively uniform, immature, rounded or polygonal chondroblast-like cells with a sharp cell demarcation, intermingled with multi-nuclear osteoclast-like giant cells (Fig. 9A). There is variable deposition of extracellular matrix, both cartilaginous and osteoid, and small areas of cartilage matrix with focal net-shaped ("chicken-wire") calcification. Occasionally, (non-atypical) mitoses are found. In about 15% of all cases the formation of a secondary aneurysmal bone cyst is observed. The cells express S100, and may express keratins.

Genetically, chondroblastoma is characterized by heterozygous mutation replacing lysine-36 with methionine-36 (K36M) in the histone H3 variant H3.3. A H3F3 K36M mutant monoclonal antibody (clone RM193) can be used to identify tumors that harbor this mutation (Fig. 9B).

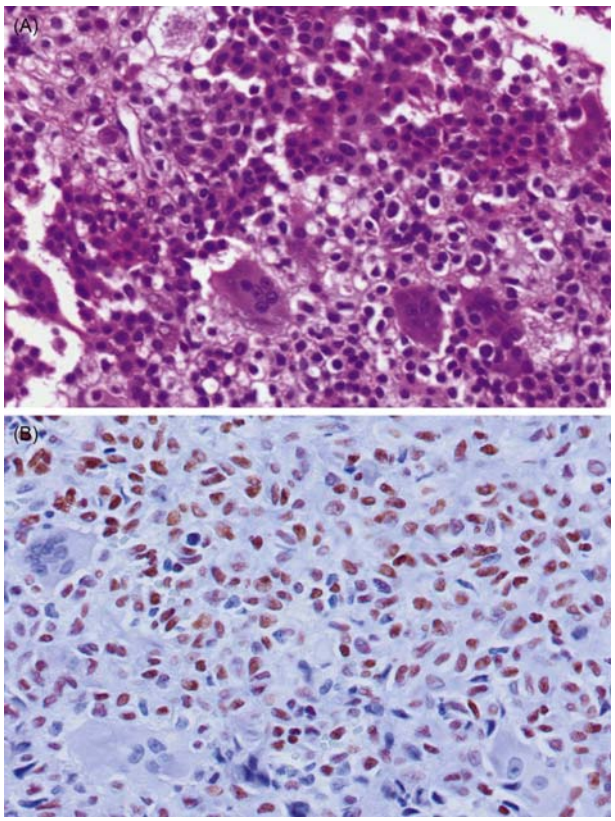

Fig. 9 Chondroblastoma. (A) Immature, chondroblast-like cells with sharp cell borders embedded in a chondroid-like matrix and admixed with multinucleated osteoclastlike giant cells. (B) A H3F3 K36M mutant monoclonal antibody (clone RM193) can be used to identify tumors that harbor this mutation.

Conventional Chondrosarcoma

Chondrosarcoma is a locally aggressive to malignant cartilaginous matrix producing neoplasm. Chondrosarcoma is mainly seen in adults in the third till sixth decade of life, with equal distribution among genders. They usually arise in the thoracic bones, pelvic and long bones. Surgery is the mainstay of treatment as chondrosarcomas are highly resistant to chemo- and radiotherapy.

Primary central chondrosarcoma arises centrally in previously normal bone as opposed to secondary chondrosarcoma arising in a pre-existing benign cartilaginous tumor. Primary central chondrosarcomas comprise about 75% of all chondrosarcomas and the majority is well differentiated.

Mutations in the isocitrate dehydrogenase genes *IDH1* and *IDH2* are found in 38%–70% of the primary central chondrosarcomas. Hotspot mutations are exclusively found at the *IDH1* R132 and the *IDH2* R172 position, of which the R132C mutation is most common in chondrosarcoma. Mutation analysis can be useful in the distinction between high-grade chondrosarcoma and chondroblastic osteosarcoma.

Secondary central chondrosarcoma is a chondrosarcoma arising in a preexisting enchondroma. The risk of malignant transformation in solitary enchondroma is estimated to be very low ($<1\%$). In patients with Ollier disease and Maffucci syndrome, the risk of developing secondary chondrosarcomas increases (18%–46%). IDH mutations are found in 86% of secondary central chondrosarcomas.

Secondary peripheral chondrosarcoma arises in a preexisting osteochondroma. A minority (up to 15% in referral centres) of chondrosarcomas develop through malignant transformation within the cartilage cap of a preexisting osteochondroma. Secondary peripheral chondrosarcoma is mainly found in the ilium (19%), followed by scapula (15%), tibia (12%), femur (11%), pubic bone (10%), and ribs (10%). The radiological and gross macroscopic documentation of the thickness of the cartilaginous cap is extremely important in the distinction of osteochondroma and secondary peripheral chondrosarcoma, as a cartilage cap exceeding 1.5–2 cm in adults is suggestive of malignancy.

While for osteochondroma formation inactivation of the *EXT1* or *EXT2* genes is required, most secondary peripheral chondrosarcomas arising in osteochondroma are *EXT* wildtype indicating that *EXT* is not important for malignant transformation and that the non-*EXT* mutated cells in osteochondroma are more vulnerable for as yet unknown (epi-)genetic changes promoting them to become malignant.

Histological Grading of Conventional Chondrosarcoma

Both conventional central and peripheral chondrosarcomas are histologically classified in three grades. Histological grade is so far the best predictor of clinical behaviour. What was previously called central chondrosarcoma grade 1 has now been renamed as atypical cartilaginous tumor, and the histology shows an abundance of predominantly hyaline cartilaginous matrix in which chondrocytes with small, condensed nuclei are seen (**Fig. 10**A). Atypical cartilaginous tumor/chondrosarcoma grade I (ACT/CS1) is distinguished from enchondroma by its higher cellularity, irregular distribution of the cells, and the occurrence of binucleated cells (**Fig. 10**B). An important criterion is the growth pattern, in which the presence of entrapment (of pre-existing lamellar bone) and the absence of encasement favor ACT/CS1 over enchondroma. Also the presence of $>20\%$ mucomyxoid changes of the matrix is an important argument for the diagnosis of ACT/CS1. For the distinction between osteochondroma and secondary peripheral chondrosarcoma no reliable histological criteria could be identified, indicating the diagnosis can only be made in a multidisciplinary team taking the thickness of the cartilaginous cap into account. In grade II chondrosarcomas the cellularity and nuclear atypia are increased, and mitoses, though scarce, can be seen (**Fig. 11**). The matrix becomes more mucomyxoid. In grade III chondrosarcomas the cellularity is high, with nuclear atypia, and mitoses are even more easily identified. At the periphery of the lobules spindle

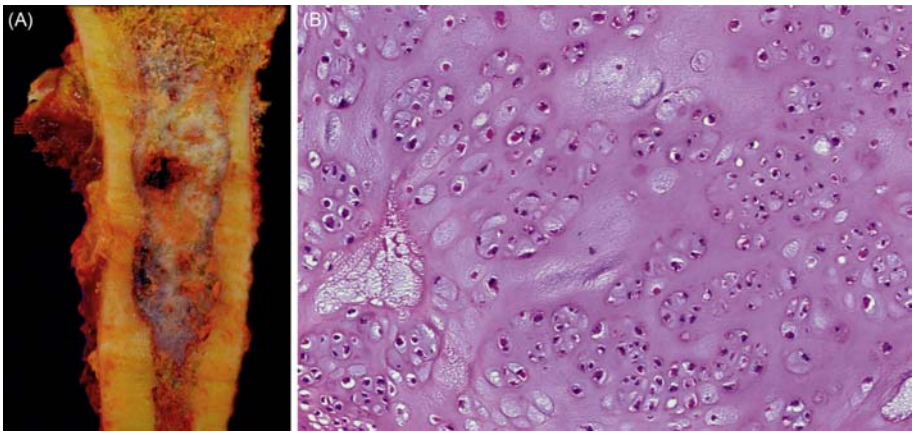

Fig. 10 Atypical cartilaginous tumor (ACT)/chondrosarcoma grade I (CS1). (A) Gross specimen, erosion of the cortex can be seen. (B) ACT/CS1 can be distinguished from enchondroma by its higher cellularity, irregular distribution of the cells, and the occurrence of binucleated cells.

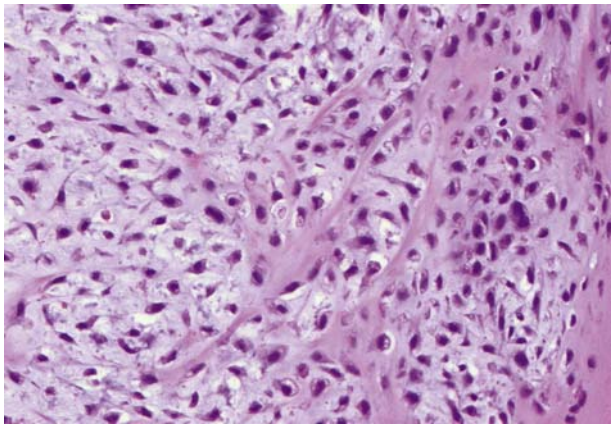

Fig. 11 Grade II chondrosarcoma. The cellularity is increased and myxoid change of the matrix can be seen.

cell changes may occur. The 10-year survival of grade I, II and III tumors is 83%, 64%, and 23% respectively. ACT/CS1 has a relatively high chance of recurrence in case of incomplete resection, but only rarely metastasize, whereas 10% of the grade II tumors and 71% of the grade III tumors metastasize. However, in approximately 13% of the recurring chondrosarcomas progression to a higher grade of malignancy as compared to the original neoplasm is described. Since considerable heterogeneity may occur in chondrosarcoma it is of importance to select several areas to be submitted for histology. The tumor needs to be graded on those areas demonstrating the highest grade.

Dedifferentiated Chondrosarcoma

Dedifferentiated chondrosarcoma is a highly malignant variant of chondrosarcoma, characterized by the occurrence of two clearly defined components; a well differentiated cartilage tumor, either an enchondroma, ACT/CS1 or grade II chondrosarcoma, juxtaposed to a high grade non-cartilaginous sarcoma. There is a histologically abrupt transition between the two components. Patients are often older than 50 years. The lesion is most often located in the pelvic bones, proximal femur or humerus, distal femur or the ribs. The prognosis is unfavorable, irrespective of the treatment. The metastases often only show the high-grade anaplastic component. The sharp transition between the two components is an important criterion in the distinction between grade III chondrosarcoma (in which the cells at the edge of the lobules show a gradual transition toward more cellular spindle shaped cells) and dedifferentiated chondrosarcoma (Fig. 12). The non-cartilaginous, anaplastic component can show characteristics of undifferentiated pleomorphic sarcoma, osteosarcoma, fibrosarcoma, leiomyosarcoma, rhabdomyosarcoma, or angiosarcoma. The demonstration of the presence of a low grade cartilaginous component is crucial for the distinction; however, on biopsy specimens one of the components can be absent. Radiological correlation is therefore crucial in the diagnosis. The rare reports on gene aberrations in dedifferentiated chondrosarcoma demonstrate that both components share identical gene aberrations with additional gene changes in the anaplastic component indicating a common precursor cell with early diversion of the two components. ~50% of dedifferentiated chondrosarcomas carry mutations in *IDH1* or *IDH2* in both components. The demonstration of an *IDH* mutation may

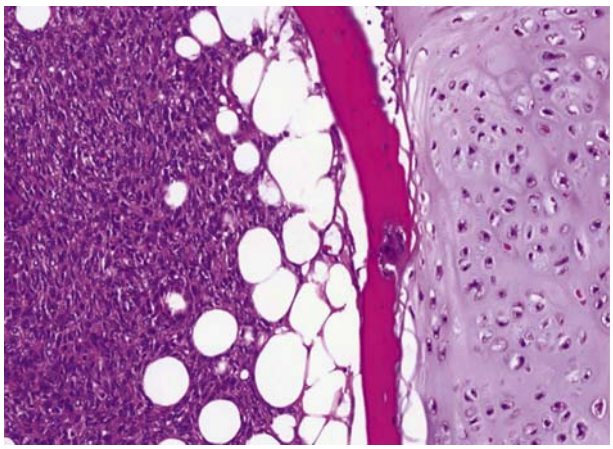

Fig. 12 Dedifferentiated chondrosarcoma. Abrupt transition between the conventional low-grade cartilaginous component (*right*) and the high-grade spindle cell sarcoma (*left*).

confirm the diagnosis of dedifferentiated chondrosarcoma in case the biopsy specimen shows the anaplastic component only, while the radiology suggests the presence of a low grade cartilaginous component as well.

Mesenchymal Chondrosarcoma

Mesenchymal chondrosarcoma is a rare malignant neoplasm characterized by a bimorphic pattern that is composed of poorly differentiated small round cells and islands of well differentiated hyaline cartilage. Mesenchymal chondrosarcoma comprises about 2% of all chondrosarcomas. The tumor can be found at all ages, with a peak in the second and third decade of life, without male or female preference. The majority (65%–86%) of mesenchymal chondrosarcomas is located in the skeleton, especially in the lower extremities such as the femur, facial bones and the pelvis. A minority (14%–34%) is primarily of extra-osseal origin, in which the meninges and the leg/thigh are mostly affected. Mesenchymal chondrosarcomas are in general of high grade malignancy, with a 10-year survival of $<30\%$. In contrast to conventional chondrosarcoma, metastases to lymph nodes and other bones are common. Radiologically, a lytical and destructive lesion is seen, with spot-like calcifications, resembling a conventional chondrosarcoma. Histologically, mesenchymal chondrosarcoma is characterized by the presence of areas with more or less differentiated cartilage mixed with vascular rich cellular areas containing undifferentiated small spindle-shaped or round cells with scant or no cytoplasm, with a haemangiopericytoma-like vascular pattern. Mitoses can be observed. The cartilaginous areas are often relatively small, sharply demarcated and cytologically benign or of low-grade. The small cell component is positive for SOX9 and variably for CD99, and can show expression of desmin. The undifferentiated small cell areas may morphologically resemble Ewing sarcoma. However, per definition, cartilage is absent in Ewing sarcoma. Furthermore, small cell osteosarcoma and dedifferentiated chondrosarcoma should also be considered in the differential diagnosis. Irregular fine trabecular deposition of osteoid, characteristic for small cell osteosarcoma, and a sharp demarcation between the two components, characteristic for dedifferentiated chondrosarcoma, are absent in mesenchymal chondrosarcoma. A recurrent HEY1-NCOA2 fusion has been identified in mesenchymal chondrosarcoma. When histologically the cellular undifferentiated component predominates, the lesions can be sensitive to chemotherapy and radiation.

Clear Cell Chondrosarcoma

Clear cell chondrosarcoma is a rare, low grade variant of chondrosarcoma, which predilects the epiphyseal ends of long bones. It is characterized histologically by bland clear cells, resembling the hypertrophic cells in the growth plate, in addition to hyaline cartilage. The tumor comprises about 2% of all chondrosarcomas and is often found in adults, with a slight preference for males, and a peak in the third and fourth decade of life. Similar to chondroblastoma, the proximal parts of the femur, humerus or tibia are most often affected. Radiologically the lesion is located in the epiphysis of the femur and humerus, can be lytic, demonstrates slight expansile growth, often with a sharp border. Macroscopically the tumor distinguishes itself by the absence of the typical glassy white-gray aspect of a conventional chondrosarcoma but is more red and granular, occasionally with cavities. Histologically round cells are seen with large round nuclei with centrally located nucleoli, and clear empty cytoplasm with sharp cell borders, which are positive for S100. Throughout the lesion metaplastic woven bone is regularly deposited, and osteoclast-like giant cells are present. Mitoses are rare. Focally, a hyaline cartilaginous matrix or even areas of more conventional chondrosarcoma can be observed. Areas of cystic degeneration resembling aneurysmal bone cyst are often seen. Based on the epiphyseal location chondroblastoma is often raised in the differential diagnosis, although clear cells are rare or absent in chondroblastoma. Metastasis of (renal) clear cell adenocarcinoma should be considered in the differential diagnosis, in which case immunohistochemistry for keratin and PAX8 may be helpful. *IDH* mutations are absent. Clear cell chondrosarcomas often recur after curettage or marginal excision, while metastases are rare.

Giant Cell Tumor of Bone

Giant cell tumor of bone is a locally aggressive bone tumor. The tumor is localized epi-metaphyseal ("end of the bone"), mainly in the long bones, especially around the knee (in $>50\%$), followed by the axial skeleton, especially the sacrum. It typically presents as an eccentric lytic lesion with a well-defined margin extending near the articular surface in patients >25 years. The gross appearance of a giant cell tumor is usually quite characteristic; the lesion is soft and dark brown, sometimes intermingled with areas that are yellow (corresponding to xanthomatous areas) or white (corresponding to fibrous areas). Hemorrhage and blood-filled cystic spaces can be seen. Histologically, giant cell tumor of bone contains an admixture of reactive round mononuclear histiocytic cells, pre-osteoclasts, numerous osteoclast-like giant cells and neoplastic spindle-shaped mononuclear stromal cells (**Fig. 13**A). Osteoclast-like giant cells have eosinophilic cytoplasm and vesicular nuclei (up to 20–50) with prominent nucleoli, and are often larger than normal osteoclasts. Mitotic activity is often seen (up to 20 per 10 high power fields). The stroma is often well vascularized with broad bands of cellular or collagenous fibrous tissue. Areas with regressive changes (e.g., hemorrhage, haemosiderin deposition, necrosis, and foamy macrophages) can be found. Areas of reactive bone formation are common especially after pathologic fracture or open biopsy. Secondary aneurysmal bone cysts (ABC) are present in 10%–14% of giant cell tumor of bone.

Metastasis of giant cell tumor to the lungs is rare. Primary malignant giant cell tumor of bone is seen at initial diagnosis as an area of high grade sarcoma containing highly pleomorphic mononuclear cells within an otherwise conventional giant cell tumor of bone. In secondary malignancy in giant cell tumor, a high-grade sarcoma arises subsequent to previous radiation or surgical therapy,

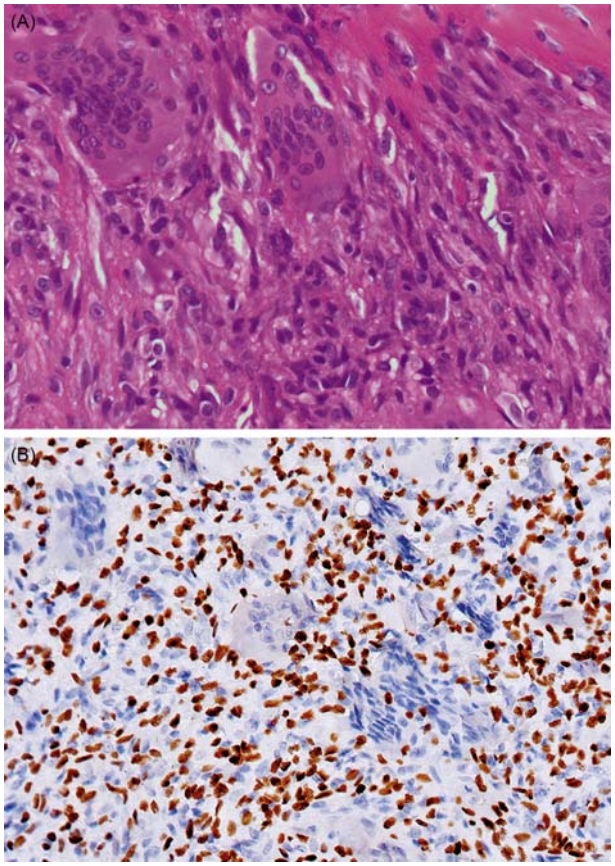

Fig. 13 Giant cell tumor. (A) The lesion is composed of a mixture of mononuclear round or spindle-shaped cells and giant cells with a large number of nuclei. (B) An anti-histone H3.3 G34 W monoclonal antibody (clone RM263) can be used to identify tumors that harbor this mutation.

and the preexisting giant cell tumor of bone is not always seen anymore. Atypical mitotic figures are suggestive of malignancy. To date, grading of histopathological features of giant cell tumor is not predictive for clinical behaviour including risk for recurrent or metastatic disease. Intra-lesioned curettage, with or without local adjuvant is the treatment of choice.

The giant cells originate from the blood and are reactive. The mononuclear cells are the proliferating and neoplastic cells, which strongly express receptor activator of nuclear factor kappa-B ligand (RANKL) thereby mediating osteoclast formation, differentiation and survival. This interplay can be blocked using denosumab (monoclonal antibody against RANK ligand) to which the tumors respond well. Denosumab treated tumors can be devoid of giant cells and mononuclear cells and composed of abundant woven bone and fibrous tissue.

Genetically, giant cell tumor of bone is characterized by a histone *H3F3A* (H3.3) gene mutation involving a substitution in glycine 34 in 96% of the cases, the vast majority of which are represented by p.Gly34Trp (p.G34W), although small numbers of G34L, V, and M variants have also been detected. An anti-histone H3.3 G34W monoclonal antibody (clone RM263) can be used to identify tumors that harbor this mutation (Fig. 13B).

Osteofibrous Dysplasia and Adamantinoma

Osteofibrous dysplasia is considered a benign fibro-osseous intra-cortical lesion of long bone, while adamantinoma is defined as a malignant biphasic tumor characterized by epithelial cells, embedded in a relatively bland osteofibrous proliferation.

Osteofibrous dysplasia is reported several times to be able to progress into adamantinoma of bone, suggesting that these lesions are part of a single spectrum. The lesions characteristically affect the cortex of the anterior midshaft of the tibia. Osteofibrous dysplasia occurs during infancy and childhood. Osteofibrous dysplasia-like adamantinoma affects children and adolescents with a relatively benign behaviour. Classic adamantinomas predominate in adults and have a more aggressive clinical course. Lesions can occur multifocal, bilateral and the fibula may also be involved.

Osteofibrous dysplasia is a well-defined lesion lying within an expanding cortex, sometimes with perilesional sclerosis. Histologically, woven bone is being formed by well-defined osteoblasts in a fibrous background. Osteoclasts and mature lamellar bone can be seen. The fibrous cells are bland and produce a myxoid or collagenous matrix. Single keratin positive cells can be seen. The

differential diagnosis includes fibrous dysplasia. In fibrous dysplasia, keratin positive cells are absent. In osteofibrous dysplasia, *GNAS* mutations are absent.

Osteofibrous dysplasia-like adamantinoma is very difficult to distinguish from osteofibrous dysplasia. In osteofibrous dysplasia keratin positive cells are sparse, and in osteofibrous dysplasia-like adamantinoma keratin positive cells are slightly more abundant and sometimes cluster together.

Classic adamantinoma demonstrates an easily distinguishable epithelial component, which can present in various patterns (basaloid, tubular, spindle cell, and squamous). The epithelial cells express keratin 5, 14, and 19, while keratins 1, 13, and 17 are variable. In addition, vimentin, EMA, p63, and podoplanin are also expressed in the epithelial component. The osteofibrous component is similar to osteofibrous dysplasia, with a storiform architecture and woven bone trabeculae prominently rimmed by osteoblasts. The epithelial component can undergo sarcomatoid transformation.

Undifferentiated High-Grade Pleomorphic Sarcoma of Bone

Previously designated as "malignant fibrous histiocytoma of bone", undifferentiated high grade pleomorphic sarcoma (UPS) of bone represents a rare, high grade malignant neoplasm characterized by pleomorphic tumor cells without obvious differentiation. The tumor predominantly affects adults, and males are more often affected than females. Histologically, either spindle cells or epithelioid cells can be seen. Pleomorphism is usually obvious and mitoses, including atypical mitoses, are often numerous. (Atypical) multinucleated giant cells and an inflammatory infiltrate can be found. UPS is a diagnosis of exclusion. Extensive sampling is required to exclude osteosarcoma. Immunohistochemistry should be used to exclude leiomyosarcoma of bone, metastatic carcinoma or melanoma. The tumors can focally express actin and keratin. Moreover, in case of a needle biopsy correlation with imaging is required to rule out dedifferentiated chondrosarcoma, in which case mutation analysis for *IDH1/2* might be helpful.

Chordoma

Chordoma is a rare malignant locally destructive tumor with characteristic morphology and immunohistochemical profile (cytokeratin 19 and T [brachyury] expression) (Fig. 14A and B). The expression of brachyury is exclusive to chordoma. Chordoma is typically located at the clivus, vertebral or sacral bones. It affects individuals of all ages and rarely occurs in the black African population. The brachyury gene (*T* gene, located on chromosome 6q27) is implicated in its pathogenesis.

Histologically, chordoma is composed of an abundant extracellular myxoid matrix among which are found columns, cords, and clusters of large round or polyhedral tumor cells with prominent vesicular nuclei and multivacuolated cytoplasm (physaliphorous cells) (Fig. 14A). Mitotic activity is rare or absent. The tumor cells may contain a single large vacuole, which gives a signet ring appearance, or are arranged as densely packed epithelioid cells, which may be mistaken for renal cell carcinoma. Tumor cells are often separated by fibrous septa. Foci of cartilage, fat, bone, and calcification may be seen within the tumor. Necrosis is frequently seen and may be extensive.

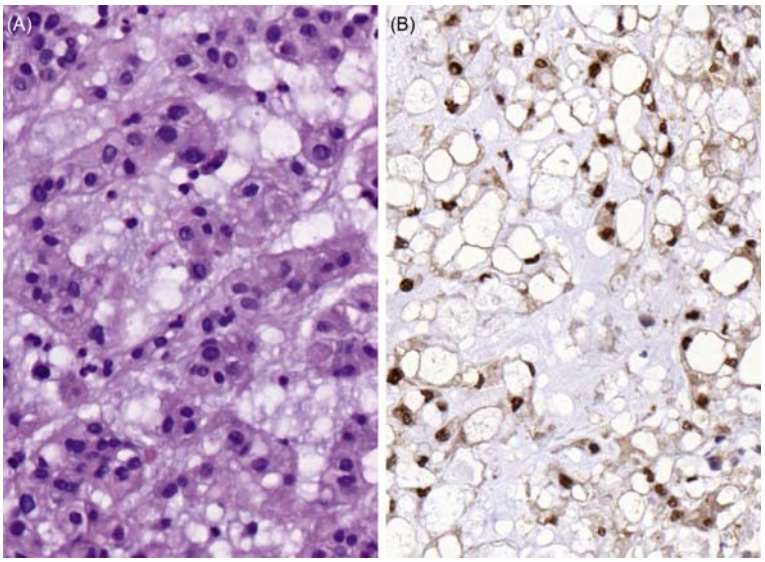

Fig. 14 Chordoma. (A) Vacuolated cells arranged in cords and nests in a mucomyxoid background. (B) Diffuse strong nuclear staining for brachyury.

Ewing Sarcoma

Ewing sarcoma is a small round blue cell tumor characterized by the pathognomonic *EWSR1* gene fusion to a member of the ETS family of transcription factors, creating a novel fusion oncogene crucial to its pathogenesis. Ewing sarcoma is the second most frequent bone sarcoma in children and young adults, about 80% of patients are younger than 20 years of age. It predominantly affects the diaphysis or the metaphyseal–diaphyseal portion of long bones but can also affect other bones or occur in soft tissue (10%–20%). Radiographically, Ewing sarcoma is an ill-defined, most often osteolytic lesion. Permeative bone destruction, periosteal reaction, and soft tissue extension are often seen. Histologically, undifferentiated uniform small round cells with round nuclei and fine chromatin are seen (**Fig. 15**A). Although not specific, immunohistochemistry typically shows diffuse membranous CD99 staining in Ewing sarcoma (**Fig. 15**B). Approximately 85% of Ewing sarcomas harbor the t(11;22)(q24;q12) translocation, fusing *EWSR1* to *FLI1*.

Recently a number of new rare translocations involving ETS family members have been described. Also, small blue round cell tumors harboring non-ETS translocations have been identified. The condensing opinion in literature is that the non-ETS translocation round cell tumors might best be considered a separate group of tumors as the clinical behaviour including reaction to chemotherapy may differ from that seen in classic Ewing sarcoma.

Tumors of Undefined Neoplastic Nature

Aneurysmal Bone Cyst

Aneurysmal bone cyst (ABC) is a cystic lesion of bone composed of blood filled spaces separated by connective tissue septations containing fibroblasts, osteoclast-type giant cells and reactive woven bone. It is considered to be of the intermediate category, locally aggressive based on its destructive and expansile growth pattern. ABC can occur at any age, although primary ABC usually affects the meta-epiphyseal region in long bones of patients in the first two decades. ABC-like areas can also be found in other benign and malignant bone tumors undergoing haemorrhagic cystic changes such as osteoblastoma or chondroblastoma (secondary ABC). Macroscopically, ABC is well circumscribed with blood filled cystic spaces separated by white septa. Solid areas can be seen. Histologically, the fibrous septa contain fibroblasts, with scattered osteoclastic giant cells and reactive woven bone, lined by osteoblasts (**Fig. 16**). The bone can be basophilic ("blue bone"). Mitoses can be found, although atypical mitoses are absent.

A recurrent translocation t(16;17) is found in primary ABC, relocating the promotor of *CDH11*, a gene that is strongly expressed in bone, in front of the *USP6*-gene (*TRE2*, *TRE17*). Later on, different translocations have been described, all resulting in oncogenic activation of the USP6 gene on chromosome 17p13. Thus, the pathogenesis of most primary ABCs involves upregulation of USP6 transcription driven by other, highly active promoters. The USP6 gene product inhibits the differentiation of pre-osteoblasts.

USP6 rearrangements were shown to be restricted to the spindle cells, and were absent in the multinucleated giant cells, inflammatory cells, endothelial cells and osteoblasts.

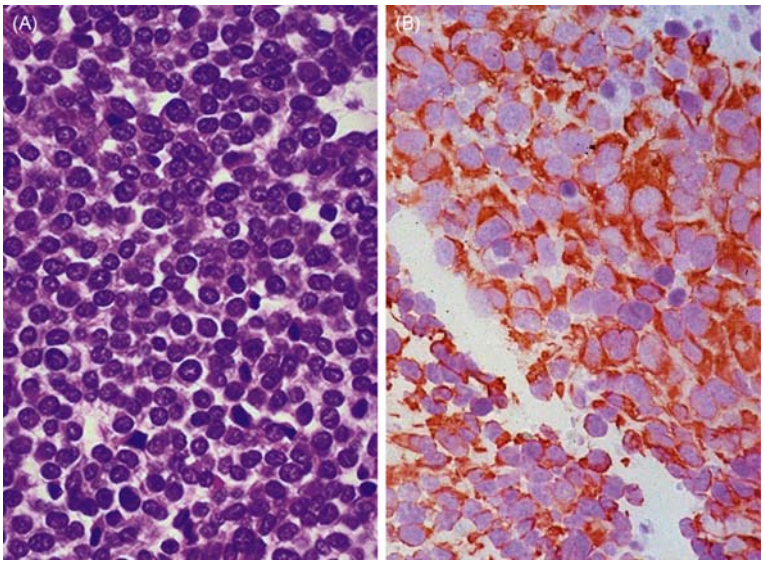

Fig. 15 Ewing sarcoma. (A) Undifferentiated uniform small round blue cells with round nuclei with fine chromatin. (B) Diffuse membrane staining for CD99.

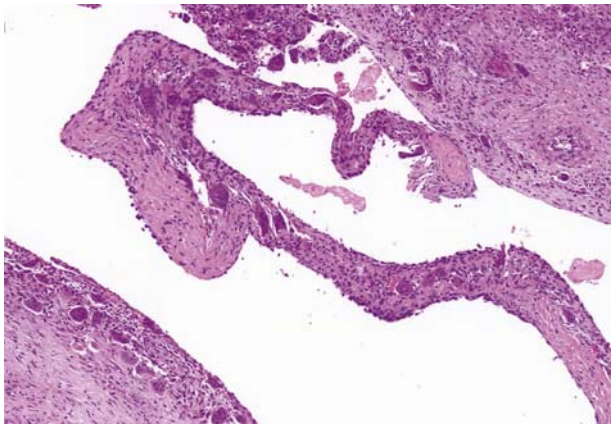

Fig. 16 Aneurysmal bone cyst. Blood-filled spaces separated by connective tissue septa with fibroblasts, osteoid, and osteoclast-type giant cells. A discontinuous layer of flattened cells lines the spaces.

Simple Bone Cyst

Simple bone cyst (unicameral bone cyst) is a benign, intramedullary, usually unicameral, cystic bone cavity lined by a fibrous membrane and filled with serous or serosanguinous fluid. The lesion mainly affects males in the first two decades of life. It can be found in any bone, specifically at the metaphyseal area of the proximal humerus and proximal femur. Lesions are typically asymptomatic. Radiology shows a lucent lesion adjacent to the growth plate. Histologically, the inner lining of the cyst consists of connective tissue, reactive new bone, hemosiderin, and scattered giant cells. Fibrinous deposits can be seen. Distinction from aneurysmal bone cyst can sometimes be difficult, especially in case of fracture. Recurrence is reported in 10%–20% of the cases.

Fibrous Dysplasia

Fibrous dysplasia is a benign fibro-osseous lesion in the medulla of bone, involving one or more bones. Fibrous dysplasia has no age and sex predilection. Craniofacial bones and the femur are most often involved, although any bone can be affected. The monostotic form is six times more common than poly-ostotic fibrous dysplasia. The latter can be associated with endocrine abnormalities and café-au-lait pigmentation in non-hereditary McCune Albright Syndrome. Fibrous dysplasia can also co-occur with intramuscular myxoma in Mazabraud syndrome. The lesion is most often asymptomatic. Radiologically, fibrous dysplasia is seen as a typical nonaggressive lesion with ground glass appearance. Histologically, fibrous dysplasia shows the typical proliferation of bland fibroblasts, intermingled with irregular, curvilinear trabeculae of woven bone, without lining by osteoblasts. The amount of ossification is variable; in the craniofacial bones ossification is usually more prominent and rounded psammomatous or cementum-like bodies can be seen. Secondary changes can be seen, including ABC-like changes, foam cells, multinucleated giant cells, or myxoid changes. Cartilaginous metaplasia can also be found.

Fibrous dysplasia is characterized by activating mutations in the Gs alpha (*GNAS1*) gene localized on chromosome 20q12–q13.3, which can be detected in 45%–93% of the cases. Mutation hotspots include R201H (57%), R201C (38%), and Q227L (5%).

Conclusion

Tumors of the bone and joints are a diverse and rare group of neoplasms. For diagnosis a experienced eye at the microscope is needed as well as communicative skills with radiological and clinical colleagues. Molecular diagnostic tests based upon the rapidly growing number of tumor specific abnormalities are becoming increasingly important and need to be interpreted in the context of morphology, clinical presentation and radiological appearance. Immunohistochemistry—while in the past of very limited use—is gaining its place in the context of the diagnosis of this challenging group of tumors.

Glossary

Copy number alteration A type of genomic structural variation resulting in gain or loss of parts of, or whole arms of, chromosomes. The degrees of change are categorized as a gain—a moderate increase in copy number at the locus, or amplification—a high-level gain, increasing the copy number at the locus substantially. Loss of copies at a locus is described as either a single copy loss or loss of both copies, also known as homozygous deletion.

Endocrine therapy, or hormone therapy A major therapeutic modality employed in the management of certain breast and other cancers. Endocrine therapy modulates systemic hormone levels through the administration of hormones or hormone antagonists. In breast cancer, this approach is indicated tumors with detectable expression of the estrogen receptor.

Gene expression profiling A microarray-based molecular technique used to measure the transcriptome (all the detectable RNAs transcribed from the DNA). This array-based technology has been superseded by RNA sequencing technologies, but was critical to the definition of the breast cancer intrinsic subtypes.

Mutation signature A peculiar pattern of DNA changes indicative of the activity of a particular mutagen or of the inactivity of DNA repair and protection mechanisms. With the advent of whole genome sequencing, it is possible to define a pattern of alterations, the mutation signature, and extrapolate the cause of this phenomenon. The first known example is the causality between ultraviolet light and a specific pattern of pyrimidine dimers.

Prognostic signature A prognostic signature is a signature used to predict clinical outcome, or prognosis. In this instance, the signature maybe a mutation signature, or a gene expression signature, where the collective expression levels of a group of genes is characteristic of a phenotype.

Nomenclature

ACC Adenoid cystic carcinoma
ACCA Acinic cell carcinoma
DCIS Ductal carcinoma in situ
ER Estrogen receptor
FLCIS Florid lobular carcinoma in situ
GRC Glycogen rich carcinoma
GWAS Genome wide association study
HER2 Human epidermal growth factor receptor 2
IC-NST Invasive carcinoma—no special type
IDC Invasive ductal carcinoma
ILC Invasive lobular carcinoma
LCIS Lobular carcinoma in situ
LN Lymph node
LRC Lipid rich carcinoma
NEC Neuroendocrine carcinoma
PILC Pleomorphic invasive lobular carcinoma
PLCIS Pleomorphic lobular carcinoma in situ
PR Progesterone receptor
SNP Single nucleotide polymorphism
TNM Tumor staging (tumor size, number of positive lymph nodes, metastatic spread)
TC Tubular carcinoma

Invasive Carcinoma of No Special Type (IC-NST)

Synonyms—invasive ductal carcinoma (IDC); ductal; IDC not otherwise specified (NOS).

IC-NST is diagnosed on the basis of exclusion of the special types of breast cancer; features indicative of a special type may only comprise up to 50% of the lesion. There are no defining inclusion characteristics of the group.

Burden: A diagnosis of IC-NST accounts for the largest proportion of breast cancers, as it includes all cases that do not fit into the so-called "special type" categories; reports put this proportion from 40% to 75%. The 5-year survival rate following a diagnosis of IC-NST is between 70% and 90%.

Risk factors: There are many contributing factors to the risk of developing breast cancer, including genetic risk, environment, and lifestyle. First and foremost, increasing age and female gender confer risk, as does a previous history of invasive or benign disease. Genetic risk is particularly important for breast cancer, with neoplasms arising from inherited mutations in high penetrance genes like *BRCA1* and *BRCA2*. A large number of genome wide association studies (GWAS) have been performed to identify genetic loci associated with breast cancer risk, which to date numbers more than 100 different loci, including for specific subtypes of breast cancer. The different risks afforded by genetic status at various loci have recently been combined into a polygenic risk score for *BRCA1/2* mutation carriers, which could improve current risk prediction algorithms and better inform current cancer risk management. Radiation and chemical exposure are thought to contribute a small increase to breast cancer risk, while increasingly, lifestyle factors such as alcohol consumption, high adiposity and reduced physical activity levels are negatively impacting risk levels. Reproductive history shows a strong association with breast cancer risk; women with early onset menarche, who are nulliparous or have a late age of first delivery, or late onset of menopause are more frequently diagnosed with breast cancer. Protective effects are specific to hormone receptor status; early age of first full-term delivery is only protective against ER (estrogen receptor) positive breast cancer. Lactation was once considered to have a strongly protective effect on risk, however this effect is not as straightforward as initially considered, and long term, cumulative breastfeeding may be most important. Parity and lactation alter endogenous hormone profiles, and the cessation of menstruation (including to some degree during lactation) minimizes exposure of the tissues to higher estrogen levels. Indeed, classes of steroids such as androgens, estrogens and progestogens play an important role in the development of breast cancer. In addition to the effects of endogenous hormones, exogenous hormones also alter a women's risk of breast cancer. Oral contraceptives and hormone-releasing intra-uterine devices have been variably demonstrated to alter a women's risk of breast cancer. Changing formulations of oral contraceptives have likely improved the risk status, as for post-menopausal hormone replacement therapies, however additional variables such as duration of therapy also influence risk. Recent changes to formulations have yet to be assessed in a prospective fashion.

Pathology: Diagnosis of an IC-NST is on the basis of exclusion of all the "special types"; IC-NST represents a collection of all non-"special" breast cancers. To this end, there are no additional inclusion criteria, and the term IC-NST can include tumors of all types of margins (infiltrative, pushing) and architectures (cords, trabeculae, clusters, solid growth). At the cellular level, variability continues, with nuclei either uniform or pleomorphic; with or without prominent nucleoli; possibly abundant cytoplasm. Mitoses may be extensive, or infrequent.

Molecular pathology and genetics: Due to the diagnosis through exclusion, there are no defining molecular pathology features of note; indeed, IC-NST encompasses the gamut of molecular features. Gene expression profiling studies have shown that IC-NST tumor profiles can be stratified into different intrinsic subtypes, such as basal, HER2 and luminal (A and B), an approach that has been developed into a prognostic test using the nanoString panel (ProSigna®). A landmark study from the International Cancer Genome Consortium, sequenced the whole genomes of 560 breast cancers and identified 93 somatic breast cancer driver genes. Together with the pioneering work from The Cancer Genome Atlas consortium, it is clear that the most commonly altered driver genes in breast cancer include; *TP53, PIK3CA, MYC, CCND1, PTEN, and ERBB2*. These mutations serve to activate the PI3 kinase/AKT signaling pathway, and to repress the JUN/MAPK pathways; critical pathways in breast cancer development. The landscape of mutational signatures was also defined, identifying 12 base substitution signatures and 6 rearrangement signatures, highlighting the importance of DNA damage repair processes and *BRCA1* and *BRCA2* mutational signatures, among others, in breast cancer.

Microenvironment including immune response: The breast tumor microenvironment comprises extracellular matrix, soluble factors (cytokines, hormones) and a variety of cell types including fibroblasts, endothelial cells, and immune cells. IC-NST may present with the spectrum of immune infiltrates (from scanty to brisk).

Staging and grading: For staging breast tumors, the American Joint Committee on Cancer (AJCC) TNM staging system is used. As of January 2018, the AJCC 8th edition will be implemented. It is updated to include biological markers (estrogen receptor, progesterone receptor and HER2 (human epidermal growth factor receptor 2)) as well as genomic tests (see below), which together with TMN could re-stage a tumor for treatment purposes. T is a measure of the tumor size (<2 cm, between 2 and 5 cm, and >5 cm) and whether the tumor has invaded the chest wall; *N* refers to the number of lymph nodes with evidence of tumor cells present (0, 1–3, 4–9, >10 positive nodes) and the position of the node in the nodal system; and *M* is a measure of distant metastasis. The status of the lymph nodes at presentation is a critical prognostic factor, as is the presence of distant metastasis; the greater the stage, the more advanced the disease. IC-NST tumors represent the spectrum of stages at diagnosis. Routine diagnostic assessment of breast tumors requires grading, an assessment of tubule or gland formation, nuclear pleomorphism and mitotic count. The Elston and Ellis modification of the Bloom and Richardson method is standardly employed, and grade is a highly prognostic component of a typical diagnostic pathology report. A final grading score (1, 2, or 3) is calculated from the scores of the individual components, broadly corresponding to well-differentiated, moderately differentiated and poorly differentiated, respectively. As for stage, IC-NST tumors represent the spectrum of grades at diagnosis (**Table 1**).

Table 1 The grading of breast tumors

Component	*Score*
Tubule/acinar/gland formation	
Majority of tumor (>75%)	1
Moderate (10%–75%)	2
Little to none (<10%)	3
Nuclear atypia	
Small, regular, uniform nuclei	1
Moderately larger nuclei with increasing variability	2
Marked variation; large nuclei, vesicular chromatin, often prominent nucleoli	3
Mitoses (per 10 high power fields; 0.50 mm diameter)	
7 or fewer	1
8–14 mitoses	2
15 or more	3

Prognostic and predictive biomarkers: The most well-known prognostic biomarkers in breast cancer are ER (estrogen receptor), PR (progesterone receptor), and HER2 (human epidermal growth factor receptor 2). The expression of these markers is assessed by immunohistochemistry and in situ hybridization, and forms part of the gold standard of breast diagnostic pathology, and indeed the clinical parameters for management. Positive expression of these biomarkers correlates with a good prognosis for the patient. Patients classed as triple negative for all three markers, tend to have a poor prognosis. ER and HER2 also classed as predictive biomarkers, with positive expression of ER indicating the use of anti-estrogen therapies such as selective estrogen receptor modulators (e.g., tamoxifen), selective estrogen receptor degraders (e.g., fulvestrant), and aromatase inhibitors (e.g., anastrazole). Providing the tumor has a significant amplification of gene dose at the *ERBB2* (HER2) locus, Herceptin, or another HER2-targetting drug can be prescribed. Trials are underway to investigate the efficacy of either tyrosine kinase small molecular inhibitors or monoclonal antibodies targeting mutated EGFR, especially in triple negative breast cancer.

The Nottingham Prognostic Index is also widely implemented, and is an algorithm based on the assessment of tumor size, number of positive nodes and the tumor grade. The generated score correlates with 5-year survival rates. Significant gene expression profiling studies published more than 15 years ago defined breast cancer intrinsic subtypes of luminal A, luminal B, HER2-enriched and basal-like, largely on the basis of proliferation and hormone related pathways. Array-based profiling of mRNA expression determined a 50-gene panel (PAM50) to refine this stratification, but immunohistochemical surrogates are also relatively widely used, and have been adopted by the St Gallen expert consensus. The four intrinsic subtypes are prognostic, and together with tumor size and lymph node status are the main factors predicting outcome for breast cancer patients. A number of molecular diagnostic signatures are available in the clinic and are variably able to predict likely benefit of chemotherapy, or more critically, whether withholding adjuvant chemotherapy would impact patient outcome. Tests include MammaPrint®, OncotypeDx®, ProSigna®, EndoPredict® and MapQuant Dx™, and have a range of inclusion criteria dependent on pathology features such as ER status, lymph node positivity and early tumor stage.

Invasive Lobular Carcinoma

Invasive lobular carcinoma (ILC) is characterized by cells lacking cohesion, which arrange in a linear fashion (single-file) within fibrous stroma (**Fig. 1**). Over 90% of the tumor must be morphologically lobular to be classified as such. There are also a number of histological variants of ILC, including classic, alveolar, solid, pleomorphic, tubulolobular and those of mixed phenotypes.

Burden: ILC is the second most common type of breast cancer (behind IC-NST), and accounts for up to 15% of all breast cancers. Together, classic and mixed ILC tumors account for ~75% of all ILCs. The 5-year survival rate for ILC is significantly better than for a ductal carcinoma however, over the longer term (15–20 years), the prognosis for ILC patients significantly worsens, compared to IC-NST.

Risk factors: Risk factors include those as described in IC-NST above. In addition, patients diagnosed with ILC have a slightly higher mean age than those with IC-NST (57–65 years). There is a small increase in ILC risk for women who have received a previous diagnosis of lobular carcinoma in situ (LCIS). Due to the highly hormone dependent nature of ILC (most are ER positive), there is an increased risk of ILC in patients with early menarche, late menopause and late age at first birth. ILC poses an increased risk of developing contralateral breast cancer compared to IC-NST. In female carriers of *CDH1* mutations (see below), the risk of developing ILC is approximately 50%. A genome-wide association study (GLACIER) to identify risk SNPs associated with lobular breast cancers identified a number of candidate polymorphisms, including a strong association between ILC and rs11977670 (7q34), and we await functional studies to better understand the impact of such associations.

Pathology: ILC are comprised of cells classed as either type A (small, with a classic appearance), or type B (larger cells with vesicular nuclei, demonstrating mild pleomorphism). The cells lack cohesion, and cause minimal disruption to the tissue architecture. In

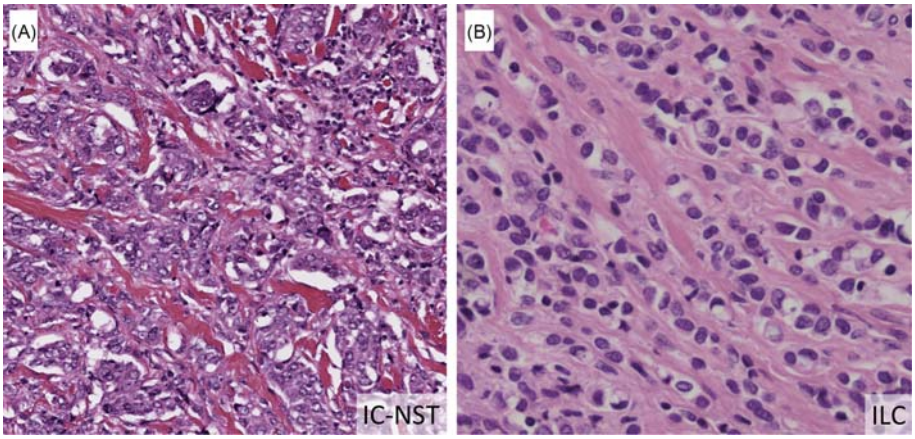

Fig. 1 The most common invasive breast cancer histologies. (A) Invasive carcinoma of no special type; grade 3. (B) Invasive lobular carcinoma; note the small, uniform cells in single files. Figure reproduced from Lal, S., McCart Reed, A.E., de Luca, X.M. and Simpson, P.T. (2017). Molecular signatures in breast cancer. Methods. **131**, 135–146. Doi: 10.1016/j.ymeth.2017.06.032, with permission from Elsevier.

classic ILC, the cells often form a targetoid or concentric pattern around ducts. Alveolar variants demonstrate cells in globular, circumscribed aggregates of more than 20 cells, while solid variants contain either irregular nests or sheets. Pleomorphic ILC (PILC) retain the typical growth pattern of classics, however there is marked cellular atypia and an increase in mitoses (and therefore a concomitant increase in grade). Tubulolobular variants have small, round tubules (*c.f.* angulated tubules of tubular carcinoma), admixed with lobular cells.

Molecular pathology and genetics: The archetypal feature of ILC is its lack of cellular cohesion, and this stems from the loss or mutation of E-cadherin, disrupting the adhesion complex. The *CDH1* gene encodes *CDH1* result in families with predisposition to both diffuse gastric cancer and ILC, and both tumor types share the typical discohesive phenotype. Other frequent genomic alterations in ILC include 1q gain, and 8p and 11q13 amplification, however ILC are considered to be diploid with relatively few genomic changes. *CDH1* is mutated in up to ~60% of ILCs, and promoter methylation is an alternative mechanism of loss. ILC are enriched for mutations in *FOXA1*, *PTEN* and *TBX3*, and activation of the AKT pathway. Mutations in the *ERBB2* gene are statistically associated with solid variants in HER2-negative ILC tumors. Indeed, mutation and amplification of *ERBB2* is frequent in ER-negative PILC tumors. Most ILC are classified as luminal tumors, and can be further stratified into "immune-related," "proliferative" and "reactive-like" on the basis of their gene expression profile.

Microenvironment including immune response: ILC tumors are often regarded as having a high stromal content, due their infiltrative pattern of growth. Lymphocytic infiltrate and composition has not been linked to prognosis in ILC, and ILC are generally associated with lower levels of lymphocytic infiltrate than other tumor types.

Staging and grading: ILC tumors are on average, larger than IC-NSTs, at 24 mm. At diagnosis, <10% of ILC have distant metastases, while ~40% have axillary lymph nodes with tumor cells present. The pattern of distant metastases differs in ILC compared to IC-NST, with cells also colonizing the gynecological and gastrointestinal tracts, in addition to the liver and bone, and less frequent presentation of lung and brain metastases. Around 75% of all ILC are histological grade 2, with grade 1 accounting for ~15%, and grade 3, 10%. Indeed, grade 3 ILC are largely non-classic, and often of the pleomorphic histotype.

Prognostic and predictive biomarkers: ER is expressed in as many as 90% of all ILC, with some of the variants showing either uniform positivity (e.g., alveolar, 100%) or much reduced (e.g., pleomorphic, ~10%). PR expression is less predictable in ILC than ER, with expression in up to 70% of tumors, a similar proportion to IC-NST. HER2 amplification is far less frequent in ILC than in IC-NST, however there is emerging evidence that the gene encoding HER2 (*ERBB2*) maybe mutated in a subset of ILC tumors. As for IC-NST, the NPI is also employed in ILC clinical management. Molecular signatures such as MammaPrint® have been shown to be of value in node-negative ILC, while the utility of other tests remains to be seen.

Tubular Carcinoma

Tubular carcinomas (TC) are defined by the presence of well-differentiated tubular structures, with a single layer of cells lining open lumen (**Fig. 2**).

Burden: TC account for approximately 2% of all invasive breast cancers.

Risk factors: The risks for developing tubular carcinoma are as detailed in IC-NST. TC are frequently detected in mammographic screening programs.

Pathology: The tumor is composed of characteristic tubules, either angulated or ovoid/round, arranged irregularly. The clear lumens are lined by a single layer of epithelium, often presenting with apical snouts, a non-pathognomonic feature. Tumor cells are typically small to moderately sized, with regular nuclei and infrequent mitoses.

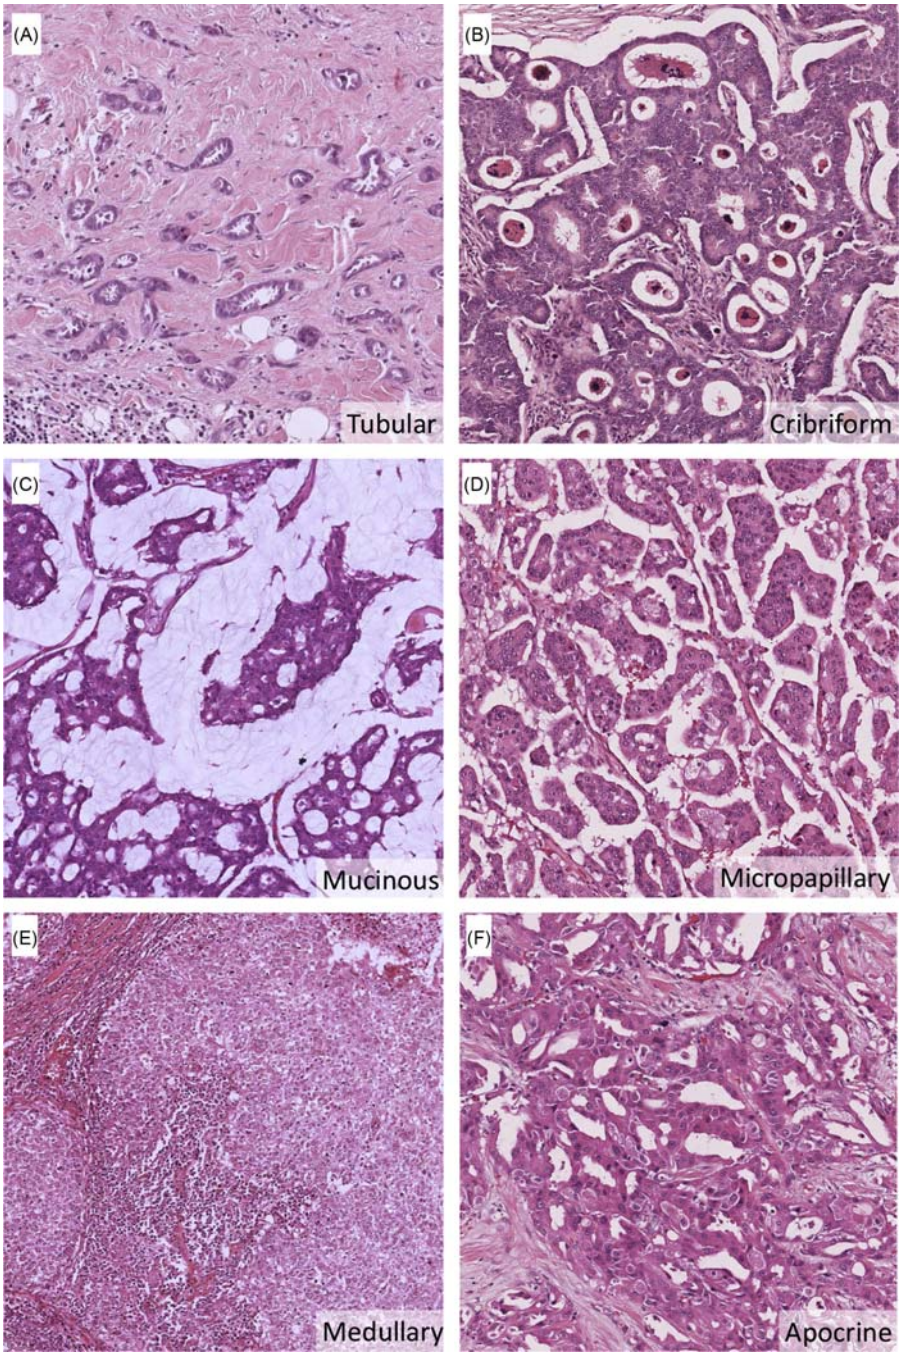

Fig. 2 Examples of special breast cancer morphologies. (A) Tubular; (B) cribriform; (C) mucinous, note the lakes of mucin; (D) micropapillary; (E) medullary; (F) apocrine carcinoma.

Molecular pathology and genetics: TC are diploid, with relatively few large scale genomic alterations. Most frequent is the concomitant loss of 16q and gain of 1p, however these are changes typical of many low-grade breast carcinomas. Only subtle differences at the transcriptomic level set TC apart from other low-grade tumors, and they are categorized as luminal A.

Microenvironment including immune response: The tubules in TC are surrounded by a characteristic desmoplastic stroma.

Staging and grading: Regarding tumor grade, it is implicit in their diagnosis that TC must score 1 for tubules, 1–2 for nuclear atypia, and 1 for mitoses, resulting in a grade of 1. Spread to the lymph nodes is detected in ~15% of TC, and correlates with tumor size, although typically TC are small (average 14 mm).

Prognostic and predictive biomarkers: TC as a histological subtype is in itself an independent prognostic indicator, and the favorable outcome associated with TC provides a survival rate comparable to that of the general population. Considering immunohistochemical biomarkers, TC are usually ER and PR positive, and HER2 negative.

Cribriform Carcinoma

Invasive cribriform carcinoma (ICC) is defined on the basis of its cribriform or "lattice-like" growth pattern (Fig. 2B).

Burden: Frequency of invasive cribriform carcinoma is reported at between ~1% and 4%.

Risk factors: The risks for developing cribriform carcinoma are as detailed in IC-NST.

Pathology: A fenestrated appearance is conferred by the presence of round or ovoid glandular spaces. The mild to moderately pleomorphic cells are arranged in angular islands; mitoses are rare. DCIS of the cribriform morphology is often present. Luminal secretions with microcalcifications may be present.

Molecular pathology and genetics: ICC share similar alterations as TC, and are also luminal A.

Microenvironment including immune response: Fibroplastic stroma features prominently in the ICC phenotype, and occasionally there may be osteoclast-like giant cells.

Staging and grading: This well differentiated tumor is normally of a low grade, with an average size of ~30 mm. Spread to the axillary lymph nodes is detected in approximately 14% of ICC, with the specialized growth architecture retained in the node.

Prognostic and predictive biomarkers: As for TC, ICC have an excellent prognosis, by virtue of their inherent low grade and stage, with a 5-year survival of 100%. They are routinely ER positive, and PR positive in approximately 70% of cases. HER2 positivity is very uncommon.

Mucinous Carcinoma

Mucinous carcinoma, also known as a colloid tumor, is identifiable by its characteristic clusters of small, uniform cells within lakes of extracellular mucin (Fig. 2C).

Burden: A diagnosis of pure mucinous carcinoma is made in up to 2% of all invasive breast cancer diagnoses.

Risk factors: Risk factors include those as described in IC-NST above. Mucinous carcinoma often occurs in older patients, with an average age of diagnosis of 65 years.

Pathology: Mucinous tumors present with a distinctive gelatinous cut surface, and are generally well-circumscribed. Neoplastic cells are arranged in nests or trabeculae within the mucinous lakes. Nuclear pleomorphism is mild to moderate. There are two recognized types of mucinous tumors; the classic type A, and a more aggressive, hypercellular form, type B, which also shows frequent neuroendocrine differentiation.

Molecular pathology and genetics: Mucinous carcinomas are frequently diploid, have minimal genetic instability and show few recurrent chromosomal alterations. Gene expression profiling stratifies mucinous tumors into the luminal A category.

Microenvironment including immune response: The microenvironment is remarkable due to the large amounts of extracellular mucin.

Staging and grading: Up to 14% of mucinous carcinoma show lymph node positivity, and there is a strong positive correlation with tumor size. Type A tumors tend to be of lower grade, and have a favorable 10-year survival prediction, while type B tumors tend towards a survival profile similar to IC-NST. Late, distant metastases have been recorded for pure mucinous tumors. Mixed mucinous tumors (where the mucinous compartment accounts for $<90\%$ of the tumor), have a high rate of lymph node metastases and a worse outcome when compared to their pure counterparts.

Prognostic and predictive biomarkers: Mucinous carcinomas are typically positive for ER and PR expression, and do not harbor HER2 amplifications.

Neuroendocrine Carcinoma

Primary neuroendocrine carcinoma (NEC) of the breast, is a tumor with neuroendocrine morphological features and positive immunoreactivity to neuroendocrine markers, such as neurone-specific enolase, chromogranin and/or synaptophysin, in at least 50% of tumor cells.

Burden: Breast NEC account for $<0.1\%$ of all breast cancers, and $<1\%$ of all neuroendocrine tumors. However, regions of neuroendocrine differentiation as defined by IHC are identified in up to 30% of IC-NST and special types (e.g., mucinous).

Risk factors: NEC tend to be diagnosed in women in their sixth or seventh decade of life.

Pathology: Classification of NEC tumors of the breast is controversial but currently follows that of NECs of other organ sites, in that there are three categories: (1) well differentiated neuroendocrine tumor; (2) poorly differentiated/small cell carcinoma; (3) invasive breast carcinoma with neuroendocrine differentiation. The well differentiated tumors (group 1) are densely cellular, with the cells arranged in nests or trabeculae. Cells vary from spindle to plasmacytoid and large clear cells, divided by fine fibrovascular stroma. The poorly differentiated/small cell carcinoma (group 2) are comprised of densely packed hyperchromatic cells with scant cytoplasm. Frequent mitoses are present, as are focal necrotic areas. Group 3 comprises invasive breast carcinoma with neuroendocrine differentiation; IHC identifies regions of neuroendocrine differentiation in approximately 30% of IC-NST and other special types like mucinous. Indeed, the hypercellular variant of mucinous carcinomas account for a quarter of breast cancers with neuroendocrine differentiation and these tumors are almost always low grade.

Molecular pathology and genetics: Recent molecular analyses have shown that NEC stratify equally into either luminal A or B intrinsic subtypes; approximately half had a high risk of score using Prosigna, but this did not completely correlate with luminal B status. NEC tumors showed a low rate of *PIK3CA* mutation. No correlation between histologic category and molecular features were observed.

Microenvironment including immune response: Lymphovascular invasion has been reported, however there is a paucity of data regarding lymphocytic invasion.

Staging and grading: The majority of NEC group 1 type tumors are grade 1 or 2; two thirds of NEC are grade 2.

Prognostic and predictive biomarkers: NEC are most often ER and PR positive, and HER2 negative.

Invasive Micropapillary Carcinoma

Invasive micropapillary carcinoma (IMPC) is composed of hollow or solid nests of epithelial cells, surrounded by a clear space (**Fig. 2D**). Characteristically, the cells display an "inside-out," or reverse polarity phenotype, where the apical pole is facing outwards.

Burden: Pure IMPC account for between 1% and 2% of all invasive breast cancers, however ~7% of all invasive mammary tumors display some micropapillary morphology.

Risk factors: The risks for developing IMPC are as detailed in IC-NST.

Pathology: The neoplastic cells of IMPC are cuboid-to-columnar, with an eosinophilic cytoplasm. The cells are arranged in tufts with a serrated-like edge, which can be either solid or hollow, but which are surrounded by clear spaces. These empty stromal spaces are not lined by endothelial cells (i.e., they are not dilated lymphatic channels, despite their appearance) and may actually be retraction artifact. Nuclear pleomorphism is variable, but unlikely to be overt; equally, the cells are not highly mitotic. A common feature of micropapillary tumors is that the cells have a reverse polarity or an "inside-out" growth pattern. To this end, the cells' apical pole is arranged to face the empty stromal space, rather than the central region of the neoplastic aggregate. MUC1 staining is useful to confirm this feature.

Molecular pathology and genetics: IMPC are typically classed as luminal A or B intrinsic subtype. Genomically, recurrent gains of chromosomes 8q, 17q, and 20q, and deletion of 6q and 13q are noted, and genes encoding polarity-regulating proteins reside in these loci.

Microenvironment including immune response: Immune infiltrate is variable but rarely brisk, and lymphoid follicles can occur in the breast stroma.

Staging and grading: IMPC are typically grade 3 (~75%) or 2 (~25%), and have an average size of 24 mm. Most importantly, IMPC display an angioinvasive phenotype, with a high rate of lymphovascular invasion. Equally, rates of lymph node positivity are high, recorded at between 69% and 95% of cases, and the total number of involved nodes is also high in IMPC. Extranodal extension in the axilla is also more frequent in IMPC than in IC-NST.

Prognostic and predictive biomarkers: ER positivity is noted in 70% of IMPC, with PR in 60%, and HER2 in 40%. In spite of these relatively good prognostic features, IMPC have a poor prognosis overall, due to their angioinvasive nature and frequent lymph node positivity. Indeed, the lymph node metastasis is the single most important prognostic feature in IMPC. Survival is comparative to other tumor types when matched for grade and stage, however skin involvement is strongly correlated with poor outcome.

Metaplastic Carcinoma; Metaplastic Breast Cancer

Metaplastic breast cancer (MBC) is a unique and lethal neoplasm of the breast. It encompasses a heterogeneous group of lesions exhibiting squamous differentiation and/or mesenchymal—looking components, such as spindle, chondroid, rhabdoid or osseous forms. A descriptive classification from the WHO working group categorized the tumor into low-grade adenosquamous carcinoma, fibromatosis-like metaplastic carcinoma, squamous cell carcinoma, spindle cell carcinoma, metaplastic carcinoma with mesenchymal differentiation, and mixed metaplastic carcinoma.

Burden: MBC constitute approximately 0.2%–5% of invasive breast cancers. The 5-year survival rate for this subtype is relatively 65%, less than conventional IDC. A uniform therapeutic approach is yet to be established owing to the tumor's heterogeneity and inherent special characteristics. In the spectrum of morphology reported in a series of 45 patients, chondroid (24%), spindled (20%), sarcomatoid (16%), squamous (11%), and mixed/others (29%) subtypes were identified.

Risk factors: The risk factors are covered in the IC-NST section. The tumor is found in women >50 years of age.

Pathology: Low-grade adenosquamous carcinoma is characterized by a stellate arrangement of highly infiltrative glandular and tubular cells, surrounded by foci of squamous differentiation in a spindle-cell background. Fibromatosis-like tumors are composed of banal fibroblasts arranged in sweeping fascicles, or long fascicles with finger-like extensions infiltrating neighboring tissues. Squamous cell carcinoma histologically reveals infiltrating nests and tongues of malignant squamous epithelium, with or without keratin pearls. The cystic areas are lined by neoplastic cells that are mildly to markedly pleomorphic with an extensive range of nuclear atypia. Spindle cell morphologies display varying degrees of differentiation, atypical-looking spindle cells with short fascicles forming a storiform architecture, or long fascicles in herringbone pattern. The nuclei are usually moderately to highly pleomorphic. The background stroma may be collagenous or focally myxoid in appearance. MBC with heterologous mesenchymal elements

include tumors composed of invasive adenocarcinomas with mesenchymal elements, the most common of which are chondromyxoid, chondroid, or osseous. Islands of chondrocytes with round-to-spindle-shaped nuclei within a homogeneous and basophilic matrix are seen singly or in groups. Bony structures that display minimal atypia to frankly malignant features are seen intermingling with carcinomatous areas, that are in the form of glandular structures and/or foci of neoplastic squamous cells. Mixed metaplastic carcinomas have been previously observed developing with other growths such as complex sclerosing lesions or papillomas.

Molecular pathology and genetics: MBCs segregate into either a basal-like or claudin-low molecular subtype. The claudin-low intrinsic subtype is associated with epithelial to mesenchymal transition, including positivity with cancer stem cells markers CD44 and Yes-associated proteins. *TP53* is frequently mutated (69%), as is the phosphatase and tensin homolog (*PTEN*; 11%); both are critical players in the mammalian target of rapamycin (mTOR) signaling pathway. Compared with triple-negative IC-NST, MBC have genetically discriminative mutation profiles in *PIK3CA*, *PIK3R1*, *PTEN*, and Wnt pathway genes. Almost 60% of MBCs harbor at least one nonsynonymous somatic mutation affecting PI3K/AKT/mTOR pathway-related genes, compared with 22% in triple-negative IC-NST. *PIK3CA* mutations are absent from chondroid variants. Molecular analysis of a small cohort identified *ERBB4*, *FLT3*, and *CSF1R* mutations, all of which are susceptible to targeted therapeutics in other cancers. Other mutations reported are *EGFR*, *TOP2A*, and *BRCA1*; however, a conclusive molecular signature has yet to be formulated. Copy number alterations are akin to that of triple-negative IC-NST; frequent copy-number gains of 1q, 3q, and 8q, copy-number losses of 1p, 3p, 5q, 8p, and 17p and high-level copy number amplifications of 8q. Evidence suggests that the different morphological regions of an MBC are genetically similar, and that epi-genetic and non-coding alterations may be important in the genesis of this breast cancer type.

Microenvironment including immune response: The tumor microenvironment is as diverse as the neoplastic cells themselves. MBC may contain a plethora of immune infiltrates, with lymphocytes and dendritic cells permeating or abutting the tumor area. The lymphocytes at the periphery may form a "cannonball" pattern, and may appear scant to brisk.

Staging and grading: A small study reported that 62% of patients (28 out of 45) had T2 disease (tumor size 2–5 cm), and metastasis to the lymph nodes were documented in 24% of patients. In many cases, distant metastasis occurs without positivity in the LN, and there is a predilection for lung and brain as sites of metastasis. The prognostic value of histologic grading in MBC is uncertain. For the low-grade adenosquamous and fibromatosis-like carcinoma, the grade is implicitly low, and prognostic outcome is better than for the majority of MBC.

Prognostic and predictive biomarkers: MBCs are of triple negative phenotype; therefore, they are not responsive to either hormone- or HER2 targeted-therapies. They are relatively resistant to conventional chemotherapeutic agents, with common recurrences and poor prognoses. The neoplastic cells in MBCs express stem cell markers ALDH-1 and $CD44^{+}/CD24^{-}$ and novel therapies for stem cell markers is presently an area of interest in clinical trials. There is currently no widely accepted prognostic significance to the morphologic subtype of MBC.

Medullary Carcinoma; Carcinoma With Medullary Features

The histologic criteria required for a medullary carcinoma diagnosis are: a predominant syncytial growth pattern; cells with high-grade nuclei; lymphoplasmacytic infiltration; and/or, a circumscribed or pushing border (Fig. 2E).

Burden: Medullary carcinoma accounts for $<5\%$ of breast cancers, however this is dependent on the stringency of diagnostic criteria employed.

Risk factors: Risk factors for medullary carcinoma are as described in IC-NST above. Additionally, tumors with medullary features occur more frequently in younger patients, and in women with a mutated *BRCA1* gene (up to 10% of this population).

Pathology: Four histologic features are used to define medullary tumors: (i) a predominant syncytial growth pattern ($>75\%$), (ii) cells with high-grade nuclei (iii) diffuse lymphoplasmacytic infiltration, and (iv) a circumscribed or pushing border. The tumor cells are generally round with pleomorphic, vesicular nuclei containing one or more nucleoli, and an abundance of cytoplasm. The inter-observer reproducibility of the application of said criteria has been poor, and the tumors are now more broadly considered to be "carcinomas with medullary features," to account for those tumors with fewer than four of the criteria present (e.g., atypical medullary carcinoma, and also, IC-NST with medullary features). These features are also seen in BRCA1-associated cancers.

Molecular pathology and genetics: Medullary tumors demonstrate high levels of genetic instability; broad copy number profile is consistent with age and grade-matched IC-NSTs. Considering the transcriptome, medullary carcinomas fall into the expression category of basal-like breast cancers, and are also recognized to over-express genes within the 12p13 and 6p21 loci. Approximately half of all carcinomas with medullary features show loss of *PTEN*, and overexpression of TP53 due to mutation is common.

Microenvironment including immune response: This tumor type is typified by a prominent lymphoid response. Characterization of the infiltrates identified a predominance of $CD3^{+}$ T-lymphocytes, with higher levels of $CD8^{+}$ cytotoxic T-lymphocytes.

Staging and grading: Medullary tumors are more likely to present at a higher grade than IC-NST tumors; however, they have lower rates of lymph node metastases.

Prognostic and predictive biomarkers: Carcinomas with medullary features infrequently express ER, PR and HER2 making them "triple negative," and thus precluding them from hormone- and HER2 targeted- therapies. They variably express basal markers such as keratin 5/6 and EGFR, as well as smooth muscle actin, p63 and vimentin (among other myoepithelial markers). In spite of these characteristics, medullary cancers tend to have a significantly better distant relapse free survival than IC-NST. Indeed, the presence of lymphoplasmacytic infiltrate correlates strongly with a good prognosis.

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma (ACC) is the most common "salivary gland-like" tumor of the breast, and is considered to be of low malignant potential. They are neither adenomas, nor cysts.

Burden: These tumors are rare, and account for $<0.1\%$ of all breast tumors.

Risk factors: The risk factors for ACC are as described in IC-NST above. Additionally, 96% of patients are post-menopausal, and the incidence is $\sim$40% lower for black women than white women.

Pathology: ACC lesions are well circumscribed, and average 30 mm in size. Microscopically, epithelial and myoepithelial cells comprise typical architectures such as cribriform or tubular, and/or solid nests. The presentation is biphasic, with two forms of component structures. The first, true glandular spaces, are lined with epithelial cells with round nuclei and eosinophilic cytoplasm; they contain periodic acid-Schiff (PAS)-positive mucin. The second, the pseudolumina or pseudocysts, account for most of the tumor and result from stromal invagination. They are comprised of small, hyperchromatic basal/myoepithelial cells with sparse cytoplasm. The pseudolumina are generally round and Alcian blue positively stains the myxoid stromal substance.

Molecular pathology and genetics: ACCs harbor a recurrent chromosomal translocation, t(6;9) (q22–23;p23–24), which results in the generation of *MYB* and *NFIB* fusion transcripts in more than 90% of ACC cases. ACC have a basal-like expression profile. ACCs display a relatively stable genome, with few high-level alterations and recurrent 17q21–q25.1 gains and 12q12–q14.1 losses. In spite of a low mutation rate overall, these tumors show recurrent mutations in *TLN2*, *MYB*, and *BRAF*, and an absence of mutations in *TP53* and *PIK3CA*.

Microenvironment including immune response: ACCs are noted for their prominent myxoid secretions.

Staging and grading: ACC have an excellent prognosis, and rarely present with axillary lymph node metastases, or distant metastases. ACC are generally low grade, and in fact standard grading is of limited use. The salivary gland tumor grading system maybe more appropriate, whereby tumors with an increasing proportion of solid tumor architecture have an increasing grade. Grade 1 tumors are broadly cystic and glandular.

Prognostic and predictive biomarkers: ACC are typically triple negative for ER, PR, and HER2, while overexpression of EGFR has been described in 65% of cases.

Secretory Carcinoma

Also known as juvenile carcinoma, this rare subtype of breast cancer is composed of cells that produce intracellular and extracellular secretory material.

Burden: These tumors are rare, and account for $<0.15\%$ of all breast tumors.

Risk factors: Secretory carcinoma was originally described in children, but is now recognized to occur in both sexes, and a broad age range (median 25; range 3–87 years). Just under 40% of patients are younger than 40 years. No associations with hormonal deficiency have been described, neither has a link with pregnancy been proven. Some coexisting cases of juvenile papillomatosis have been described.

Pathology: The lesions present as a well-circumscribed, palpable mass of approximately 3 cm on average, frequently located near the areola in pre-pubertal or male patients. Three growth patterns are seen in a variety of combinations, with most tumors containing areas of all three: microcystic, solid, and tubular. Cells are polygonal, with regular nuclei and minimal mitoses. Prominent intracellular and extracellular amphophilic/granular eosinophilic cytoplasm.

Molecular pathology and genetics: Secretory carcinomas are diploid, with characteristic recurrent alterations including gain of 8q and 1q, and loss of 22q. The chromosomal translocation t(12;15) results in the expression of a fusion transcript *ETV6-NTRK3*, a chimeric tyrosine kinase. This alteration is unique to secretory carcinomas, but is not present in every case.

Microenvironment including immune response: Secretory carcinoma display prominent extra-cellular amphophilic/granular eosinophilic deposits.

Staging and grading: Secretory carcinoma are regarded as having a favorable prognosis, especially in children and young adults; they are generally low grade. Axillary lymph spread rarely involves more than three nodes, and distant metastasis is also infrequent.

Prognostic and predictive biomarkers: ER, PR and HER2 positivity is uncommon in secretory carcinomas. The tumors have a basal-like immunoprofile.

Apocrine Carcinoma

Tumors with more than 90% of neoplastic cells demonstrating apocrine differentiation are considered to be an apocrine carcinoma, as opposed to those with focal regions of apocrine differentiation (**Fig. 2F**).

Burden: Tumors with extensive apocrine differentiation account for up to 4% of all breast cancers; focal apocrine differentiation is a common feature in breast cancers.

Risk factors: The risk factors are as described in IC-NST above.

Pathology: Neoplastic cells with an apocrine phenotype demonstrate either a PAS-positive, eosinophilic, granular (type A cells) cytoplasm, an abundant foamy cytoplasm (type B cells) or a combination of both cell types. Nuclei are enlarged and feature prominent nucleoli. Cells have sharply defined borders.

Molecular pathology and genetics: Chromosomal alterations detected in Apocrine carcinomas include losses of 1p, 12q, 16q, 17q, 22q and gains of 1p, 1q, 2q; these changes are not specific to apocrine tumors. Microarray-based gene expression profiling has described a subtype of breast cancer named "molecular apocrine." This grouping is defined by increased androgen receptor (AR) signaling, and contains those HER2 positive tumors that are not classified as basal. Importantly, not all tumors with an apocrine phenotype stratify into this group.

Staging and grading: Apocrine breast cancers tend to have a similar or slightly better prognosis than grade-matched IC-NST.

Prognostic and predictive biomarkers: Apocrine carcinomas are typically ER and PR negative, and AR positive. HER2 may be over-expressed. These tumors may be candidates for AR-targeted therapies.

Inflammatory Carcinoma

Inflammatory carcinoma represents a clinical manifestation of breast cancer, rather than a histopathological subtype. The presence of abundant dermal lymphocytic emboli alone indicates the presence of an occult breast cancer.

Burden: Inflammatory carcinoma accounts for up to 2% of all breast cancers, and there is evidence to suggest that the incidence is rising.

Risk factors: Inflammatory breast cancer occurs most frequently in African-American women, and is far less frequent in Asian and Pacific Islander populations. A high body-mass index and younger age of disease have been correlated with this tumor type in African-Americans.

Pathology: The defining histology of inflammatory carcinoma is the presence of dermal lymphatic emboli, composed of tumor cells, in the skin encompassing the breast; however, an absence of emboli in a small diagnostic specimen does not preclude its diagnosis. The emboli cause significant obstruction of the lymph system in the skin, and consequent edema, however there is not an increase in inflammatory cell infiltrate. The tumor cell histology is often IC-NST, and high grade but can be any subtype.

Molecular pathology and genetics: The tumor emboli stain strongly for E-cadherin; a hallmark of the disease. Approximately 40% of inflammatory breast cancers overexpress HER2, with much greater numbers highly expressing p53 and sialomucin MUC1. Genetically, *HER2* amplification and *TP53* mutation are common, and the tumors' expression profiles are consistent with the basal-like or HER2 subtypes. There is increasing evidence for copy number gain of *ALK* in inflammatory breast cancer.

Microenvironment including immune response: As inflammatory breast cancer is a clinical presentation, rather than histological subtype, there is no specific microenvironment description; rather, it is determined by the tumor's histotype.

Staging and grading: Inflammatory carcinoma is considered to be stage T4d.

Prognostic and predictive biomarkers: Fifty percent of inflammatory breast cancers are triple negative for ER/PR/HER2, affording these tumors a poorer prognostic outcome. Approximately 40% overexpress HER2, indicating the use of HER2 targeted therapies. The role of ALK is under investigation, but there is potential for ALK over-expressing patients to be prescribed targeted therapies such as crizotinib.

Rare Carcinomas

Invasive Papillary Carcinoma

Invasive papillary carcinoma is recognized as an adenocarcinoma of the breast, demonstrating an exclusive papillary morphology. This tumor type excludes solid papillary and encapsulated tumors.

- *Burden*: This tumor type is rare, and accounts for less than 1% of breast cancers.
- *Risk factors*: Invasive papillary tumors are most frequently diagnosed in older, post-menopausal, non-white women.
- *Pathology*: Invasive papillary carcinoma has a well-defined border. Invasive cells are arranged in papules, or finger-like projections, and the tumor has a permeative front. Notably, invasive papillary lesions contain true fibrovascular cores, unlike micropapillary tumors. Due to the tumor's rarity, the primary diagnostic pathology goal is to exclude the possibility that the breast lesion is a metastatic deposit.
- *Staging and grading*: Clinical data on stage and grade, and indeed outcome, are lacking for this rare tumor type.
- *Prognostic and predictive biomarkers*: There is a paucity of data available for this rare tumor type.

Glycogen-Rich Carcinoma

Glycogen-rich carcinoma (GRC), a type of clear cell carcinoma, is diagnosed when more than 90% of a tumor contains cells an abundant, glycogen-rich cytoplasm.

- *Burden*: This tumor accounts for 1%–3% of breast cancers.
- *Risk factors*: The risk factors for GRC are as described in IC-NST above.
- *Pathology*: Neoplastic cells are arranged in sheets or nest, and contain clear cytoplasm. GRC usually present with DCIS of a solid, clear cell type.

- *Staging and grading*: GRC present with numerous mitoses, and are typically grade 3. Up to 20% of axillary dissections have shown detectable metastases.
- *Prognostic and predictive biomarkers*: ER is positive in approximately 50% of cases; PR expression is negative. HER2 positive cases have also been reported. Some evidence suggests that GRC have a worse prognosis than IC-NST, however after matching for grade, size and LN status, this association with poor survival is lost.

Lipid-Rich Carcinoma

Lipid-rich carcinoma (LRC), is a type of clear cell carcinoma, reported when at least 90% cells demonstrate abundant cytoplasmic lipids.

- *Burden*: This tumor type is rare, and accounts for less than 1% of breast cancers.
- *Risk Factors*: A case report demonstrated an association with neuroleptic drugs, which interfere with inhibition of prolactin secretion.
- *Pathology*: LRC present with infiltrating margins and cells contain numerous vacuoles of a range of sizes; the vacuoles are negative for PAS staining. LRCs stain positively for oil red O or Sudan black. LRC may present with associated DCIS or LCIS.
- *Staging and grading*: LRC tend to be grade 2 or 3 tumors, with over 50% presenting with lymph node metastases. Over 50% of LRC patients go on to develop distant metastasis, and an extremely poor first year mortality rate of 38.5% has been reported.
- *Prognostic and predictive biomarkers*: Although most cases are triple negative for ER/PR/HER2, there are cases of ER positive tumors, which indicate the prescription of endocrine therapy.

Acinic Cell Carcinoma

Acinic cell carcinoma (ACCA) of the breast shows strong similarity to the ACC of the parotid gland in terms of morphology and immunoprofile, with evident serous differentiation.

- *Burden*: This tumor type is rare, and accounts for less than 1% of breast cancers.
- *Risk factors*: There is a paucity of data available for this rare tumor type.
- *Pathology*: ACCA show small glandular structures composed of cells with irregular nuclei, varying from round to ovoid, and single nucleoli. The cells have abundant cytoplasm which is granular, consistent with zymogen granules, and ranges from amphophilic to eosinophilic in response to stains. Cells with a clear cytoplasm, reminiscent of "hypernephroid" or adrenal cortex histology, can predominate. This tumor types shows an infiltrating growth pattern.
- *Molecular pathology and genetics*: ACCA does not appear to harbor the t(6;9) (q22–23; p23–24) of the other salivary-like carcinoma of the breast (adenoid cystic carcinoma, see above)
- *Staging and grading*: tumors may range in size from 1 to 5 cm, and average 15 mitoses per 10 high powered fields however, no specific data is available for tumor grade frequencies.
- *Prognostic and predictive biomarkers*: ACCA are triple negative for ER/PR/HER2 and also negative for androgen receptor (AR).

Sebaceous Carcinoma

Sebaceous carcinoma is a rare tumor type presenting with prominent sebaceous differentiation in at least 50% of cells.

- *Burden*: This tumor type is rare, and fewer than 20 cases have been reported.
- *Risk factors*: The risk factors for sebaceous carcinoma are as described in IC-NST above.
- *Pathology*: Sebaceous carcinoma present with a nested growth pattern. There is an admixture of cell types; those with abundant, finely vacuolated cytoplasm (oil red O-positive), and smaller round to ovoid cell with eosinophilic, not vacuolated cytoplasm. There are numerous mitoses evident.
- *Staging and grading*: There is a paucity of data available for this rare tumor type.
- *Prognostic and predictive biomarkers*: ER, PR, and HER2 may be expressed.

Oncocytic Carcinoma

Oncocytic Carcinoma is defined when at least 70% of cells show an oncocytic phenotype, that is, they accumulate high numbers of mitochondria and have a highly eosinophilic cytoplasm.

- *Burden*: This tumor type is rare, and accounts for less than 1% of breast cancers.
- *Risk factors*: The risk factors for Oncocytic carcinoma are as described in IC-NST above.
- *Pathology*: Oncocytic carcinomas are circumscribed, with a solid growth pattern. Nuclei morphology varies from pleomorphic to monotonous, and may show prominent nucleoli. There is no polar condensation of the abundant mitochondria, which are dispersed throughout the cytoplasm.
- *Molecular pathology and genetics*: Chromosomal gains of 11q13.1–11q13.2 and 19p3 are reported for oncocytic carcinoma, as for the similar oncocytic tumors in the thyroid and kidney.

- *Staging and grading*: Oncocytic carcinoma afford the same prognosis as stage- and grade-matched IC-NST. LN metastases are reported at diagnosis in up to 44% of patients.
- *Prognostic and predictive biomarkers*: In a single series of 32 cases, ER positivity was calculated to be approximately 80%, PR positivity at ~60% and HER2 positivity at 25%.

In Situ Carcinoma

Ductal Carcinoma In Situ

Ductal carcinoma in situ (DCIS), also known as intraductal carcinoma or ductal intraepithelial neoplasia, is a heterogeneous group of proliferative, neoplastic lesions confined to the ductalobular network (Fig. 3).

- *Burden*: DCIS detection has increased significantly since the onset of mammographic screening programs, from previous palpably detected rates of 2%–3% of all breast cancers to up to a quarter of all newly diagnosed breast cancers.
- *Risk factors*: The risk factors for DCIS are as described above for IC-NST, and increases if a benign breast lesion (e.g., atypical ductal hyperplasia) has previously been diagnosed. DCIS is considered to be a non-obligate precursor to invasive breast cancer.
- *Pathology*: The definition of DCIS requires that the lesion is confined by the basement membrane and does not penetrate into the stromal areas. Depending on whether the lesion is low- or high-grade, the neoplastic cells may be small and regular, with infrequent mitoses, or large and pleomorphic with clumped chromatin and prominent nucleoli, respectively. Typically, DCIS can exhibit architectural morphologies including; comedo, cribriform, micropapillary and solid, but often present as a mixed phenotype. Micropapillary DCIS tends to a more extensive presentation of disease.
- *Molecular pathology and genetics*: Typically, low grade DCIS lesions are near diploid, with up to half of intermediate grade DCIS being aneuploid, and high-grade DCIS frequently aneuploid. Consistent with increased nuclear anomaly, high-grade DCIS harbor a much higher rate of chromosomal copy number abnormality than those with intermediate or low nuclear grade; the most frequent changes being losses of 1p, 8p, 17p, and gains of 1q and 8q. High grade lesions are most likely to have

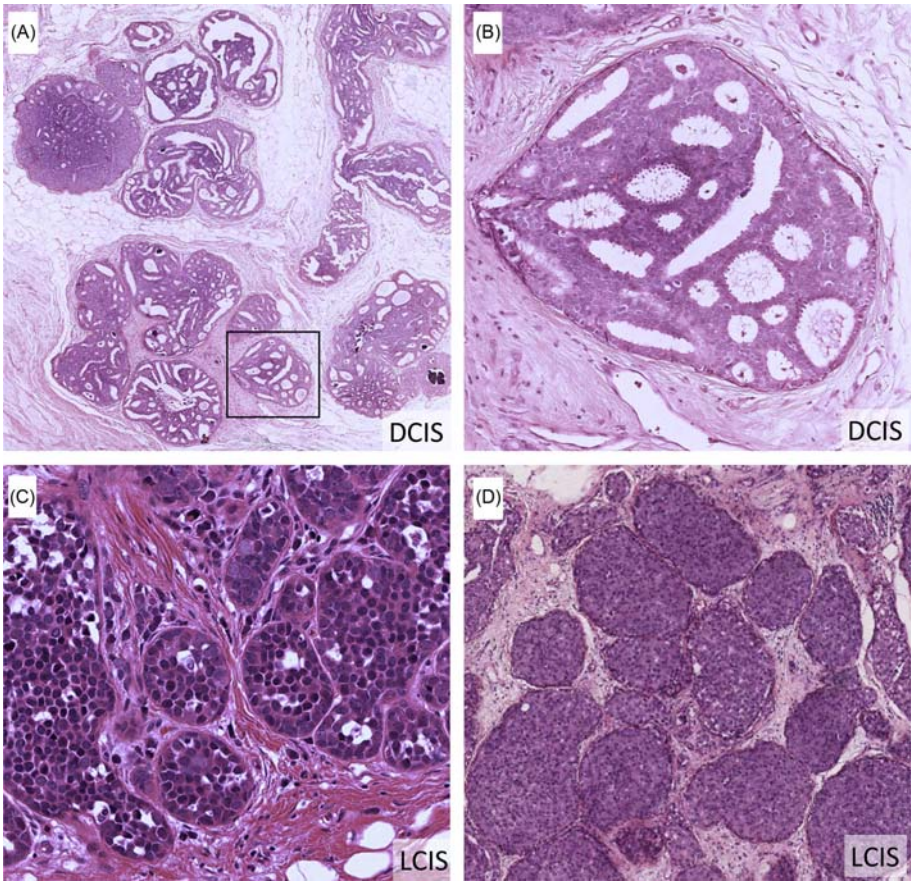

Fig. 3 In situ carcinoma of the breast. (A) Ductal carcinoma in situ, with a higher power view exemplifying the cribriform morphology in (B) (boxed region). (C) Classic lobular carcinoma in situ, with (D) showing bulky or florid disease, which would require E-cadherin and p120-catenin biomarker staining to distinguish from DCIS.

chromosomal amplifications; frequently at 1q, 8q, 17q, and 20q. In spite of significant advances in applying novel sequencing technologies to invasive breast cancer, still relatively few DCIS lesions have been adequately characterized. Most recently, targeted next generation sequencing elucidated that the cohort has a higher frequency of *PIK3CA* mutations than previously reported, and confirmed that a correlation between *GATA3* mutation and ER positivity holds true in pre-invasive lesions. While mutations in *PIK3CA* and *GATA3* are mostly mutually exclusive in invasive breast cancer, four cases harbored mutations in both genes. Intrinsic subtyping of DCIS lesions has shown that low-grade lesions are most often luminal A; intermediate lesions are luminal A or B; and, high-grade lesions are more likely to be luminal B, HER2 or basal.

- *Microenvironment including immune response*: Recent research has demonstrated that lymphocytic infiltrate is present in all DCIS to varying degrees, indicating an immune response even at this pre-invasive stage. While neoplastic DCIS cells do not express PD-L1 (the immune checkpoint marker), PD-L1 positive infiltrating lymphocytes were found in ~80% of DCIS lesions.
- *Staging and grading*: DCIS is defined as Stage 0, however the grading of DCIS is more complex. Historically, DCIS was classified based on architecture alone, however more recently a move to applying either nuclear grade alone, or in addition to necrosis and polarization has been made. Expectedly, high grade DCIS are more proliferative than the low and intermediate grades. As for invasive breast cancer, there is unlikely to be progression through the grades in a lesion's natural history, although this can occur.
- *Prognostic and predictive biomarkers*: DCIS recapitulates the variability of biomarker expression as seen in invasive carcinomas.

Lobular Carcinoma In Situ

Lobular carcinoma in situ (LCIS), like its ductal counterpart (DCIS), is a neoplastic lesion confined to the ductalobular network, that shows a characteristic lobular phenotype, with a lack of cohesion between neoplastic cells (**Fig. 3**).

- *Burden*: LCIS is not visible mammographically and is almost always diagnosed as an incidental finding through a biopsy for another indication, making estimation of true incidence difficult. However, less than 4% of excised invasive carcinoma specimens, and up to 4% of otherwise benign biopsies contain associated LCIS.
- *Risk factors*: The risk factors for LCIS are as described above for IC-NST, and increases if a benign breast lesion (e.g., atypical lobular hyperplasia) has previously been diagnosed. LCIS is considered to be a non-obligate precursor to invasive breast cancer, and a risk factor for developing ILC in the ipsilateral breast.
- *Pathology*: LCIS presents as a multicentric lesion in up to 85% of patients, and bilaterally in up to two thirds of patients. Pagetoid spread along the duct is common. Neoplastic cells can be either type A (uniform nuclei with inconspicuous nucleoli and scant cytoplasm) or type B (bigger cells with clearer cytoplasm, obvious nucleoli, and clumped chromatin). Lesions presenting with mild to moderate nuclear atypia are considered to be classic. Those lesions with larger cells with marked nuclear atypia and granular cytoplasm, are pleomorphic LCIS, and a third classification of LCIS is florid, or FLCIS.
- *Molecular pathology and genetics*: LCIS is highly similar to ILC at the genetic level. Common chromosomal changes include loss of 16p, 16q, 17p, 22q and gain of 1q and 11q13. As for ILC, LCIS are generally diploid, however the pleomorphic variant shows much greater genomic instability, as does FLCIS. The gene encoding E-cadherin is altered in a similar fashion, indeed, in co-occurring ILC and LCIS, the *CDH1* mutation status is identical, supporting that LCIS is a non-obligate precursor, not solely a risk indicator. In a large genome wide association study, a risk SNP was identified for LCIS in the *LGR6* gene (rs6678914), we await functional studies to further understand this finding.
- *Microenvironment including immune response*: There is limited information on this topic for this lesion.
- *Staging and grading*: LCIS is defined as Stage 0.
- *Prognostic and predictive biomarkers*: LCIS recapitulates the variability of biomarker expression as seen in ILC.

Prospective Vision

The advent of cost effective next-generation sequencing technologies, and the increasingly collaborative nature of research consortia, has resulted in the whole genomes of hundreds of breast cancers being characterized. With increasing optimization of these technologies for archival material, we anticipate that the specific genomic details of the various morphological subtypes of breast cancer will soon be delineated, affording clinicians detailed insights into the biology of different breast tumors, and hopefully informing the use of targeted therapies.

Cancer Disparities

Ivana Kulhánová, Section of Cancer Surveillance, International Agency for Research on Cancer, Lyon, France
Salvatore Vaccarella, Section of Infections, International Agency for Research on Cancer, Lyon, France

Introduction

Cancer disparities may be described as systematic differences in cancer outcomes, such as incidence, survival, mortality, between certain population groups, disproportionally affecting the most disadvantaged individuals and occurring across many axes, socioeconomic (household income, education or occupation), racial/ethnic, gender or geographical. Social conditions and social factors account for a substantial part of the total burden of cancer and may be measured by different indicators, each of which may suggest different aspects and mechanisms for the role of social determinants. The consensus is that the observed disparities in cancer are largely driven by a complex set of causal processes. Multiple pathways are involved representing the consequence of a combination of social, economic, environmental, historical and political factors, including childhood experiences, that result in a differential exposure to risk factors, such as tobacco smoking, alcohol drinking, unhealthy diet, occupational exposures as well as differential access to the health care system. Although health care system should assure and regulate the access to prevention, early detection and treatment for the entire population, individuals with lower socioeconomic status (SES) benefit less from the health system compared to people with higher SES.

It is important to acknowledge that the systematic differences in cancer occurrence and on the patterns of the specific cancer types that are observed both within and between countries are thought to be in principle largely preventable. Here we provide a summary of cancer disparities between and within countries and a description of the reasons underlying these disparities.

Disparities in Cancer Within and Between Countries

Cancer disparities largely reflect the environment in which individuals are born, reside and work, and the uneven distribution of resources and services within and between countries. Cancer incidence and mortality patterns show distinct variations between and within more or less developed countries and regions of the world. From a global perspective, it has been observed that the overall cancer incidence rates increase with increasing level of human development, as measured by Human Development Index (HDI) (a summary measure of life expectancy, years of schooling and standard of living), Fig. 1. In 2012, the total number of new cases of cancer was 14.1 million, of which 41% observed in very high HDI countries, and 28%, 16%, and 6% in high, medium, and low HDI countries, respectively. Despite the larger burden of cancer incidence in highly developed countries, similar cancer mortality rates are observed between countries with different HDI levels, with the possible exception of low HDI countries that are at a slightly lower level compared to other categories, Fig. 2. The discrepancy between incidence and mortality is much higher in high-income countries (HICs) than in low- and middle-income countries (LMICs) and it roughly suggests that, despite the high cancer incidence rates, high-quality health systems in HICs were able to have a major impact in limiting mortality.

Not only the cancer burden but also the cancer profiles differ by HDI level. The relationship of cancer incidence and mortality with HDI may change substantially for specific cancer types, Fig. 3. For instance, cancer incidence is directly associated with HDI for cancers of the colorectum, breast, prostate, thyroid, melanoma, and inversely for cancers of cervix, lung, and stomach. The most

(2013). *GLOBOCAN 2012 v1.0, cancer incidence and mortality worldwide: IARC CancerBase No. 11 [Internet]*. Lyon, France: International Agency for Research on Cancer.

frequent cancers in high and very high HDI countries (prostate, breast, colorectal, and lung cancers) are related to increased exposure to certain risk factors such as smoking, obesity and unhealthy diet that are associated with "Westernization". Infection-related cancers (e.g., cervical, liver and stomach cancers) dominate the low and middle HDI countries. The patterns described above however are only general tendencies and there are several exceptions to these trends, depending on the country or area and cancer type.

Cancer and cancer disparities are not static. Changes in population structures, declining fertility and increasing longevity, with population growth and ageing, as well as declines in cardiovascular diseases, have already led cancer to be an increasingly more important non-communicable disease. The result of societal, economic and lifestyle changes associated with globalization have also led and will lead to major changes between and within countries in cancer occurrence. Although once considered a disease of affluent individuals and countries, cancer is a global problem affecting all countries, with approximately two-thirds of cancer deaths already occurring in transitioning LMICs. LMICs are increasingly suffering from cancers typical of more affluent countries, e.g., colorectum, breast and prostate. The future incidence of cancer in LMICs is expected to increase proportionally more than in HICs and the dose-response relationship between cancer incidence and HDI may anticipate the future scale of the problem that LMICs will face in the decades to come. It is not clear whether LMICs, already suffering from a disproportionate burden of infection-related cancers, will be able to contain the expected epidemic of cancer. Disparities between countries can only be expected to widen if efficient and cost-effective interventions will not be implemented.

Disparities in cancer incidence and mortality are not only observed between countries but also within countries, according to socioeconomic status and race/ethnicity regardless of the country economic development, Fig. 4. Although the social gradient for cancer incidence may show different directions, depending on the cancer site, mortality is usually higher among individuals with lower SES. There is a clear gradient of worsening overall cancer mortality and survival from high to low SES, and therefore almost everyone's health is affected to a certain degree. The existence of a gradient implies that possible interventions to reduce cancer disparities may be beneficial for whole populations, even though disadvantaged groups may clearly benefit the most from these interventions. Data in low-income countries are insufficient, but when available reveal poor cancer outcomes, including very high mortality and low cancer survival even for preventable or curable cancers (e.g., cervix and childhood cancers), which are due to limited or complete absence of resources and infrastructures at all steps of cancer control. It is however important to point out that even in high-income countries, cancer outcomes among individuals living in poverty, indigenous and racial/ethnic minorities, are much worse compared to other groups. Cancer mortality trends in the past decades have been generally more favorable for the

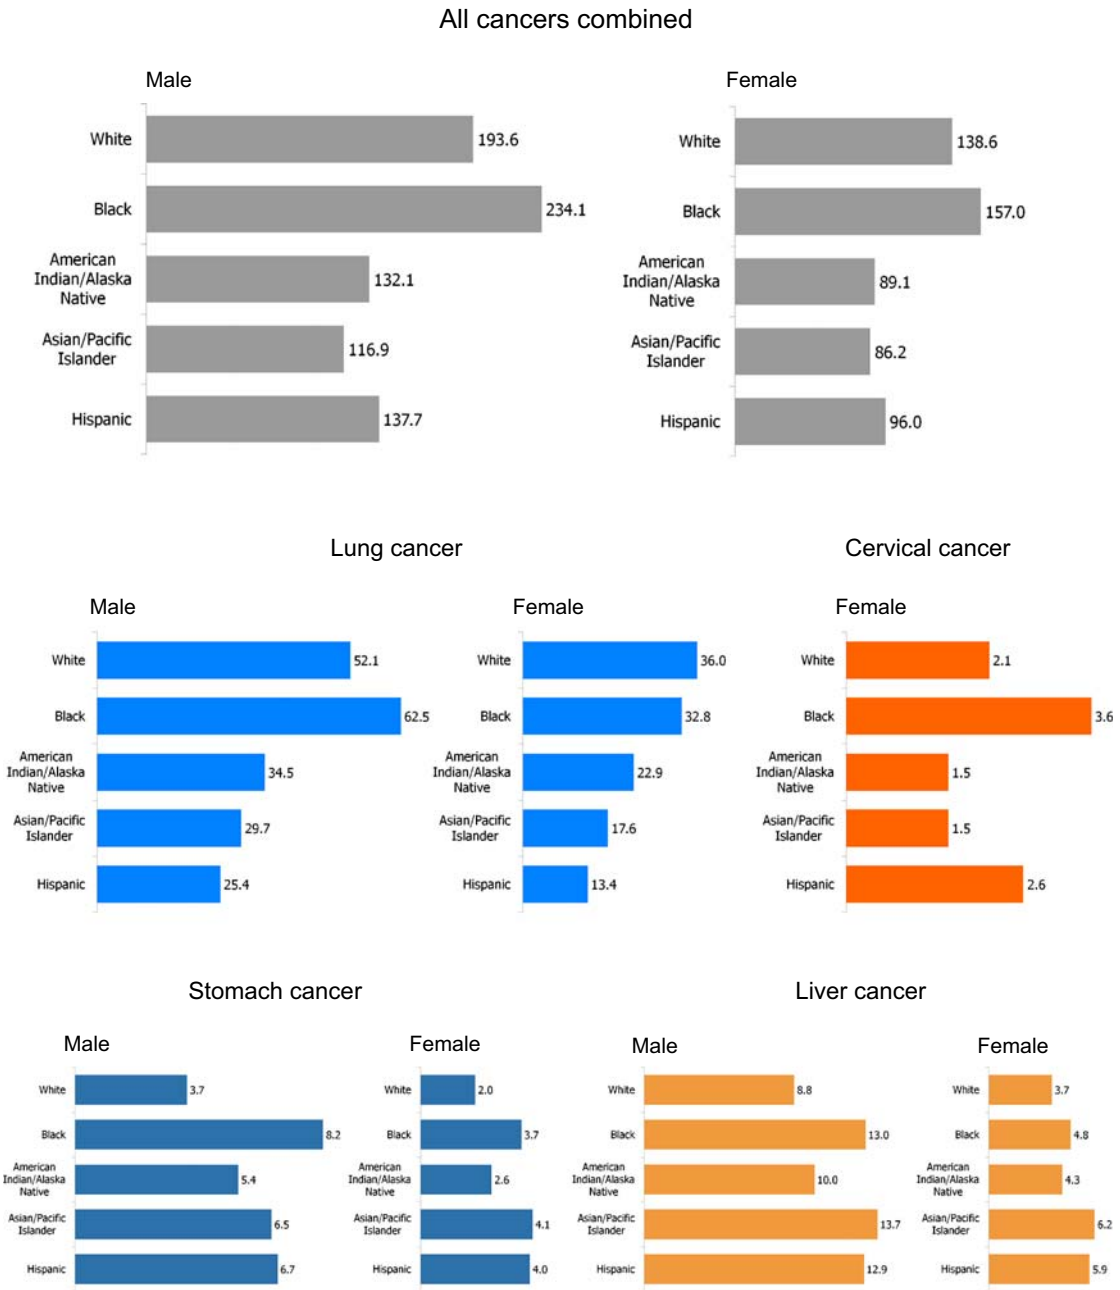

Fig. 4 Age-standardized (US population) mortality rates of all cancer combined and selected cancers types in the US in 2014, by demographic groups. Centers for Disease Control and Prevention (CDC).

higher socioeconomic groups, who apparently have benefited more from advances in prevention and treatment of cancer. Higher socioeconomic groups are in better position to benefit because they have access to a greater array of material and non-material resources, such as less financial barriers to health care or greater health literacy. As example can be mention that whereas cancer mortality among high educated men and women has largely declined, cancer mortality among low educated individuals declined with a lower speed, remained stable or even increased.

Regarding the cancer types, large socioeconomic inequalities with higher cancer incidence and mortality among low SES groups were reported for smoking-related cancers (such as lung, oral cavity and pharynx, larynx and esophagus), and infection-related cancers (such as stomach, liver, and cervical cancer).

Substantial cancer disparities have also been reported by race/ethnicity. In the US, blacks were observed to have an increased risk of cancer, especially for cervix uteri and prostate. Regarding indigenous population, a study from New Zealand showed an increased risk of lung, breast, stomach, endometrial, and liver cancer for Maori population.

Disparities between and within countries are also observed in cancer survival. The highest survival rates are usually observed in affluent countries, and within countries in affluent and high-educated patients. Social determinants influence cancer survival patterns in countries in transition, although survival data are not always available, particularly in LMICs. Over the most recent periods, improvements in 5-year survival are observed for most cancers in many LMICs, although with major differences between cancer types and between countries having different possibilities to benefit from high qualities health care services. The stage at diagnosis, the quality of treatment and the quality of health care services importantly contribute to disparities in cancer survival. Specifically the stage at diagnosis had the largest effect on racial/ethnic survival disparities in breast, prostate and colorectal cancer, showing that black patients had the lowest survival for all cancer sites. The characteristics of the patient, in particular comorbidities in people with low SES, may also contribute to reduce survival.

Disparities in Risk Factors and Access to Health Care

Disparities in cancer mortality are often linked to known risk factors which may have an impact at each stage of the cancer continuum, and include behavioral/lifestyle individual factors as well as factors related to the environment and to the context of culture, politics and policy, including price policies and tobacco, alcohol and soft drink taxations, of each country, depending on a specific cancer type. The prevalence of underlying cancer risk factors including cigarette smoking, cancer-related infections, occupational exposures, obesity, diet, or physical inactivity is not distributed equally by socioeconomic status or race/ethnicity. Exposure to these risk factors is higher in low SES and underprivileged populations, such as ethnic/racial minorities and indigenous populations. Several known occupational carcinogens, such as for example, asbestos, are concentrated among manual and industrial workers.

While for some cancers, like stomach, childhood circumstances play a key role, for others, like lung, breast or colorectal cancer, risk factors in adulthood are essential. In cancers such as breast or cervical cancer, access to screening is an important factor contributing to the cancer disparities.

Lung cancer is the most common cause of incidence and mortality in the past decades. Cigarette smoking is the most important cause of lung cancer causing about 90% of all lung cancers. Both lung cancer incidence and mortality rates were estimated to be higher among blacks than whites and in the individuals with lower SES. From this point of view, the social disparities in lung cancer incidence are closely related with social disparities in smoking prevalence. The diffusion of smoking in the population follows a process described as the smoking epidemic. According to the smoking epidemic, smoking had an initial higher uptake among affluent people but progressively became more concentrated among socially deprived individuals. The contribution of smoking to the cancer disparities increases as the smoking epidemic progresses. Countries at the most advanced stage of the epidemic such as the United States, Canada, Scandinavian countries, the United Kingdom and the Netherlands demonstrate the highest smoking-related cancer disparities. Based on the process of the smoking epidemic, an increase in smoking-related cancer disparities may be expected in countries at an earlier phase of the smoking epidemic, i.e., LMICs.

The incidence of breast cancer is usually higher among individuals with higher SES. The positive association between SES and breast cancer incidence may be explained by certain factors, such as delayed age at first birth, nulliparity, lower body mass index, higher use of oral contraceptives and hormone replacement therapy that are more common among women with a higher social status. Differences in diagnostic factors may also play an important role as high SES women are more likely to participate in breast cancer screening programs and therefore to be diagnosed with the disease. Breast cancer survival is however lower, and mortality higher, among women from poor socioeconomic background and from LMICs mainly because these women are more likely to be diagnosed at a later stage compared to high SES women and to experience delays in treatment.

Prostate cancer is a significant public health burden and a major cause of morbidity and mortality among men worldwide. Similarly to breast cancer, incidence of prostate cancer is generally higher in high SES individuals and affluent countries but low SES is associated with poorer survival and higher mortality, most likely as a consequence of differences in treatment across racial and socioeconomic strata. Particularly high prostate cancer incidence and mortality rates are observed among Africans and black Americans although the reasons for racial/ethnic differences remain unclear, as the risk factors of prostate cancer have not been clearly determined yet.

The incidence of colorectal cancer has markedly increased in the past decades in HICs, most likely due also to changes in lifestyle characteristics, including dietary habits linked to overweight/obesity, reduced physical activity, tobacco and alcohol consumption

("Westernized lifestyle"). There is clear positive association between the incidence of colorectal cancer and HDI values at the country-level, with rates at least six times higher in very high HDI countries relative to low HDI countries in both sexes. However, characteristics and risk factors for colorectal cancer typically cluster in low SES and disadvantaged populations, which are likely to have the highest mortality rates for this disease. In the very recent past, colorectal cancer incidence rates have stabilized or declined in a several affluent countries, this possibly due to several factors including colorectal cancer screening, which has the potential to protect against the disease. Even in this case, strong socioeconomic inequalities exist in the access and uptake of colorectal screening programs.

A large majority (86% or 453,000 cases) of the global burden of cervical cancer is recorded in LMICs, particularly in Africa, Asia and in Latin America, where one in nine new cancer cases are of the cervix. Cervical cancer has now become relatively rare in HICs, like North America, Northern and Central Europe, and Japan, where historical investments have been done in effective screening programs. Incidence rates of cervical cancer have been declining in the recent past in some populations in Asia and Latin America, whereas increasing rates have been recorded in other areas of the world where limited or no screening programs are available, for example, Baltic and Eastern European countries as well as some African countries, like Zimbabwe and Uganda, where high quality cancer registry data are available. Persistent infection of the ano-genital tract with high-risk types of human papillomavirus (HPV) is a known, necessary cause of pre-invasive and invasive cancer of the cervix. Although the prevalence of HPV may vary substantially between countries and it is higher in the African continent, no clear gradient is observed with average levels of socioeconomic development of the country. In addition, although cervical cancer risk is consistently associated with low SES in screened and unscreened population, this excess risk does not seem to be explained by a different prevalence of HPV infection, as HPV prevalence does not vary substantially across SES levels within countries. Rather, differences in cervical cancer are likely due to differential access to health care, in particular to (organized or even opportunistic) screening. Vaccination against HPV infection is now available with follow-up data showing safety and efficacy in protecting against high-risk HPV types 16 and 18 (as well as low risk types 6 and 11) and related cervical lesions for over 10 years. A nonavalent vaccine has also being developed that can additionally protect against HPV types 31, 33, 45, 52, and 58. HPV vaccination may reduce cervical cancer disparities by reducing the prevalence of HPV in the population. However, the roll out of HPV vaccination programs has been particularly challenging in most LMICs because of the high cost of the vaccine, and major inequalities in uptake of HPV vaccination still exist even in HICs. Although HPV vaccination is an important preventive measure to reduce cervical cancer, its impact on cancer in the population will be visible only after few decades after its implementation. It is therefore still necessary to implement high-quality screening programs, such as screening based on HPV-testing. Cervical cancer screening and HPV-vaccination programs certainly have the potential to reduce dramatically the future rates of cervical cancer. However, disparities in the uptake of screening and of vaccine exist, with lower compliance and coverage for low SES groups and racial/ethnic communities.

It is thus of great importance for reducing cancer disparities the availability and access to health care, from early detection to treatment, which, particularly in LMICs, may suffer from major weaknesses and fail to provide sufficient health care services. There are marked differences in access to health care and health care outcomes between LMICs and HICs as well as people of low versus high SES. Poorer countries typically provide the worst quality of care and spend the least amount of national resources on health care. Even within HICs, access to high-quality cancer care and treatment is far from equal across different population groups. It has been shown that racial and ethnic minorities and individuals from lower socioeconomic groups are less likely to receive appropriate cancer treatment. Disparities in cancer screening participation by SES and ethnicity were observed in all types (organized and opportunistic) of breast and colorectal cancer screening programs. The lower participation in cancer screening in more disadvantaged populations may result in further disparities in the stage at diagnosis, being at more advanced stage among individuals from lower SES or from racial/ethnic minorities.

The largely reported socioeconomic or racial/ethnic disparities in early detection and treatment may be the consequence of structural barriers such as geographical distance to the health care facilities and access to transportation, education, lack of health insurance or other financial support. Women from minority racial/ethnic groups have been shown to have longer waiting times from the abnormal cytology screening result to an appointment for a final diagnostic procedure. Furthermore, among women with abnormal cervical cytology screening results, Hispanic, Asian, and black women have significantly lower odds of being scheduled for treatment and clinical recommendations given by physicians often differ for patients of different race/ethnicity or lower SES.

Lack of private health insurance was associated with lower participation in mammography and with worse quality of diagnostic services. Women with private health insurance have access to facilities with better quality of breast cancer screening such as for example, academic facilities, breast imaging specialist, and digital mammography. Digital mammography may be better at detecting cancerous lesions in younger women and women with extremely dense breasts. As black and Hispanic women tend to be diagnosed with breast cancer at an earlier age and with more aggressive breast cancer than their white counterparts, the differences in access to digital mammography may play an essential role for the disparities in the stage at diagnosis.

Although financial aspects and lack of adequate health insurance may play a significant role in disparities in cancer screening attendance, disparities in cancer screening participation exist not only in countries with private health insurance like the United States, where health insurance status can be a barrier for lower income groups, but also in countries with free health care like in the United Kingdom or the Netherlands suggesting that other risk factors are an important contributor to these disparities.

Individuals from disadvantage groups such as, for example, lower SES, racial/ethnic minorities or immigrants perceive cancer screening tests as threatening and difficult to accomplish, or may feel embarrassed, afraid of pain and do not recognize the benefits

of early detection. Furthermore, lack of confidence in dealing with the health system may also contribute to the disparities in cancer screening participation. Not attending cancer screening may also be related to inadequate knowledge of cancer, illiteracy, and linguistic or cultural obstacles. Low health literacy rates are commonly observed in the ethnic minorities, elderly, immigrants and nonnative speakers. Immigration status functions as a predictor of screening uptake independent of ethnicity or race. For instance, immigrants in the Netherlands were found to have lower participation in cancer screening probably due to the lack of the Dutch language proficiency. Cultural differences including lack of acceptance of care from male providers contributes to low rates of cervical cytology screening in immigrant women.

Economic Considerations

Disparities in cancer have also large economic consequences. These disparities raise the total costs of health care and social security and reduce labor productivity and the gross domestic product (GDP). Elimination of disparities in cancer incidence would also result in cost savings attributable to improved labor market outcomes, that is, fewer disability days, more hours worked and higher wages for working age adults. In the United States, the costs of cancer disparities across racial or ethnic groups and across socioeconomic groups were estimated and quantified. The annual costs of racial and/or ethnic disparities were $193 billion for premature death, $2.3 billion for direct medical costs and $471.5 million for lost productivity. The reduction in the number of new cancer cases would result in $2.3 billion savings on annual medical expenditure for persons with cancer if racial disparities in cancer incidence were eliminated. The elimination of poverty disparities in cancer incidence would lower health expenditure by $236 million nationally.

Reducing Cancer Disparities

Many cancers in LMICs and excess cancers among disadvantaged groups within countries are amenable to prevention through policies and strategies at addressing risk factors of cancer such as comprehensive tobacco control policies, strategies to address obesity, including supporting a healthy diet and increased physical activity, and policies for equitable access to high quality vaccination and screening programs. Access to affordable, appropriate, effective health care with a focus on cancer prevention, diagnosis and treatment is critical. There are vast disparities between HICs and LMICs, with many of the latter having weak health systems and very poor access to cancer treatment services. Ongoing global urbanization and disorganized growth of urban areas is leading to substantial challenges for health generally. Higher levels of overcrowding, reductions in physical activity, increased consumption of unhealthy food leading to higher rates of obesity, and higher rates of tobacco and alcohol consumption, are risk factors for many cancers, and these trends tend to affect the most disadvantaged groups. In addition, conflicts and other catastrophic events have led to the massive dislocation of entire populations, and the dissolution of structures and process to protect the health of those people. Lack of universal health coverage in many LMICs is a barrier both to development, and to addressing cancer outcome disparities. Progress toward meeting the health-related SDG of UHC will likely have a major impact in reducing cancer disparities both between and within countries. The evidence to support interventions to reduce inequalities within HICs is largely focused on single aspects of complex systems. However, comprehensive systems-level approaches are most likely to succeed. There is some evidence that this broad, organized approach may be effective in reducing cancer disparities within HICs. For example, socioeconomic disparities in breast and cervical cancer screening participation are less likely to be found in countries with organized screening programs, socioeconomic disparities are more marked in the US than in Canada where universal healthcare is available, and in New Zealand, ethnic disparities in cancer care and survival have reduced over time in the context of organized screening programs that include an explicit focus on reducing disparities.

Conclusion

There are major disparities in cancer incidence and mortality between and within countries that change over time and that are potentially modifiable. Social determinants influence cancer risk factors such as for example tobacco and alcohol consumption, exposure to infections, occupational exposures, unhealthy diet, physical inactivity and obesity, and have an impact on the access to appropriate early detection, treatment, and palliative care, and contributing to the large cancer disparities between certain population groups. Cancer disparities between and within countries may be reduced or even eliminated by effective health policies targeting the disadvantage populations but without appropriate action, however, cancer disparities are likely to increase. It is of great importance to collect high-quality scientific evidence on the magnitude of these disparities and increase the understanding and the knowledge on the many dimensions of the problem. Also, although social determinants affect all stages of the cancer continuum, from prevention to end-of-life care, it is prevention that has the largest potential for reducing cancer disparities in all settings. Therefore, there is the need to expand both research focus and investments in prevention. Furthermore, all interventions and cancer control programs, from prevention to treatment measures, should be explicitly designed to account not only for the overall effect, but also to avoid increasing cancer disparities, and ideally to decrease or eliminate them. This represents an attainable and ethical goal.

AML Acute myeloid leukaemia
APC Annual percent change
ARC Alcohol-related cancers
ASpR Age-specific incidence rate
ASR Age-standardized (world population) incidence rate
CI5 Cancer incidence in five continents
CR Crude cancer incidence rate
EBV Epstein-Barr virus
FOBT Fecal occult blood tests
FVRC Low intake of fruits and vegetables-related cancers
HICs High-income countries
HIV Human immune deficiency virus
HPV Human Papilloma virus
IARC International agency for research on cancer
LE Life-expectancy
LMICs Low- and middle-income countries
MIR Cancer mortality-to-incidence ratio
OORC Overweight and obesity-related cancers
PAF Population attributable fraction
PIR Physical inactivity-related cancers
PSA Prostate-specific antigen
TRC Tobacco-related cancers

Introduction

Cancer is the leading cause of death in many developed countries and is set to become a major cause of morbidity and mortality in the next few decades in every region of the world. Transition of cancer in population has led the world a steep increase in the burden of the disease. It is evident that the transition of cancer burden in populations is a continuous transformation process, more complex, dynamic and not unidirectional as some cancers are declining and others increasing or re-emerging.

From the GLOBOCAN series, cancer estimates for the year 1990 were a total of 8.1 million new cases, which is an increase of 37% from the year 1975 (5.9 million new cases) (annual growth rate 2.1%, faster than annual world population growth rate of 1.7%). In 2012, these were 14.1 million new cases, which is an increase of 139% from the year 1975. The common cancers such as lung (13.0%), breast (12.0%), colo-rectum (9.7%), prostate (7.8%), stomach (6.8%), liver (5.6%), cervix-uteri (3.8%), urinary bladder (3.1%), non-Hodgkin's lymphoma (NHL) (2.7%), leukaemia (2.5%), kidney (2.4%) and oral cavity (2.1%), constitute 72% of the total burden (14.1 million) of cancers world-wide in 2012. The increasing burden is a changing spectrum of common cancers, which differs from high-income countries (HICs) to low- and middle-income countries (LMICs).

Several mechanisms are involved in the transition of cancer in populations. Demographic transition such as reduction in mortality and fertility, thereby increased life-expectancy, changes the structure of the global population and, in turn, in the scale of the increased burden of cancer. Moreover, it is widely held that 80%–90% of cancer in populations are attributed to environmental and life-style factors. Thus, epidemiologic transition in the prevalence of risk factors such as tobacco and alcohol consumption, certain dietary habits, obesity, physical inactivity and infection has mainly attributed to the transition of cancer in populations. Further, transitions in the detection practices, cancer screening and access to care have all resulted increased burden of many cancers now.

This article assesses the transition of cancer in populations according to the changes in the demographic, epidemiologic and detection practices occurred during the past 30 years. This article has four sessions such as (i) transition of leading cancers, (ii) cancer incidence due to demographic transition, (iii) cancer incidence due to transition of epidemiologic risk factors, and (iv) cancer incidence due to transition in access to care. All the comparisons were made separately by HICs and LMICs and by gender.

The data sources were cancer incidence in five continents (CI5), published by the international agency for research on cancer (IARC) (http://ci5.iarc.fr) volumes VI to XI. A total of 8 HICs [Canada (British Colombia and Ontario), United States (SEER black and White), United Kingdom (England, New South Wales), Germany (Saarland), Denmark, Finland, Norway, and Australia (New South Wales)] and 9 LMICs [Brazil (Goiania), Colombia (Cali), Costa Rica, Ecuador (Quito), China (Hong Kong and Shanghai), India (Chennai), Philippines (Manila), Thailand (Chiang Mai), and Uganda (Kyadondo)] were chosen for assessing the transition of cancer in populations during the past 30 years. The various registries mainly from LMICs were chosen according to the availability and quality of data in the CI5, volumes VI to XI (Parkin et al., 1992, 1997, 2002; Curado et al., 2007; Forman et al., 2014; Bray et al., 2017).

Further data sources were, GLOBOCAN series (http://globocan.iarc.fr) for the year 1990 and 2012 (Parkin et al., 1999; Ferlay et al., 2013), incidence and mortality data of various HICs and LMICs from http://ci5.iarc.fr/CI5plus/pages/online.aspx, http://www-dep.iarc.fr/WHOdb/WHOdb.htm, https://data.worldbank.org for life-expectancy at birth of the various countries, https://data.worldbank.org, Giovino (2002) and Gilmore (2000) for smoking prevalence, http://apps.who.int/gho/data/node.main (A1026, A900A and A893) respectively for per-capita consumption of alcohol, prevalence in overweight and obesity and prevalence of insufficient physical activity. Comprehensive estimates of the population attributable fractions (PAF) of cancer cases or deaths due to various risk factors such as tobacco, alcohol, low intake of fruits and vegetable, overweight and obesity, physical inactivity and infection were used (Ezzati et al., 2002; Danaei et al., 2005, de Martel et al., 2012, 2017; Plummer et al., 2015, 2016). Further references used were IARC (1987) and US Surgeon General Report (2004) for tobacco; Hamajima et al. (2002), Baan et al. (2007), Connor (2017) for alcohol; IARC (2016) for overweight and obesity; Schmid and Leitzmann (2014) for physical inactivity; Oyebode et al. (2014) for low-intake of fruits and vegetables and Parkin (2011), Plummer et al. (2015), de Martel et al. (2015) for infection-related cancers.

The various measures used in this article are (i) crude cancer incidence rate (CR) to assess the burden; (ii) age-specific incidence rate (ASpR), to assess the peak age at incidence; (iii) mean age at diagnosis of various cancers; (iv) age-standardized (world population) incidence rate, to compare the rates with various countries (ASR); (v) annual percent change, to assess the transition in rates (APC); and (vi) cancer mortality-to-incidence ratio (MIR), to assess whether a region/country has higher or lower cancer mortality, normalized to its incidence.

We fitted linear regression to the natural logarithm of the estimated rates APC. JointPoint linear regression was used to determine trends in cancer incidence (APC), a statistical algorithm detects joint points, or points in time where the slope of the regression line significantly changes. Thus, the model described trends during different time segments. At each segment, trends in rates were measured using the estimated APC, which assumes that rates changes by a constant percentage each year. The JoinPoint regression software was used for the trend analysis.

The following session presents the changing spectrum in the burden of all and common cancers between HICs and LMICs by gender using GLOBOCAN series for the year 1990 and 2012.

Transition of Leading Cancers

Among males, a total of 4.3 million new cases (49% in HICs and 51% in LMICs) in 1990, these were 7.4 million new cases (44% in HICs and 56% in LMICs) in 2012. Among females, 3.8 million new cancer cases (equally distributed in HICs and LMICs) in 1990 and these were 6.7 million new cases (42% in HICs and 58% in LMICs) in 2012. The top 10 cancers among males in HICs (mainly prostate, lung, and colo-rectum: 51%) and in LMICs (mainly lung, liver, and stomach: 40%) accounted for nearly 80% of the burden and the same among females in HICs (mainly breast, colo-rectum, and lung: 50%) and in LMICs (mainly breast, cervix uteri, and lung: 43%) accounted for nearly 77% in 2012 (**Figs. 1**A, B and **2**A, B).

Among males in HICs, relative proportion and rank ordering increased for prostate and kidney cancers, no change in the proportion and rank ordering for colo-rectum and bladder cancers, and melanoma, emerged as the 8th leading cancer in 2012. Relative proportion decreased for lung and stomach cancers, no change in the proportion, rank ordering declined for NHL, pancreas and liver. Oral cavity was not a leading site in 2012. Among males in LMICs, relative proportion increased for prostate, lung and colo-rectum, with increase in the rank ordering for prostate. Relative proportion decreased for stomach, esophagus, oral cavity and leukaemia (**Fig. 1**A and B).

Among females in HICs, relative proportion increased for breast, lung, corpus uteri, pancreas and thyroid cancers. Like in males, melanoma emerged as the 9th leading cancer (3.2%) in 2012. Relative proportion decreased for colo-rectal and stomach cancers. Cervix-uteri cancer was not a leading site in 2012. Among females in LMICs, relative proportion increased for breast, colo-rectum, lung and corpus-uteri cancers. Like in HICs, thyroid cancer emerged as the 9th leading site (3.6%) in 2012. Relative proportion decreased for cervix-uteri and stomach cancers (**Fig. 2**A and B).

Among males in the selected HICs, 30 years ago, lung was the leading site, which is replaced by prostate cancer. Lung is still the 2nd common cancer in HICs. Currently, colo-rectum/bladder shared the 3rd, bladder/colo-rectum/NHL/kidney, shared the 4th and NHL/bladder/esophagus/liver/kidney shared the 5th position in the selected HICs. Among the five leading cancers, kidney is an emerging cancer in the selected HICs. Among males in the selected LMICs, 30 years ago, stomach/lung was the leading cancer sites, which is replaced by prostate/lung cancer. Stomach/liver shared the 2nd, liver/prostate/colo-rectum/lung/NHL shared the 3rd; colo-rectum/lung/stomach/NHL shared the 4th position and NHL shared the 5th position in the various regions among the selected LMICs (**Table 1**).

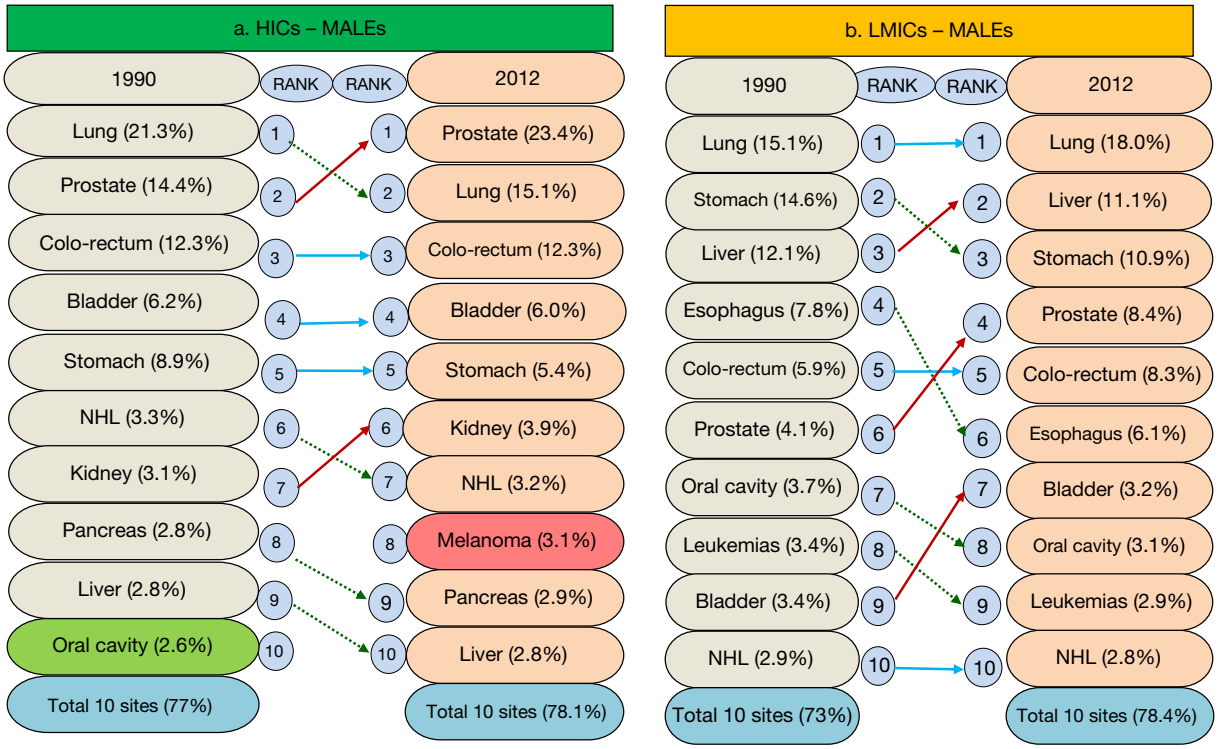

Fig. 1 Transition in rank ordering and relative proportion of leading cancer sites (1990 vs. 2014) in HICs and LMICs: males.

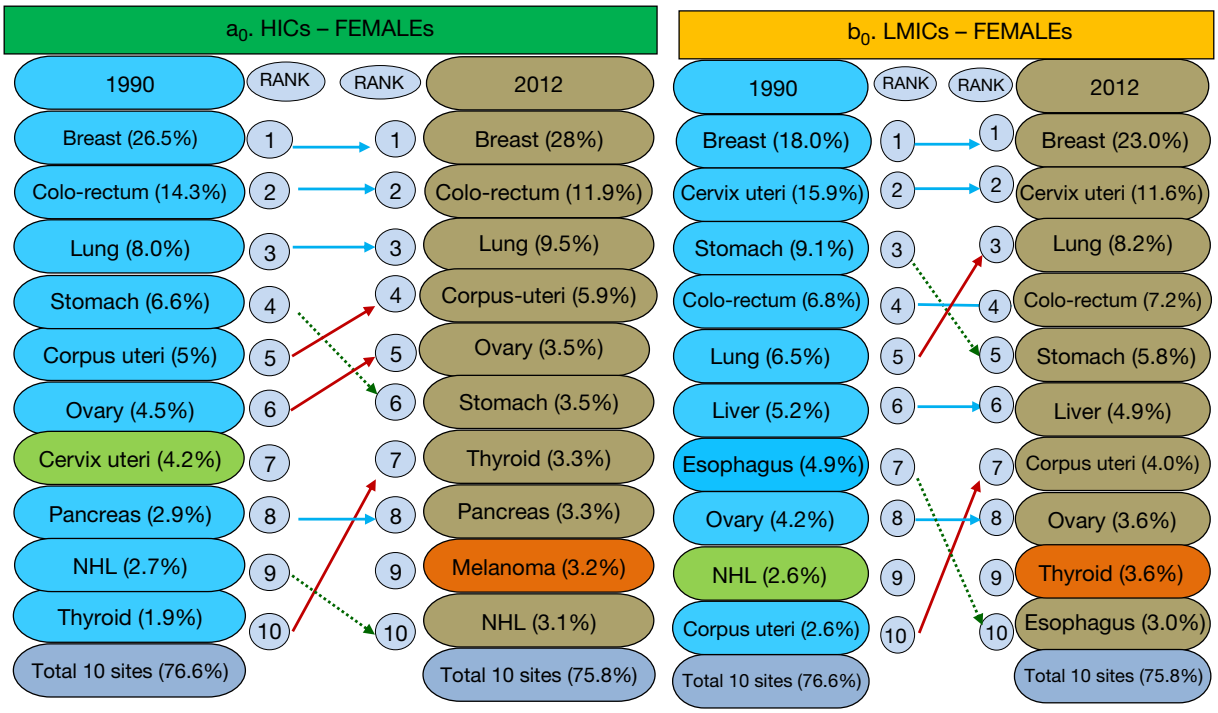

Fig. 2 Transition in rank ordering and proportion of leading cancer sites (1990 vs. 2014) in HICs and LMICs: females.

Among females in the selected HICs, breast cancer remains the leading cancer site in the past 30 years. Currently, lung/colo-rectum shared the 2nd, colo-rectum/corpus-uteri shared the 3rd, corpus-uteri/thyroid, shared the 4th and NHL/ovary shared the 5th position in the selected HICs. The emerging cancer site is thyroid in HICs. Among females in the selected LMICs, cervix uteri/lung cancers were the leading sites in 30 years ago, which is replaced by breast cancer now. Cervix-uteri/thyroid shared the 2nd and 3rd, stomach/liver shared the 4th and colo-rectum shared the 5th position in majority of LMICs (Table 1).

Source: https://data.worldbank.org/indicator, Parkin et al. (1992, 1997, 2002), Curado et al. (2007), Forman et al. (2014), Bray et al. (2017).

In summary, burden of cancer has been increasing worldwide with higher relative proportion in LMICs for the last three decades and its transition is not uniform between HICs and LMICs. The emerging cancers among males in HICs are prostate, colo-rectum, kidney and melanoma and in LMICs are lung, liver, colo-rectum and prostate. Among females in HICs, the same are breast, lung, corpus-uteri, pancreas and thyroid and in LMICs are breast, colo-rectum, lung, corpus-uteri and thyroid.

The following session presents in demographic transition and cancer incidence rates (CR, ASpR and mean age) by gender in HICs and LMICs.

Demographic Transition and Cancer Incidence

Demographic transition over the past two or more decades has left the world struggling with the issues of an aging population. Life-expectancy, an estimate of how long a person can expect to live, is a statistic that applies to populations. Changes in life-expectancy can occur through changes in overall mortality rate in a population over time as well as shifts in relative mortality rates in particular age-groups within the population. Increased life-expectancy is leading to a major change in the structure of the global population. As it increases, so does the certainty that people will become more and more prone to develop cancer that are more common among older age groups.

Life-Expectancy and Cancer Incidence

Life-expectancy has been increased in both HICs and LMICs (Fig. 3). However, the current life-expectancy is <70 years in most of the LMICs and is as similar they were in HICs 30 years ago. Wide range in CRs (per 100,000 person-years) of all sites was observed in LMICs, the CRs and the common cancers such prostate, breast, colo-rectum in LMICs were only one-fourth or less than the rates, what we observed in HICs. CRs for lung cancer among males in HICs showed declining trend, contrary to this, CRs among females

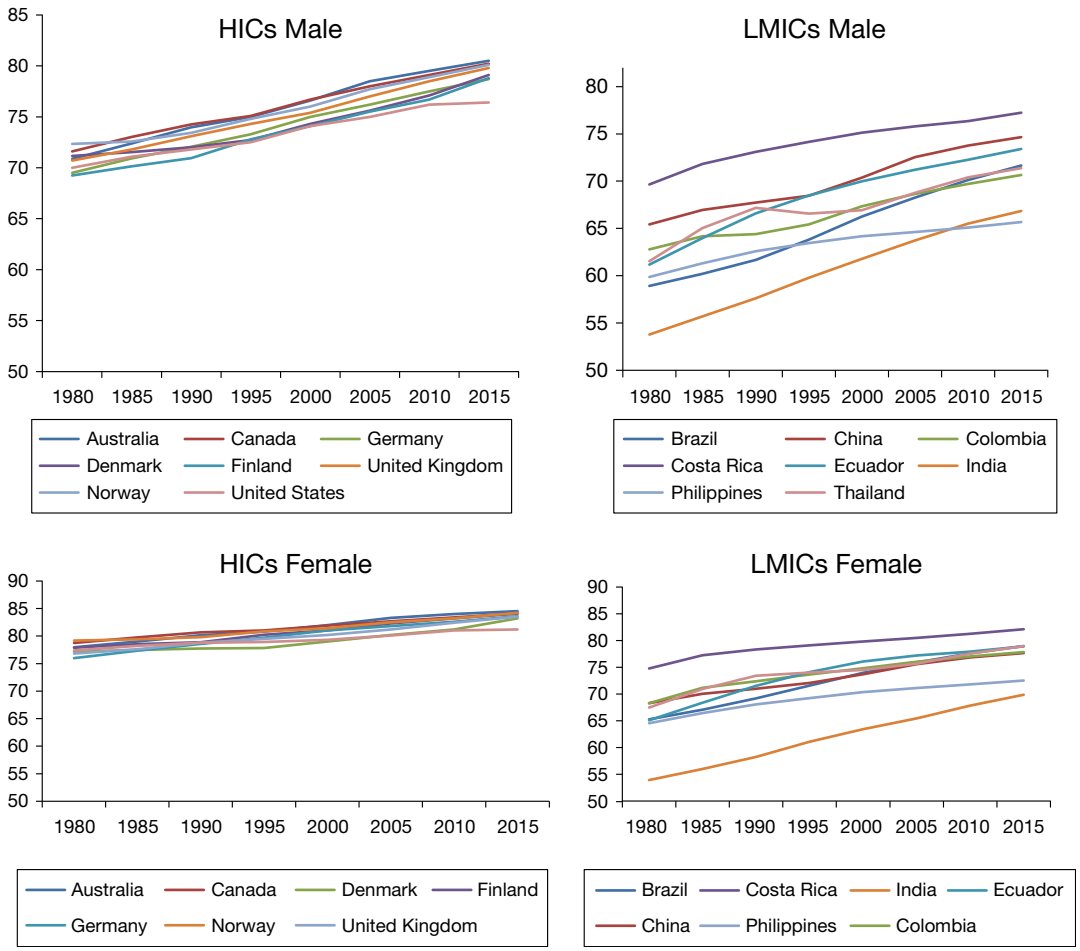

Fig. 3 Demographic transition (life-expectancy) (1980 vs. 2015) in selected HICs and LMICs.

showed increasing trend. CRs for liver cancer increased in most of the LMICs in males. Increased life-expectancy did not affect for stomach and cervix-uteri cancers as it showed a declining trend in HICs and most of the LMICs (Tables 2 and 3).

Even though the CRs of all sites and the common cancers were comparatively low in LMICs, the percent change in the rates was much higher in these countries compared to the HICs. Since the cancer registry data collection system is active, in most of the LMICs, it is possible that the case-ascertainment might not be complete and thereby low incidence rates in the early periods and later on improvements in the data collections system in LMICs, the rates in the initial period might be under-estimated and thus observed higher rate of increase in LMICs.

Age is an established risk factor in the occurrence of many cancers. The CRs increased with age for most cancers worldwide. The ASpRs of prostate cancer increased with age and reached to a peak age at incidence in 70s and then the rate decreased in both HICs and LMICs. The peak ASpR for breast cancer is in 65–70 years. For colo-rectal cancers, it increased with age with peak in the 75+ age group in both genders in HICs and LMICs. Contrary to this, the peak ASpR of cervix-uteri cancer is in late 30s in HICs where as it is in late 60s in LMICs. The peak ASpR of oral-cavity cancer is in late 60s in both HICs and LMICs (Fig. 4).

Transition in Age at Diagnosis of Cancer

Mean age at diagnosis of all cancer sites together has increased in HICs and LMICs with higher increase in LMICs in both genders in 2008–12. However, the mean age at diagnosis is much lower in LMICs than HICs in both genders. In the selected HICs, it is >66 years in males and >61 years in females (except United States, SEER black) where as in most of the LMICs, it is <63 years in males and <59 years in females (except China) in 2008–12. A downward shift in the mean age at diagnosis for prostate cancer in most of the HICs, and a few LMICs for colo-rectal cancers in the United States in both genders and for stomach and cervix uteri cancers in a few LMICs and an upward shift in the mean age at diagnosis for corpus-uteri cancers in HICs (except United States and Canada), for lung cancer in most of the HICs and LMICs in both genders (Tables 4 and 5).

Upward shift in the mean age at diagnosis of cancers is closely associated with the increase in the life-expectancy and thereby growth in the older age population and downward shift in the mean age, could be due to the availability of early detection programs. Another possible reason for this is that the cancer registry data collection system is active in majority of cancer registries in LMICs, the age of the patient is collected only the reporting age and not linked with their date of birth. Thus there is a possibility of incorrect reporting in the age at incidence.

Epidemiologic transition reflects shifts in cancer incidence that has taken place in the vast majority of countries over the past three to four decades. Transitions in many cancers are accompanied by changes in exposure due to certain factors. Adoption of a life-style characterized by a more "industrialized" diet, rise in obesity, chronic physical inactivity will attenuate the expected gains in life-expectancy. The following session deals with the comparison of the transition of various established risk factors and related cancers in the HICs and LMICs.

Epidemiologic Transition and Related Cancers

A link between a particular risk factor and cancers has been established. Comprehensive estimates of the fractions of cancer cases or deaths attributable to various risk factors (population attributable fraction) such as tobacco, alcohol, low intake of fruits and vegetable, overweight and obesity, physical inactivity, and infection have been made separately by HICs and LMICs. In the past three to four decades, a lot of changes in the prevalence of these risk factors and there by a lot of transition in the related cancers have been taking place world-wide.

Tobacco

PAF due to tobacco and related cancers

Of the several causes investigated for cancer, the use of cigarette smoking and smokeless tobacco has shown strong and consistent associations with cancer at several sites in the body. During the past 30 years, the number and strength of the conclusions on active smoking and exposure to second-hand smoke as a cause of cancer have increased markedly, moving from the specific causal conclusions on lung cancer in males. The top tobacco-related cancers (TRC) (exposure due to active and passive) include lung, oral cavity, other pharynx (oropharynx and hypopharynx), larynx, esophagus, and urinary bladder. Other than these cancers, the International Agency for Research on Cancer (IARC) monograph (1987) stated that tobacco smoking is associated with stomach, liver, pancreas, kidney, cervix-uteri, and acute myeloid leukaemia (AML). The US Surgeon-General's report for 2004 stated that the evidence is sufficient to infer a causal relationship between smoking and cancer of the lung, oral-cavity, larynx, esophagus, urinary bladder, kidney, stomach, pancreas, cervix-uteri, and AML. The population attributable fraction (PAF) of the various TRCs in HICs and LMICs varied markedly. The PAF for all TRCs (mouth, pharynx, esophagus, stomach, liver, pancreas, lung, cervix uteri, bladder, and leukaemia) together in HICs is 29% and in LMICs is 18%, the same for lung in HICs is 86% whereas the same in LMICs is 60%. Similarly, the PAF for esophagus/larynx/other pharynx/oral cavity in HICs is 71% and the same in LMICs is 37% (Fig. 5A).

Table 2 Life-expectancy and crude incidence rates of all three leading sites (1983–87 to 2008–12) of the selected HICs by gender

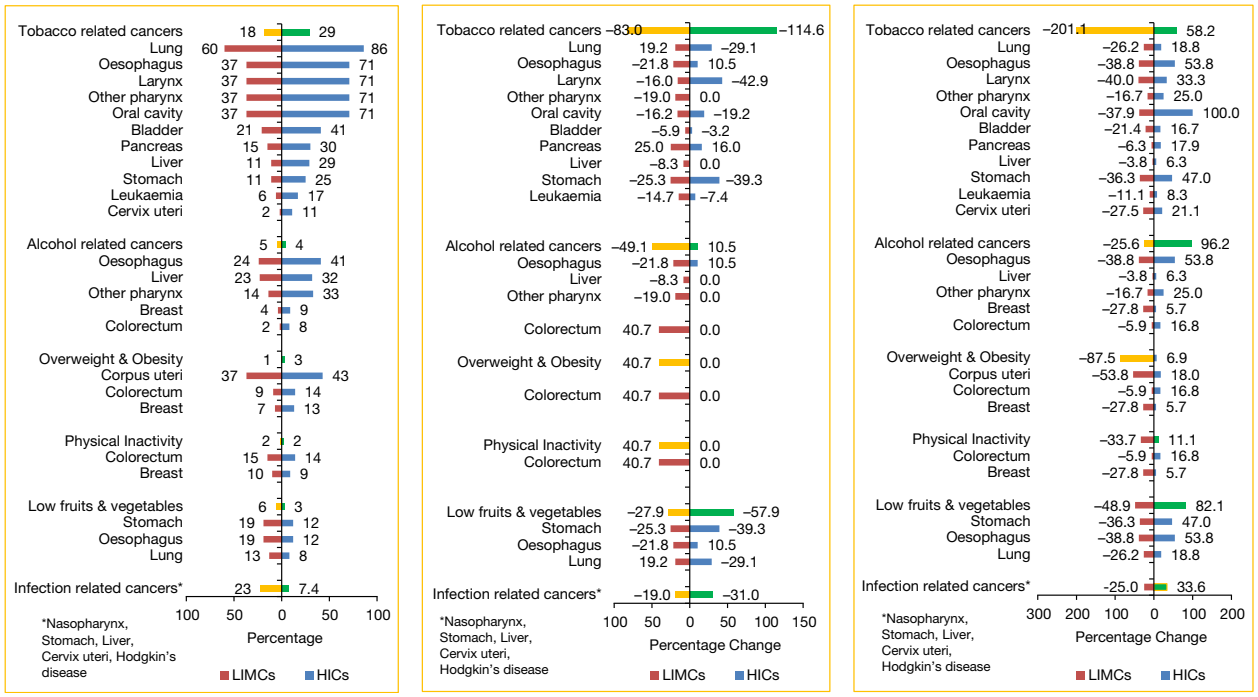

Fig. 5 Population attributable fraction of cancers according to risk factors (tobacco, alcohol, overweight, obesity, physical inactivity, low fruits, and vegetables and infection in 2011 and percentage changes (1983–87 vs. 2008–12) in the respective cancers by gender.

Transition in cigarette smoking and smokeless tobacco and related cancers

In the past 30 years, TRCs declined among males in both HICs (% change: 115%) and LMICs (% change: −83%). It is counteracted by a worrisome increase in among females in HICs (% change: 58%) (Fig. 5B and C). Due to public health effort during the past three to four decades, tobacco prevalence has been declined in many countries (Fig. 6), but still it is the highest risk factor for many cancers. APC for TRCs such as lung, oral cavity, other pharynx, larynx, esophagus, and bladder cancers with a high PAF due to tobacco and APC for these sites pooled, were estimated for the selected HICs and LMICs by gender (Table 6).

Among males, the pooled APC (lung, oral cavity, other pharynx, larynx, esophagus, and bladder) for TRCs, declined, significantly in Canada (Ontario), Denmark, Finland, Germany, United Kingdom (England), and Australia (New South Wales). All the major TRC sites (lung, oral cavity, other pharynx, and larynx) with high PAF (Fig. 5A) due to tobacco use, declined significantly among males in the selected HICs (Table 6). These trends clearly reflect the decline in cigarette smoking since early 80s in these countries (Fig. 6A). Contrary to this, the pooled APC for TRC in females showed an increasing trend with significance in Norway, Germany, Denmark, Finland, United Kingdom, and Australia. However, lung, other pharynx, oral cavity, and larynx declined in all the selected HICs significantly in Canada, United States, United Kingdom, and Australia (Table 6). Decline in oral cavity cancer is due to the encouraging decline in the use of smokeless tobacco use. Even though smoking prevalence declined (Fig. 6) in all the selected HICs, increased incidence of bladder cancer was observed in Norway (significant among males), Finland and Germany (Table 6), which could be due to incidental detection.

The incidence of esophageal cancer did not decline but actually increased significantly in Norway, Denmark, United Kingdom, and Australia. The interpretation of these trends is unclear given that the two types of esophageal cancer [squamous cell carcinoma (SCC) and adenocarcinoma (AC)] have very distinct patterns and risk factors as SCC is more smoking-related. Since the data do not distinguish between the two histological types of esophageal cancer, trends are presented for all esophageal cancers combined and this could be the reason for not being observed a declining trend for this disease.

Pooled TRC declined in both genders among the selected LMICs significantly in Colombia (Cali), Costa Rica, China (Hong Kong and Shanghai), Philippines (Manila), and Thailand (Chiang Mai). In contrast to this, oral cavity, other pharynx, and bladder cancers increased significantly among males in Brazil. Colombia, Philippines, and Thailand showed declining trend in most of the TRCs, with significant decline in lung and esophagus in both genders.

Alcohol

PAF due to alcohol and related cancers

Consistent use of alcohol is linked to other pharynx, breast, esophagus (SCC), liver, colo-rectum. Unlike tobacco, the estimated PAF due to alcohol for all related cancers (ARCs) together in both HICs and LMICs is very low. PAF due to alcohol for ARCs of individual

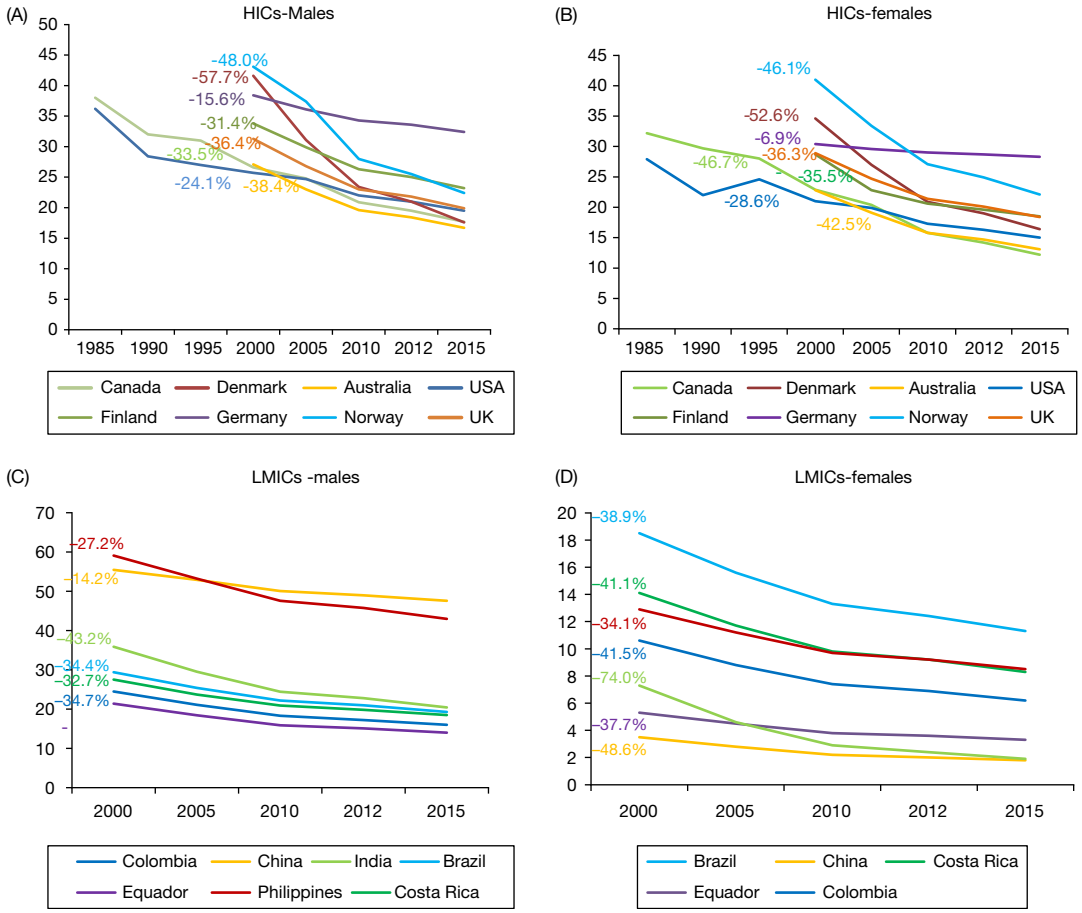

Fig. 6 Transition in tobacco prevalence (% change) (1985–2014) in selected HICs and LMICs by gender.

sites between HICs and LMICs varied markedly, the PAF for esophagus in HICs is 41% and in LMICs is 60%, for liver in HICs is 32%, in LMICs 23% and other pharynx in HICs is 33% and in LMICs is 14% (Fig. 5A).

Transition in alcohol consumption and related cancers

The percentage change in ARCs decreased in both HICs and LMICs among males, with a worrisome increase among females mainly in HICs (% change: 96%) from 1983–87 to 2008–12. ARCs such as esophagus, other pharynx and breast declined in LMICs in both genders, whereas these sites showed an increasing trend among females mainly in HICs [% change from 1983–87 to 2008–12 for esophagus: 96% and other pharynx: 25%]. Increased change (%) for colo-rectal cancers was observed among females in HICs (17%) and among males in LMICs (41%) (Fig. 5B and C).

Almost all the country/region showed significantly declining trend in the pooled ARCs in both HICs among males except Denmark, United Kingdom (England NSW) and Brazil (Goiania). However among females, in all the selected European countries (Denmark, Germany, Norway, United Kingdom, England) and Australia in HICs and Brazil (Goiania), Costa Rica and Uganda (Kyadondo) in LMICs showed significantly increasing trend in the pooled ARCs (Table 7). Significantly, high increasing trend, for liver cancer among males in Canada (BC), Canada (Ontario), United States (SEER, Black and White), Germany (Saarland), Australia, Brazil, Colombia (Cali), Ecuador (Quito), and India (Chennai) was observed. Prevalence of alcohol consumption has increased drastically in LMICs (Fig. 7B). Among females, significantly increasing trend in the ARCs was observed in all the selected European countries (Denmark, Finland, Germany, Norway, United Kingdom, England), Australia, Brazil (Goiania), Costa Rica, and Uganda (Kyadondo) (Table 7). APC related to colo-rectum and breast cancers will be provided in the physical inactivity session.

Overweight and Obesity

PAF due to overweight and obesity and related cancers

Changing dietary patterns are thought to be the contributing to the risk in overweight and obesity. Increasing obesity rates in HICs are confirming the epidemiological transition as the epidemic leads to an increase in the risk of many cancers such as corpus uteri, colo-rectum, breast and esophagus (adenocarcinoma). The picture is more nuanced in LMICs, where there are signs of a protracted

[b]Borderline significance.

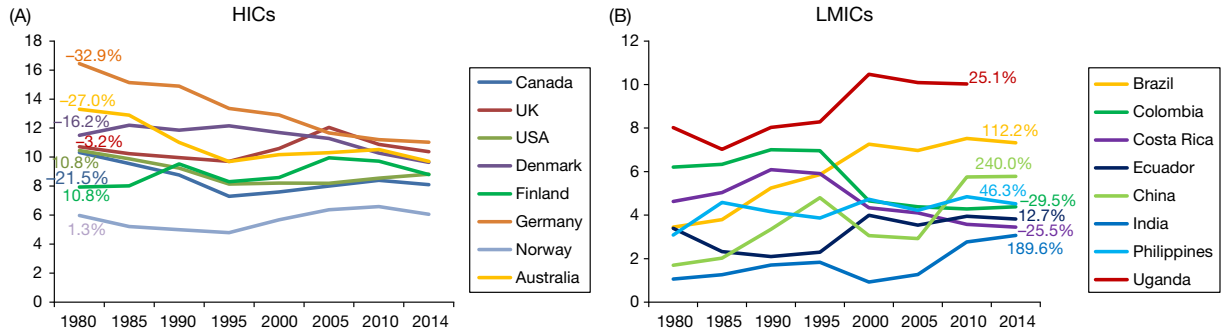

Fig. 7 Transition in alcohol prevalence (% change) (1980-2014) in selected HICs and LMICs.

transition in the burden of cancer due to increased rates in over weight and obesity. The estimated PAF of related cancers (corpus uteri, colo-rectum and breast) due to overweight and obesity in HICs and LMICs is minimal. The PAF for corpus uteri cancer due to overweight and obesity is 43% in HICs and the same in LMICs is 37% (Fig. 5A).

Transition in the prevalence of overweight and obesity and related cancers

Increased % change in overweight and obesity-related cancers (OORCs) (colo-rectum, breast and corpus uteri) was observed in HICs in both genders (Fig 5A and B). As esophagus (adenocarcinoma), could not be separated, not included for the pooled analysis. APC for OORCs due to overweight and obesity were estimated for the selected HICs and LMICs (Table 8). Most of the European countries showed significantly increasing trend in the pooled OORCs in both gender [Denmark, Finland, Germany (Saarland), Norway, United Kingdom (England NSW), and Australia]. All the selected LMICs showed increasing trend in both gender (except Philippines (Manila) females and Thailand (Chiang Mai) males). The APCs were >2% in most of the LMICs [Brazil (Goiania), Colombia (Cali), Costa Rica and Ecuador (Quito), China (Shanghai), and India (Chennai)]. Increase in the OORCs is due to the increase in the prevalence in overweight and obesity during the past two to three decades in many countries (Fig. 8). As SCC and AC esophagus could not be separated, excluded in the estimation of pooled APC due to OORC.

Significantly increasing trend for corpus-uteri cancer in many selected HICs and LMICs was observed [Canada (BC and Ontario), United States (SEER, Black and Whites), Germany (Saarland), Australia, Brazil (Goiania), Colombia (Cali), Ecuador (Quito), and India (Chennai)] (Table 8).

Physical Inactivity

PAF due to physical inactivity and related cancers

Physical activity is a key determinant of energy expenditure and thus fundamental to energy balance and weight control. Rapid technological advancements has occurred hand in hand with widespread urbanization, the rise of more service-based economies, significant changes to transportation system and new opportunities for sedentary leisure pursuits (e.g., television, mobile phone, and other electronic media). Physical inactivity is strongly linked to colo-rectal and breast cancers. The estimated PAF of related cancers due to physical inactivity in both HICs and LMICs is 2%. The PAF for colo-rectum due to physical inactivity is 14% in HICs and 15% in LMICs, the same due to breast is 9% in HICs and 10% in LMICs (Fig. 5A).

Transition in the prevalence of physical inactivity and related cancers

Percentage change in rates between the period 1983–87 and 2008–12 among females in HICs are 11% and among males in LMICs are 41% (Fig. 5B and C). Physical inactivity-related cancers (PIRCs) (colo-rectum and breast) increased in both HICs (except in Canada and United States, males) and LMICs in both genders (Table 8).

Most of the European countries showed significantly increasing trend in the pooled PIRCs in both gender (Denmark, Finland, Norway, United Kingdom (England NSW), and Australia. All the selected LMICs showed increasing trend in females. The significant APCs were in Brazil, Colombia, Costa Rica, Ecuador, China Hong Kong, China (Shanghai), India, Thailand, and Uganda.

Increase in the PIRCs is due to the increase in the prevalence physical inactivity during the past two to three decades in many countries. The prevalence of insufficient physical activity rose according to the level of income. HICs had more than double the prevalence compared to LMICs for both men and women, with 41% of men and 48% of women being insufficiently physically active in HICs as compared to 18% of men and 21% of women in LMICs (Fig. 9).

Nutrition

Nutritional transition is characterized by a shift away from indigenous staple grains, local legumes, fruits and vegetables and limited foods of animal origin in favor of more animal based food products and processed food high in saturated fats and sugar. Low-intake of fruits and vegetable-related cancers include esophagus (SCC), stomach, and lung.

Table 8 Transition (average annual percent change, APC) of obesity, physical inactivity and low intake of fruits and vegetables-related cancers (ARCs) in selected HICs and LMICs by gender

[a]Statistically significant at 5% level.

[b]Borderline significance.

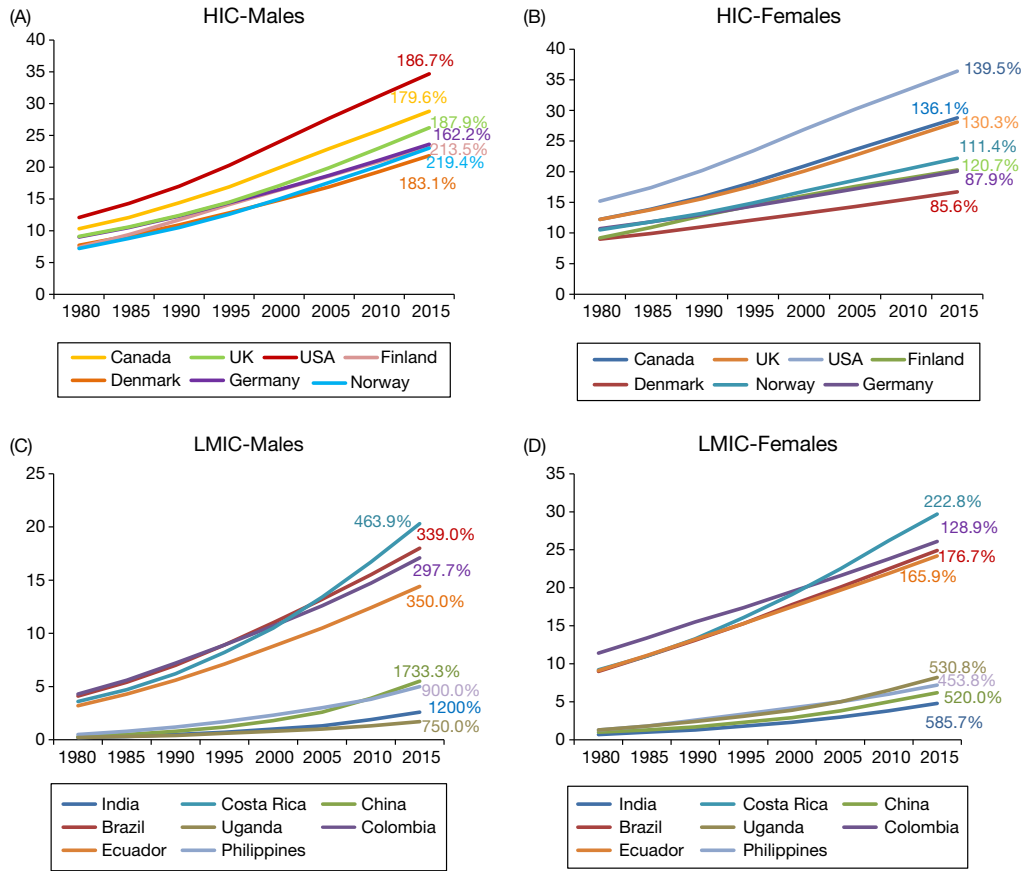

Fig. 8 Transition in overweight and obesity prevalence (% change) (1980–2015) in selected HICs and LMICs by gender.

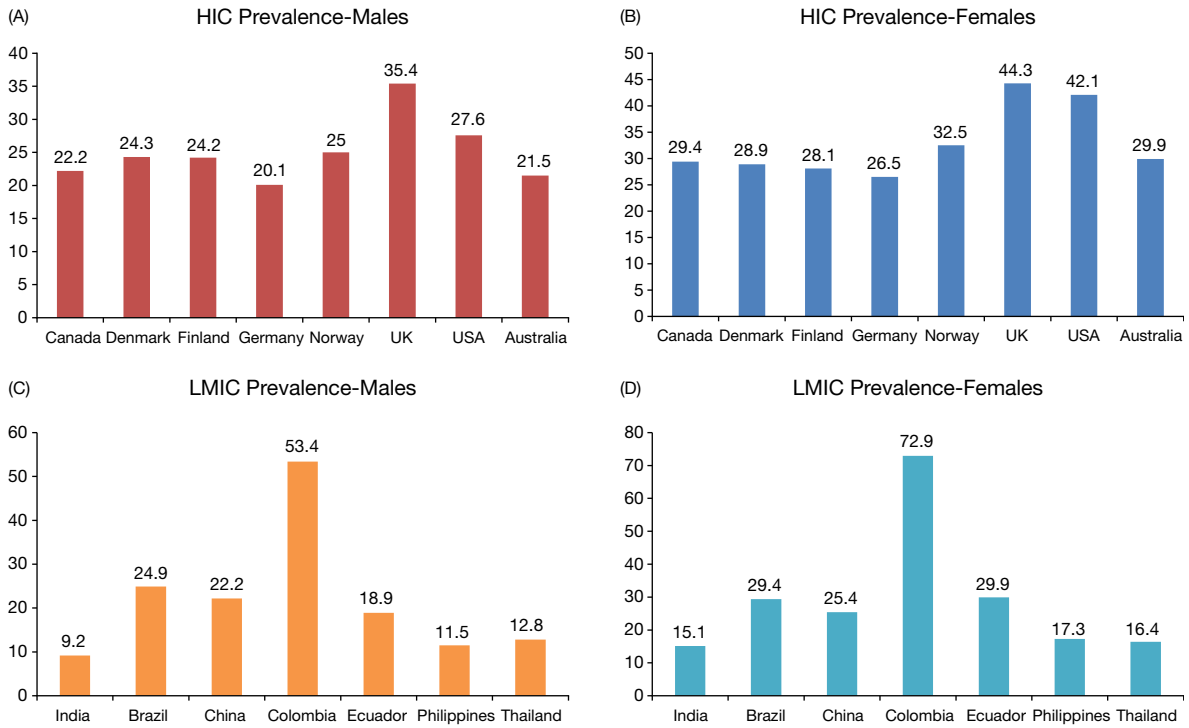

Fig. 9 Prevalence in physical inactivity (2010): selected HICs and LMICs by gender.

PAF due to low intake of fruits and vegetables and related cancers

The estimated PAF for related cancers (esophagus, stomach and lung) due to low intake of fruits and vegetables for both stomach and esophageal cancers are 19% in LMICs and the same in HICs is 12% and the same for lung is 13% in LMICs and 8% in HICs (Fig. 5A).

Transition in the prevalence and related cancers

Low intake of fruits and vegetables-related cancers (FVRCs) declined in both HICs and LMICs in males and among females in LMICs. Percentage changes in rates between the period 1983–87 and 2008–12 are in males −58% in HICs, −28% in LMICs in females, −49% in females (Fig 5B and C). Pooled FVRCs (included stomach, esophagus and lung) declined significantly in most of the HICs and LMICs in both gender (Table 8). Decline in the FVRCs are due to the increased consumption in the prevalence of fruits and vegetables during the past two to three decades in many countries.

Infection

PAF due to Low Intake of Fruits and Vegetables and Related Cancers

Infection-related cancers include mainly cervix-uteri, liver, Hodgkin's disease, nasopharynx, stomach, and Kaposi's sarcoma. The established risk factors for cervix uteri is infection with the human Papilloma virus (HPV), transmitted through sexual intercourse, for liver cancer, chronic liver infection with hepatitis B or hepatitis C virus, for Hodgkin's disease, infection with the Epstein-Barr virus (EBV) or the human immune deficiency virus (HIV), for nasopharyngeal carcinoma, infection with the EBV and for stomach cancer, infection with helicobacter pylori. The estimated PAF due to infection for related cancers (cervix-uteri, liver, Hodgkin's disease, nasopharynx, stomach, and Kaposis sarcoma) is much higher in LMICs (23%) than the HICs (7.4%) (Fig. 5B and C).

Transition in the prevalence of infection and related cancers

Infection-related cancers (IRCs) declined in both HICs and LMICs in males and among females in LMICs. Percentage changes in rates between the period 1983–87 and 2008–12 are −31% in males in HICs, and in LMICs −19% in males and −25% in females (Fig. 5B and C). Pooled IRCs (nasopharynx, stomach, liver, cervix uteri, and Hodgkin's disease) declined significantly in most of the HICs and LMICs in both gender (Table 8). Decline in the IRCs could be due to the decline in the prevalence of various infections in many countries through the vaccination programs and public health effort during the past two to three decades.

In summary, transition in economic status and life-style modification happened in many countries reflected reduction in infection-related cancers, but there is a drastic increase in cancer burden due to epidemiologic transition. Among males in HICs have experienced a decrease in tobacco prevalence and related cancers, but among females in HICs and males in LMICs, such cancers are emerging as its prevalence has not been declined much. In addition to this, the increased prevalence of alcohol consumption, overweight, obesity and physical inactivity in HICs and in many LMICs, the burden of cancer has been increased with higher rate of increase in LMICs.

Increased use of imaging and other sensitive techniques in various fields of medicine, has led to an increased frequency of incidental cancer lesions. The following session presents transition of cancer due to changes in the detection practices.

Transition in the Cancer Detection

Many cancers such as prostate, colo-rectum, breast, cervix-uteri, oral cavity can be detected in early stages. For example, widespread use of prostate-specific antigen (PSA) test, and the rapid increase in the incidence of prostate cancer in early stages; more sensitive techniques to detect small thyroid tumors, before clinical signs are present and the drastic increase in thyroid cancers, high-sensitivity fecal occult blood tests (FOBT) and increase in the incidence of colo-rectal cancers in early stages, Pap-smear test for detection of cervix-uteri cancers in pre-malignant stages. There is wide difference in the cancer detection practices between HICs and LMICs. GLOBOCAN series indicated that mortality rates for all cancers are only 8%–15% higher in more developed countries, even though the incidence rates are more than four times higher in HICs than LMICs. This disparity is primarily due to the differences in the in-equalities in the detection and survival between HICs and LMICs.

There is a reduction in the MIR values for several early detectable cancers in both HICs and LMICs in 2012 compared to 1990, but the values in LMICs are much higher than HICs (Fig. 10), which indirectly indicated that the proportion of late stage at diagnosis is much higher in LMICs.

Conclusion

Burden of cancer is increasing worldwide and over the next few decades, the majority of the cancer burden will occur in LMICs, as these regions/countries continue to experience rapid changes in urban environment, technological advancement, industrialization and material prosperity. Transition in economic status and life-style modification happened in many countries reflect reduction in infection-related cancers, but there is a drastic increase in cancer burden due to epidemiologic transition. HICs among males have experienced a decrease in tobacco prevalence and related cancers, but not much among females in HICs and males in LMICs. The

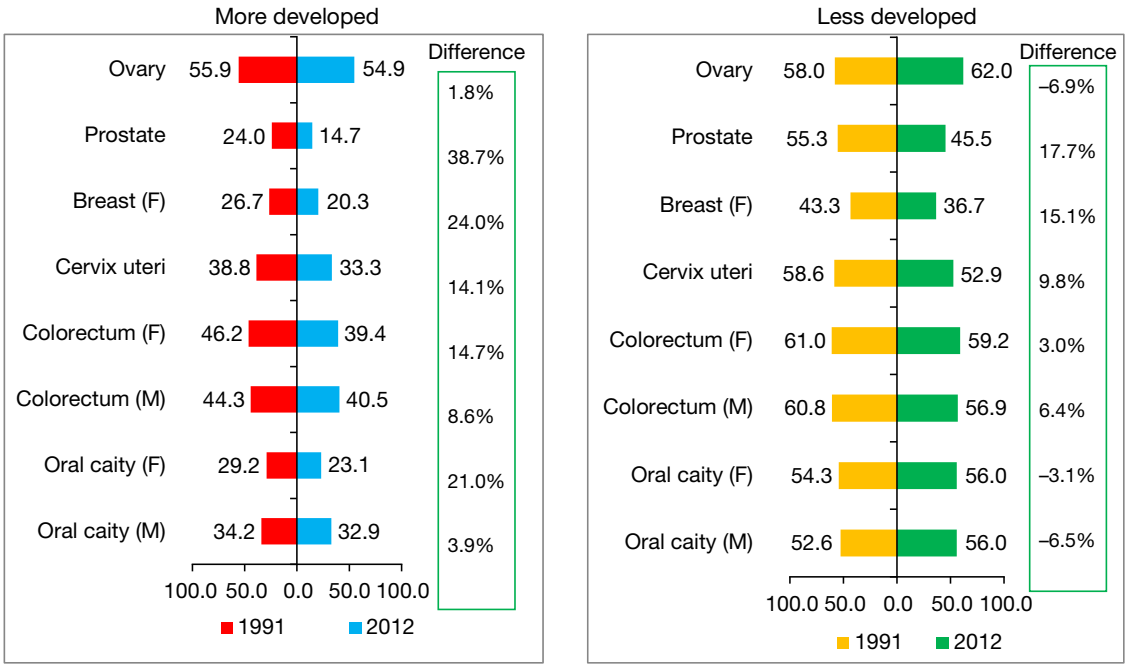

Fig. 10 Transition in mortality-to-incidence ratio (1990 vs. 2012).

future burden of cancers will already expect to be large due to demographic effects. In addition to this, with the tobacco epidemic, increase in alcohol consumption, increased prevalence in overweight, obesity and physical inactivity, the burden will be very heavy with higher rate of increase in LMICs. Continued public health efforts for the increasing prevalence in overweight, obesity, physical inactivity and alcohol consumption in addition to the tobacco prevention and control are needed especially among females to reduce the cancer burden.

Higher MIR values for several cancers in LMICs indicated that the proportion of late stage at diagnosis is much higher in LMICs. For equitable access to cancer treatment for patients in less-developed nations, proper system should be developed to ensure that the patients complete treatment and are on regular follow-up.

A substantial portion of cancer cases and deaths could be prevented by broadly applying effective prevention measures and the use of early detection tests. It is high-time that cancer should be included as a notifiable disease in all countries even in LMICs and the burden in terms of both incidence and mortality needs to be assessed more accurately. Region/country-wise relevant "tool kit" has to be set up for down-staging and effective cancer control program.

Cancer in Sub-Saharan Africa

Sub-Saharan (SS) Africa consists of all African countries that are fully or partially located south of the Sahara Desert. It includes 48 countries and, in 2016, its population consisted of almost 1 billion people, of which 47% live on less than $1.25 a day. However, the United Nations predicts that, in 2050, it will be between 1.5 and 2 billion people.

Burden of Cancer

In SS Africa, the overall incidence of cancer (all cancers, excluding nonmelanoma skin cancer) is in general much lower than in more developed regions; among the latter, the estimated incidence rates in 2012 were nearly ninefold higher in men and fivefold higher in women. This primarily reflects differences in countries' age distributions, with SS Africa presenting a lower proportion of the population in the older age-groups, among whom most cancers tend to be more frequent. However, even the age-standardized rates, using the world standard population (ASIR-W), were more than twice higher in more developed regions. These differences are depicted in Fig. 1. The overall cancer incidence is also heterogeneous among SS African countries; for example, in South Africa, the incident rates (per 100,000) were 148.7 in men and 156.5 in women, yet they were below 60 in several other countries, such as Angola, Djibouti, or Tanzania.

Limited access to diagnosis contributes to lower incidence rates in many SS African settings due to underdiagnosis. This is illustrated by a report of a steep increase in the incidence of stomach cancer in rural Kenya soon after an endoscope became available, or by the fact that the 2006 report of the population-based registry of Beira, in Mozambique, referred no cases of prostate cancer. Further, overdiagnosis of breast and prostate cancers is substantially lower than in developed countries, since mammography screening and prostate specific antigen (PSA) testing are available to a much lesser extent in SS Africa, and are also unevenly distributed throughout the region. Risk factors such as tobacco smoking, obesity or low parity have remained infrequent in many SS

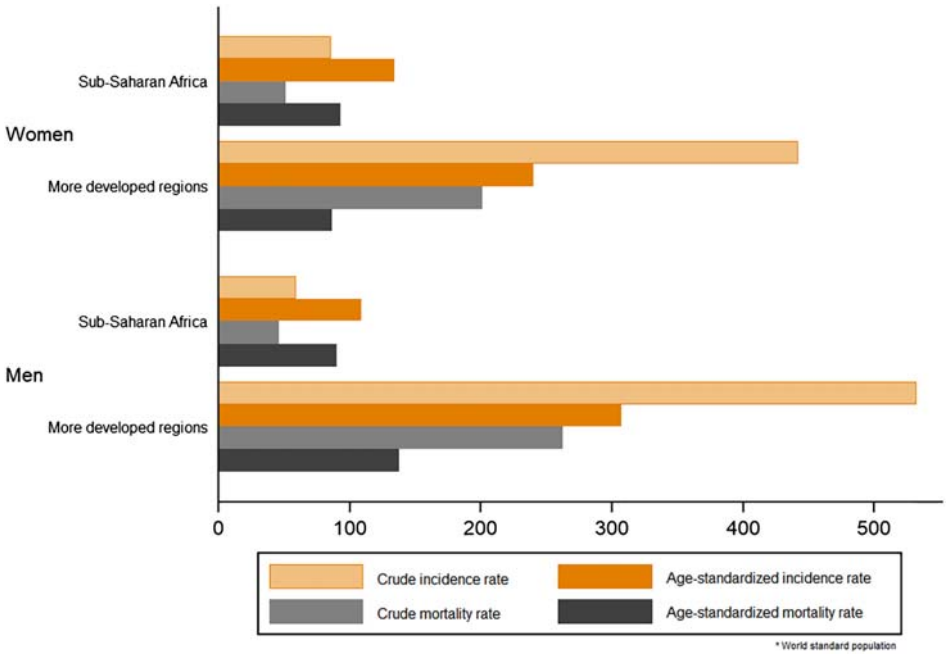

Fig. 1 Incidence and mortality rates in Sub-Saharan Africa and more developed regions. From Ferlay, J., Soerjomataram, I., Ervik, M., Dikshit, R., Eser, S., Mathers, C., Rebelo, M., Parkin, D. M., Forman, D., Bray, F. (2013). GLOBOCAN 2012 v1.0, Cancer Incidence and Mortality Worldwide: IARC CancerBase No. 11 [Internet]. Lyon, France: International Agency for Research on Cancer. Available from: http://globocan.iarc.fr, accessed on 30/01/2018.

African regions, contributing to the low incidence of some of the cancers that account for a large proportion of cases in developed countries. In SS Africa and in more developed regions, the ASIR-W (per 100,000) for lung cancer among men were 4.8 and 44.7, respectively, for breast cancer among women were 33.8 and 73.4, respectively, and for colorectal cancer in both sexes were 5.8 and 29.2, respectively. Conversely, infection-related cancers are frequent in SS Africa; for example, for Kaposi sarcoma among men, the ASIR-W (per 100,000) were 7.2 in SS Africa and 0.3 in more developed regions, the corresponding figures for cervical cancer were 34.8 and 9.9, and for liver cancer, both sexes, were 7.6 and 5.4.

Taken together, these factors contribute to explain the lower cancer rates in SS Africa, but also the distinct patterns of occurrence of different cancers compared with other regions. In SS Africa, it was estimated that, in 2012, the most frequent were prostate and liver cancers and Kaposi sarcoma among men, and breast, cervical and liver cancers among women. In more developed regions, the leading cancers were prostate, lung and colorectal cancers among men, and breast, colorectal and lung cancers among women. In SS African countries, in men, prostate and liver cancers and Kaposi sarcoma were the most frequent in 23, 12, and 6 countries, respectively. Among women, cervical (28 countries) and breast (20 countries) cancers were the most frequent (**Fig. 2**).

In SS Africa, low priority is usually given to cancer prevention and control, because other conditions may constitute more immediate threats to public health. However, the absolute number of cases of cancer diagnosed and requiring treatment is currently high in SS Africa—over 600,000 cases were estimated in 2012—and in many settings, the health systems are unable to promote early diagnosis or to provide appropriate care to these patients, as will be discussed in more detail along this article. This leads to cancer patients' low survival, as shown in some of the few population-based estimates available from SS African regions (**Table 1**). Compared to the incidence gap, this results in much smaller differences in mortality estimates between SS African countries and more developed regions. Among men, the age-standardized mortality rates, world standard population (ASMR-W), were higher in more developed regions by only 50%, whereas among women the ASMR-W were actually nearly 10% higher in SS Africa. For cervical cancer, the estimated ASMR-W was nearly sevenfold higher in SS Africa, whereas for the ASIR-W the ratio was 3.5.

Disability adjusted life years (DALYs) are computed by combining the number of years of life lost (YLLs) due to premature mortality in the population and the years lost due to disability (YLDs) in people living with cancer, and may be interpreted as the years of "healthy" life lost. Therefore, the low survival of cancer patients results in a small contribution of YLDs to this more comprehensive indicator of the burden of cancer. For 2016, the Institute of Health Metrics estimated an overall number of nearly 16.5 million DALYs in SS Africa, from which just over 200,000 were from YLDs (1.2%). However, for high-income countries, the YLDs accounted for 4.4% of the DALYs; this gap is wider when considering cancers with higher potential survival, such as female breast (2.0% vs. 8.8%) or prostate (2.8% vs. 14.8%) cancers.

Mortality trends in more developed countries have been characterized by declining age-standardized rates, reflecting improvements in living conditions, specific preventive measures to decrease the exposure to risk factors, vaccination, earlier detection of cancer and improved access to effective treatments. This also shows the potential and points to strategies for controlling cancer in SS Africa. Yet, this will be challenging due to regional specificities of the epidemiology of cancer and its risk factors, the shortage of financial and human resources to tackle cancer, competing priorities in already overburdened health systems, and the need to tailor prevention and control measures to the SS African setting. Despite the progress that has been observed in more developed regions, the growth and aging of the population have contributed to an increasing absolute number of cancer deaths in most countries, showing that advances in prevention and control remain insufficient to overcome the impact of demographic changes in cancer mortality. This will bring additional difficulties to the prevention and control of cancer in SS Africa, since its population is expected to increase substantially in absolute numbers and average age over the next decades. Taking into account only the expected demographic changes, the GLOBOCAN projections for 2035 show 100% increases in the number of incident cancers and cancer deaths, in relation to 2012.

Monitoring the Burden of Cancer

The currently high frequency of cancer and its projected variation in SS Africa emphasize the importance of monitoring its burden and management in the region. Cancer registries are essential for this purpose, but in SS Africa these dedicated structures are often unavailable, or do not produce quality data. In the context of *Cancer Incidence in Five Continents*, volume X, it was estimated that 10.5% of the population was covered by population-based cancer registries with a completeness of case finding equal to or higher than 70%, and only four registries met the standards to be cited in this report, corresponding to less than 2% of the total population. This also results in scarce population-based survival estimates, as depicted in **Table 1**.

The GLOBOCAN project provides incidence and mortality estimates for most SS African countries, based on the best sources available for each country and sometimes on data from neighboring countries or registries in the same area. However, 19 countries had no incidence data, and only three had high quality regional data, with a coverage lower than 10%. Mortality data was only available in three countries, with complete vital registration classified as low or medium quality.

Although it is not surprising that low priority may be given to demanding cancer registration activities, when specialized human resources are lacking and financial capacity is limited, accurate population-based data are difficult to obtain when there is limited access to cancer health care services by the population and when cancer mortality statistics are not reliable. In these settings, hospital-based registries are important sources of data for population-based registries, and may support the evaluation of cancer management in each hospital, towards an efficient use of the available resources.

Cancer Prevention and Screening

The burden of some of the most frequent cancers in SS Africa can be reduced through decreasing the exposure to risk factors, vaccination, or early diagnosis and treatment. In fact, there is robust evidence on the causes of cancer and interventions that have proven effective for both preventing and reducing its morbidity and mortality through screening. Many SS African countries have already started to develop cancer prevention programs, often with foreign help. However, these efforts are challenged by competing problems, such as the human immunodeficiency virus (HIV) and malaria infections, and limited resources. This has a potential impact both on the perception of cancer as a major health problem and on the allocation of resources for its prevention and control. Additionally, adapting to local culture and traditions constitute a great challenge to the implementation of cancer prevention strategies.

Table 1 Age-standardized survival (95% confidence intervals), by country and type of cancer

Reducing Exposure to Risk Factors

Tobacco consumption increases the risk of developing different types of cancer, such as lung, head and neck or esophageal cancers, among others. Many of the tobacco-related cancers are not among the most frequent in SS Africa, but there is a large potential for an increase in the prevalence of smoking and in the frequency of these cancers. Tobacco consumption is currently one of the most targeted risk factors throughout Africa. National level legislation is already in place in some countries, such as Gambia, Uganda, Nigeria or Kenya. They comprise prohibition of smoking in public or working places, banning of tobacco advertising, restriction of sales to minors, among others. The World Health Organization (WHO) also established a Centre for Tobacco Control in Africa in 2011 that is currently focusing on policies, legislation and regulations in several countries, namely Botswana, Ethiopia, Gambia, Gabon, and Niger. Moreover, private nongovernmental organizations (NGOs) developed antitobacco campaigns targeting different communities. However, tobacco control can prove difficult in Africa due to its role as an income provider for some communities, where tobacco leaf farming is still promoted as a way to reduce poverty, leading to increased consumption. Traditional tobacco products, other than manufactured cigarettes, are also frequently consumed in some settings, and may require more specific interventions for its control.

The amount of alcohol consumed in SS Africa is the second highest in the world (19.5 L of pure alcohol per year) and this is expected to increase. Alcohol is one of the leading causes of death in SS Africa, and is also related to the development of different cancers, namely esophageal, and head and neck cancers. Alcohol consumption depends on social influence and cultural changes that are closely linked to globalization, such as the growth of urban areas, industrialization, and marketing. Community norms and beliefs towards alcohol, neighborhood characteristics and peer effect are also determinants of drinking patterns, mostly in adolescents and young adults. The lack of specific governmental policies aiming to reduce alcohol consumption, the absence of community education and the increasing exposure to marketing of alcoholic beverages may contribute to increased consumption. However, countries such as Malawi, Equatorial Guinea or Zambia have already invested in political and regulatory changes with favorable outcomes in reducing consumption levels. Policy changes encompass, among others, raising taxes on alcohol, controlling advertising and enforcing drink-driving laws.

Exposure to mycotoxins through contaminated food is an established risk factor for liver (aflatoxins) or esophageal cancer (fumonisins), which are among the most frequent in SS Africa. Environmental conditions such as high levels of humidity and temperature favor the development of fungus responsible for the production of these toxins. Moreover, the disruption of the food preservation chain and constrained economic conditions increase the consumption of such products. Harvest practices, transportation and product processing are already regulated, in some countries, to help reduce contamination and exposure. However, a high portion of the SS African population is believed to still be exposed to contaminated food.

Cancers caused by infectious agents, such as cervical cancer (human papillomavirus, HPV), liver cancer (hepatitis B virus, HBV/hepatitis C virus, HCV), or Kaposi Sarcoma (herpesvirus 8, HHV8), are among the most common in Africa. HIV coinfection further increases the risk of developing these and other cancers by impairing immune response. Thus, reducing the risk of infection with these agents is an important step for cancer prevention. Strategies based on healthcare regulation and education of healthcare personnel are currently the focus of the WHO and various NGOs across multiple SS African countries. These include changing high-risk behaviors, by promoting measures such as the use of barriers to prevent exposure to body fluids, hands hygiene, prevention of injuries, screening of blood products and sterilization of medical equipment. Furthermore, community education plays a major role in preventing infections, mostly HIV and HPV, by reducing high-risk sexual behaviors. Some community educational programs encourage abstinence, monogamy and condom use. Circumcision may reduce high-risk HPV infection and transmission, and the WHO has proposed a target rate of 80% circumcision in men in low-income countries as the fallout of different randomized controlled trials. Sociocultural and healthcare barriers are being addressed in order to achieve high circumcision rates and several programs are currently in place to achieve this goal. In fact, the Joint United Nations Programme on HIV/AIDS (UNAIDS) defined 14 priority countries to scale-up circumcision. However, in some of those countries such as Lesotho, Malawi, Namibia, Rwanda, and Zimbabwe, the prevalence of circumcised men remains below 35%. Finally, in HIV infected patients, the use of highly active antiretroviral therapy has been shown to reduce the incidence of cancer. While this is true for some types of cancer such as Kaposi sarcoma, there is still insufficient evidence to establish a clear association between HIV treatment and the reduction of other cancers, like cervical tumors.

In SS Africa, *Schistosoma haematobium* is an important risk factor for bladder cancer. It ranks as the second most common parasitic infection in the region and 11.7 million people were treated for schistosomiasis in 2008. It is considered a neglected tropical disease and is estimated to cause over half a million deaths per year in SS Africa. *Schistosoma* can be transmitted by bathing in larvae infested water and the deposition of parasitic ova in the bladder induces severe inflammation leading to carcinogenesis and the development of squamous cell carcinoma. There are effective drugs for eliminating *Schistosoma* and preventing cancer, such as praziquantel. Therefore, there are several NGOs currently improving treatment coverage in order to reduce the burden of this infection in SS Africa.

Globalization is responsible for several changes in the exposure to risk factors for cancer. Obesity is also now being considered an important risk factor among countries in SS Africa, mostly in urban areas, where the intake of highly caloric food and physical inactivity is increasing. Paradoxically, increasing levels of obesity are side-by-side with severe undernutrition and stunting. Overweight and obesity incidence in adults reaches 40% in some countries, such as Burundi, alongside a 50% prevalence of stunting. Thus, healthcare interventions may also be needed in SS Africa to prevent and control weight gain and obesity, at least in some subsets of the population.

Other risk factors that are common in high-income countries are becoming more frequent in low-income countries. Younger menarche, later age at pregnancy and low parity are known risk factors for breast cancer that are clearly increasing in low-income settings.

Vaccination

There are currently two vaccines known to reduce cancer incidence: HPV vaccine and HBV vaccine. The Global Alliance for Vaccines and Immunization (GAVI), a global vaccine alliance, working closely with the United Nations Children's Fund (UNICEF), is responsible for improving access to vaccines in low-income countries.

Vaccination against HPV proved to be highly effective in preventing the development of high-grade premalignant cervical lesions that lead to cervical cancer. Currently, several HPV vaccines are available, protecting against different high-risk HPV subtypes. They also protect against some low-risk HPV subtypes. In SS Africa, HPV vaccines are usually administered to girls aged 9–14 years, using different delivery strategies, such as school based vaccination, routine immunization in conjunction with national vaccination plans, or in coordination with other healthcare programs. GAVI started several demonstration projects in different countries for HPV vaccination before its definitive inclusion in the national vaccination plan, first in Kenya, in 2013, and then in countries such as Rwanda, Cameroon, Gambia, Kenya, Malawi, Mozambique, São Tomé & Principe, among others. The price of HPV vaccine is decreasing, which enables a potential increase in vaccination, along with the possibility of including preadolescent boys in vaccination programs. Male vaccination proved to be cost-effective and is capable of further interrupting HPV transmission. Moreover, it may offer protection against other HPV-related cancers, such as head and neck or anal cancers.

A vaccine against HBV is available since the 1980s, but the world's population coverage by this vaccine is still expanding. The WHO recommends a three-dose vaccination schedule, with the first dose being administered within 24 h of birth and the other two at least 4 weeks apart. At a global level, the three-dose HBV vaccination coverage is estimated to be 84%, and in SS African increased from 5% in the year 2000 to an estimated 76% in 2015. This ranges broadly throughout different countries in the region, starting at 16% in Equatorial Guinea and reaching 98% in Rwanda and other countries. Thus, further progress must be made in many SS African countries in order to improve vaccination coverage and control of HBV infection.

Screening

Cancer screening may contribute to reduce the incidence and mortality of cancer, by diagnosing and treating premalignant lesions, or to promote timely treatment of malignant lesions with reduced morbidity. The first is best depicted by cervical cancer screening and the second by breast cancer screening. The potential benefits of cancer screening in resource constrained countries has been thoroughly discussed but even if the screening tests are available, most SS African countries still lack trained healthcare personnel and technical capability to diagnose and treat suspected cancers. Cervical and breast cancers screening are the most frequently available in SS Africa, reflecting the fact that these have been studied in resource constrained settings, mostly after adapting strategies and methods to the available human and financial resources, and cultural characteristics.

Cervical cancer screening

Despite the increasing coverage of HPV vaccination in SS Africa, scarce resources and failure to complete full schedules make screening an essential tool for prevention and control of cervical cancer. Screening with the Papanicolaou (Pap) test contributed greatly to the reduction in cervical cancer mortality in developed countries. However, cytology testing is expensive, and requires highly trained professionals and complex logistics. Furthermore, screening with the Pap test requires a follow-up visit for treatment, which is frequently impractical in resource constrained countries. Therefore, "test & treat" strategies try to obviate these difficulties by diagnosing and treating in the same visit, and they are currently proposed by the WHO for low-income settings. Test can be accomplished with visual inspection with acetic acid (VIA), digital cervicography, HPV test or with a combination of methods (e.g., HPV test and visual inspection). Treatment can be provided using cryotherapy. This approach was shown to be cost-effective, safe and culturally adapted. Other approaches are being evaluated to improve screening uptake in different cultural settings. Self-sample collection by women has proved to be reliable and reproducible, and urinary detection of HPV is being perfected. Also, recently developed rapid and portable HPV detection tests may contribute for increasing screening coverage.

Breast cancer screening

Mammography-based screening was shown to reduce breast cancer mortality in developed regions, and organized screening programs are available in many countries, with varying coverage. However, the logistics leading to a successful detection, diagnosis and treatment of breast cancer constitute a highly complex multidisciplinary undertake. Breast screening programs are expensive and require infrastructures that are often unavailable in low-income countries. This has led to a simplified screening approach based first on awareness and education, then on self-examination of the breast and finally on clinical examination of the breast. Currently, there is no screening program based exclusively on self or clinical examination, but several programs are including these methods to increase awareness for breast cancer and screening uptake. Also, randomized controlled trials showed an increase in the detection of invasive breast cancer using clinical breast examination screening. Nevertheless, none of these strategies proved to be effective in reducing breast cancer mortality and randomized trials are underway.

Cancer Diagnosis

Cancer diagnosis requires clinical evaluation of patients through various procedures, such as imaging, clinical laboratorial tests, and microscopic examination of cells and tissue samples (cytology or histopathology). The availability of resources needed for cancer diagnosis varies across SS Africa, and diagnostic capacity is often suboptimal, mainly due to the lack of adequate pathology capacity and infrastructure, as well as low quality of these services. This situation leads to delays in diagnosis and treatment, inadequate treatment strategies and follow-up, with increased morbidity and mortality.

Pathology

All patients should have a pathologic diagnosis before cancer treatment, and both anatomic and clinical pathology are crucial for its control. Cancer screening and diagnosis, including the identification of cancer type, grading and staging, as well as guidance of surgical resections and evaluation of the effectiveness of treatment depend on pathology investigation. The accuracy of cancer registration data also relies to a large extent on the quality of the pathological diagnoses.

Histopathology and cytology, such as fine needle aspiration cytology (FNAC), are needed for microscopic diagnosis. Complementary methods, namely immunohistochemistry, flow cytometry and molecular pathology, are used for phenotyping tumors (including leukemia and lymphomas), and for the demonstration of genetic alterations. These results may be used for a finer characterization of tumors, leading to a better definition of treatment and prognosis.

The availability of pathology providers and services varies widely among SS African countries. The number of pathologists per inhabitant is less than 1:500,000 (Fig. 3), which is about one tenth of the observed in high-income-countries (about 1:15–20,000) and some countries have no pathologists at all. Therefore, the number of pathologists and technicians is clearly insufficient for the provision of adequate services. Moreover, only a few countries have more than 50% of cancers with a pathologic diagnosis and, when available, the turnaround time of diagnosis can reach 1 month.

In places where pathology services are available, the quality of diagnosis is further limited by factors such as lack of maintenance of equipment, inadequate supply chain of quality reagents, inadequate specimen fixation and transportation from the operating room to pathology services, and absence of quality control programs. Immunohistochemistry and molecular testing are available in just over half and in less than 20% of SS African countries, respectively. Consequently, and as an example, the study of hormone receptors in breast cancer, which is fundamental to its management, is limited or absent in many countries. The African Strategies for Advancing Pathology (ASAP) Group, created in 2014, generated a 5-year strategic plan aiming to increase and improve pathology services in SS Africa, including advocacy for pathology, education and training of pathologists, as well as building, strengthening and maintaining operational laboratories of pathology. Local strategies for improving pathology in a specific country or site must also be encouraged.

In the last decades, FNAC has gained importance as an alternative pathological method for cancer diagnosis in low-income countries. For example, in Mozambique, in 2009–10, 57% of all diagnoses of pediatric cancers in the Department of Pathology of the Maputo Central Hospital were based on FNAC. In other series, when considering Burkitt lymphoma alone, FNAC was

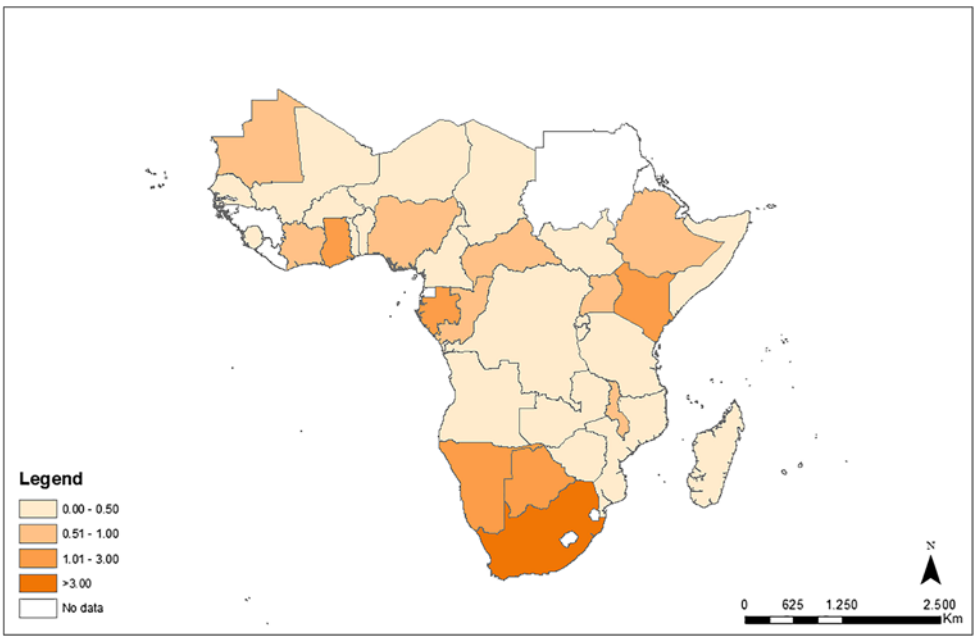

Fig. 3 Total density of pathologists per million population in 2011–13, in Sub-Saharan Africa. From African Strategies for Advancing Pathology [Internet]. Available from: http://www.pathologyinafrica.org/, accessed on 30/01/2018.

responsible for 82% of the diagnoses. Although core biopsy with histology is the preferred method for the preoperative diagnosis of breast cancer, FNAC is widely used for the initial diagnosis of palpable breast cancer in many parts of SS Africa, when core biopsy and histology are not available. Most breast cancer patients present with advanced disease and mastectomy is done many times on the basis of FNAC results, when triple assessment (clinical, radiological, and cytological findings) is conclusive for malignancy. FNAC can be conducted faster and at a lower cost than conventional histology, and with only minimal laboratory pathology infrastructures. However, diagnostic accuracy varies widely with the technique used, the specific site being sampled, and the expertise of the personnel collecting the sample and reading the slide. Samples may have poor quality when the technique is done by a person that only performs FNAC occasionally, but the proportion of inadequate samples drops from 15%30% to 12% when FNAC is performed by a trained cytopathologist. Therefore, when used appropriately and with well-trained personnel, it constitutes a quick and accurate tool for diagnosis and follow-up of cancer.

Clinical Diagnosis

Although the gold-standard for cancer diagnosis is based on tissue sample evaluation, due to the limited access to pathologic diagnosis, in some cases of specific cancers with high prevalence, treatment may start with clinical diagnosis only. Examples include bulky cutaneous Kaposi sarcoma associated with HIV, and some hepatocellular carcinomas that are diagnosed based only on ultrasonography in combination with clinical presentation and laboratorial tests. Additionally, and as already mentioned, cervical premalignant or malignant lesions can be visualized directly using acetic acid and treated with cryotherapy during the same visit. Clinical diagnosis of certain highly prevalent cancers do not require specialized personnel, are less dependent on laboratory facilities and are easier to perform.

Imaging

In the last few decades, imaging became an important tool for diagnosis, treatment planning and follow-up of patients with cancer. Currently, there are many methods available, such as conventional X-rays, ultrasound, mammography, endoscopies, computerized tomography (CT) scans, magnetic resonance imaging (MRI) and nuclear medicine, used for different purposes, namely diagnosis, staging, evaluation of response to treatment and detection of relapses.

After conventional X-rays, that are still important to detect bone tumors in many SS African countries, ultrasonography is the second most used imaging method. It is useful for the initial investigation of signs and symptoms, especially to detect and localize neoplastic lesions in the abdomen and thyroid. It is also useful to guide core needle biopsies or FNAC, and for staging and follow-up. However, its use is limited due to the lack of trained personnel.

Most of the other imaging methods, such as CT scans, MRI and nuclear medicine are scarcely available in many SS African countries. But even in countries which have this equipment, radiologists are often not adequately trained on the diagnosis and follow-up of cancer lesions, namely in the assessment of response to cancer treatment. Additionally, access to endoscopy services, which are extremely important for early detection of esophageal cancer, is also limited. Finally, the low number of mammography units in many SS African countries (Fig. 4) is a barrier for the implementation of breast cancer screening through this method. Alternatively, as mentioned, in some countries, screening is being based on clinical examination of the breast.

Treatment of Cancer

Conceptually, the management of cancer includes the treatment of local disease with surgery, radiation therapy, or both, and the treatment of systemic disease with cytotoxic chemotherapy, endocrine therapy, targeted therapy, immunotherapy or combinations of these. The choice of treatment strategy is based on the tumor extent/location and biology (pathology including biomarkers and gene expression) as well as on the age and general health status of the patient, and personal preferences. However, in SS Africa, the availability of surgery, radiation and systemic therapy varies widely between and within countries. Moreover, many patients are not managed in a multidisciplinary manner, being referred from surgeon to medical oncologist or radiation oncologist, without a proper discussion in a multidisciplinary tumor board. This impairs the achievement of the best possible treatment for the individual patient, adds delays in the patient care pathway and increases the chance of discontinuing care, all of which compromise survival outcomes. Moreover, access to different forms of treatment depends on patients' socioeconomic status.

Surgery

In the most developed countries, surgical treatment of solid tumors has evolved substantially in the last decades, which may be related to the combination with neoadjuvant and adjuvant chemotherapy, targeted therapy and radiotherapy, as well as the development of techniques such as the sentinel-node biopsy and laparoscopy. Therefore, surgery is now much less aggressive in most tumors (e.g., breast-conservation surgery, partial nephrectomy), allowing for a preservation of organ function, with decreased morbidity and mortality, and a benefit in the quality of life of cancer survivors. At the same time, the training of most surgeons on basic cancer principles (e.g., systematic lymphadenectomy in certain cancers and achievement of clear margins in most tumors), has led to an improvement in survival.

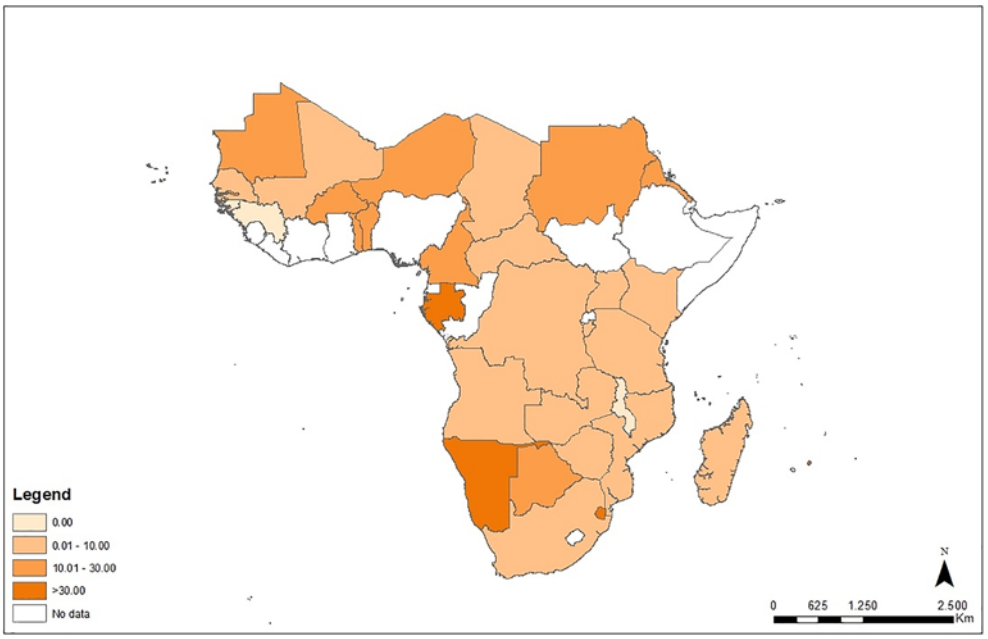

Fig. 4 Total density of mammography units per million females aged from 50 to 69 years old in 2014, in Sub-Saharan Africa. From Global Health Observatory (GHO) data [Internet]. Geneva: World Health Organization. Available from: http://www.who.int/gho/en/, accessed on 30/01/2018.

However, in SS Africa, surgery is still highly centered in cases of trauma and acute conditions. Therefore, surgical training is usually more focused on these situations and not so much on the performance of adequate oncological resections with clear margins, the achievement of a broad lymphadenectomy or the need to send the surgical specimen for proper fixation for histological assessment. Additionally, in some SS African countries, due to the absence of a proper cancer diagnosis prior to surgery and/or lack of awareness of some types of tumors, cancer surgeries may sometimes be performed by nonphysicians, who do not have the expertise to carry out these types of complex surgeries. On top of that, many of the organ-sparing approaches are also not possible due to the lack of trained cancer surgeons in organ-sparing approaches and the absence of radiotherapy. Another problem is that patients frequently present with extensive local tumors that are not suitable for surgery due to the absence of effective neoadjuvant therapies, such as radiotherapy and/or systemic treatment (e.g., trastuzumab in HER2-positive breast cancer).

As an example, currently, in Western Europe ~60%–80% of newly diagnosed breast cancers are amenable to breast conservation (wide local excision and radiation therapy). However, in low-income countries, mastectomy is still the most common intervention for breast cancer—in SS Africa, 85% of the surgeries are mastectomies. Even so, in a retrospective study from Nigeria, only 35% patients underwent mastectomy, as many of the patients presented with inoperable local or metastatic tumors at diagnosis. Also, in Rwanda, from 145 patients receiving breast cancer care, only 48% underwent mastectomy. This is in contrast with Europe, in which over 90% of women receive surgical treatment.

Radiation Therapy

Radiation therapy is an important component of cancer control programs. Given that cervical, breast, prostate, esophageal, and head and neck cancers are among the most common types of cancer in SS Africa, radiotherapy plays a very important control as a radical as well as an adjuvant therapy.

However, according to the WHO, in 2013, only 20 countries were known to have radiotherapy, and these facilities were concentrated in the southern and northern states of the region (Fig. 5). According to a survey conducted by The International Atomic Energy Agency in 2010, brachytherapy resources (high-dose rate or low-dose rate) were only available in 20 countries as well. Additionally, access can be difficult even when radiation therapy facilities are available due to the large number of people covered by each of the centers. This leads to long patient waiting lists, which results in large numbers of patients referred for radiation therapy not being treated in due time. Also, due to the out of pocket expense of traveling daily to the radiotherapy facility, some patients have a low treatment compliance, which undermines its effectiveness, especially in very radiosensitive cancers, such as head and neck tumors.

Systemic Treatment

Systemic therapy can be neoadjuvant, adjuvant or palliative, contributing to substantial improvements in survival and symptom burden, depending on its intended use. A good example is breast cancer, in which more than half of the women with localized cancer who would otherwise die of metastatic breast cancer remain disease-free when treated with the appropriate systemic regimen.

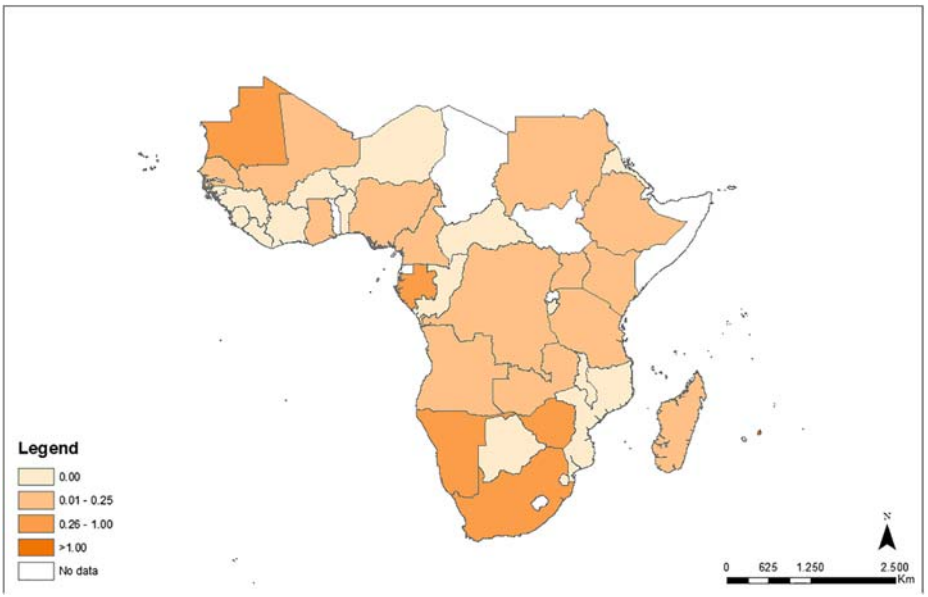

Fig. 5 Total density of radiotherapy units per million population in 2013, in Sub-Saharan Africa. From Global Health Observatory (GHO) data [Internet]. Geneva: World Health Organization. Available from: http://www.who.int/gho/en/, accessed on 30/01/2018.

However, there are multiple problems regarding the delivery of systemic treatment in SS Africa. For example, the safe administration of systemic chemotherapy, which is crucial to improve outcomes for a number of common cancers (e.g., colon, breast, cervical, and head and neck), depends on the availability of drugs, infrastructure for drug administration, and well-trained medical and nonmedical staff. Unfortunately, adequate infrastructures and trained staff are scarce in low-resource countries, and treatments are often interrupted due to the irregular supply of systemic drugs. The effectiveness of chemotherapy protocols can be further impaired by inadequate management of toxicity due to limited access to support treatments, including blood transfusions, granulocyte-colony stimulating factors, antibiotics and antiemetics.

There are examples of programs trying to overcome the absence of specialists and specialty centers in SS Africa. As an example, since 2014, the Gulbenkian Foundation has been providing support for Mozambican medical and nonmedical staff to be trained in Portugal in different cancer areas (surgery, radiation therapy, medical oncology, oncological nursing and pathology, among others) during short-term fellowships, allowing for an effective education in multidisciplinary cancer care. This has led to the implementation of new surgical cancer techniques in Mozambique and to the creation of the first multidisciplinary tumor board in the country. Also, an international partnership of Partners in Health and the Dana-Farber Cancer Institute, Harvard Medical School, and Brigham and Women's Hospital, is working in rural Malawi and Rwanda. They are operating health centers and hospitals in rural districts, supporting and training local physicians and nurse teams on the delivery of chemotherapy to patients with multiple cancers, including breast, cervical, rectal, head and neck, Hodgkin's and non-Hodgkin lymphoma, and Kaposi sarcoma.

However, the difficulty lies in scaling up these projects to a national level. One of the reasons is that the cost of present chemotherapeutic agents for all patients with cancer exceeds the healthcare budgets of low-resource countries. Therefore, many SS African countries cannot ensure that the drugs in the WHO essential drug list for cancer and newer drugs are available. This also leads to out-of-pocket payments that are unaffordable to most patients, leading to treatment nondelivery or interruption. Besides, patients that progress during first-line chemotherapy, which is usually limited to the available drugs and may not include the best possible treatment, have even more limited options for further treatment.

Regarding endocrine therapy (e.g., in breast cancer), the absence of advanced pathology services to establish hormone-receptor status continues to obstruct appropriate decision making for this treatment. However, the potential savings with the selective use of endocrine therapy are expectedly greater than the costs of hormone-receptor testing, so it would be important to develop it instead of carrying on with the blind prescription of endocrine therapy. In terms of breast cancer, tamoxifen is accessible in most countries and, in some of them, it is free of charge. Yet, newer agents, like aromatase inhibitors are mostly not available in public hospitals.

With respect to targeted therapy, in several SS African countries, agents such as trastuzumab or rituximab are not available due to their high price, even if they are part of the WHO essential drug list. However, biosimilars are already available in countries like India at a reduced cost, so they could be introduced in Africa in the near future, helping in the reduction of cancer mortality.

The development of guidelines for drug selection and administration would be very important to ensure that all patients with cancer receive the best available drugs in appropriate and therapeutic doses. For example, guidelines regarding cervical cancer treatment in limited-resource settings were issued in 2016 by the American Society of Clinical Oncology, to help with the optimization of clinical outcomes. However, it would also be important to have the technology for a better characterization of each tumor, as it could lead to a more personalized and effective treatment—for example, use of platinum drugs, that are cheap and usually available, and avoidance of endocrine therapy in triple negative breast cancer.

Clinical Trials

Clinical trials are an essential part of cancer research efforts, enable patients to have access to more treatment options and expand the possibilities of use of each drug. However, in SS Africa, the number of cancer clinical trials is still very low: in a recent review of randomized controlled trials in breast cancer registered on ClinicalTrials.gov ($n = 1099$ trials), only 6.3% occurred in one or more low- and middle-income country. Besides, among the 44 SS African countries, studies were only being conducted in Nigeria, Kenya, Ghana and South Africa; the latter had 91% of the 54 studies taking place in the region.

This is worrisome because it is paramount to undertake cancer clinical trials in SS Africa, in order to: (a) develop new drugs and treatments for cancers that are less frequent in the West, but predominant in SS Africa (e.g., esophageal cancer); (b) study diseases that are frequent in the West, but have a different presentation and course in SS Africa (e.g., higher proportion of triple negative breast cancer compared to Europe); and (c) develop more affordable ways of delivering cancer care in SS Africa (e.g., hypofractionated schemes of radiotherapy in prostate cancer).

Patients with HIV

The prevalence of HIV in SS Africa is highly variable among countries, but can be as high as 37% of the population (in urban women in Swaziland), according to the WHO. Furthermore, more than 70% of the global burden of HIV infection is in SS Africa. This is important because, since the discovery of HIV, it is known that infected patients have a higher risk of developing cancer, mainly due to the immunosuppression induced by the virus. When some of these cancers are diagnosed in an HIV-positive patient, it means that the patient has developed the stage of HIV infection called "acquired immune deficiency syndrome" (AIDS). Therefore, these cancers are called "AIDS-defining malignancies" and include Kaposi sarcoma, primary central nervous system lymphoma, peripheral intermediate- and high-grade B-cell non-Hodgkin lymphoma, and cervical cancer. HIV-positive patients also have an increased risk of developing other cancers, such as Hodgkin lymphoma or lung cancer, but these are considered non-AIDS defining malignancies. Meanwhile, due to the scale-up of highly active antiretroviral therapy (HAART) in SS Africa, HIV infection is turning into a chronic condition, with aging and growth of HIV-infected populations. Reports from countries like Brazil and United States show a decline in AIDS-defining malignancies and an increase in non-AIDS defining malignancies.

Yet, despite the high burden of HIV in SS Africa and its relation with cancer, HIV infection status is often missing for cancer patients, which is troublesome since HIV infection also influences cancer treatment and prognosis. In 2017, among a series of 1137 cancer patients from Nigeria, the HIV status was not recorded for nearly one-third of the patients, and 32% of the remaining were HIV-positive.

Regarding survival, data in HIV-positive cancer patients comes mainly from American or European series, and they all show that these patients have worse cancer-specific survival compared to those not infected. In a very large American series, even after adjustment for stage and cancer treatment, HIV-positivity was associated with higher cancer-specific mortality for colorectal cancer (hazard ratio [HR] 1.40, 95% CI 1.09–1.80), lung cancer (HR 1.28, 95% CI 1.14–1.44), melanoma (HR 1.93, 95% CI 1.14–3.27) and breast cancers (HR 2.64, 95% CI 1.86–3.73). This could be attributed to the effect of immunosuppression (as we nowadays know that an intact immune system is essential for the effectiveness of anticancer drugs) and to suboptimal therapy due to increased toxicity and higher rates of infection. On the contrary, there are known pharmacological interactions between HAART and common chemotherapy drugs, such as alkylating agents, taxanes, and anthracyclines. There are also interactions with targeted agents, like imatinib or erlotinib. Therefore, HIV-positive patients are at risk of overlapping toxicity, namely hematological, which can compromise treatment. As an example, in a case-control study in the United States (with 52 HIV-positive and 104 HIV-negative breast cancer patients), the HIV-positive women needed dose reductions and/or had chemotherapy delays due to toxicity more often (56% vs. 30%; $P = .03$). Therefore, in order to avoid immunosuppression-related infections, CD4+ cell count should be closely monitored and the use of prophylactic G-CSF/GM-CSF is strongly recommended following chemotherapy. However, these drugs may not be available in all SS African clinical centers.

Additionally, even in clinical trials regarding cancers with higher risk in HIV-positive patients (like lung or cervical cancer), these patients are usually excluded, so data regarding the efficacy and safety of new cancer therapies in HIV-positive patients is scarce. Therefore, the creation of specific guidelines to cancer treatment and management of complications in HIV-infected patients in low-resource settings, such as SS Africa, is essential in order to maintain treatment intensity and achieve the best possible survival outcomes.

Palliative Care

In SS Africa, supportive care, which broadly includes the treatment of side effects, palliative care and end-of-life care, is still an emerging specialty. Even if palliative care is now delivered in nearly 50% of SS African countries, still less than 5% of people in need receive it. This is extremely worrisome, especially because about 80% of cancer patients in SS Africa are diagnosed at advanced stages of the disease, and in many of these patients, palliative care is often the only choice of treatment.

One of the core components of palliative care is pain control. However, there are a number of barriers to the use of inexpensive opioid analgesics in SS Africa, including legal and regulatory restrictions, inadequate training of health care providers, concerns about abuse and cultural misperceptions about pain. For instance, a survey directed to medical doctors, conducted in a University Hospital in Nigeria, showed that only 40% of the respondents routinely conducted pain assessments among cancer patients, only 20% used strong opioids and over 90% of the respondents had no formal training on pain management.

According to an American Cancer Society/African Organization for Research and Training in Cancer (AORTIC) report, in 2008, the actual procurement of morphine and equivalent opioids reported by SS African governments to the International Narcotics Control Board corresponded only to about 10% of the quantity needed just for the terminal months of cancer and HIV-positive patients. This means that the vast majority of cancer patients in SS Africa do not have access to opioid treatment.

However, there are some inspiring examples, such as Kenya and Uganda that have been pointed as leaders in palliative care development in SS Africa. Through a strategy based on education and training of health care providers, improved access to opioid medications, better professional and public attitudes towards palliative care, integration of palliative care into national health care systems, and palliative care research, these countries have incorporated palliative care as part of their mainstream health service. An interesting strategy was the involvement of lay community volunteer workers, who advocate for palliative care in the community and help to clarify the myths related with the process of dying. Also, education programs were offered not only to health professionals, but also to community volunteer workers, spiritual caregivers and traditional healers.

While governments should take steps towards an easier and more comprehensive access to palliative care for their cancer patients, NGOs can lobby to put palliative care on the public agenda, and also to help on the design and implementation of palliative care programs on a local and national level.

Prospective Vision

As explained above, cancer control in SS Africa is not an easy task, due to the increasing incidence of cancer, and lack of proper healthcare networks for diagnosis and treatment. However, as this burden is growing at a fast pace, new solutions will have to be provided. First, vaccination programs, covering HBV and HPV are fortunately expanding and that could substantially decrease the burden of liver and cervical cancer, respectively, as well as head and neck cancer. Second, even if legislation control over known risk factors like tobacco and alcohol is still in its beginning, it is predictable that it will tighten in the near future, which would also be valuable for cancer control. However, "western" risk factors such as obesity are becoming more frequent and, even with educational strategies, will be hard to overcome. Third, regarding screening, diagnosis and treatment, a change of mind-set will have to occur: as it is not feasible to implement strategies used in developed countries, due to their complexity and cost, new ways of delivering cancer care will have to be pursued. For that, clinical trials in SS Africa regarding new strategies for screening (like clinical breast examination) and diagnosis (such as portable HPV detection tests) should be carried out, in order to assess their effectiveness, cost and application in SS African health systems, as well to adapt them to local habits. At the same time, trials regarding new treatment strategies with old or new drugs and combinations are also urgently needed, as a way to improve survival outcomes. Investing in strengthening pathology for early detection and diagnosis with quality is crucial. Also, a better organization of drugs' supply chain, and the use of generic drugs and biosimilars could decrease the costs and improve the delivery of systemic treatment. Finally, it is essential to train a whole new generation of physicians, nurses and technicians on cancer principles and care, in order to improve their expertise in the delivery of care and, at the same time, raise awareness for this growing problem. This would be an important step for the change of attitudes in SS Africa regarding the importance of cancer prevention and care.

Cancer in the Middle East

Iman El Sayed, Medical Research Institute, Alexandria University, Alexandria, Egypt

Glossary

Age-standardized death rate (ASDR) A weighted average of the age-specific mortality rates per 100,000 persons, where the weights are the proportions of persons in the corresponding age groups of the WHO standard population.

Area under the curve (AUC) for screening test Represents an overall indication of the diagnostic accuracy of a ROC curve. AUC values closer to 1 indicate the screening measure reliably distinguishing diseased and nondiseased subjects, whereas values at 0.50 indicate that the predictor's diagnostic accuracy is no better than chance.

Disability-adjusted life years (DALYs) A measure of overall disease burden, expressed as the number of years lost due to ill health, disability, or early death. It was developed as a way of comparing the overall health and life expectancy of different countries.

Early diagnosis The early identification of cancer in patients who have symptoms of the disease.

Incremental cost The increase in total costs resulting from an increase in production or other activity. For instance, if a company's total costs increase from $320,000 to $360,000 as the result of increasing its machine hours from 8000 to 10,000, the incremental cost of the 2000 machine hours is $40,000.

Primary prevention It is concerned with preventing the onset of disease; it aims to reduce the incidence of disease. It involves interventions that are applied before there is any evidence of disease or injury.

Relative risk The ratio of the probability of an event occurring (for example, developing a disease, being injured) in an exposed group to the probability of the event occurring in a comparison, nonexposed group.

Screening Identification of unrecognized (preclinical) cancer or precancerous lesions in an apparently healthy target population.

Epidemiology of Cancer in the Middle East

Cancer is a global health problem. The growing burden of cancer includes increasing global trend of 1% every year. Low- and middle-income countries report more than two-thirds of cancer mortality all over the world. Cancer kills one-quarter of a million people each year in the WHO Eastern Mediterranean Region alone. According to GLOBOCAN (global cancer observatory) cancer incidence and mortality data, in Eastern Mediterranean region in 2012, the overall age-standardized cancer incidence rate was almost 25% higher in men than in women. Cancer incidence rates among males were 119.5 cases per 100,000 with a corresponding mortality rate of 90 per 100,000 males. The incident cancer cases in females were 126.2 per 100,000 (79.4 deaths/100,000). Using age-standardized incidence rate from all ME countries, lung, bladder, and prostate cancers recorded the highest incidence in males (Table 1) while breast cancer is the commonest type in females (Table 2). Country-specific cancer incidence among males revealed the highest rate being stomach in Iran, Afghanistan, Colorectum in Saudi-Arabia, lymphoma in Sudan and Djibouti, and liver cancer in Egypt (Table 3)

An overview of age-standardized death rates from World health organization (WHO) mortality data 2000–2014 for selected Middle East (ME) countries revealed; a steady high mortality pattern of both sexes for some countries and prominent rising trend for others. The highest cancer mortality among men is reported in Israel, Cyprus, and Egypt, also high mortality but insufficient data is in Turkey (Fig. 1). Females' breast cancer mortality is the highest in Israel and Egypt (Fig. 2).

Despite advances in cancer treatment, a minimal decline in cancer mortality along the recent years in the ME. Many cases are diagnosed at a late stage with subsequent poor prognosis and lower survival than the European region. The proportion of mortality to total incident cases of both genders is greater in the WHO Eastern Mediterranean region than the WHO European region as well as the European Union and USA (Fig. 3).

Risk Factors for Cancer in the ME

It is crucial to illustrate the possible causes and prominent risk factors that contribute to cancer in developing countries so that preventive strategies and cancer control programs can be properly allocated.

Tobacco Smoking and Alcohol

Tobacco is responsible for 5 million deaths worldwide every year. About 80% of one billion smokers live in the low-middle income countries where tobacco has harmful health effects and deaths are the heaviest. Waterpipe smoking (Shisha) is popular in the ME

Table 1 WHO Eastern Mediterranean countries (2012): estimated cancer incidence, all ages (male)

Cancer	*Numbers*	*Crude rate*	*ASR (W)*	*Cumulative risk*

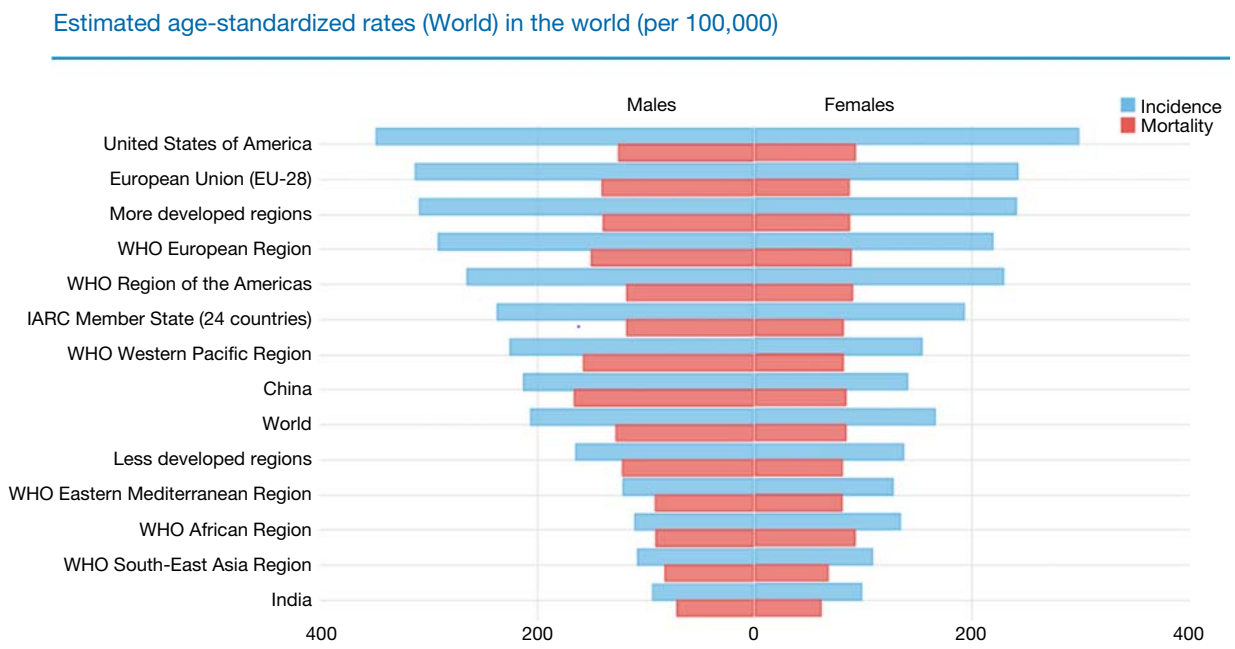

Fig. 3 Estimated age-standardized rates per 100.000 in the world.

not only among elderly but also in youth, university students, and even high-school-aged children. Daily waterpipe smoking produced a 24-h urinary cotinine level that is equivalent to smoking of 10 (95% CI: 7–13) cigarettes/day. Occasional waterpipe smoking (one session of waterpipe use during a 4-day period) produced a 24-h urinary cotinine level equivalent to smoking of two cigarettes in one pipe session. Active tobacco smoking has been considered as a strong risk factor for lung cancer, with an average risk ratio (RR) of 15–30. However, One fourth of lung cancer cases are not attributable to active smoking. The association also between second-hand smoking (i.e., environmental tobacco smoke) and lung cancer was established for all histological types of lung cancer: 1.26 (95% CI: 1.10–1.44) for adenocarcinoma, 1.41 (95% CI: 0.99–1.99) for squamous cell carcinoma, 1.48 (95% CI: 0.89–2.45) for large cell lung cancer, and 3.09 (95% CI: 1.62–5.89) for small cell lung cancer. Bladder cancer, which reports the second common incident cancer type among males in The ME, is proved to be triggered by smoking with a causal association between bladder cancer and current (RR 3.14) or former (RR 1.83) cigarette smoking, pipe (RR 1.9), or cigar (RR 2.3) smoking. Exposure to tobacco smoke causes a sharp drop in oral peroxidase (OPO) activity, an enzyme in the saliva resulting in increased incidence of oral cancer. Tobacco smoke was more likely to overexpress p53 that is the most frequently mutated gene in human oral cancer. WHO revealed the prevalence of current tobacco smoking (2011) to be the highest in Tunisia, Jordan, and Egypt for men and Lebanon, Israel, and Cyprus for women. In Jordan, Narghile (waterpipe) smoking was significantly associated with oral cancer at a younger age (45 years). A few studies from the ME illustrated the association between excessive alcohol intake and cancer risk. WHO reported low alcohol intake in most of ME countries with a relative increase in Cyprus, Jordan, UAE, and Turkey (Table 3). Excessive alcohol drinking is reported to be associated with increased incidence of oral cancer in Jordan (17%) and Sudan (10%).

Obesity, Unhealthy Lifestyle, and Environmental Factors

Many countries of the ME showed a rising pattern of cancer due to changes in the dietary habits. These countries could be divided into high- and low-income countries. The dietary habits of dates, milk, excess fruit and vegetables intake were replaced with an excess intake of energy-dense foods rich in fat and free sugars and deficient in complex carbohydrates, with daily energy intake exceeding 3000 kcal/per capita especially in high income Arab countries (e.g., Bahrain, Kuwait, Oman, Qatar, Saudi Arabia, and United Arab Emirates) resulting in overnutrition. In low-income Arab countries, contaminated food with carcinogens as well as the unhealthy life style, obesity, and lack of physical activity contribute significantly to increased cancer incidence (Table 3). Higher dietary inflammatory index (DII) was associated with increased odds of colorectal cancer among Jordanian population ($OR_{continuous\ DII} = 1.45$, 95% CI: 1.13, 1.85). Food contamination by mycotoxins has been recognized as a public health threat. Aflatoxin B1 (AFB1), Aflatoxin M1 (AFM1), as well as Ochratoxin A (OTA) and Deoxynivalenol (DON) are considered potent toxic mycotoxins. AFB1 is the strongest carcinogen and chronic exposure to AFB1 was considered to increase the risk of liver cancer especially when associated with hepatitis B or C. AFB1 has been classified as "carcinogenic to humans" (group 1) by the International Agency for Research on Cancer. The carcinogenicity of AFB1 is 10 times more than that of AFM1. Four mycotoxins (AFB1, AFM1, OTA, DON) were evaluated in diet of adult Lebanese urban population. Average and excessive consumer exposure estimates (p95) were calculated and compared with appropriate

toxicological reference values (TRVs) of these myotoxins. Average dietary exposure levels to OTA and DON represented 29.9% and 156.8% of the respective TRVs, with the p95 exposure estimates approaching or exceeding the TRVs for these mycotoxins (95.1% and 355.8%, respectively). Average dietary exposure to AFB1 and AFM1 was associated with increased cancer risk to 0.0527–0.0545 cases/100,000 persons/year and a population risk of 0.0018–0.0027 cases/100,000 persons/year, respectively. Polycyclic aromatic hydrocarbons (PAHs) and their derivatives are also associated with many cancer types including prostate cancer which reports the highest incidence in Israel and the second incident type in Turkey. The adult population in Israel is widely exposed to PAHs. The Urinary concentrations of all PAHs were significantly higher among current smokers and increased significantly with smoking frequency. Dermal and inhalation exposures to PAHs were also assessed in the Turkish population. >99% for inhalation and 28% for dermal exposure route exceeded the acceptable level in the Turkish population.

Infection

In 2012, 15% of cancer is attributable to infection. Many types of infections can cause cancer, human papilloma virus (HPV), *Helicobacter pylori*, hepatitis B, C viruses, and Epstein-Barr virus (EBV).

Human papilloma virus

Recent studies proved the contribution of HPV, the most common sexually transmitted infection, not only to the progression of cervical cancer but also to head and neck, breast and colorectal cancer, with roughly 30%–80% of these cancer types are positive for high-risk HPV infection. HPV include onco proteins (e.g., E5, E6, and E7) induce cellular alteration and lead to carcinogenesis. Recent evidence showed a prevalence of ~50%–90% of HPV in cases of cervical cancer in ME countries. Studies from Syria, Turkey, and Tunisia on women with breast cancer concluded the presence of HBV types 16, 18, 31, 33, and 35 and their role in initial and progression of cancer.

Hepatitis C, B viruses (HCV, HBV) and human immunodeficiency virus

HCV reports high prevalence in Northern Africa, which is highly notable in Egypt that recorded the highest prevalence of HCV worldwide (15%–20%) especially after massive treatment of Schistosomiasis. Also, high rates were reported in Pakistan. Many studies addressed the association between HCV and hepatocellular carcinoma. In 2010, worldwide deaths associated-HCC reached 77% from HBV/HCV-linked HCC. Meta-analyses were conducted and proved the association between HCV and hepatocellular carcinoma; HCV and HBV coinfection was determined as independent risk factor for HCC occurrence. In Egypt, Prevalence of HBV and HCV is 6.7% and 13.9% among patients without HCC, and 25.9% and 78.5% among HCC patients. The estimated pooled OR was higher in regions where HCV is predominant; OR 16.8 (95%: 11.9–24.1) in Mediterranean countries. Cohort and case control studies were also conducted and proved the association between HCV and HCC after taking into account the confounding effect of smoking and alcohol consumption. Hepatitis C virus genotype 4 is the most prominent in Arab countries of the ME including Egypt, Iraq, Saudi Arabia, and Syria with rates of 86% (95% CI: 85%–88%), 60% (95% CI: 56%–64%), 56% (95% CI: 54%–55%), and 57% (95% CI: 54%–61%), respectively. Hepatitis C virus genotype 1 is the most prevalent in non-Arab countries in the ME region including Turkey, Iran, Cyprus, and Israel. A Joint epidemiology of HIV and HCV infections was pronounced in the ME region especially among injecting drug users,***[29] HCV infection could predict HIV prevalence especially low-level HIV epidemic $RR_{HCV/HIV}$ 16.3 (95% CI: 11.5–23.1) rather than emerging epidemic $RR_{HCV/HIV}$ 3.8 (95% CI: 3.1–4.7) or established HIV epidemic $RR_{HCV/HIV}$ 2.8 (95% CI: 2.1–3.6). HIV epidemic was high among injecting drug users in Egypt, Lebanon, Palestine, Saudi Arabia, and Syria, and less in Afghanistan, Morocco, and Tunisia.

Epstein-Barr Virus (EBV) and H. pylori

Iran reported the highest incidence of gastric carcinoma in the ME. However, EBV-Gastric Carcinomas (EBV-GCs) occur in 3% of the gastric carcinomas in Iran and most of gastric carcinoma are EBV negative. The causal association could be proved by virus predisposition in neoplastic cells and colonization in tumor cells by in situ hybridization of EBV-encoded small RNA-1(EBER-1), but not in surrounding epithelial cells. The most commonly expressed latent proteins of EBV are EBNA1 (98.1%) and LMP2A (53.8%) which differ from the standard pattern of EBV proteins transcription in cases of gastric carcinomas. So, more researches are needed to explain EBV-associated carcinogenesis. Nasopharyngeal carcinoma (NPC) is rare cancer in ME, but the geographical variation of this cancer is due to combined Epstein-Barr virus (EBV) infection, genetic predisposition, and environmental factors including diet. Breast cancers showed a positive EBV genome in 40.0% of cases in Algeria, and 32.8% of cases from Tunisia. The incidence of non-Hodgkin's lymphoma (NHL) caused by EBV is increasing in North Africa especially Burkitt's lymphoma where EBV could be detected in almost all cases but less frequently observed in sporadic lymphoma. The risk of NHL in human immunodeficiency virus-seropositive (HIV+) subjects is also double that of HIV-seronegative (HIV−) individuals. Regarding *H. pylori* infection, the cytotoxin associated gene A (CagA) protein is one of *H. pylori* virulent proteins associated with atrophic gastritis, peptic ulcer, and gastric carcinogenesis. The distribution of this protein is high in Turkey, Iran, Iraq, and very low in Egypt. The Vacuolating cytotoxin activity (VacA) is another *H. pylori* virulence factor that is associated with gastric cancer and gastric ulcer in Iran and Iraq.

Preventive Strategies and Cancer Control

Core components for comprehensive cancer control include prevention, screening, early diagnosis, treatment, and palliative care.

Cancer Primary Prevention Policies

While primary prevention presents the optimal solution for cancer control based upon knowing the causative agents, many preventive measures are not suitable for certain cancer types. It is important to consider the available local evidence and availability of country-specific resources.

Tobacco smoking and alcohol

Low-middle income countries are fighting with tobacco dependence in the ME. By 2030, death forecast reveals that these countries will suffer from 80% of tobacco deaths. Collaborative efforts should be exerted to apply the consensus smoking cessation guidelines considering the limited available resources. The guideline documents involve the following domains for tobacco control:

Policies for tobacco prevention

Six policies are highly cost-effective and suitable for ME countries to reduce tobacco demands:

- Higher taxes on cigarettes and other tobacco products
- Bans/restrictions on smoking in public and workplaces
- Comprehensive bans on advertising of all tobacco products
- Better consumer awareness and information
- Large warning labels on all tobacco products
- Support programs for smoking cessation

Support programs for treating tobacco dependence

A program for treating tobacco dependence includes psychological, behavioral, and pharmacological therapies. Clinicians should consider that tobacco smokers may persist for several years till achieving the required outcome and they may pass through several cycles of attempts, remission, and relapse. Health care providers could use either the individualized approach by using the most effective treatment strategy or the combined approach of either counseling with medications or several types of therapies. Two forms of counseling are effective: practical counseling (problem solving/skills training) and social support delivered as part of treatment. The combination of counseling and medication is more effective than either alone. Brief interventions are also effective especially in low-middle income countries as could reach large population within short period (10 min) of time. The 5 A model is an example of these interventions that can be conducted in the primary care settings (**Fig. 4**). It consists of ask, advise, assess, assist, and arrange for the treatment of tobacco dependence. Another approach is the algorithm derived from the New Zealand Ministry of Health guidelines. The following are summaries of the recommendations that could be adapted in the ME:

- Ask about smoking status.
- Give positive feedback with regular checkup for nonsmokers.
- Advice smokers to quit tobacco use.
- If the smoker has a smoking-related disease, advice could be linked to the related condition to encourage quitting.
- The smoking status should be checked every one year for those willing to quit to ensure cessation.
- If primary health care worker could not provide support, he should refer the patients to the appropriate smoking cessation services.
- Support of smoking cessation services involves setting of cessation date, arranging of follow-up visits especially at the start of cessation, and providing the suitable medications. First-line medications reliably increase long-term smoking abstinence rates:
  - Bupropion (sustained release, usual duration up to 14 weeks)
  - Nicotine gum (usual duration 6–14 weeks)
  - Nicotine inhaler (usual duration up to 6 months)
  - Nicotine nasal spray (usual duration up to 6 months)
  - Nicotine patch (usual duration 6–14 weeks)
  - Varenicline (usual duration up to 14 weeks)

Updated data from ME are needed to describe the observable new rising trend of alcohol intake. WHO promotes public policies worldwide that can be implemented in the ME to reduce the burden of harmful use of alcohol:

- Regulating the marketing of alcoholic beverages (in particular to younger people);
- Restricting availability of alcohol;
- Reducing demand through taxation and pricing mechanisms;
- Raising the public awareness of different health problems caused by excessive use of alcohol and ensuring support for effective alcohol policies;

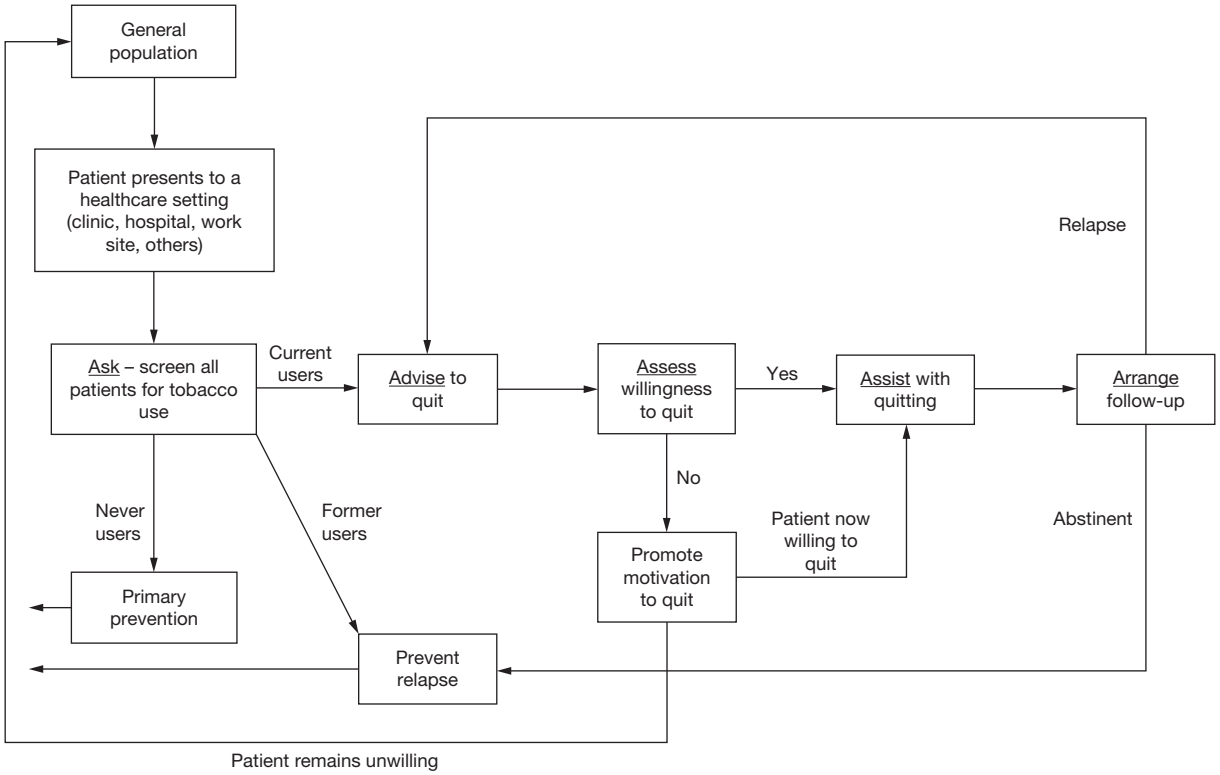

Fig. 4 The 5 A model for treating tobacco dependence.

- Providing accessible and affordable treatment for alcohol use-associated disorders; and
- Implementing screening programs for hazardous and harmful drinking in health services.

Obesity, unhealthy lifestyle, and environmental factors

Although cancer incidence in the Non-European Mediterranean region is still now less than that reported in the European Union, projection of the next two decades denotes a sharp rising trend which could be attributed to insufficient effective cancer prevention strategies and control programs together with population aging and worsening of dietary and environmental habits. Health care professional should apply the appropriate counseling for high-risk population.

Infection

Human papilloma virus

Control of HPV infection can reduce the incidence of cervical as well as other cancer types as breast cancer that was proven by two metaanalyses and a study from the ME. Vaccination for human papilloma is highly effective, safe, and licensed by national control authorities in developed countries. However, vaccines are not easily available in most of developing countries in the ME (**Table 4**). Some countries even lack the appropriate investigations for detection of high-risk HPV besides the expensive vaccination programs that are not affordable in many ME countries. Synthesis of population and epidemiologic data for 20 countries in the Extended Middle East and North Africa (EMENA) was done to study the effect of vaccination in preadolescent girls estimated by averted cervical cancer cases and deaths, disability-adjusted life years (DALYs) and cost-effectiveness ratios (I$ [international dollars] per DALY averted). When the cost per vaccinated girl exceeded I$50 in Lebanon and Turkey and I$150 in Algeria, the vaccine was not cost-effective. It was affordable only in five countries when its cost was I$200. Two available vaccines are available according to HPV type; Gardasil® for HPC types 6, 11, 16, and 18 and Cervarix for HPV types 16 and 18. However, these vaccines can protect against only 70% of HPV infection and not effective for high-risk HPV virulent strains that trigger various types of cancer. The United Arab Emirates health system was the first to introduce HPV free of charge vaccine for high school girls. One of the best preventive measures in addition to sexual health education is the development of vaccine covering the most frequent 9 types of HPV that cause carcinogenesis (6, 11, 1, 18, 31, 33, 45, 52, and 58) but not yet implemented in the high-risk countries of ME.

Hepatitis C virus

Egypt represents the highest burden of Hepatitis C virus in the ME. However, the prevalence of HCV was reduced by 30% from 2008 to 2015. Strategies to eliminate HCV subsequently reduced the incidence of HCC. Recently, the National Committee for Control of

Source: WHO Cancer country profiles (http://www.who.int/cancer/country-profiles/en/).

Viral Hepatitis (NCCVH) was established to provide a novel model of care (MOC). The mission of MOC is to provide national treatment programs supplying antiviral therapy either at very minimum cost or totally free of charge. Egypt has succeeded to negotiate in reducing the price of sofosbuvir with previous commitment in treatment by Peg-interferon/RBV. Preventive strategies were provided to raise public awareness especially the high-risk groups to further minimize the risk of HCV transmission, improve infection control, ensure safe injection practices, and adopt safe blood products. The MOC activity also establishes the practice of adapted national guidelines for chronic HCV treatment as supplied by national expert hepatologists and training of health care professionals for efficient counseling of chronic HCV patients. The national guidelines were adapted from guidelines for screening and management of patients with Hepatitis C virus. It involves stepwise approach for screening, diagnosis, and treatment of HCV infection and follow-up of patients to prevent hepatocellular carcinoma.

- *Screening for HCV*: Patients on haemodialysis, blood/tissue donors, and health care professional who are exposed to procedures should be tested for HCV. Screening also includes patients with persistently elevated alanine aminotransferase, injecting drug users, patients diagnosed with HIV infection, patients with medical and dental treatment or those making tattoo or piercing in ME countries known to be endemic with HCV, children born to HCV-infected mothers and finally, household contact with HCV-infected patients.
- *HCV diagnostic testing*: It should be tested on serum or plasma where possible and HCV genotyping should be undertaken if antiviral therapy is being considered. If health care professionals are suspected of percutaneous exposure to infection, they should be tested for HCV ribonucleic acid (RNA) at 6, 12, and 24 weeks and anti-HCV testing should be considered at 12 and 24 weeks.
- *Treatment of acute infection*: Patients require close monitoring, both clinical and laboratory for the first 3 months so that the infection may be resolved spontaneously. They should be offered IFN therapy either pegylated IFN or nonpegylated IFN for 24 weeks regardless the genotype.
- *Treatment of chronic HCV infection*: All patients should be treated with antiviral therapy and sustained virological response should be a marker for viral clearance. The selection of antiviral therapy is based on the genotype:

– Genotype 1

Treatment: Naïve and treatment-experienced patients should be treated with pegylated IFN, weight-based ribavirin, and a protease inhibitor as triple therapy. The duration of therapy varies depending on early viral response at 12 weeks. The treatment should continue until 48 weeks; those with still positive virus RNA at 24 weeks, should discontinue the treatment.

– Genotype 4

Patients with HCV genotype 4 infections: Standard treatment should be 48 weeks of pegylated IFN and weight-based ribavirin.

Caution should be taken to avoid adverse effects of interferon (IFN) and ribavirin therapy. They should not be prescribed in pregnant women and in patients with psychiatric illnesses.

Hepatitis B virus

Hepatocellular carcinoma is caused by HBV in most ME countries with the exception of Egypt and Pakistan. Prevention of HBV involves three levels: primary prevention by effective HBV vaccination for healthy population, secondary prevention through hepatitis B antiviral agents, and tertiary prevention to prevent infection recurrence. Hepatitis B vaccine is safe and very cost-effective as licensed and incorporated by WHO into expanded program immunization (EPI) worldwide with wide coverage in the low-middle income countries (>90% response rate in nonimmunocompromized subjects). It is available in three doses that significantly reduce the prevalence of HBsAg in children and young adults (**Table 4**). WHO recommends a birth dose vaccine given to all newborns within the 24 h after birth. Although the birth dose vaccine significantly reduced HBV infection by about 70% in infants born to highly infectious mothers, not all African countries adopt it; even these counties face difficulties in implementing the vaccine. Some Countries didn't not yet integrate it. This may be due to the minimal estimated perinatal transmission and lack of sufficient evidence and clinical trials conduction for it in pregnant women in the African countries (**Table 4**).

The following strategies are needed for better control of both HCV and HBV infections and decrease HCC incidence:

- *Operational research programs*: Epidemiological surveys and population-based screening programs are needed to assess research priorities about risk factors of transmission and to determine cost-effective approaches for screening and treatment. Unfortunately, most of the screening programs in Africa are expensive and are not of considerable quality. The PROLIFICA (Prevention of Liver Fibrosis and Cancer in Africa) program is a screening regimen that was conducted in Gambia, not in the ME. It is concluded that only 1% of positive HBs antigen in the adult previously tested and aware of their diagnosis. Though the PROLIFICA program estimated around 50% of HBV infection in the Gambia was attributed to vertical mother to infant transmission, only 3% of infants received the birth dose HBV vaccine due to recognized social and financial barriers that are similar to the situation in many ME countries.
- *Improving screening and early treatment of infected patients*: WHO facilitates the selection criteria for infected patients who need early treatment in resources constrained countries: (a) A patient who is HBsAg positive and has cirrhosis and (b) patients with HBsAg who are over 30 and have persistently raised alanine aminotransferase (ALT) levels. Policy makers should focus on resource allocation for treatment, negotiation with generic drugs production companies to supply drugs at lower prices. Treatment of

HBV is challenging in the ME. Proper screening and treatment programs are lacking in many ME countries because the cost of the programs are the responsibility of patients and due to their availability in private sector only. Tenovir, the drug of choice for HBV treatment, is supplied by the global funds at a lower price of $50 per patient per year but not for HBV monoinfection and even not licensed by some African countries.

- *Surveillance for HCC in cirrhotic patients*: Cirrhosis is the main causative agent for occurrence of HCC. Regular surveillance interval at 6 months is recommended than annual surveillance to improve the survival of cirrhotic patients and minimize the incidence of HCC. The best-known surveillance option is the liver ultrasound that is available with good accuracy in most of ME countries, but not in the rural areas and it is highly dependent on operator experience. It is imperative to train health care providers on ultrasound as an easy and applicable surveillance system tool.

H. pylori infection

WHO recommends all countries consider screening for *H. pylori* for primary prevention of gastric cancer. The International Agency for Research on Cancer (IARC) *Working Group of international experts suggested population-based* screening for eradication of *H. pylori* which reduce the incidence of gastric cancer by 30%–40%. However, low-middle income countries recognized with high burden of gastric cancer do not properly implement this screening program. The screening program consists of three steps: *First:* culture, histology, rapid urease test (RUT), histopathology, PCR, and a serology test to screen for *H. pylori* in healthy individuals. Second step involves the eradication treatment with antibiotics from a primary care doctor if required, then the final step is retest by urea breath test (UBT), stool antigen test (SAT), and second-line treatment if required. *H. pylori* screening programs are cost-effective. A cost-effectiveness of a *H. pylori* serology-based screening program in New Zealand, a country with relatively high gastric cancer rates, illustrated that the incremental cost for national screening program was US$196 million (95% uncertainty interval [95% UI]: $182-$211 million) with health gains of 14,200 quality adjusted life years (QALYs) (95% UI: 5,100–26,300) and the screening program was more cost-effective by US$8,000 ($3,800-$18,500) per QALY.

H. pylori eradication therapy was proved to protect against the occurrence of gastric carcinoma and reduce its incidence (risk ratio (RR) 0.66; 95% CI: 0.46–0.95). However, in patients with preneoplastic lesions, *H. pylori* eradication measures do not play a significant role for gastric cancer prevention. It is available in many forms: (1) proton pump inhibitor (PPI) dual therapy (PPI plus either amoxicillin or clarithromycin); (2) PPI triple therapy (PPI plus any two of the following: amoxicillin, macrolide, 5-nitroimidazole); (3) histamine 2-receptor antagonist (H2RA) triple therapy (H2RA plus any two of the following: amoxicillin, macrolide, 5-nitro imidazole); (4) bismuth triple therapy (bismuth salt and 5-nitroimidazole with either amoxicillin or tetracycline); (5) bismuth quadruple therapy (as bismuth triple therapy, but with the addition of a PPI); (6) ranitidine bismuth citrate (RBC) dual therapy (RBC plus either amoxicillin or clarithromycin); (7) RBC triple therapy (RBC plus any two of the following: amoxicillin, macrolide, 5-nitroimidazole); (8) clarithromycin monotherapy. Antibiotic resistance is a possible cause of *H. pylori* treatment failure in the ME. The combined levofloxacin, and clarithromycin and esomeprazole-based regimen as first-line triple therapy for *H. pylori* eradication can give better eradication rate with same safety when compared with standard triple therapy (clarithromycin 500 mg twice daily, Amoxicillin 1000 mg twice daily, plus esomeprazole 20 mg twice daily for 7 days). The rapid urease test (RUT) is a popular, easy, and cheap screening test based on the presence of Urease in the *H. pylori*-infected gastric mucosa. It could be easily used in low-middle income countries of the ME. However, the former intake of proton pump inhibitors (PPI) should be taken into account prior to testing to avoid false negative results. Also, More than 10,000 bacterial cells are required to achieve positive test results.

In Iranian population, Gemifloxacin-containing quadruple therapy (amoxicillin 1 g, bismuth 240 mg, and omeprazole 20 mg for 14 days) provides high *H. pylori* eradication rate ($\geq$90% per protocol cure rate) after the failure of first-line standard quadruple therapy (clarithromycin–amoxicillin–bismuth–omeprazole).

Early screening and prevention of EBV could prevent gastric carcinoma, lymphoma, and nasopharyngeal carcinoma. IgA antibody titres to EBV viral capsid antigen (EBV-IgA-VCA) and EBV early antigen (EBV-EA) can be used for the serologic screening of nasopharyngeal carcinoma. However, even after screening, attempts to develop vaccines continue and still under investigations because the success of this vaccine depends on cancer pattern in each country and the cost versus benefit.**Table 4** illustrates the summary of cancer primary prevention policies in all ME countries as adapted from WHO country profiles report.

Cancer Screening and Early Detection

The focus of cancer control is to diagnose cancer in the earliest possible curable stage, thus improving the quality of life and prognosis of cancer patients.

WHO summarized the major elements for cancer early diagnosis into three main domains:

1. *Step 1*: Awareness of cancer symptoms and accessing care
2. *Step 2*: Clinical evaluation, diagnosis, and staging
3. *Step 3*: Access to treatment, including pain relief.

Step 1: Awareness of cancer symptoms and accessing care

The patient should be aware of cancer symptoms (symptom appraisal interval). He or she should be encouraged to overcome fear and cancer stigma, and access primary care. Thus, awareness of symptoms will be translated into health-seeking interval.

Barriers

(a) Poor health literacy
(b) Cancer stigma
(c) Poor access to primary care

Solutions

(a) Empower and engage people and communities
(b) Improve health literacy and reduce cancer stigma
(c) Leadership and governance to improve access to care

Step 2: Clinical evaluation, diagnosis, and staging

This step is known as diagnosis interval. It involves three stages: First, the patient should be evaluated by health care provider to ensure if cancer may be present (diagnostic evaluation); second, the patient receives diagnostic testing for confirmation including clinical, laboratory, and pathological confirmation testing and patients undergo staging to determine cancer spread (diagnostic testing and staging). Finally, if patient confirmed by cancer presence, he or she should be referred for treatment to specialized centers providing safe and effective treatment across ranges of modalities needed (treatment interval).

Barriers

(a) Inaccurate clinical assessment and delays in clinical diagnosis
(b) Inaccessible diagnostic testing, pathology, and staging
(c) Poor coordination and loss to follow-up

Solutions

(a) Improve provider capacity at first contact point
(b) Strengthen diagnostic and pathology services
(c) Develop referral mechanisms and integrated care
(d) Provide supportive counseling and people-centered care

Step 3: Access to treatment

Many patients from LMIC recently diagnosed with cancer do not immediately initiate treatment due to financial, geographic, logistical, and sociocultural barriers.**Table 5** shows how ME countries use cervical, breast, and colorectal cancer screening and early detection strategies at the public primary health care level for early diagnosis of cancer types.

An example of early detection program is the EUROMED CANCER Network project. It aimed to support the non-EU Mediterranean countries about the appropriate cancer screening programs. It illustrates the importance of public health surveillance through a structured questionnaire survey applied to 15 countries (Albania, Algeria, Bosnia and Herzegovina (BiH), Croatia, Egypt, Jordan, UN Interim Administration Mission in Kosovo, Lebanon, Montenegro, Morocco, Palestinian National Authority, Serbia, Syria, Tunisia, and Turkey). Many of them are ME countries. It is concluded that applying a uniform strengthening system for cancer control for all these countries may not be feasible. However, tailored surveillance of early detection programs considering each country's resources should start early with appropriate uniform health information system. One of the project's recommendations is breast cancer (BC) and cervical cancer (CC) screening as the commonest female cancers in the region. The most frequent breast cancer screening test is mammography, either alone or combined with clinical breast examination (CBE), breast self-examination (BSE), or ultrasound. It is feasible and applied in all project's studied countries (**Table 5**). The starting age in BC organized screening is 40–45 years in most countries but in others, screening starts even earlier. The age upper limit is 69 years in most countries, but in Lebanon, it goes up to 75. An interview by structured questionnaire in a multicenter survey among the Qatari women showed that fewer than half of the participants were aware of breast cancer screening recommendations; less than one third performed this screening. Around one-quarter of them stated that they were counseled by their doctors about appropriate BC screening. Most of the participants stated that they were ready for a mammogram appointment based on a recommendation by their health care professional, hence, notifying the important role of heath care providers for women counseling about different cancer screening programs. Many ME countries lack the National Organized Cervical Cancer Screening (NOCCS) program due to the insufficient political support of public health programs, lack of resources, little participation due to cultural factors, and insufficient women knowledge. This subsequently contributes to late detection of cervical cancer. Screening by Pap test could be possible in many countries (**Table 5**). It is usually in use starting at about 20 and ending at 60 years. In Morocco, an alternative to Pap test is visual inspection after application of acetic acid (VIA). Comparison of the cost-effectiveness of different cervical cancer (CC) screening tests in Lebanon using either cytology or HPV testing and at different coverage percentage concluded that 20% coverage by annual cytology testing reduced CC risk by 14% with an incremental cost-effectiveness ratio of I$80,670/year of life saved (YLS). Increased coverage to 50% with 3 and 6 years intervals yielded CC reduction of 26.1% and 21.4%, respectively at lower costs compared to 20% coverage with annual screening. Screening every 5 years with HPV DNA testing at 50% coverage resulted in 23.4% reduction in CC (than cytology at the same frequency) with an incremental cost-effectiveness ratio of I$12,210/YLS. The main implication of this research that repeated cytology covering a small percentage of women may be inefficient, while increased coverage up to

50% and extending screening interval are cost-effective. More attention should be paid toward novel HPV screening strategies providing greater CC reduction and more cost-effective than cytology. Colorectal cancer (CRC) screening program adoption is variable. While some countries as Lebanon did not provide any information either optimistic or organized about it, Turkey has a well-organized screening program. The immunochemical faecal occult blood test (i-FOBT) is the most commonly adopted test. In Oman, although CRC screening test could be implemented immediately upon physician's order, an operational cancer policy or action plan does not exist in addition to the lack of official statistics measuring regular uptake of screening services. A survey among Omani physicians and nurses to identify their practice toward CRC screening concluded that a few percentage did not exceed 40% who practice the following for screening:

- Order CRC screening for patients
- Refer patients to get CRC screening
- Health educates patients about CRC screening
- Order genetic testing for patients suspected of inherited susceptibility to CRC
- Health educate patients with suspected inherited susceptibility to CRC and refer them whenever possible for genetic testing

The following recommendations were perceived by Omani physicians and nurses to positively influence the process of CRC screening:

- Availability of system to identify patients eligible for CRC screening services
- Continuing professional education on cancer prevention
- Availability of a specialist in cancer
- Evidence published in scientific journals (somewhat influential)
- Policy on cancer screening

Barriers for implementation of CRC screening test were:

(a) Patients-related barriers

- Fear of finding out that they have cancer.
- Believe screening is not effective.
- Embarrassment or anxiety about screening tests.
- Unawareness of CRC screening tests and when they should be done.
- Patients do not perceive CRC as a serious health problem.
- Culture is not favorable to procedures used for CRC screening.

(b) System-related barriers:

- Screening costs are expensive.
- Long waiting time for screening appointments.
- Lack of hospital policy or protocol on cancer screening.
- Health care providers do not actively recommend CRC screening to patients.
- Shortage of trained health care workers to conduct CRC screening and follow-up with invasive procedures.

One of effective primary prevention tools for HCC is regular follow-up of cirrhotic patients with ultrasound. Early cancer detection measures for screening of HCC are serum alpha-fetoprotein (AFP), but still expensive with poor sensitivity and urinary markers. The urinary metabolite panel, comprising inosine, indole-3-acetate, galactose, and an *N*-acetylated amino acid (NAA), showed an area under ROC curve of 0.88 to differentiate between cases with HCC and only Cirrhosis. The measurement of Alfa-fetoprotein should not be used in isolation for screening or surveillance of the development of HCC in patients with hepatitis C, but, combined with ultrasound every six months and should be confined to patients with cirrhosis. Prostate cancer incidence is relatively low in ME with high incidence in Cyprus, Israel, and Somalia. Screening by total prostate-specific antigen (tPSA) may enhance early detection. A multicentered study from 22 Arab countries of the ME and North Africa investigates the proportion of patients with tPSA $>$ 10 ng/mL who had prostate cancer. Although evidence from Europe and USA denotes around 50% chance of prostate cancer with a high level of tPSA $>$ 10 ng/mL, there was prominent overlap in proportion of high PSA among ME patients with Prostatitis (20.5), benign prostatic hyperplasia (63.8), and prostate cancer (11.2). Absence of indicative tumor marker in light of low sensitivity and specificity of tPSA necessitates close follow-up of patients with high tPSA for a progressive decline in or return to normal PSA values with or without treatment of prostatitis, but certainly after transurethral resection of prostate (TURP) for large symptomatic BPH, to confirm the absence of prostate cancer. Persistent rising of tPSA is preliminary suggestive of prostate cancer and needs further investigation by trans rectal ultrasonography (TRUS) of the prostate and biopsy of suspicious lesions for histological diagnosis.

Palliative Care Policies

Cancer remains one of the most important challenges for the population in the ME. Around 50% of cancer patients consult physicians for the first time at stage 3 or 4. Nothing is left except palliation. Palliative care (PC) is defined according to WHO as "an approach that improves the quality of life (QOL) of patients and their families facing the problem associated with

life-threatening illness, through the prevention and relief of suffering by means of early identification, assessment, treatment of pain and other problems, physical, psychosocial and spiritual."

PC is still in its infancy in many ME countries. Application of cancer care model from western developed to developing countries proves to be unrealistic due to many reasons:

- The dysfunctioning primary health care system: Lack of well-trained family physicians in many countries compels cancer patients to seek treatments at tertiary care centers for minimal symptoms that could be managed by trained local treating physicians.
- Current beliefs that hinder the best cancer care: These include cultural, religious, and family opinions. Fear and stigma associated with cancer let many patients hesitate to seek treatment. Cultural concepts affect the female patients' adherence to treatment and follow-up due to insufficient professional female caregivers. Also, many terminal cases refuse cancer care due to "God's will" concept; therefore, patients are less demanding all possible treatments.
- Limited available cancer treatment in terms of radiotherapy and chemotherapy: While there is debate in developed countries about the use of newly advanced technology radiotherapy (e.g., proton beam, IGRT, IMRT, etc.), there are debates in some countries of the ME about who gets treated and who does not. Radiotherapy is cost-effective and 40% of cancer cure could be achieved by radiotherapy that should be available in every ME country. Analgesic opioids consumption is also the lowest in ME. Many physicians face patients' treatment rejection for fear of addiction.

One of the strategic actions for cancer prevention and control in the Eastern Mediterranean region was to improve cancer management and support PC and pain relief through the following action plans:

- Strengthen cancer diagnosis and treatment programs through all levels of care.
- Promote and implement interventions in childhood cancers at different levels of the health system.
- Strengthen the development of human resources in cancer management.
- Develop or strengthen PC services, including promotion of community nursing and home care.
- Ensure accessibility and affordability of PC medicines.
- Support integration of cancer management and PC in primary health care.

It is crucial to put resources difference apart from in ME countries and to develop a third part collaboration to integrate PC like Middle East Cancer Consortium (MECC). It is a nongovernmental unique valuable organization that collaborates with regional ministers of health and international health care organizations. Members of it include Egypt, Jordan, Palestine, Israel, Cyprus, Turkey, and the USA. Countries such as Pakistan, United Arab Emirates, Lebanon, Morocco, Iraq, Sudan, Qatar, and Oman are actively participating in MECC's training programs. MECC seeks to over bridge the barriers of palliative care by offering training for oncologists, developing palliative care programs, and improving communication between health care givers and patients. Many countries are in the capacity building stage to improve PC. Turkey initiated a model to other countries through a novel program whereby population-based and home-based palliative care teams were developed throughout the country, including peripheral areas where appropriate care was not available. Bahrain started PC unit in 2009 that serves patients through follow-up, pain clinics, and a hotline for home care patients. Jordanian Ministry of health is now integrating PC in inpatient and outpatient services with around 400 new patients per year and care for about 60–80 patients a month (30–40 patients through home care). However, attention should be paid to postgraduate education and training programs for health professionals. Oman is still in the earliest stage of PC services. The increasing incidence of cancer in Oman necessitates training of oncologists especially for opioid administration, and awareness programs for patients with cancer to help with the opioidphobia. Egypt with >90 million residents in 2015 and with cancer prevalence of 215,000 cases in 2012 has no oral morphine which is problematic in patients with end-stage cancer. Slow-release morphine tablets (30 mg) were previously prescribed and manufactured under licence by a single supplier in the United Kingdom of Great Britain and Northern Ireland. Nowadays, it is not available in Egypt. Immediate action should be taken to avoid such shortage and support cancer pain relief. PC is not also well established in other countries as in Iraq and Syria relative to advances in Saudi Arabia where specialized PC centers are available and embrace intensive management unit, consultation service, outpatient clinics, and home health care programs. The Saudi PC team consists of physicians, nurses, social workers, and other supportive care providers (dieticians, physical therapist, a unit translator, home health care nurses, health educator, and pharmacists). Dedicated PC centers in UAE and Qatar were well established and efforts are made to best integrate home health care services.

Cancer Risk Reduction Through Lifestyle Changes☆

Christina Bamia, National and Kapodistrian University of Athens, Athens, Greece

Glossary

Epidemiology The science concerned with the study of factors determining and influencing the frequency and distribution of disease and other health-related events and their causes in a defined human population.

Micronutrient A vitamin or mineral that the body must obtain from outside sources. Micronutrients are essential to the body in small amounts because they are either components of enzymes (the minerals) or act as coenzymes in managing chemical reactions.

Nutrigenetics The science to identify how genetic variation affects response to nutrients.

Nutrigenomics The science of the effects of foods and food constituents on gene expression.

Oncogene Mutated and/or overexpressed version of a normal gene that in a dominant fashion can release the cell from normal restraints on growth and thus, alone or in concert with other changes, convert a cell into a tumor cell.

Pharmacotherapy The treatment of diseases or conditions by medicines.

Polymorphism The occurrence of different forms (alleles) of a gene (typically $>1\%$) in individual organisms or in organisms of the same species, independent of sexual variations.

Primary prevention The identification, control, and avoidance of environmental factors related to cancer development.

Randomized, controlled trials A clinical trial that uses a control group of people given an inactive substance (placebo) and an intervention group given the substance or action under study.

Sunscreen A substance applied to the skin to protect it from the effects of the sun's rays; sunscreens act by either absorbing ultraviolet (UV) radiation or reflecting incident light. Their effectiveness is rated by their sun protection factor (SPF); for example, a sunscreen with an SPF of 15 allows only 1/15 of the incident UV radiation or light to reach the skin.

Introduction

Cancer remains a leading cause of mortality. It is estimated that by 2020 there will be 16 million new cancer cases, and 10 million related deaths, whereas there may be >20 million new cases of cancer in 2030. Lifestyle behaviors are modifiable key factors for cancer prevention and cancer survivorship. It is now acknowledged that lifestyle habits including tobacco use, poor diet, physical inactivity, alcohol abuse and overexposure to sunlight are associated with 50% to 70% of all cancers, meaning that 281,000 to 395,000 cancer deaths each year could be prevented through changes in health behaviors in population level.

Effective interventions have been suggested in clinical trials for modifying lifestyle habits and specifically so for reducing tobacco use, increasing physical activity, reducing sun exposure, and reducing alcohol excess intake. Nonetheless millions of adults are engaged in risky behaviors: approximately 23% smoke, $<25\%$ follow dietary recommendations (e.g., about fruits and vegetables) and about 40% are physically inactive.

The previous figures may indicate a failure in transferring evidence-based findings to the general public. Therefore, disseminating the scientific knowledge about the importance of behavioral changes in cancer prevention and survivorship, as well as, delivering, through health care systems, effective interventions towards healthier lifestyle choices, are major, urgently needed tasks for public health policy makers worldwide.

Diet and Cancer

The association of diet with health outcomes, including cancer is of special interest due to the essential role of diet in human being. On the other hand, diet is a modifiable risk factor which can be directed towards healthier choices, in individual and population level through clinical advice and public health policies. Many studies focused on single foods, food groups or nutrients in association to cancer incidence/mortality worldwide. In addition, studies have also focused on the association of *dietary patterns* with cancer incidence and survival. Notably, the importance of the growing body of research regarding the benefits of healthy eating in cancer prevention/mortality is reflected in the recent reports of the World Cancer Research Fund (WCRF)/American Institute

☆*Change History:* November 2017. C. Bamia updated the text and updated Table 1 with two additional smoking cessation methods.
This article is an update of Peter Greenwald, Darrell E. Anderson, and Sharon S. McDonald, Cancer Risk Reduction (Diet/Smoking Cessation/Lifestyle Changes), in Encyclopedia of Cancer (Second Edition), edited by Joseph R. Bertino, Academic Press, 2002, Pages 311–317.

for Cancer Reduction (AICR) and in certain dietary guidelines (e.g., US Department of Health and Human Services and US Department of Agriculture, 2015).

Individual Foods, Food Groups and Nutrients

The strength of the overall evidence for specific dietary constituents in relation to cancer incidence depends on the number and quality of published studies, as well as, on the consistency of the reported findings. The level of evidence can be ranked from "low/unlike" to "convincing".

In the 2017 major review of WCRF/AICR on the role of diet, somatometry and physical activity in cancer risk and mortality, the global research based on studies published up to 2017, was evaluated. The evidence for *increased* cancer risk was rated as "convincing" for the following associations: aflatoxins and liver cancer; processed meat and colorectal cancer; beta-carotene, in the form of high dose supplements, and lung cancer; alcohol intake and cancers of: (a) mouth, pharynx and larynx, (b) esophagus (squamous cell carcinoma), (c) liver, (d) colorectum and (e) postmenopausal breast. In addition, the evidence for increased cancer risk was evaluated as "probable" for the following associations: red meat and colorectum cancer; processed meat, foods preserved by salt and alcohol and stomach cancer; alcohol and premenopausal breast cancer.

On the other hand, the evidence concerning foods and nutrients associated with *decreased* risk of cancer has been evaluated at the most as "probable' (but not convincing). Such associations have been highlighted for: colorectum cancer and consumption of wholegrains, foods rich in dietary fiber, dairy products and calcium intake, either from diet or from through supplements (200–1000 mg/day); lung cancer and fruit intake; mouth, pharynx and larynx and fruit, as well as, starchy vegetables intake; liver and endometrium cancers with increased coffee consumption, and; kidney cancer with alcohol intake.

Associations that have been investigated, but were judged as "unlikely" were those for beta carotene intake either through diet or as supplement intakes in relation to prostate and skin cancer risk.

Dietary Patterns

Dietary patterns (DPs) are an alternative approach to assess diet in a holistic way, that is, as a combination of, rather than as isolated, dietary components. A DP can be hypothesis-driven (a priori DP), expressing adherence to a distinct diet for example, the Mediterranean Diet (MD), or, level of compliance with formal dietary guidelines such as the WCRF/AICR guidelines for cancer prevention. DPs can be also empirically derived (a posteriori DPs) through the application of mathematical/statistical methods which identify suitable combinations of a set of dietary variables.

A-priori DPs

The Mediterranean Diet Score (MDS), which quantifies the traditional diet of people living in olive-growing areas around the Mediterranean basin is characterized by high intake of vegetables, fruits, fish (high in n-3 fatty acids), legumes, cereals and olive oil (high in monounsaturated fatty acids), low intake of dairy and meat, and moderate alcohol intake, and has been repeatedly investigated with respect to cancer incidence/mortality. Other frequently-used indices in studies of cancer outcomes include: (a) the Healthy Eating Index (HEI) based on the 1992 USDA Food Guide Pyramid and the 1995 Dietary Guidelines for Americans, (b) the Dietary Approaches to Stop Hypertension (DASH) diet index, (c) the Diet Diversity scores, and (d) WCRF/AICR index, as well as variations of the above.

A-posteriori DPs

A-posteriori DPs may include both, "healthy" and "unhealthy" dietary choices and are labeled in various ways, the most frequent ones being: "prudent", "vegetable/fruit", "traditional", "western-type", "animal", "fat and salty", "refined", "alcohol-based", "drinking", based on the foods mainly characterizing these patterns and their suspected relation with specific cancer sites. A-posteriori DPs that share common labels (e.g., "healthy") may, however, include different foods/food groups.

Dietary patterns and cancer incidence/mortality

Many systematic reviews and meta-analyses for adult populations have been undertaken on the indicated a priori and a posteriori DPs in relation to cancer risk/mortality overall, as well as, by cancer site. A 2016 comprehensive review examined 64 studies of prospective design, including many large multiregion cohorts reporting on a priori dietary patterns. Meta-analyses have been also undertaken for quantifying the overall evidence regarding the association of MDS, as well as, HEI, AHEI, and DASH diet with cancer incidence or mortality. A posteriori patterns have been also studied in systematic reviews in relation to colorectal, breast, gastric, esophageal and lung cancer.

Accumulated evidence from the aforementioned research indicates that there may exist a priori and a posteriori DPs that are associated with reduced cancer risk, and specifically so for colon cancer, breast cancer (especially for the postmenopausal breast cancer) and gastric cancer. From the a priori DPs, collective evidence seems to consistently indicate inverse associations of overall cancer risk with MDS, HEI, AHEI and DASH dietary indices and variations of those. The same holds for a posteriori DPs that have been considered/labeled as "healthy". Evidence is less conclusive for DPs that have been found to be associated with increased cancer risk, mainly the a posteriori "unhealthy" DPs.

Interactions likely occur among many dietary constituents. However, neither these interactions nor their influence on cancer risk are well understood. Thus, at present it is difficult to tease out the specific effects of individual dietary components from diet and cancer research data.

Randomized, Controlled Trials

Most of the evidence relating diet with cancer risk/mortality relies on observational studies. On the other hand randomized controlled trials (RCTs) offer one of the best means for testing diet and cancer hypotheses developed from the insights provided by epidemiologic and experimental studies. Specific dietary constituents have been investigated in RCTs such as vitamins A, C, D and E, folic acid, calcium, and selenium, beta-carotene etc. Interventions in these trials consisted of high-dose daily supplements of the aforementioned vitamins compared to placebo or to no special dietary advice in the group of controls. From these, vitamin D, calcium and selenium have shown promise in reducing overall/site-specific cancer risk.

A few RCTs have been also undertaken with respect to dietary patterns such as low-fat diets for the prevention of breast cancer and MD for the prevention of cancer in general, but due to limited number of studies results are still inconclusive.

Gene–Nutrient Interactions

Recently, research on the relationship between diet and cancer has also focused in gene–nutrition interactions, since genetic factors play a key role in the development of cancer *and* are affected by nutrition. Exposure to the same quantitative level of dietary factor(s)/carcinogens can increase cancer risk in one individual but not in another, depending on specific susceptibilities to gene–nutrient interactions. Therefore, studying the gene–nutrition interactions may help to explain inter-individual differences in response to the same nutritional intakes and, therefore, may shed light to the underlying mechanisms linking diet to the risk of developing cancer. *Nutrigenetics* and *nutrigenomics* are the related research areas and are defined according to Wikipedia as: "the science to identify how genetic variation affects response to nutrients (nutrigenetics)", and "the science of the effects of foods and food constituents on gene expression (nutrigenomics)", respectively.

Genes are involved in carcinogenesis through metabolic activation/detoxification, DNA repair, chromosome stability, activity of oncogenes or tumor suppressors, cell cycle control, signal transduction, hormonal pathways, vitamin metabolism pathways, immune function, and receptor or neurotransmitter action. To date many animal and observational studies have evaluated a number of hypotheses regarding specific diet–gene interactions with respect to cancer risk and prognosis, focusing on cancer sites for which certain diet-related genes, as well as, nutrients/foods have been identified as possible risk factors. Perhaps, some results on colorectal cancer risk may hold promise, for example, the interplay between high consumption of well-done meat (as a source of exposure to heterocyclic amines (HAAs)), and NAT2 and CYP1A2 phenotypes; the association of folic acid and vitamin 12 with DNA methylation and DNA synthesis processes; the association of fruit and vegetable intake with *K-ras* mutations. Results, however, from such studies are still in very early stage.

Understanding gene–nutrient interactions and individual differences in genetic susceptibilities will enhance, in the long run, the development of personalized nutrition strategies for cancer prevention. Moreover it will help researchers to design future dietary intervention strategies to reduce cancer risk. Focusing on polymorphisms in intervention studies will allow investigators to develop study designs, stratify participants, and analyze results based on genetic differences within the study population. For example, polymorphisms in genes affecting the use of vitamin D seem to confer different levels of risk for prostate cancer. This kind of information is important for researchers in designing trials to investigate the role of vitamin D, or its analogs, in prostate cancer risk.

Notwithstanding the promising results of nutrigenetics and nutrigenomics, it should be acknowledged that, at this point in time, any evidence coming from this area is still at premature stage. The challenge for the future is to use any knowledge gained about how genetic polymorphisms influence cancer risk through specific dietary constituents or patterns in order to allow for tailor-made dietary recommendations based on genetic testing or gene expression, as well as, metabolic/nutritional status biomarkers. Under this concept of individualized dietary recommendations, diagnosis, prevention and treatment of cancer could be optimized.

Dietary Guidelines

As research into the role of diet in cancer risk continues, it is important that clinicians and the public be advised about the importance of modifying diets to reduce cancer risk. Since the mid-1970s, various scientific organizations around the world, including the WCRF/AICR, the American Cancer Society (ACS), and the US National Cancer Institute (NCI), have developed dietary guidelines to promote cancer risk reduction as a population strategy. As an example, the WCRF dietary recommendations for the prevention of cancer advise to: (1) avoid high-calorie foods (e.g., processed foods high in fat or sugar intake) and sugary drinks, (2) eat more of wholegrains, vegetables, fruit and pulses (e.g., legumes and beans), (3) limit red meat intake to no more than 500 g/week (cooked weight) and avoid totally, if possible, processed meat (e.g., ham and bacon), (4) avoid alcohol intake or limit alcoholic drinks to the level suggested by national guidelines, (5) avoid eating foods preserved in salt and limit salt intake to less than 6 g/day, (6) avoid mouldy grains and cereals because they may be contaminated with aflatoxins, and, (7) do not rely on supplements but follow a healthy diet in order to protect against cancer.

Dietary guidelines are not followed, however, by the general public. For example the average American consumes too much fat (too much saturated fat, too little monounsaturated fat), too little fiber, and too few vegetables, fruits, and whole grains. This pattern is seen in many developed countries worldwide. It is therefore urgently needed that physicians and nutritionists try to better educate people about components of healthful and cancer-preventing diets and small changes in eating patterns that can lower cancer risk and improve cancer outcomes—this is particularly important nowadays that information on "good" or "bad" diets has become readily available but with questionable scientific gravity and validity.

Smoking Cessation

Smoking and Cancer Risk

In the United States, health conditions related to smoking are responsible for 480,000 deaths each year, 12 years in advance of what would be normally expected (given sex and age distributions). These figures translate to an aggregated annual loss of >5 million life-years. Moreover, about 32% of cancer deaths and 20% of all premature deaths in the United States are attributable to smoking.

Tobacco use is a major avoidable contributor to the cancer burden, accounting for one third of all cancer deaths and 87% of lung cancer deaths each year. Cigarette smoking is a risk factor contributing highly to the amount of cancers not only of the lung, but also of trachea, bronchus, larynx, pharynx, oral cavity, nasal cavity, and esophagus, and is also related to cancers of the pancreas, kidney, bladder, stomach, and cervix. At least 20 carcinogens (e.g., the polycyclic aromatic hydrocarbons (PAHs), including the carcinogen benzo[*a*]pyrene (BaP)) and the nicotine-derived tobacco-specific nitrosamine, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK)) that are components of tobacco smoke cause lung tumors in either animals or humans. Smoking also affects nonsmokers. Secondhand tobacco smoke as a result of household or occupational exposure, is responsible for inhalation and metabolization of components of the smoke and, thus, has been associated with increased incidence of lung cancer.

In 2014, estimated rates of current smokers in the US adults were 18.8% and 14.8% among men and women, respectively. The prevalence of smoking is inversely associated with education level and with years of education. In the last 30 years, the prevalence of current smoking decreased overall and especially so among men. This decline in smoking prevalence since 1980s was followed by a decline in mortality rates from lung cancer in men.

Smoking cessation has a dramatic impact in reducing the risk of cancer among former smokers even if these quit smoking at older ages. Smokers who stop smoking before the age of 50, succeed in halving mortality risk within 15 years after quitting as compared with people who continue to smoke. In specific, lung cancer risk after 10 years of abstinence is 30% to 50% lower than that of people who continue smoking, whereas the risk of oral and esophageal cancer is 50% lower in former (as compared to current) smokers after 5 years of smoking cessation.

From the above figures it is evident that educational strategies to prevent the start of smoking and promotion of effective approaches to permanently stop tobacco use by smokers are very important elements in reducing smoking-related cancer risk. Policy strategies encouraging reduction of tobacco use at the community level in various countries have been credited with notable reductions in smoking prevalence. These strategies include, pursuing smoke-free laws, media campaigns, increasing the minimum legal age of access to tobacco products, increasing the cost and/or apply excise taxes to tobacco, and offering quitting programs to people through primary health and other health care organizations.

About 70% of smokers claim to be interested in quitting smoking. When smokers, however, try to quit on their own, only about 7% succeed. Long-term success rates can be increased to 15%–30% if smoking cessation interventions are used. These include pharmacotherapies, as well as, behavioral therapies such as individual or group counseling, intensive physician advice, or combinations of the above.

Pharmacotherapies for Smoking Cessation

Pharmacotherapies are effective interventions for smoking cessation. These can be divided to nicotine replacement therapies (NRTs) and non-nicotine medications (**Table 1**). Nicotine, present in all tobacco products, is an addictive substance. For most users, tobacco use results in drug dependence, although in different levels, depending on patterns and quantity of daily smoking. Evidence demonstrating that pharmacotherapies can help people addicted to nicotine to quit smoking is strong and consistent, and NRTs such as nicotine gum, patch, spray, lozenge, and inhaler have been approved for smoking cessation by the US Food and Drug Administration. A 2004 meta-analysis of 110 randomized trials concluded that NRT treatments, alone or in combination, improved significantly cessation rates over placebos after 6 months of use.

There are also non-nicotine pharmacotherapies that have been efficacious for smoking cessation, by lessening nicotine craving and withdrawal symptoms, namely bupropion, an antidepressant, and varenicline, a selective alpha-4-beta-2 nicotinic receptor. Based on 31 randomized trials comparing bupropion to placebo, bupropion was associated with a statistically significant increase in the likelihood of quitting smoking after 6 months of follow-up. Varenicline also improves cessation rates over placebo as shown

Table 1 Pharmacotherapies for smoking cessation

Pharmacotherapy	*Availability*	*Side effects*
Nicotine gum	Over-the-counter only	Mouth soreness, indigestion, stomatitis, sore throat
Nicotine patch	Over-the-counter and prescription	Skin reaction at patch site, insomnia
Nicotine Lozenges	Prescription only	Local irritation (warmth and tingling)
Nicotine nasal spray	Prescription only	Nasal/throat irritation, sneezing, coughing
Nicotine inhaler	Prescription only	Mouth/throat irritation, coughing
Bupropion	Prescription only	Insomnia, dry mouth, dizziness, rhinitis
Varenicline	Prescription only	Nausea, insomnia

in a meta-analysis of nine trials including 7267 participants (4744 under varenicline) where the pooled risk ratio (RR) for continuous abstinence at ≥ 6 months for varenicline versus placebo was 2.33. Moreover in this meta-analysis varenicline was shown to be superior to bupropion or NRTs after 1 year of follow-up.

Both bupropion and varenicline have certain adverse effects. In 2009 and after post marketing surveillance the risk of serious neuropsychiatric symptoms associated with both products were added to the Boxed Warnings Symptoms—these include: "changes in behavior, hostility, agitation, depressed mood, suicidal thoughts and behavior, and attempted suicide."

Combinations of pharmacotherapy

Using more than one NRTs seems to increase smoking cessation rates as compared to using a single type NRT. Some studies have shown that NRT in combination with bupropion may be more efficacious than bupropion alone.

Behavioral Interventions

Many behavioral interventions are available to encourage smoking cessation in adults. These interventions can be delivered in the primary or in the community care settings and include in-person behavioral support and counseling, telephone counseling, and self-help materials. It has been shown that behavioral interventions may increase smoking abstinence from a baseline 5%–11% in control groups to 7%–13% in intervention groups.

Effective individual or group counseling is essential to help a smoker, who is willing to quit, achieving long-term success in smoking cessation and can be delivered by various types of primary care providers, such as physicians, nurses, psychologists, social workers, and specialized counselors. Counseling aims to helping smokers to organize a specific plan on how to quit, acknowledge situations that increase their risk of smoking and, accordingly, develop resistance skills. Effective counseling, therefore, offers basic information about smoking/quitting, describes coping strategies and identifies sources of social support that can be useful (e.g., community resources).

Physician-advice of either minimal (<20 min in 1 visit) or intensive (≥ 20 min plus >1 follow-up visit) type is also effective for successful smoking cessation. Relevant studies seem to suggest a dose–response relationship of the intensity of counseling and smoking cessation rates. Accordingly, the Public Health Service guidelines of the United States, state that "smokers should receive at least 4 in-person counseling sessions".

Telephone counseling provided by trained counselors or health care providers can be also effective. Self-help materials targeting to the needs of the individual smoker rather than simply presenting the adverse health consequences of smoking can be also helpful for smoking abstinence. Recently, computer- or mobile phone-based programs have been also proposed as behavioral interventions for smoking cessation.

Combinations of behavioral and pharmacotherapy interventions

Interventions that combine behavioral and pharmacotherapy strategies seem to increase cessation rates from about 8% to 14% as compared to these interventions given separately. These combinations frequently consist of NRTs and a variety of behavioral approaches usually delivered in >1 sessions from specialized staff.

Tobacco Cessation Guidelines

In 2008 the US Public Health Service, published the updated 2008 guidelines, "Treating Tobacco Use and Dependence" which are available online. In brief, the broad elements of these guidelines include: the need from primary care providers of: recording the smoking status of every patient at every visit, enquiring about his/her willingness to quit (if smoker) and informing those who wish to quit about effective interventions, brief or intense. The guidelines also emphasize on the importance of: (a) encouragement and assistance by the clinicians to those who are trying to quit smoking, (b) close monitoring of the process of smoking cessation in patients' every visit and, (c) training patients under smoking cessation programs in order to confront with situations that may provoke their smoking-abstinence program.

Lifestyle Changes

Physical Activity

Physical activity (PA) is any form of movement using skeletal muscles. Physical activity increases energy expenditure and is a factor of energy balance.

Different activities can be classified according to when (time window) and how (in terms of intensity) these are realized. According to "when", activities are usually grouped as occupational, household, transport, and recreational. Based on "how", PAs can be vigorous, moderate, light, or sedentary. People can be moderately or vigorously physically active at work (manual/labor) or can be occupied in jobs that request light or sedentary PA. In transport (walking, riding, cycling, driving or using public transportation) people can be lightly or moderately physically active. Exercise and other forms of physical training but also activities done during household are types of recreational physical activity—these may be of light, moderate, or vigorous intensity depending on the

nature/intensity of activities, hobbies, and pursuits. Total PA levels for a given timeframe (e.g., day, month, year, etc.) are evaluated as the combination of frequency, intensity, and duration of all activities that take place at the specific time frame.

In the 2017 WCRF/AICR report the only factor for which the evidence regarding its inverse association with cancer risk was judged as "convincing" was PA (moderate and vigorous) in relation to colon cancer. According to this report, PA also "probably" decreases the risk of post- and pre-menopausal breast, as well as, of endometrial cancers. The evidence suggesting that PA protects against cancers of the lung and pancreas was evaluated as "limited." The report also notes that "… all types and degrees of physical activity are or may be protective, excluding extreme levels of activity: the evidence for any specific type or degree of physical activity is limited."

These results are consistent with the message that, the more physically active people are the better. Regular PA may be associated with reduced cancer risk through various mechanisms, including altering hormone levels and increasing immune system activity, energy expenditure, and antioxidant activity. Given that PA is a way to preserve energy balance and retain normal body weight it seems that PA protects against cancers the risk of which is increased by overweight, weight gain, and obesity, such as cancer of the colon, rectum, prostate, endometrium, breast, and kidney.

Physical activity guidelines

Most people in urbanized and industrialized settings worldwide lead sedentary ways of life. The amount of PA needed to maintain a healthy weight, lose weight, and promote good health, including reducing cancer risk, as recommended by various organizations in the United States, including the NCI, ACS, and WCRF/AICR is, at least 30 min of moderate physical activity on most days of the week either continuously, or, in time intervals. This level of activity might include walking briskly (3–4 miles/hour) for about 2 miles, gardening and yard work, jogging, or swimming. In the recommendations of WCRF/AICR it is also emphasized that one: (a) should limit sedentary habits such as watching television and, (b) as fitness improves, he/she should aim for 60 min or more of moderate, or for 30 min or more of vigorous, physical activity every day.

Sun Exposure

Cancer of the skin is the most frequent type of cancer. Basal cell and squamous cell carcinomas, both highly curable, account for the majority of skin cancers whereas malignant melanoma, the most dangerous form of skin cancer is less frequent. The incidence of skin cancer is increasing over the last 30 years, partly due to an increase in awareness about and detection of this cancer. It is estimated that non melanoma skin cancers (NMSCs) affected 3,000,000 subjects living in the United States in 2012. For melanoma skin cancer the number of people living in the United States who will be diagnosed with melanoma in 2017, is predicted to be about 87,000 whereas the associated deaths are expected to be about 10,000.

People with red or blond hair and fair skin that freckles, tans poorly or burns easily are at especially high risk for skin cancer. Increased (in intensity and/or duration) exposure to sunlight, the main source of ultraviolet (UV) radiation, is implicated as a causative factor in the development of skin cancer in observational studies.

Abundant evidence has established that skin cancer risk can be reduced by increasing awareness in people about skin type prone to skin cancer and of skin damage (burn and solar keratoses) due to sun exposure, as well as, by limiting exposure to sunlight and, thus, to UV radiation. For melanoma cancer there is some evidence that patterns of sun exposure may also be important. In 2009 a pooled analysis of 15 case–control studies (5700 melanoma cases and 7216 controls) investigated patterns of sun exposure, sunburn and solar keratoses (only three studies) with melanoma cancer risk. This study concluded that melanoma cancer risk at different body sites is associated with different amounts and patterns of sun exposure. Recreational sun exposure and sunburn were consistently associated with melanoma cancer at all latitudes, whereas occupational and total sun exposure were associated with melanoma risk, predominately at low latitudes.

Suggested effective protective behaviors include avoiding the sun during midday (especially between 10 AM and 2 PM), wearing protective clothing and broad-brimmed hats, wearing sunglasses, avoiding tanning beds and sun lamps (these are also sources of UV radiation), and using sunscreen that has a sun protection factor (SPF) of 15 or higher, even on hazy or cloudy days—however the respective evidence of these strategies acting as interventions for reducing NMSCs is not yet conclusive.

The relationship between sunscreen use and melanoma cancer risk, as practiced in the general population, is, also, not absolutely clear. Many epidemiologic studies investigating this association have found either reduced risk or no clear association. There are also findings from some studies suggesting that sunscreen use is associated with an increased risk for melanoma. This may be attributed to the fact that people who use sunscreen primarily to avoid sunburn during intentional sun exposure, might increase their sun exposure time when using sunscreen, thus increasing their exposure to UV radiation and risk for melanoma. A meta-analysis of 18 studies that evaluated the association between sunscreen application and melanoma risk highlighted different degrees of quality among the included studies and estimated an overall weak inverse association.

At present, accumulated evidence on sun exposure and skin cancer warrants using sunscreen as part of an overall sun protection strategy, during both intentional and unintentional exposures (e.g., in gardening or hiking).

Glossary

Actuarial life-table method The survival experience of a group is summarized by cumulative survival probabilities that are calculated only at the end of each equally spaced follow-up interval.
Cancer fatality rate The proportion of individuals who experienced death within the population of individuals diagnosed with cancer, over the course of the disease.
Cancer mortality rate The number of deaths due to a cancer within a population during a period of time (1 year or more). It is usually expressed per 100,000 person-years. Mortality rate = (Cancer deaths/population) × 100,000 person-years.
Cancer survival The state of continued life in spite of a diagnosis of malignant cellular growth.
Cancer survivorship Examines the state of the cancer survival experience of an individual or population, considering the complex reality of a present or long-term cancer diagnosis that can substantially influence survival. This includes physical symptoms and conditions, psychosocial concerns, health-related quality of life, health behaviors, tools and platforms for research, special populations, economic impact, and quality of care.
Censoring A condition in which the survival experience of the study subject has not experienced the event of interest because (1) he/she is lost to follow up or drop out of the study, (2) if the study ends before the event can occur, or (3) have an event other than the outcome of interest. A censored subject is counted as alive or disease-free for the time he or she was enrolled in the study.
Corrected survival rate When reliable data on cause of death are available, a correction is made for deaths due to causes other than the disease under study by censoring causes of death other than the cause of interest. Also sometimes called net survival rate, net survival, or cause-specific survival.
Follow-up In a survival analysis and to calculate survival rates, enrolled subjects must be followed at intervals to assess vital status from the time elapsed between beginning and end of observation period.
Hazard function $\lambda(t)$ The probability that the event of interest did not occur before the study observation period, t.
Independent-censoring assumption The assumption that the event of interest in survival analyses is unrelated to whether or not a subject is censored.
Kaplan–Meier method Estimates the proportion of people living after each increment of time during the study observation period. Cumulative survival probabilities are calculated when an event occurs or when a subject is censored.
Lead-time bias A systematic error of apparently increased survival that occurs when disease is detected at an early stage. Lead-time bias is evident when disease detection does not alter the time from disease conception until the event of interest, but only appears so because the observation period after diagnosis ended before the event could occur. Also called information bias.
Log-rank test A univariate statistical analysis comparing the survival distributions between two groups during the observation period, based on the null hypothesis that there is no difference in survival. Also called the Mantel–Cox test.
Observed survival rates The proportion of individuals who did not experience death over the population diagnosed with cancer during an observed study period (e.g., 5 years). Also called the overall survival rate.
Relative survival rate The ratio of the observed survival rate of cancer patients to the expected or background survival rate in a comparable set of cancer-free individuals. Often used for populations when cause-of-death data is not available.
Survival function $S(t)$ The probability that the event S did not occur before the study observation period, t.
Time-to-event The time from entry into a study until the subject has a particular outcome. The "event" can be death, recurrence, symptom reduction, or hospital discharge.

Introduction

Cancer survival is an all-inclusive term that refers to the state of continued life in spite of a diagnosis of malignant cellular growth. It is measured by survival statistics that display the proportion of patients alive over a specific observation period. In addition to life or death, survival statistics can examine outcomes that influence survival, such as cancer progression and recurrence within the observed time period. Cancer survivorship broadens the cancer survival definition, taking into consideration the complex reality of a present or long-term cancer diagnosis that can substantially influence survival. This includes physical signs and symptoms,

Table 1 Positive influences that increase cancer survival rate for common cancers by cancer type

	Early diagnosis/screening	*Treatment*
Lung	(−)[a]	−
Prostate	(−)[b]	+
Breast	+	+
Colorectal	+	+
Stomach	(−)[c]	−
Cervix	+	+
Liver	−	−
Acute lymphoblastic leukemia in children	−	+

[a]Screening is recommended in the United States only for current heavy smokers or those who have quit in the past 15 years and are between 55 and 80 years old, but has not been implemented in most other countries yet. Clinical trials evaluating the benefits and risks of lung cancer screening are ongoing.
[b]Prostate-specific antigen level screening is recommended for some populations, but not widely recommended to all male population with average risk.
[c]In countries with very low incidence, gastric cancer screening is not recommended. Gastric cancer screening programs exist nationwide for Japan and Korea and some regions of China.

psychosocial concerns, health-related quality of life, health behaviors, tools and platforms for research, special populations, economic impact, and quality of care.

Cancer survival is influenced by two main determinants that are consistent across populations: early stage at diagnosis or screening and improved cancer management strategies (Table 1). These factors vary by cancer type and thus play a key role in observed differences in cancer survival rates. Acute lymphoblastic leukemia and testicular cancer, which have effective cancer treatment strategies, have 5-year survival rates greater than 85%, while pancreatic cancer, which has no effective treatment, has a 5-year survival rate of 1%. Access and utilization of oncological health care is another factor influencing each of the two survival determinants. These differ between populations based on a breadth of sociopolitical and economic factors and are reflected in survival rates across countries (Table 2).

Survival and survivorship data are routinely collected and analyzed by cancer registries to monitor and assess cancer control programs in all patients registered in a population-based cancer registry. Survival data may also be collected in observational and randomized-control studies to compare groups of patient and effects of treatment and/or management strategies. The appropriate analysis and interpretation of survival data requires an understanding of the correct application of quantitative tools, metrics, assumptions, and limitations imposed by data source and availability.

Cancer survival rates often use a 5-year survival rate, although 1-year and 10-year rates are also used. Survival rates of interest are cancer type, stage, and treatment groups, for a multitude of survival outcomes, including death, recurrence, and/or new symptoms. Although certain cancers can recur beyond the 5-year period, chance of a later recurrence for most cancers is very small.

It is worth noting that survival rates and morality rates are not direct opposites. Survival rates differ from mortality rates in that they are highly dependent on when cancer is diagnosed or treated. While mortality rates of cancer within a certain time interval are absolute measures of cancer deaths regardless of when the cancer was diagnosed, cancer survival rates provide an outlook of the possibility of living past a fixed time period using the time of diagnosis or treatment as the starting point. The practical goal for analyzing survival data is to provide an estimated cancer prognosis for a patient based on the survival rates of a large number of patients diagnosed or treated for that cancer. However, as a prognostic benchmark, survival probability may be different for each individual patient and strongly depends on stage at medical diagnosis, his or her comorbidities, past medical history, and tumor characteristics.

Data from Allemani, C., Weir, H. K., Carreira, H., et al. (2014). Global surveillance of cancer survival 1995–2009: analysis of individual data for 25,676,887 patients from 279 population-based registries in 67 countries (CONCORD-2). *Lancet*. https://doi.org/10.1016/S0140-6736(14)62038-9.

Concepts of Survival Data

A database suited for survival studies must have three key features: a defined event of interest, a specific start and end of each individual subject's observation period, and a set observation time-scale, such as years or months. Randomized-control trials may use date of randomization, date of entry into the cohort, or date of diagnosis as start points. The dataset may also contain variables that could be evaluated for their relationships with survival. These variables can include sex, cancer stage and type, carcinogenic exposures, or treatment modalities.

Survival statistics use time-to-event data. This is the time (t) from study entry until an individual is observed to have a particular outcome. Both the time enrolled in the study and the event of interest are recorded for each individual. A binary outcome of interest is typically used: no occurrence of event (0) or occurrence of event (1). Occurrence or nonoccurrence of the event is restricted to the observed study period only.

If an individual leaves a study before the event of interest, the outcome is censored. Individuals are censored if they are lost to follow-up, drop out from study for any reason, or if the study is terminated before the outcome of interest occurs. The dataset would contain a record that the individual survived at least to time t. A study proposing to assess the probability that the event did not occur before t is interested in the survival function $S(t)$. The proportion of persons not observed to experience the event by the time the study ends is reported as the survival experience for that group.

Vital status of study subjects can be determined through two methods of follow-up: active and passive. Active follow-up collects vital status information by repeated residential visits, surveys, physician notes, death registry offices, or other social or community gatherings. Passive follow-up is more common in regions with established cancer registries and is accomplished by linking a subject's personal identifiers to an institutionally recorded vital status.

Although survival data often use life or death as the events of interest, other outcomes may be of clinical interest. Examples of other outcomes include developing a complication of disease, treatment of a side effect, resolution of symptoms, progression, and recurrence.

Methods for Survival Analyses: Descriptive Measures

The first step in survival analysis is to estimate the overall survival experience of the entire population or cohort. Unlike incidence or mortality statistics where the total population is included in the ratio denominator, only cancer-diagnosed patients are included in survival fractions. The observed survival rate or overall survival rate is the proportion of individuals alive after receiving a cancer diagnosis or treatment. It includes all deaths for these patients, regardless of whether the cause was from the cancer itself, a cardiovascular disease, injury, or other cause. When reliable information on cause of death is available, a corrected, net, or cause-specific survival rate can be calculated. Deaths occurring only due to the disease of interest are counted as an observation of the event, while deaths due to other causes are treated as a nonevent. Treating other causes is controversial, particularly for studies examining the relationship between exposures and cancer. The cancer may still have occurred had an individual not experienced the competing cause of death. In these circumstances, competing risks can be calculated (see section "**Competing Risks**").

When cause of death data is unavailable or unreliable, a relative survival rate can account for survival from noncancer causes. Relative survival is a ratio of the observed survival rate of cancer patients to the expected or background survival rate in a comparable set of cancer-free individuals. An example of background survival rate can be cancer-free patients or overall survival of cancer patients when race, sex, and age, race, sex, or year information is missing. In practice, overall, corrected, and relative survival rates are very similar. Because they are calculated differently, relative and corrected survival estimates cannot be compared.

Disease-free survival rate is another specific type of survival rate. This is the proportion of subjects with cancer who achieve complete remission. Progression-free survival rate is the proportion of subjects who still have cancer, but the cancer has not progressed over a specific time period. To be free of progression may have an impact on further therapy and is correlated to tumor-specific survival.

When survival rates are compared between populations of varying age distributions, such as different countries, an age-adjusted survival rate is necessary to account the different age structures of different patient populations. Age-adjusted survival rates are calculated by multiplying specific survival rate for each age group with the corresponding proportion of persons in that age group in the population.

Survival probabilities can be summarized in a tabular and graphical form in a survival curve. These cumulative survival probabilities can be calculated by the actuarial life-table method or the Kaplan–Meier method. In the actuarial life-table method, cumulative survival probabilities are calculated only at the end of each equally spaced follow-up interval. If the percent of the patients surviving until the end of the first, second, and third intervals are 90%, 83%, and 67%, the cumulative survival percentage (or the chance of surviving until the beginning of the fourth interval) is 50% ($0.9 \times 0.83 \times 0.67 = 0.50$) (**Table 3**). Conversely, the Kaplan–Meier method calculates survival probabilities at the time that the death takes place, resulting in a stepped figure (**Fig. 1**). Both curves allow the estimation of the time beyond which 50% of study subjects are expected to survive (median survival time), comparison of survival of different groups in the study over time.

Table 3 Calculating cumulative survival probabilities, actuarial life-table

Time interval (months)	*Number at risk during interval*	*Number of deaths during interval*	*Probability of death during interval*	*Probability of surviving during interval*	*Cumulative probability of surviving at the beginning of the time interval*
0–4	100	10	0.10	0.90	1.00
5–9	90	15	0.17	0.83	0.90
10–14	75	25	0.33	0.67	0.75
15–19	50	25	0.50	0.50	0.50
20–24	25	3	0.12	0.88	0.25

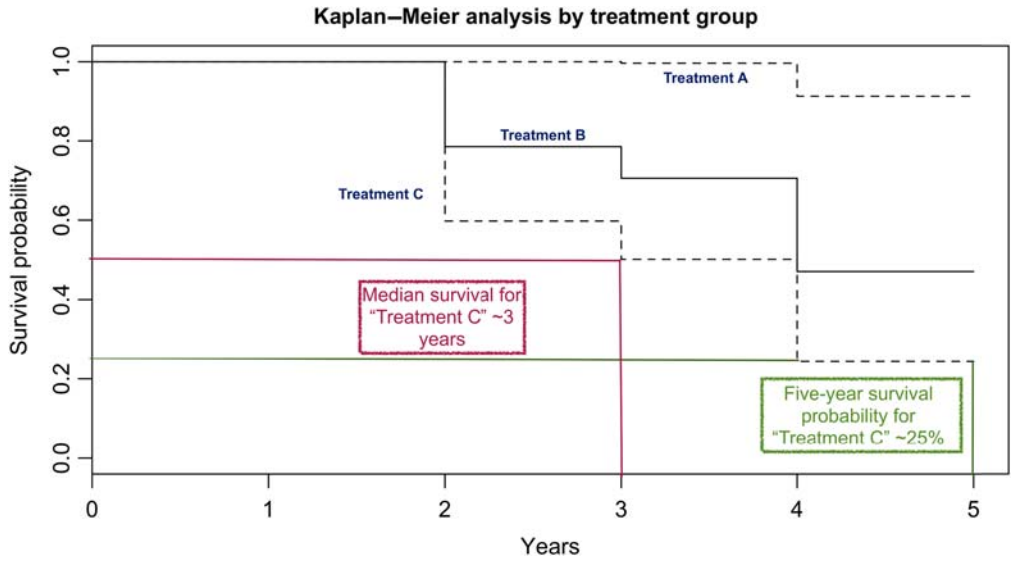

Fig. 1 Five-year survival of cancer patients by treatment modalities A, B, and C using the Kaplan–Meier method.

Care must be taken when interpreting cumulative survival probabilities and two main underlying assumptions must be accounted for. Firstly, at any point during the study course, subjects who are censored at one time have the same survival probability as those who continue to be followed. Events such as undergoing new treatment or achieving complete remission within time t may otherwise alter the survival rate. Secondly, in studies with long enrollment periods, survival probabilities must be the same for subjects recruited early and late in the study. Some individuals recruited earlier in a study before effective treatment availability may be more susceptible to a cause of death that differs from subjects recruited later and the interpretation of the survival rate may be erroneous.

Comparison of cumulative survival rates is calculated by a log-rank test, comparing the survival distributions, based on the null hypothesis that there is no difference in survival. This calculation has the form of a chi-square probability distribution, equally weighing the differences of observed survival rate compared to the expected survival rate for each group at each event time. The number of degrees of freedom is the number of groups to be compared, -1. If the difference between the observed and expected survival distribution has $<5\%$ probability to be due to chance, then the null hypothesis is rejected and the alternative hypothesis of a significant difference in survival is expected. The log-rank test is only a test of significance and provides no estimate of the magnitude of difference between the groups studied. For comparative methods with ability to account for multiple variables influencing survival rates, multivariate models are used.

Methods for Survival Analyses: Basic Statistical Assessments for Comparisons Between Groups

To evaluative the survival–predictor relationship or quantitatively compare groups, multivariate regression models such as the Cox model or proportional hazard regression analysis and Poisson regression are applied. These models both assume that the time-estimated hazard ratios (Cox) or incidence rate ratios (Poisson) are proportional to the length of time t and that the impact of each predictor in the model is constant in the relationship to the outcome for time t. Like any survival analysis, censoring must be independent or noninformative. That is, the censoring of subjects must not be related to the probability of an event occurring.

Table 4 A comparison of the Cox model versus Poisson regression for survival analysis

	The Cox model or proportional hazards regression	*Poisson regression*
Distribution of response event	Semiparametric; does not estimate baseline hazard but instead uses arbitrary baseline hazard	Parametric; baseline hazard is estimated
Response variable in equation	Hazard function gamma(t); reported as hazard ratio (HR)	Incidence rate: natural log counts of event with a model offset for the amount of risk each individual had until the event (person-years)
Dataset preconditions	Nonaggregate or individual subject data are needed	Can be used for both aggregate and nonaggregate data
Survival distribution	Does not make assumptions about survival distribution	The incidence must fit a Poisson distribution (the mean and variance are equal)
Use in longitudinal studies	Allows to account for repeated observations for each record	Allows to account for repeated observations for each record, but must be compressed prior to analysis
Proportional hazard assumption	Proportional to the predictor over time t and constant	Proportional to the predictor over time t and also constant
Limitations	Cannot use if assumption of proportionality is violated, though stratification for some covariates can be done	Difficult to set up dataset. Data on individual subjects must be organized into event-time tables that are stratified on time and other covariates
Advantages	No assumption is made about the shape of the baseline hazard function	If Poisson distribution assumption is violated, alternative methods are available, including quasi-likelihood and binomial regression

The Cox model and Poisson regression differ in assumptions of survival distributions. For the event rate of interest, the Cox model assumes a semiparametric distribution whereas the Poisson model assumes a parametric distribution. Differences between the two model types are displayed in Table 4.

The Cox Model

A Cox model is a statistical technique that can be used for survival-time (time-to-event) outcomes on one or more predictors. The response variable is the hazard function $\lambda(t)$, which assesses the probability that the event of interest (in this case, death) occurred before t. The equation models this hazard as an exponential function (exp) of an arbitrary baseline hazard (λ_0) when all covariates are null, and β is the regression coefficient of the covariate, x.

$$\lambda(t) = \lambda_0(t)\exp(\beta_1 x_1 + \cdots \beta_k x_k)$$

The Cox proportional hazards model makes two assumptions: (1) survival curves for different strata must have hazard functions that are proportional over the time t and (2) the relationship between the log hazard and each covariate is linear, which can be verified with residual plots. Examples of covariates can be categorical such as race or treatment group, or continuous such as biomarker concentrations.

Competing Risks

So far, we have assumed that only a single event of interest occurs in a subject. In practice, one cause of death may alter the survival observed for another cause of death. An increase in cardiovascular deaths in a susceptible population may lead to an apparent increased survival for cancer deaths. The basic Cox model does not differentiate between subjects lost to the competing death and subjects who were alive at the end of his or her observation period. This leads to an erroneous estimation of the cancer-specific survival rate and, in comparisons between predictors or characteristics, an erroneous interpretation of the effect of these variables on survival. A second example occurs when the suspected predictor is linked to multiple causes of death. Smoking, for instance, is linked to multiple cancers of interest, but the event of interest is prostate cancer death, which is not as lethal as lung cancer. Lung cancer would be a competing cause of death. Another phenomenon can occur in clinical trials. A particular cancer management strategy may result in two outcomes: death or recurrence. Recurrence is related to death, but is a competing event that alters survival risk and would result in earlier death. Each of these scenarios violates the assumption that the risk of death is unrelated to censoring (independent-censoring assumption).

There are a few strategies for handling competing risks that quantify more accurate hazard probabilities. Adjusting models for competing risks is useful in circumstances where it is highly suspected that the competing event alters the risk of the event of interest. For example, the patient could have died from the cause of interest given the predictor, but the competing cause of death obscured the true risk. Unlike censoring, which obstructs you from viewing the event probability, a competing event prevented the event of interest from occurring altogether. The most frequently used methodologies for adjusting analyses to take competing risks into account is the Fine and Gray method. The Fine and Gray method is a modification of the Cox model that postulates a model for the sub-hazard function of a failure event of primary interest. Instead of a binary outcome with one possible event of interest, the Fine and Gray method is able to account for additional competing events.

Poisson Regression

Poisson regression uses the natural log of event counts and an exposure or offset parameter (person-years) to measure the relationship between predictors and the event of interest. Instead of comparing hazard rates, as the Cox model, the Poisson model compares incidence rates for predictors:

$$\text{In } (\lambda) = \beta_0 + \beta_1 x_1 \ldots \beta_k x_k$$

In this case, In is the natural logarithm of the incidence rate, λ, β represents the coefficient of each predictor, x, and β_0 is the baseline rate or intercept. The event rates over time t follow a Poisson distribution where Ln(λ) has mean equal to its variance.

Both Poisson regression and the Cox model can be used to analyze survival data. Both equations enable an analysis aimed at understanding the relationship between predictors to survivorship outcomes. However, Poisson regression is useful for aggregate data in which only cancer rates for the co-variates of interest, rather than each individual, are known. This may be the case for public use or registry-based datasets. Although the response variables differ (hazard ratios vs. incidence rate ratios), both methods provide an estimated relative risk (Table 4).

Cancer Survivorship at a Glance

The number of cancer survivors has increased substantially over the past four decades. Many patients diagnosed with most cancers are now expected to survive. In countries with a high gross-domestic-product per capita, this survivor proportion is well over half of those diagnosed with cancer. In high-income countries, the increase has been by 40%–70% over the past four decades. Although cancer survival is increasing, aging populations in both high- and low-income countries suggest that the projected number of people living with or beyond a cancer diagnosis will grow. With more cancer survivors and advances in cancer diagnosis and treatment, greater emphasis is being placed on improving survival estimations, identifying key survival determinants, and utilizing these summary measures to improve cancer preventive planning and investment.

Cancer survivorship studies merge clinical and public health efforts to improve patient cancer outcomes. Survival statistics' accuracy and completeness requires systematic collaboration between clinicians and cancer registries. General practitioners, health institutions, hospitals, and death registries notify cancer registries using a standardized coding system. Cancer registries systematically collect data for the purposes of calculating cancer statistics and conducting cancer research. It must therefore be stated that the currently available survival statistics are less reliable for many low-income countries with fewer resources and infrastructure available than for high-income countries.

Cancer survivorship is being recognized as a multifaceted field that is influenced not only by key differences in cancer survival, such as by cancer type and age at diagnosis, but also by several non-prediagnostic factors such as economics, culture, and society. These community-related factors include an individual's socioeconomic status, healthcare-seeking behavior and consistency with follow-up, health care service efficiency, and personal treatment choices. In considering these many cancer survivorship variables, it is important to observe them within the context of stage at diagnosis and treatment access/availability.

Cancer stage makes a significant impact on survival—those with higher clinical stage cancers are likely to have a lower survival rate than those with low-stage cancers. Cancers can be detected at a lower stage when the length of survival would be longer than the 5-year follow-up period. This cancer can be said to have a lead-time bias. Lead-time or information bias can lead to the erroneous interpretation that earlier cancer screening prolongs life, when in actuality, the cancer was only detected at an earlier starting point in time. In other words, the patients would have died at the same time whether they had screening or not, but would have known about the disease earlier. It is important to note that while 5-year survival is useful in monitoring progress for early detection and treatment of cancer, it does not represent the total proportion of people who are cured because cancer death can occur beyond 5 years after diagnosis. Lead-time bias is often observed for cancers in which a diagnostic method is discovered, but no known effective treatment exists regardless of stage at diagnosis.

Factors that affect survival are unique to each type of cancer. For cancers without early detection or effective treatment, such as liver, lung, or pancreatic cancer, survival rates vary little across countries. In contrast, the largest survival differences between countries are observed for cancers with a better prognosis through screening and access to treatment: female breast, colorectal cancer, cervical cancer, and childhood leukemia (treatment only).

Within countries, it has been widely recognized that survival differences are distributed differently across socioeconomic status groups and race. While survival has mostly improved over time, differences in survival by race that existed in 1975 are still evident in contemporary times. Indeed, survival rates for the most common cancers have improved among both US blacks and whites due to early detection and treatment, but US blacks still have an approximately 10% lower 10-year survival rate (Fig. 2).

Breast Cancer

Among women worldwide, breast cancer survivors make up a third of those living with a cancer diagnosis in the past 5 years. When breast cancer is detected at an early stage, treatment is more effective and a cure is more likely. The 5-year survival rate for breast cancer in the United States in 2005–2009 was 88.6%, compared with 60.4% in India and 68.4% in Tunisia (Table 2). Within India, 5-year survival for early-stage (I or II) breast cancer ranged from 41% to 78% by region, indicating wide variation in health services

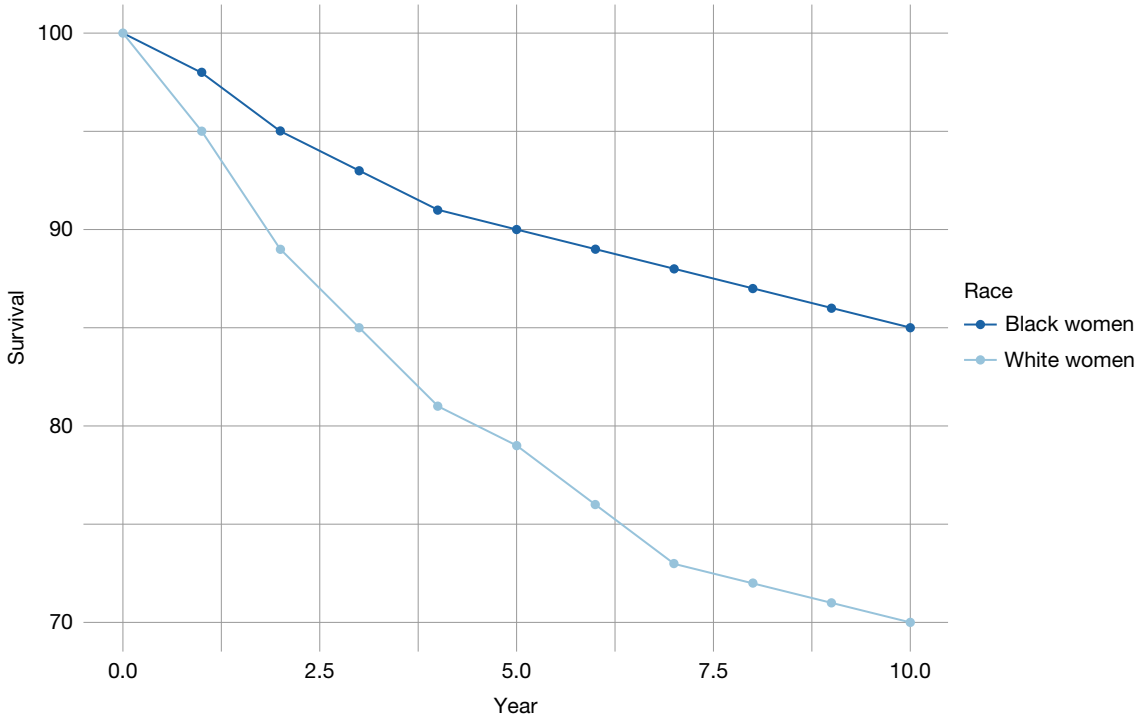

Fig. 2 Five-year relative survival by race for female breast cancer, United States, 1988–2013. Data from Surveillance, Epidemiology, and End Results (SEER) Program (www.seer.cancer.gov) SEER*Stat Database: Incidence – SEER 9 Regs Research Data, Nov 2016 Sub (1973–2014) <Katrina/Rita Population Adjustment>—Linked to County Attributes—Total U.S., 1969–2015 Counties, National Cancer Institute, DCCPS, Surveillance Research Program, released April 2017, based on the November 2016 submission.

delivery. In high-income countries, over 75% of breast cancers are diagnosed at an early stage, which is reflected in the high 5-year overall survival rate (80%+). By contrast, in several low-to-middle income countries, the majority of women are diagnosed with late-stage disease (clinical stage III or IV). Reasons for late-stage diagnoses include lack of awareness as well as limited access to adequate detection and diagnostic services. In some cultures, breast cancer or having any cancer at all, is associated with a social stigma and reduces a woman's social status or the potential for her childrens' marriage within her community. Cancer fatalism, a belief that cancer is preordained in one's destiny and cannot be altered, can also hinder cancer screening programs and may delay or prevent cancer treatment. Additionally, women living in deprived or remote areas are less likely to receive breast-conserving surgery, and would have lower 5-year survival than women in more affluent areas.

Cervical Cancer

When detected at an early stage, invasive cervical cancer is one of the most successfully treated cancers. The 5-year net survival rate ranges from 42.4% in Tunisia to 77% in South Korea and 71% in Norway, although it is between 60% and 70% in most countries. The Papanicolaou (Pap) test screens for precancerous cervical cells that can be treated to prevent cervical cancer, but this test requires a clinician to swab for a cell sample directly from the cervix and a trained cytologist, cytotechnician, or pathologist to examine these cells under a microscope. As the main cause of cervical cancer is a persistent infection with high-risk strains of human papilloma virus (HPV), HPV tests are being currently introduced as a mean of primary or secondary screening in several countries. This test has a higher sensitivity but lower specificity than the Pap test and using HPV in screening will be particularly useful in the future, when most women will hopefully become vaccinated for HPV. In many cultures, social barriers to screening exist, such as the reluctance to have a gynecological exam by a male doctor. Additionally, many remote areas or low-resource countries do not have the technology, expertise, or resources to support an effective cervical cancer screening program.

Colorectal Cancer

Survival rates for colorectal cancer vary worldwide. In high-income countries, colon and rectum cancer 5-year net survival is about 50%–65%, while in Asia a wider range exists. Five-year colon and rectal cancer survival rates of more than 65% have been reported in Israel and South Korea, while they range from about 20% to 55% in other countries in Asia. As colorectal cancer is not one of the highest causes of cancer deaths in many Asian countries (with cervical cancer and cancer of the stomach being more common), there is less public awareness about screening in many areas. Survival is much higher when colorectal cancer is detected at an early stage.

Colorectal cancer is amenable to screening, and there are several screening modalities available such as fecal immunochemical test, fecal occult blood test, sigmoidoscopy, and colonoscopy. However, these screening modalities have been implemented almost exclusively in high-income countries. In some countries with routine screening practices for middle-age adults, colorectal cancers are diagnosed at an earlier and more treatable stage, and survival rates are consequently higher as observed in the United States and Germany, with 5-year survival rates of 64.7% and 64.6%, respectively.

Liver Cancer

Liver cancer is one of the most fatal cancer types, with 5-year survival rates ranging between 10% and 20% across all countries. A cancer fatality rate is the proportion of individuals who experienced death within the population of individuals diagnosed with cancer, over the course of the disease. Liver cancer risk factors vary substantially by country. It main risk factors are alcohol abuse, liver cirrhosis, exposure to food contaminants such as aflatoxins, and—importantly—different types of hepatitis infections. Hepatitis infections, mainly hepatitis B and C, are the largest cause of liver cancer in many parts of the world. There is an effective vaccine for hepatitis B to be given to newborns/infants, and persons at risk, and hepatitis C can be effectively cured.

Liver cancer incidence rate is increasing worldwide, making preventive studies and randomized clinical trials a high priority for patients' prognostic improvement.

Lung Cancer

Although there have been improvements in surgical techniques and combined therapies over the past several decades, lung cancer is one of the most lethal cancers and the most difficult to treat. For the general population, no screening is available and it is often not diagnosed until late stages. Most lung cancers are also difficult to remove surgically even for localized cases, although survival for this small proportion of patients is higher. For populations with less access to trained surgeons and tertiary health care centers, the 5-year survival rate is only slightly lower (around 10%) than high-resource countries (up to 30% or slightly more). Clinical trials are currently underway to determine the risks and benefits of lung cancer screening modalities. Currently, the United States is the only country with lung cancer screening for certain populations. The US Preventive Task Force recommends annual screening for lung cancer with low-dose computed tomography in adults aged 55–80 years who have a 30 pack-year smoking history and currently smoke or have quit within the past 15 years. Once a person has not smoked for 15 years, he develops a health problem that limits life expectancy, or cannot have curative lung surgery, screening should be discontinued. Screening eligibility constitutes a fraction of all lung cancer patients and it should be noted that the US population 5-year survival rate for all lung cancers is 18.7%, which is not substantially higher than other countries.

Stomach Cancer

In addition to differences in screening availability and treatment, international differences in stomach cancer survival rates are also affected by differences in screening policy and patient awareness, as well as access to treatment. For example, Japan has a high stomach cancer survival rate due to nationwide gastric screening; the 5-year net survival is of 54% and most cases are diagnosed at an early stage. In China, another country with high stomach cancer incidence rates but without nationwide screening, the average 5-year survival rate is 31.3%. In the United States, where only about 26% of cases are diagnosed at an early stage, the 5-year survival rate is 29%. Generally, the observed differences have been attributed to lack of awareness of signs and symptoms and greater delay in seeking care among particular groups.

Prostate Cancer

Among men worldwide, over a quarter of all cancer survivors have had a diagnosis of prostate cancer. Since the widespread use of prostate-specific antigen testing in the late 1980s to early 1990s, the dramatic survival improvement in high-income countries has been attributed to lead-time bias. Many asymptomatic cancers would never have become clinically evident and for elderly men, the risks of invasive surgery outweigh the benefit. The 5-year net survival rate for patients diagnosed with prostate cancer is more than 90% in some countries (Israel, Canada, United States, Brazil, Ecuador, Germany, and many Western European countries). Survival rates are lower in Asia, where prostate cancer is less common or where public health programs or access to early diagnosis and treatment are unavailable.

Outlook in Cancer Survivorship

Cancer has become a significant health burden internationally with survivorship not always being attainable for a variety of socioeconomic, cultural, and environmental reasons. There are currently more survivors in high-income countries than in low- and middle-income countries (**Table 5**). Given the economic and political transitions, diagnostic, treatment, and care may not be accessible and/or available and result in different survival rates. Efforts are underway by the SURVCAN project to estimate, compare, and identify survival in low-to-middle income countries. This new survival database established at the International Agency for Research

Table 5 Prevalence of cancer survivors (number of survivors diagnosed with cancer within the past 5 years per 100,000 adults) (15+ years), 2012

Country	*Prevalence per 100,000 persons*
United Kingdom	1594
United States	1892.1
Norway	2020.1
Germany	1964.6
Italy	1933.8
Slovenia	1648.8
Ecuador	534.3
Brazil	720.2
China	456
India	202.9
Japan	1830.7
Tunisia[a]	310.1
Mauritius[a]	530.2

[a]Survival estimate considered less reliable.

on Cancer allows a comparison for cancer survival across cancer types and by country, incorporating survival analyses methodology and recommendations for improving survival statistics in lower-resources areas.

Patients face medical and nonmedical challenges in cancer survivorship. Results of cancer survivorship statistics reflect the impact of health-seeking behaviors, social inequities, natural histories, and health care service efficiencies in responding to diagnosis, treatment, and follow-up.

Sharing expertise between clinical and population-based research will simultaneously enhance the inference potential of data collected in both types of resources and also provide a cost-effective solution to targeting key issues in oncological research.

Increasing access to and improving screening program quality in high-risk groups, improving access to cancer treatment and management programs, and creating public health programs tailored toward health care barriers faced by each community are necessary to improve cancer survivorship.

Prospective Vision

Accurate estimation and interpretation of survival statistics is necessary for understanding patient prognosis. Currently, survival statistics are mostly unreliable or unavailable for many low-resource countries. Methodologies and public health efforts aimed at building institutions and programs are currently underway. As with any clinical diagnosis, cancer patients are not all the same and have different survivorship struggles. Cancer survivorship is a new and burgeoning field that seeks to understand the barriers to cancer diagnosis and treatment faced by individuals and their communities. Several indicators are being explored by the collaborative efforts of epidemiologists and clinicians to make public health programs relevant to patients and their community, and to improve cancer survivorship.

Cancer Vaccines: Dendritic Cell-Based Vaccines and Related Approaches☆

Laurence Chaperot, Olivier Manches, and Caroline Aspord, Institute for Advanced Biosciences, Immunobiology and Immunotherapy in Chronic Diseases Team, Inserm U 1209, CNRS UMR 5309, University Grenoble Alpes, Grenoble, France

Glossary

C-type lectin receptors Receptors that bind to carbohydrates in a calcium-dependent manner. They are able to recognize microbial antigens and can be expressed on dendritic cells and monocytes/macrophages.

Dendritic cells Professional antigen-presenting cells located in the skin, mucosa, lymphoid tissues, and circulating in blood. Dendritic cells form a cellular network of cells able to capture, process antigens and present them on the cell surface to activate T cells. They link the innate and the adaptive immune systems.

Immune checkpoint blockers Immunotherapeutic drugs (usually antibodies) that help release the brakes cancer cells put on the immune system to prevent their destruction. They have revealed efficient, particularly in patients with metastatic melanoma. They target for example CTLA-4, PD-1, or PD-L1 coinhibitory molecules.

Neoantigens Antigens specifically expressed by tumor cells and not by normal cells, generated from somatically mutated genes. They are ideal target for personalized cancer vaccine design.

Therapeutic cancer vaccine Vaccines developed to treat an existing cancer by stimulating patients' natural immune response against its own cancer. They are designed to activate cytotoxic T cells.

Toll-like receptors Receptors expressed on sentinel cells such as macrophages and dendritic cells, that recognize structurally conserved molecules derived from pathogens. TLR play a key role in the initiating immune responses.

Tumor-associated antigens Antigens differentially expressed by tumor cells compared to normal cells, corresponding to overexpressed proteins, tissue-specific molecules, cancer-testis or oncofetal antigens.

Whole exome sequencing Exome sequencing allows to identify mutations found in the coding region of genes which affect protein sequences.

Vaccination was first developed to prevent infectious diseases, and in this specific context, its efficacy relies on the induction of neutralizing antibodies targeting viral or bacterial pathogens. In the past decades, vaccines have also been developed to prevent virus-induced cancers such as uterine cancers driven by papillomaviruses, or hepato-carcinomas associated with hepatitis B virus. In these cases, blocking cell infection prevents cancer development. Therapeutic vaccination is different, as it aims at curing patients with cancer or chronic viral infection by boosting immune responses targeting diseased cells, whether malignant or infected, for elimination. Cytotoxic T lymphocytes (CTL) are the main immune effectors involved in these responses, hence the need to develop new vaccinations strategies that cannot simply reproduce disease prevention schemes that aim at triggering B cell responses. The scope of therapeutic vaccination covers priming of naïve T cells to reactivation of existing but anergic or dormant antitumor memory T cells.

Cellular cancer therapeutic vaccines can be based on killed cancer cells that carry a specific cancer-associated antigen(s) or on immune cells that are modified to present such an antigen(s) on their surface. Other types of cancer vaccines use viruses, yeast, or bacteria as vehicles to deliver both antigens and immunogenic signals. Alternatively, molecules of DNA or RNA coding for tumor-associated antigens (TAA) can be injected either alone (naked nucleic acid) or packaged into a vector.

Among immune cells, dendritic cells (DC) are considered "professional" antigen presenting cells (APC), due to their unique capacity to prime naive T cell responses. They function as sentinels, searching for and integrating so-called "danger" signals, and upon infection, they drive the most suitable immune response (Steinman and Banchereau, 2007). For this reason, dendritic cells are central for the antitumor vaccines approaches we describe here (Saxena and Bhardwaj, 2018; Bol et al., 2016; Palucka and Banchereau, 2013a): the injection of DC loaded with tumor antigen (Ag), and the injection of medicinal products targeting DC in vivo. Priming of both CD4+ helper and CD8+ cytotoxic antigen-specific T cells by DC is fundamental for therapeutic vaccine efficacy. These lymphocytes can recognize Ag expressed by tumor cells, either derived from mutation containing proteins (neoantigens), or overexpressed compared to healthy cells, or aberrantly expressed by tumor cells (spatially or temporally) (Coulie et al., 2014). Tumor-specific neoantigens are often considered as ideal tumor-rejection antigens, enabling the development of personalized vaccines.

The Ag recognized by T lymphocytes are peptides, arising from processed endogenous proteins, and presented in association with major histocompatibility (MHC) complex molecules (human leukocyte antigen (HLA) system in human). Antitumor T

☆*Change History*: March 2018. Laurence Chaperot, Olivier Manches, and Caroline Aspord rewrote the entire chapter.
This article is an update of James W. Young, Jean-Baptiste Latouche and Michel Sadelain, Cancer Vaccines: Gene Therapy and Dendritic Cell-Based Vaccines in Encyclopedia of Cancer (Second Edition) edited by Joseph R. Bertino, Academic Press, 2002, Pages 319–325.

lymphocytes activated upon vaccination will be efficient if they succeed in (i) migrating toward the tumor and their metastases, (ii) escaping the immune-subversion mechanisms found inside tumors (e.g., regulatory T cells, immunosuppressive soluble or membrane-associated factors), and (iii) lysing malignant cells. In order to exert long-lasting effects and prevent relapses, these T lymphocytes must retain their capacity to proliferate and persist as memory cells (Palucka and Banchereau, 2013a).

Dendritic Cells: Professional Antigen Presenting Cells

Dendritic cells represent critical regulators of the host immune system, involved in immune surveillance and bridging innate and adaptive immunity. They are native adjuvants, dictating the specificity and type of immune responses, depending on the microorganism or diseased cells they encounter. Multiple dendritic cell subsets have been described; they are produced in the bone marrow and derive from common myeloid progenitors (Gardner and Ruffell, 2016), and are found in almost all tissues, including blood, lymph nodes, spleen, skin or mucosae, where they act as sentinels and first activators for immune responses. Dendritic cells localized in tissues can take up Ag through specialized receptors, (by phagocytosis, endocytosis, or pinocytosis), detect associated danger signals, and migrate to secondary lymphoid organs. They integrate the environmental signals they receive, mature accordingly, process and present the Ag they have captured, in association with major histocompatibility complex class II and class I molecules, to finally activate both CD4+ and CD8+ T lymphocytes (Reis e Sousa, 2006). The diversity of dendritic cells in mice and humans is still under investigation, and the differential role that these subsets play in antitumor responses remains a matter of debate. DC subsets have been classified according to ontogeny, functionality, location or by transcriptome analyses. They are characterized by the expression of different surface molecules allowing the recognition of conserved pathogenic structures, their activation, migration, and interaction with various immune cells. Differential cytokine and chemokine secretion by different DC subsets accounts for the diverse mobilization, activation, and polarization of adaptive immune responses. A better understanding of DC heterogeneity is essential to improve the development DC-based antitumor immunotherapies.

Human Dendritic Cell Subsets

In human blood, three major DC subsets have been identified: plasmacytoid DC (pDC), CD1c+and CD141+ DC, that lack lineage markers (CD3, CD19, CD14, CD56, and GlycophorinA) and express high levels of MHC class II molecules (Dzionek et al., 2000). PDC express BDCA-2(CD303) and BDCA-4 (CD304), and are known to produce high levels of type I interferon (IFN) upon viral infection (Cella et al., 1999). Conventional or classical myeloid DC (cDC) produce interleukin (IL)-12 and are comprised of two subsets: BDCA-1 (CD1c)+ DC that may be particularly efficient for priming CD4+, and BDCA-3 (CD141) high DC, a minor population of DC in blood that are specialized in cross-presentation of exogenous antigen, allowing priming of CD8+ T cells against pathogens that do not infect DC. The diversity of DC subsets is still under investigation, and recently, single-cell RNA-seq and CyTOF uncovered an underestimated phenotypic heterogeneity of cDC, identifying a new AXL+SIGLEC6+ circulating cDC subset named AS DC (Villani et al., 2017; Alcantara-Hernandez et al., 2017) (**Table 1**). In the skin, Langerhans cells (LC) are localized in the epidermis, while the dermis contains mostly DC expressing CD1a or CD14 (thought to be monocyte-derived cells), but also CD141^{hi} DC (Gardner and Ruffell, 2016) and CD16+ SLAN DC (Gulley et al., 2016). Upon inflammation, the skin can also present with increased numbers of inflammatory DC (CD11c+, CD1c+, HLA-DR+) and pDC (Nestle et al., 2009). In the intestinal mucosae, three subsets of classical DC are found, characterized by their differential expression of Sirpα and CD103 (Watchmaker et al., 2014), whereas in the lung CD1c+ and CD141+ cDC have been described (Yu et al., 2013).

Table 1 Circulating DC subsets in human

	cDC CD1c+	*cDC CD141+*	*DC CD16+*	*AS DC*	*PDC*
Phenotype	CD45+, lin (CD3, CD19, CD56, CD14, GlycophorinA)-, HLA-DR+				
	CD11c+, CD123-			CD11c+/−, CD123+/−	CD11c-, CD123+
	CD1c+	BDCA-3+, CLEC9A+	CD16+	AXL+, SIGLEC6+	BDCA-4+
TLR expression	TLR1, **2**, 3, **4**, **5**, 6, 8, 10	TLR1, 2, **3**, 6, 8, 10	TLR1, **2**, **4**, **5**, 6, 8, 10	?	TLR1, 6, **7**, **9**, 10

Expression of surface markers, Toll-like receptors, C-type lectin, and cytokine production by human DC populations.
−, negative; +, positive; bold numbers, main TLR expressed; ?, for controversial data, or not yet defined expression.

Antigen Capture by Dendritic Cells

In peripheral tissues, skin and mucosae where they are located, DC function as sentinels sampling self and foreign antigens for presentation. PDC and cDC express complementary sets of receptors allowing the recognition of different kinds of pathogens. Antigen (Ag) capture by cDC involves C-type lectin receptors (Caminschi et al., 2008; Sancho and Reis e Sousa, 2012): mannose receptor (MR, CD206), DC-SIGN (CD209), langerin (CD207), dectin-1 and 2, DEC-205 (CD205), LOX-1, DCIR, CLEC-9a, as well as receptors for immunoglobulin Fc regions (CD32 and CD64). PDC express CD32, allowing endocytosis of antibody-opsonized Ag; they may also capture Ag using BDCA-2, and DCIR. Following their uptake by DC, Ag are first directed to endosomes and *endo*-lysosomes, and processed via the exogenous pathway for presentation on MHC class II molecules to CD4 + T lymphocytes. Ag-derived peptides can also be loaded on MHC class I molecules via two cross-presentation pathways: the cytosolic and the vacuolar pathways (Blum et al., 2013). Cross-presentation, that is, the presentation of peptides derived from exogenous Ag by MHC class I molecules (Joffre et al., 2012), is crucial for initiation of CD8 + T cell responses, and is predominantly performed by DC, acting as bona fide professional APC.

Dendritic Cells Maturation and Migration

Ag capture mediated by CLR must be associated with the recognition of a danger signal for DC to trigger a protective immune response. Pattern recognition receptors (PRR) are environmental sensors that include the surface or endosomal toll-like receptors (TLR), and intracellular NOD-like (NLR) and helicases (RIG-like) (Krishnaswamy et al., 2013; van Kooyk and Geijtenbeek, 2003; Geijtenbeek and Gringhuis, 2009; Goutagny et al., 2012). These receptors recognize highly conserved structures expressed by pathogens: the so-called pathogen-associated molecular patterns (PAMP). The expression of TLR is somehow difficult to evaluate, since specific antibodies are not available for all TLR, and most analyses were made by RT-qPCR or functional assays with TLR-ligands. While CD1c+ cDC mainly express TLR 2, 4, 5, allowing recognition of peptidoglycan, LPS, flagellin, or zymozan, CD141+ cDC express high levels of TLR3, and pDC express TLR7 and 9, specific for viral single-stranded RNA (ssRNA) and hypomethylated CpG motifs of bacterial double-stranded DNA (dsDNA) (Hemont et al., 2013; Leal Rojas et al., 2017). Triggering of PRR modulates DC phenotype, DC maturation (upregulation of MHC class II molecules, expression of costimulatory molecules, for example, CD40, CD80, CD86, 4-1BBL, OX-40L) and cell shape modifications (dendritic morphology is acquired). DC migration to secondary lymphoid organs is driven by chemokine receptors such as CCR7 (receptor for the lymph node homing chemokines CCL19 and CCL21), where their cytokine secretion allows efficient T cell priming, activation, and polarization (Reis e Sousa, 2006). Mature DC phenotype can vary according to the nature of PAMP detected, and is further influenced by microenvironment clues, tissue integrity or local inflammation. Of note, DC are able to detect immunogenic signals produced by other cells, such as cell and tissue damage, and recognize "eat-me signals" expressed by necrotic and apoptotic cells (phosphatidyl-serine, calreticulin); they can also be activated by soluble factors released by dying-cells (ATP, HMGB-1) (Hemont et al., 2013).

DC are also found infiltrating tumors, and correlations have been described between tumor prognosis and the presence of mature or immature cDC, or the presence of pDC (Vacchelli et al., 2013). However, the tumor-microenvironment may contain many immunosuppressive factors (e.g., IL-10, TSLP, TGFβ, IDO), secreted by tumor cells, stromal cells, myeloid-derived suppressor cells (MDSC), or regulatory T cells that can locally suppress DC functions, blocking their recruitment, Ag presentation capacity, their activation or their maturation (Hargadon, 2013; Palucka and Banchereau, 2012; Faget et al., 2012; Le Mercier et al., 2013; Sisirak et al., 2012; Aspord et al., 2013). Understanding the complex interactions between dendritic cells and the tumor microenvironment is crucial to decipher how tumors subvert DC functions, in order to restore these functions (Palucka and Banchereau, 2012).

T Cell Responses Driven by Dendritic Cells

In secondary lymphoid organs, mature DC loaded with Ag present antigenic peptides and initiate CD4 + and CD8 + responses, and their functional plasticity is responsible for triggering different types of response according to the context of Ag encounter. In addition, the functional specialization of different DC subsets may help drive various classes of T cell responses. PDC are specialized in initiating antiviral immune responses and through their capacity to secrete huge amounts of type I interferon (Liu, 2005), they are involved in innate and adaptive immune responses (Colonna et al., 2004; Lande and Gilliet, 2010; Reizis et al., 2011). In vitro, pDC have been shown to capture and cross-present tumor or viral antigens (Lui et al., 2009), and stimulate specific adaptive T cell responses. In vivo, they are crucial for the development of cytotoxic effector cells in the context of cancer or viral infections (Villadangos and Young, 2008). Because they secrete cytokines such as IFNα and express costimulatory molecules (ICOSL, GITRL, OX40L, or CD70…), they can interact with innate and adaptive immune cells, modulate natural killer (NK) and iNKT cell responses, and activate B lymphocytes (Swiecki and Colonna, 2015). PDC can also prime Th1 or Th2 responses following contact with virus or IL-3 (Ito et al., 2004). Functional specialization of cDC has also been described, and different subsets can produce IL-12, IL-15, type I or III interferon, as well as regulatory cytokines, depending on the context of their activation. Among cDC, CD14 + DC preferentially activate follicular helper T cells, facilitating/enhancing humoral responses; CD1c+ DC may polarize T cells toward Th1 or Th17 pathway through their IL-12p70 and IL-23 secretion, CD141+ cDC seem as efficient as CD1c+ cDC to prime Th1 polarization, however, they can also induce Th2 cells through their expression of OX-40L (Leal Rojas et al., 2017; Durand and

Segura, 2015; Yu et al., 2014). Ag-specific T cells recognizing their cognate Ag presented by DC differentiate and proliferate (Kapsenberg, 2003). DC-derived IFNα, IL-12, or IL-15 skew differentiation of CD4+ T lymphocytes toward the Th1 phenotype, that favors differentiation of CD8+ CTL. Conversely, if DC express IDO (indoleamine 2,3-dioxygenase), secrete IL-10, TGFβ, or express coinhibitory molecules such as CTLA-4 or PD-L1, they can drive the differentiation of CD4+ regulatory T cells, with tolerogenic functions (Clark and Kupper, 2005). Of note, immature DC are intrinsically tolerogenic, and can induce specific T cell anergy. Altogether, the quality of the generated T cell response depends on the functional status of DC and the DC subtype, and DC plasticity is a key element for orchestrating this diversity of immune responses.

Naïve T lymphocytes migrate to secondary lymphoid organs where they scan MHC-bound peptidic antigens on DC through their T cell receptor (TCR). Upon specific antigen encounter, T lymphocytes are activated, proliferate and differentiate, and then leave the lymph node to reach the tissues where the Ag is expressed. This specific migration is governed by expression of a set of chemokine receptors and adhesion molecules at the surface of T cells (Sheridan and Lefrancois, 2011). T lymphocytes expressing CLA, CCR4, and CCR10 migrate to the skin, if they express CD49a they will preferentially home to the lung, whereas CCR9 and α4β7 integrin expressing T lymphocytes migrate to the intestine. Thus, effector T cell function clearly depends on their capacity to migrate to the site where Ag are located, and to exert their function despite an immunosuppressive environment, to effectively counteract immune evasion (Hargadon, 2013; Gajewski et al., 2013).

Dendritic Cell-Based Therapeutic Vaccination

The goal of cancer vaccines is to induce efficient CTL responses directed toward tumor-associated antigens. Several approaches have been developed, based on the injection of the defined antigens, in the form of whole proteins or antigenic peptides, or by the delivery of genes encoding these peptides or proteins, associated or not with adjuvants or costimulatory signals. Since dendritic cells are very efficient APC, many cancer vaccine approaches use these cells, either by injecting them loaded with the Ag, or by using vectors to address the Ag to specific DC subsets in vivo. Several parameters must be taken into account to optimize the design of therapeutic cancer vaccines based on DC or on other approaches of Ag delivery.

Diversity of Dendritic Cells

As described above, DC belong to a complex multicellular system whose role in initiating potent immune responses is crucial for antitumor immunotherapy. Different strategies taking advantage of this potency are used at the forefront of cancer immunotherapy. However, due to the heterogeneity and plasticity of DC subtypes, several parameters have to be taken into account and tested individually to devise an optimal DC-based immunogen.

Previous studies have shown how difficult it is to identify the best DC subset and DC differentiation protocol to be used for maximal clinical efficacy. Blood DC represent a tiny percentages of mononuclear cells (less than 1% for CD1c+ DC and even less for CD141+ DC), so DC purified from blood have been used only sporadically in immunization protocols (see for example the clinical trial NCT01690377 in advanced melanoma that relies on injection of purified CD1c+ DC). To obtain sufficient numbers of DC, and for logistic and economic purposes, monocyte-derived DC have been the predominant source for vaccination in human clinical trials.

Indeed, monocyte-derived DC (moDC) can be obtained in large numbers by isolation of monocytes, followed by incubation with GM-CSF and IL-4, yielding pure moDC populations in a relatively easy and scalable way. However, moDC may not be endowed with the same stimulation, migration, and functional capabilities as endogenous DC (transcriptomic analysis suggest a phenotype close to inflammatory DC) (Segura et al., 2013), although they are very potent at MHC-II presentation and CD4+ T cell activation. DC generated from monocytes by culture in GM-CSF and IFNα may be more efficient for cross-presentation to CD8+ T cells (Lapenta et al., 2006). CD34+ hematopoietic progenitor cells (HPCs) can be used as precursors for DC differentiation. HPC treated with c-kit ligand and tumor necrosis factor-α (TNF-α) yield subsets of myeloid DC in different stages of differentiation, including Langerhans cells (Caux et al., 1996). Alternatives to in vitro-derived DC include cell lines with similar functionalities as primary DC, such as the myeloid MUTZ-3 cell line derived from leukemic myeloid cells; however these cells have not yet been used in clinical trials. As described further below, a cell line was derived from the leukemic cells of a patient with plasmacytoid DC leukemia, which shares many phenotypic and functional features with primary pDC; this cell line (GENius-Vac) was recently used in a phase I clinical trial in melanoma.

Provenge®/Sipuleucel, developed by Dendreon Corporation, which was FDA approved in 2010, represents a unique case, as the injected cells are not strictly DC per se. Indeed, patients' monocytes are incubated for a short period of time (4 days) with a fusion protein of GM-CSF and prostatic acid phosphatase (PAP). No differentiation factor, such as IL-4 or IL-15, is added, and no maturation is induced. The actual mechanisms of action of the vaccine are not known, but injected cells may complete their differentiation in vivo to stimulate CD4+ and CD8+ T cells.

It is to be noted that injected DC may not directly prime specific T cells. Thus, it has been demonstrated in mouse models that antigen-loaded DC do not prime T cell responses without the help from endogenous DC (Yewdall et al., 2010). Antigen transfer between DC populations in the lymph node, through transfer of MHC-peptide (cross-dressing), exosome secretion, or capture of apoptotic cell, likely plays a role in CD4+ T cells activation and cross-presentation to CD8+ T cells. Studies of T cell activation in viral infection have identified choreographed interactions between antigen-carrying migratory DC and

lymph node resident XCR1+ DC that are necessary to cross-present viral antigen to CD8+ CTL (Hor et al., 2015; Eickhoff et al., 2015).

Nature and Formulation of Tumor Antigens

A critical aspect of vaccination is the nature of the targeted antigens, as well as the form with which they are delivered to DC. Most clinical trials have used DC pulsed by MHC class I restricted peptides to specifically induce CD8+ T cells. In order to optimize the uptake and presentation of antigens, in vitro-derived DC can be loaded with short (9-mer) or long peptides, whole proteins, tumor antigen coding RNA, DNA, or tumor lysate. In other approaches, the Ag (peptides, proteins, RNA, or DNA) can also be directly injected in diverse formulations, associating vectors and adjuvants for optimal targeting to tissue dendritic cells. Peptide or protein-based vaccines can be associated with heat shock proteins, or encapsulated into liposomes (Hu et al., 2018). DNA-vaccines seem safe and promising. Autologous cells at the injection site, upon electroporation or other delivery processes, will up take the nucleic acids and synthesize the antigens, allowing development of immune responses directed toward these antigens. Different mechanisms of action are proposed for DNA vaccines, depending on the route of injection. If the vaccine is injected intranodally, or in the skin, Ag are directly produced by local dendritic cells, whereas if the DNA is injected intramuscularly, Ag are secreted by muscular cells, and must be taken-up by dendritic cells to trigger immune responses. The current strategies to improve the efficacy of DNA vaccine have been described recently (Tiptiri-Kourpeti et al., 2016): they include optimization of delivery systems, association with adjuvants, and introduction of sequences coding for costimulatory signals, cytokines, chemokines, or danger signals to improve vaccine immunogenicity.

Whatever the form chosen for the vaccine candidate antigens, it is crucial to succeed in targeting them to dendritic cells, in order to ensure optimal T cell priming. Targeting multiple defined or undefined (lysate) antigens is likely to be advantageous, by limiting the risk of tumor escape through antigen loss. In addition, recent studies have shown that tumors can take advantage of MHC locus inactivation to prevent presentation of too diverse a repertoire of peptides, such that tumors with loss of heterozygosity in HLA class I, resulting in HLA-homozygosity, is a prevalent immune escape mechanism in lung cancer (McGranahan et al., 2017). Maximal heterozygosity at HLA class I loci (A, B, and C) and particular HLA class I supertypes are associated with increased overall survival after immune checkpoint blockade (Chowell et al., 2018). Long antigenic sequences (DNA, RNA encoded or long peptides) can potentially enable both CD4+ and CD8+ T cell activation. Concomitant activation of helper CD4+ T cell responses and CD8+ cytotoxic T cells has been associated with clinical benefit, as demonstrated with DC pulsed by MHC-I and MHC-II restricted peptides (Aarntzen et al., 2013). Antigen choice is crucial, as highlighted by the fact that not all tumor-associated antigenic sequences are immunogenic, and that not all immunogenic sequences can induce T cell-mediated tumor rejection, which defines a limited subset of tumor rejection antigens. The size and functional status of the specific T cell repertoire has to be considered. As an example, differentiation antigens, such as Melan-A or tyrosinase in melanoma, are immunogenic and a number of DC vaccine trials have shown potent CD8+ T cell amplifications against these antigens. However, the functionality and avidity of specific T cell may be suboptimal to mediate tumor rejection, due to the potential peripheral tolerance to these self-antigens. Ideal tumor antigens are either selectively expressed by the tumor, but not by healthy somatic tissues, or are specifically and uniquely expressed by the tumor. The first category is exemplified by the so-called cancer-testis (CT) antigens (e.g., NY-ESO-1, MAGE antigens), whose expression is restricted to germline and placental tissue, and absent in somatic tissues. Tumors of diverse origins often express CT antigens due to epigenetic dysregulation. CT antigens are being used in a large number of clinical trials and have been shown to be highly immunogenic, despite relatively limited clinical responses up to now. In the latest years, progress in sequencing technologies has opened the door to the identification of the full spectrum of somatic mutations in one particular tumor. In conjunction with the improvements in MHC binding prediction algorithms, it is now possible to identify and select tumor neoantigens (derived from somatic mutations) expressed by the tumor in a highly specific fashion (Kroemer and Zitvogel, 2012). As an example, a large scale high-throughput analysis was performed by the Xpresident platform, combining sequencing of HLA-bound peptides, RNA sequencing and whole exome DNA sequencing of renal cell carcinoma and healthy autologous tissue, to identify a combination of 10 peptides specifically expressed by the tumor (TUMAP). These peptides are now being used for vaccination in conjunction with GM-CSF injection (Walter et al., 2012). An extensive catalog of somatic mutations in 7042 cancers was published, identifying 4,938,362 mutations and 20 distinct mutational signatures, of which some are shared among different cancers, and others are unique (Alexandrov et al., 2013). Such neoantigens are now being targeted in a large number of clinical trials (Hu et al., 2018). Preliminary results seem to indicate that both the quantity and the quality of neoantigens expressed by a tumor are important in determining the efficacy of vaccination. Thus, tumor with the highest somatic mutation and neoantigen burden (e.g., lung cancer, melanoma), patients with microsatellite instability, tend to respond better to immune checkpoint inhibitors (Rizvi et al., 2015; Van Allen et al., 2015). Most mutations are in nonessential genes (passenger mutations) and vastly outnumber mutations in driver genes. Recent studies have uncovered the role of presumably immunodominant neoantigenic sequences in determining clinical outcome in long-term cancer survivors (Luksza et al., 2017). Both the probability of binding to MHC molecules and homology with microbial peptide sequences signal a high probability of recognition by specific CD8+ T cells, and tumor expression of these high quality neoantigens predicts a better clinical outcome. Characterization of the specificity of tumor infiltrating lymphocytes (TILs) will further validate these observations and enhance predictions of immunogenic tumor antigens (Linnemann et al., 2013). Finally, DC vaccination can potentially be enhanced by the use of epigenetic drugs that can augment the expression of tumor antigens and MHC molecules, in addition to their direct antioncogenic and pro-apoptotic effect (Heninger et al., 2015).

Dendritic Cell Maturation and Injection Route

We mentioned the importance of DC maturation stage, which determines the quality and magnitude of induced T cell responses. The generation of local inflammation increasing the immunogenicity of a vaccine can be obtained by using adjuvants such as Montanide water-in-oil emulsions (Clancy-Thompson et al., 2013; Valmori et al., 2007). By using TLR or NLR agonists (mimicking microbial stimulation) as adjuvants, one can specifically activate one or the other DC subset, endowing them with the requisite immunostimulatory properties. Thus, imiquimod, a TLR7 agonist, can activate pDC to produce type I IFN, whereas poly-IC can activate cDC through TLR3 to produce IL-12. Poly-I:C stimulation seems to be optimal for CD8 T cell priming by moDC, whereas triggering other TLR, such as TLR4, may induce suppressive IL-10 secretion that could impede on IL-12 secretion and Th1 priming (Bogunovic et al., 2011). CD40 agonists can also be used for maturing and "licensing" DC, partially alleviating the need for CD4+ T cell help. GM-CSF has been incorporated in several cancer vaccines to enhance their immunostimulatory capacities, for example in the GVAX strategy based on transduction of autologous or allogeneic whole tumor cells (Burkhardt et al., 2013; Lipson et al., 2015). Transduction of DC with constructs knocking down negative regulators of DC activation, such as SOCS1 (Evel-Kabler et al., 2006), can help potentiate cytokine secretion and prolong antigen presentation by injected DC to enhance antitumor immune responses (Shen et al., 2004).

Many questions remain as to what is the best route for therapeutic vaccine injection. Regarding DC-based vaccines, subcutaneous injection is the most frequently used, while intranodal injection has also been tested to bypass DC migration to secondary organs. DNA vaccine can be administered by intradermal, intranodal, or intramuscular routes. Other approaches include device-mediated (gene gun) DNA delivery to keratinocytes or Langerhans cells. Electroporation by local application of electrical pulses causes transient cell membrane permeabilization, allowing DNA entry into cell cytoplasm.

It is crucial to garner knowledge on DC circulation upon immunization, as this will likely impact on activated T cell trafficking, or on the differentiation of central and effector memory T cells. Thus, immunization against cutaneous and pulmonary tumors probably requires different routes of injection for optimal antitumor T cell activation and homing (Sandoval et al., 2013). Preconditioning of draining lymph nodes in animal models has shown that it can highly increase DC migration and vaccine efficacy (MartIn-Fontecha et al., 2003). Some strategies currently being tested in clinical trials involve direct intratumor injection of TLR agonists, with or without concomitant T cell costimulatory activation. They aim at modifying the tumor microenvironment, while recruiting DC and T cells, inducing DC migration to draining lymph nodes. Remarkably, in situ injection of CpG oligonucleotides (TLR9 agonists) in conjunction with OX40L agonistic antibodies in various murine tumors triggers systemic cytotoxic immune responses, eradicating metastasizing tumor cells and preventing tumor growth upon rechallenge (Sagiv-Barfi et al., 2018). Despite these advances, it is not clear yet which DC activation protocol and vaccine injection route will induce adequate T cell stimulation, in view of the frequent immune dysfunction observed in various malignancies.

Dendritic Cells in Cancer Immunotherapy Clinical Trials

Increased knowledge of DC biology and optimized protocols for DC generation have translated into the design of immunotherapeutic strategies that are now being tested in multiple clinical trials. Safety and clinical evaluations are most of the time complemented with immunomonitoring protocols that quantify the induction of specific helper and CTL responses against tumor antigens.

Ongoing DC-Based Vaccines

A pilot clinical trial in lymphoma utilizing DC pulsed by tumor-specific idiotype was performed more than two decades ago. However, as of today, only two commercial DC vaccines are approved as drug products. The most prominent is Provenge®/Sipuleucel for the treatment of advanced prostate cancer. CreaVaxRCC® developed by the company CreaGene was approved in 2007 in Korea for the treatment of metastatic renal carcinoma. The National Institute of Health website (clinicaltrials.gov) represents an invaluable database cataloguing worldwide information about clinical trials. An analysis of the number of ongoing and completed DC vaccine trials highlights the positive dynamics of therapeutic DC vaccines for the treatment of cancer. Thus, a keyword search for "dendritic cell" and "vaccine" identifies 400 clinical studies. Sixty-seven of them are actively recruiting at the time of this writing. A large number of these studies are in phase 1 (257) and phase 2 (221), whereas only 10 protocols are currently tested in phase 3 trials, reflecting the challenges facing many early clinical trials and the difficulty in demonstrating clinical benefit. The ongoing trial NCT00045968 in glioblastoma multiforme is one of the few phase 3 DC-based studies. Developed by Northwest Biotherapeutics, DCVax®-L consists in autologous DC pulsed with an autologous tumor lysate. Patients are injected with DCVax®-L over a period of 120 weeks, while the placebo group receives mononuclear cells. Phase 1/2 evaluation of DCVax®-L demonstrated an increase in median overall survival (>4 years in 33% of patients and more than 6 years in 27%, compared to 14.6 months with conventional treatments) warranting further evaluation in a phase 3 trial.

Many approaches are being tested to optimize immunization by DC. The vast majority (99%) of these studies focus on immunization by cDC, whether directly purified from blood, or differentiated from monocytes or CD34+ HSC. However, two teams have also exploited the antigen presenting capabilities of pDC to immunize patients with metastatic melanoma. In the first trial (NCT0190377) (Tel et al., 2013), patients received intranodal injection of purified and tumor antigen-loaded autologous pDC.

In the second one (NCT01863108), the semi-allogeneic (HLA-A2+) pDC cell line GENius-Vac was used as vaccination platform upon loading pDC with melanoma-associated HLA-A2-restricted peptides. This approach, relying on the use of a well-characterized cell line, allows large cell numbers of a homogeneous cell preparation to be injected, at reduced costs. Similarly, in clinical trial NCT01373515 HLA-A2+ patients with acute myeloid leukemia were injected with a semi-allogeneic (HLA-A2+) acute myeloid leukemia cell line that differentiates into functional mature dendritic cells upon anthracycline treatment. Rather than relying on injection of whole dendritic cells, an original approach exploits the immunogenic properties of DC-derived nanovesicles termed "exosomes" that can mediate MHC-dependent immune responses. A phase II trial of vaccination with tumor antigen-loaded dendritic cell-derived exosomes was performed in nonsmall cell lung cancer (NCT01159288).

Source of Antigen

It is still unclear which antigenic targets will prove to be the most beneficial for long term clinical efficacy. Defined shared antigens, such as cancer-testis antigens or carcinoembryonic antigens are either loaded as peptides onto in vitro-derived DC, or targeted to DC through endocytic receptors. An example of this latter strategy is the intranodal injection of a DEC-205- NY-ESO-1 fusion protein with or without Sirolimus (rapamycin) administration in astrocytoma (NCT01522820). Targeting of antigens to DEC-205 on DC has been shown to potentiate cross-presentation to CD8+ T cells (Bonifaz et al., 2002). As mentioned above, it is becoming widely appreciated that including multiple antigens in a vaccine could prevent tumor immune escape by outgrowth of antigen-loss variants. This may be one of the reason for the efficacy of the DCVax®-L trial, where undefined but numerous antigens are loaded onto DC in the form of a cellular lysate. Several clinical trials are ongoing with DNA vaccines (Tiptiri-Kourpeti et al., 2016), mainly in melanoma, prostate or HPV-associated cancers, targeting various kinds of tumor-associated Ag (over-expressed, CT, or onco-viral). Recently, a clinical trial based on a DNA vaccine coding for two epitopes from gp100 melanoma-derived Ag inserted in a human IgG1 antibody sequence has been shown to be safe and stimulated T cell responses in melanoma patients (Patel et al., 2018).

The new sequencing technologies (whole exome sequencing, RNAseq analysis) provide the opportunity to identify and target many tumor-specific neoantigens at the same time. So far, several phase I trials evaluating vaccination with personalized neoantigens are ongoing or have been completed in melanoma. The NCT00683670 study used DC loaded with short HLA-A2-restricted neoantigen peptides (Carreno et al., 2015). The NeoVax trial (NCT01970358) involved subcutaneous administration of up to 20 long neopeptides, admixed with poly-IC-LC (carboxymethylcellulose, polyinosinic-polycytidylic acid, and poly-L-lysine) (Ott et al., 2017). In the IVAC MUTANOME trial (NCT02035956) several doses of RNA encoding shared tumor antigen (tyrosinase and/or NY-ESO-1) and neoantigens were injected into inguinal lymph nodes (Sahin et al., 2017). The latter two studies rely on neoantigen uptake and presentation by tissue- or lymph-node resident DC to activate antitumor T cells. Although performed on a small number of patients, impressive immune responses against neoantigens were observed in all three studies. Some patients experienced vaccine-related objective clinical responses in the NeoVax and IVAC MUTANOME trials, warranting further evaluation in large scale studies. Neoantigens can also be used in DNA vaccine approaches, as in the ongoing clinical trial NCT03122106, in pancreatic cancer patients. This neoantigen DNA vaccine, administered with an electroporation device, incorporates neoantigens and personalized mesothelin polyepitopes, with the aim to activate both CD4+ and CD8+ T lymphocytes.

Reversing Immunosuppression

Due to the systemic and local immune dysregulation observed in the tumor microenvironment, and the sensitivity of DC to immunosuppressive cytokines and ligands, it is likely that the best immunization regimens will require coadministration of DC vaccines with other therapies. Current combination trials testing DC vaccines have been extensively described (Saxena and Bhardwaj, 2018), and we will briefly mention here a few important themes. One goal is to improve antigen delivery to DC in an immunogenic environment, which is being tested in different ways. DC vaccination combined with chemotherapy inducing "immunogenic cell death" (doxorubicine and cyclophosphamide) (e.g., NCT00082641), or with concomitant injection of antitumor T cells (unmodified autologous T cells (e.g., NCT00338377), antigen-specific TCR transduced T cells (e.g., NCT00910650, NCT01697527)), will test this concept in different malignancies. Another aim is to bypass immunosuppressive pathways, whether metabolic (e.g., IDO), induced by tumor-secreted mediators (e.g., prostaglandins) or through surface receptors (such as the PD-1/PD-L1 interaction). Thus, the breast cancer clinical trial NCT01042535 combines p53-targeted DC immunization with administration of the IDO inhibitor 1-methyl-D-tryptophan, whereas in trial NCT01560923 patients with advanced prostate cancer receive Sipuleucel with the IDO inhibitor indoximod. Immune checkpoint inhibitors (anti-PD-1 antibodies nivolumab, pembrolizumab, and anti-PD-L1 atezolizumab) are used to reawaken and prevent deactivation of T cell immune responses. Building on the results of the first DCVax-L trial, a phase 2 trial is being initiated, that combines vaccination with tumor lysate-loaded DC with nivolumab injection (NCT03014804). Finally, a few studies test sequential immunotherapy with multiple immunomodulators, in a multipronged strategy to enhance vaccine-induced immune responses. In trial NCT02677155, patients with lymphoma receive sequential intratumor injections of low-dose rituximab (anti-CD20) combined with local radiotherapy, and autologous DC with subcutaneous GM-CSF injection, with the aim of enhancing tumor antigen delivery and uptake by DC. Patients also receive intravenous anti-PD-1 antibody (Pembrolizumab) to overcome tumor tolerance. This strategy reflects the growing trend toward combination of standalone promising approaches, such as DC vaccination, immunogenic conditioning by cytotoxic therapy, neoantigen targeting, and immune checkpoint inhibitors blockade, which when used together will hopefully translate into greater clinical benefits for cancer patients.

Defining Responders and Nonresponders Patients

Understanding the effects of DC vaccines on the immune system is crucial to better characterize the pathways required to induce protective antitumor responses. The status of patient immune system affects the capacity to trigger antitumor T cell responses, modulates responses to immunotherapies, and also affects clinical responses. It is crucial not only to define the factors required for the activation of effector T cells, but also to define the interactions between DC and innate immune cells. The modulation of suppressive cells in peripheral blood but also at the tumor site have to be better characterized to potentiate vaccine efficacy and design. Identification of response biomarkers differentiating early responder and nonresponder patients will guide future developments. System-wide immunologic approaches, combining transcriptome profiling with multiparametric analysis by flow cytometry and proteomic analysis, may lead to the identification of new biomarkers of efficacy (Pulendran et al., 2010). Isolation of molecular and cellular signatures predicting the immunogenicity and efficacy of immunotherapies, and their correlation with induction of protective immune responses, will help optimize future vaccines.

Clinical Evaluation

In addition, RECIST (response evaluation criteria in solid tumors) criteria of clinical evaluation (Eisenhauer et al., 2009) may not be appropriate to evaluate the clinical efficacy of immunomodulatory therapies. Indeed, in early time points after the beginning of immunotherapeutic treatment, a temporary tumor "growth" can be observed preceding a durable regression, the former reflecting inflammatory processes associated with active immune responses and tumor infiltration. Clinical evaluation based on irRC (immune-related response criteria) (Wolchok et al., 2009) will be more suitable to define the real clinical impact of immunotherapies.

Future Directions With Cancer Vaccines

Therapeutic DC vaccines in clinic trials have often been disappointing, despite exciting results obtained in animals and preclinical trials. However with the development of new generation products such as combination with novel adjuvants or other immunotherapies, the use of new DC subsets (pDC) and clinical evaluation based on immunological criteria (Wolchok et al., 2009), these approaches should evolve toward potent anticancer therapies. Clinical trials performed in the last 20 years proved that DC-based vaccines are well tolerated, highly immunogenic, and trigger tumor-specific and functional T-cell responses in many patients. Despite limited objective clinical responses, these responses are often durable, correlate with the induction of antitumor immune responses, and have been associated with objective tumor regressions in some instances, demonstrating the capacity of the immune system to control tumor development. New clinical strategies are needed to improve the potential of DC vaccines to trigger tumor regression. One major problem of DC-based trials is that patients are treated in advanced stages of cancer, when the immune system is subverted by the unfavorable tumor microenvironment. Critical points to overcome for a better efficacy are (1) the absence of costimulatory signals within tumor microenvironment, (2) the presence of inadequate signals that lead to DC subversion and prevent triggering of protective antitumor immune responses, and (3) a better understanding of the mechanisms directing the response to immunotherapies. Advances in the knowledge of DC biology and in the understanding of interactions between tumor cells and the immune system have led to the emergence of new strategies that exploit the properties of various DC subsets and neutralize the immunosuppressive tumor microenvironment. Whereas past developments often required individual DC production, the trend is now to design universal products such as vaccines targeting DC in vivo, for broader use with simplified, standardized, and less expensive products. However, there is a parallel trend toward the development of personalized approaches using neoantigens. All in all, these strategies offer new therapeutic perspectives in the treatment of cancer and will hopefully translate into better clinical success (**Fig. 1**).

Exploitation of Various DC Subsets

As mentioned earlier, DC used in immunotherapy are generated from monocytes, differentiated in vitro from CD34+ HSC, or directly purified from circulating immune cells of patients. The discovery of new DC subsets with unique properties allows their use as vectors for cancer immunotherapy (Ueno et al., 2011; Palucka and Banchereau, 2013b). Distinct DC subsets trigger various T cell responses, and the quality of CTL induced by DC is crucial for antitumor efficacy. Various cytokine cocktails drive differentiation of DC with specific properties in vitro. Thus, moDC generated in the presence of GM-CSF and IL-15 induce CTL exhibiting higher antitumor activity compared to CTL induced by moDC generated in presence of GM-CSF and IL-4 (Dubsky et al., 2007), which may transfer into higher clinical efficacy. HPC can also be used to generate multiple DC subsets in sufficient numbers for immunotherapy. Differentiation of the cross-presenting CLEC9A+ DC or Langerhans cells from CD34+ HPCs brings the opportunity to use specialized DC subsets for vaccination, and is currently being tested in clinical trials. Alternative strategies consist in directly purifying DC subsets from circulating immune cells of the patients. The use of primary circulating CD1c+ DC activated and loaded with tumor-derived peptides led to the induction of strong antitumor T cell responses associated with favorable progression free survival in stage IV melanoma patients (Schreibelt et al., 2016). pDC are also crucial actors of antitumor immune responses, and represent promising vectors for immunotherapy (Tel et al., 2012). In melanoma patients, injection of purified circulating pDC that

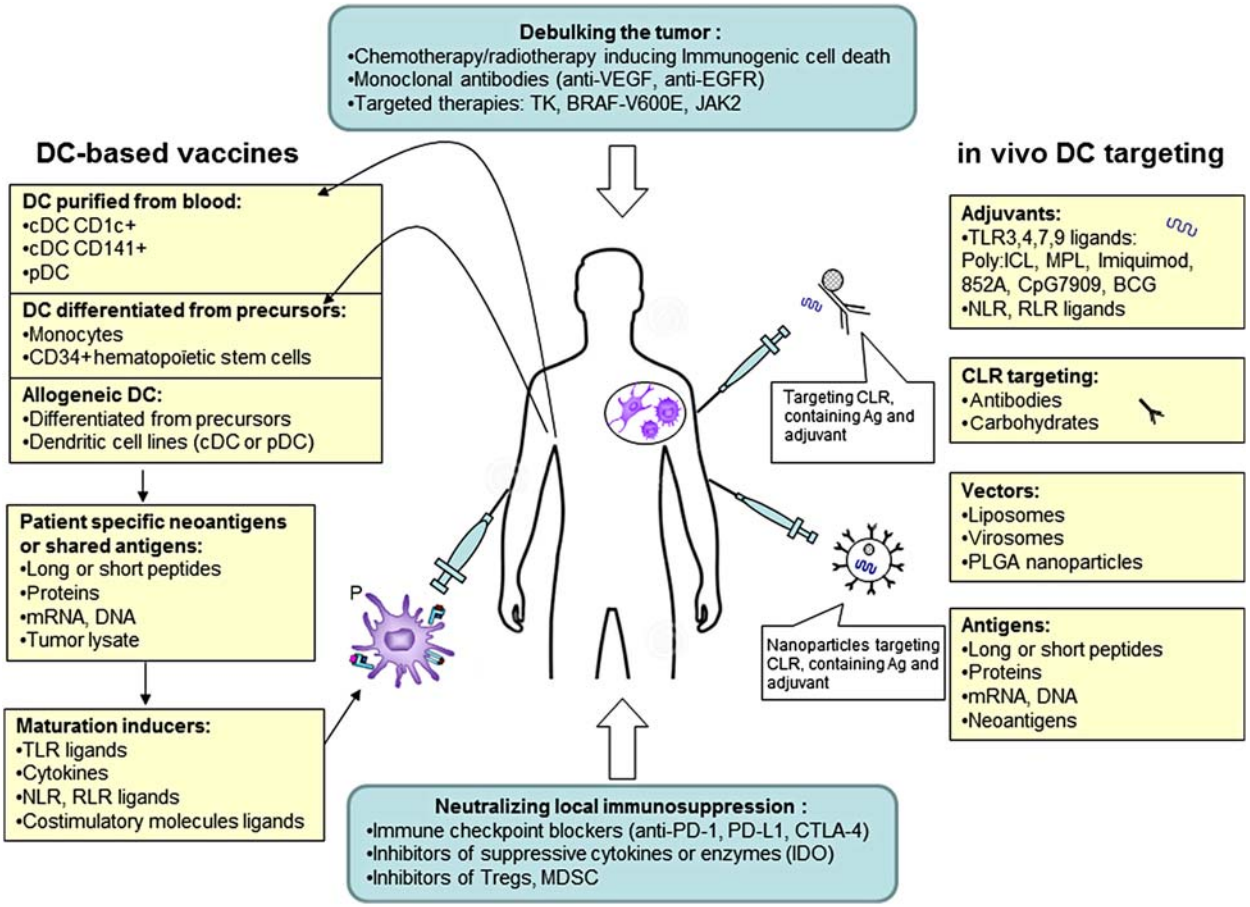

Fig. 1 Optimizing DC-based therapy. The current approaches are based on injection of autologous dendritic cells generated from monocytes or hematopoietic stem cells, or purified from patient's blood, or of allogeneic DC lines. These DC are loaded in vitro with tumor Ag (neoantigens or shared Ag), activated with different adjuvants, and injected to the patients. DC in vivo targeting approaches are emerging; they aim at specifically targeting DC in vivo using pattern recognition receptors (PRR) or C-type lectin (CLR) ligands. CLR can be targeted through antibodies or glycans conjugated to an antigen, while TLR triggering activates a signaling cascade resulting in DC activation. Combination strategies may be the key for DC vaccine success, with the use of drugs neutralizing local immunosuppression, or debulking the tumor.

have been activated and pulsed with peptides derived from tumor antigens triggered significant CD4+ and CD8+ T cell responses, and was associated with promising clinical responses (Tel et al., 2013). However, large scale therapeutic use of autologous primary DC is difficult due to the low number of circulating DC, their potential functional alteration induced by the tumor, and the individual preparation required for each patient. These obstacles can be overcome by using semi-allogeneic DC cell lines. The MUTZ3 cell line derived from human leukemic myeloid cells harbor cDC phenotype and function (Santegoets et al., 2008). We developed an alternative strategy based on the exploitation of a human pDC line HLA-A*0201+ derived from leukemic pDC. This pDC line shares phenotypic and functional properties with primary pDC. The GENiusVac strategy (Aspord et al., 2011a) is based on the use of the irradiated pDC line loaded with HLA-A*0201+-restricted peptides derived from tumor or viral antigens to trigger antigen-specific cytotoxic CD8 T cells in allogeneic but HLA-A*0201+ matched settings. We demonstrated the strong potency of this strategy to induce multispecific and highly functional antitumor and antiviral T cell responses in vitro, its therapeutic efficacy in vivo in humanized mice, and its clinical relevance ex vivo with patients' T cells (Aspord et al., 2010, 2011b, 2012). The GENiusVac strategy is currently tested in a phase I trial in metastatic melanoma. Such "one to many" strategy offers many advantages compared to existing immunotherapies, including its standardizable design, broad potential use for numerous tumoral and viral pathologies. Partial HLA matching between the vaccine and the patients further exploits the allogeneic effect to potentiate the immunogenicity of tumor or viral antigens (Fabre, 2001). Such semi-allogeneic settings have been explored in strategies using hybrid vaccines between DC and allogeneic tumor cells (Kugler et al., 2000), in another setting, allogeneic skin graft has been shown to trigger antitumor response in patients with cancer prostate (Muir et al., 2006).

Exploitation of Neoantigens

As described above, neoantigens are generated by tumor-related (driver) or spontaneous (bystander) mutations that can be presented as highly specific tumor antigens. It has been shown that the mutational load and microsatellite instability in solid tumors

correlates with the response to immune checkpoint blockers (Rizvi et al., 2015; Van Allen et al., 2015). The use of DC loaded with patient-specific peptides derived from mutated neoantigens is a powerful alternative, currently under investigation, that may trigger epitope spreading, diversification of the TCR repertoire and elicit specific CD8 T cells in cancer patients (Carreno et al., 2015).

In Vivo DC Targeting

DC scan the environment through PRR and take up antigens recognized by their CLR. Various DC subsets differentially express PRR, and CLR allowing their specific targeting to endow them with desired functionalities. Thus, emerging strategies aim at specifically targeting DC in vivo using PRR or CLR ligands. CLR can be targeted through an antibody or a glycan conjugated to an antigen that will be internalized, allowing the cross-presentation of peptides derived from the antigen. TLR triggering activates a signaling cascade resulting in DC activation: upregulation of costimulatory molecules expression and cytokine secretion, which favor innate and adaptive immune responses. Such in vivo DC targeting offers the advantage to develop universal off-the-shelf products, which is highly convenient for future transfer into the clinic.

Targeting DC through CLR

A large number of CLR can be exploited to target different DC subsets (Ueno et al., 2011). Current approaches targeting CLR with antibodies show promising preclinical results: targeting of DEC-205, DC-SIGN or MR expressed by cDC, langerin expressed by LC, CLEC9A expressed by BDCA-3+ DC, or dectin-1 and DCIR expressed by pDC (Palucka and Banchereau, 2013a; Ueno et al., 2011) allows the capture and cross-presentation of Ab-associated antigens, leading to induction of specific T cell responses. The use of DC-targeting antibodies combined to antigens together with adjuvants leads to efficient presentation of antigens by DC in vivo and to induction of specific CD4 and CD8 T cell responses (Tacken and Figdor, 2011). Many preclinical studies have demonstrated the efficacy of directly targeting DC in vivo to trigger specific immune responses (Caminschi et al., 2008; Tacken et al., 2005) and to control tumor growth (Sancho et al., 2008; He et al., 2007). CLR can also be targeted by carbohydrates ligands (Lepenies et al., 2013). Engineered glycans that have been optimized for increased binding affinity to CLR show promise as a means to enhance tumor antigen uptake and presentation; preclinical studies combining gp100 to glycans targeting DC-SIGN have demonstrated the feasibility and efficacy of these approaches. The location of targeted DC is important to determine the tropism of primed T cells, as DC from one tissue can induce T cells with migratory properties specific for that tissue. In addition, DC stimulated with different adjuvants can induce T cells with various migratory properties, so that the choice of adjuvant is critical to induce the desired type of immunity at the right location. Proof-of-concept clinical trials are on-going to determine the safety of such strategies. Targeting antigens to DC-specific receptors in vivo bypasses the need for ex vivo DC production, a long and critical step which can potentially alter DC functionality. It further allows antigen uptake and stimulation of specific DC subsets, even rare population with interesting properties. This strategy represents an alternative to strategies based on DC injections which are often costly, restricted to a limited number of patients, and limited to particular DC subsets (the ones that can be purified or produced in sufficient numbers).

Activating DC through TLR

As described in detail above, TLR recognize conserved pathogenic motifs present on virus and bacteria, and TLR ligands (TLR-L) represent potent immunomodulatory molecules that can trigger DC maturation and modulate their function. Several TLR-L are under preclinical investigation due to their adjuvant properties for antitumor vaccines (Krieg, 2007) and tested in many clinical trials in cancer. By activating DC (upregulation of MHC and costimulatory molecules, secretion of inflammatory cytokines such as IL-12 and IFNs), they provide the missing signal in DC/T interactions within the tumor microenvironment, allowing induction of Th1-oriented adaptive immunity. TLR agonists already approved by the FDA (BCG, MPL, and imiquimod) together with others (TLR-4 agonist LPS, TLR-3 agonist poly-IC, TLR-7/8 agonist resiquimod) undergo promising clinical developments (Vacchelli et al., 2012). Synthetic TLR agonists efficiently trigger antitumor immunity in vivo in melanoma. In particular, agonists engaging TLR7 and TLR9, expressed by pDC, allow the induction of antitumor immune responses by stimulating pDC function. Imiquimod (TLR7 agonist) is approved for basal carcinoma, and systemic immune activation was observed in melanoma patients in response to TLR7-L (Dummer et al., 2008) or TLR9-L (Molenkamp et al., 2008) administration. The administration of CpG- oligodeoxynucleotides potentiates patients' response to vaccination (Speiser et al., 2005) and stimulates pDC and NK cell functions (Pashenkov et al., 2006). Recently mRNA transfection-based delivery of a costimulatory molecule cocktail (CD40L, CD70, and constitutively active TLR4) called the TriMix-DC emerged as a potent DC maturation strategy leading to strong T cell responses (Van Lint et al., 2014). Vaccination with autologous TriMix-DC transfected with tumor associated antigens can trigger durable tumor responses in melanoma patients (Van Nuffel et al., 2012).

Combination of CLR and TLR

A recent development combining DC targeting through CLR and DC activation via TLR is based on biodegradable nanoparticles constituted of PLGA (poly lactic–*co*-glycolic acid), covered with anti-DC-SIGN antibodies and containing tumor antigens and adjuvants (TLR3-L, TLR7/8-L) (Tacken et al., 2011). Another strategy is based on liposomes covered with anti-DEC-205 antibodies and containing tumor antigens and adjuvants (van Broekhoven et al., 2004). Such a combination of DC targeting via CLR, antigen delivery and direct in vivo activation of DC through TLR, seems promising (Zitvogel and Palucka, 2011) due to its simple and scalable design.

Toward Combinations of DC-based Immunotherapies With Other Antitumor Therapies

With immune checkpoint blockers and inactivation of immunosuppressive cells

The discrepancy between the potent immune responses and the disappointing clinical responses observed in clinical trials using DC vaccines is partly due to the presence of regulatory T cells and an immunosuppressive tumor microenvironment (Palucka et al., 2008). Inhibition of immunosuppressive mechanisms is required to improve the clinical efficacy of immunotherapies, especially the ones based on DC vaccines or DC targeting in vivo. Antitumor effector T cells are inhibited by engagement of inhibitory molecules (CTLA-4, PD1) and the often massive infiltration by immunosuppressive cells (regulatory T cells, MDSC) at the tumor site. Immunomodulatory therapies such as anti-CTLA4 and anti-PD1/anti-PD-L1 blockade have achieved prolongation of patient overall survival for 30%–40% of patients (Ott et al., 2013), demonstrating that inhibition of immunosuppressive mechanisms can lead to tumor control. The higher efficacy of combined DC vaccine with immune checkpoint blockers compared to monotherapy is supported by many preclinical studies (Vasaturo et al., 2013), and by a clinical trial in melanoma patients in which durable tumor regressions were observed following DC vaccine combined with anti-CTLA4 treatment (Ribas et al., 2009). Enhancement of tumor-specific immunity with DC vaccines combined to reversal of T cell exhaustion by immune checkpoint blockers is an attractive strategy. In addition, inhibition of MDSC can be achieved by COX-2 and arginase inhibitors (Wesolowski et al., 2013). Regulatory T cells and MDSC can also be targeted by inhibitors of the IDO pathway (Prendergast et al., 2014), a novel class of immunomodulators that may help reverse the dysfunction of antitumor effector cells. Combination of DC vaccines with IDO inhibitors are currently under clinical investigation. The combination of optimized DC vaccines with inhibition of immunosuppressive and immunoregulatory mechanisms is likely to trigger strong antitumor immune responses, priming potent effectors T cells while protecting them from exhaustion.

With chemotherapies

Besides lowering tumor burden, many studies demonstrated that some classical antitumor chemotherapies can affect many aspects of antitumor immune responses and display immune-potentiating effects. DC may contribute to the efficacy of conventional antitumor chemotherapies that induce immunogenic cell death of tumor cells, defined as apoptotic processes favoring, rather than suppressing, immune responses. The positive immunologic consequences of certain chemotherapies are well characterized (Zitvogel et al., 2008, 2011). Immunogenic signals from tumor cells undergoing apoptosis can be detected by DC and potentiate DC maturation and cross-presentation of tumor antigens. In particular, chemotherapeutic drugs such as anthracyclin or oxaliplatin can induce an immunogenic tumor cell death of cells characterized by surface exposure of calreticulin which enhances phagocytosis of tumor cells by DC. Similarly, secretion of HMGB1 (a TLR4-L) by tumor cells inhibits phagosome–lysosome fusion in APC, preventing rapid tumor antigen degradation and enabling MHC-I restricted presentation and subsequent priming of T cells (Kroemer et al., 2013). The synergy of chemotherapies with DC vaccines has been demonstrated in colorectal cancer patients treated with DC vaccine combined to oxaliplatin (Lesterhuis et al., 2010).

With monoclonal antibodies and targeted therapies

Many preclinical studies have demonstrated the beneficial immunomodulatory effects of antibodies and targeted drugs, and the potential synergy between immunotherapy and targeted therapy (Marabelle and Caux, 2012). The efficacy of therapeutic monoclonal antibodies may also involve DC (Galluzzi et al., 2012). Indeed, some antibodies such as cetuximab, anti-EGFR, not only attenuate oncogenic signals, but also induce antibody-driven effector mechanism (antibody-dependent cell-mediated cytotoxicity, phagocytosis, complement-dependent cytotoxicity) leading to tumor cell lysis or engulfment, and help elicit specific CD8 T cells by potentiating antigenic presentation by DC and their activation (Banerjee et al., 2008; Correale et al., 2012). Bevacizumab, an anti-VEGF antibody, inhibits angiogenesis and also induces DC differentiation and tumor infiltration by CTL (Osada et al., 2008). Inhibition of angiogenic factors such as VEGF restores DC function within the tumor microenvironment and synergizes with DC-based vaccines (Tartour et al., 2011; Gabrilovich et al., 1999). Recent preclinical studies suggest that targeted therapies such as dasatinib or sunitinib (tyrosine kinase inhibitors) used in c-KIT mutated tumors, especially melanoma, gastrointestinal cancer (GIST) and mastocytomas (Yang et al., 2012), may decrease MDSC and immunosuppressive cytokines within the tumor microenvironment (Ko et al., 2009; Ozao-Choy et al., 2009) and potentiate DC vaccines in patients (Amin et al., 2015). JAK2 inhibitors not only interfere with tumor cell survival, but also potentiate DC functions by blocking STAT3 signaling, an inhibitory pathway leading to the induction of suppressive T cells (Lee et al., 2011). Indeed, in a preclinical model, the combination of anti-JAK2 targeted therapies with a DC vaccine enhanced DC maturation, induction of T cell responses, and suppressed tumor growth (Nefedova et al., 2005). Inhibition of mutated BRAF by vemurafenib blocks IL-10 and VEGF secretion by tumor cells, consequently improving DC functionality within the tumor microenvironment (Sumimoto et al., 2006). Thus, targeted therapies can directly antagonize the immunosuppressive microenvironment and restore DC functions.

Overall, antitumor treatments or targeted therapies can be beneficial or deleterious for the immune system, and this needs to be taken into account for the design of optimal combinations to potentiate DC function and promote the emergence of a robust immunity. The synergistic effect of chemotherapies or targeted therapies with immunotherapies, may help prevent escapes due to mono-therapies while acting simultaneously at different points of control of tumor progression. Such combination strategies (Vanneman and Dranoff, 2012) may achieve a better clinical success. However, optimization of duration, sequence and delivery dose of the diverse therapies is crucial for the success of these combinatorial approaches and to avoid increased toxicity and side

effects. Numerous ongoing phase I/II clinical trials are testing combinations of targeted therapies or immunomodulatory therapies with DC vaccines.

Conclusion

DC are crucial actors of the immune system, orchestrating a large panel of responses that can result in potent antitumor immune responses. However tumor cells hijack the immune system, often compromising DC function. Recent clinical trials have demonstrated that DC vaccines could trigger antitumor responses associated with a clinical benefit in subgroups of patients. DC-based cancer immunotherapy has evolved a lot, starting from initial ex vivo DC vaccines to a panel of new therapeutic options. Better knowledge of DC subsets, their biology and unique properties, together with a better understanding of the type of response triggered by specific DC subsets or engaged target receptors, open the door to the development of rationally optimized vaccines. In addition, characterization of tumor immune escape mechanisms and of DC subversion by tumors will help restoring DC functionality within the tumor microenvironment. Understanding the immunological consequences of conventional antitumor treatments will help potentiate immunotherapies. New approaches in preclinical development are promising, taking advantage of DC diversity and plasticity, of neoantigens identification, and exploitation of the synergies between immunotherapies and conventional therapies. Future developments will likely trend toward optimized personalized combined strategies depending on the properties of the immune system and characteristics of the patient's tumor, to interfere with the cancer–immunity cycle (Chen and Mellman, 2013). Combination approaches are under development to optimize tumor control, involving both DC vaccines, small molecules inhibiting signal transduction pathways, and antibodies blocking immune checkpoints. The combined expertise of immunologists and oncologists is crucial to develop innovative and efficient antitumor treatments. The current challenge of antitumor immunotherapy is to reverse the balance from tolerance to immunity within a suppressive tumor microenvironment, but also to overcome many regulatory and financial issues associated with the transfer of new strategies in human clinic.

Cancer-Related Inflammation in Tumor Progression

Alberto Mantovani, Humanitas Clinical and Research Center, Milan, Italy; Humanitas University, Milan, Italy; and Queen Mary University of London, London, United Kingdom

Glossary

Tumor microenvironment The ecological niche of cancer including inflammatory cells, immune cells and stroma.

Nomenclature

TME Tumor microenvironment
TAM Tumor-associated macrophages
IL Interleukin

The perception that cancer and inflammation are linked processes goes back to the 19th century. This perception has not attracted the limelight for a long time. Different lines of work have led to a renaissance of the inflammation-cancer connection, leading to a generally accepted paradigm. Inflammatory cells and mediators are present in the microenvironment of most neoplastic tissues, including those not causally related to an obvious inflammatory process (e.g., breast cancer). Essential characteristics of cancer-related inflammation include the presence of leukocytes, prominently tumor-associated macrophages (TAM); the presence of inflammatory cytokines (e.g., tumor necrosis factor (TNF), interleukin-1 (IL-1), IL-6, IL-23, IL-17, chemokines such as CCL2); prominent tissue remodeling and angiogenesis.

In the last 20 years we have moved from a cancer cell centric view of the essence of cancer to one that includes the tumor microenvironment (TME) and immunity. A better understanding of innate and adaptive immunity in cancer has paved the way to development of immunotherapy approaches in its broad sense (Fig. 1), from checkpoint blockade inhibitors to inhibition of inflammatory cells and cytokines.

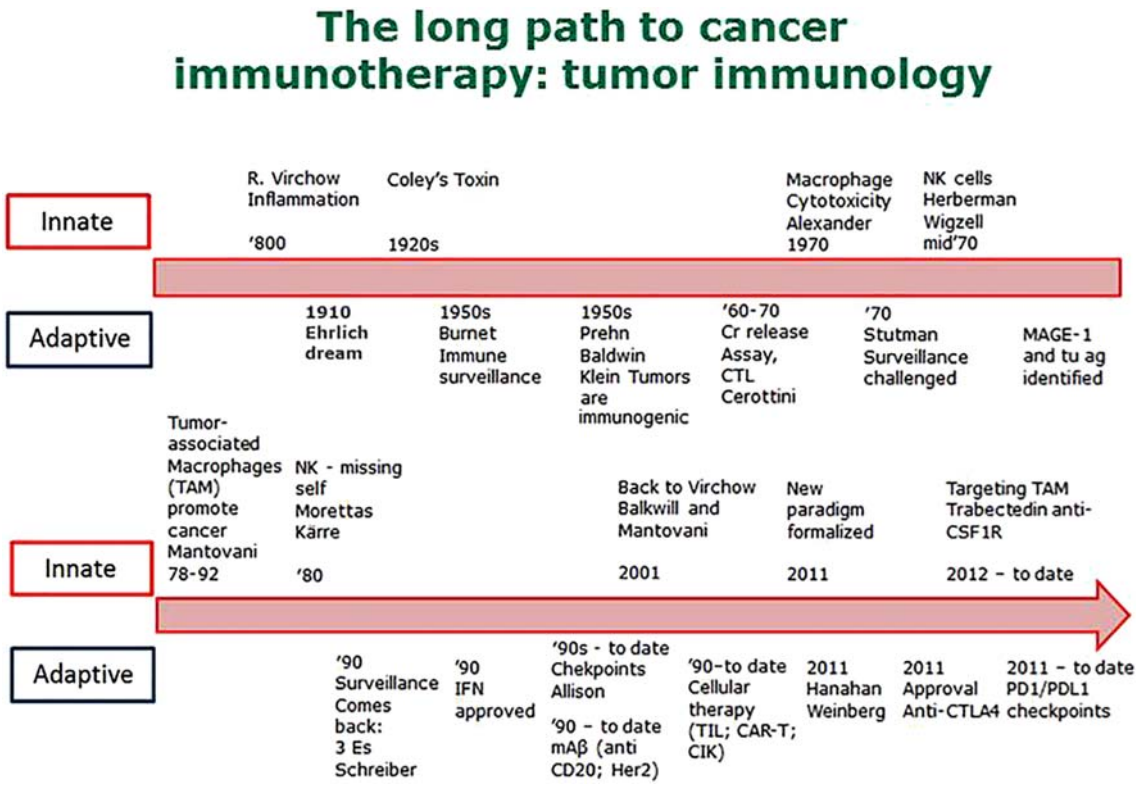

Fig. 1 A historical perspective of the development of tumor immunology and immunotherapy.

The TME includes components of inflammation and adaptive immune responses. Pathways connecting inflammation, carcinogenesis and progression are complex (Fig. 2). Under selected conditions, smoldering local od systemic inflammation increases the cancer risk. We have referred to this pathway as "extrinsic." The extrinsic pathway connection between local inflammation and cancer is illustrated by ulcerative colitis increasing the risk of developing colorectal cancer. At a systemic level, obesity causes a subclinical inflammation state and is associated to an increased risk to develop cancer, in this same extrinsic pathway perspective.

Tumors epidemiologically unrelated to overt inflammatory conditions have inflammatory cells and mediators in their TME. For instance macrophages are a component of the TME in breast cancer and promote growth and metastasis. Moreover, in triple negative breast cancer tumor-associated macrophage (TAM) infiltration is associated with poor prognosis. Activation of the kinase MER TK which drives epithelial to mesenchymal transition is an important determinant of TAM recruitment under these conditions.

Key orchestrators at the intersection of the intrinsic and extrinsic pathway include transcription factors (e.g., NFkB; STAT3), cytokines (e.g., IL-1; TNF) and chemokines. Thus, cancer-related inflammation (CRI) is an essential component of the tumor microenvironment and is now a recognized essential characteristic of cancer. TAM are now being considered as prognostic markers and therapeutic targets. Targeting TAM is a key component in the antitumor activity of Trabectedin, an EMA and FDA approved antitumor agent, thus providing proof of principle for TAM directed strategies. Based on preclinical work. Based on preckinical work, antibodies or simple molecules targeting the CSF1 pathway are undergoing clinical assessment per se or in concert with checkpoint blockade inhibitors.

A variety of inflammatory cells and mediators are present in TME (Fig. 2). Macrophages have served as a paradigm of cancer-related inflammation. Other inflammatory cells include neutrophils, eosinophils and basophils. Components of the humoral arm of innate immunity are present in the TME and have recently emerged as important drivers of tumor progression. Evidence now suggests that complement can be a component of tumor promoting inflammation. In the same perspective of complement mediated tumor promotion, the humoral pattern recognition gene PTX3 has been shown to be an extrinsic oncosuppressor gene. PTX3 interacts with factor H which regulates complement-driven inflammation in preclinical models and selected human tumors. Complement drives tumor promoting inflammation by recruiting macrophages which are the key cells in tumor promotion. Thus complement can have a yin yang role in cancer, on the one hand mediating tumor cell killing of recognition by effector cells after monoclonal antibody therapy. On the other hand, complement can be a driver of tumor promoting inflammation.

The TME is remarkably different in tumors originating in different organs and among tumors which originate in the same organ or tissue. Within the same histological type, tumors are characterized by widely different TME. For instance, in colorectal cancer four TME phenotypes have been identified based on profiling.

Assessment of components of the TME has prognostic significance. T cell infiltration ("Immunoscore") is an independent prognostic indicator of favorable outcome. Conversely, TAM infiltration is generally associated with bad prognosis. A notable exception is colorectal cancer. Recent evidence indicate that TAM infiltration predicts response to 5FU chemotherapy.

Dissection of the role and diversity of cancer-related inflammation may pave the way to improving on current immunotherapy strategies and may impact on diagnosis and prevention. The prototypic inflammatory cytokine IL-1 was shown early on to promote tumor progression. These early observations have now been translated. In the CANTOS study with over 10,000 patients treated with

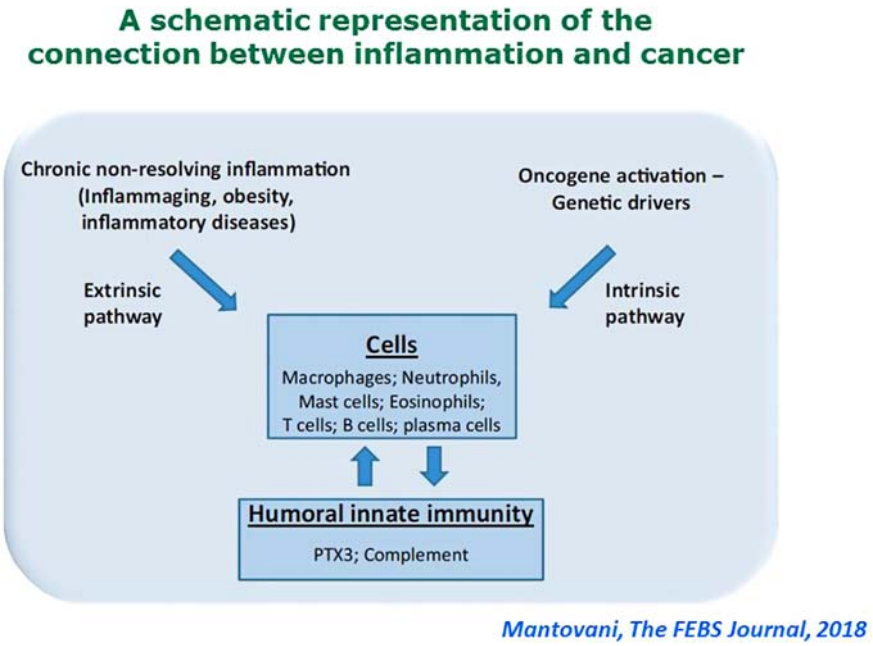

Fig. 2 A schematic representation of the connection between inflammation and cancer. Reproduced with permission from Mantovani A. (2018). *FEBS J.* **285**(*4*):638–640.

anti-IL-1 (canakinumab) with high C reactive Protein. Over 50% protection against incidence and mortality from lung cancer were observed.

Immunity is an essential component of the tumor microenvironment (TME) and a key determinant of metastasis. Inflammatory cells, tumor-associated macrophages (TAM) in particular, pave the way to tissue invasion and intravasation and provide a nurturing microenvironment for metastasis, serving as a component of the cancer cell niche at distant sites. NK cells are innate lymphoid cells (ILCs) which have long been considered to play a role in resistance against hematogenous dissemination of cancer cells, in particular to the lungs. Finally, tumor progression and escape are associated with activation of pathways of suppression of innate and adaptive anti-tumor responses which include, among others, immunosuppressive myeloid cells, activation of checkpoint blockade, induction and recruitment of T regulatory cells.

Invasion and metastasis are key to malignancy. There is also evidence for a role for neutrophils and their major growth factor, granulocyte colony stimulating factor (G-CSF), in cancer progression to metastasis. The interplay between tumor-associated macrophages and neutrophils with the extracellular matrix shapes the TME and promotes tumor growth and dissemination.

Quantification of the immune and inflammatory landscape of TME has provided novel prognostic indicators of cancer progression as shown by quantification of tumor infiltrating T cells and TAM. Genomic technologies have added a new dimension to the characterization of the TME and to classification of cancers. Finally, dissection of the mode of action of conventional cytoreductive strategies, the impact of checkpoint blockade inhibitors and adoptive cell therapy of hematological malignancies have proven the principle that the immune system can be harnessed to cope with advanced disseminated neoplastic diseases.

Full exploitation of the diagnostic and therapeutic potential of innate and adaptive immunity will require an integrated in depth analysis of its components in primary versus spreading, metastatic tumors, dissection of the diversity of metastatic niches, identification and development of new molecular and cellular tools. Given the diversity of the involved innate and adaptive players and of the environmental clues involved, only an integrated effort with expertise from different fields can lead to the identification of new biomarkers and therapeutic strategies for metastatic disease.

Cancers as Ecosystems: From Cells to Population

Graham A Colditz, Alvin J. Siteman Cancer Center and Institute for Public Health, Washington University School of Medicine, St. Louis, MO, United States

Much of our research focuses on the causes and outcomes of cancer. Epidemiology studies the genetic and nongenetic risk factors (genes and environmental factors (MacMahon and Pugh, 1970)) and places these in the context of the assumed underlying disease process. Historically epidemiology has defined non-genetic factors as environmental, thought this embraces a broad range of lifestyle, occupational, and reproductive factors as well as medications. Using a reductionist approach, we work to separate the effects of each factor from the others, focusing on measurement and the role of exposures in etiology and modifying survivorship. However, humans live in communities and broader societies, and often the interplay between cells, human bodies, individuals, and society are ignored (Colditz and Sutcliffe, 2016). This is particularly important for considerations of the underlying causes of variation in cancer risk, and the role of lifestyle in survivorship (Colditz, 2001). Early studies of causes of cancer focused heavily on variation in incidence between countries and within countries according to occupation (Ziegler et al., 1993; MacMahon, 1965).

Let me use the example of breast cancer. We have identified a range of reproductive and other lifestyle factors that modify risk (Hankinson et al., 2004). Each may be studied as an independent risk factor or combined into a model that summarizes risk making assumptions of the underlying disease process (Rosner et al., 1994, 2013; Rosner and Colditz, 1996), which Pike called breast tissue age (Pike et al., 1983). The individual risk factors such as first pregnancy may be studied in humans in relation to changes in circulating hormone levels (Hankinson et al., 1995), and intermediate markers such as breast mammographic density (McCormack et al., 2010). Pregnancy may also be studied in animal models to refine understanding of the cellular changes associated with a first full-term pregnancy (Medina, 2013). Other lifestyle causes of breast cancer include alcohol (IARC Working Group on the Evaluation of Carcinogenic Risks to Humans, 2010), obesity (Lauby-Secretan et al., 2016), physical activity (International Agency for Research on Cancer, 2002), and use of contraceptives and menopausal hormone therapy (IARC Working Group on the Evaluation of Carcinogenic Risks to Humans, 2007). These have been studied for action at the cellular level and then with more recent and larger epidemiologic studies they are related to risk of subtypes of breast cancer defined by receptor status (Colditz et al., 2004). For weight, the field has evolved to address timing of adiposity and weight gain (Rosner et al., 2015, 2017).

In parallel to these studies of environmental causes of cancer, the details of genetic predisposition have been refined from a family history of breast cancer diagnosis (1800s) to genetic changes that carry varying levels of risk (Colditz et al., 1996; Miki et al., 1994; Couch et al., 2014). Molecular mechanism for genetic predisposition are described in other articles.

After diagnosis of breast cancer, lifestyle is again a focus, as components of lifestyle may modify survival outcomes (adiposity increases mortality (Chan et al., 2014), physical activity may reduce mortality (Holmes et al., 2005)). Furthermore, socially isolated women have a greater reduction in their physical function after cancer diagnosis than those who are more socially integrated (Michael et al., 2002). Similar associations are studied for outcomes after colorectal cancer (Van Blarigan et al., 2018; Chan et al., 2008) and prostate cancer (Khan et al., 2018; Imm et al., 2017), to name a few.

These risk factors do not occur in isolation. Rather they are the proximate measures that are easily accessible for epidemiologists to study. Many of these factors studied in isolation have been reviewed by the International Agency for Research on Cancer (IARC) and classified as carcinogens (IARC, 2011). However, many of these exposures and the attained level of risk is often driven by broader social forces. Take parity as an example. Before commercial contraception was readily available women had an average of 6–8 pregnancies. This level continued in rural China and other low-income countries until very recently (Lewington et al., 2014). Meanwhile, with industrialization and access to contraception parity has fallen. In addition, with increasing education and career options, women have deferred childbearing to later in life. Mean age at first pregnancy is now 30 or more in most OECD countries (OECD, 2012). Thus, the risk factor age at first birth is not isolated from the broader social changes of education, income, and opportunity (Bumpass et al., 1978). Changes in sun exposure over decades reflect changing social norms regarding sunbathing, swim suits, development of sunscreens, and now commercial tanning industries (Wehner et al., 2014). Likewise, consumption of sugar sweetened beverages has changed dramatically over decades with increasing serving size reflecting marketing and commercial targets over public health concerns.

Age at menarche is another long-studied risk factor, marking the beginning of menstrual cycling and monthly breast proliferation and involution (Pike et al., 1993). The drivers of age at menarche have changed dramatically—age at menarche has fallen from 18 to 12 or less in a century (Lewington et al., 2014), and with it more adiposity in childhood (Dietz and Gortmaker, 2001), greater attained height (Sung et al., 2009), and fewer infections have covaried. In Korea, for example, mean age at menarche decreased from 16.90 ± 1.25 years for women born between 1920 and 1925 to 13.79 ± 1.37 years for those born between 1980 and 1985, indicating a downward trend of 0.68 years per decade (95% CI, 0.64–0.71) in age at menarche (Cho et al., 2010).

Some have worked to understand the relations between these societal changes and the change in age at menarche (Berkey et al., 2000). Nutrition is one clear driver of both adiposity (excess energy intake for energy expenditure) and sources (animal vs. vegetable) modifying age at menarche (Berkey et al., 2000). Higher animal protein intake is related to greater height and also earlier menarche. So, while the cellular changes in the breast may be the driver of breast cancer risk; societal changes in access to food, healthy living conditions, and so forth modify the expression of the underlying biologic process.

To refine understanding of pathways and modifiers of predisposition, studies have more recently included blood markers (hormone levels, nutrients, inflammatory markers) and related them to cancer risk (Colditz and Hankinson, 2005). Often this is in the context of understanding or refining understanding of exposures and cancers (McMichael, 1994). While these markers may serve as more proximate measures of exposure, to date they do not address the cellular environment in all levels of richness and are not specific to individual organ tissues.

Moving From Causes to Prevention

The causal role of HPV in the etiology of cervical cancer demonstrates the refinement of understanding of causes of cancer over time, and the broader social context that can modify the effectiveness of prevention even when effective strategies are scientifically justified. The evolution of epidemiologic understanding from number of sexual partners as a risk factor for cervical cancer (hypothesized to reflect transmission of on infectious agent) (Pereyra, 1961; Schiffman et al., 1993; Beral, 1974) to defining the etiologic agent (Franco et al., 1999), and then developing an effective vaccine for cervical and anal cancer (Giuliano et al., 2011), has variable effectiveness as a prevention strategy at the population level (Walling et al., 2016). This is not due to varying biologic effectiveness at the cellular level, but rather due to differences in society approaches to implementing comprehensive vaccination programs (Walling et al., 2016). In the span of 20 years or less global evidence moved such that Australia has among the most effective programs (vaccine purchased by the Federal government and administered by school nurses) (Gertig et al., 2013) while the US on the other hand has hap hazard prescribing by primary care providers (USA) (Rahman et al., 2015). Australia has documented the dramatic decrease in premalignant cervical lesions on biopsy, and modified its surveillance program to every 5 year vaginal testing for HPV (Brotherton et al., 2016). The US still has a vaccination rate of only 43% of adolescents up to date on all recommended doses of HPV (https://www.cdc.gov/hpv/hcp/vacc-coverage.html).

Synthesis

From these perspectives and others, the social ecologic model for prevention has been proposed as an approach to place the cellular level biologic processes of carcinogenesis in the broader context of society (Swinburn et al., 2011). For obesity, Story described how access to food and nutrients, as well as safe places to play and exercise modify energy balance; the built environment also supports or inhibits physical activity, active commuting, and so forth (Story et al., 2008; Shelton et al., 2011). A similar model applies globally (Swinburn et al., 2011). Food and agriculture policies modify access to foods/nutrients and the composition of diet. Marketing, home and workplace environments, also contribute to the enticement for food and drinks, such as sugar sweetened beverages, alcohol, etc.; and modify how we spend our time—watching television—or in occupations that do not burn energy the way our forebears did in manual labor. In this spirit Warnecke and others have defined how the interplay of processes from the cellular level through individual and community level measure and broader social policies interact to drive cancer risk and outcomes (Warnecke et al., 2008). Moving forward to reduce disparities in cancer risk across populations and within populations greater focus from cell to society will be needed to maximize our return on investment in cancer research (Emmons and Colditz, 2017).

Glossary

Carcinogen-DNA adduct The addition product between two molecules, in this case a carcinogen and DNA, involving one or more covalent bonds.
Cytochrome P450 A member of a superfamily of closely related heme-containing oxygenases that oxidize a wide variety of substrates.
Exposure biomarker A xenobiotic, its metabolite, or the product of an interaction between a xenobiotic and some target molecule such as DNA or proteins that are reflective of an individual's exposure.
Metabolic activation The metabolism of a compound lacking the ability to react covalently with DNA (or proteins) to a product(s) that does.
Xenobiotic Describing or relating to a foreign compound.

Introduction

Some years ago Christopher Wild, director of the International Agency for Research on Cancer (IARC), introduced the "exposome" as a complementary concept to the "genome." The exposome reflects all of the encountered exposures of an individual over the course of her/his lifetime. According to epidemiological studies, approximately 90% of cancer deaths can be attributed to the presence of certain environmental factors, and are not related to the genetic makeup of an individual. So far IARC has classified around 120 compounds as carcinogenic to humans (Group 1 carcinogens). The list of carcinogens contains organic chemicals, inorganic material, biological agents, mixtures, and radiation. The underlying pathways leading to cancer for most of those compounds are not yet fully understood.

Chemical carcinogens can exert their effect either through genotoxic (involving DNA damage) or nongenotoxic mechanisms. Some highly reactive genotoxic carcinogens are capable of directly interacting with DNA (e.g., alkylating agents) but most chemical carcinogens (e.g., polycyclic aromatic hydrocarbons [PAHs], aromatic amines, heterocyclic aromatic amines, nitrosamines) are not chemically reactive as such and require metabolic activation to reactive intermediates capable of binding to DNA (i.e., nucleobases), forming covalent adducts. Xenobiotics that need metabolic activation to exert their genotoxic/carcinogenic properties are termed pro-carcinogens or indirect-acting carcinogens.

A wide variety of enzymes are involved in xenobiotic metabolism and these xenobiotic-metabolizing enzymes can be divided into two groups. Phase I (functionalisation) reactions include oxidation, reduction and hydroxylation catalyzed by enzymes such as cytochrome P450s (CYPs), cyclooxygenases (COXs), and aldo-keto reductases (AKRs) with the aim to make hydrophobic xenobiotics more hydrophilic and thus excretable. Phase II (conjugation) reactions further add polar moieties, such as glucuronic, acetic or sulfuric acids or glutathione thereby increasing polarity, which further assist in excretion. Examples of phase II enzymes include uridine diphosphate glucuronosyltransferases, *N*,*O*-acetyltransferases, sulfotransferases and glutathione *S*-transferases. However, phase I and II enzymes can arguably be in either category.

As an example Fig. 1 shows the bioactivation and DNA adduct formation of benzo[*a*]pyrene (BaP), a PAH that has been classified as human carcinogen (Group 1) by IARC. The major pathway in humans involves the oxidation of BaP by CYP1A1 or CYP1B1 to an epoxide (i.e., BaP-7,8-oxide) that is then converted to BaP-7,8-dihydrodiol by microsomal epoxide hydrolase (mEH). BaP-7,8-dihydrodiol can be further activated by CYPs (i.e., CYP1A1 or CYP1B1) or COX to BaP-7,8-dihydrodiol-9,10-epoxide (BPDE) which is the ultimate reactive species capable of reacting with DNA to form covalent adducts preferentially at the exocyclic amino group at N^2-guanine (i.e., 10-(deoxyguanosin-N^2-yl)-7,8,9-trihydroxy-7,8,9,10-tetrahydro-BaP [dG-N^2-BPDE]) (see Table 1). Other activation pathways for BaP lead to radical-DNA interactions and DNA depurination but their role in BaP carcinogenesis is under discussion.

Some representative carcinogens, their environmental sources, their reactive metabolites and their most abundant DNA adduct are shown in Table 1.

☆*Change History:* November 2017. Annette M. Krais, Rajinder Singh, and Volker M. Arlt wrote a new article. Only couple of sentences of the old chapter have been incorporated into the present version of chapter.
This article is an update of Alan M. Jeffrey, M.I. Straub, Carcinogen–DNA Adducts, in Encyclopedia of Cancer (Second Edition), edited by Joseph R. Bertino, Academic Press, 2002, Pages 345–357.

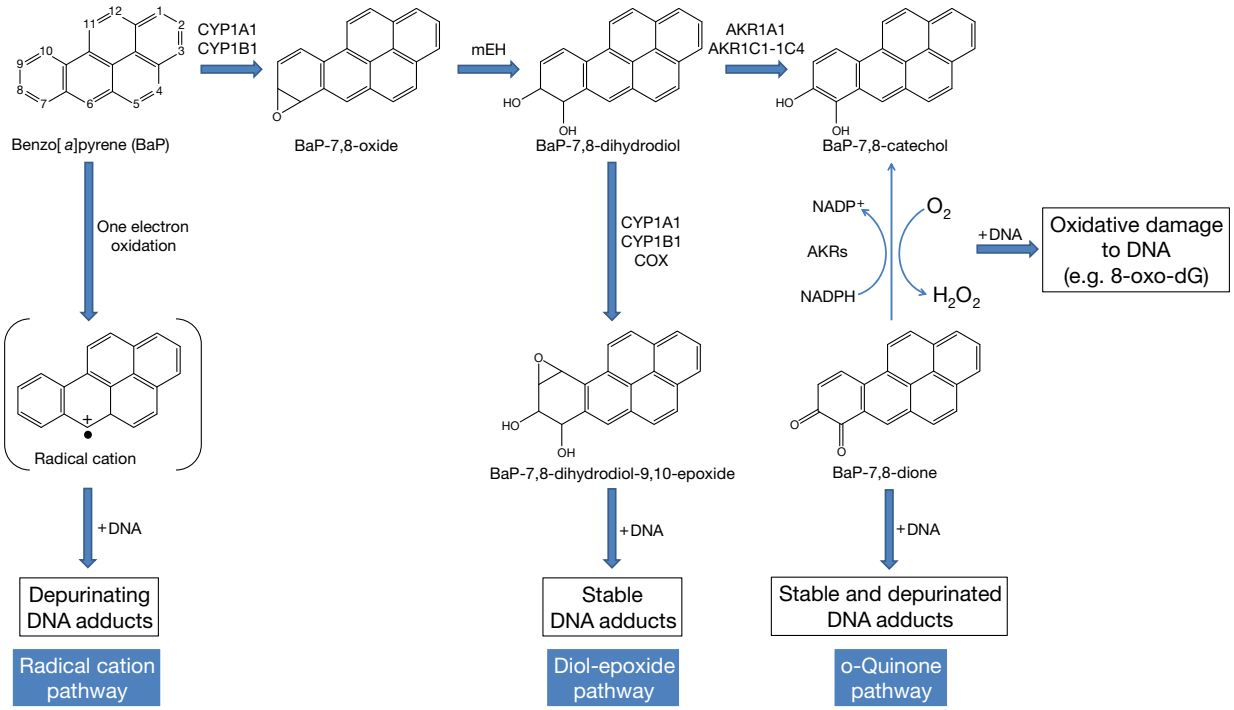

Fig. 1 Pathways of BaP bioactivation leading to DNA adduct formation. *CYP*, cytochrome P450; *mEH*, microsomal epoxide hydrolase; *COX*, cyclooxygenase; and *ARK*, aldo–keto reductase. See text for details.

DNA adducts can also originate from endogenous processes, including normal metabolism, oxidative stress, lipid peroxidation and chronic inflammation (Fig. 2). The most abundant lesion linked to oxidative damage to DNA is 7,8-dihydro-8-oxo-2′-deoxyguanosine (8-oxo-guanine [8-oxo-dG]) which is formed by free radical attack on DNA (i.e., addition of •OH to the C8 position of guanine). As shown in Fig. 1 BaP quinone redox cycling can generate reactive oxygen species which leads to the formation of 8-oxo-dG in DNA (see Fig. 2). Thus some genotoxic carcinogens that do not appear to directly modify DNA can instead damage it through inducing reactive oxygen species leading to oxidative base modifications.

The DNA adductome is defined as the sum of all DNA adduct types and levels present in cellular DNA and can be considered reflective of the internal exposome. These DNA adducts, if not repaired before DNA replication, can lead to DNA mutations or chromosomal damage, thus possibly resulting in carcinogenesis. Therefore as adducts can lead to mutations, and mutations in critical genes are a characteristic feature of tumors, DNA adduct formation is considered to be the first critical step (i.e., initiation) in chemical carcinogenesis (Fig. 3).

With few exceptions, however, carcinogens form DNA adducts in many tissues (in both target and nontarget tissues), leading to the view that adducts are necessary, but not sufficient, for carcinogenesis. Thus, although there are linear relationships between dose, adduct levels in target tissues and tumor incidence, it may be difficult to identify which tissues are targets for carcinogenicity by an agent purely from a consideration of the levels and persistence of DNA damage. Nevertheless, the identification and structural characterization of DNA adducts in human tissues can provide important clues on the etiology of human cancer. DNA adducts have the potential to be used as biomarkers of exposure (to carcinogens) and markers of cancer risk (from exposure to carcinogenic agents).

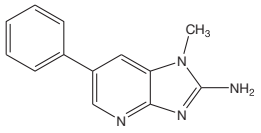
Application of DNA Adduct Analysis

A major goal of adduct analysis is to improve our ability to extrapolate data on carcinogen exposure to human risk. It is reassuring to find that good correlations have been obtained between carcinogenicity of genotoxic compounds and their ability to bind to DNA, especially when closely related series of compounds are investigated. Sensitive DNA adduct detection methods make it possible to monitor carcinogen-DNA adduct formation in humans. Thus, DNA adduct formation in an exposed cell or tissue can be used: (*i*) to determine the mutagenic or carcinogenic potential of an agent; (*ii*) for monitoring human exposure to environmental carcinogens to study the etiology of cancer; (*iii*) for mechanistic investigations into carcinogen activation, tumor initiation or DNA repair; (*iv*) monitoring the environment for the presence of genotoxins (e.g., by detecting DNA adducts in aquatic species); and (*v*) assessing a patient's response to cytotoxic cancer drugs.

Since humans are exposed not only to one but to a complex mixture of carcinogens, direct proofs of an association of chemical exposure to the development of a specific cancer type are scarce. The plant carcinogen aristolochic acid and the mycotoxin aflatoxin B_1 are two rare examples where distinct environmental exposures are linked to tumor development in humans. For both agents DNA adduct formation could be linked to cancer incidence, by combining molecular epidemiological data on chemical exposures,

Table 1 Examples of environmental carcinogens and drugs that form DNA adducts

Carcinogen	*Major active metabolite*	*Major DNA adduct/site of modification*	*Environmental source*
 Benzo[*a*]pyrene (BaP)	 BaP-7,8-dihydrodiol-9,10-epoxide (BPDE)	 N^2-guanine	Tobacco smoking combustion processes diet
 Aflatoxin B_1(AFB_1)	 AFB_1-8,9-epoxide	 N^7-guanine	Mycotoxin
 Aristolochic acid I	 *N*-Hydroxy-aristolactam I	 N^6-adenine	*Aristolochia* species



2-Amino-1-methyl-6-phenylimidazo-[4,5-*b*]pyridine (PhIP)

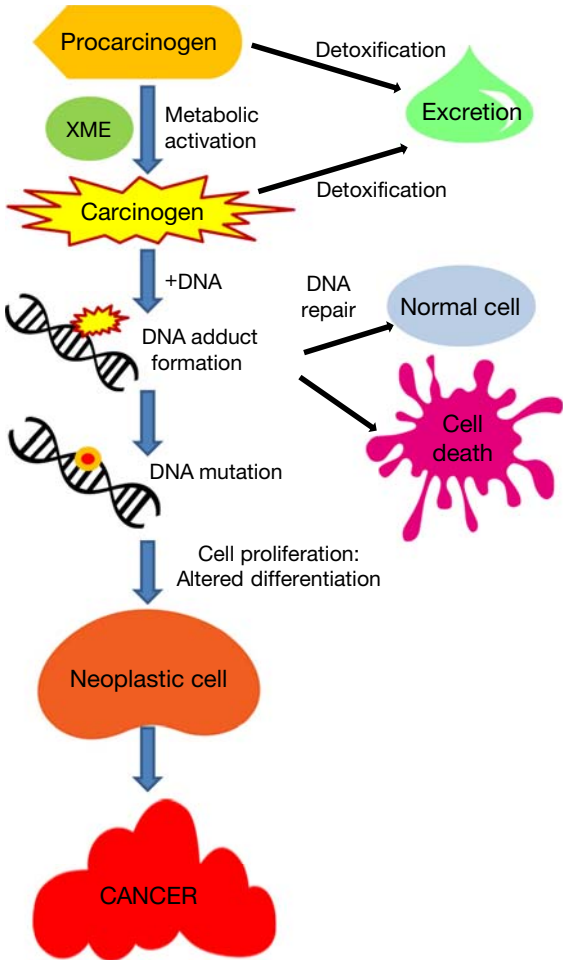

Fig. 3 The role of DNA adducts in the initiation process of carcinogenesis. See text for details.

chemical-specific DNA adducts in target tissues and mutation spectra in tumor-related genes. Thus aristolochic acid and aflatoxin B_1 have both been classified as Group 1 human carcinogen by IARC. Aflatoxin B_1 is a potent liver carcinogen that can be found as a contaminant in various crops and dietary exposure to aflatoxin B_1 has been associated with hepatocellular carcinoma in certain areas of Asia and Africa. Those observations have been strengthened by the detection of N^7-guanine adducts of aflatoxin B_1 (see **Table 1**) in the urine of exposed individuals. These adducts lead to characteristic G:C → T:A transversion mutations selectively in codon 249 of the *TP53* tumor suppressor gene in aflatoxin B_1-induced liver cancers. Aristolochic acid, the plant extract derived from *Aristolochia* species, causes upper urothelial tract cancer in patients suffering from aristolochic acid nephropathy (AAN) and Balkan endemic nephropathy (BEN). Exposure to aristolochic acid has been demonstrated in many parts of the world and linked to medicinal herbal remedies or dietary intake. The 7-(deoxyadenosin-N^6-yl)aristolactam I adduct (see **Table 1**) is the most abundantly found in urothelial tissue of AAN/BEN patients. It has even been detected in individuals over 20 years after exposure to aristolochic acid had ceased. The abundance and exceptionally long-term persistence of 7-(deoxyadenosin-N^6-yl)aristolactam I in DNA can therefore be exploited as specific biomarker of AA exposure in human biomonitoring. This adduct also leads to otherwise rare A:T → T:A transversion mutations, which are frequently detected in *TP53* in urothelial tumors of AAN/BEN patients. This characteristic mutation pattern is also found by whole-genome sequencing of AA-exposed tumors.

It is clear from numerous studies that DNA adducts are intrinsically present in DNA. These "background" levels of adducts or DNA damage have been detected in individuals for whom no specific exposure to the agent of interest was known. Background DNA damage can have multiple origins including diet, air pollution or smoking and thus need to be taken into account when selecting control groups of individuals for comparison with a putative "exposed" population in molecular epidemiology studies. This will ensure that any difference in adduct levels between the study groups are due to the exposure of interest and not just linked to differences in other lifestyle factors. Besides "normal" environmental exposures, endogenous sources also contribute to background levels of DNA damage.

DNA adducts have been detected in the range of 1 adduct per 10^7–10^{11} normal nucleotides in human tissues. The remainder of the chapter considers methods for carcinogen-DNA adduct detection in humans and how identified adducts in human tissues can be used to study cancer etiology.

Methods for Adduct Detection

A variety of sensitive methods have been developed for the detection and characterization of carcinogen-DNA adducts (**Table 2**). In order to be applicable for human biomonitoring the assays used must be sufficiently sensitive to detect low levels of DNA adducts, require only small amounts of DNA, provide results quantitatively related to the exposure, be applicable to unknown DNA adducts that may be formed from complex mixtures and be able to resolve, quantitate, and identify DNA adducts.

The main methods that have been used to detect DNA adducts include ^{32}P-postlabeling, immunoassay, gas chromatography mass spectrometry (GC-MS), liquid chromatography (LC) coupled with electrochemical, fluorescence or mass spectrometry (MS) and accelerator mass spectrometry (AMS). Each of these methods adopts very different approaches for the detection of carcinogen-DNA adducts, and differs in their detection limits and requirements for quantities of DNA for analysis (**Table 2**). They all are sufficiently sensitive to be employed in human biomonitoring but they all have their strengths and weaknesses, so the method of choice has to be selected on a case-by-case basis.

Radioactive Labels

Most early work on adducts required the use of radiolabeled compounds (labeled either with ^{3}H or ^{14}C). The DNA binding is measured by the detection of radioactivity in DNA isolated from exposed animal tissue or cells in culture achieving sensitivities of detection of 1 adduct in 10^8 nucleotides; ^{14}C-labeling is less sensitive than ^{3}H-labeling. The advantage of ^{3}H is that it is relatively easily introduced into the carcinogen and can be obtained at higher specific activities than ^{14}C because of the former's shorter half-life. However, ^{3}H is also very susceptible to loss during metabolism or by exchange reactions. This can result in the formation of tritiated water which in turn may become incorporated into nonexchangeable positions in newly synthesized DNA. Although

Table 2 DNA adduct detection methods applicable to human biomonitoring and their limits of detection

Method	*Variations*	*Amount of DNA required*	*Approximate detection limits*
^{32}P-postlabeling	Nuclease P_1 digestion, butanol extraction, TLC, HPLC, PAGE	1–10 μg	1 adduct per 10^9–10^{10} nucleotides
Mass spectrometry		Up to 100 μg	1 adduct per 10^9 nucleotides
Immunoassay	ELISA, DELFIA, CIA, IHC	20 μg	1.5 adduct per 10^9 nucleotides
Fluorescence	HPLC fluorescence, SFS	100–1000 μg	1 adduct per 10^9 nucleotides
Accelerator mass spectrometry		Up to 100 μg	1 adduct per 10^8–10^{12} nucleotides

TLC, thin-layer chromatography; *HPLC*, high-performance liquid chromatography; *PAGE*, polyacrylamide gel electrophoresis; *ELISA*, enzyme-linked Immunosorbent assay; *DELFIA*, dissociation-enhanced lanthanide fluoroimmunoassay; *CIA*, chemoluminescence immunoassay; *IHC*, immunohisto-chemistry; *SFS*, synchronous fluorescence spectroscopy.

now at very low specific activity, this ^{3}H can contribute significantly to the overall level of apparent binding. The major limitation of this approach to prelabel the carcinogens is the requirement of highly radioactive test compounds which cannot be used in human biomonitoring studies.

The ^{32}P-postlabeling assay also uses radiation as a measure to detect and quantify carcinogen-DNA adducts, the underlying principle is however that adducts are labeled after their formation. ^{32}P can be obtained at about 300 times higher specific activity than ^{3}H and can be counted with higher efficiency due to the higher energy of the emitted β particle allowing the method to be intrinsically much more sensitive. The detection limit is approximately 1 adduct per 10^{9}–10^{10} nucleotides (see **Table 2**) using only a few micrograms of DNA which makes the assay widely applicable in human biomonitoring. As shown in **Fig. 4**, the method consists of four principle steps: (*i*) modified DNA is digested enzymatically to deoxyribonucleoside-3′-monophosphates using micrococcal

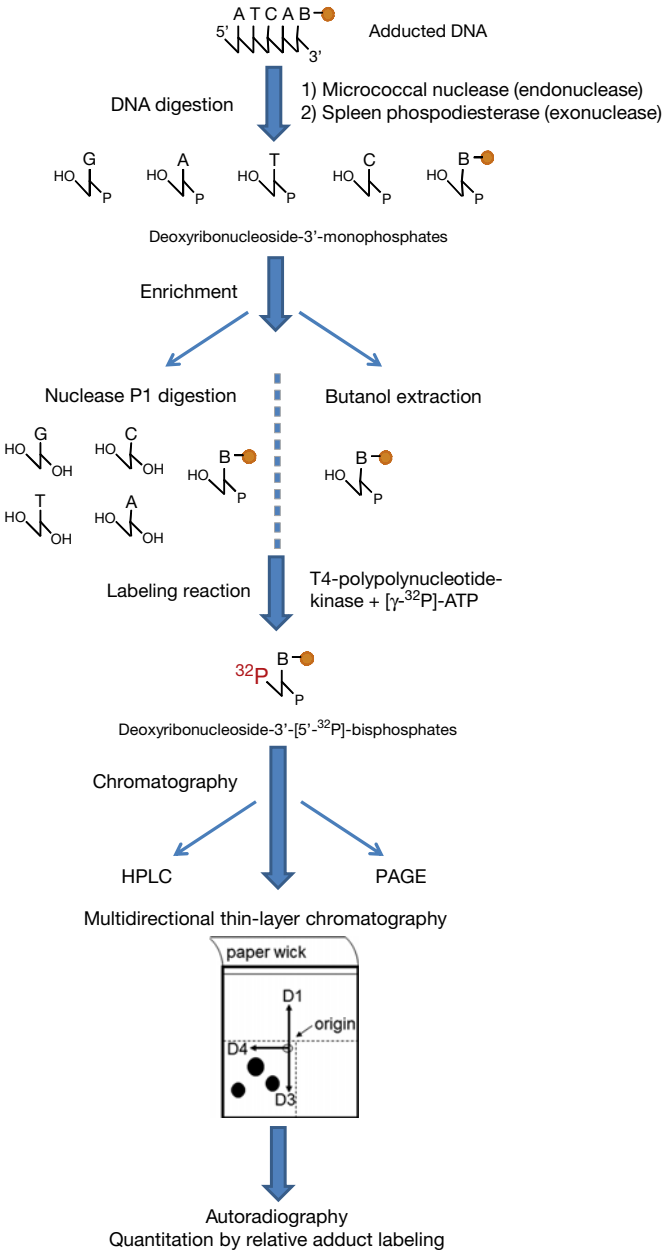

Fig. 4 DNA adduct analysis using ^{32}P-postlabeling. DNA (B indicates the modified base) is digested with micrococcal nuclease and spleen phosphodiesterase and subsequently phosphorylated by radioactive ^{32}P using T4-polynucleotide kinase. The enrichment procedures include nuclease P_1 digestion, which hydrolyzes most of the unmodified nucleotides to nucleosides, which are not kinase substrates. Many bulky DNA adducts, not linked to C8 purine position, are resistant to this enzyme. Butanol enrichment mainly extracts hydrophobic adducts. Radioactive-labeled adducts are separated by chromatography, mainly by using multidirectional thin-layer chromatography (TLC), but also high-performance liquid chromatography (HPLC) or polyacrylamide gel electrophoresis (PAGE) are occasionally used. Adducts separated by TLC are subsequently visualized by autoradiography and quantitation is achieved by calculating relative adduct labeling.

nuclease (endonuclease) and spleen phosphodiesterase (exonuclease); (*ii*) the adduct fraction is enriched using nuclease P1 digestion or butanol extraction; (*iii*) the DNA adduct is 5′-labeled by transfer of ^{32}P-orthophosphate from [γ-^{32}P]-ATP using T4-polynucleotide kinase resulting in deoxyribonucleoside-3′,[5′-^{32}P]-bisphosphates; and (*iv*) the chromatographic or electrophoretic separation of ^{32}P-labeled adducts and quantitation by the measurement of their radioactive decay.

As shown in Fig. 4, two principle enrichment procedures that follow DNA digestion have been developed. Digestion of deoxyribonucleosides-3′-monophosphates (modified or unmodified) with nuclease P_1 prior to labeling, resulting in normal nucleotides but not many adducts, being converted to nucleosides which are no substrate for T4-polynucleotide kinase. Enrichment using nuclease P_1 digestions works well for PAH-like adducts but is less suited for many aromatic amine adducts. Often adducts formed at C8-guanine appear not to be resistant to nuclease P1 digestion. The other enrichment procedure uses extraction of the aromatic/hydrophobic adducts into butanol to separate them from the unmodified normal nucleotides (which remain in the water phase) for selective ^{32}P-postlabeling.

Chromatographic resolution of ^{32}P-labeled adducts is mainly achieved by thin-layer chromatography (TLC) or alternatively by high-performance liquid chromatography (HPLC) (Fig. 4). Electrophoretic separation using polyacrylamide gel electrophoresis (PAGE) are also be utilized but is less frequently used. The major difficulty is the separation of the overwhelming excess of radioactivity associated with residual ATP, the normal nucleotides which also become phosphorylated, and any radiochemical decomposition products that might have been formed. Clearly, depending on the level of modification of the DNA by the carcinogen, which may be in the range of 1 adduct per 10^6–10^{10} nucleotides, only about that fraction of the disintegrations will be that of interest. Subsequently an elaborate separation technique was developed to remove any excess of radioactivity associated with residual ATP. This is illustrated here for the TLC version of the assay (see Fig. 4). The enriched fraction of adducts which have been labeled with ^{32}P is placed in the center of a polyethylenimine cellulose TLC plate and the plate is washed first in one direction (D1) using a phosphate buffer, cutting away the edge of the plate with an attached filter paper which contains the bulk of the unwanted radioactivity moved. Multidirectional resolution in two directions of chromatography (i.e., D3 and D4), using solvent systems optimized for the adduct(s) of interest, allow for the separation of the carcinogen-modified bases. Chromatography in D2 is now often omitted. Subsequently, DNA adducts are visualized by placing the TLC plates in cassettes using autoradiography films or plates are scanned using radiation imaging systems (e.g., Instant imager or phosphoimager).

^{32}P-postlabeling can be applied to detect a variety of bulky carcinogen-DNA adducts as illustrated in Table 1. Prior structural characterization of adducts is not required, although some assumption about the likely chromatographic properties may be necessary. Thus the method can also be applied to the detection of DNA adducts formed by complex mixtures such as those present for example, in tobacco smoke. Total smoking-related adducts can be measured as a diffuse radioactive zone on the TLC plate that can be considered representative of PAH-DNA and other aromatic/hydrophobic adducts thereby providing a summary measure of a complex mixture of adducts present in the postlabeling chromatograms. Although the method does not provide direct structural information of adducts, identification of adducts can be achieved by co-chromatography with characterized synthetic standards, usually using a combined approach employing TLC and HPLC for confirmation.

Mass Spectrometry

Mass spectrometry analysis is currently recognized as the "gold standard" for DNA adduct detection. MS analysis enables accurate quantitation and provides structural information about the DNA adduct, with only micrograms amounts of DNA or small volumes (from μL to mL) for adducts excreted in urine required for analysis. Detection is possible for DNA adducts at levels of up to one DNA modification per 10^9 deoxynucleosides (see Table 2), and sensitivity is still improving due to technical advancements in the MS instrumentation with regard to the efficiency of ionization, ion transmission and detection. Samples can be analyzed by using chromatographic separation coupled with various MS detection methods, for example, GC-MS, LC-MS/MS and AMS (see Section "Accelerator Mass Spectrometry"). Two different types of approaches can be used when studying genotoxin exposure using MS-based methods, targeted DNA adduct determination and screening of multiple DNA adducts (either targeted or untargeted); the latter adductomics approach is described in the "Adductomics" section. The targeted approach implies the identification and quantification of a limited number of DNA modifications. Using targeted DNA adduct detection, all known exposure types or exposure to specific chemicals can be analyzed in order to characterize the exposure. This implies that the MS system specifically scans for the presence of certain DNA adducts of interest, while the analysis of all other adducts that may be present in the sample is omitted.

GC-MS can be used for the analysis of several DNA adducts, but samples require chemical derivatization prior to analysis to increase the volatility of the DNA adducts under investigation. It provides excellent separation and resolution due to the employment of capillary column chromatography as well as structural information about the adduct. Furthermore, GC-MS can use different MS modes for carcinogen-DNA adduct detection such as electronic impact (EI) and negative ion chemical ionization (NICI) mode. GC-EI-MS has been used to analyze polar deoxynucleosides and aglycone adducts as well as BaP-tetrols (i.e., *r*-7,*t*-8,*t*-9,*c*-10-tetrahydroxy-7,8,9,10-tetrahydro-BaP) released by acid hydrolysis of DNA, as a marker for BPDE-DNA adduct formation. The main application of GC-EI-MS has been the detection of oxidized DNA bases, such as those resulting from the reaction of reactive oxygen species with DNA (e.g., 8-oxo-dG). The chemical derivatization of the DNA hydrolysate at high temperature has to be carefully monitored as artifacts of oxidized bases can easily be generated. Compared to the positive-ion EI mode, NICI possesses higher selectivity and superior sensitivity toward compounds with high electron affinities. GC-NICI-MS has been applied for DNA adducts caused by lipid peroxidation by-products, and tobacco smoke. However, GC-MS is less commonly used for carcinogen-DNA adduct

detection compared to LC-MS, due to labor-intensive sample preparation such as the extensive derivatization steps required to increase the volatility of the adduct and the potential to generate artifact adducts.

LC-MS/MS is the primary method for the detection and quantitation of DNA adducts in DNA from biological matrixes. LC is more suited than GC for the analysis of DNA adducts since it allows the analysis of polar and nonvolatile molecules. Most analyses are performed using electrospray ionization (ESI) which is a soft ionization technique. LC-ESI-MS allows for the detection of adducted nucleobases, adducted deoxynucleosides, deoxyribose-phosphate adducts as well as modified oligonucleotides. LC-MS/MS typically employs two quadrupole mass analysers in series separated from each other by a collision cell, which yields fragment ions following collision-induced dissociation (CID), and normally analyses are performed in selected reaction monitoring (SRM) mode. Several studies have used LC-MS/MS for the detection of modified bases in human urine including 8-oxo-dG, etheno-DNA adducts (see **Fig. 2**), N^7-ethylguanine, and N^7-guanine adducts of aflatoxin B_1 (see **Table 1**). Examples for the application of LC-MS/MS in human tissues include 1,N^2-propanodeoxyguanosine adducts derived from acetaldehyde and crotonaldehyde and acetaldehyde-derived adducts (as a possible marker of ethanol genotoxicity), 4-aminobiphenyl, aristolochic acid and 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (PhIP) adducts (see **Table 1**).

Accelerator Mass Spectrometry

AMS is an analytical technique that can quantify long-lived isotopes with attomole (amol) (10^{-18}) sensitivity in isotope-labeled drugs and toxicants. AMS counts atoms of a rare isotope of interest and reports the ratio of the counted isotope to that of the total number of atoms of the element. Radiocarbon ^{14}C ($t_{1/2} = 5730$ years) and tritium ^{3}H ($t_{1/2} = 12.3$ years) are commonly used to label the compound or drug of interest for DNA adduct analyses. The excellent sensitivity of AMS enables analysis of DNA adduct formation for human biomonitoring. Human studies using AMS include adduct formation of the food carcinogen 2-amino-3,8-dimethylimidazo[4,5-*f*]quinoxaline (MelQx) and tamoxifen, a compound used in the treatment of breast cancer. AMS has also been used to determine DNA adduct formation in rodents following the exposure of ^{14}C-labeled benzene, ochratoxin A, and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin. Despite the excellent sensitivity of AMS, sample preparation is labor-intensive and the instrumentation requires high levels of maintenance. Additionally, AMS does not provide any structural information about the DNA adduct, but it can be coupled to HPLC and identification can be achieved by using adduct standards. For example, HPLC separation followed by AMS analysis was employed for determining the distribution of [^{14}C]oxaliplatin-induced DNA adducts in drug-sensitive testicular and drug-resistant breast cancer cells at a clinically relevant drug concentration.

Immunological Methods

These approaches rely on the preparation of antisera which recognize specifically the carcinogen-DNA adduct. To date around 20 different carcinogen-DNA adducts can be detected by immunological methods, limited by the need to raise antibodies against synthetically prepared and characterized adducts in order to detect them in human tissues. These antisera include those raised against alkylation adducts such as O^6-methyl- and O^6-ethylguanine, N^7-methylguanine, and N^6-methyladenine, or adducts formed by oxidative stress such 8-oxo-dG (see **Fig. 2**). Other antibodies that detect bulky DNA adducts include those derived from BaP, 4-aminobiphenyl and aflatoxin B_1. Many variations exist on the method by which the antisera may be used. Most of the immunological studies have been based on enzyme-linked immunosorbent assay (ELISA) but modified assays such as the dissociation-enhanced lanthanide fluoroimmunoassay (DELFIA) and chemiluminescence immunoassay (CIA) have been employed in molecular epidemiology because they have sensitivities approaching those of ^{32}P-postlabeling.

The underlying principle for the ELISA is that DNA to be tested is coated onto the surface of a suitable plate. Antiserum, specific for the adduct of interest, is added and after incubation any noncomplexed antibody is removed. A secondary antibody linked to a suitable marker enzyme, for example, alkaline phosphatase, is then added. This secondary antibody will bind to the plate only if there was an interaction between the adducted DNA and the primary antibody. After washing the plate, *p*-nitrophenylphospate is added as the enzyme substrate. As hydrolysis proceeds, which will be proportional to the extent of modification originally present in the DNA, the color formed from the released nitrophenyl anion can be measured. A standard curve is generated by serial dilution of either modified denatured DNA or monoadduct and mixing with the adduct-specific primary antibody. Samples with unknown levels of DNA adducts are tested in a similar way. The sensitivity of the ELISA can be further increased by using competitive versions of the assay, using substrates which yield fluorescent products. In the DELFIA assay the alkaline phosphatase conjugate is replaced by a biotin-europium-labeled streptavidin signal amplification system which releases europium into the solution forming a highly fluorescent lanthanide chelate complex. The assay principle of CIA is similar to that of competitive ELISA but uses chemiluminescene instead of a colored end product.

Immunohistochemistry can also be used to detect DNA adducts in cells and tissue sections. Although the method is less sensitive than the immunological assays described above, it can provide valuable information on the localization of carcinogen-DNA adduct formation within a tissue or cell population. Assessment uses subjective estimation of staining intensity and/or number of positively stained cells with an arbitrary scale and thus need to be regarded as semiquantitative in its assessment of adduct levels. As with all immunohistochemical methods appropriate control experiments need to be conducted to validate the specificity of cell staining.

Slot- or dot-blot immunological methods also provide a means to detect DNA adducts using antisera. The principle of the slot/dot-blot methodology is that DNA is immobilized on nitrocellulose and then incubated with primary adduct-specific antibodies. Again enzyme-labeled secondary antibodies are subsequently used to measure the degree of binding using colored or

chemiluminescent end products. Immuno-dot/slot-blot methods have been developed to detect DNA adducts derived from PAHs, alkylating agents or malondialdehyde (see Fig. 2).

Fluorescence Techniques

DNA adducts derived from PAHs (e.g., BaP) or aflatoxin B_1 that contain fluorescent chromophores can be detected by means of their fluorescent emissions. This also includes some methylated DNA adducts. Usually HPLC separation coupled with fluorescence detection is used for the determination of carcinogen-DNA adduct formation. Combining the fluorescence characteristics (specific excitation and emission wavelengths) with HPLC separation makes it even possible to detect stereoisomers. The advantage of fluorescence analysis is that it requires no prior knowledge or preparation of the DNA adduct, only the knowledge that it is adequately fluorescent. However this is also a major limitation as only few carcinogen-DNA adducts are intrinsically fluorescent. HPLC with fluorescence detection has been applied in molecular epidemiological studies to determine DNA adducts but necessitated using fairly large quantities of DNA to achieve the required sensitivity.

Other applications include using the fluorescence generated of BaP-tetrols, the hydrolysis products of BPDE-DNA adducts, as measures of BaP-derived DNA adduct formation by HPLC. Synchronous fluorescence spectrometry can also be used to detect BPDE-DNA adducts (sensitivity of $\sim$1 adduct/10^7 nucleotides). Samples are scanned synchronously with a fixed difference between the excitation and emission wavelengths (e.g., 34 nm for BPDE-DNA adducts) where the peak formed correlates linearly with the level of adducts. Fluorescent labeling of nonfluorescent DNA adducts is another approach to exploit fluorescence spectroscopy. Capillary electrophoresis and laser-induced fluorescence has been used to measure DNA adducts formed by BaP and aristolochic acid (sensitivity of $\sim$1.5 adducts/10^7 nucleotides).

Electrochemical Detection

Electrochemically active DNA adducts which readily undergo reduction or oxidation reactions can be determined by HPLC coupled with electrochemical detection including 8-oxo-dG and N^7-alkylguanines.

Adductomics

The DNA adductome is part of the exposome. It is defined as the sum of all DNA adduct types and levels present in a DNA sample reflecting both known and unknown exogenous and endogenous exposures. Untargeted analysis refers to the total amount of all DNA adducts present, and in case of sufficient sensitivity, full scan MS data can be searched for the presence of known or unknown DNA adducts, in parallel or retrospectively (see also Section "Mass Spectrometry"). This approach however requires specialized untargeted screening technologies and methodologies as well as extensive data processing using specialized software. Despite its expense and complexity, screening studies have been suggested to be the future of cancer epidemiology. Recent improvements in MS scanning acquisition capabilities and instrument sensitivity potentially allow the use of MS in high-throughput applications in DNA adductomic approaches.

DNA adductomics analyses usually takes advantage of the common structural feature of adducted deoxyribonucleosides which involves the cleavage of the labile glycosidic bond between the deoxyribose moiety (dR) and the adducted nucleobase. Hence, different approaches for the detection of these DNA adducts can be used by screening of the neutral loss of the dR moiety (116 *u*) and detecting the adducted base (Fig. 5A), which is the most common approach utilized or by analyzing the formation of the nucleobase-ion from the aglycone nuceloblase adduct (Fig. 5B).

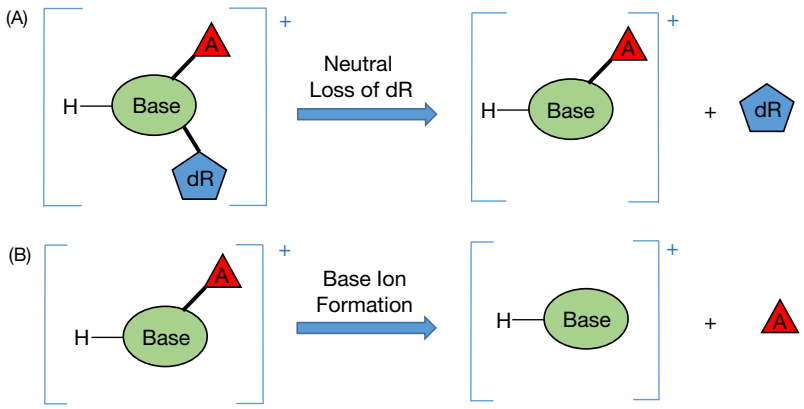

Fig. 5 The most common fragmentation pathways for adducted deoxynucleosides are (A) the neutral loss of the 2′-deoxyribose moiety and (B) formation of the nucleobase ion. Base, nucleobase; A, adduct; and dR, 2′-deoxyribose.

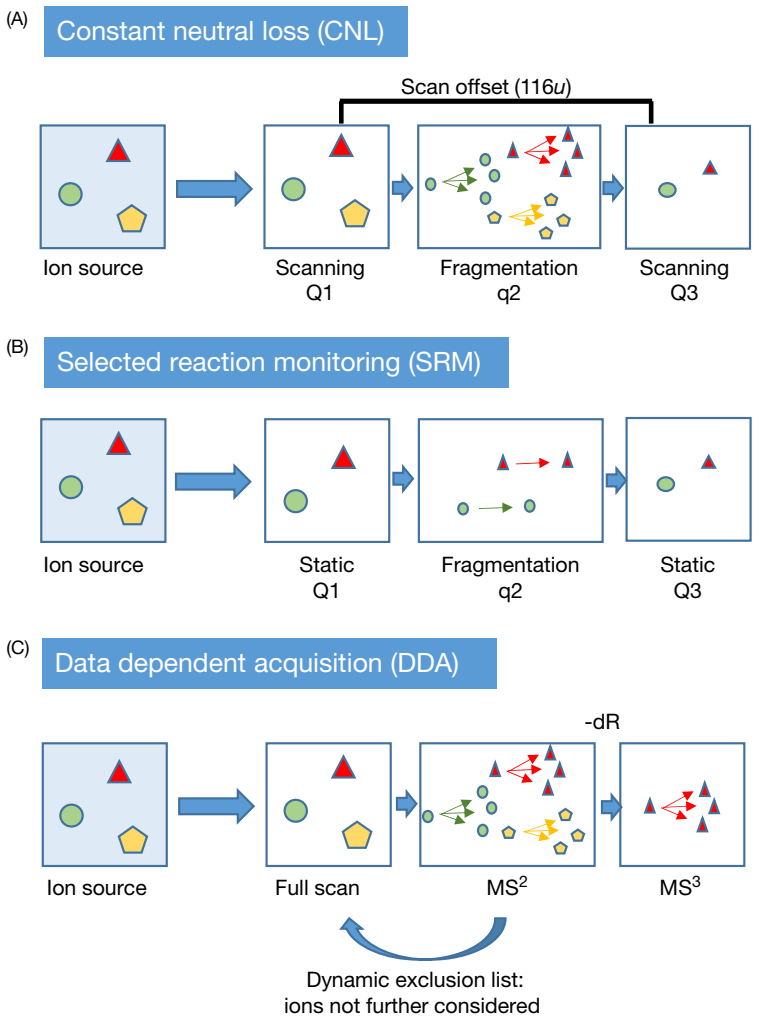

Fig. 6 Schematic illustrating the variety of data acquisition modes in the context for DNA adduct screening. The acquisition of DNA adductomics data can be performed in (A) CNL mode (only ions that fragment with the neutral loss of 116 *u* will be recorded as a signal), (B) in SRM mode (both Q1 and Q2 are operated in static mode and only ions of the user-specified *m/z* that produce specific fragments in q2 are detected), or (C) in DDA mode (the ions not showing the neutral loss of 116 *u* [*green* and *yellow*] are put into an exclusion list so that they are no longer eligible for fragmentation).

Several different modes of detection can be applied for DNA adductomic analyses, SRM, constant neutral loss (CNL), or data dependent acquisition (DDA) (Fig. 6). SRM methods offer the greatest sensitivity and are used primarily for targeted detection and quantitative analysis of DNA adducts, while the other two modes provide structural information and are useful for identification and characterization of novel DNA modifications.

Constant neutral loss (CNL) scanning using a triple quadrupole mass spectrometer has been a common mode of detection for DNA adductomic analysis. This scan mode monitors the neutral loss of 2′-deoxyribose (from positively ionized 2′-deoxynucleoside adducts). As shown in Fig. 6A, quadrupole 1 (Q1) and Q3 are run in scan mode with an offset of mass difference 116 *u*, while ions are fragmented in the collision cell (q2). Only ions that fragment with the specific neutral loss of 116 *u* will be recorded as a signal. Alternatively, instead of using both quadrupoles in scan mode, a number of contiguous SRM transitions can be monitored all involving the neutral loss of 116 *u*. As shown in Fig. 6B, Q1 precursor ions are selected that undergo fragmentation (q2), followed by product ion selection Q3, thus allowing for selective detection of adducted 2′-deoxynucleosides using the $[M+H]^+$ to $[M+H-116]^+$ transition. The potential of using MS for the screening of DNA adducts by monitoring a large range of such SRM transitions led to the concept of producing an adductome map of all DNA adducts in a sample. This approach was first applied for the mapping of the DNA adductome by Kanaly and colleagues that used a series of SRM transitions totalling 374 for monitoring the neutral loss of 2′-deoxyribose. This LC-MS/MS approach for monitoring multiple SRMs has been used to analyze tissue from human lung for multiple DNA adducts derived from lipid peroxidation, furfuryl alcohol, and methyleugenol. Similar methods have been used for the simultaneous characterization of exocyclic DNA adducts derived from exogenous industrial chemicals and endogenous by-products of lipid peroxidation in human DNA. An alternative LC-MS/MS adductomic approach can be used for the detection of N^7-alkylguanine guanine adducts which are released from the DNA by thermal depurination. The transition of the adducted

nucleobase $[M+H]^+$ precursor ion to the protonated guanine (m/z 152) product ion can be used as a generic method for monitoring N^7-alkylguanines.

An advancement for the detection and identification of unknown DNA adducts is the development of high resolution mass spectrometry (HRMS) and MS^n detection. HRMS can provide accurate mass information enabling the determination of minute differences in mass between two compounds that would appear to be identical on a standard low resolution triple quadrupole instrument. By providing accurate mass measurements, HRMS provides data for the determination of elemental composition allowing identification of the DNA adduct. New approaches for DNA adductomics research may be achieved by using quadrupole-TOF (time of flight) instruments which provide accurate mass data. TOF-MS instruments can be used for the DNA adduct screening and characterization using DDA. DDA uses repeated acquisition of spectra from full scans as well as multistage scans (MS^n). This scanning mode is performed in real-time and it thus requires preprogrammed decision making by the MS software during consecutive scans. For example, masses of ions selected for fragmentation can be placed into a dynamic exclusion list and these masses are no longer eligible for fragmentation in subsequent full scan spectra (Fig. 6C). Alternatively, an inclusion list containing masses of interest can be used to trigger analysis of targeted analytes. Furthermore, a reject mass list can be programmed containing a list of interfering background ions that will be excluded from analysis. DDA can also be used with ion trap instrumentation whereby ion trap MS analyzers allow the acquisition of multistage scan events (MS^n) that can provide additional structural information about the DNA adduct. A linear ion trap LC-DDA-CNL-MS^3 approach was developed, where the detection of a DNA adduct ion (listed in a targeted mass-list) in a limited m/z scan range leads to MS^2 acquisition. Then the detection of the $[M+H-116]^+$ ion among the top 10 of the most abundant MS^2 ions triggers MS^3 fragmentation. This approach has been used to study the formation of DNA adducts of derived from aromatic amines, heterocyclic aromatic amines, PAHs, and aldehydes.

Other types of mass analysers such as the Orbitrap also provide very accurate mass detection information due to a high resolving power and mass accuracy. The Orbitrap mass analyzer is often coupled to a quadrupole or an ion trap and is well suited for small molecule analysis and untargeted adductomics applications and a high resolution LC-DDA-CNL-MS^3 method was developed, using a linear ion trap-Orbitrap instrument. The instrumentation can also be applied to data-independent acquisitions (DIAs). In DIA, the MS data is collected systematically and independent of precursor ion information. The aim of DIA is to comprehensively obtain fragmentation data on all analytes that are present thereby allowing the data to be searched for the presence of known or unknown DNA adducts.

Matrix-assisted laser desorption ionization (MALDI) is like ESI a soft ionization technique, but it provides far fewer multiply charged ions in the gas phase compared to ESI. This potentially simplifies data interpretation as well as analysis of complex mixtures. It has been a useful tool for the analysis modified oligonucleotides as well as determining their sequences. MALDI-TOF MS has been applied to characterize oligonucleotides carrying a DNA photoproduct as well as 5-hydroxymethylcytosine, 5-formylcytosine and 6-oxothymine. Nontargeted analysis of modified nucleotides in DNA (as well as RNA) has been performed, involving derivatization of the deoxynucleotides with isotopologue benzoylhistamines followed by MALDI-TOF or MALDI-TOF/TOF analysis.

Triple quadrupole LC-MS/MS instruments operated in SRM mode are still the most sensitive mass spectrometers for detecting low levels of DNA adducts. New technological improvements enable very fast scanning times and rapid switching between SRM transitions without loss of sensitivity. Modern instruments operated in SRM mode can increase throughput with the capability of simultaneously acquiring hundreds of SRM transition channels per second while maintaining accuracy and precision, including multiple transitions per analyte. Though HRMS systems are excellent tools for identifying unknown DNA adducts, sensitivity may not be sufficient to detect background levels of DNA adducts that are present in human and animal DNA. However the sensitivity of these instruments can be improved by coupling with nano-LC and a nanospray ionization source.

Summary

For many carcinogens the mechanism of tumor initiation is causally associated with carcinogen-DNA adduct formation. DNA adducts, if not repaired prior to DNA replication, can lead to mutation in critical genes of carcinogenesis (e.g., proto-oncogenes, tumor suppressor genes) which can drive malignant transformation of the cell and tumor development. DNA adduct formation is considered a critical step in the initiation of carcinogenesis and in many molecular epidemiology studies it has been shown that DNA adducts are valid biomarkers of exposure and cancer risk. A variety of sensitive methods have been developed for the detection and characterization of carcinogen-DNA adducts which are suitable for their applicability in human biomonitoring in order to study cancer etiology. The measurement of carcinogen-DNA adducts can also employed to evaluate mechanism(s) of carcinogenesis including host factors mediating the carcinogenic response/potency. All methods available for DNA adduct detection have their strengths and weaknesses, so the method of choice has to be decided on a case-by-case basis considering the study design and research question.

Prospective Vision

Looking into the future, the field of DNA adductomics is still under development with many challenges still remaining however the hybrid HRMS/MS^n methodology represents an important advance in the investigation of DNA adduct structures in complex

mixtures. This approach could be an extremely powerful tool for DNA adductome mapping. If sensitivity is sufficient, this could enable the discovery of yet unknown DNA adduct biomarkers. MS-based DNA adductomics is particularly suited for research on the exposure of the human body to both known and unknown hazardous agents (either *exo*- or endogenous) and any subsequently formed DNA adducts. However, limited availability of DNA adduct standards (in particular stable isotope labeled standards) is currently limiting full characterization and correct identification of unknown DNA adducts with MS. To improve DNA adductomics, a database could be set up with information on chemical structure and characteristics of DNA adducts, stability, prevalence, origin, and route of exposure. A multidisciplinary approach is needed, involving epidemiologists, clinicians, pathologists, analysts and bioinformaticians, to further unravel the DNA adductome.

Carcinogenesis: Role of Reactive Oxygen and Nitrogen Species☆

Jean Cadet and J Richard Wagner, University of Sherbrooke, Sherbrooke, QC, Canada

Glossary

Complete carcinogen A carcinogen that causes cell initiation and promotes cell transformation and growth to benign tumors, as well as mediates progression to malignancy.

Growth factors Low molecular weight substances produced by cells that induce growth of the same (autocrine response) or other (paracrine response) cells.

Inflammation A very complex process that is initiated by a release of cytokines and chemokines leading to the infiltration of phagocytic cells. Upon stimulation, phagocytes generate copious amounts of reactive oxygen and nitrogen species, proteases, as well as other enzymes and proteins. It can be manifested by fever, edema, hyperplasia, phagocytic infiltration, and oxidative stress.

Oxidative stress Excessive production of and/or impaired removal of oxidants with a concomitant decrease in reducing capacity of cells.

Oxidatively generated DNA damage Direct oxidation is characterized by a decrease in electron density. Such a modification can occur by oxidation of a double bond in a normal DNA base, of a methyl group or by ionization. Indirect oxidatively produced modifications occur when another molecule or macromolecule is oxidized and the product or by-product of that oxidation reacts with DNA.

Reactive oxygen species (ROS) and reactive nitrogen species (RNS) These are important players in normal physiology and signal transduction. They also participate in a plethora of damaging reactions, which lead to the dysregulation of normal cell controls, thus contributing to various pathologies, including cancer.

Transcription factors Factors needed for the transcription of genes into mRNA by binding to the specific recognition sequences in the promoter or enhancer regions of DNA.

Tumor promoters Agents that support the development of initiated cells into transformed cells and tumors.

Tumor suppressor genes Genes that prevent cell transformation and growth of tumors. Mutation of such genes usually abrogates their normal functioning and facilitates tumor development.

Nomenclature

•NO Nitric oxide
•NO_2 Nitrogen dioxide
•OH Hydroxyl radical
1,N^2-εGua 1,N^2-ethenoguanine
$^1O_2$ Singlet oxygen
4-HNE 4-Hydroxy-2-nonenal
5-CaCyt 5-Carboxycytosine
5-ClCyt 5-Chlorocytosine
5-ClGua 5-Chloroguanine
5-FoCyta 5-Formyluracil
5-FoUra 5-Formylcytosine
5-HmCyt 5-Hydroxymethylcytosine
5-HmUra 5-Hydroxymethyluracil
5-OHCyt 5-Hydroxycytosine
8-ClAde 8-Chloroadenine
8-oxoAde 8-Oxo-7,8-dihydroadenine
8-oxodG 8-Oxo-7,8-dihydro-2′-deoxyguanosine
8-oxoGua 8-Oxo-7,8-dihydroguanine
AID Activation-induced deaminase

UraHyd 5-Hydroxyhydantoin
UV Ultraviolet
εA 1,N^6-ethenoadenine
εCyt 3,N^4-ethenocytosine

Introduction

Carcinogenesis is a complex multistage process often taking decades until malignancy appears. Conventionally, the carcinogenic process has been divided into three main stages: initiation, promotion, and progression. Initiation requires an irreversible genetic damage causing mutations in transcribed genes. Promotion consists of a potentially reversible oxidant-mediated conversion step followed by a clonal expansion of the initiated cells into benign tumors, which can progress to malignancy when they acquire many additional genetic changes. Those genetic changes include modifications of DNA bases, insertions and deletions, genetic instability consisting of loss of heterozygosity, chromosomal translocations, and sister chromatid exchanges, activation of oncogenes, and suppression of tumor suppressor genes. Although cell initiation is a frequent occurrence, tumor promotion and progression usually require a long time because of all of the genetic changes that have to accumulate within the same few cells.

It has been known for many years that antioxidants inhibit formation of tumors, even though they might not decrease DNA adducts, thought to be the initiating lesions. Hence, antioxidants are likely to interfere with the oxidant formation during promotion and/or progression stages of tumor development. Since then, numerous publications have shown that various types of reactive oxygen species (ROS) are generated during all stages of carcinogenesis, but especially during that long time required to take an initiated cell to a fully disseminated cancer. This long period between the initiation stage and cancer development provides a large window of opportunity to interfere with and suppress the carcinogenic process. This can be accomplished more readily when processes of tumor promotion/progression and factors responsible for them are known.

The importance of oxidative stress to human cancer is underscored by the existence of cancer-prone syndromes characterized by the production of high levels of oxidants, loss of adequate defense, or deficiencies in DNA repair processes. Human congenital syndromes related to oxidative stress include Fanconi's anemia, Bloom's syndrome, ataxia telangiectasia, Wilson's disease, and hemochromatosis, among others. The last two conditions point to the contribution of an excess of bioavailable transition metal ions, such as copper and iron, leading to an overload of oxygen radicals in the liver and to the progression and outcome of those diseases. Hussain and colleagues clearly showed that livers of patients with Wilson's disease and hemochromatosis contain increased levels of inducible nitric oxide synthase (iNOS), as well as mutations in the p53 tumor suppressor gene, especially G:C to T:A transversions at codon 249. This finding is particularly important because hydrogen peroxide (H_2O_2)/iron treatment, as well as lipid peroxide-derived mutagenic reactive aldehydes, such as 4-hydroxy-2-nonenal (HNE), cause the same type of mutations at codon 249. Etheno-base adducts are present in liver DNA from patients having these two diseases. Interestingly, HNE causes the formation of etheno derivatives in DNA and induces mutations at the 249 codon of the *p53* gene in HNE-treated lymphoblastic cells. Notably, not only congenital syndromes exhibit mutations in the p53 gene, but also noncancerous colon tissues from ulcerative colitis patients, a colorectal cancer-prone chronic inflammatory disease. Frequencies of p53 mutations at codons 247 and 248 are strongly correlated with the progression of the disease being appreciably higher in inflamed than in noninflamed tissues. These studies strengthen the idea that chronic inflammation contributes to cancer, and the results are consistent with the hypothesis that p53 mutations at 247–249 codons are due to chronic inflammation-associated oxidative stress.

Oxidants are continuously formed and scavenged during various normal cellular processes including mitochondrial respiration. ROS are required for the normal functioning of an organism and for the protection from invading bacteria. They are produced or utilized during mitochondrial respiration, metabolism of fats and xenobiotics, melanogenesis, and other peroxide reactions. Many types of cellular defenses keep these oxidants under control, but when they fail, extensive repair systems remove the damage attempting to restore DNA integrity. ROS produced in small amounts can serve as second messengers in signal transduction. However, when ROS are formed at a time when they are not needed and/or in amounts exceeding antioxidant defenses and DNA repair capacity, then ROS can contribute to various diseases, with cancer being prominent among them. Tumor promoters and complete carcinogens induce chronic inflammation, ROS production, and oxidatively generated DNA damage. Some of the oxidized DNA base derivatives are mutagenic, cytotoxic, and cross-linking agents. They can also cause a change in DNA methylation that leads to changes in gene expression. This process might perhaps account for the ROS-mediated enhanced levels of various growth and transcription factors, and genes involved in antioxidant defenses.

Oxidants: Formation and Reactivity

The nucleus is subjected to continuous exposure to ROS that are generated during mitochondrial respiration as the result of incomplete one-electron reduction. In addition, the generation of ROS and also of reactive nitrogen species (RNS), likely involved in one-electron oxidation of guanine is enhanced during inflammation processes as further discussed below. Both types of oxidation reactions are also associated with exposure of exogenous physical agents including solar UV and ionizing radiation.

Reactive Oxygen and Nitrogen Species

The three main reactive species involved in oxidative reactions included ROS, RNS and halogenating agents. Superoxide anion radical ($O_2^{\bullet -}$) is the predominant initial ROS that is generated during respiration and numerous various biochemical and chemical reactions. These include solar radiation activation enzymes such as of NADPH oxidase, UV and ionizing radiation and photosensitized reactions. Extensive amounts of ($O_2^{\bullet -}$) and RNS are produced during inflammation, a normal bactericidal and tumoricidal process. However, chronic inflammation contributes to the long-lasting pathologic effects of the carcinogenic course of action,

regardless of the type of cancer. ROS and RNS are generated by activated phagocytic cells (PMNs, neutrophils, granulocytes) and both circulating and resident macrophages. Target cells (i.e., epidermal keratinocytes or hepatocytes) can also form these species in response to treatment with appropriate stimuli, such as tumor promoters or allergens. Although absolute amounts of ROS and RNS are much lower than those produced by stimulated phagocytes, these oxidants can set off the synthesis and release of a cascade of various cytokines and chemotactic factors, which are instrumental to the initiation of inflammatory responses by phagocytic cells. ROS and RNS also mediate increased formation of growth and transcription factors needed for the accelerated proliferation of initiated cells.

In addition to $O_2^{\bullet -}$ four main other ROS are generated in cells, which include hydrogen peroxide (H_2O_2), hydroxyl radical ($^{\bullet}OH$), peroxyl radicals (ROO$^{\bullet}$) and singlet oxygen ($^1O_2$). H_2O_2 is mainly produced by enzymatic dismutation of $O_2^{\bullet -}$ by superoxide dismutase. $^{\bullet}OH$ arises from either transition metal-mediated reduction of H_2O_2 according to Fenton reactions or radiolysis of water molecules through the indirect effects of ionizing radiation. Peroxyl radicals are generated by the addition of molecular oxygen to carbon-centered pyrimidine radicals. In contrast, the formation of $^1O_2$ can be explained by the involvement of endogenous type II photosensitizers that are able upon excitation by UVA radiation/visible light to transfer energy to molecular oxygen. Mammalian heme peroxidases represent other sources of oxidizing agents that are activated in inflammatory tissues. They consist of myeloperoxidases, lactoperoxidases and eosinophil peroxidases that are able to trigger the formation of hypochlorous acid/hypochlorite ($HOCl/OCl^-$).

RNS are also produced during inflammation and contribute to its pathologic effects. Nitric oxide ($^{\bullet}NO$) as a major player is generated through activation of epidermal inducible nitric oxide synthase (iNOS). The distinction between ROS and RNS is further blurred because of an avid reaction between $O_2^{\bullet -}$ and $^{\bullet}NO$ at near diffusion rate giving rise to peroxynitrite ($ONOO^-$), a potent oxidizing and nitrating agent (**Table 1**).

One-Electron Oxidants

Other main oxidative degradation pathways of DNA are initiated by the ionization of DNA bases and sugar moieties. Nucleobases are susceptible to several one-electron oxidants in the following decreasing order of reactivity guanine -> adenine > cytosine ≈ thymine. Thus, guanine preferentially undergoes one-electron oxidation by type I photosensitizers (riboflavin, menadione), bi-photonic ionization mediated by high intensity nanosecond UVC laser. In addition, guanine is oxidized by the carbonate radical anion ($CO_3^{\bullet -}$), a biologically relevant oxidizing radical that derives from the thermal decomposition of nitrosoperoxycarbonate, arising from the reaction of peroxynitrite ($OONO^-$) with CO_2 or carbonates. Another one-electron oxidant includes bromate. The highly energetic photons emitted by ionizing radiation are able to oxidize both nucleobases and the 2-deoxyribose moieties through the so-called direct effect. Lastly, purine and pyrimidine radical cations generate aminyl radicals that are strong oxidants of neighboring DNA bases in DNA.

Reactivity

Reactive oxygen species

Various cellular ROS and oxidants exhibit a wide diversity of reactivity toward nucleic acids ranging from the totally unreactive $O_2^{\bullet -}$ to the highly oxidizing $^{\bullet}OH$. H_2O_2 is another poorly reactive ROS that unlike $O_2^{\bullet -}$ is able to cross membrane and migrate within cells to reach the nucleus. In the presence of reduced transition metals such as ferrous and cuprous ions, H_2O_2 is able to generate $^{\bullet}OH$ that reacts essentially at the site where it is produced with the nearest molecule. For example, H_2O_2 will react with DNA bound Fe^{2+} and Cu^+ to generate $^{\bullet}OH$ that subsequently reacts with DNA in a site specific manner. The diffusion of $^{\bullet}OH$ in biological

Table 1 Major cellular oxidants and their reactivity toward nucleic acids

ROS or RNS	*Reactivity*
$O_2^{\bullet -}$	Undetectable toward DNA constituents
H_2O_2	Very low reactivity with adenine; involved in Fenton reaction
$^{\bullet}OH$	High reactivity with bases and the 2-deoxyribose moiety
Peroxyl radicals	Pyrimidine peroxyl radicals may either abstract hydrogen atom from vicinal thymine or add to vicinal guanine giving rise to tandem base lesions
$^1O_2$	Guanine the only reaction target via cycloaddition
One-electron oxidants	Give rise to oxidized bases and intra- and interstrand crosslinks through initial formation of base radical cation
$HOCl/OCl^-$	Chlorination of amino-substituted bases
$^{\bullet}NO$	No detectable reactivity toward nucleic acid components at the exception of deamination of nucleobases
$ONOO^-$	One-electron oxidant of guanine through the transient formation of nitrosoperoxycarbonate with subsequent release of carbonate radical anion ($CO_3^{\bullet -}$)
Lipid hydroperoxides	Reactive aldehydes generated through the thermal decomposition of lipid hydroperoxides form covalent adducts with amino-substituted bases

medium is very short (1–10 nm), and thus, difficult to scavenge with antioxidants. The reaction of •OH with nucleobases and the sugar moiety occur at close to diffusion-controlled rates with formation of modified bases and strand breaks, respectively.

Peroxyl radicals (ROO•) in general exhibit a much lower reactivity than •OH. However, when inserted into DNA, pyrimidine ROO• have been shown to efficiently react with vicinal bases, preferentially when they are located on the 5′-terminus, giving rise to tandem base modifications. Two reactions have been identified in model studies: pyrimidine ROO• is able to either abstract a hydrogen atom from the methyl group of an adjacent thymine or add to vicinal guanine at C8. $^1O_2$ is, in addition to •OH, a potent oxidizing ROS that among DNA components reacts exclusively with guanine. It may be noted that $^1O_2$ due to its highly selective reactivity shows an intracellular diffusion distance within the range of 150–220 nm that is much higher than that of •OH.

DNA base radical cations

Base radical cations of nucleobases produced by one-electron oxidation reactions are highly unstable intermediates that may undergo two main reactions. One is deprotonation that leads to the formation of carbon-centered radicals at the methyl group of thymine that is identical to the radical produced by •OH-mediated H-atom abstraction. Similarly, the competitive reaction for base radical cations involves hydration which leads to the formation of the same radicals that are generated by •OH although hydration occurs specifically at C6 of the pyrimidine ring. More generally the guanine radical cation is the predominant species in irradiated DNA partly due to redistribution on guanine bases of initially generated radical cation present on other bases. Furthermore, guanine radical cations are prone to nucleophilic addition leading to DNA–protein crosslinks and intrastrand crosslinks with opposite cytosines.

Reactive nitrogen species

•NO is a poorly reactive species with the exception however of its ability to trigger the deamination of cytosine, adenine and guanine. This explains why •NO is able to migrate within cells and efficiently react with $O_2^{\bullet -}$, another unreactive radical, giving rise to $ONOO^-$. Evidence has been provided that one of the main modes of action of $ONOO^-$, a moderately reactive compound, is to react with CO_2 or bicarbonates yielding unstable nitrosoperoxycarbonate that decomposes into carbonate radical anion ($CO_3^{\bullet -}$) and nitrogen dioxide ($^\bullet NO_2$).

Hypochlorous acid/hypochlorite

Hypochlorous/hypochlorite ($HOCl/OCl^-$) that is generated by peroxidases in inflammatory tissues is partly scavenged by amino containing compounds within membranes forming much-longer acting chloramines. However, $HOCl/OCl^-$ is able to diffuse in cells and reach the nucleus where it reacts with DNA amino-substituted nucleobases.

Reactive aldehydes as breakdown products of lipid hydroperoxides

Decomposition of lipid hydroperoxides formed by either the oxidation by •OH or $^1O_2$ gives malondialdehyde and 4-hydroxy-2-nonenal among the main reactive aldehydes. The released electrophilic species are able to migrate intracellularly from oxidized membranes to the genome where they are involved in the formation of adducts with amino-substituted nucleobases.

Oxidatively Generated Damage to DNA

Both ROS and RNS can induce a plethora of various types of modifications to DNA with the bases and the 2-deoxyribose moiety as the main targets. For this purpose numerous studies have been dedicated to the identification of the main DNA degradation products arising from exposure of isolated DNA and model compounds to •OH, one-electron oxidants, $^1O_2$, hypochlorous acid and reactive aldehydes. Thus, more than 100 different types of modifications including isomers have been identified so far in model studies and the mechanisms of their formation have been elucidated in most cases. In parallel, numerous attempts have been made to develop methods aimed at measuring oxidized bases in cellular DNA, still an analytical challenge as further discussed in the next section. It may be emphasized that in most cases, even under conditions of oxidative stress, the levels of the main oxidized bases, such as 8-oxo-7,8-dihydroguanine (8-oxoGua), is at best only a few modifications per 10^6 normal bases in nuclear DNA.

Measurement of Oxidized Bases in Cellular DNA

The accurate detection and quantitative measurements of oxidized bases in cellular DNA have been hampered by the use of inappropriate methods. This was the case of the gas-chromatography–mass spectrometry (GC–MS) method that was found to lead to artifactual overestimation of the yields of oxidized bases by at least two orders of magnitude. The main origin of unreliable GC–MS data lies on efficient spurious oxidation during the hydrolysis and derivatization step of DNA bases involving heating of the samples at 140°C prior to the chromatographic analysis. Another questionable method that unfortunately is still widely applied particularly by clinicians and biologists involves the use of poorly specific immunoassays. In this respect, it was shown that monoclonal and polyclonal antibodies directed against 8-oxoGua suffer from a lack of antigenicity, showing a cross-reactivity with guanine on the order of 10^{-4}. Other methods lead to inconsistent results including the [^{32}P]-postlabeling technique, the ligation-mediated polymerase chain reaction (LM-PCR) assay and high performance liquid chromatography analysis associated with single mass spectrometry detector (HPLC-MS). The first sensitive measurement of oxidatively generated base damage in cellular DNA concerned

8-oxo-7,8-dihydro-2′-deoxyguanosine (8-oxodG), which was achieved by HPLC coupled with electrochemical detection (ECD) operating in the oxidative mode. Versatile HPLC-electrospray-tandem mass spectrometry (EIS-MS/MS), which is more sensitive and quantitative than previous methods, allows for the unambiguous assignment of detected lesion and has become the gold standard method for measuring a wide range of oxidized nucleosides and bases. However, the possibility of adventitious oxidation of nucleobases still remains a problem if precautions are not taken to prevent this reaction from occurring during DNA extraction and the subsequent work-up prior the HPLC analysis. Thus, HPLC based analytical methods are limited to the measurement of oxidatively base damage only under conditions of severe oxidative stress. These difficulties can be partly overcome using enzymatic based assays: recognition and hydrolytic cleavage of the *N*-glycosidic modified bases is performed by DNA repair glycosylases including bacterial endonuclease III (Endo III) for oxidized pyrimidine bases and either bacterial formamidopyrimidine DNA *N*-glycosylase (Fpg) or human 8-oxoguanine DNA glycosylase (hOGG1) for modified purine bases. The resulting abasic sites are converted into single strand breaks, which are suitably measured in a highly sensitive way by either the alkaline comet assay or the alkaline elution technique. Despite a lack of specificity compared to HPLC-ESI-MS/MS measurements, the enzymatic assays are suitable tools for the detection of low variations in the levels of oxidized bases. In the subsequent sections only the oxidatively generated base lesions that were accurately measured by either HPLC based method or enzymatic assays are discussed.

Hydroxyl Radical-Mediated DNA Damage

•OH is able to react with both the bases and the sugar backbone leading to the formation of a large spectrum of modifications.

Oxidized pyrimidine bases

So far, the main •OH-mediated oxidation products that were identified in model studies in the presence of oxygen have been detected in cellular DNA. Two main classes of oxidized bases were found to be generated according to the nature of the initial •OH reaction. Thus, addition of •OH across the 5,6-double bond of pyrimidine bases gives rise to hydroxyhydroperoxides that are reduced or rearrange into more stable oxidation products. Two main stable products of thymine oxidation include 5,6-dihydroxy-5,6-dihydrothymine, also called "thymine glycol" (ThyGly) and 5-hydroxy-5-methylhydantoin (ThyHyd). In the case of cytosine, 5-hydroxycytosine (5-OHCyt), 5-hydroxyhydantoin (UraHyd) and 1-carbamoyl-4,5-dihydroxy-2-oxoimidazolidine (ImidCyt) are the main cytosine oxidation products (**Fig. 1**). The second main •OH decomposition pathway of pyrimidine bases involves initial H-atom abstraction from the methyl group of thymine and 5-methylcytosine. In both cases, the transient formation of a peroxyl radical leads to the generation of alcohol and aldehyde derivatives that were identified as 5-hydroxymetyhyluracil (5-HmUra), 5-formyluracil (5-FoUra), 5-hydroxymethylcytosine (5-HmCyt) and 5-formylcytosine (5-FoCyt), respectively.

Modified purine bases

The main degradation products of the purine bases arise from the transient formation of 8-hydroxy-7,8-dihydropurinyl radical formed by direct •OH addition at C8 of the bases or more indirectly through vicinal •OH-induced pyrimidine peroxyl radical. In a subsequent step, one-electron oxidation of 8-hydroxy-7,8-dihydroguanyl radical by O_2 gives rise to 8-oxoGua while competitive one-electron reduction of the latter radical, likely by thiol compounds, generates an open-ring 2,6-diamino-4-hydroxy-5-formamidopyrimidine (FapyGua). Similar reactions take place for adenine with the formation of 8-oxo-7,8-dihydroadenine (8-oxoAde) and 4,6-diamino-5-formamidopyrimidine (FapyAde) albeit with an about 10-fold lower efficiency than the formation of guanine products (**Fig. 2**). An additional oxidation product that arises from initial •OH at C4/C5 followed by a complex degradation pathway has been identified as 2,2,4-triamino-5(2*H*)-oxazolone (Oz). A major difference between •OH-mediated reactions and one-electron oxidation of DNA bases involves the efficient reaction of •OH with the sugar leading to DNA strand cleavage.

Strand breaks and other sugar degradation products

Evidence has been provided that •OH-mediated hydrogen atom abstraction at C3, C5 and to a lesser extent C4 of the 2-deoxyribose moieties leads to the formation of DNA single strand breaks (SSBs). As a competitive reaction to SSB generation, the C4 oxidized abasic site is also involved in the formation of interstrand crosslinks. This is rationalized by the formation of a covalent bond between the reactive aldehyde generated from the oxidized abasic site and the exocyclic amino group of cytosine opposite to the abasic site.

It may be pointed out that double strand breaks (DSBs) are not generated by one •OH attack. The formation of DSBs requires two independent radical hits on the two opposite DNA sites that are separated by less than 25 base pairs. This is typically achieved upon exposure of cellular DNA to ionizing radiations that also gives rise to non DSB oxidatively generated clustered damage.

One-Electron Oxidation of DNA

One-electron oxidation of nucleobases generates purine and pyrimidine radical cations. These radical cations are able to migrate along the DNA chains with preferential trapping by guanines bases as sinks for the positive hole that are converted into stable degradation products identified as 8-oxoGua and FapyGua. In addition, minor degradation products arise from the partial conversion of other base radical cations as detected by HPLC-ESI-MS/MS. Thus, 8-oxoAde and FapyAde are formed by oxidation and reduction, respectively, of transiently generated 8-hydroxy-7,8-dihydroadenyl radical upon hydration of the adenine radical cation. Relatively minor pyrimidine oxidation products including ThyGly, 5-HmUra, 5-FoUra and 5-OHCyt have also been detected in cellular DNA,

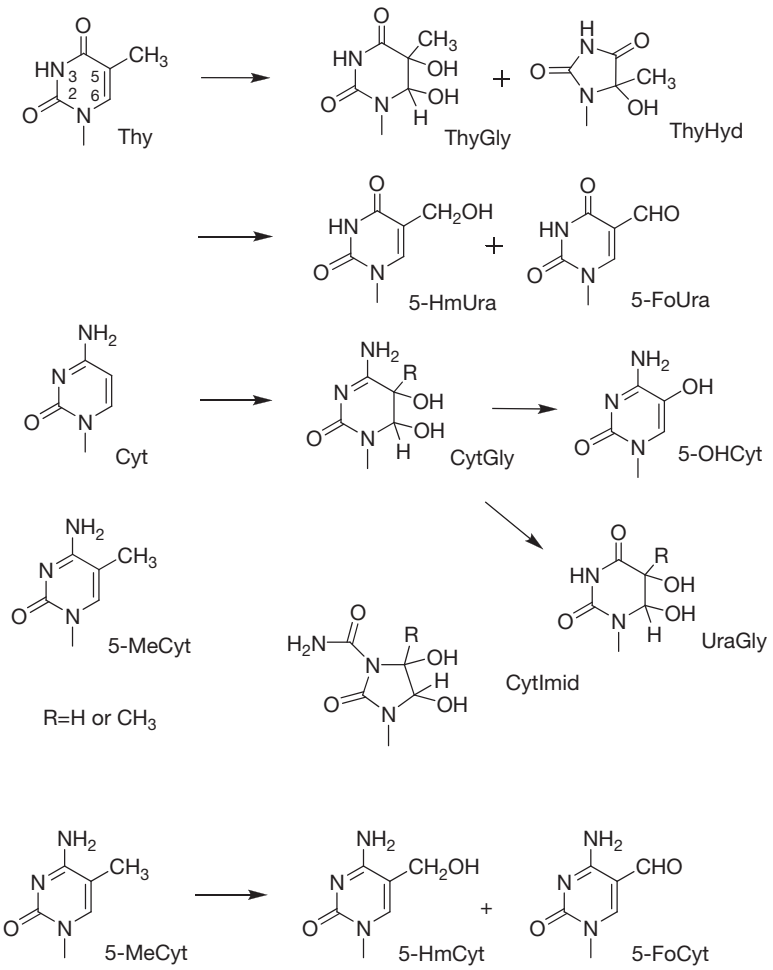

Fig. 1 Oxidation of thymine (Thy), cytosine (Cyt), and 5-methylcytosine (5-mCyt) by one-electron oxidation and •OH. One-electron oxidation and •OH give the same products except that the distribution changes, for example, one-electron oxidation gives greater methyl oxidation products (5-HmUra and 5-FoUra for Thy, and 5-HmCyt and 5-FoCyt for 5-MeCyt).

resulting from thymine and cytosine radical cations. It may also be pointed out that a guanine–thymine intrastrand cross-link is formed by nucleophilic addition of N3 of thymine to that guanine radical cation albeit the reaction is about 100-fold less efficient than the formation of 8-oxoGua.

Singlet Oxygen Oxidation of DNA

Exposure of cellular DNA to $^1O_2$ selectively reacts with guanine and leads to the predominant formation of 8-oxoGua with the exclusion of SSBs. Evidence has been provided that the UVA-induced generation of 8-oxoGua in the DNA of cells and human skin is accounted for the predominant involvement of $^1O_2$ by type II photosensitization.

Modifying Base Activity of Hypochlorous Acid/Hypochlorite

In addition to its oxidizing feature, $HOCl/OCl^-$ is able to trigger the chlorination of amino-substituted bases leading to the generation of 5-chlorocytosine (5-ClCyt), 8-chloroadenine (8-ClAde) and 8-chloroguanine (8-ClGua) as measured by HPLC-ESI-MS/MS in cellular DNA (Fig. 3).

Indirect Oxidatively Generated Damage to DNA Bases

In addition to the direct effects of oxidants on nucleobases, DNA may also be indirectly modified through interactions with electrophilic species produced by a ROS attack on other molecules or during ROS formation by such molecules. These consist essentially of etheno-base adducts formed in DNA by breakdown products of lipid peroxides. ROS including •OH and $^1O_2$ react with

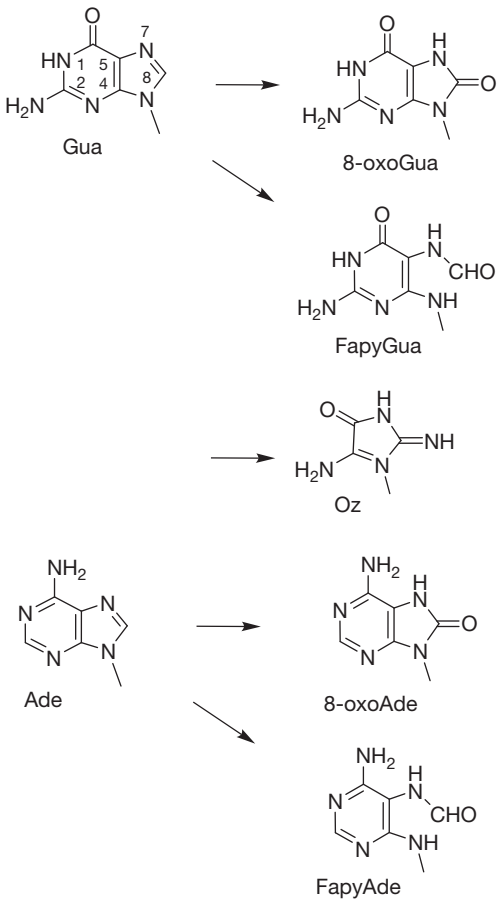

Fig. 2 Oxidation of guanine (Gua) and adenine (Ade) by •OH, one-electron oxidants and singlet oxygen ($^1O_2$). The formation of 8-oxoGua and Fapy depends on the presence of reducing agents and oxygen. The reaction of $^1O_2$ with Gua specifically gives 8-oxoGua. The yield of Ade oxidation products either by one-electron oxidation and •OH are 10-fold lower than those of Gua.

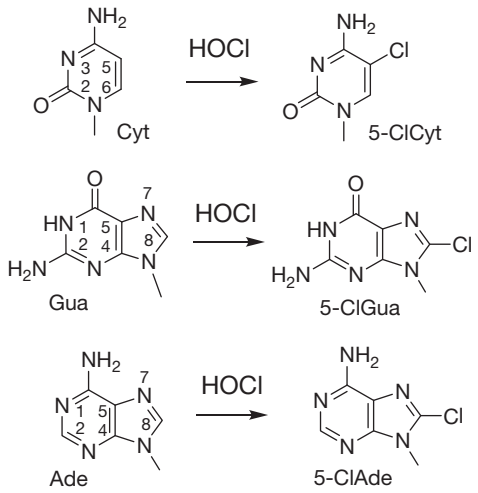

Fig. 3 Halogenation of DNA bases (Cyt, Gua and Ade).

unsaturated lipids leading to the formation of lipid peroxides, which upon decomposition release aldehydes, such as malondialdehyde (MDA) and 4-hydroxy-2-nonenal (4-HNE). Both MDA and 4-HNE are mutagenic because they react with the exocyclic amino group of guanine, adenine and cytosine to form etheno derivatives including pyrimidopurinone 3-pyrimidopurin-10 (3H) one (M1Gua), 1,N^6-ethenoadenine (εA), 3,N^4-ethenocytosine (εCyt), N^2,3-ethenoguanine (N^2,3-εGua), and 1,N^2-ethenoguanine (1,N^2-εGua). The aldehyde adducts transform further into products with an additional ring attached to purines and

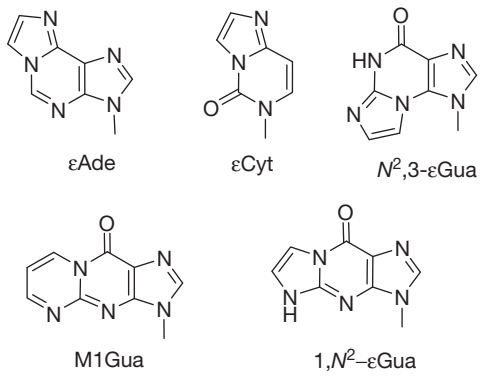

Fig. 4 Adducts of lipid peroxidation and DNA bases.

pyrimidines (Fig. 4). Etheno compounds are present in DNA isolated from various types of tumors or from nontumorous specimens of tumor-bearing animals and humans attesting to the increase of ROS-induced lipid peroxidation in cancerous cells.

DNA Repair and Mutagenesis of Oxidatively Generated Damage

There are four basic pathways of DNA repair: Base excision repair (BER); nucleotide excision repair (NER); mismatch repair (MMR); and double strand break repair (DSBR) including nonhomologous end joining (NHEJ) and homologous recombination (HR). Each of these pathways involve various proteins that recognize DNA damage, undergo enzymatic steps (DNA cleavage, polymerization, ligation), provide access, support and stability to repair complexes, engage in crosstalk between repair pathways, and elicit DNA damage response signals. In the case of ROS-induced base and sugar damage, the main repair pathway is BER although certain types of damage are repaired by NER and MMR pathways. On the other hand, the presence of excessive BER substrates and intermediates at the replication folk can also lead to double strand breaks, and thereby set DSBR repair into motion. The conventional method to study DNA repair and mutagenesis of ROS-induced damage is to insert a modification into synthetic oligonucleotides and examine the ability of purified enzymes, nuclear extracts and whole cell extracts to cleave the oligonucleotide at the site of damage by gel electrophoresis. There have been considerable methodological advances in the study of DNA repair and mutagenesis of specific lesions applying mass spectrometry strategies, using DNA repair arrays, incorporating oligonucleotides containing lesions into cellular DNA by transfection, constructing nucleosomes core particles containing lesions. The location and efficiency of repair proteins can be monitored in real time by the incorporation of fluorescent nucleotides during DNA repair synthesis or labeling repair proteins directly. A typical feature of DNA *N*-glycosylases is their broad substrate specificity toward oxidized bases in DNA and their ability to backup or be redundant in cellular and animal model systems. For example, the removal of uracil from DNA involves uracil-DNA *N*-glycosylase (UNG), single strand specific mono-functional uracil-DNA glycosylase 1 (SMUG1) as well as two mismatch specific DNA glycosylases consisting of thymine DNA glycosylase (TDG) and methyl CpG binding protein 4 (MBD4). Other DNA glycosylases in mammalian cells include endonuclease III-like protein 1 (NTH1), 8-oxoguanine DNA *N*-glycosylase (OGG1), endonuclease 8-like proteins (NEIL1–3) and apurinic/apyrimidinic endonuclease 1 (APE1), which collectively remove a broad spectrum of oxidatively induced lesions in single and double stranded DNA. To avoid mutations from 8-oxoGua formation, cells contain three other enzymes, which include hOGG1 for the removal of 8-oxoGua:C, mutY DNA glycosylase (MUTHY), which excises premutagenic 8-oxoGua:A mispairs, and human mutT protein (MUT1), which cleanses the cellular pool of 8-oxodG triphosphate. APE1 efficiently converts abasic sites to single strand breaks and also incises a number of pyrimidine modifications though a subpathway known as nucleotide incision. In contrast, the excision of purine 5′,8-cyclo-2′-deoxyribonucleosides in which the C5′ of the sugar is covalently attached to the C8 of either adenine or guanine are repaired by NER. The predominate occurrence of C to T transition mutations has largely been attributed to cytosine and 5-methylcytosine deamination or oxidation. Although thermally induced deamination is widely assumed to occur, it should be noted that ROS or RNS-induced reactions with pyrimidines lead to an enormous acceleration of the rate of deamination at the exocyclic amino group. The lifetimes of intermediate oxidation products of C and 5-mCyt, such as the corresponding 5,6-glycols and hydantoin derivatives, may explain the propensity of C to T transition mutations and the overwhelming C to T mutations at CpG dinucleotides in cancer. Once deamination occurs, the resulting modifications resemble uracil or thymine in their base pairing properties, and thus, they will mispair during replication and generate a C to T transition mutation.

Ten-Eleven Translocation Enzymatic Oxidation of 5-Methylcytosine and Epigenetics in Cancer

The methylation of DNA, mediated by DNA methyltransferases (DNMTs), converts cytosine to 5-methycytosine (5-mCyt), predominantly at CpG dinucleotides such that 60%–90% of these sites are methylated in mammals. Cytosine methylation is a well-known

epigenetic mark that generally silences the expression of genes during development and plays a regulatory role in maintaining genome integrity and the ability to modulate gene expression. In the past 8 years, a novel epigenetic mark of DNA has emerged that arises from the oxidation of 5-mCyt to 5-hydroxymethylcytosine (5-HmCyt) by ten-eleven translocation family of enzymes (TET1–3). The level of 5-HmCyt accumulates in the genome to levels as high as 20% of 5-mCyt. They are the highest in embryonic stem cells and as well in differentiated neurons that maintain a high degree of plasticity. Based on new sequencing methods that discriminate between 5-mCyt and 5-HmCyt, the distribution of 5-HmCyt in the genome is unique with respect to 5-mCyt and 5-HmCyt populated sites possess different binding partners compared to 5-mCyt. In contrast to 5-mCyt, 5-HmCyt appears to elevate gene expression with the levels of 5-HmCyt positively correlated with greater expression of hydroxymethylated genes. TET enzymes contain Fe^{2+}, require α-ketoglutarate as a cosubstrate, and have the ability to oxidize not only 5-mCyt to 5-HmCyt but also 5-HmCyt into further oxidized forms: 5-formylcytosine (5-FoCyt) and 5-carboxycytosine (5-CaCyt). The levels of 5-FoCyt and 5-CaCyt in the genome, however, are one to two orders of magnitude lower than those of 5-HmCyt. The active removal of 5-FoCyt and 5-CaCyt by BER involving TDG keeps the levels of the latter two modifications low and completes the multistep conversion of 5-mCyt to cytosine. Other enzymes from BER, which include activation-induced deaminase (AID) apolipoprotein B mRNA editing enzyme catalytic polypeptide 1 (APOBEC), SMUG, MBD2, have also been implicated in 5-mCyt demethylation. The cycle of cytosine methylation and demethylation of cytosine may explain the ability of pluripotent cells to turn genes off and on as necessary for their function and survival. The level of 5-HmCyt in the DNA of cancer cells is generally much lower than that observed in normal cells in brain, melanoma, breast and various other types of cancer. The lack of 5-HmCyt in the genome of cancer tissues has been associated with loss of TET activity. This may occur by the presence of mutations within TET genes, isocitrate dehydrogenase (IDH) genes, or other genes. Mutations in IDH switch activity from wild-type activity in which isocitrate is transformed into α-ketoglutarate to the production of 2-hydroxyglutarate, an inhibitor of TET. Interestingly, vitamin C increases the global level of 5-HmCyt in cells in culture, underlining the importance of a reducing agent to maintain the iron center of TET in a reduced state for optimal activity. Low concentrations of oxygen observed in hypoxic solid tumors may also decrease TET activity. Lastly, a reduction of 5-HmCyt in the genome may be due to passive dilution as a result of the high proliferative state of cancer cells. Despite extensive work, the role of TET and 5-HmCyt, and their interplay with DNMT enzymes and 5-mCyt, remain central questions in cancer development and growth.

Prospective Vision

There is increasing evidence today that oxidative stress, oxidatively induced DNA damage, deficiencies in DNA repair are intimately entrenched in the process of carcinogenesis and tumorigenesis. In particular, inflammation and expression of inflammatory cytokines lead to escalation of oxidative stress and the release of ROS and RNS. It is clear that mutations accumulate in cancer development and it is necessary to achieve a required number of mutations and mutant genes to achieve the transformation from normal to cancerous cells. Further structural analyses of damage has led to the characterization of many novel lesions in the past 10 years, including tandem base lesions, clustered lesions, DNA–DNA crosslinks, DNA–protein crosslinks and putative secondary purine oxidation products. The study of formation of intermediate and stable products in double stranded DNA and higher order DNA structures such as telomeres and nucleosomes has given a wealth of new information. However, the analysis in cellular DNA and the biological processing of many lesions remains incomplete. Sequencing techniques have greatly advanced our knowledge concerning the site of DNA damage and particularly toward the distribution of epigenetic marks in the genome. A major challenge today remains to home in on the location and distribution of various oxidatively generated modifications in the genome. It will be necessary to determine the effect of sequence on the formation of damage and biological processing to establish the cause of mutation signatures and align these mutations within passenger and driver genes involved in cancer. It will also be necessary to explain how epigenetic marks become profoundly altered in cancer. The development of single and multiple gene ablation and editing methods in cells and mice continues to shed much light on the biological importance of DNA damage and repair pathways in cancer.

Heinz Läubli, University Hospital Basel, Basel, Switzerland

Glossary

Angiogenesis Is a physiological process of blood vessel formation from the preexisting vessels. Neoangiogenesis describes the formation of blood vessels in the tumor tissue.

Epithelial-to-mesenchymal transition (EMT) Describes a process during cancer progression wherein carcinoma cells can change their epithelial phenotype into a mesenchymal phenotype. Mesenchymal cells are characterized by enhanced migratory and invasive properties required for metastasis.

Extracellular matrix (ECM) Is a collection of extracellular molecules secreted by cells that provides structural and biochemical support within a tissue. The animal ECM includes the interstitial matrix filling out the space between cells and basement membrane, which is a structured ECM found in the epithelial tissues.

Extravasation Is a process describing the migration of tumor cells or leukocytes out of the blood vessel during hematogenous metastasis or immune response.

Glycan Is carbohydrate structure composed of many monosaccharides linked via glycosidic bonds. This term is used to refer to a carbohydrate portion of a glycoconjugate, such as glycoprotein or glycolipid.

Hematogenous metastasis Is spread of cancer cells from the primary tumors through blood circulation.

Homophylic/heterophylic interactions Homophylic interactions describe cell-cell interactions through the same adhesion molecule from the adjacent cells (e.g., cadherins). Heterophylic interactions describe binding of different proteins or glycans (e.g., integrins, selectins).

Lectins Are carbohydrate-binding proteins, macromolecules that are highly specific for sugar moieties.

Myeloid cells Are leukocytes of the innate immune system. To myeloid-derived cells belongs: granulocytes, monocytes, macrophages and immature myeloid precursors that are often detected during cancer progression and associated with suppression of anti-tumor immunity.

Thromboembolism Is the development of blood clots within the vascular system and dissemination of such clots (embolism). Patients with cancer are prone to develop thromboembolic complications.

Tumor embolus Embolus of tumor cells is composed of blood constituents including platelets and leukocytes and is known to promote hematogenous metastasis.

Tumor microenvironment Is the cellular environment of a tumor, which is composed of blood vessel, immune cells, fibroblast, soluble signaling molecules and ECM. Tumor cells modulate the microenvironment by various cues that promote angiogenesis, immune suppression and thereby promote tumor growth and metastasis.

Introduction

Cell–cell adhesion determines the polarity and the physiological function of cells within tissues. On every cell, adhesion molecules facilitate interactions within the cell microenvironment that consist of other cells and the extracellular matrix. Since cell adhesion receptors are connected to signal-transduction pathways, these cell–cell and cell–matrix interactions modulate cell phenotype, survival, differentiation, and migration. As a consequence, alterations in cell adhesion directly contribute to tumorigenesis and metastasis. In a developing tumor, there is general loss of stabilizing cell adhesions between cells enabling them to gain the migratory phenotype required for invasiveness and metastasis. On contrary, the invasive capacity of metastatic tumor cells depends on efficient cell adhesion during transit in the circulation, colonization of distant organs and interactions with the extracellular matrix at secondary metastatic sites. The metastatic dissemination of tumor cells is the primary cause of death in cancer patients. Therefore, the understanding of the cell adhesion mechanisms in cancer will enable to design new targeted therapies. Finally, cell adhesion plays a major role for the immune response to cancer and could be modulated to improve cancer immunotherapy.

During tumorigenesis and metastasis several families of adhesion molecules including: cadherins, integrins, junctional-adhesion molecules, and selectins have been studied. This chapter covers the current understanding of cell adhesion mechanisms in cancer and describes the known pathophysiological functions associated with tumor progression, angiogenesis and modulation of immune responses. In solid tumors, mostly originating from epithelial tissues, the loss of cell polarity is a profound change associated with a malignant transformation resulting in a ubiquitous presence of adhesion molecules (Fig. 1). Changes in expression of cell adhesion receptors and their binding partners (ligands) define both the malignant progression and interactions within the tumor microenvironment.

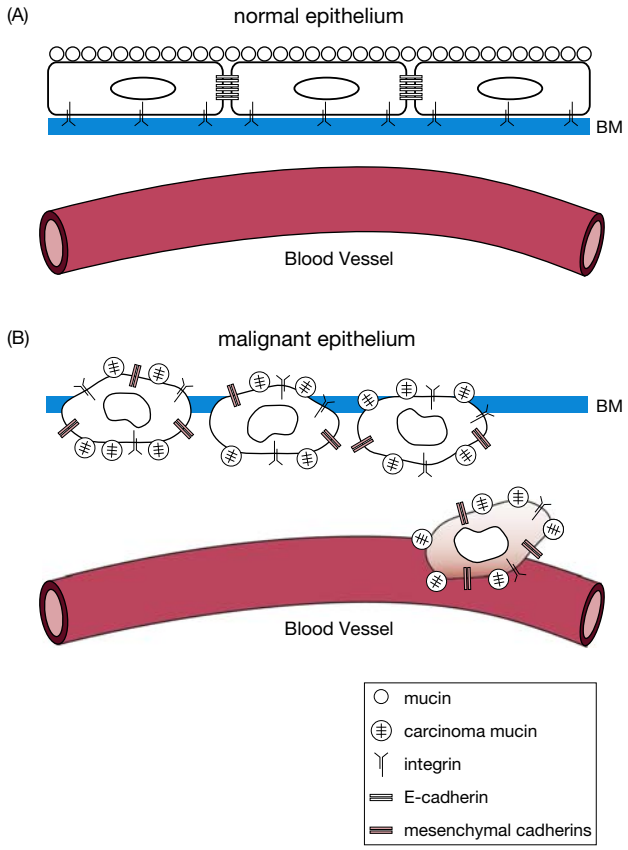

Fig. 1 *Cell adhesion changes leading to metastatic tumor cells during transformation from a normal to a malignant epithelium.* (A) *Normal epithelium* consists of polarized epithelial cells that are bound together through E-cadherin adhesions. The epithelium is organized on the basement membrane (BM) consisting of various extracellular matrix proteins (e.g., type IV collagen, glycosaminoglycans, laminin, and small adaptor proteins). On a basolateral site of the epithelium integrins facilitates the interaction with BM. On the apical site, epithelial cells produce mucus that is composed of mucins, proteins containing a large amount of O-glycans. This glycosylated mucus creates a mechanical barrier between epithelial cells and the lumen of a tissue. (B) *Malignant epithelium*. The profound change during malignancy is associated with: loss of cell polarity, loss of E-cadherin-mediated epithelial adhesions; increased production of mucus carrying altered glycan structures, degradation of BM; and increased migration and invasiveness of the malignant cells. Malignant tumor cells with altered cell adhesion preferences are able to invade into blood vessels and thereby gain access to other organs in an organism.

Cadherin-Mediated Cell Adhesion

Cadherins are cell adhesion molecules that play a major role in cell–cell interactions, tissue patterning during development and in cancer, particularly during tumor cell dissemination. E-cadherin is the most prominent cadherin expressed in epithelial cells (Fig. 1). Cadherins comprise of a large family of proteins with over 110 known members in humans with multiple functions. In a context of cancer, E-cadherin acts as a tumor suppressor. E-cadherin expression inhibits tumor progression by controlling epithelial to mesenchymal transition (EMT) that is associated with specific signaling pathways.

Cadherins are a family of transmembrane glycoproteins with at least five subfamilies. Type I cadherins, so-called classical cadherins, includes also E-cadherin. While type II cadherins are closely related to type I cadherins, there are additional subfamilies with specific structures. Type I and II cadherins, have five extracellular cadherin domains, a single transmembrane domain and a highly conserved intracellular domain that interacts with the intracellular adaptor proteins. E-cadherin mediates homophilic calcium-dependent interactions between epithelial cells that affect intracellular signaling cascades. E-cadherin-based cell adhesions regulate multiple signaling pathways that are linked to intracellular recruitment of catenins and other intracellular signaling molecules. For instance, E-cadherin alters the Wnt-signaling pathway that is important for development, tissue homeostasis and cancer progression. In mature epithelial cells, β-catenin is bound to E-cadherin in the adherent junctions. Free cellular β-catenin is sequestered in the cell through binding to adenomatous polyposis coli (APC)-Axin complex, and is immediately phosphorylated through glycogen synthase kinase 3β (GSK3β). Phosphorylated β-catenin is further ubiquitinylated and destined for degradation in the proteosomes. Upon external activation of the Wnt pathway, which blocks GSK3β activity, β-catenin is not degraded and accumulates in the cytoplasm eventually reaching the nucleus, where it induces transcription program. The nuclear signaling

pathway of β-catenin has a major role in maintaining and promoting mesenchymal and stem cell-like phenotypes that are essential in cancer progression and metastasis.

Cadherins Modulate Cancer Progression

E-cadherin is a major component of the *adherens junctions* of epithelial layers. The epithelial phenotype and the polarization of an epithelial tissue is dependent on E-cadherin expression. E-cadherin is considered as a key regulator of epithelial phenotype, since it is anchored in actin-myosin cytoskeleton and thereby contributes to stabilization of the epithelial architecture. During tumorigenesis, the loss of epithelial cell polarization (Fig. 1) is associated with reduced expression of E-cadherin coded by the *CDH1* gene. Mutation in the *CDH1* gene can lead to hereditary gastric cancer. E-cadherin loss has been found in different other cancers including hepatocellular carcinoma, squamous cell carcinoma of the skin, head and neck and esophagus, as well as in melanoma. In these cancers, E-cadherin is usually lost by epigenetic regulation via promoter methylation. A major pathway involved in the tumor suppressor function of E-cadherin is mediated by the interaction of the intracellular domain with β-catenin. E-cadherin binding to β-catenin inhibits the pro-tumorigenic β-catenin signaling. Downregulation or depletion of E-cadherin in experimental models leads to undifferentiated, highly invasive tumor cells.

E-cadherin expression is usually lost in cells that undergo EMT while the expression of other mesenchymal cadherins, including N-cadherin (CDH2), R-cadherin (CDH4) or P-cadherin (CDH3) is upregulated. These changes are known as "cadherin switch" and are regulated by several transcription factors linked to EMT such as SNAIL, SLUG, TWIST, ZEB1, and ZeB2. EMT is considered as major prerequisite for many cancers to gain an invasive phenotype and to become metastatic. The p120 catenin is an important mediator of downstream signaling linked to the cadherin switch. EMT also induces a program in epithelial cells that can generate cancer stem cells and promote thereby metastatic progression. Binding of p120 to E-cadherin suppresses tumor progression while its association with mesenchymal cadherins, such as P-cadherins, mediates interactions with Rac1 leading to promotion of tumor cell invasiveness. In addition, N-cadherin promotes anchorage-independent growth and influences growth receptor signaling and the overexpression of P-cadherin leads to an increase of MMP secretion and enhanced tumor cell invasion.

CDH2 or neuronal cadherin (N-cadherin) also has autonomous functions apart from cell adhesion. N-cadherin stimulates fibroblast growth factor receptor1 (FGFR1) and thereby promotes malignancy. Moreover, N-cadherin is also expressed on stromal cells and overexpression on tumor cells can mediate invasion and metastasis. Based on this knowledge, N-cadherin is an interesting target for cancer therapy. CDH3 or placental cadherin (P-cadherin) exercise a context-dependent role in cancer. P-cadherin upregulation during a cadherin switch has been observed in some cancers. In epithelial ovarian cancer, gonadotropin-releasing hormone receptors through interactions with p120-catenin leads to increased P-cadherin expression and tumor growth and cancer progression.

While the type I cadherins E-cadherin, N-cadherin, P-cadherin and R-cadherin (CDH4) are associated with cancer progression, type II cadherins can also influence cancer progression. In addition, vascular endothelial cadherin (VE-cadherin, CDH5) is a major cadherin in endothelial cells. VE-cadherin is important for homophilic interactions between endothelial cells and tumor cells and this interaction potentiates tumor cell intravasation and metastasis. Desmosomal cadherins, such as desmoglein and desmocollins, have tumor suppressive function through modulation of oncogenic Wnt-β-catenin signaling. Protocadherins differ from cadherins by other domains that mediate homophilic interactions and different intracelullar domains. In many cases, intracellular interaction partners are not well described, but the expression of protocadherins is often tumor suppressive.

Integrin-Mediated Adhesions

Integrins represents a family of cell adhesion molecules, which control tumor cell proliferation, migration and survival. Integrins directly binds components of extracellular matrix (ECM), and thereby provide traction necessary for cell motility and invasiveness. During cancer progression, integrins contribute to ECM remodeling by controlling the localization and activity of proteases. In addition, other integrin-expressing cells present either at the primary tumor site or at metastatic sites can contribute to the malignant process.

Integrins are heterodimeric cell surface receptors that mediate cell adhesion to ECM proteins or to other cells through binding to immunoglobulin superfamily cell adhesion molecules (IgCAMs). Two major groups of receptors belong to IgCAMs: vascular cell adhesion molecule 1 (VCAM1), and intracellular cell adhesion molecules (ICAMs). More than 24 different integrin heterodimers exist, which are composed of α- and β-subunit and bind to different counter-receptors. There are at least 18 α- and 8 β-integrins identified, that combine many unique α/β integrin receptors, with a specific preference for distinct ligands. The presence of a particular integrin on a cell surface defines the adhesion and migratory properties of the cell in dependence on the adjacent ECM (e.g., fibronectin, vitronectin, laminin, or collagen). The first binding site for integrins that has been identified is defined by a specific tripeptide RGD (arginine-glycine-aspartic acid). This motif is recognized by α5β1-integrin and αv-containing integrins. Different probes carrying the RGD epitope has been tested for integrin targeting in several pharmacological trials.

Upon adhesion to ECM, integrins cluster in the cell membrane and form structures called *focal adhesions*, which further recruit signaling and adaptor proteins. Integrins facilitate through the adaptor proteins the coupling of ECM to the cytoskeleton and allow physical attachment, which affect the cell shape and migratory properties of the cells. The integrin-mediated recruitment and

activation of kinases, such as focal adhesion kinases (FAKs), Src family kinases or GTPases of the Ras/Rho family induces signal transduction, known as "outside-in" signaling. Conversely, intracellular signals (e.g., growth factors or cytokines) can induce alterations in the integrin conformation and thereby modulate the ligand-binding affinity of integrins to ECM that is known as an "inside–out" signaling. In addition to the well-established role of integrins during migration and invasion, integrins also regulate cell proliferation, cell survival and angiogenesis, all of which contribute to cancer progression. Integrins on the cell surface constantly interrogate their microenvironment through their capacity to bind to ECM. Ligated integrins convey cell survival, while unligated integrins may trigger pro-apoptotic pathways. The enhanced cell survival triggered by ligated integrins is mediated by several mechanisms, including expression of Bcl-2 or activation of PI3K-Akt or NF-kappaB signaling. This process is further dependent on a communication between integrin-growth factor pathways. On contrary, unligated integrins may trigger activation of Caspase-8 and initiate apoptosis, which is no longer blocked by the Bcl-2. Thus, integrins can paradoxically initiate either pro-survival or pro-apoptotic pathways that is dependent on integrin engagement.

Integrins Adhesion in Cancer and During Metastasis

A wide variety of integrins on tumor cells are linked to cancer progression. Most solid tumors of the epithelial origin express integrins on a cell surface (**Fig. 1**). However, integrin expression may strongly vary between normal epithelial cells and malignant carcinoma cells. Particularly, αvβ3 and αvβ6 integrins are highly expressed in some tumors, while their presence in epithelial cells is negligible. The correlation between integrin expression and cancer patient's survival was evaluated in many cancer types as discussed elsewhere (see further reading). For example, αvβ3 integrin expression correlates with a poor prognosis in many cancers including breast, colon, prostate, pancreatic, and ovarian carcinomas.

Tumor cell seeding to a "metastatic niche" in a specific tissue is at least partially dependent on interactions between tumor cells and the available ECM. The unique binding specificities of integrins may therefore dictate the ability of tumor cells to colonize distinct tissues, and thus serve as a critical homing factor promoting metastasis. The metastatic susceptibility of certain tissue has been linked to a presence of specific ECM proteins at these sites. For example, tenascin C is a ligand for β1 and β3 integrins, and is present in the metastatic niche of the lungs, driving breast metastasis to this organ. Laminin is another ECM protein present in the lungs that is recognized by α6β4 or α6β1 integrins expressed both on tumor cells and platelets. αvβ3 of α4β1 integrins expressed on tumor cells play key roles in bone metastasis, where they enable tumor cell adhesion to ECM proteins such as osteopontin or type I collagen. The enhanced expression of α4β1 integrins on melanoma cells enables binding to VCAM1 on activated lymphatic endothelial cells thereby promoting lymph node metastasis. While the experimental evidence links integrin expression to tissue-specific metastatic seeding of tumor cells, the question how tumor cells reach ECM, which is normally not accessible from the lumen of blood vessels, remains open.

Integrins From the Tumor Microenvironment Promote Cancer Progression

Tumor microenvironment consists of a variety of host cells, where the bone marrow-derived myeloid cells represent the major population of cells virtually in any cancer type. The expression of α4β1 integrin (also known as VLA-4) on bone marrow-derived cells enables their recruitment to the tumor microenvironment. The endothelial remodeling in growing tumor induces the expression of VCAM and cellular fibronectin that facilitates integrin-based adhesion of bone marrow-derived myeloid cells. In addition, VLA-4-driven recruitment of monocytic cells to the activated endothelium, commonly observed in growing tumor and at metastatic sites, promotes angiogenesis. A positive role of platelets in tumor metastasis has been already defined. Apart from the initial P-selectin-dependent interactions, αIIbβ3 integrin on platelets was shown to facilitate tumor cell-platelet interactions. Mechanistically, ECM proteins, such as fibrinogen serve as a bridge for platelet αIIbβ3 integrin dependent adhesion and tumor αvβ3 integrin mediated interaction. This interaction contributes to arrest of tumor cell emboli leading to metastasis. Tumor-activated activated endothelial cells express αvβ3 integrin, which together with basic fibroblast growth factor (bFGF) or tumor necrosis factor α (TNF-α) stimulates angiogenesis. However, the expression of αvβ3 on activated endothelial cells is not unique to tumors, but has been detected in different pathophysiological situations. Finally, tumor-activated endothelium expresses VCAM1, ICAMs, which served as ligands for the integrin-mediated leukocyte recruitment (**Fig. 2**). The dominant members of leukocyte integrin families, facilitating leukocyte recruitment leading to their extravasation are the β2 integrins, e.g., αLβ2 = CD11a/CD18 or αMβ2 = CD11b/CD18, and β1 integrins, e.g., α4β1 = VLA-4. In addition, to integrin-mediated firm adhesion of leukocytes to VCAM1 and ICAMs, a direct interaction between αLβ2 or αMβ2 on endothelial cells directly promotes leukocyte extravasation.

Analogous to growth factor receptors, clustering of integrins in the plasma membrane directly regulate the amplification of signal transduction. In fact, there is accumulating evidence for a cooperative signaling between growth factor/cytokine receptors and integrins. This process is further regulated by other binding partners such as galectins. Galectins is a family of β-galactoside-binding lectins, which are expressed by tumor cells in soluble forms. Galectins influence tumor cell behavior through binding to carbohydrates on the cell surface receptors, such as integrins, and thereby promote their clustering. Galectin-1 expression in low metastatic lung carcinoma cells induced their migration, invasiveness and metastasis, through integrin activation. In addition, Galectin-3 induces β3 integrin-mediated tumor growth and drug resistance. Mechanistically, αvβ3 integrins on tumor cells, without binding to a ligand, recruit the oncogene KRAS to the tumor cell plasma and activate downstream signaling such as NF-kB pathway and thereby promote tumor growth. Thus, integrin αvβ3 was shown to be both necessary and sufficient for tumor initiation and resistance to receptor tyrosine kinase inhibitors in pancreatic carcinomas.

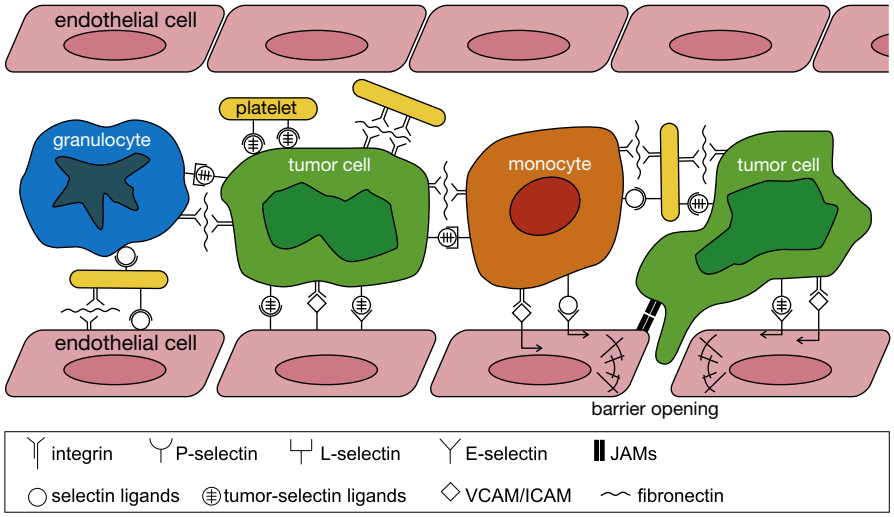

Fig. 2 *Cell adhesion facilitates tumor cell intravascular survival and tumor cell extravasation.* In the circulation, tumor cells interact with blood constituents (e.g., platelets, granulocytes, monocytes, and blood vessel wall = endothelial cells), which is primarily mediated by adhesion of selectins to altered glycan structures (carcinoma mucins) presented on the tumor cell surface. Platelet-tumor cell interactions are directly facilitated by P-selectin, and indirectly through integrin binding both from platelet and tumor cells to extracellular components (e.g., fibronectin). Platelets "coating" of tumor cells protect them from immune responses, and contribute to higher tumor cell mobility of tumor cells. Tumor cell interactions with leukocytes are both L-selectin- or integrin-mediated. Tumor cell-endothelial cells adhesion may trigger endothelial activation through *E*-selectin or immunoglobulin superfamily cell adhesion molecules (IgCAMs) such as ICAM or VCAM that are recognized by integrins from tumor cells. The resulting increase in vascular permeability is linked to specific cytoskeletal rearrangements in the endothelial cells and loosening of endothelial cell junctions. Although tumor cells may individually migrate through the endothelium, *trans*-endothelial migration of tumor cells is significantly potentiated by monocytes. In addition, interactions between tumor and endothelial cells through junction adhesion molecules (JAMs) further modulate tumor cell extravasation.

In conclusion, it is important to emphasize that individual integrins may affect very different aspects of cancer progression. While unligated αvβ3 integrin promotes tumor cell stem-like properties, its ligation to ECM drives cell invasiveness and proliferations. Thus, the role of integrins in cancer biology is dependent on particular cues present in a tumor microenvironment.

Selectin-Mediated Cell Adhesion

Selectins are vascular cell adhesion receptors that bind to glycans presented on cell surface proteins. The physiological function of selectins is to facilitate the initial tethering of leukocytes at inflammatory sites or secondary lymphoid organs before leukocyte adhesion and extravasation. Three different selectins (P-, E-, and L-selectin) can be found in mammals, which are conserved between species. Selectins are C-type lectins that bind preferentially to glycans with a terminal tetrasaccharide structure of sialyl-Lewis x (sLe^x) and sialyl-Lewis a (sLe^a) (Fig. 3), which are usually further modified with a sulfate group. The biosynthesis of sLe^x and sLe^a ligands is orchestrated by a set of glycosyltranferases, where the expression of sialyltransferases and fucosyltransferases is essential. In addition, selectins also bind to certain glycolipids (sulfatides). Heterophilic binding of selectins to glycans is usually calcium dependent. Structurally, all selectins possess an N-terminal C-type carbohydrate recognition domain (C-type lectin), an EGF domain, short consensus repeats, a transmembrane and an intracellular domain. The engagement of selectins by their ligands activates outside-in signaling through e.g., Ca^{2+} and p38 MAP kinase pathway.

P-selectin is stored in granules of platelets and endothelial cells, which bring P-selectin on the surface upon activation. *E*-selectin is present only on endothelial cells and its expression is regulated on a transcription level. L-selectin is constitutively expressed on

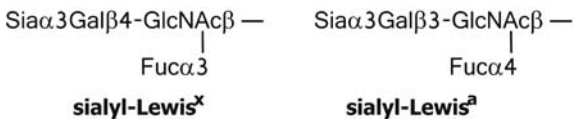

Fig. 3 *Structures of sialyl Lewis x* (sLe^x) *and sialyl Lewis a* (sLe^a). Selectins bind to glycans with a terminal tetrasaccharide structure known as sialyl Lewis $^{x/a}$. The core of the terminal tetrasaccharide is a disaccharide of galactose linked to *N*-acetylglucosamine (GlcNAc), either in α1,4 (sLe^x) or α1,3 (sLe^a) linkage. This disaccharide is further modified by α2,3sialyltransferases linking the sialic acid to the galactose. The fucosyltransferases completes the tetrasaccharide by the addition of fucose to GlcNAc either in α1,3 linkage forming sLe^x or α1,4 linkage forming sLe^a. Depending on a selectin type, this structure is further sulfated either on 6-position of the Gal or 6-position of the GlcNAc. Alternatively, the protein backbone of the selectin ligand carrier is sulfated in a close proximity to the sLe^x structure.

most subsets of leukocytes, but lost upon antigen-mediated T cell memory formation. Selectins bind to properly posttranslationally modified glycan ligands, carrying mostly sLe^x or sLe^a structures. The most studied selectin ligand is P-selectin Glycoprotein Ligand 1 (PSGL-1), where the sLe^x is further sulfated. All three selectins bind to PSGL-1 that is mostly expressed in leukocytes. In addition, E-selectin binds to a variety of glycosylated protein ligands such as E-selectin Ligand-1 (ESL-1) or CD44. L-selectin binds to a group of glycans called addressins that includes: MADCAM, PNADs like CD34, and podocalyxin. These glycans are present in high endothelial venules of lymph nodes or Peyer's patches, where they enable lymphocyte trafficking to secondary lymphoid organs. Moreover, P- and L-selectins also bind to glycosaminoglycans, like heparan sulfate and heparin, but the nature of this cell adhesion remains under investigation.

On a functional level, selectins mediate the first steps of extravasation. Endothelial cells line up the blood vessels and circulating leukocytes do not interact with the vessel wall. Inflammatory stimuli activate endothelial cells that upregulate expression of adhesion molecules including P-selectin and E-selectin. Interactions of vascular selectins with their ligands lead to the leukocyte rolling on activated endothelium, followed by integrin-mediated firm adhesion and finally leukocyte extravasation into the parenchyma, where the effector functions of leukocytes can be executed.

Selectin-mediated cell adhesion modulates two different aspects during cancer progression and metastasis: (A) tumor cell interactions with endothelial cells, platelets and leukocytes; (B) leukocyte recruitment and trafficking to developing tumors (Fig. 2).

Selectin-mediated tumor cell interactions

Malignant transformation is associated with profound changes in cell surface glycosylation of tumor cells and this leads to upregulation of ligands for selectins. These changes in glycosylation are the result of epigenetic and genetic changes of glycosyltransferases and glycosidases. While changes can lead to increased branching of *N*-glycans, the prominent glycan alterations occur on *O*-linked glycans which are present on mucin producing tumor cells. Importantly, the upregulation of sialic-acid containing glycans on tumor cells together with an increased expression of truncated glycan structures has been detected across all cancer types. The upregulation of sialic acid-containing glycans is a result of alterations in expression of sialyltransferases or sialidases. Such sialylated glycans e.g., on mucins serve as ligands for selectins and enable interactions between tumor cells and selectin-carrying cells. Thus, reciprocal interactions between platelets, leukocytes, endothelial cells and tumor cells have been associated with cancer progression. While many of these cell–cell-interactions have been demonstrated in various assays in vitro, their relevance in cancer progression has been confirmed in mouse models using selectin-deficient mice. Importantly, enhanced expression of sLe^x and sLe^a structures is frequently associated with cancer progression and cancer patient's poor prognosis in various tumors including colon, gastric, lung; renal and breast cancers; melanomas and others.

Metastasis is a multistep process which begins with dissemination of tumor cells through the blood circulation and leads to colonization of a distant organ. Selectin-mediated interactions contribute to hematogenous dissemination and organ colonization. During hematogenous metastasis platelets bind to tumor cells and this platelet-"shield" protects tumor cells from elimination by NK cells. A strong reduction of metastasis was observed in mice lacking P-selectin, indicating that P-selectin could be a target for anti-metastatic therapy. Endothelial E-selectin has been shown to promote tumor cell adhesion and thus has been implicated in metastatic dissemination. A special glycoform of CD44 in human cells, named as HCELL, has been identified as an E-selectin ligand on tumor cells. In breast cancer cells, selectin-mediated interactions with HCELL on microvascular endothelial cells promotes homing of cancer stem cells to the bone marrow. Selectin-selectin ligand interactions can influence signaling both in tumor cells and in selectin-bearing cells; thereby modulating cancer progression.

Cancer patients have a significantly increased risk to develop thromboembolic complications. This hypercoagulability first described by Trousseau is also to some part attributed to selectin-mediated interactions between cancer mucins, platelet P-selectin and L-selectin on leukocytes. Carcinoma-derived highly sialylated and glycosylated mucins enhance platelet interactions with myeloid leukocytes that promote thrombus formation. This finding might explain why heparin and heparin derivatives are potent inhibitors of thromboembolic events in cancer patients, when compared to other anticoagulants (e.g., Warfarin).

Selectin-mediated recruitment and trafficking of leukocytes in cancer

Selectin-mediated interactions promote the leukocyte recruitment to tumors and enables their interactions within a tumor microenvironment. Increased leukocyte recruitment supports cancer progression through promotion of tumor cell invasion, intravasation, dissemination, and extravasation. In particular, selectins were shown to influence the recruitment of innate immune cells during metastatic colonization. Analysis of metastatic colonization in various mouse models have shown that selectin-mediated interactions is essential for the recruitment of myeloid cells and monocytes that enhances tumor cell extravasation and facilitate organ colonization. Increased production of chemokines (e.g., CCL2, CCL5, or CXCL12) within the metastatic microenvironment further promotes recruitment of monocytes and myeloid cells, which is further supported by selectin interactions. Interestingly, both endothelial E-selectin and the leukocyte L-selectin were shown to be implicated in the process of monocyte-assisted transendothelial migration of tumor cells in lungs. These studies show that metastatic tumor cells "highjack" the physiological function of selectins and leukocyte recruitment to promote tumor growth and metastasis.

In the case of hematogenous malignancies, the tumor cells express not only selectin ligands, but also the L-selectin. The cell surface expression of L-selectin on leukemia cells can significantly influence their trafficking and distribution. For instance, in patients with chronic lymphocytic leukemia (CLL) tumor cells re-circulates to lymph nodes through L-selectin mediated rolling, which promotes cancer progression.

In conclusion, selectin-mediated interactions between tumor cells, platelets, endothelial cells and leukocytes are involved in various steps of metastasis and can facilitate the formation of a metastatic niche. Interestingly, glycosaminoglycans (GAGs) such as heparin and heparan sulfates bind to selectins and thereby inhibit interactions with tumor-associated ligands. Besides, glycomimetics of PSGL-1 can inhibit P-selectin mediated interactions and is currently tested in cancer therapy. The abundance of selectin ligands on virtually all cancer types, together with the overall access to vascular selectin during hematogenous metastasis strongly suggest that any interference in selectin-mediated cell adhesion in a temporal manner might have an antimetastatic potential also in clinical settings.

Other Cellular Adhesion During Cancer Progression

There are other cell adhesion molecules associated with cancer progression, but their function is only partially elucidated. CD44 is a cell surface adhesion molecules, which was initially shown to be the receptor for an ECM glycosaminoglycan hyaluronan. Many cancer types express high levels of CD44 that upon cleavage from the cell surface serves as a marker for cancer progression. Besides the special glycoform HCELL found in cancer that can serve as ligands for selectins (see above), tumor-specific alternatively spliced CD44 has been described. The current evidence linked altered CD44 expression to cancer stem cell phenotype, while the intracellular domain is critically involved in this process.

Junctional adhesion molecules (JAMs) are expressed on endothelial cells, where their homophilic interactions strengthen the endothelial barrier functions. During inflammation JAMs, together with endothelial ICAMs interact with αLβ2 or αMβ2 on leukocytes thereby promoting leukocyte extravasation through the retracted endothelium. Recent evidence suggests that JAM-c on melanomas actively contribute to lung metastasis though promotion of tumor cell extravasation through enhanced transendothelial migration of the tumor cells without affecting tumor cell adhesion (**Fig. 2**). Whether other tumor cells express JAMs or whether JAMs binding is relevant for metastasis to other organs remains to be defined.

Adhesion Molecules in Antitumor Immunity and Cancer-Associated Inflammation

Recent advances in our understanding how the immune system recognizes and eliminates tumor cells and how tumor cells evade this immune control has led to the introduction of successful immunotherapies into the clinical routine. In particular, targeting of inhibitory receptors on T cells including PD-1 and CTLA-4 have revolutionized the treatment of patients with advanced cancers including melanoma, nonsmall cell lung cancer, kidney cancer or bladder cancer. While antitumor immunity has gained much interest, the virtually omnipresent cancer-associated inflammation associated with recruitment and polarization of myeloid-derived cells usually supports cancer progression by the generation of an immune-suppressive microenvironment.

Dysfunction in the leukocyte recruitment with antitumor activity to tumors and increased recruitment of immune suppressive immune cells such as myeloid-derived suppressors, regulatory T cells or tumor-associated macrophages has been observed in many cancers. Cell adhesions facilitate leukocyte recruitment through selectin- and integrin-mediated interactions that influence also the adaptive immunity. Infiltration of CD8 positive T cells preferentially happens in the periphery of tumors, which is well studied in melanoma lesions. Moreover, in a murine melanoma model, endothelial cells downregulated ligands for the recruitment of cytotoxic T cells. PSGL-1 on T cells modulates T cell trafficking and the development of regulatory T cells therefore PSGL-1 represents an interesting drug target for cancer immunotherapy.

T cells including regulatory T cells (Tregs) recirculate and control immune homeostasis including peripheral tolerance. Homing of naïve T cells to secondary lymphoid organs requires L-selectin binding to addressins on high endothelial venules. Selectin receptors as well as integrins have an important function in the recruitment and homing of Tregs to sites of inflammation and to tumors. Tregs play an important role in suppressing antitumor immune responses thus targeting of cell adhesion mechanisms leading to Tregs recruitment could be an interesting way to improve antitumor immune responses.

Prospective Vision

Current evidence describes the role of cell adhesion in different processes associated with cancer progression, ranging from stemness of cancer cells; tumor growth survival, invasiveness, migration, and metastasis; to modulation of immune responses. While the biology of cell adhesion during cancer is rather complex, the function of certain integrins, cadherins and selectins has been extensively evaluated in several preclinical models. Nevertheless, no agent that specifically targets interactions of these molecules is currently used in clinical practice. Clearly, the complete identification of underlying mechanisms in the complexity of the tumor microenvironment is still ongoing and will hopefully help to develop therapeutic strategies. There are several studies testing targeted delivery of therapeutics to tumor sites through cell adhesion molecules. For example, tumor targeting by IL-2 cytokine-fusion proteins with RGD domains that bind to integrins have demonstrated promising results in mouse models together with checkpoint blockade. While timely-defined targeting of selectins resulted in reduced metastasis in many experimental models, selectins can also serve as targets for delivery of nanoparticles coated with selectin ligands. For example, P-selectin was targeted for cancer-directed drug-delivery with nanoparticles coated with a fucosylated polysaccharide. Interestingly, P-selectin expression could be initiated on endothelial cells by radiotherapy. This finding represents a very interesting concept; where drug targeting could be initiated by specific irradiation of a tumor lesion. In this context, new insights into function of cell-cell interactions, especially during

metastasis, will certainly open up new strategies to interfere in cancer progression. Interference in cell adhesion based processes during cancer lies in a combinational approach with other approaches e.g., direct tumor cell targeting or modulation of anticancer immunity.

Cell Responses to DNA Damage☆

Jean YJ Wang, University of California San Diego, La Jolla, CA, United States

Glossary

AT Ataxia telangiectasia, which is an autosomal recessive genetic disease characterized by ataxia, immune deficiency, sterility, and mortality early in life, caused by loss-of-function mutation in the ATM gene

BER Base excision repair, which is mechanism that repairs damaged bases in DNA, involving excision of damaged base by N-glycosylase excising the damaged base followed by endonuclease cleavage of DNA strand at the abasic site, followed by DNA polymerase filling and ligase sealing of the strand.

BSE Bystander effect, which describes DNA damage-induced biological effects in cells that are not directly targeted by genotoxins, but are in the vicinity of directly damaged cells.

DDR DNA damage response, which describes the compilation of cellular processes activated by lesions in genomic DNA.

FA Fanconi anemia, which is an autosomal recessive genetic disease characterized by genome instability, defects in DNA repair, anemia and cancer susceptibility, caused by loss-of-function mutations in some 20 genes, collectively known as the FA genes.

FHA Fork head associated, which is an evolutionarily conserved protein domain that specifically binds to a phospho-threonine epitope.

MMR Mismatch repair, which is a mechanism that repairs mismatched base pairs and small insertions or deletions during DNA replication, involving protein complexes that recognize those lesions in newly synthesized daughter strand, followed by recruitment of nucleases to cleave the daughter stand, polymerases to fill the gap, and ligases to seal the strand.

NER Nucleotide excision repair, which is a mechanism that repairs photo-adducts of bases in DNA, involving protein complexes that recognize those lesions in actively transcribed DNA (transcription coupled repair) or genomic DNA in general, followed by endonuclease cleavage of DNA strand surrounding the photo-adducts, DNA polymerase filling and ligase sealing.

PIKK Phosphotidyl-inositol-3 (PI3K) kinase-related kinase, which is a protein kinase domain that is highly conserved in eukaryotic cells and is related to the lipid kinase PI3K. Upon DNA damage, three members of the PIKK family, namely ATM, ATR, and DNAPK, are activated by lesion recognition and sensing factors and these PIKKs function as master kinases to switch on DDR.

XP Xeroderma pigmentosa, which is an autosomal recessive genetic disease characterized by UV sensitivity, defects in NER, developmental defects, and cancer susceptibility, caused by loss-of-function mutations in a dozen or so genes, collectively known as the XP genes.

Overview

The study of DNA damage response (DDR) spans multiple disciplines and experimental approaches that defy a comprehensive review in one chapter. The goal of this chapter is therefore to provide a DDR framework that is amenable to expansion in biological directions by readers according to their interests. This DDR framework organizes factors and processes into three functional categories: (1) lesion recognition and damage sensing, (2) damage-signal transduction, and (3) downstream biological effectors (Fig. 1).

DNA lesions can be generally divided into four major groups: base modifications (alkylation, oxidation), mismatched base pairs (non-Watson Crick base pairing, small insertions, or deletions), interstrand crosslink (ICL), and strand breaks (double-stranded or single-stranded breaks). These lesions are repaired by a number of DNA repair mechanisms, for example, base excision repair (BER), nucleotide excision repair (NER), mismatch repair (MMR), crosslink repair, nonhomologous end joining (NHEJ), and homologous recombination (HR). Each of these repair pathways is initiated by a lesion recognition factor, for example, the MSH2/MSH6 complex recognizes mismatched base pairs, Ku and MRN complexes recognize double-stranded breaks (DSB). The lesion recognition factors not only recruit DNA repair enzymes but also interact with signal transducers to activate additional DDR pathways (Fig. 1). Besides those factors that recognize specific DNA lesions, eukaryotic cells also possess an evolutionarily conserved "damage sensor," that is the 9-1-1 hetero-trimeric DNA clamp. The 9-1-1 DNA clamp is loaded unto stalled replication forks and other damage sites where structures that resemble stalled replication forks are formed.

The dual roles for lesion-recognition proteins to stimulate DNA repair and to activate damage-signal transduction ensures that DDR is terminated when lesions are repaired. With this design, the rate of DNA repair becomes an important determinant of the

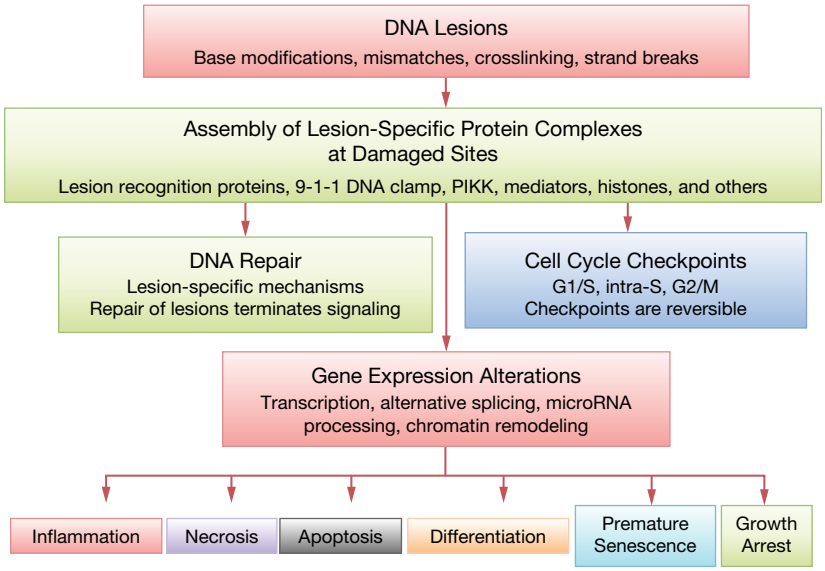

Fig. 1 A framework of DNA damage response (DDR). A variety of DNA lesions occur under physiological conditions and are further induced by exposure to genotoxins. Damage recognition by lesion-specific detectors initiates the assembly of protein complexes through regulated protein–protein interactions involving covalent modifications of preexisting proteins (see **Fig. 3** for an example of complex assembly at a double strained break site). These complexes serve two functions—to stimulate DNA repair and to propagate the DNA damage signal. The *immediate early* action (within minutes of DNA damage) is to stimulate DNA repair. In proliferating cells, another *immediate early* action is to inhibit cell cycle progression. In both proliferating and nonproliferating cells, the third *immediate* action is to alter gene expression. Because transcription of new RNA and translation of new protein require time, gene expression-dependent biological responses are *delayed* (illustrated by the longer arrow). In DDR, gene expression-dependent responses include cell cycle arrest, premature senescence, inhibition or stimulation of cellular differentiation, apoptosis, necrosis, cell–cell communication, and inflammation. Because the cell type and developmental stages control the epigenetic landscape, the *delayed* responses driven by gene expression alterations exhibit cell-context dependency and cannot be easily generalized across all cell types.

biological outcomes in DDR. Because RNA transcription and protein translation require more time (longer arrow in **Fig. 1**) than covalent modifications of preexisting factors (short arrows in **Fig. 1**), a rapid extinction of DNA lesions (efficient repair) can prevent or reduce gene expression alterations to blunt the *delayed* responses. Therefore, it is the persistence of DNA lesions that triggers the downstream effects, such as premature senescence or cell death (**Fig. 1**).

It must be emphasized that DDR exhibits not only *temporal* dependency but also cell type dependency (**Fig. 1**). In proliferating (cycling) cells, the *immediate early* effects (within minutes of lesion detection) are to stimulate DNA repair and to inhibit cell cycle progression. These rapid DDR maximizes genome protection, cell survival, and resumption of proliferation. By contrast, *delayed* effects such as premature senescence or death *eliminate* rather than *protect* the damaged cells. Therefore, the upstream factors in lesion detection and signal transduction can activate pro-survival or pro-death downstream effects. Under conditions when lesion removal (DNA repair) is highly efficient, the DDR signaling proteins contribute to cell survival. However, under conditions when DNA lesions overwhelm the repair capacity, DDR signaling proteins contribute to cell death.

Lesion Recognition and Damage Sensor

Modified Bases

Base modifications, such as guanine base alkylation (6-meG) or oxidation (8-oxoG), are recognized and repair by several different mechanisms. For example, MGMT (O^6-methylguanine DNA methyltransferase) recognizes and demethylates O^6-methylguanine. On the other hand, N-glycosylase enzymes recognize and cleave the N-glycosidic bonds to remove the modified bases in BER (base excision repair). In nucleotide excision repair (NER), which is the major repair mechanism of UV-induced photo-adducts, several XP protein complexes and the elongating RNA polymerase II serve as lesion detectors. The XP genes are those mutated in an autosomal recessive genetic disease Xeroderma pigmentosum (XP). XP patients display extreme sensitivity to UV; they also suffer from developmental defects and susceptibility to cancer.

Mismatched Base Pairs

Mistakes during DNA replication occur at an appreciable rate despite the proofreading function of DNA polymerases and must be recognized and repaired to ensure the faithful transmission of genetic information. These replication-induced mismatched bases and small deletions or insertions are repaired by the mismatch repair (MMR) mechanism. In eukaryotic cells, heterodimeric

complexes of MSH2/3 or MSH2/6 proteins detect mismatched bases and then recruit other MMR proteins (MLH1, MLH3, PMS2) to initiate repair. In human, genetic defects in MSH2 or MLH1 cause cancer susceptibility in the Lynch syndrome.

Cross-Linked DNA

Inter-strand cross-linking (ICL), where two strands of DNA are covalently linked, for example, by cisplatin, impedes transcription and DNA replication. The repair of ICL requires proteins encoded by more than 20 FA genes that are mutated in Fanconi anemia (FA), an autosomal recessive genetic disease characterized by anemia and cancer susceptibility. A complex of FA gene products recognize replication forks at ICLs to activate a complex repair mechanism that requires the coordination of nucleotide excision (NER), trans'lesion DNA synthesis, and homologous recombination (HR).

Double-Stranded Breaks (DSB)

Double-stranded breaks (DSB) occur at stalled replication forks and during the process of repairing interstrand crosslinks. DSB are also induced by genotoxins, for example, ionizing radiation or topoisomerase inhibitors. Two evolutionarily conserved protein complexes are detectors of DSB: the hetero-dimeric Ku antigen (Ku-70, Ku-80) and the hetero-trimeric MRN complex (MRE11, RAD50, NBS1). In mammalian cells, the Ku antigen recruits DNA-PK to stimulate nonhomologous end joining (NHEJ) for the non-faithful repair of DSB, whereas the MRN complex recruits ATM and many other factors to stimulate homologous recombination (HR) for the faithful repair of DSB by using an intact homolog of the broken DNA (Fig. 2).

The 9-1-1 Complex

The 9-1-1 complex is a hetero-trimeric DNA clamp consisting of three evolutionarily conserved proteins: Rad9, Rad1, and Hus1. The 9-1-1 DNA clamp is structurally similar to the homo-trimeric PCNA DNA clamp required for DNA replication and repair. The 9-1-1 complex is loaded onto double- and single-stranded hybrid DNA at stalled replication forks through the action of a damage-induced Replication Factor C (RFC) clamp loader containing the RAD17 protein. The 9-1-1 clamp is also loaded onto similar DNA structures that are generated during DNA repair. The 9-1-1 complex differs from other lesion-specific binding proteins because it is a sensor of an abnormal DNA structure rather than a modified base or a DNA end. Similar to other lesion sensors, the 9-1-1 complex serves as a scaffold to promote DNA repair and damage signal transduction (Fig. 2).

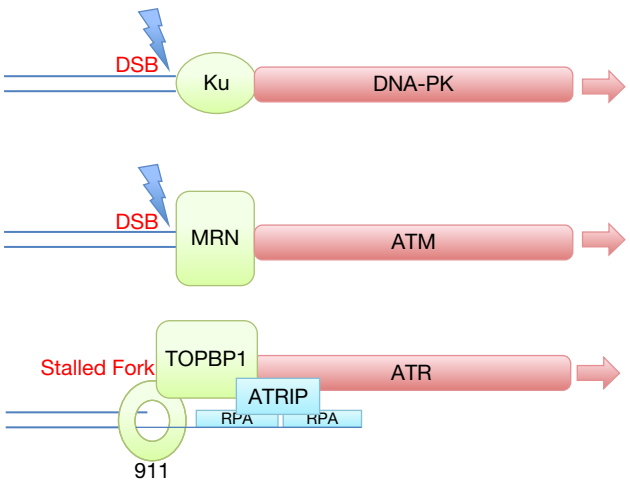

Fig. 2 Activation of PIKK by DSB or stalled replication fork. Double-stranded breaks (DSB) are recognized by the Ku-antigen (a heterodimer of Ku-70 and Ku-80) or by the MRN complex (a heterotrimer of **M**RE11, **R**AD50, and **N**BS1). Ku antigen interacts with DNA-PK (DNA-dependent protein kinase), a member of the PIKK family, which activates the nonhomologous end-joining mechanism for DSB repair. MRN interacts with ATM, another member of the PIKK family, which stimulates the phosphorylation of hundreds of substrates to regulate the homologous recombination mechanism for DSB repair, the cell cycle checkpoints and gene expression at several levels, including transcription initiation, alternative splicing and microRNA biogenesis. Stalled replication fork with double- and single-stranded hybrid DNA is sensed by the RAD17-containing RFC, which loads the 9-1-1 DNA clamp. The 9-1-1 complex and the single-stranded DNA binding protein, RPA, jointly recruit the ATR kinase associated with TOPBP1 (topoisomerase II binding protein 1) and ATRIP (ATR interacting protein). ATR, also a PIKK family of kinase, is essential to the repair and the restart of stalled replication forks, and therefore, ATR is essential to cell viability.

DNA Damage Signal Transduction

PIKK Family of Protein Kinases

In eukaryotic cells, DNA damage activates a family of evolutionarily conserved protein kinases belonging to the phosphoinositide 3-kinase-like kinase (PIKK) family. The mammalian PIKKs central to the transduction of DNA damage signal are ATM (ataxia telangiectasia mutated), ATR (ATM and Rad3 related), and DNA-PK (DNA-dependent protein kinase) (Fig. 2). Loss of the ATM function causes Ataxia telangiectasia, an autosomal recessive genetic disease characterized by cerebellum degeneration, radiosensitivity, immune-deficiency, sterility, and cancer predisposition. Loss of DNA-PK is associated with severe combined immune deficiency (SCID) in mice.

The mammalian ATR function is required throughout S-phase and plays an essential role in DNA replication. ATR is recruited to stalled replication forks or resected DSBs by a complex array of protein–protein interactions (Fig. 2). At the stalled fork, a long stretch of single-stranded (SS) DNA is formed and this ss-DNA is recognized and bound by RPA (an evolutionarily conserved ss-DNA binding protein), which guides the loading of 9-1-1. Together, the 9-1-1 DNA clamp and RPA then facilitate the recruitment and activation of the ATR kinase in collaboration with TOPBP1 (topoisomerase II binding protein 1) and ATRIP (ATR interacting protein) (Fig. 2).

Upon activation, the PIKKs phosphorylate hundreds of cellular proteins of diverse functions to mobilize an array of biological responses to DNA damage. Among the PIKK substrates, the most highly conserved are the mediators and the checkpoint kinases.

Mediators

The mediators are scaffold proteins that play essential role in DNA damage signal transduction. The PIKKs phosphorylate the mediator proteins to regulate the assembly of protein complexes for DNA repair and signal propagation (Fig. 1). In DDR, the forkhead-associated (FHA) and the BRCA1 C-terminal (BRCT) domains serve as the phospho-epitope binding sites for the assembly of signaling and repair complexes. The FHA domain binds to phospho-threonine (pT) containing peptide motifs. The BRCT binding to phospho-peptide motifs requires two BRCT in tandem. The structural basis for phospho-epitope binding by the FHA and the BRCT domains has been elucidated.

A prototypical mediator in DNA damage signal transduction is the mammalian MDC1 (mediator of DNA damage checkpoint 1), which is a large scaffolding protein with an FHA domain at the N-terminus, two tandem BRCT domains at the C-terminus, and numerous phosphorylation sites throughout the length of the protein (Fig. 3). The phosphorylated MDC1 can recruit proteins with the FHA, the tandem-BRCT, and other phospho-binding domains. At the same time, the FHA and BRCT domains of MDC1 can interact with other PIKK-phosphorylated substrates (Fig. 3).

Checkpoint Kinases

Among the highly conserved PIKK substrates are the CHK1 and CHK2 protein kinases, which are members of the Protein Kinase superfamily, characterized by a highly conserved kinase domain that is distinct from the PIKK. CHK1 and CHK2 are phosphorylated by the PIKK, with CHK1 being primarily the substrate of ATR, and CHK2 of ATM. However, the PIKKs and the checkpoint kinases

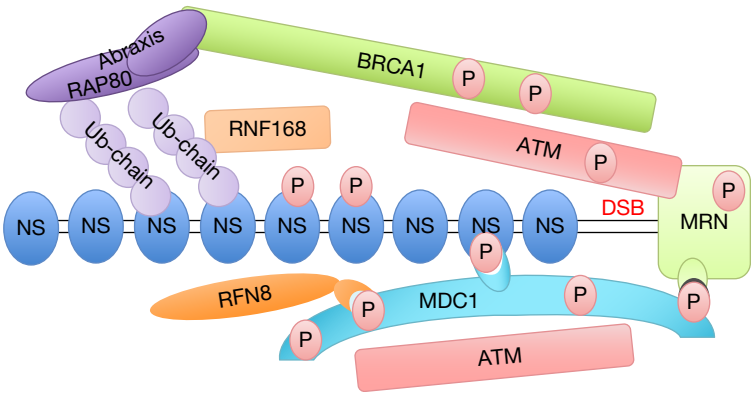

Fig. 3 Assembly of protein complexes at DSB site. This diagram illustrates an example of protein complex assembly at a double-stranded break (DSB) site. The MRN complex (MRE11, RAD50, NBS1) binds to the DSB, recruits, and activates ATM. Activated ATM phosphorylates itself (phosphorylation sites are indicated as pink balls with **P**), the MRN, the H2AX histone in the nucleosomes (NS), and the mediator MDC1. The tandem BRCT domains of MDC1 interact with the phospho-epitope in the phosphorylated H2AX (aka γH2AX). Some phospho-epitopes in MDC1 bind to the BRCT and FHA domains of NBS1 in the MRN complex. Other phospho-epitopes in MDC1 bind to RNF8, which then ubiquitinates H2A and H2AX in the nucleosomes. The poly-ubiquitin chains, further elaborated by RNF168, recruit RAP80 and Abraxis, which then recruit BRCA1 that is also phosphorylated by ATM. Note that activated ATM is distributed beyond the DSB site to phosphorylate many other substrates. The BRCA1 complex at the DSB site facilitates homologous recombination repair.

are components of a highly dynamic signaling network with nonexclusive interactions. ATM phosphorylation of CHK2 causes oligomerization of this kinase via intermolecular phospho-epitope binding to its own FHA domain and this ATM-induced CHK2 oligomerization results in CHK2 kinase activation. In addition, checkpoint kinases interact with mediators, which control the compartmentalization and stability of CHK1 and CHK2. The checkpoint kinases play essential roles in the activation of cell cycle checkpoints. They also regulate DNA repair and gene expression by phosphorylating various downstream effector proteins.

Other Kinases

Besides CHK1 and CHK2, other kinases of the Protein Kinase superfamily also participate in the transduction of DNA damage signal. These include the stress-activated protein kinases, for example, p38 and JNK, the ABL tyrosine kinase, and many others. The stress-activated protein kinases can activate the cell cycle checkpoints independent of CHK1 and CHK2. They also regulate gene expression. The ABL tyrosine kinase is localized to the cytoplasm and the nucleus. In response to DNA damage, the ABL kinase becomes accumulated in the nucleus through the action of ATM. Nuclear ABL tyrosine kinase activates pro-apoptotic gene expression by activating the p53 family of transcription factors (p53, p63, p73) and histone acetyltransferase, for example, Tip60 (KAT5).

Other Protein-Modifying Enzymes

Besides phosphorylation, DNA damage activates other protein modifying enzymes to induce a variety of protein covalent modifications, including ubiquitination, poly-ubiquitination (Fig. 3), sumoylation, neddylation, ADP-ribosylation, acetylation, methylation, and possible other less studied modifications such as nitrosylation and succinylation. For example, the mediator protein BRCA1 (together with BARD1) functions as an E3 ubiquitin ligase to ubiquitinate proteins involved in DSB repair and gene expression. Some of these protein covalent modifications occur on preexisting proteins that are assembled into complexes at the damage sites (Fig. 3). However, covalent modifications in DDR can also occur on proteins that are induced in the delayed responses to regulate biological processes other than checkpoints and repair (Fig. 1). In other words, protein covalent modifications participate in the *immediate* and the *delayed* responses to DNA damage.

Assembly of DNA Damage Signaling Complexes at DSB

Live cell imaging technology combined with laser micro-irradiation to generate DSB of defined patterns has observed a series of temporally distinct steps in the *immediate* response to DSB lesions (Fig. 3). Recruitment of the MRN complex and ATM at the DSB sites is followed by ATM acetylation, auto-phosphorylation, and the phosphorylation of H2AX (the ATM-phosphorylated H2AX is commonly known as γH2AX). Formation of γH2AX occurs initially at or near the DSB site and is then extended outward from the break site for several megabases. The mediator MDC1 is recruited to the DSB sites by binding to the phospho-epitope motif in γH2AX with its tandem BRCT domains (Fig. 3). MDC1 is then phosphorylated to generate binding sites for the FHA and BRCT domains of NBS1 in the MRN complex (Fig. 3). Other phospho-epitopes in MDC1 bind to the FHA domain of an ubiquitin ligase RNF8, which ubiquitinates H2A and H2AX at the DSB sites. The ubiquitinated histones then recruit another ubiquitin ligase RNF168 (Fig. 3). The polyubiquitin chains then recruit additional factors, such as the RAP80 protein, which contains a pair of ubiquitin interacting motifs (UIMs) that bind to polyubiquitin chains. RAP80, together with a coiled-coil scaffold protein Abraxis, in turn, create binding sites for BRCA1, which promotes homologous recombination to repair the DSB. Together, these live cell-imaging results illustrate the complexity of protein assembly at DNA lesions (Fig. 3).

Downstream Biological Effects

Cell Cycle Checkpoints

DNA damage activates three major checkpoints to halt the progression of the cell cycle (Fig. 4). The G1/S checkpoint is activated in G1 cells to inhibit S-phase entry. The intra-S checkpoint is activated in S-phase cells to prevent the not-yet-activated origins from initiating DNA replication. The G2/M checkpoint is activated in G2 cells to inhibit the entry into mitosis. The cell cycle checkpoints are triggered by protein phosphorylation that is readily reversible upon protein dephosphorylation so that cell cycle progression can resume after DNA lesions are repaired (Fig. 4).

G1/S checkpoint

A critical downstream effector in G1/S checkpoint is Cdc25A. DNA damage induces the phosphorylation, nuclear exclusion, and degradation of Cdc25A through PIKK-Mediator-CHK1/2. Inactivation of Cdc25A prevents the activation of Cdk2/Cyclin to block the initiation of DNA replication (Fig. 4). The G1/S checkpoint is an *immediate early* response to DNA damage as it is activated by protein phosphorylation within minutes of lesion detection. In mammalian cells, persistence of DNA lesions can prolong the G1/S checkpoint via the upregulation of p21/Cip1, which directly binds to and inhibits the Cdk2/Cyclin complexes. This p21Cip1-mediated G1 arrest is a *delayed* response as it takes hours for the transcription and the translation machineries to produce this protein above the levels of Cdk2/Cyclin complexes.

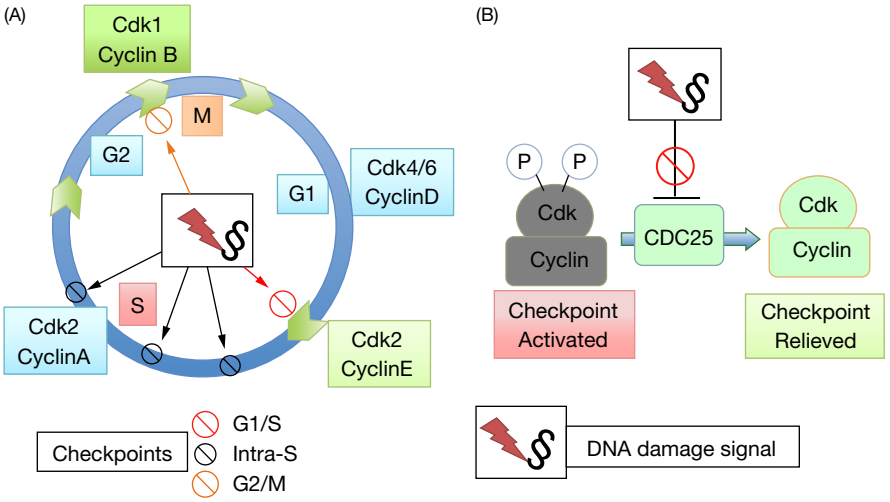

Fig. 4 DNA damage activates cell cycle checkpoints. (A) Cell cycle progression is coordinated by Cdk/Cyclin. D-type cyclins are expressed in G1 to activate Cdk4 and Cdk6. E-type cyclins are expressed in late G1 to stimulate G1/S transition by activating Cdk2. A-type cyclins are expressed throughout S and G2 to activate Cdk2. B-type cyclins are expressed in late G2 and early M to stimulate G2/M transition by activating Cdk1. DNA damage activates three checkpoints: the G1/S checkpoint (red) inhibits the entry of G1 cells into S-phase by blocking the initiation of DNA replication, the intra-S checkpoint (black) inhibits firing of replication origins that have not been activated in S-phase cells, the G2/M checkpoint (orange) inhibits the entry of G2 cells into mitosis. (B) Cell cycle checkpoint is activated when Cdk/cyclin kinase activity is inhibited. Cdc25 phosphatase, which dephosphorylates Cdk, is a critical activator of Cdk/cyclin kinase. In response to DNA damage, PIKK phosphorylates and activates the checkpoint kinases (CHK1 and CHK2) to phosphorylate, sequester, and degrade Cdc25, thus inhibiting cell cycle progression.

Intra-S checkpoint

The intra-S checkpoint is a transient inhibition of DNA replication triggered by DNA damage in S-phase cells. The eukaryotic genome is divided into tens of thousands of replication units (replicons), each with an origin where replication initiates. These replication origins are activated (fired) nonsynchronously throughout S-phase, with the timing of origin firing being dependent on the chromatin conformation and other factors. When activated, the intra-S-phase checkpoint prevents the firing of uninitiated origins (Fig. 4). The ATM kinase activates an intra-S checkpoint that requires the phosphorylation of SMCs, which are components of the sister chromatin–cohesion complex. The ATM-induced intra-S checkpoint is an *immediate early* and *short-lived* response, possibly because the resumption of DNA replication can facilitate repair.

G2/M checkpoint

The G2/M checkpoint mechanism is activated to prevent damaged cells from entering into mitosis. The Cdk1/Cyclin B kinase complex, also known as the Mitosis Promoting Factor (MPF), is the activator of mitotic entry. During late S and G2 phases of the cell cycle, Cdk1/Cyclin B is inhibited through threonine (Thr) and tyrosine (Tyr) phosphorylation of Cdk1 by the Wee1 kinase. Dephosphorylation of Cdk1 by the Cdc25 phosphatases (Cdc25A, B, and C) activates MPF to initiate mitosis (Fig. 4). DNA damage causes the inactivation of all three Cdc25 phosphatases through the actions of PIKK and checkpoint kinases to prevent MPF from being activated and thus block cells in G2. The p38 family of stress-activated protein kinases and the Polo-like kinases (Plk1 and Plk3) can also inhibit MPF to activate G2/M checkpoint.

Gene Expression

The upregulation of p21Cip1 followed by the cell cycle arrest in G1 is one of the best established examples for how gene expression controls the cellular responses to DNA damage. DNA damage alters the expression of protein-coding mRNA as well as long non-coding RNA (ncRNA) and microRNA (miR) at the levels of transcription, splicing, and miR biogenesis.

Transcription

The most well-studied transcription effector in DDR is the tumor suppressor p53, which is a classical transcription factor with a trans-activating domain (that interacts with transcription coactivators), a sequence-specific DNA binding domain, and an oligomerization domain. In response to DNA lesions, PIKK and CHK2 phosphorylate p53, MDM2 (an E3 ubiquitin ligase that targets p53 for degradation), and several other proteins to cause the stabilization and activation of p53. The activated p53 binds to enhancers containing p53-responsive elements (p53-RE) that are found in many promotes and enhancers. While p53 activation is a universal response to DNA damage across mammalian cell types, the tissue-specific responses to DNA damage are mediated by the combinatorial effects of p53 and many other tissue-specific transcription factors.

Alternative splicing

Alternative splicing of nascent RNA is a key mechanism for diversifying the coding capacity. Downstream of DNA damage signaling are effectors that regulate alternative splicing. For example, DNA damage induces covalent modifications of splicing factors to skip or to include exons, thus altering the relative levels of protein isoforms in damaged cells. Alternative splicing of DDR signal transducers themselves, such as p53 and its related p63 and p73, can have deterministic influence on the biological outcomes. However, current knowledge on DNA damage-induced alternative splicing remains insufficient to identify such deterministic effects, possibly because of the highly context-dependent nature of splicing regulation and interactions among protein isoforms.

MicroRNA biogenesis

MicroRNAs (miRs) are small (~22 nt) single-stranded noncoding RNAs that are loaded into the RNA-induced silencing complexes (RISCs) and function as guides to target specific mRNAs for translation inhibition or degradation. The DDR-activated p53 can stimulate transcription initiation from specific miR genes, with the miR-34 family being the most notable example. The biogenesis of mature miRs requires (a) transcription of primary microRNA, pri-mir, that is generally a long RNA, (b) cleavage of pri-mir by the microprocessor complex (consisting of Drosha and DGCR8) to generate a ~70 nt precursor microRNA hairpin, pre-mir, which is exported to the cytoplasm, and (c) processing of pre-mir by Dicer to form the mature miR that is loaded into the RISC complex. In response to DNA damage, the processing of pri-mir to pre-mir and from pre-mir to mir can be stimulated by ATM-dependent phosphorylation of specific RNA binding proteins. The ABL tyrosine kinase phosphorylates DGCR8 to stimulate pri-mir-34c processing to pre-mir-34c.

The biological functions of miRs are highly dependent on the cellular context, because each miR is designed to target a large battery of different mRNAs. With its interesting features of stability and versatility in target selection, DNA damage-induced microRNAs can play important roles in the execution, the maintenance, or the termination of downstream biological effects in DDR.

Chromatin Modifications

Chromatin modifications control the epigenetic landscape of a genome; thus, alterations in chromatin can have a profound and overarching influence on gene expression. Generally speaking, chromatin modifications involve regulations of: (a) the composition of histone isoforms in the nucleosomes; (b) the covalent modifications, for example, phosphorylation, acetylation, methylation, ubiquitination, sumoylation, etc., of histones; and (b) the positioning of nucleosomes. Each of these chromatin regulatory mechanisms is engaged in DDR to promote lesion recognition, repair, and signal transduction. As discussed above, PIKK-mediated phosphorylation of histone H2AX generates γH2AX (Fig. 3) that functions as a chromatin marker for the assembly of repair and signaling complexes. Phosphorylated γH2AX also recruits the INO80 complex that regulates the spacing of nucleosomes.

Cellular Differentiation

In DDR, the differentiation checkpoint describes a biological response in which DNA damage inhibits the differentiation of tissue stem cells (Fig. 5). This response has been observed in adult muscle satellite cells and embryonic muscle stem cells. This differentiation checkpoint delays terminal differentiation to allow time for DNA repair in lineage-committed muscle stem cells. With

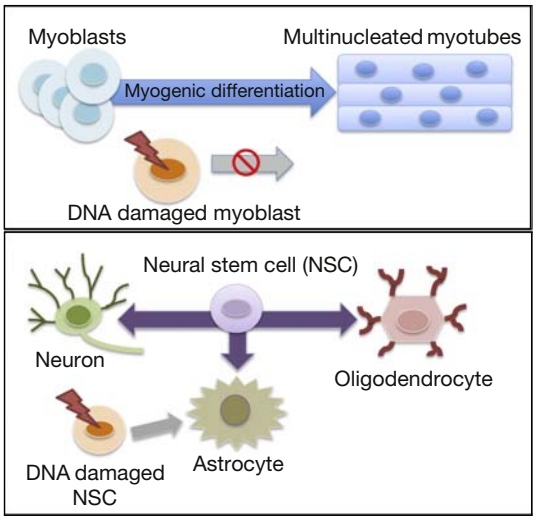

Fig. 5 Effects of DNA damage signaling on cellular differentiation. In committed muscle stem cells (myoblasts), DNA damage signal inhibits the myogenic transcription factors, in particular, MyoD, to block muscle differentiation. In multipotential neural stem cells, DNA damage signal promotes growth arrest and differentiation toward astrocytes but not other neural cell types.

multipotential neural stem cells, on the other hand, DNA damage stimulates growth arrest and accelerates differentiation toward astrocytes but not other neural cell types (Fig. 5). These findings show that DNA damage signals can regulate differentiation in stem cells and the effects are dependent on the stem cell types.

Cell Death

DNA damage activates distinct cell death mechanisms, including but not limited to apoptosis, necrosis, and mitotic death (premature senescence) (Fig. 6). Depending on the cell context, death induction can occur at widely different lesion concentrations. On one end of the spectrum is the induction of apoptosis by a single DSB. This hypersensitivity to DSB-induced apoptosis occurs in the developing central nervous system where a dose of ionizing radiation (IR) as low as 0.5 Gy is sufficient to activate ATM and p53-dependent apoptosis in neuroblasts within 6 h of irradiation. This hypersensitivity to IR-induced apoptosis is more of an exception than a rule as most mammalian cell types do not undergo apoptosis after 0.5 Gy of IR. On the other end of the spectrum is the resistance of tissue stem cells and terminally differentiated neurons or muscle cells to DNA damage-induced apoptosis. These resistances underlie the recovery of cancer patients after treatment with lesion-inducing agents, such as ionizing radiation (generates DSB) temozolomide (generates alkylated bases), cisplatin (generates ICL), and doxorubicin (generates DSB). The finding of such widely divergent sensitivity suggests that the death response in DDR is controlled not only by the concentrations and/or the persistence of DNA lesions, but it is also controlled by the proliferative status and the developmental lineages of the damaged cell (Fig. 6).

Apoptosis

The word "apoptosis" was coined to describe a specialized form of suicidal cell death that is characterized by the morphological features of chromatin condensation and degradation, as well as cell shrinkage and fragmentation. The condensed cell fragments (apoptotic bodies) express surface-exposed "eat-me" signals that stimulate their uptake by macrophages or other healthy cells. This death mechanism is employed in embryonic development to eliminate excess cells. Apoptosis also eliminates many (but not all) types of terminally differentiated cells throughout adult life.

In DDR, apoptosis induction requires alterations in gene expression (transcription initiation, alternative splicing, microRNA biogenesis). The most well established apoptotic pathway in DDR is that of p53-dependent transcription of pro-apoptotic genes, for example, PUMA (BBC3) and NOXA (PMAIP1). PUMA and NOXA are BH3-only members of the BCL2 family of apoptosis regulators. Accumulation of pro-apoptotic PUMA and NOXA proteins together with reduction in antiapoptotic BCL2, BCLxL proteins cause BAX/BAK-dependent release of cytochrome *c* from the mitochondria to activate the apoptosome and the effector caspases that bring about the morphological features of apoptosis.

It should be noted that p53 activation is an *immediate early* response in DDR, mediated by PIKK phosphorylation of MDM2 and p53. However, apoptosis execution is a *delayed* response and only occurs in some but not other cell types. Because activated p53 not only stimulates pro-apoptotic genes but also stimulates p21Cip1 to cause G1 arrest and premature senescence (Fig. 6), p53 activation is necessary but not sufficient to determine the choice of apoptosis in DDR. Generally speaking, DNA damage is more likely to induce apoptosis in highly regenerative tissue where there is continuous turnover of differentiated cells.

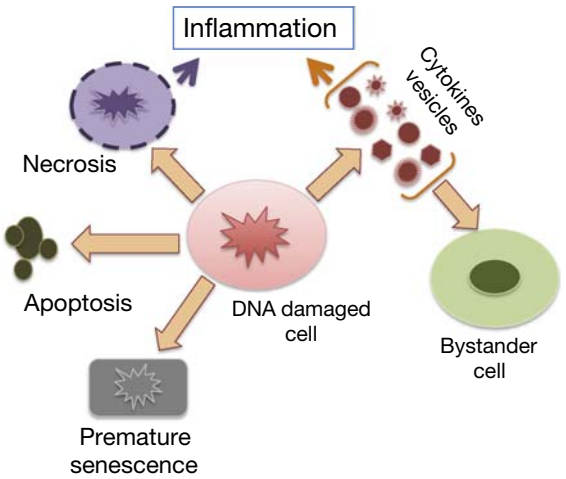

Fig. 6 Cell death choices, cell–cell communication, and the induction of inflammation in DDR. A cell suffering from DNA damage (red) can choose three types of death: namely necrosis, apoptosis, or premature senescence. The senescent cell is not physically dead but it is dead to mitosis as senescence is an irreversible cell fate. A damaged cell can communicate with neighboring bystander cell by secreting cytokines and vesicles. The DNA damage can also trigger tissue inflammatory responses that are stimulated by those factors secreted by the damaged cell or dumped by a damaged cell that underwent necrosis.

Even within a single cell type, the timing of apoptosis execution is variable, depending on the status of cell cycle. The best example to illustrate this timing variation is with neuroblasts (hypersensitive to IR-induced apoptosis) in the developing central nervous system. Experimenting with three different genetically engineered mouse strains that are knockout for ATM, p53, or with a p53 mutant lacking the ATM phosphorylation site, it can be established that IR-induced neuroblast apoptosis absolutely requires the ATM-p53 pathway. Although ATM phosphorylation of p53 is activated immediately after IR, apoptosis occurs 6 h after IR in neuroblasts that are out of S-phase at the time of irradiation. However, apoptosis only occurs 24 h after IR in neuroblasts that are in S-phase at the time of irradiation. How S-phase cells suppress apoptosis execution despite the activation of ATM and p53 is not yet understood.

Necrosis

Necrotic cell death is characterized by the loss of membrane integrity, cell bursting, and the release of cellular content. Necrosis can be accidental or regulated. The necrotic death that is actively induced by stress signals has been referred to as "*programmed necrosis*" or *necroptosis*. Upon infections or injuries, several inflammatory cytokines, for example, tumor necrosis factor-alpha (TNF), stimulate programmed necrosis of cells in the vicinity of the injuries to amplify the inflammatory signals. Either accidental or regulated, necrotic cell death contributes to the inflammatory responses triggered by infections or injuries (**Fig. 6**). In the most general and simplified terms, necrosis is activated when ATP (energy source) and/or NADH/NADPH (reducing power) become depleted and can no longer support the integrity of the plasma membrane. TNF-induced necrosis has been linked to the formation of a "mitochondrial attack complex," which may also mediate necrosis activated by calcium and reactive oxygen species.

In DDR, necrosis activation has been linked to the depletion of NAD by poly-ADP-ribose polymerase (PARP), which is a class of enzymes that convert NAD into poly-ADP-ribose chains on target proteins. PARP1 is an abundant chromatin protein that is activated by single-stranded ends in DNA and it can add poly-ADP-ribose onto a large number of proteins to stimulate DNA repair. Under conditions when excessive lesions or futile repair causes the accumulation and persistence of single-stranded ends, the continuous activation of PARP1 can lead to NAD depletion to trigger programmed necrosis. Other pathways linking DNA damage to regulated necrosis are under active investigation.

Mitotic death (premature senescence)

Mitotic death is a phrase coined by radiobiologists to describe IR-induced "death to mitosis." In the literature, this phrase is also used to describe *mitotic catastrophe* where cells die from catastrophic failure in chromosome segregation. In DDR, mitotic death and mitotic catastrophe are activated by different mechanisms. The death to mitosis is a premature senescence (**Fig. 6**), describing a prolonged or a permanent growth arrest in response to DNA damage. In DDR, premature senescence is induced in part through p53-dependent upregulation of p21Cip1, which inhibits Cdk2/Cyclin complexes to prevent phosphorylation of the RB family of pocket proteins, including RB, p107, and p130. The dephosphorylated RB-family proteins promote the assembly of repressive chromatin complexes at pro-proliferation genes to cause growth arrest. In DDR, mitotic catastrophe is induced when chromatin condensation and spindle assembly occur on incompletely replicated DNA to cause chromosome fragmentation. This event occurs as a result of failures to activate or to maintain the G2/M and/or the spindle checkpoints in cells suffering from DNA damage.

Cell–Cell Communications

The initiation of DDR occurs within the cell that suffers directly from damage to its genomic DNA. Interestingly, DDR can also be propagated to neighboring cells that are not directly targeted by genotoxins. This propagation of DDR is demonstrated by media transfer experiments, in which media conditioned by irradiated cells can activate DDR in naïve, non-irradiated, bystander cells. The radiation-induced bystander effects (BSE) result from cell–cell communications where irradiated cells produce factors to induce DDR in non-irradiated bystander cells. The directly irradiated cell can affect neighboring non-irradiated cells through gap junction communication. The directly irradiated cell can also secrete factors to communicate with other cells in its vicinity (**Fig. 6**). In whole animals, DNA damage inflicted in one part of the body can generate DDR at a distance from the site of damage. These "off-field" or "abscopal" effects may involve production of cytokines, chemokines, and vesicles by the DNA-damaged cells. For example, IR can stimulate the directly targeted cells to produce CSF1 that attracts macrophages to the tissue microenvironment where the DNA-damaged cells reside. These activated macrophages can then elaborate an inflammation reaction with long-range effects on other tissues. Because radiation and genotoxins have remained as the mainstay cancer therapeutic modalities, mechanistic understanding of the bystander and abscopal responses to DNA damage in the body is likely to provide new insights on how to mitigate the side effects and enhance the efficacy of cancer therapy.

Prospective Vision

Basic Research

DNA is the blue print for all biological processes; thus, it is not surprising to find that DNA damage activates a wide array of responses. This chapter describes a framework for DDR, from molecules to cells to organisms. The present framework, however,

is still rather primitive and based mostly on studies in model systems such as yeast, mouse, and cultured cells. While model system research is continuingly required to address many pressing questions on the molecular mechanisms of DDR, future attention should be paid to the human tissue and cell-type specificity of these processes in order for us to understand the relevance of DDR in human diseases. The DDR in different human cell types, tissues, and the whole organism needs to be investigated directly in the human systems. In particular, how cells of different developmental lineages and proliferative potential decide to live or to die, and how apoptotic versus necrotic cell death affects neighboring or distant cells, are important but as yet unsolved problems. Because DNA damaging agents are widely used to treat many different cancer types, the ongoing Cancer Genomics efforts in finding genetic and genomic determinants for tumor response to genotoxic therapies can be leveraged to expand the knowledge of DDR in the human body.

Cancer Translational Research

Knowledge gained from model organism research on DNA repair, which is the most highly conserved mechanism in DDR and is therefore readily applicable to the human system, has been translated to improve or develop cancer therapies.

The best example for how knowledge on DNA repair can impact cancer therapy is that of PARP inhibitors, which were developed to target cancer with defects in homologous recombination (HR). PARP (poly-ADP-ribose polymerase) is activated by single-stranded DNA ends to facilitate DNA repair. PARP is not found in yeast cells, and its activity is not essential to cells with competent HR repair However, HR-defective cells become dependent on PARP and are thus sensitive to the PARP inhibitors. In the clinic, PARP inhibitors have improved progression-free survival, although not overall survival, of patients with BRCA1 or BRCA2 mutant cancers. The development of PARP inhibitors to target HR-defective cancers has provided the proof of concept that DDR defects in cancer cells can be exploited to develop targeted therapies.

Cancer cells with HR defects are also hypersensitive to platinum-based drugs that generate ICLs in the genomic DNA. Because platinum resistance can be linked to recovery of HR function such as reversion of BRCA2 mutation back to wild type, deliberate disruption of HR function could in theory enhance the efficacy of platinum-based therapy. A flurry of research activities are ongoing in the public and the private sectors to find drugs that target DNA repair in cancer cells.

DNA repair defects can also impact cancer immunotherapy as exemplified by the increased response of MMR-defective cancers to immune checkpoint blockade antibodies. As discussed above, MMR corrects replication errors and MMR-defective cancer cells suffer from hypermutations. The increased mutation rate causes a higher probability in the expression of neo-antigens to trigger antitumor immunity. In patients with MMR-defective cancer, therapeutic blockade of immune checkpoints, therefore, is more likely to activate tumor-specific cytotoxic T-lymphocytes to kill tumor cells expressing neo-antigens that are generated as a result of DNA repair defects.

Given the already established therapeutic impacts from the current knowledge on DDR, it is not unreasonable to anticipate future developments of therapies to target not only repair but also the other DDR defects in cancer as we gain further understanding on DNA damage response in the human body.

Cervical Cancer: Screening, Vaccination, and Preventive Strategies

Paolo Giorgi Rossi, AUSL Reggio Emilia, IRCCS, Reggio Emilia, Italy
Francesca Carozzi, ISPO, Cancer Prevention and Research Institute, Florence, Italy

Glossary

Ascertainment (second-level test) The test or set of tests used to ascertain the presence of a disease or clinically relevant lesion in women positive to first-level test and, in case of an algorithm including a triage test, to the triage test as well. In cervical cancer screening guidelines for high-income countries, ascertainment is always colposcopy with colposcopy-guided biopsy; see-and-treat strategies are not recommended. Treatment should follow a histological diagnosis on biopsy.

Cotesting This term defines a screening algorithm in which two primary screening tests are performed in parallel; women are managed according to the results of both tests. This strategy has been proposed for HPV and Pap test by the US guidelines. The rationale is to maximize sensitivity, although the number of false positives and the number of tests needed to screen the population do increase. It is the opposite of the triage strategy, in which two tests are performed in sequence, the second only if the first one is positive.

Detection rate The number of clinically relevant lesions found by screening divided by all the screened women.

Organized screening program An organized preventive intervention aimed at screening the population in which the target population, the testing protocols, including age to start and stop screening, interval between tests, management of abnormal tests and treatment are all clearly defined. A monitoring and quality assurance system is also in place. Programs are population-based if they actively invite the entire target population on a regular basis. The alternative model of care is opportunistic (or spontaneous) screening, where a physician takes the opportunity of any contact with each individual to recommend or prescribe the screening test.

Participation rate The proportion of women participating in the screening program out of the total target population. In the absence of an organized screening program, this indicator can be called test coverage or uptake; it is computed as the proportion of the population having had a test within the recommended interval.

Positive predictive value The probability that a woman who tests positive has a clinically relevant lesion, usually CIN2 or more severe.

Primary screening test The screening test that is performed first in the screening algorithm and the only one that is administered to the entire population. HPV DNA, Pap test and VIA are recommended as primary screening tests.

Referral rate The proportion of women that are referred to second-level test or ascertainment.

Regressive lesion In the natural history of cervical neoplasia, HPV-induced lesions often regress. Cervical intraepithelial neoplasia grade 1 (CIN1) is typically a regressive lesion; its probability of progression to a more severe lesion is so low that it is no longer considered a precancerous lesion. CIN grades 2 and 3, which are considered high-grade lesions and precancer, are highly regressive, but the balance between the risk of cancer and the very low morbidity related to the treatment favors surgical excision of these lesions. All guidelines therefore recommend it for CIN3 and most guidelines recommend it also for CIN2. In recent years, some authors have suggested that strict follow up can be appropriate for CIN2 in young women, when the probability of regression is higher.

Screening interval The period of time recommended between a negative screening test and the subsequent screening test. It defines the screening round, that is, the 3- or 5-year cycle in which a program should invite the whole target population to achieve complete invitation coverage.

Screening The systematic application of a test to a healthy population to detect a disease or its precursors early in order to begin treatment immediately, thereby improving prognosis or, in the case of targeting precursors of the disease, to avoid the onset of the disease.

Triage test In certain screening algorithms, women who test positive to the primary screening test are referred to a triage test in order to distinguish between those who need immediate ascertainment and those who can be followed up, thereby avoiding referring too many women to ascertainment test, which can be invasive and resource-consuming.

Nomenclature

CIN Cervical intraepithelial neoplasia. See regressive lesion in the glossary for a distinction between different grades of CIN.

High-risk HPV A restricted group of HPV types that infect human mucosae and that can induce cellular transformation. They are associated with some epithelial cancers in humans, and are virtually a necessary cause of cervical cancer. High-risk HPV types include the 12 types classified by the International Agency for Research on Cancer (IARC) as surely cancerogenic for humans (group 1): types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59. Some available commercial tests also include types 68 and 66, classified as probably (group 2a) and possibly (group 2b) cancerogenic, respectively, by IARC.

 https://doi.org/10.1016/B978-0-12-801238-3.65138-3

HPV Human papilloma virus. DNA capsuled virus including >200 types which infect human skin and mucosae. Some of them produce papillomas and other flat lesions, which are mostly asymptomatic.
HPV DNA test Test for the presence of HPV DNA. In screening, the test should target only high-risk types and be validated on clinical endpoints, that is, having high sensitivity and specificity for clinically relevant lesions and not for any HPV infection (Meijer et al., 2009).
Pap test Papanicolaou test is a cytological analysis of cells scraped from the cervix. Cells can be put directly on a slide, thus obtaining a smear, or suspended in a fixative medium and then transferred onto a slide in thin layer (liquid-based cytology).

Introduction

Cervical Cancer Burden of Disease: The Role of HPV and Screening

It is estimated that every year, >527,000 new cervical cancer cases and 265,672 deaths occur worldwide. The vast majority of the burden—84% of cases and 87% of deaths—occurs in less developed countries (Bruni et al., 2017). Cervical cancer affects relatively young women, with incidence peaking at between ages 40 and 55, then plateauing or decreasing slightly.

Geographic distribution is extremely heterogeneous, ranging from an age-standardized rate of >50/100,000 in some countries of East and Central Africa, to <4/100,000 in many North African and Middle Eastern countries (**Fig. 1**A). There are large differences within Europe as well: Switzerland, Finland, and some Mediterranean countries have low incidence (about 4/100,000), while many Eastern European countries have an incidence of >20/100,000 (Bruni et al., 2017; Li et al., 2011).

Both molecular biology and epidemiological studies have demonstrated that cervical cancer is causally linked to human papillomavirus (HPV) infection; persistent infection of oncogenic HPV types (hereafter named hrHPV) is a necessary cause for the onset of high-grade precancerous cervical lesions (cervical intraepithelial neoplasia, CIN grades 2 or 3) and progression to invasive cancer (zur Hausen, 1999; Walboomers et al., 1999).

Among the hrHPV types, HPV16 is responsible of >65% of cancers worldwide, followed by HPV18 (Clifford et al., 2005; Bruni et al., 2017; de Sanjose et al., 2010; Plummer et al., 2016). The distribution of HPV types does not necessarily reflect the prevalence of infections in the healthy population; in fact, as cervical cancer is a relatively rare consequence of a very common infection, the proportion of cancers due to each type is mostly related to the ability of a certain type to induce cellular transformation (de Sanjosé et al., 2007; Guan et al., 2012). Based on epidemiological studies on HPV infection, CIN and cancer incidence distribution by age and through modeling studies, it is possible to estimate that the process from infection to cancer takes decades (Schiffman and Wentzensen, 2013; Baussano et al., 2013; Bruni et al., 2017), although this time varies according to the virus and to host factors that are not yet fully understood. The natural history includes long-lasting precancerous tissue modifications that can be detected through cytological or molecular tests and treated (Schiffman et al., 2016). The combination of all these characteristics of the cervical cancer pathogenetic process makes it possible to design an effective screening strategy. Observational studies based on time trend and geographical differences, as well more analytical case–control and cohort studies have shown that screening with Pap test can effectively prevent the incidence of cervical cancer through the identification and conservative treatment of preinvasive lesions (IARC, 2005). The impact of population-based programs with high test coverage of the population can be very strong, with a >80% reduction of incidence (Anttila, 2007; Quinn et al., 1999).

The prevalence of HPV infection (**Fig. 1**B), the most important risk factor, and the diffusion of effective screening programs, which is to date the most impactful preventive measure, explain most of the differences in cervical cancer incidence (Li et al., 2011; Giorgi Rossi and Ronco, 2013). In particular, countries with low screening coverage or ineffective screening programs show high variability in cervical cancer incidence, according to the prevalence of hrHPV infection in the population in previous decades, while countries with high screening test coverage and effective programs (**Fig. 1**C), which assure correct follow up and treatment, all have incidence below 10/100,000, with very small differences even when HPV prevalence is very different (Giorgi Rossi and Ronco, 2013). This phenomenon can be observed in women immigrating to high-income countries as well: they maintain the risk of their origin country for about 10 years or more after arrival (high if coming from countries with high prevalence of HPV and low if they come from low prevalence regions); afterward, thanks to having undergone more than one screening round, their excess risk is dramatically reduced. This is true even for women from high prevalence countries (Azerkan et al., 2008; Mousavi et al., 2012; di Felice et al., 2015).

The sexual revolution at the end of 20th century caused an epidemic of HPV infection in most western countries, but the consequences of this epidemic in terms of cervical cancer incidence have been more or less completely controlled by the spread of well-organized screening programs. Several epidemiologic studies provide evidence of this phenomenon (Bray et al., 2005a, b; Peto et al., 2004).

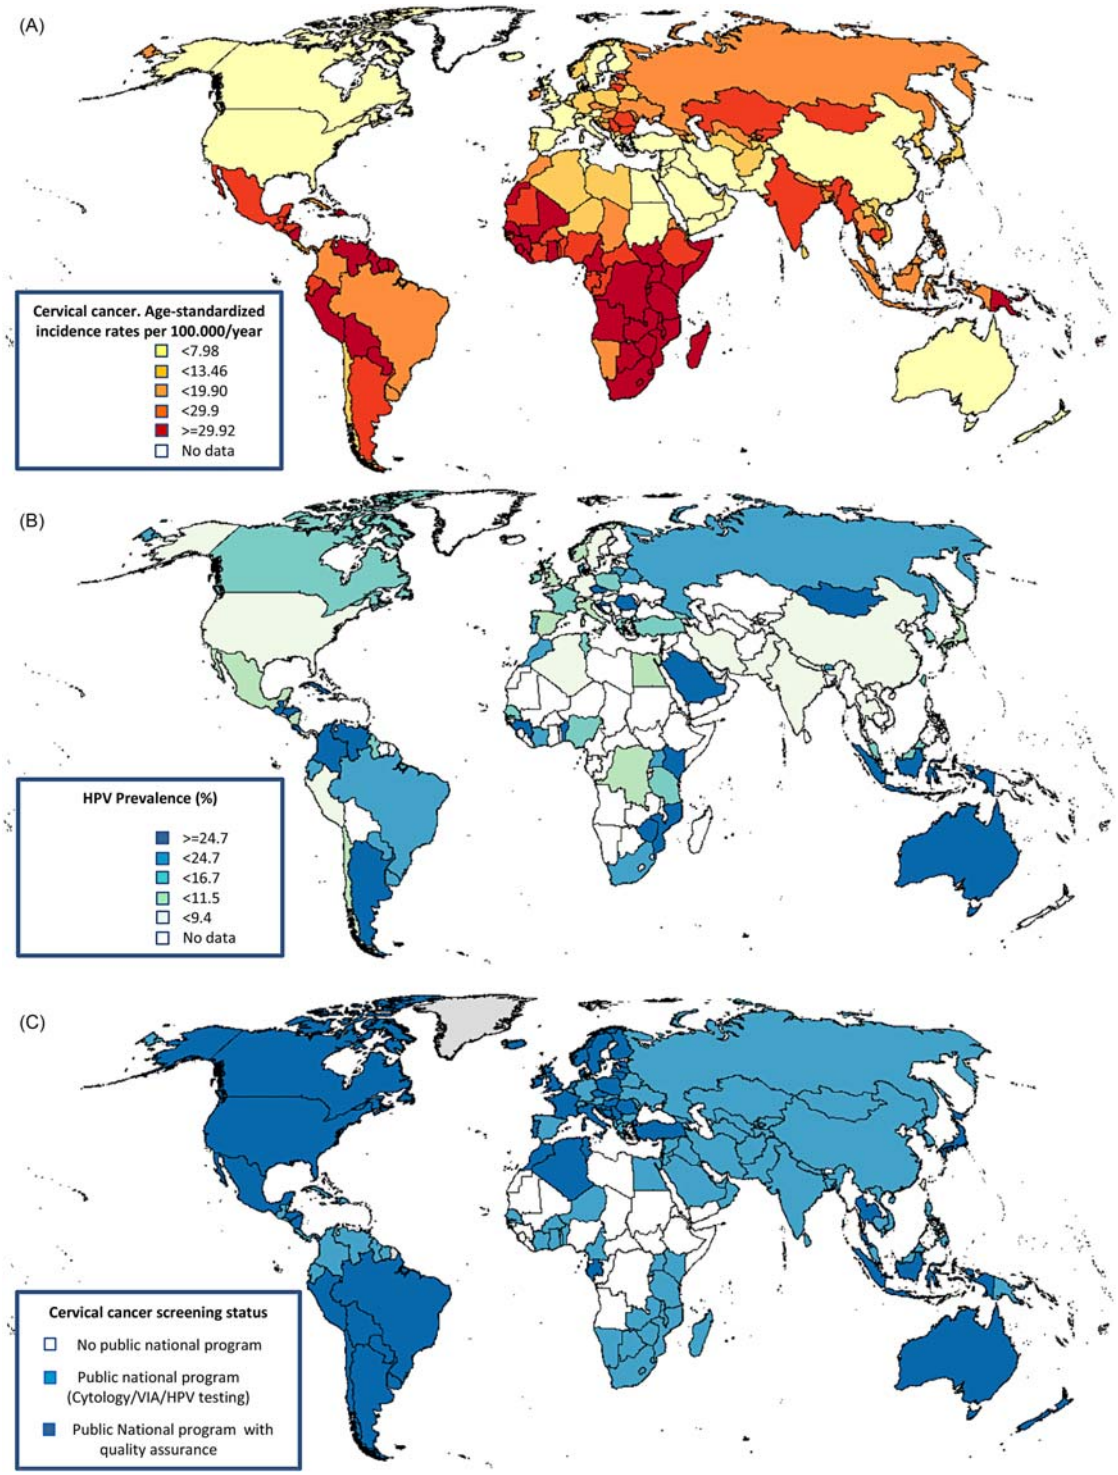

Fig. 1 Worldwide distribution of cervical cancer and its determinants. (A) Age-standardized incidence rates of cervical cancer in the world (estimates for 2012). Rates per 100,000 women per year. For Sudan, South Sudan: Estimate for Sudan and South Sudan. Data sources: Ferlay, J., Soerjomataram, I., Ervik, M., et al. (2013). *GLOBOCAN 2012 v1.2, Cancer Incidence and Mortality Worldwide: IARC CancerBase No. 11*. Lyon, France: International Agency for Research on Cancer. (B). Prevalence of HPV among women with normal cervical cytology in the world. The samples for HPV testing come from cervical specimens (fresh/fixed biopsies or exfoliated cells). Systematic review updated 30 June 2015 (Bruni et al., 2017). (C) Worldwide status of cervical cancer screening programs. Availability of a cervical cancer screening program: Public national cervical cancer screening program in place (Cytology/VIA/HPV testing). Countries may have clinical guidelines or protocols, and cervical cancer screening services in the private sector but without a national public program. Publicly mandated programs have a law, official regulation, decision, directive or recommendation that provides the public mandate to implement the program with an authorized screening test, examination interval, target group and funding and copayment determined. Self-reported quality assurance: Organized programs provide for a national or regional team responsible for

Pathogenesis

The Natural History of the Disease: Preinvasive Phase

The identification of HPV infection as the necessary cause of cervical cancer has led to an enormous improvement in the knowledge of its pathogenesis. HPV infection has been identified as a carcinogen for other sites as well, but cervical cancer accounts for most of the HPV-related burden of disease and is the only cancer with virtually 100% of population attributable fraction to HPV.

More than 200 HPV genotypes have been identified and grouped into different genera. Papillomaviruses are classified into types depending on L1 sequencing; a new type is defined when its genome differs by at least 10% from that of all other classified types (Burk et al., 2013). Out of the five genera of HPVs, four (beta, gamma, mu and nu) contain only viruses that infect cutaneous epithelia. The fifth, the alpha genus, is unique in that it contains HPVs tropic to both cutaneous and mucosal epithelia. The oncogenic HPVs are a subset of the mucosotropic alpha-HPVs.

Most of our knowledge about the natural history of HPV infection comes from studies conducted on the epithelium of the uterine cervix. Twelve types (16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, and 59), also known as high-risk types, have been classified as certainly carcinogenic to humans according to the International Agency for Research on Cancer (WHO and IARC, 2012). Low-risk types, including HPV6 or HPV11, generally cause benign diseases such as genital warts (Egawa and Doorbar, 2017), while other types classified as probably or possibly carcinogenic are rarely found in large series of cancers, so their oncogenicity remains to be clarified (IARC, 2007).

In contrast to low-risk HPV types, hrHPV can transform infected cells, although only a minority of hrHPV-infected individuals will develop precancerous lesions or invasive carcinomas during their lives.

The papillomavirus family is a remarkably heterogeneous group of viruses that share the same genome structure and organization (Bravo and Felez-Sanchez, 2015). A circular double-stranded DNA genome of approximately 8 kb is structured into three main regions: (a) the early region (E) encodes genes that are necessary for the viral cycle and has an important role in cell transformation (E1, E2, E4, E5, E6, and E7); (b) the late region (L) encodes the L1 and L2 capsid proteins; (c) the upstream regulatory protein, referred to also as the long control region, is a noncoding region containing the replication origin and transcription factor-binding sites that contribute to regulate DNA replication by controlling the viral gene transcription.

The expression of E6 and E7, together with that of E1, E2, E4, and E5, is essential for viral genome replication and virion synthesis and release, but they also play a key role in cell transformation (Doorbar et al., 2012).

The HPV life cycle begins with the infection of the basal layer through microtraumas that compromise the epithelial barrier (Stubenrauch and Laimins, 1999). HPV genome is maintained at low copy number in the infected host basal cells. Upon differentiation of epithelial cells, the virus replicates to a high copy number and expresses the capsid genes (L1 and L2), resulting in the production of new progeny virions that are released from the epithelial surface. For persistence, HPV must infect basal cells showing stem cell-like features that are still able to proliferate (Egawa et al., 2015). This phenomenon is far less common in low-risk HPV types. The epithelial transition zones, and especially the endo-/ectocervix, are regions more susceptible to carcinogenesis by HPV type (Yang et al., 2015). High-risk types are more prone to activate cell proliferation in basal and differentiated layers, thereby promoting the transition from a productive infection to an infection that can activate several pathways essential for epithelial transformation (de Sanjose et al., 2017). One plausible explanation of the increased oncogenic capacity of the high-risk types resides in the activity of the E6 and E7 oncoproteins. Although E6 and E7 activity is present in high- and low-risk types, its role in low-risk types is limited to increasing viral fitness and viral production and is largely insufficient to trigger the development of preneoplastic lesions and cancer (Schiffman et al., 2016). Key functions of the HPV oncogenes are immune evasion, E7-mediated degradation of pRB family members, E6-mediated degradation of p53 and PDZ binding domain proteins and E6-mediated upregulation of telomerase.

The main role of early E6 and E7 proteins in the carcinogenic process is through their inhibition of p53 and pRB tumor suppressors (Psyrri and DiMaio, 2008; McLaughlin-Drubin and Munger, 2008). E6 functions also include the activation of telomerase activity and deregulation of pathways involved in immune system response, of epithelial differentiation, of cell proliferation and of survival signaling. Besides cell cycle deregulation and proliferation, E7 enhances genomic instability and promotes the accumulation of chromosomal abnormalities. The deregulation of the cell cycle, the activation of the telomerase activity and genomic instability create a favorable environment for epithelial cell transformation. HPV integration can also drive the carcinogenic process through the inactivation of the E2 expression, the main inhibitor of E6 and E7, and the disruption of host genes because of the viral

implementation and require providers to follow guidelines, rules, or standard operating procedures. They also define a quality assurance structure and mandate supervision and monitoring of the screening process. To evaluate impact, organized programs also require ascertainment of the population disease burden. Quality assurance consists of the management and coordination of the program throughout all levels of the screening process (invitation, testing, diagnosis and follow up of screen-positives) to assure that the program performs adequately and provides services that are effective and in line with program standards. The quality assurance structure is self-reported as part of the national cancer programs or plans. For some countries, when $<$50% of its regions does not have a quality assurance plan, the country is categorized as not having quality assurance (Bruni et al., 2017). From Bruni, L., Barrionuevo-Rosas, L., Albero, G. et al. (2017). *Human papillomavirus and related diseases in the world.* Summary report 27 July 2017 Barcelona: ICO Information Centre on HPV and Cancer (HPV Information Centre). (Accessed 13/11/2017).

sequence insertion (McBride and Warburton, 2017). The carcinogenic process, initiated with E6 and E7 activation, needs to be complemented by the accumulation of additional alterations in the host gene to lead to the invasive cancer phenotype.

Growing evidence suggests that epigenetic alterations directly or indirectly related with E6 and E7 activity are common events during the early phases of epithelial malignization, and have been described as potential biomarkers for cervical cancer (Mirabello et al., 2016; Clarke et al., 2012).

High-risk HPV types have developed several mechanisms to avoid host immune response, which is important for viral persistence and progression to HPV-associated neoplastic diseases. One of the first strategies to avoid detection is to maintain a very low profile (Stanley et al., 2012; Kanodia et al., 2007). The HPV cycle is exclusively intraepithelial and not lytic, thus preventing the associated proinflammatory signal. As a result, the recruitment of antigen-presenting cells such as Langerhans cells (LC) and the release of cytokines that mediate the immune response are absent or very low after HPV infection. Other mechanisms of HPV immune evasion include the regulation of interferon signaling, inhibition of LC by E6 and E7 activity, inhibition of adherence molecules such as the CDH1 and modulation of intracellular signaling pathways. At some point during most HPV infections, the cell-mediated immune system is alerted to the infection, thereby inducing regression of infected cells and lesions (Stanley, 2012). The role of the humoral immune response in natural infection is not clear; many infected individuals do not seroconvert, leaving them vulnerable to subsequent infection by the same virus. This is in contrast with the extremely high levels of humoral antibodies and the protection they provide, which results from immunization with the HPV vaccine.

In addition to the viral characteristics, environmental or exogenous factors have long been identified as modifiers of the natural history of HPV infections leading to cervical cancer. Many of the early case–control studies were conducted in populations with low screening coverage for cervical cancer. The most relevant cofactors identified at the time that increased cervical cancer risk were long-term smoking, multiparity (International Collaboration of Epidemiological Studies of Cervical Cancer, 2006) and long-term use of hormonal contraceptives (International Collaboration of Epidemiological Studies of Cervical Cancer et al., 2007), with an average increased risk in HPV-positive women of 1.5–2 times (Castellsagué et al., 2002). The fact that HPV infection has higher probability of persistence in smokers than in nonsmokers should alert women of the increased risk and reinforce the message to quit smoking. In HPV-positive long-term oral contraceptive users, a closer surveillance for cervical disease may be advisable. Coinfection with sexually transmitted infections such as Chlamydia trachomatis has been inconsistently associated with the risk of progression to cancer. HIV has always been associated with HPV as a major cofactor inducing cervical cancer. The mechanism has been largely associated to the immunosuppression conferred by active HIV infection and not by a direct effect of HIV. Many HIV-infected women are now following antiretroviral therapy (ART); it is therefore expected that good compliance with treatment will be followed by a reduction of cervical lesions and cervical cancer in this population (Kelly et al., 2015).

Stages of HPV Infection of the Uterine Cervix

Oncogenic human papillomaviruses can subsist in the epithelium in three major infection stages, referred to as latent, permissive (productive) and transforming infection (Doeberitz and Vinokurova, 2009; Doorbar, 2006; Doorbar et al., 2012). It is thought that the virus initially gains access to the epithelial basal cells via minor breaches in the epithelium (Kines et al., 2009) and that it can establish a long-term, persistent infection within these cells. Once taken up by the basal cells, the virus is transported to the nucleus, where the viral circular genome is released.

When these infected cells differentiate and move up toward the surface of the epithelium, high-level viral replication and gene expression is induced (**Fig. 2**). Virions are assembled in the superficial layers and are released from the epithelium in viral-laden squames. This strategy of infecting self-renewing cells ensures long-term viral persistence, while restricting high levels of viral proteins to more differentiated layers of the lesion is thought to help the virus escape detection by the immune system.

During the latent infection stage, the HPV genomes are believed to reside in the infected basal cells in an extra-chromosomal (episomal) physical state at low copy numbers (Kalantari et al., 2009; Maran et al., 1995). Viral activity appears to be highly restricted, potentially mediated by epigenetic silencing of the viral genome (Prigge et al., 2017). The latent stage of HPV infection generally remains clinically unapparent. However, it may account for reactivation of a clinically meaningful HPV infection later in life, for example, under circumstances of immunosuppression (Maglennon et al., 2014).

In contrast, the permissive stage of infection is characterized by high viral gene expression, replication of the virus at high copy numbers and packaging and release of newly synthesized infectious viruses at the epithelial surface (Doeberitz and Vinokurova, 2009). The expression of viral genes occurs in close relation to epithelial differentiation during the permissive infection stage. Expression of the HPV E6 and E7 oncogenes primarily occurs in the basal and suprabasal cell layers and is tightly controlled. This limited expression allows for controlled cellular proliferation, resulting in the multiplication of cells that carry viral genomes (Pyeon et al., 2009). In the more differentiated cells of the superficial cell layers, genome packaging and virus assembly occur under the increased expression of the HPV late genes L1 and L2. The infectious viruses are subsequently released from decaying, fully differentiated cells at the epithelial surface. From a histopathological point of view, the permissive infection stage is regularly accompanied by distinct morphologic hallmarks, the so-called koilocytes, which represent virus replicating cells and are characterized by nuclear hyperchromasia, perinuclear vacuolization and a thickened cytoplasmic rim. These cells are frequently found in cervical intraepithelial neoplasia grade 1 (CIN1) or low-grade squamous intraepithelial lesions of the uterine cervix (LSIL), respectively (Prigge et al., 2017).

A shift from the permissive to the transforming mode of infection may occur in a minority of HPV infections, at least through the start of a new infection from the virions released by the permissive infection. In contrast to the latent and permissive HPV infection

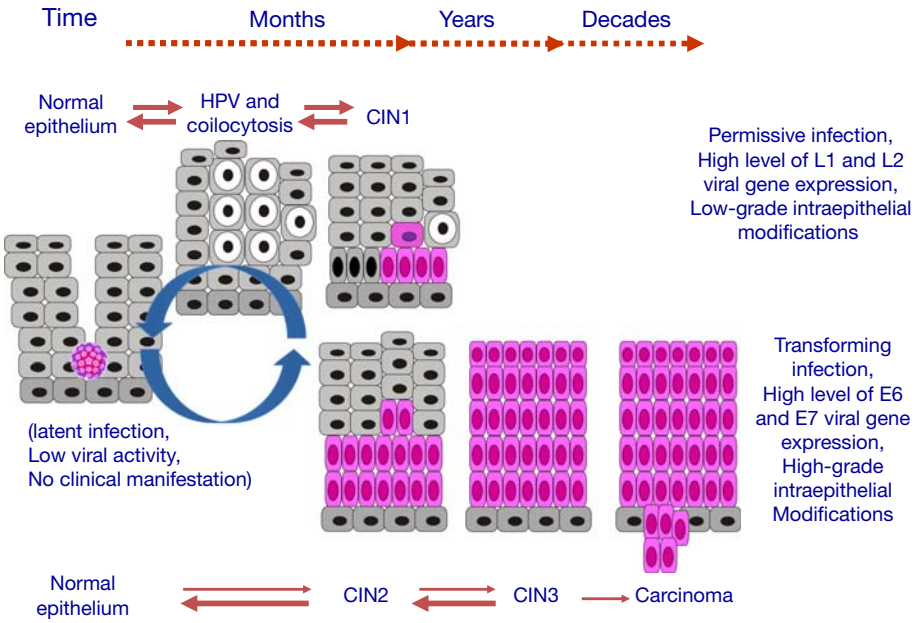

Fig. 2 Molecular and histological processes during HPV infection and neoplastic transformation in the cervix. Infection of basal cells is thought to occur through microtraumas that compromise the epithelial barrier. Infections can be latent, permissive, or transforming. During the latent infection, the HPV genomes are believed to reside in basal cells at low copy numbers; viral activity is restricted, and there are no clinical manifestations. However, latent infection may account for reactivation of a clinically meaningful HPV infection later in life, for example, under circumstances of immunosuppression. In permissive infections the virus replicates itself completely, leading to cellular death and releasing the virions from the epithelium in viral-laden squames; capside proteins encoded by the viral genes L1 and L2 are produced; the cells and the tissue morphology are that of low-grade intraepithelial neoplasia (CIN1 or LSIL); the process takes some months, and infections usually clear after 1 or 2 years. In the transforming infection the virus does not replicate itself, but tends to stimulate cell replication; the viral proteins coded by E6 and E7 genes are highly expressed; only E6 and E7 proteins of cancerogenic HPV types, that is, the high-risk types, can inhibit p53 and pRB tumor suppressors; cell and tissue morphology are that of high-grade intraepithelial lesions or cancer. The whole process from infection to invasion generally takes 10–40 years although, in a very few cases, it may only take only 2–3 years; nevertheless, regression of high-grade lesions is common. The distinction between the modes of infections occurs very early, implying that CIN1 is not considered a precancerous lesion. The presence of infecting virions in the permissive infection makes a shift from permissive to transforming infection possible, through the start of a new infection.

stages, the transforming stage is characterized by a substantial upregulation of HPV E6 and E7 oncogene expression. Clinically and histologically, the transforming HPV infection stage may present as CIN grades 2 or 3 or high-grade squamous intraepithelial lesions (HSIL, both considered as precancerous lesion) or invasive cancer. Herfs et al. suggest that the shift from a permissive to a transforming stage of infection is restricted to specific cells in the squamocolumnar junction zone that are characterized by a distinct gene expression profile (Herfs et al., 2012).

HPV Prevalence, Acquisition and Clearance in the Population

HPV prevalence shows substantial geographical, sexual behavior and age-dependent differences. The majority of anogenital HPV infections are acquired through sexual contact, and acquisition is strongly determined by the number of sexual partners and their respective sexual behavior. The probability of transmission per single episode of intercourse is high compared with other sexually transmitted infections, and it occurs with skin to skin or mucosa to mucosa contact. A new infection can be detected soon after the first sexual contact with an infected partner, and most infections will still be detectable 1 year later (Winer et al., 2008; Moscicki et al., 2010a); about 30% of young women become infected within 24 months of their sexual debut (Gravitt, 2011).

As a result of this high transmission rate, HPV infections are very common in women younger than 35 years (de Sanjosé et al., 2007), with a peak in prevalence generally around 20–25 years of age. It is estimated that the vast majority of sexually active women in western countries have at least one infection during their life. Transmission is also common among women having sex with women, suggesting a different way of transmission compared to other STDs.

An abrupt decline in the prevalence of infection follows as a result of frequent clearance and reduced exposure to new partners. This pattern is consistent in populations all over the world and confirms that sexual activity is the main mode of transmission. Instead, the prevalence of genital infections in men shows no clear age dependence (Giuliano et al., 2011a).

While persistent oncogenic HPV infections are a major risk factor for the subsequent development of HPV-induced high-grade intraepithelial neoplasia (CIN) or invasive carcinomas, clearance of HPV infections in the cervical regions is common.

Following women over time has demonstrated that up to half of HPV infections clear within 6 months and that the great majority (>90%) clear within a few years after acquisition (Rodríguez et al., 2010; Winer et al., 2011). Innate and adaptive immune responses are interplayers in the resolution of such common infections (Schiffman et al., 2016). A Th1 proinflammatory response in the genital tract has been suggested as a potential mechanism for clearance (Scott et al., 1999), but cell-mediated immune response may be the most common mechanism.

Several recent studies have observed a differential pattern of the vaginal microbiome, with more abundant *Lactobacillus* spp. among women clearing the infection compared with those with persistent infections (Shannon et al., 2017; Brotman et al., 2014; di Paola et al., 2017). Others have identified bacterial vaginosis associated with persistence of HPV infections among pregnant women (Kero et al., 2017). More data are needed to fully understand how HPV infections are modulated by the vaginal environment.

HPV antibodies acquired through natural infection are observed in a limited number of infected people. A systematic review of the acquired natural immunity against subsequent genital HPV infection identified a range of seroprevalence estimates against HPV16 of 6.2%–45.5%, with a relative modest protection for HPV16 reinfection of 0.72 (0.62–0.82); it is thus unlikely to play a major role in clearance (Beachler et al., 2016).

In some circumstances, after follow up of a positive HPV test, HPV may simulate a cleared infection and thus go undetected. It is now accepted that HPV infection may be latent and controlled by a cellular immune surveillance environment in which viruses are kept in very low copy numbers, escaping its detection. Reactivation may occur under moderate (menopausal state, aging) to relevant immunosuppressive situations (Maglennon et al., 2014), with or without hormonal influence. This reactivation could explain the second peak in HPV prevalence observed in postmenopausal women in some populations.

Only a proportion of persistent infections progress via several infection stages toward neoplasia (Moscicki et al., 2006, 2014; Nyitray et al., 2011).

Persistent carcinogenic HPV infection clearly predicts the risk of cervical cancer in women (Ronco et al., 2014; Khan et al., 2005). Although persistence does not have a standardized definition, is a very relevant concept, as many populations undergoing screening using HPV tests will rely on measures of persistent infection. Munoz et al. defined persistence as those infections that last more than the median duration, but this concept is relevant for natural history studies. Others define persistence as two consecutive positive HPV DNA tests with undetermined time interval (Marks et al., 2012; Munoz et al., 2009).

Besides age, strong risk factors for the acquisition and persistence of an HPV infection and the subsequent development of neoplasia are immunosuppression and tobacco abuse (Schiffman and Kjaer, 2003; Rositch et al., 2013).

Irrespective of the time window, major determinants of HPV persistence are HPV type and viral load at first detection. It remains unclear whether age is a key element in persistence. However, in the prospective study by Munoz et al. previously described, median duration of HPV incident infection was longer for high-risk HPV types than for low-risk types and for HPV16. Women younger than 30 years had a longer mean duration for HPV16 infections (16.6 months), while women >30 years had a significantly shorter duration (9.5 months). Others suggest that persistence increases with age (Castle et al., 2011a).

Moreover, the presence of concomitant HPV infections, a phenomenon very common in younger populations, is reported not to influence the duration of infection (Campos et al., 2011).

During the period of persistent infection, there is no apparent immune detection of the virus (Stanley, 2012). This is partly due to the viral life cycle itself, which ensures that high levels of viral activity occur only in the upper, differentiated cell layers that are not exposed to immune defenses.

Conclusions

The pathogenesis of cervical cancer historically has been interpreted as a continuum from infection to cancer in which progression to a more severe lesion was always less probable than regression until invasive cancer. The nomenclature reflects this interpretation: from normal epithelium to CIN1, CIN2 and CIN3, or from low-grade lesions to high-grade lesions. As has emerged in this section, the molecular interpretation of these morphological stages progressively suggests that in fact two different pathways can be distinguished in the course of an infection: the permissive and the transforming mode (**Fig. 2**).

Some indirect molecular and clinical evidence suggests that this distinction between the modes of infections occurs very early: the viral methylation pattern of infection without any colposcopically and histologically detected CIN that will develop into a CIN3 in the subsequent 3 years is more similar to that of CIN3 than to that of CIN1 and of many CIN2 (Ronco et al., 2017); the probability of progression to CIN2 or 3, given an hrHPV infection, is the same whether in the presence of no detectable histological abnormality or whether a CIN1 is found (Mittal et al., 2017, Giorgi Rossi et al., 2013; Castle et al., 2011b; Sørbye et al., 2011), suggesting that CIN1 is not a necessary step for progression to abortive infections, but only the manifestation of an HPV infection, and therefore it represents the same risk as any initial detection of the virus.

Cervical Cancer Prevention

The identification of HPV infection as a necessary cause of cervical cancer has opened the way to two new prevention tools: vaccines and a molecular test for screening. Although the focus of this article is the transformation of screening, it is impossible to address

this issue without a brief description of the characteristics of the available vaccine and of the main strategies adopted for HPV immunization worldwide.

While HPV testing is an improvement on an existing preventive measure, that is, screening with Pap test, vaccination is a completely new approach. Despite the fact that vaccination has the potential to decrease or to entirely eliminate the need for screening in the future, the two interventions will both be used until the near future. In fact, the vaccine is not effective in women who are infected, and mass vaccination has thus far been implemented for teenagers only (Obel et al., 2015; Dorleans et al., 2010; de Vuyst et al., 2015; GAVI Alliance Board, 2012; Bosch et al., 2016). Finally, to date, most women have been vaccinated only for HPV 16 and 18 and are thus still at risk of cervical cancer for other HPV types; this reduced but not negligible risk will require different, less intensive screening (Ronco and Giorgi Rossi, 2017; Franco et al., 2006, 2009; Cuzick et al., 2006). Screening in vaccinated women and how to implement these preventive measures more quickly is the focus of the "Prospective Vision" section of this article.

Vaccination

The existing vaccines and the proof of efficacy and safety

There are three registered vaccines against HPV: Cervarix (GlaxoSmithKline GSK, London, UK) covers HPV16 and 18; Gardasil (Merck, Kenilworth, New Jersey, USA) covers HPV 16, 18 and the low-risk types 6 and 11; Gardasil9 (Merck, Kenilworth, New Jersey, USA) covers the four types covered by Gardasil plus five other high-risk types: 31, 33, 45, 52 and 59. All the vaccines have shown almost complete protection against persistent vaccine-type HPV infections and precancerous lesions in studies recruiting 16–26-year-old women (Lehtinen et al., 2012; Joura et al., 2015). Efficacy was limited only to those women that were not infected at the time of vaccination. Studies on clinical outcomes have been conducted only in women older than 16, but the most interesting target population in order to prevent infections are preadolescent girls. Since it is impossible to observe clinically relevant outcomes in a population that is still not sexually active, studies in 9–12-year-old girls could only measure the immunogenicity of the vaccine. These so-called "bridging studies" have shown that vaccines are more immunogenic in girls than in young women (Schiller and Müller, 2015). So far, vaccines have shown long-term protection of up to at least 10 years (Elfstrom et al., 2014; Kjaer et al., 2009). More recent studies have shown protection also in women up to age 40 (Castellsagué et al., 2011; Skinner et al., 2014) and in males for precancerous anogenital lesions (Giuliano et al., 2011b). Cross protection against nonvaccine types, in particular against 31, 33 and 45 for Cervarix (Wheeler et al., 2011) and 31 for Gardasil (Brown et al., 2009), has been observed. The vaccines are safe, and no serious adverse effect associated with the vaccine has been demonstrated (Phillips et al., 2017).

Implementation strategies and their effectiveness

Vaccination of girls

The first and most adopted immunization policy against HPV has been vaccinating only girls before the onset of sexual activity (in most countries, around the 11th year of life) (Obel et al., 2015; Dorleans et al., 2010; de Vuyst et al., 2015). The rationale for this choice is to target cohorts that are virtually all HPV-naïve, but delaying the vaccination as long as possible to assure the longest vaccine protection possible, thereby avoiding any need for a booster dose. The first vaccination campaigns started in 2007 and 2008 in Australia and in some European countries; now, almost all industrialized countries include HPV in their routine vaccine schedule. This strategy has achieved high coverage in countries with active invitation and particularly in those with school-based campaigns (de Vuyst et al., 2015). Obviously, this strategy will show benefits, that is, cancer incidence reduction, only several years after the start of the vaccination campaigns, when these cohorts will reach the age where at least precancerous lesions are worth treating and when screening starts; the effect on cervical incidence will be observed even later.

Great emphasis has been given to equity in HPV vaccination for two reasons. The first is the intrinsic value given to equity of access to effective preventive measures, which all health systems recognize, particularly when vaccination is financed with public money. The second reason is the possible detrimental interaction of the inequity of access both to vaccination and to screening (Venturelli et al., 2017; Malagón et al., 2015). In the plausible hypothesis that those girls who are not vaccinated when they are 12 will also be those that do not participate in screening as adults, the impact of vaccination on the burden of disease in the population will be small. In fact, most invasive cervical cancers in many industrialized countries occur in the few women that are not screened or are under-screened (Sung et al., 2000; Leyden et al., 2005; Morrell et al., 2005; Bos et al., 2006; Andrae et al., 2008; Ingemann-Hansen et al., 2008; Lönnberg et al., 2010; Zucchetto et al., 2013). Furthermore, these women usually come from socioeconomically or culturally disadvantaged groups (Chiu, 2003; Giorgi Rossi et al., 2014); if the health system fails to vaccinate these women, it is missing the opportunity to really impact disease burden. Many authors have argued that the only way to be sure that vaccination is actually reaching a consistent part of these women is to have high population coverage, but results are inconsistent (Venturelli et al., 2017; Drolet et al., 2016).

Catch-up strategies

To accelerate the impact of vaccination campaigns, many countries have organized catch-up strategies, vaccinating girls aged 16 or even older. In most countries, these campaigns have achieved low coverage; in some cases, however, they have been quite successful (Pollock et al., 2014; Brotherton et al., 2015). These vaccinated cohorts of young women now make it possible to measure the effectiveness of the vaccine; the results are confirming the high protection of the vaccine against the targeted infection and related lesions, and in those areas with high coverage of the population, there is evidence of herd immunity (Drolet et al., 2015).

Vaccination of boys

Herd immunity is the main driver for the proposal of universal vaccination, that is, including boys and girls. With growing evidence of the involvement of HPV in a relevant proportion of head and neck cancers, in particular oropharynx (Plummer et al., 2016), it has become clear that the burden of vaccine-preventable disease in males is not negligible (de Martel et al., 2017). The vaccine has proven to be effective also on precancerous lesions of genital mucosae in males (Palefsky et al., 2011). Nevertheless, most models still predict that the largest benefit of vaccinating boys is the indirect effect on cervical cancer in women due to the reduction of circulating virus and to establishing of herd immunity faster (Brisson et al., 2011). The opportunity and cost effectiveness of vaccinating boys is still under debate, with the extreme heterogeneity of policies adopted in industrialized countries reflecting this uncertainty.

Given the very high incidence of HPV-related cancers in males having sex with males, there is consensus that vaccinating this group is opportune (Markowitz et al., 2014; Kirby, 2015; Sauvageau and Dufour-Turbis, 2016), even though implementing effective strategies to target high-risk populations without indirectly fostering discrimination or stigmatization is challenging.

Screening

The characteristics of cervical cancer's natural history have made screening with Pap test one of the most successful preventive interventions ever implemented in industrialized countries. As already discussed in the **Introduction** of this article, screening has completely changed the epidemiology of this disease in some countries, reducing both incidence and mortality, and making cervical cancer a rare disease. Nowadays there are three possible tests to screen for cervical cancer, according to WHO guidelines: Pap test, HPV test (alone or in parallel with Pap test, so-called co-testing) and the visual inspection of the cervix after application of acetic acid (VIA). VIA is recommended only for low-resource countries, as this type of screening is strongly influenced by the attempt to overcome the lack of human and technological resources. The strategies proposed for Pap test and HPV-based strategies have been developed for application in industrialized countries, with a few exceptions. The aim is to find the best balance between possible harms and benefits for women; sustainability is rarely an issue, given the very high cost effectiveness of cervical screening and that screening with very intensive protocols is already in place in most high-income countries.

In the following paragraph we will describe the recommendations given by the European Commission guidelines (Arbyn et al., 2008), with their recent update (Anttila et al., 2015), as an example of guidelines on how to implement organized screening programs, and of the most recent US guidelines as defined by the most influential scientific societies (ACS, ASCCCP, ASCP) (Saslow et al., 2012) and by the US Preventive Services Task Force (Moyer and US Preventive Services Task Force, 2012). For low-income countries, we report the 2013 recommendations of the World Health Organization (WHO, 2013).

Proof of efficacy and effectiveness

Pap test

The use of Pap test began to spread throughout most industrialized countries starting in the late 1960s, reaching very high population coverage by the end of the last century. Its introduction occurred in the absence of any experimental evidence of efficacy. Nevertheless, many observational studies demonstrated its effectiveness in reducing incidence and mortality just a few years after its introduction (IARC, 2005). The most convincing trend study on the effectiveness of Pap test screening reports the case of Finland, where organized screening was introduced in 1969, when opportunistic uptake of Pap test was still very low. Just 10 years after screening introduction, incidence decreased eightfold in the age class targets of screening (Anttila, 2007). The introduction of Pap test in many other countries was more gradual and the decrease in incidence was less dramatic. Nevertheless, most studies showed that an increase in Pap test coverage corresponded to a sharp decrease in cervical cancer incidence (Quinn et al., 1999; Serraino et al., 2015; Giorgi Rossi et al., 2015; Nygård et al., 2002). Case–control and cohort studies confirmed the trend studies (Sasieni et al., 2009; Ronco et al., 2005; Nieminen et al., 1999), and highlighted the additional protection of organized screening compared to opportunistic screening. (Ronco et al., 2005; Nieminen et al., 1999).

Some studies have also reported examples of ineffective screening with Pap test. Observational studies from Latin America showed very low impact on cervical cancer incidence (Herrero et al., 1992), mostly because of low participation by the target population (Hernández-Avila et al., 1998) and due to the low quality of cytology and follow-up procedures (Lazcano-Ponce et al., 1996). One large cluster randomized trial conducted in India found no reduction in cervical cancer incidence and mortality after only one Pap test compared to no intervention. However, the screening intervention in this trial was minimal and the authors suggested that the low effectiveness of Pap test and VIA could have been due to low compliance to follow up and treatment rates (Sankaranarayanan et al., 2009).

HPV test

HPV DNA in cervical cancer screening was first introduced as a triage test in cases of borderline (atypical squamous cells of undetermined significance, ASC-US) Pap tests (Solomon et al., 2001). A large body of evidence on HPV DNA test accuracy shows that it is much more sensitive, but less specific, than Pap test in detecting CIN2 or more severe lesions (Arbyn et al., 2012). Four large trials nested in population-based screening conducted during the first decade of this century tested whether the HPV test's higher sensitivity could also result in better prevention than Pap test screening (Naucler et al., 2007; Kitchener et al., 2009; Ronco et al., 2010; Rijkaart et al., 2012). In fact, the main endpoint of these four trials was the detection of high-grade lesions after the screening test.

Although none of these trials was powered to detect a difference in the incidence of invasive cancers after a negative screening test, an extremely rare event in regularly screened women, the pooled analysis of the four trials clearly showed a significant reduction in invasive cancer incidence in the HPV arm compared with the Pap test arm (Ronco et al., 2014). Furthermore, these trials were designed to gather information necessary to understand which screening algorithms could optimize the process, minimize colposcopy referral and the risk of overtreatment and maximize the preventive efficacy. Thus, the vast majority of women recruited in the experimental arm received both HPV and Pap test and were managed according to the results of both. The very small number of lesions found in women HPV-negative and Pap test-positive made it possible to definitely attribute cervical cancer incidence reduction to the HPV test and not to the combination of the two tests. On the other hand, some trials referred all HPV-positive women to colposcopy, regardless of Pap test results, while others referred only HPV- and Pap test-positive women to immediate colposcopy, the so-called triage strategy, and referred to short interval follow up women HPV-positive and cytology-negative. The reduction in CIN2 or more severe lesion at the following round was similar in those trials with immediate referral to colposcopy for all women and in those adopting a triage strategy (Ronco and Giorgi Rossi, 2017).

VIA

Visual inspection methods, including those with naked eye or with minimal magnification after acetic acid or Lugol, have been proposed as first-level screening test in low-resource settings because the cost of materials and reagents is very low and because no infrastructural resources are necessary. If included in a see-and-treat strategy, they can be used in a one-step screening that does not require follow up, an important consideration in remote rural areas.

Several studies have compared the accuracy of VIA versus HPV or cytology. Older studies, included in the systematic review conducted by the IARC (IARC, 2005), showed similar sensitivity and specificity of VIA compared with HPV test and similar sensitivity and lower specificity than cytology. However, the sensitivity of HPV test in these studies was implausibly low ($<80\%$) compared to what large population-based screening trials have now established. The recent systematic review by the WHO working group on cervical cancer prevention estimated a pooled sensitivity for HPV test of 95% versus 79% for VIA and HPV specificity of 84% versus 87% for VIA (WHO, 2013).

Apart from accuracy studies, one large randomized trial compared the effectiveness of one VIA, one HPV, or one cytology in a lifetime to no intervention at all. HPV was the only screening strategy that could reduce cervical cancer mortality with only one screening episode (Sankaranarayanan et al., 2009). As already commented for the Pap test, the researchers who conducted the study suggest that low compliance to treatment could explain the lack of effectiveness of VIA in this context. This could also explain the heterogeneity between this trial comparing VIA, Pap and HPV and the trials conducted in southern India a few years before, where VIA showed a 25% incidence reduction and 35% mortality reduction (Sankaranarayanan et al., 2007).

The protocols for screening now: Comparison of existing guidelines

High-income countries

Until 2010, according to guidelines developed for high-income countries the only recommended primary screening test was cytology, that is, the Pap test. It is still the most used test, even if most guidelines now recommend HPV as preferable primary screening test. The protocols now used for Pap test-based screening vary for starting age from 21 to 30 and for the interval from 1 to 5 years, with most guidelines recommending 3-year interval after a negative Pap test. The second-level test is colposcopy in order to guide biopsies. Treatment is only recommended for CIN2 or more severe lesions, while CIN1 should be followed up. Many guidelines recommend HPV test to triage ASC-US or borderline lesions. The trend is to introduce a less intensive protocol, primarily for two reasons: (1) the target populations in most industrialized countries has a very low prevalence after years of screening; (2) observational and modeling studies from Northern European countries have shown that screening programs with long intervals and very low colposcopy referral are extremely effective in reducing cancer risk (IARC, 2005).

With very few exceptions (Canadian Task Force on Preventive Health Care et al., 2013; Hamashima et al., 2010), the most recent guidelines in industrialized countries recommend HPV DNA test as primary screening. In some guidelines, Pap test-based and HPV-based strategies are considered comparable options (Moyer and US Preventive Services Task Force, 2012), while in other guidelines, HPV-based strategies are clearly identified as preferable (Anttila et al., 2015; Saslow et al., 2012).

Guidelines for the use of HPV are quite consistent regarding the starting age (not before 30) and interval for HPV-negative women (at least 5 years; **Fig. 3**). The main difference in the recommendations is the use of cotesting or a triage strategy. The European guidelines have adopted a triage strategy in which HPV is a stand-alone test, followed by cytology in case of positivity; women testing positive to cytology are referred to immediate colposcopy, while a follow up in 6 or 12 months is recommended for those with negative Pap test (Anttila et al., 2015). The US guidelines recommend cotesting with HPV and cytology in parallel; women who are HPV-positive and Pap test-negative are referred to repeat cotesting after 1 year, as are those who have negative HPV and low-grade cytology, while those with high-grade cytology, regardless of the HPV result, and those who are HPV-positive and have any kind of cytological abnormality are referred to immediate colposcopy (Saslow et al., 2012; Massad et al., 2013).

Low-income countries

In 2013, the WHO released new guidelines for screening, proposing a clear decision-making flowchart. According to these recommendations, whenever enough resources are available, HPV-based screening should be preferred to VIA, and cytology is recommended only if an ongoing program fulfilling the quality assurance criteria is in place (**Fig. 4**). VIA should be chosen only if there are no resources to implement HPV-screening or as second-level test after a positive HPV test. In this context, screen-and-treat approach is

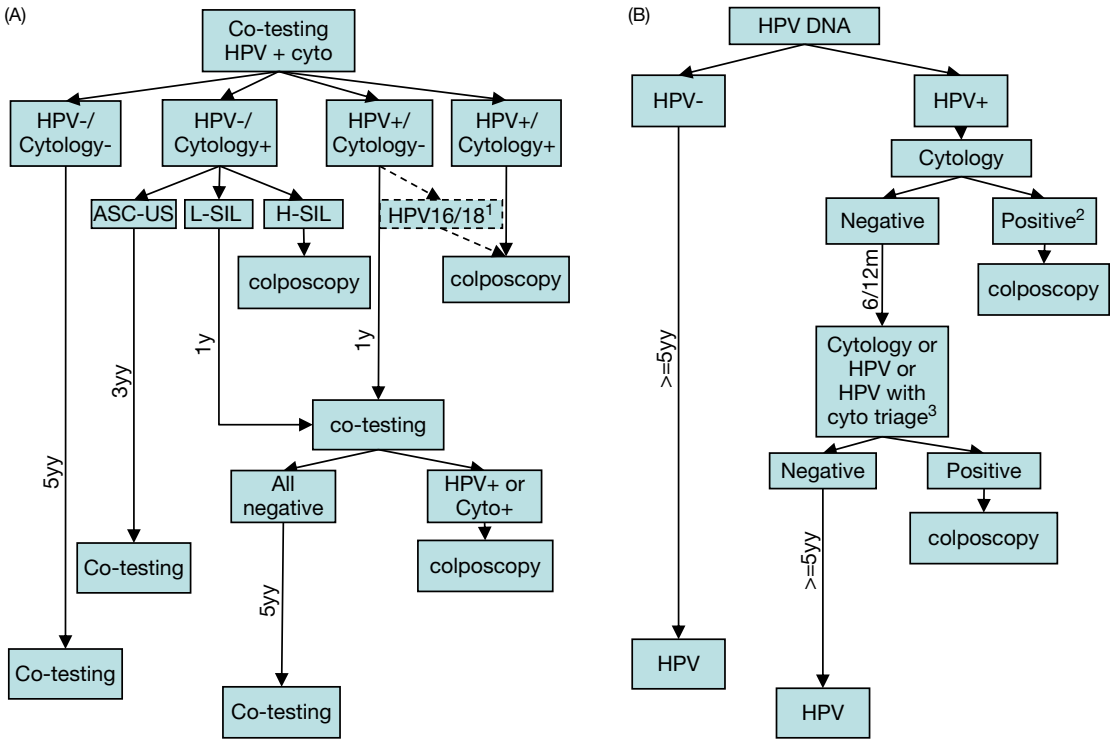

Fig. 3 Cervical cancer screening algorithms as recommended by US and European guidelines. (A) US algorithm according to USPSTF (Moyer and US Preventive Services Task Force, 2012) and multisociety guidelines by American Cancer Society, American Society for Colposcopy and Cervical Pathology, American Society of Clinical Pathology (Saslow et al., 2012). Management of HPV-negative/cytology-positive women is reported in the American Society for Colposcopy and Cervical Pathology guidelines (Massad et al., 2013). (B) European algorithm according to the 2015 supplements of the Quality Assurance Guidelines for Cervical Cancer Screening (Anttila et al., 2015). (1) Women with HPV 16 or 18 can be referred directly to colposcopy even if cytology is negative. (2) Positivity threshold can be set at abnormal squamous cells of undetermined significance (ASC-US) or at high-grade lesions only. Thus, immediate colposcopy or follow up are both possible options for borderline and low-grade lesions. (3) The following optimal managements are recommended for HPV-positive/cytology-negative women: cytology after 6/12 months; HPV followed by colposcopy if test positive not earlier than 12 months; HPV with cytology triage not earlier than 12 months.

recommended, that is, when there are no resources and facilities to perform a colposcopy and to obtain histological confirmation on biopsy, women who test positive can be treated immediately.

Treatment of precancerous lesions

As described previously, although the management of women with abnormal findings in cervical cancer screening is a complex process, when a clinically relevant lesion is found, it must be treated. In high-income countries, treatment should always follow a histological assessment on biopsy; see-and-treat approach during colposcopy is not recommended at all (Arbyn et al., 2008; Massad et al., 2013).

As explained above, CIN1 is no longer considered a precancerous lesion; treatment, therefore, is not recommended except for when there are some specific conditions, that is, cytological findings strongly suggesting the presence of a high-grade lesion that the biopsy has not captured or a lesion persisting >24 months (Arbyn et al., 2008; Massad et al., 2013). Treatment options should always be discussed with the woman.

Very few studies have directly measured the progression rate of CIN2, and even fewer that of CIN3. Only one unfortunate cohort of untreated CIN3 had a long enough follow up to measure a 30% probability of progression to cancer in 30 years (McCredie et al., 2008). For CIN2, some studies reporting the rate of regression with a relatively short follow up have inconsistent results (Uchimura et al., 2012; Moscicki et al., 2010b); certainly, the probability of regression is higher in women below 35 years of age (Ronco et al., 2006, 2008). CIN3 are considered lesions with a relevant risk of progression for which the balance between the benefit of preventing invasive cancer is definitely greater than the harms of the treatment. With a few exceptions, treatment is recommended by almost all guidelines for CIN2 as well. In some cases, strict follow up may be an option for young women because they have a higher probability of rapid regression and progression to cancer usually takes a long time.

The entire rationale for cervical cancer screening is based on the availability of very safe, noninvasive treatment options for precancerous lesions, making the balance between benefits and harms clearly in favor of the benefits, even when the probability of progression is quite low. Treatment options can be divided into ablative and excisional: in the former, as the tissue is destroyed, it is not available for postsurgery histological analysis; the latter maintains the integrity of the excised tissue. The most used

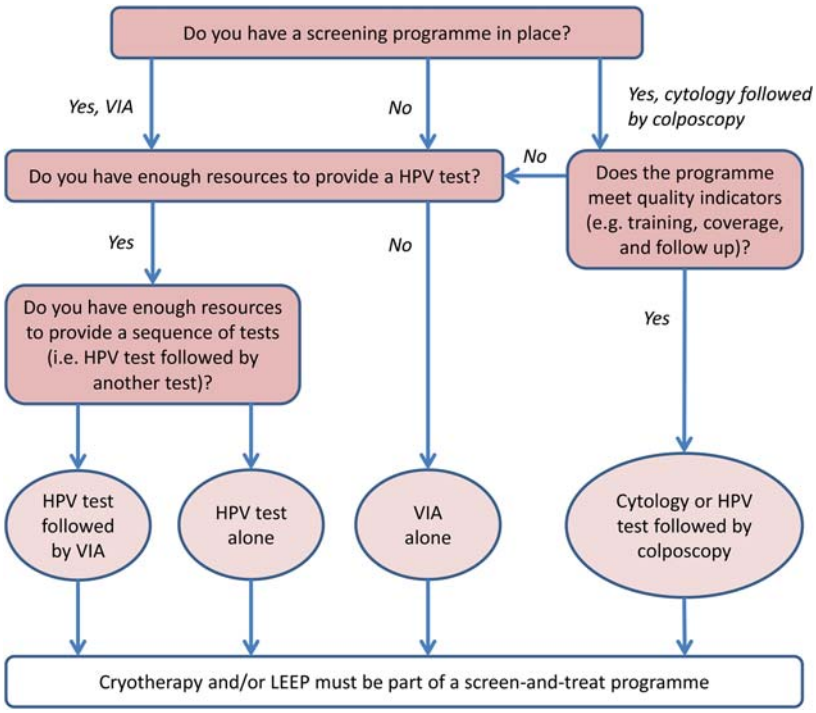

Fig. 4 Decision-making flowchart for screening program managers as defined by the WHO guidelines for screening and treatment of precancerous lesions for cervical cancer prevention. *Light pink bubbles* identify the screening strategy, from the left: HPV test followed by VIA for HPV-positive to triage those to be treated immediately and those to be rescreened after 1 year; HPV test alone and VIA alone are screen-and-treat strategies; cytology or HPV followed by colposcopy are strategies in which an assessment through colposcopy-guided biopsy is possible although not mandatory. No triage test is considered by these recommendations. HPV-negative women should be rescreened after at least 5 years; VIA or cytology-negative women should be rescreened after 3–5 years. From WHO. (2013). WHO guidelines for screening and treatment of precancerous lesions for cervical cancer prevention. Geneva: World Health Organization.

commonly techniques today are cryotherapy and laser ablation for ablative treatments, and large loop excision of transformation zone (LLETZ or LEEP, loop electrosurgical excision procedure), laser excisional conization, needle excision of the transformation zone (NETZ) and cold knife conization for the excisional treatments. These techniques are all effective, and a recent systematic review did not find strong differences in recurrence rate (IARC, 2005; WHO, 2014). The treatment-related morbidity is minimal and similar for all these outpatient procedures, except for cold knife conization, which is a more invasive technique and is now recommended only when other options are not feasible. However, these interventions have all proven to have an impact on pregnancy, doubling the probability of preterm birth. It is difficult to quantify precisely the effect of treatment on this outcome because CIN2 and 3 lesions are also associated with preterm birth; it is thus difficult to distinguish between the excess risk due to treatment and that related to the preexisting lesion itself. This excess risk is higher for cold knife conization, while the risk is very similar for other types of treatment. Clearly, the risk increases with the depth of the tissue excised (Kyrgiou et al., 2016).

Even though the harms of these treatments are very small compared to the consequence of an invasive cervical cancer, they are not negligible for women in their reproductive age. Therefore, the screening algorithm should minimize the probability of treating regressive lesions and false-positive lesions on biopsy, two different phenomena that nevertheless lead to the same kind of harms. False positives are an unavoidable consequence of any test; as for most tests, they are more frequent when the prevalence of the disease is low. Therefore, we can minimize false positives if we refer to colposcopy only those women with high prevalence of CIN2 or 3. In fact, it has been demonstrated that the probability of a false-positive biopsy, and thus of unnecessary treatment, increases when we refer to colposcopy women who have a very low probability of precancer, for example, HPV-negative women (Dalla Palma et al., 2008). The other cause of unnecessary treatment is over-diagnosis of regressive lesions. As mentioned previously, cervical cancer screening aims to treat precancer to avoid the incidence of cancer, and we accept that many of the lesions we treat will never become a cancer. Nevertheless, we should define protocols that try to minimize the diagnosis of regressive lesions to maintain the incidence of cancer as low as possible. Data from one of the European trials on HPV as primary screening, the ARTISTIC UK trial (Kitchener et al., 2009), clearly shows that lesions found in HPV-negative women are more regressive than HPV-positive lesions, at least when cytologists classify as positive a large proportion of the women, that is, they have low specificity. All these considerations led the working group that developed the European guidelines issued in 2015 (Anttila et al., 2015) to recommend against cotesting as primary screening strategy and to recommend an algorithm with HPV stand-alone followed by cytology triage. In this algorithm, only HPV-positive women are referred to colposcopy.

Prospective Vision

Screening in the Vaccine Era

Screening should be adapted to the new disease epidemiology that will emerge in those countries that have high vaccination coverage against HPV16/18 when cohorts of women who were vaccinated in their 12th year of life arrive at the target age of screening. For those countries that started vaccination campaigns in 2007/2008, this will happen in the early 2020s.

The main changes will be:

- >60% decrease in the prevalence of clinically relevant cervical lesions (Bruni et al., 2017; Li et al., 2011).
- About 25% decrease in low-grade and borderline lesions, which are the vast majority of abnormal Pap tests (Bruni et al., 2017; Li et al., 2011).
- As a consequence, a strong decrease in the positive predictive value of Pap test (Kiviat et al., 2008).
- Pap test sensitivity will also probably decrease because finding lesions among an enormous number of negative slides is as difficult as finding a needle in a haystack (Franco et al., 2009; Evans et al., 2011), the so-called prevalence bias.

Given that Pap test is still the only recommended screening test below the age of 30, this is an issue. It is worth to note that also the HPV test will decrease its positive predictive value, but much less than Pap test, since the positive predictive value of HPV test is not influenced by the prevalence of the disease (Giorgi Rossi et al., 2012).

On the other hand, we know that vaccinated women will have virtually no lesions from HPV16/18. These two HPV types are responsible for most cervical cancers overall, and in particular for early onset cancers, probably because their greater ability to transform the cell (Schiffman and Wentzensen, 2013) corresponds to a faster transition through the several progressive phases of the cancerogenic process and thus to a shorter lag time between infection and cancer. A lower absolute risk and longer lag time than in nonvaccinated women suggest that screening can safely be started later than today's protocols. The only recommendation produced to date according to an evidence-based process is to delay the age to start screening. This is based on the estimate that starting screening at age 30 in vaccinated women would maintain the same or slightly smaller number of prescreening cancers now observed in nonvaccinated women starting at 25 (Giorgi Rossi et al., 2017).

The same characteristics—low prevalence of disease and long lag time between infection and cancer—suggest that longer intervals should be adopted to maintain the same level of protection and to avoid overtreatment-related harms (**Fig. 5**).

The predicted low performance of Pap test and the probable increase of the screening starting age to 30 in those countries that now start screening at age 25 make the choice of HPV as primary test the most reasonable in vaccinated women.

The scientific and public health community is discussing whether changes in screening protocols should be applied to the entire target population (one-size-fits-all strategy) or only to vaccinated women (tailored strategy). Obviously, vaccination status is a strong predictor of cervical cancer risk and can define the best screening algorithm for each woman; in the framework of an organized screening program, information on administered vaccine doses should be linked with screening history to correctly invite vaccinated and nonvaccinated women according to two different algorithms (Giorgi Rossi et al., 2017).

On the other hand, herd immunity has been observed when coverage is high. Thus, beyond a certain level of vaccination coverage, the risk in nonvaccinated women will also be very low. Which coverage level and how long it should be sustained are subject matters for research. The answers are probably country-specific, as local sexual habits and social norms are important contributing factors (Baussano et al., 2016).

The here-described changes in screening protocols were developed to apply to women vaccinated before their sexual debut. For those vaccinated when they were already possibly HPV-infected, we know the vaccine is only effective in preventing new infections and has no effect on prevalent infections. To apply less intensive screening, algorithms should be designed that take this into consideration.

Finally, the introduction of 9-valent vaccine will further reduce cervical cancer risk in vaccinated women. How to screen, and whether it is opportune to do so, will be the next challenges of the scientific community.

Accelerating the Worldwide Control of Cervical Cancer

The proposed vaccination strategies, together with the very low diffusion of effective HPV-based screening in low-income countries, imply that the benefits of this revolution in cervical cancer prevention will only be enjoyed in the quite distant future. Trials of HPV vaccination in women aged up to 55 years have shown very high efficacy against HPV16/18-related precancer in women not infected by HPV16/18-DNA when vaccinated.

A group of authoritative researchers have advocated for extending routine vaccination programs to women of up to 30 years, paired with the use of HPV-screening with at least one test at age 30 years or older in low-resource countries and up to 5/6 screening episodes in high-income countries (**Fig. 5**) (Bosch et al., 2016).

Furthermore, HPV test has good accuracy also on self-collected samples (Arbyn et al., 2014), meaning that it is possible to develop new strategies to reach under-screened women, thereby increasing test coverage (Verdoodt et al., 2015).

All these strategies together have the potential to accelerate the decline in cervical cancer incidence and mortality in countries in Central and Eastern Europe, Latin America, Asia and Africa, where the burden of disease is higher because of the absence or low effectiveness of screening programs.

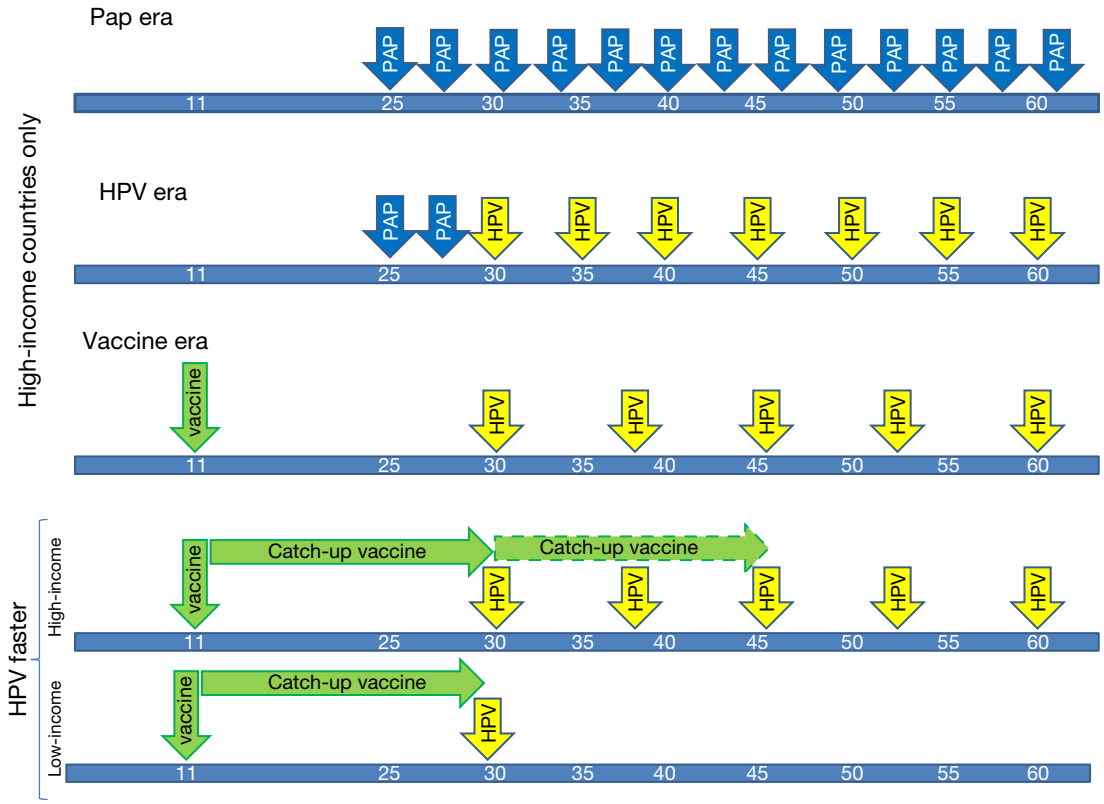

Fig. 5 The evolution of cervical cancer prevention. From programs based on Pap test requiring repeat test every 3 years, we now have HPV-based screening, recommended only after the age of 30, but with longer intervals (at least 5 years). In the near future, we will need to integrate vaccination and screening, with vaccinated women undergoing less intensive screening protocols which start later and which adopt longer intervals. Finally, the extension of more effective and faster strategies to reduce cervical cancer incidence in low-income countries as well, as proposed by Bosch et al. (2016) with the HPV faster program.

Most cost-effectiveness models suggest that the health benefits of extending the age of the vaccination target population (Jit et al., 2014; Brisson et al., 2016) have a very low cost, although this is still a subject matter of research. Nevertheless, this extension requires resources that are difficult to obtain in most of those settings that would reap the largest benefits; budget impact is thus much more an issue than is cost effectiveness.

Chemoprevention of Cancer: An Overview of Promising Agents and Current Research

Elizabeth G Ratcliffe and Andrew D Higham, University Hospitals of Morecambe Bay NHS Foundation Trust, Lancaster, United Kingdom
Janusz A Jankowski, University Hospitals of Morecambe Bay NHS Foundation Trust, Lancaster, United Kingdom; National Institute of Health and Care Excellence, Manchester, United Kingdom; and Royal College of Surgeons in Ireland, Dublin, Ireland

Cancer diagnosis and treatment is distressing for patients and carries a high burden of morbidity and mortality. Preventable cases of cancer can be reduced through lifestyle changes and to augment this chemoprevention is becoming an increasingly vital area of research.

The principle of chemoprevention is to find a medication or dietary supplement which when given to certain groups of the population can reduce the risk of carcinogenesis before invasion. Optimum agents need to be well understood from a pharmacokinetic and safety perspective, be cost effective for broad usage and be well tolerated by patients.

A key draw back is chemoprevention agents must be taken for prolonged periods, creating a unique conundrum for clinicians in that within a population, for a proportion of people cancer may be delayed by a few years, yet this benefit may be outweighed by healthy patients who succumb to complications. Hence many agents that are studied are concurrently used for secondary prevention of other conditions and therefore may have multiple benefits to balance the risks (Fig. 1).

Here we give an overview of some of the potential chemoprevention agents (Table 1), with an emphasis on aspirin which has shown the most promise.

Statins

HMG-CoA reductase inhibitors act against the conversion of HMG CoA to mevalonate, thought to prevent disruption to Ras/Rho signaling proteins which in turn can affect normal cell differentiation, survival and growth. Statins also regulate the RAF–MAPK–ERK pathway which makes them proapoptotic, anti-inflammatory and immunomodulatory via both HMG-CoA independent and dependent pathways.

Statins have possible associations with colorectal (CRC), hepatocellular (HCC), gastric, esophageal, and advanced prostate cancers. Tsan et al. in a population-based cohort study of chronic hepatitis found a 53% reduction in risk of HCC in patients on statins. In a meta-analysis of 10 studies by Singh et al. (2013) the statin group showed a 37% reduction in HCC (adjusted OR 0.63; 95% CI 0.52–0.76) though the number needed to treat (NNT) was 5209 in East–Asian men.

Statins are well tolerated; common side effects include myalgia and deranged liver function tests. Concerns have been raised regarding an increased cancer risk in the elderly. Moreover a large epidemiological study into secondary effects of statins showed NNT (1266) to reduce esophageal cancer were markedly offset by number needed to harm (NNH) with severe liver derangement(136), moderate to severe myopathy (91 men 259 women) and renal impairment (434).

Statins are already widely used and are an attractive chemoprevention agent given their high efficacy at lowering all-cause mortality, particularly cardiovascular, and cerebrovascular. Persuading the public of a firm association with a specific cancer will require further research to justify the risks.

Metformin

The metabolic syndrome, sedentary lifestyle and high energy low complexity western diet have been linked with many cancers. Malignant cells are highly catabolic, and links between metabolic pathways, such as the AMPK/LKB1, and how these maybe affected by metformin chemoprevention are driving research. An energy stress response dependent on AMPK triggered by metformin is thought to reduce survival in cancer cell lines. A secondary effect of reducing proliferation of cells via inhibition of phosphoinositide 3-kinase/Akt/mammalian rapamycin signaling has been described.

Meta-analysis of retrospective data for diabetic patients showed an overall reduction in all cancers (31%), this was most evident for pancreatic and HCC. A nonsignificant association was seen with breast, prostate, and CRC cancers. Meta-analysis of studies looking at HCC risk showed a 50% reduction of risk in patients who had ever used metformin versus those who had never, even accounting for adjustments for other medications. Higurashi et al. performed a multicenter double-blind, randomized controlled trial of metformin in nondiabetic patients and showed a significantly lower colonic adenoma recurrence rate ($P = .034$, risk ratio 0.67 [95% CI 0.47–0.97]).

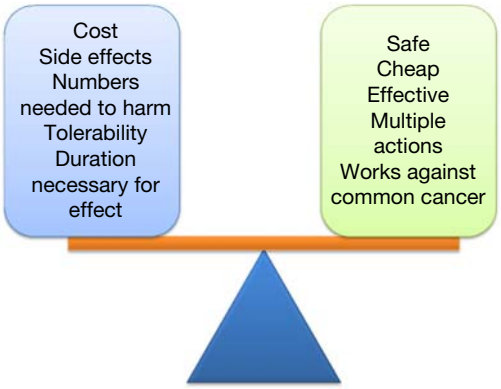

Fig. 1 Considerations when choosing a chemoprevention agent.

Table 1 Overview of agents discussed

Agent	*Cancer prevented*	*Risks*
Statins	CRC, HCC, gastric, esophageal, prostate	Liver injury, myopathy, renal derangement, increased cancer risk in the elderly
Metformin	Pancreatic, HCC, all cancers	Diarrhea, nausea, abdominal discomfort
Vitamin D	Breast, esophageal, CRC	Increased risk of adenocarcinoma of esophagus
Tamoxifen	ER positive breast cancer	VTE, Endometrial cancer, cataract formation
Aspirin	CRC, esophageal, hereditary CRC, breast, ovarian, pancreatic, prostate, lung	GI Bleeding, Intracranial hemorrhage, all bleeding

Metformin can be troubling for patients with many experiencing diarrhea, nausea, and abdominal discomfort. More serious adverse effects such as lactic acidosis are dose dependent and studies into optimum dosing are still needed.

The risk reduction of other conditions makes metformin a good agent which for the general public could seem appealing. The rising incidence of diabetes and risk of obesity related illnesses including cancers such as colorectal and postmenopausal breast cancer increase the case for its use in chemoprevention.

Vitamin D

The mechanism explored in in vitro settings suggests vitamin D levels can affect apoptosis, cell proliferation, and differentiation. Dietary vitamin D is hydroxylated to its' circulating form 25-hydroxyvitamin-D which can be measured in the circulation, the active form (1,25-HO-vitD) is created through a second hydroxylation allowing it to bind to VDR which results in a biological signaling cascade.

Vitamin D levels have been linked to reductions in breast, esophageal and CRC among others. Dietary vitamin D intake showed a possible relationship that was protective for squamous cell carcinoma of the esophagus but increased risk of adenocarcinoma (nonsignificant). Gandhini et al. through meta-analysis found an inverse relationship between 25-HO-vit D and CRC but could not show significant associations with breast or prostate cancer. They felt some bias could come from many case-control studies taking vitamin D levels after cancer diagnosis—when patients' diet, activity or sun exposure may have changed.

Side effects from vitamin D are few, however in some studies an adverse link has been raised, for example an increased association with adenocarcinoma of the esophagus. This seems to particularly relate to the use of supplementation, whereas studies looking at lifetime UV exposure seemed to be more favorable in outcome.

Vitamin D is certainly an attractive choice for patients, with few side effects as a supplement and when gained through sun exposure there is likely to be an association with physical activity, reducing other cancer risk factors such as sedentary behavior and obesity.

Tamoxifen

Tamoxifen produces an antiestrogen effect in breast tissue and weakly estrogenic effects in the bone and uterus. Estrogen normally binds with the estrogen receptor (ER) which causes CoA to bind with the receptor creating a transcription complex. The complex is then able to commence DNA transcription from an estrogen-receptive gene. Tamoxifen binds with the ER-α part of the receptor

preventing it from recruiting CoA molecules therefore causing an antiestrogen effect in breast tissue. However, where CoA levels are greater a weakly estrogenic effect occurs—in the uterus and bone—and through an association with fos/jun proteins stimulates the activating protein-1 (AP1) causing gene sequencing. Since these early mechanisms were described, studies into tamoxifen resistance have highlighted the importance of paired box-2 (PAX) in both signaling in breast tissue and the carcinogenesis in the endometrium.

Patients who have been treated with tamoxifen were found to have fewer contralateral breast lesions than other patients raising the possibility of a role as a chemoprevention agent. Meta-analysis of 9 trials by Cuziak et al., found a significant risk reduction in estrogen receptor positive breast cancer in both average and higher risk women who had no prior disease. They calculated a NNT of 42. There was a nonsignificant increased risk of ER negative cases, which they hypothesized could relate to mutation from ER sensitive to hormone resistance.

Significant adverse risks are associated with tamoxifen particularly venous thromboembolism (VTE) (reported up to twice as often as placebo) and endometrial cancer (2–5 times above the baseline rate). The risks are less for premenopausal women, with no increased risk of VTE or endometrial cancer, however in postmenopausal women there was an increase in VTE, Endometrial cancer and cataract formation.

As a treatment of breast cancer tamoxifen is well tolerated, the routine side effects are few and as chemoprevention for high risk women it is recommended by NICE and approved for use by the FDA in the United States. For the wider, "healthy" population, the more serious complications, particularly endometrial cancer, will be harder to justify.

Aspirin

The mechanism of chemoprevention via aspirin (Fig. 2) has been linked to prostaglandins, particularly PGE2, via COX signaling. Prostaglandin E2 has been associated with stimulating angiogenesis, increasing a cell's proliferation, migration potential, and invasiveness whilst modulating immunity and preventing apoptosis. In animal colonic models deletion of receptors for PGE2 resulted in reduced abnormal crypt formation and adenomas. Nan et al. through gene versus environment case-control study in CRC identified two genes which showed a greater prevention outcome with aspirin and NSAIDS that are functionally linked with increased PGE2 production. Inhibition by aspirin of COX-2-mediated platelet production of thromboxane has been hypothesized to affect tissues' response to damage caused by disruption by neoplasia resulting in reduced cell proliferation. COX-2 inhibition in epithelial cells occurs at higher doses than in platelets, however, chemopreventative effects have been shown at low doses too which supports platelet mediated mechanisms. Aspirin also reduces the cellular quantity of β-catenin through inactivation of protein phosphatase

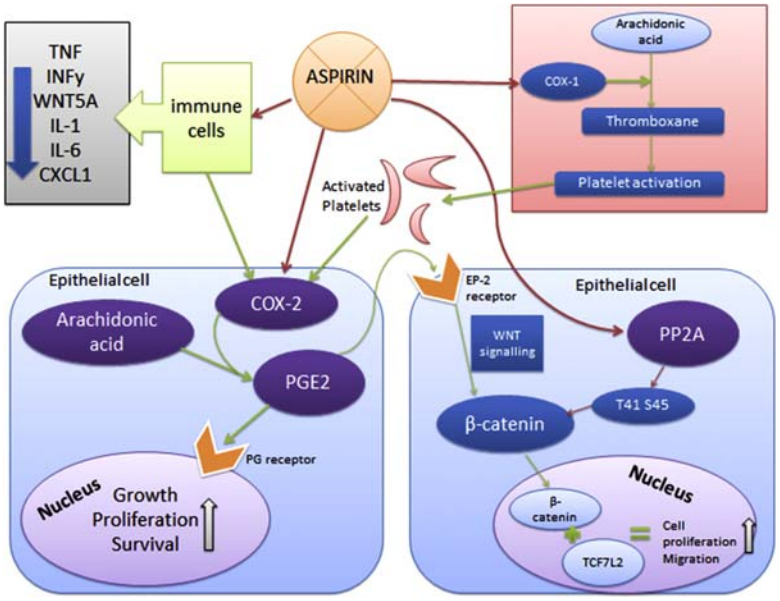

Fig. 2 Mechanism of aspirin chemoprevention. A diagram showing the pathways hypothesized to be affected by aspirin, *Green arrows* represent stimulation pathways and *red arrows* inhibitory. Aspirin affects pathways in four ways: affecting platelet activation (top right) by inhibiting the release of thromboxane; inhibiting the stabilization of β-catenin through inactivation of protein phosphatase 2A (PP2A) promoting ubiquitylation (bottom right panel);through inhibiting COX-2 mediated production of prostanoids (bottom left) by preventing COX-2 converting arachidonic acid to prostaglandin E2 (PGE2); and through the antiinflammatory effect of reducing circulating cytokines (*CXCL1*, C-X-C motif chemokine 1; *MIC1*, macrophage inhibitory cytokine 1; *IFN-γ*, interferon-γ; *IL*, interleukin; *PGT*, prostaglandin transporter; *sTNFR2*, soluble TNF receptor 2; *TNF*, tumor necrosis factor). Modified from a diagram by Drew, D. A., Cao, Y., Chan, A. T. (2016). Aspirin and colorectal cancer: The promise of precision chemoprevention. *Nature Reviews Cancer* **16**(*3*), 173–186. doi: 10.1038/nrc.2016.4.

Table 2 Current trials pending publication or completion

Status	*Trial name*	*Cancer target*	*Agent*	*Phase*	*Participants*	*Masking*	*Randomization*	*Completion date*	*Locations*
Completed	A randomized, double-blind, placebo-controlled, multicentre efficacy and safety study of toremifene citrate for the prevention of prostate cancer in men with high grade prostatic intraepithelial neoplasia (PIN)	Prostate	Toremifene	3	1590	Triple	Yes	Feb-10	35 Study locations
Completed	Physicians health study II: trial of vitamins in the chemoprevention of cancer, CVD and eye disease	Prostate, colorectal, all cancers	Vitamin E, C, multivitamin, beta carotene	N/a	14641	Factorial assignment	Yes	Jun-11	National Cancer Institute US
Completed	Phase III placebo-controlled chemoprevention study of oral cavity squamous cell carcinoma patients	Oral cancer	13-Cis retinoic acid	3	342	Single	Yes	Sep-12	National Taiwan University
Completed	A study to assess the efficacy and safety of enteric-coated acetylsalicylic acid in patients at moderate risk of cardiovascular disease (ARRIVE)	Colorectal cancer (secondary end point)	Aspirin	3	12546	Triple	Yes	Nov-16	Bayer, 673 International Centres
Completed	Phase I multiple-dose safety, pharmacokinetic and pharmacodynamics clinical study of nitric oxide releasing aspirin (NCX 4016)	Colorectal cancer	Nitric-oxide releasing acetylsalicylic acid	1	240	Double	Yes	Dec-16	Stony Brook University
Completed	The seafood (systematic evaluation of aspirin and fish oil) polyp prevention trial	Colorectal cancer	Aspirin	N/a	755	Double	Yes	Oct-17	University of Leeds, UK Centres
Active	A phase III, randomized, study of aspirin and esomeprazole chemoprevention in Barrett's metaplasia (AspECT)	Esophageal	Omeprazole, aspirin	3	2513	Open label	Yes	May-17	Oxford
Active	Pioglitazone for lung cancer chemoprevention	Lung cancer	Pioglitazone	2	391	Quadruple	Yes	Aug-17	Colorado/Tennessee
Active	Aspirin in reducing events in the elderly (ASPREE)	Colorectal cancer	Aspirin	4	19000	Quadruple	Yes	Jan-18	Berman Centre for Outcomes and Clinical Research
Active	Metformin hydrochloride in preventing breast cancer in patients with atypical hyperplasia or in situ breast cancer	Breast cancer	Metformin	3	Aim 128	Double	Yes	Feb-19	Alliance for Clinical Trials in Oncology, United States

Active	The HOT study: hormone replacement therapy opposed by low dose tamoxifen. A phase III trial of breast cancer prevention with low dose tamoxifen in HRT users	Breast cancer	Tamoxifen	3	1884	Triple	Yes	Dec-19	European Institute of Oncology
Active	International breast cancer intervention study	Breast cancer	Anastrozole		3864	Quadruple	Yes	Jan-22	Queen Mary London 75 study locations
Recruiting	Mesalamine for colorectal cancer prevention program in Lynch syndrome—MesaCAPP	Colorectal cancer	Mesalamine	2	Aim 540	Double	Yes	Sep-20	Medical University of Vienna
Recruiting	Targeted chemoprevention of gastric carcinogenesis in high risk populations	Gastric cancer	Eflornithine	2	Aim 300	Double	Yes	Dec-20	Colombia/Honduras/Puerto Rico
Recruiting	A trial looking at different doses of aspirin to prevent cancer in people who have Lynch syndrome (CaPP3)	Colorectal cancer	Aspirin	3	Aim 2000	Double	Yes	2023	CRUK and International
Recruiting	Assessment of the effect of a daily chemoprevention by low-dose aspirin of new or recurrent colorectal adenomas in patients with Lynch syndrome	Colorectal cancer	Aspirin	3	Aim 852	Quadruple	Yes	Dec-24	Hospital Avicenne France
Recruiting	Add-aspirin: A trial assessing the effects of aspirin on disease recurrence and survival after primary therapy in common nonmetastatic solid tumors	Breast, gastric, colorectal, esophageal, prostate	Aspirin	3	11000	Triple	Yes	Oct-26	University College London
Recruiting	Aspirin intervention for the reduction of colorectal cancer risk (ASPiRED)	Colorectal cancer	Aspirin	N/a	Aim 180	Double	Yes	Jul-28	Massachusetts General Hospital

2A—a protein which breaks down amino acid residues (T41 and S45) that are responsible for flagging β-catenin for ubiquitylation. β-catenin when it moves to the nucleus of a cell causes a sequence of gene expression resulting in increased cell migration and proliferation. Most of the cancers which seem to be prevented by aspirin have an inflammatory prodrome, such as Barrett's to esophageal, aspirin is thought to reduce circulating levels of inflammatory cytokines and proteins which have been linked with these cancers.

Parkin et al. estimated that if aspirin was taken for 10 years between the ages of 50–65 years a reduction in all cancers of 7%–10% could be achieved. The strongest associations appear to be with CRC, esophageal, gastric (all by around 1/3 reduction), prostate, breast, and lung cancers (10%–15% reduction). Rothwell et al. in meta-analysis of eight trials showed a significant reduction in 20 year cancer mortality verses placebo for all solid cancers, GI cancers and the benefit increased with age and duration of aspirin use. CRC cohort studies on large populations showed an inverse relationship between aspirin use and CRC incidence—with the Cancer Prevention Study II describing a reduction of 40% in regular aspirin users. The CAPP-2 randomized controlled trial in Lynch syndrome patients showed a significant reduction in CRC cancer risk in this population which was sustained after the end of the randomization to 4 years. Many studies show a reduction in esophageal cancer with aspirin, even reduction in Barrett's length and dysplasia progression. Further studies are underway to look at use in specific high risk groups such as in the AspECT trial—the largest RCT using PPI and aspirin in combination with end points of developing dysplasia and esophageal cancer. Aspirin for CRC chemoprevention has been endorsed by The US Preventative Services Task Force for use in 50–59 year olds with a 10% or greater cardiovascular 10 year risk profile and low bleeding risk, and also on an individual basis for 60–69 year olds, though emphasizing the need for further investigation into the mechanism of action.

The consequences of long term aspirin use are well understood, chiefly increased risk of bleeding due to the unselective nature of aspirin's COX inhibition. COX-1 inhibition reduces the secretion of prostaglandin E2 in the gastric mucosa, increasing ulceration and risk of upper gastrointestinal bleeding. Aspirin reduces thromboxane production in platelets hence reducing atherosclerotic risk but increasing bleeding risk. The risk of severe adverse effects increases dramatically after the age of 60. The international consensus paper suggested that given premalignant lesions often present in middle age- around age 50–60, commencing treatment between the ages of 40–50 years may help prevent most premalignant lesions before the risk of adverse events goes up. Cuzick et al. estimated that for 100 average risk 55 year olds taking aspirin for 10 years there would be 2.29 fewer myocardial infarctions, cancers, and strokes in men and 1.32 in women over 15 years, yet only 0.49 more GI bleeds in men and 0.25 in women. They also estimated a clear reduction in mortality from cancer which outweighed the mortality risk from GI bleeding (a ratio of 7:1 in the general population).

Aspirin is familiar to most lay populations, and has well studied risks meaning counseling healthy populations about it is very feasible. Many people understand its' use in cardiovascular prevention hence the step to use in cancer should be straight forward and well received. Patient preference has been studied in Barrett's esophagus patients with 76% open to the idea of using aspirin. The more knowledge that is gained through risk stratifying populations, as is already done in cardiovascular disease, the greater a case can be put to healthy subjects.

Conclusion

Cancer chemoprevention as a principle is an exciting prospect for researchers, clinicians and patients. There are significant draw backs at present, centered around the risk of causing adverse events and treatment associated mortality in an otherwise healthy population. Rather than a one pill fits all approach the future of chemoprevention is likely to mimic the principles of cardiovascular prevention by targeting higher risk populations. Further studies are ongoing to define these populations and gene profiling is being used to narrow down even more specifically (**Table 2**).

Chemoprevention Trials☆

Kunal C Kadakia, Ashley G Matusz-Fisher, and Edward S Kim, Levine Cancer Institute, Carolinas HealthCare System, Charlotte, NC, United States

Introduction

Epithelial cancers have historically been a cause for frustration by both patients and practitioners. Despite decades of cancer research, the mortality rate from epithelial malignancies has improved only 1%–2% per year for both men and women (Siegel et al., 2017), largely driven by decreased tobacco use (Jemal et al., 2008). Although some patients will present with early stage disease, the majority of patients will present with locally advanced or metastatic disease. Surgical intervention with adjuvant or neoadjuvant treatment, including radiotherapy and/or chemotherapy, has offered some improvements in long-term survival rates. However, local and distant relapse remain unacceptably high in many cancers. Thus, novel approaches to these epithelial cancers are needed, specifically the prevention of carcinogenesis prior to the onset of invasive cancer (Meyskens, 1992).

Prevention strategies can occur at three broad levels: primary, secondary, and tertiary. A chemopreventive agent is a compound, either natural or synthetic, that prevents, reverses, or blocks the development of invasive cancer and can be considered at any level of prevention (Wattenberg, 1985). Primary prevention targets risk-reducing techniques in asymptomatic "normal" individuals and includes interventions such as diet and exercise. A high-risk individual such as one with a known inherited cancer syndrome who undergoes prophylactic surgery is also an example of primary prevention (e.g., BRCA carrier undergoing mastectomy). Treatments of individuals with premalignant findings to prevent progression to invasive cancer are considered secondary prevention. This can include surgical or ablative therapy for known precancerous conditions such as polypectomy for colonic adenomas or photodynamic therapy for Barrett's esophagus as well as topical chemopreventive therapies for actinic keratoses, the precursor to squamous cell carcinoma of the skin. Tertiary prevention involves reducing the risk of recurrence after established malignancy and is exemplified by studies targeting secondary primary tumors of the aerodigestive tract following definitive treatment.

Biologic Rationale for Chemoprevention

It is well established that advanced metastatic carcinomas are heterogonous invasive masses of genomically complex cells (Hanahan and Weinberg, 2011). Multiple dysregulated cellular-signaling pathways lead to the inevitable metastatic phenotype. The molecular heterogeneity observed occurs not only between patients with the same malignancy (interpatient heterogeneity) but also within metastatic sites of a given patient (intrametastatic heterogeneity). This complexity highlights the rational for targeting earlier neoplastic changes (i.e., intraepithelial neoplasia) prior to the onset of genomically diverse invasive carcinoma.

As a result of a variety of environmental and genotoxic insults, normal epithelium transforms to neoplasia most often via a stepwise accumulation of molecular and genetic aberrations over the course of many years. This sequential accumulation of abnormalities was typified by the model of colorectal tumorigenesis by Fearon and Vogelstein in 1992 (Fearon and Vogelstein, 1990) and has since been described in multiple tumors. Chemopreventive agents have the potential to interrupt or perhaps reverse these changes throughout the carcinogenic process.

Numerous potential molecular targets within neoplastic development are putative drivers. These include those that involve independence from growth signals (e.g., EGFR, PI3K), resistance to antigrowth signals (e.g., CDK, SMADs), evasion of apoptosis (e.g., mTOR, PTEN, *Ras*), immortal replicative potential (e.g., p53, pRb), angiogenesis (e.g., HIF-1a, VEGF, FGF), and tissue invasiveness and metastatic potential (e.g., E-cadherin, MAP-kinase) (Hanahan and Weinberg, 2011; Kelloff et al., 2006). Although inhibition of single transduction pathways has had clinical efficacy in the advanced cancer setting (e.g., anti-EGFR therapy in lung and colorectal cancers), the toxicity associated with complete inhibition of select pathways as well as the presence of bypass tracks (i.e., alternative proliferative pathways or downstream mutations) limits the applicability of single site blockade in complex tumors. This is highlighted by the failure of erlotinib, an anti-EGFR monoclonal antibody, to reduce oral cancer-free survival in high-risk individuals with oral premalignant lesions (William et al., 2016).

In addition to aberrations in signal transduction, dependence of cancer cells on a single oncogene (i.e., oncogene addiction) remains an important potential target. This is suggested by the inherent sensitivity of the addicted cell to blockade of the oncogene. For example, preclinical data support the antiproliferative effect of even partial inhibition of cyclin D1, a purported addicted oncogene in esophageal cancer (Weinstein, 2002; Jain et al., 2002). Further clinical study of manipulation of oncogene addiction and tumor suppressor hypersensitivity is ongoing (Weinstein et al., 2008; Jacobi et al., 2017).

Other significant chemopreventive avenues have evolved from the improved understanding of the role of inflammation in neoplasia. Multiple studies support the effects of chronic inflammation on promoting carcinogenesis (Caruso et al., 2004; Philip et al., 2004). Nuclear factor-kappa β, a proinflammatory transcription factor, along with regulatory proteins (e.g., tumor necrosis factor-α, cyclooxygenase-2, inducible nitric oxide synthase) play an integral role in the development and progression of neoplasia and have been proposed to serve as therapeutic targets as well as potential biomarkers (Aggarwal, 2004). Additionally, states of chronic inflammation caused by inflammatory bowel disease (IBD) and Barrett's esophagus, or due to infections such as human papilloma virus (HPV) and hepatitis B (HBV) lead to prolonged inflammation that can progress to carcinogenesis (Shacter and Weitzman, 2002). Importantly, the development of vaccines for HPV and HBV has resulted in marked reduction in the incidence of cervical and hepatocellular carcinoma, respectively, representing the importance of targeting upstream molecular events prior to the development of frank carcinoma (Chang et al., 2009; Garland et al., 2016).

Drug Development of Chemopreventive Agents

Similar to drug development for other indications, translational efforts for chemopreventive agents follow a similar process. The chemoprevention drug-screening program outlined by the United States National Cancer Institute's Cancer Preclinical Drug Development Program (PREVENT) provides such a pragmatic approach involving a stage-gate process with go/no go decision points throughout the drug development process (Shoemaker et al., 2016). Ideally, preclinical testing includes biochemical prescreening assays, in vitro efficacy models, in vivo short-term screening, and animal efficacy prior to testing in human trials. Despite significant improvements in the preclinical sciences, the translation of findings from these models into clinical success in human chemoprevention trials has been limited. Although the reasons for this are multifactorial, murine/rodent models often consist of a genetically homogenous population that follows a strict dietary regimen in tightly controlled laboratory conditions. In contrast, even well-controlled human trials inherently include genetically diverse populations with varied dietary and environmental exposures that cannot be fully measured (Meyskens et al., 2016).

Similar to other oncologic therapeutics, evaluation of the clinical safety and efficacy of chemopreventive agents undergo phased testing. Understanding the nuances specific to prevention, as compared to treatment, are integral to the successful design and implementation of chemoprevention trials. These include the wide therapeutic index required of the agents, the long latency to neoplastic transformation, the necessity for prolonged adherence, and the complexity underlying risk evaluation (Shureiqi et al., 2000). Therapeutic index is driven by a combination of the agent's efficacy as well as its associated short- and long-term toxicities. Early phase studies are integral to understanding the optimal dosing, frequency, and acceptable toxicities prior to undertaking larger scale studies. The inherent principle of chemoprevention requires drug therapy in a largely asymptomatic patient and therefore greater understanding of detection, evaluation, and avoidance of toxicities is highly warranted. Such strategies include defining the minimally effective dose, evaluating the pharmacokinetic and pharmacodynamics of intermittent or combination therapies, and optimizing toxicity monitoring (Kelloff et al., 2006).

In latter phases, the ideal endpoint of chemoprevention trials is a reduction in cancer incidence. Because cancer incidence is extremely low among the general population with no known cancer risk factors, demonstrating a treatment-induced reduction in cancer incidence among the general population requires large randomized studies, which are expensive and time-consuming. Targeting high-risk populations and utilizing validated intermediate biomarkers can significantly reduce the time and resources required for chemoprevention trials.

Biomarkers can be defined as measurable and evaluable indicators of normal biologic processes, pathogenic processes, or pharmacologic responses to therapeutic interventions. Currently, the most common biomarker utilized in chemoprevention studies is histopathologic intraepithelial neoplasia (IEN). Examples of histopathologic IEN include adenomas in colorectal cancers, leukoplakia in oral cancers, bronchial dysplasia in lung cancers, and cervical intraepithelial neoplasia in cervical cancer. The goal of such a biomarker is to be a true surrogate of a future invasive process. The ideal biomarker should be variably expressed throughout the carcinogenic process, detectable early in the course or carcinogenesis, modulation with intervention should accurately be associated with clinical benefits, and ideally should be able to be quantified directly, reliably, noninvasively, and with technical and cost feasibility. As histopathologic changes are a result of a multiple molecular, proteomic, and genomic changes, establishing a biomarker that accounts for this interplay is most ideal. For example, gene set enrichment analyses where genes in a critical pathway are mapped to determine which are affected and not affected in cancer tissue might allow to better target tissue-specific molecular aberrations (Mootha et al., 2003). Although significant progress is being made with advanced technologies such as the gene set enrichment analysis described; newer proteomic, imaging, and microarray techniques might allow for a truly practical, prognostic, and predictive biomarker for each organ system to be fully realized (Fabian and Kimler, 2016).

Clinical Trials Involving Chemoprevention

Cancer chemoprevention continues to evolve and its role in oncologic practice continues to expand. A multitude of chemopreventive agents have been studied in over 100 randomized trials over the past four decades. Some clinical activity has been demonstrated proving the potential utility of drug therapy for cancer prevention. Over 10 agents have been FDA approved for cancer risk reduction in select high-risk cohorts as well as the treatment of premalignant lesions (**Tables 1 and 2**). Although an exhaustive review of all chemoprevention trials is not possible in this article, a discussion regarding the major contemporary and historically significant chemoprevention trials by organ system is provided.

Table 1 FDA approved therapies for cancer risk reduction

Agent	*FDA indication and cohort*[a]
Tamoxifen	1. Reduction in risk of invasive breast cancers in women with DCIS following breast surgery and radiation. 2. Reduction in incidence of breast cancer in women at high risk for breast cancer ("high-risk" defined as women at least 35 years of age with a 5-year predicted risk of breast cancer 1.67%, as calculated by the Gail Model.)
Raloxifene	1. Reduction in the risk of invasive breast cancer in postmenopausal women at high risk for invasive breast cancer (high risk is defined as at least one breast biopsy showing lobular carcinoma in situ or atypical hyperplasia, one or more first-degree relatives with breast cancer, or a 5-year predicted risk of breast cancer $>1.66\%$ [based on the modified Gail mode].)
Cervarix (HPV Vaccine)	1. Female 9 through 25 years of age for the prevention of the following diseases caused by oncogenic human papillomavirus (HPV) types 16 and 18: • cervical cancer. • cervical intraepithelial neoplasia (CIN) Grade 2 or worse and adenocarcinoma in situ. • cervical intraepithelial neoplasia (CIN) Grade 1.
Gardasil9 (HPV Vaccine)	1. Girls and women 9 through 26 years of age for the prevention of the following diseases: • Cervical, vulvar, vaginal, and anal cancer caused by human papillomavirus (HPV) types 16, 18, 31, 33, 45, 52, and 58. • Genital warts (condyloma acuminata) caused by HPV types 6 and 11. And the following precancerous or dysplastic lesions caused by HPV types 6, 11, 16, 18, 31, 33, 45, 52, and 58: • Cervical intraepithelial neoplasia (CIN) grade 2/3 and cervical adenocarcinoma in situ (AIS). • Cervical intraepithelial neoplasia (CIN) grade 1 • Vulvar intraepithelial neoplasia (VIN) grade 2 and grade 3 • Vaginal intraepithelial neoplasia (VaIN) grade 2 and grade 3 • Anal intraepithelial neoplasia (AIN) grades 1, 2, and 3. 2. Boys and men 9 through 26 years of age for the prevention of the following diseases: • Anal cancer caused by HPV types 16, 18, 31, 33, 45, 52, and 58. • Genital warts (condyloma acuminata) caused by HPV types 6 and 11. And the following precancerous or dysplastic lesions caused by HPV types 6, 11, 16, 18, 31, 33, 45, 52, and 58: • Anal intraepithelial neoplasia (AIN) grades 1, 2, and 3.

Table 2 FDA approved therapies for the treatment of precancerous lesions

Agent	*FDA indication*[a]
Imiquimod	1. Immunocompetent adults for the topical treatment of clinically typical, nonhyperkeratotic, nonhypertrophic actinic keratoses on the face or scalp.
Ingenol mebutate	1. Males and females for the topical treatment of actinic keratosis on the face, scalp, trunk, and extremities.
Diclofenac sodium	1. Males and females for the topical treatment of actinic keratoses.
Fluorouracil	1. Males and females for the topical treatment of multiple actinic or solar keratosis.
Photodynamic therapy with 5-aminolevulinic acid	1. Males and females for the topical treatment of minimally to moderately thick actinic keratoses of the face or scalp
Photodynamic therapy with photofrin	1. Males and females with high-grade dysplasia in Barrett's esophagus. Ablation of high-grade dysplasia in Barrett's esophagus who do not undergo esophagectomy
Bacillus-Calmette-Guerin	1. Males and females with carcinoma in situ of the urinary bladder. Intravesical use in the treatment and prophylaxis of carcinoma in situ of the urinary bladder and for the prophylaxis of primary or recurrence stage Ta and/or T1 papillary tumors following transurethral resection (TUS).
Valrubicin	1. Males and females with BCG-refractory carcinoma in situ. Intravesical therapy of BCG-refractory carcinoma in situ of the urinary bladder in patients for whom immediate cystectomy would be associated with unacceptable morbidity or mortality.

Chemoprevention Trial Results by Cancer Type

Head and neck cancers

Currently, the primary risk factors for squamous cell carcinoma of the head and neck (SCCHN) include tobacco smoke, alcohol consumption, and HPV (Forastiere et al., 2001). Originally described in 1953 (Slaughter et al., 1953), field cancerization is the predilection of the surface epithelium of the upper aerodigestive tract, or field, to develop additional cancers in patients with known carcinogen-related SCCHN. The specific premalignant changes found in areas of carcinogen-exposed epithelium adjacent to tumors can progress concurrently to form second primary tumors (SPTs). SPTs are a leading cause of mortality in head and neck cancer and typifies the concept of field cancerization (Vokes et al., 1993). The reversal of oral premalignant lesions (oral IEN or dysplastic oral IEN as intermediate biomarkers of invasive cancers) and prevention of SPTs have been the focus of extensive research since the 1980s.

Despite significant preclinical rational (Uray et al., 2016) and early phase trial success (Hong et al., 1990; Hong et al., 1986; Lippman et al., 1993) of retinoids, the most commonly tested chemopreventive agent, multiple large randomized clinical trials of these agents have failed to generate an FDA approval for oral cancer prevention (van Zandwijk et al., 2000; Bolla et al., 1994; Papadimitrakopoulou et al., 2009; Khuri et al., 2006). Although retinoids have not yet proven effective for SCCHN cancer prevention, numerous correlative studies within these trials have led to the discovery of markers of cancer risk including loss of heterozygosity (LOH) profiles (Mao et al., 1996), EGFR copy number gain (Taoudi Benchekroun et al., 2010), genetic variation (Lee et al., 2011), and gene expression signatures (Saintigny et al., 2011). For example, a large single nucleotide polymorphism (SNP) analysis of a cohort within the Retinoid Head and Neck Second Primary Trial of 13-cis-retinoic acid found that patients carrying the common genotype of rs3118570 in the retinoid X receptor were at a greater than threefold increased risk and that this locus along with two other genetic loci (CDC25C:rs6596428 and JAK2:rs1887427) identified those that had a 76% reduction in SPT/recurrence with chemoprevention (Lee et al., 2011). This data suggests that pharmacogenetic analysis might allow for improved targeting of "higher-risk" populations in future retinoid chemoprevention trials.

The Erlotinib Prevention of Oral Cancer (EPOC) study represents the first chemoprevention trial that was based a priori on personalized molecular characterization (William et al., 2016). Erlotinib, an EGFR tyrosine kinase inhibitor, was chosen based on the preclinical data, suggesting that EGFR amplification is associated with oral premalignant lesions (OPLs) transformation (Taoudi Benchekroun et al., 2010) and that EGFR inhibition prevents oral dysplasia (Leeman-Neill et al., 2011). In this trial, patients with OPLs were first evaluated for LOH at select loci and were considered high risk if LOH was present at 3p14 and/or 9p21 in patients with a history of invasive cancer or LOH at 3p14 and/or 9p21 plus an additional site including 17p, 11p, 13q, 4q, or 8p and were low-risk if not meeting either of these criteria. High-risk LOH patients (N = 150) were randomized to erlotinib or placebo and the primary endpoint was oral cancer free survival (CFS). The 3-year CFS rates in erlotinib versus placebo-treated patients were 70% and 74%, respectively, and were not statistically significant ($P = .45$). The study, however, did validate LOH as a marker for oral cancer risk as the 3-year CFS rates for LOH-positive versus LOH-negative groups were 74% and 87%, respectively ($P = .01$).

HPV-positive oropharyngeal squamous cell carcinoma (OPSCC) has increased in incidence by 225% from 1998 to 2004 and continues to rise (Chaturvedi et al., 2011). Approximately 7% of the adults aged 14–69 population harbor active oral HPV infection, however only 1% of woman and 3% of men have the high-risk HPV16 subtype (Gillison et al., 2012). Although it is not certain that HPV vaccinations have directly reduced OPSCC, secondary evaluation of a large HPV16/18 vaccine trial suggested that oral HPV prevalence 4 years after vaccination was significantly reduced as compared to control (Herrero et al., 2013).

Lung cancers

The rationale for prevention of lung cancer is similar to that in HNSCC. In both diseases, chronic exposure to tobacco is the major risk factor and dysplastic epithelial lesions are thought to represent a premalignant stage. Unfortunately, despite decades of work, a variety of agents including α-tocopherol (Alpha-Tocopherol, Beta Carotene Cancer Prevention Study Group, 1994), β –carotene (Hennekens et al., 1996; Omenn et al., 1996), retinoids (van Zandwijk et al., 2000; Lippman et al., 2001), selenium (Karp et al., 2013), and a combination of multivitamins and minerals (Kamangar et al., 2006) were all ineffective or deleterious (e.g., beta carotene) in large randomized phase III trials. These studies exemplify the limitations of utilizing epidemiological evidence and secondary endpoints in the absence of strong preclinical rational when planning chemoprevention trials.

For example, three large randomized, double-blind, placebo-controlled trials of β-carotene were conducted primarily based on epidemiological data alone. The Alpha-Tocopherol, Beta Carotene (ATBC) Cancer Prevention study was a primary-prevention trial in which 29,133 Finnish male smokers received α-tocopherol 50 mg a day, β-carotene 20 mg a day, both, or placebo. These men were between 50 and 69 years of age and all smoked five or more cigarettes a day and were followed for 5–8 years. Lung cancer incidence, the primary endpoint, did not change with the addition of β-tocopherol alone, nor did overall mortality. However, both groups who received β-carotene supplementation (alone or with α-tocopherol) had an 18% increase in the incidence of lung cancer. There appeared to be a stronger adverse effect from β-carotene in those men who smoked more than 20 cigarettes a day. This trial raised the serious issue that pharmacologic doses of β-carotene could potentially be harmful in active smokers. The β-Carotene and Retinol Efficacy Trial (CARET) confirmed the results of the Finnish ATBC trial (Omenn et al., 1996). This trial tested the combination of β-carotene 30 mg and retinyl palmitate 25,000 IU against placebo in 18,314 men and women aged 50–69 years at high risk for lung cancer; 14,254 had at least a 20 pack-year smoking history and were either current or recent former smokers. This trial was stopped after 21 months because no benefit and lung cancer incidence, the primary endpoint, increased 28%

in the active intervention group. Overall mortality also increased 17% in this group. The Physicians Health Study included 22,071 healthy male physicians treated with β-carotene 50 mg on alternate days or placebo (Hennekens et al., 1996). In contrast to the ATBC and CARET, the use of supplemental β-carotene showed virtually no adverse effects, however no beneficial effects on cancer incidence or overall mortality during a 12-year follow-up were observed. Given these results, high-dose β-carotene is not recommended for chemoprevention of lung cancer.

Although not based on epidemiologic data, the ECOG 5597 trial of selenium supplementation was largely based on a secondary analysis endpoint observed in a skin cancer prevention trial suggesting reduced lung cancer incidence (Karp et al., 2013; Clark et al., 1996). In this trial, 1561 patients with resected stage I NSCLC were randomly assisted to selenium 200 μg versus placebo daily for 48 months. The study was stopped early due to futility and showed no benefit of selenium over placebo.

Given the inaccessibility of the lungs for repeated histologic evaluations, practical intermediate biomarkers remain an area of unmet need. An interesting avenue of research is the potential role of bronchial airway gene expression signatures as a measure of risk and as a treatment response biomarker. In a murine model, researchers performed transcriptome sequencing to analyze bronchial airway gene expression and found activation of PI3K and Myc signaling in normal bronchial epithelial cells with precancer lung squamous cell carcinoma lesions (Xiong et al., 2017). Most notably, the activation of PI3K and Myc was reversed by treatment with the PI3K Inhibitor XL-147 and pioglitazone, respectively. If validated, these and similar biomarker studies might provide improved tools to analyze the effect of chemopreventive agents in high-risk individuals. The negative randomized trials described earlier highlight the need for coordinated efforts integrating epidemiological data, validated intermediate biomarkers, and most importantly a strong biologic rational prior to undertaking large chemoprevention trials (Szabo et al., 2013).

Colorectal cancers

Colorectal cancer (CRC) is associated with premalignant lesions, including adenomatous polyps and dysplastic epithelium. Large polyps with villous elements and dysplastic epithelia are more likely to progress to carcinoma than small, tubular polyps. The premalignant stages of colon carcinogenesis present an evaluable process for chemoprevention trials. Based on the well-established role of the cyclooxygenase (COX) enzymes and inflammation in colorectal carcinogenesis (Janakiram and Rao, 2014), aspirin and NSAIDs have been most extensively studied. In addition, fiber supplementation, hormone replacement therapy, and calcium salts have also underwent considerable evaluation.

The effects of aspirin on primary prevention of colon cancer have been examined in two large population-based trials including the Physician's Health Study (PHS) and the Women's Health Study (WHS). In the PHS, there was no benefit observed for aspirin at 325 mg every other day in the primary prevention of CRC at 5 or 12 years of follow up (Stürmer et al., 2006). In contrast, the WHS of aspirin at 100 mg every other day found no reduction in CRC at 10 years but after a median of 18 years of follow up, there was a reduction in risk (HR 0.80), which was primarily for proximal cancers (Cook et al., 2013). Though the reason for the discrepant results is not fully established, the PHS study only tested 5 years of aspirin and longer duration of treatment might be needed given the relatively prolonged latency to CRC development (Chan et al., 2005). Further supporting the role of aspirin for primary CRC prevention comes from the pooled secondary analysis of four large European and British trials that evaluated the effect of aspirin on vascular events. This analysis included 14,033 patients and suggested that the 20-year incidence of colon, but not rectal cancer, was decreased by nearly 25% (HR 0.76) when given beyond four years and at a dose of at least 75 mg daily (Rothwell et al., 2010). This compelling evidence led the US Preventive Services Task Force (USPSTF) to recommend "low-dose aspirin use for the primary prevention of cardiovascular disease (CVD) and colorectal cancer in adults ages 50 to 59 years who have a 10% or greater 10-year CVD risk, are not at increased risk for bleeding, have a life expectancy of at least 10 years, and are willing to take low-dose aspirin for at least 10 years (Bibbins-Domingo, 2016)". For patients 60–69 years old, the USPSTF suggested consideration of low-dose aspirin after discussion of risks and benefits and for patients $\leq$49 or $>$70 years, there was insufficient evidence to recommend aspirin as chemoprevention. The USPSTF suggested utilizing the freely available ASCVD Risk Estimator from the ACC/AHA for estimating 10-year cardiovascular risk (Goff et al., 2013).

The role of aspirin as secondary prevention of recurrent adenomas after resection of adenomas is supported by a metaanalysis involving four clinical trials with 2967 randomly assigned patients (Cole et al., 2009). The risk of adenoma recurrence was lower for aspirin at any dose versus placebo (risk ratio [RR], 0.83), corresponding to an absolute risk reduction of nearly 7%. For advanced lesions, as defined as tubulovillous adenomas, villous adenomas, adenomas $\geq$1 cm in diameter, adenomas with high-grade dysplasia, or invasive cancer, the risk reduction was even greater (RR 0.72). These data suggest that aspirin is associated with a 20%–35% reduction in colonic adenomas and CRC incidence in average risk adults.

The role of aspirin in hereditary CRC syndromes has also been evaluated in a pragmatic series of studies within the Colorectal Adenoma/Carcinoma Prevention Programme (CAPP). CAPP1 randomized 133 patients with familial adenomatous polyposis (FAP) to 600 mg aspirin daily or placebo and found a nonsignificant trend suggesting reduction in polyp count (RR 0.77) (Burn et al., 2011). In CAPP2, 937 patients with hereditary nonpolyposis colon cancer (Lynch Syndrome) were similarly randomized and no significant effect on incidence of adenoma formation or carcinoma was observed with aspirin therapy (Burn et al., 2008). Notably, in a perprotocol secondary analysis, patients in CAPP2 who received aspirin 600 mg daily for at least 2 years had a nearly 60% reduction in colorectal cancer incidence (Burn et al., 2011). An ongoing study evaluating different doses of aspirin in Lynch Syndrome is ongoing (CAPP3) and eagerly awaited.

Similar to aspirin, COX-2 inhibitors and sulindac have also been extensively studied. Forms of the COX enzyme include COX-1, which is constitutively expressed, and COX-2, which is overexpressed in inflammatory cells and has been associated with colorectal adenomatous polyp and cancer formation. Most NSAIDs inhibit both enzymes, however inhibition of COX-2 specifically reduces

untoward side effects such as ulcers and gastritis. The Prevention of Colorectal Sporadic Adenomatous Polyps (PreSAP, $N = 1561$) and Adenomas Prevention with Celecoxib (APC, $N = 2035$) were large randomized placebo-controlled trials in patients with resected adenomas and both found significant 30%–50% reduction in recurrent polyp formation (Bertagnolli et al., 2006; Arber et al., 2006). However, both trials also observed a significant increase in adverse cardiovascular events (two- to threefold) precluding the routine use of this agent. Similarly, a smaller study of celecoxib in FAP showed significant benefit and led, in part, to the accelerated approval of celecoxib for patients with phenotypic expression of FAP (Steinbach et al., 2000). However, this indication was subsequently voluntary removed in 2011 by the manufacturer due to delays in completing follow up studies required under the approval. Additionally, despite three small ($N = 10–24$) studies of sulindac suggesting secondary preventive benefit of adenoma regression, number, and size in phenotypic FAP, a study of 41 genotypically confirmed, but not phenotypically affected, patients with FAP over four years failed to show sulindac prevented the development of adenomas compared with placebo (Giardiello et al., 2002). Given the established harm (cardiovascular and gastrointestinal) associated with long-term use of NSAIDs, these agents cannot currently be recommended for primary or secondary prevention of CRC.

Fiber in the prevention of colon cancer has been examined in several studies. The Polyp Prevention Trial studied 2079 patients with a history of colorectal adenomas randomized to receive counseling, a low-fat, high-fiber diet rich in fruits and vegetables, or to continue their current diet without counseling (Schatzkin et al., 2000). Colonoscopy after one and four years found no difference in the incidence of recurrent adenomas. Another study by the Phoenix Colon Cancer Prevention Physician's Network studied 1429 patients with a history of colorectal adenoma (Alberts et al., 2000). These patients were randomized to receive supplemental wheat bran, 2.0 or 13.5 g a day. Again, no difference in the incidence of recurrent adenomas was found between the two groups. Currently, there is no prospective evidence that fiber supplementation is effective for colorectal cancer prevention.

Hormone replacement therapy in women in the form of combined estrogen plus progestin was observed to reduce the risk of CRC by nearly 45% in the Women's Health Initiative (WHI). However, extended follow up of WHI suggested that with longer-term therapy, women receiving combination therapy had more advanced CRC diagnosis with a higher, albeit, nonstatistically significant increase in CRC morality rate (Simon et al., 2012). Given this data along with the negative data of unopposed estrogen (Lavasani et al., 2015), and the long-term cardiovascular concerns of HRT, HRT cannot be recommended for CRC prevention.

High intake of calcium salts has been associated with lower risk of colorectal cancer along with synergistic chemopreventive effects when combined with vitamin D (Grau et al., 2003; Pence, 1993). Despite the biologic rational and epidemiological data, a large randomized trial of 2259 patients receiving vitamin D3 1000 IU, calcium carbonate 1200 mg, both, or neither daily showed no difference in colorectal adenoma formation over a 3–5-year period (Baron et al., 2015). Another similar randomized trial of 36,282 postmenopausal women showed no benefit of calcium and vitamin D over placebo in the development of CRC during a seven-year period.

Nonmelanoma and melanoma skin cancers

Chemoprevention of skin cancers represents an ideal target organ for chemoprevention due to the sheer incidence in humans and practical accessibility of the skin. The vast majority of nonmelanoma skin cancers (NMSC) include cutaneous squamous cell carcinoma (cSCC) and basal cell carcinoma (BCC). cSCC accounts for 10%–20% of NMSC and occurs largely as a result of intraepithelial ultraviolet (UV)-induced damage which leads to a sequence of molecular changes, most often involving mutations of the p53 tumor suppressor gene (de Gruijl et al., 2001). cSCC has been the focus of the most chemoprevention trials due to the presence of the identifiable premalignant lesion, the actinic keratosis (AK) in 60%–70% of cSCC (Fernandez Figueras, 2017).

Currently, the primary strategy for lesion-directed therapy for a single or few AKs involves ablative modalities with curettage, cryosurgery, or electrodessication. Field-directed topical therapies, including 5-fluorouracil cream, imiquimod cream, diclofenac gel, ingenol mebutate gel, and delta-aminolevulinic acid photodynamic therapy have all been FDA-approved for the treatment of AKs (see **Table 2**). These topical agents have been extensively studied in randomized controlled trials; however, no large trials comparing the efficacy between these agents have been undertaken. Despite inherent limitations of cross trial comparisons, their effect on AK clearance and adverse effects are comparable (Haque et al., 2015; Gupta et al., 2012).

Retinoids, including retinol, acitretin, isotretinoin, and etretinate, have been the mainstay of oral chemoprevention trials directed at reduction of NMSCs. In a phase III trial, 2297 patients who were at moderate risk for skin cancer, including patients with a history of >10 AKs and ≤ 2 prior NMSCs, received oral retinol 25,000 IU or placebo daily for 5 years (Moon et al., 1997). Retinol treatment was effective in reducing the incidence of cSCC (HR 0.74), but not BCC. However, another much larger ($N = 22,071$) primary prevention trial of β-carotene compared with placebo showed no effect on cSCC or BCC (Frieling et al., 2000). Importantly, even in higher-risk patients with a history on NMSCs, three phase III trials that tested the effects of retinol (Levine et al., 1997), β-carotene (Greenberg et al., 1990), and low-dose isotretinoin (Tangrea et al., 1992) demonstrated that these retinoids had no effect on the incidence of SPTs.

The immunosuppression required for organ transplant patients is an established strong risk factor (65–250-fold) for the development of aggressive cSCC (Tufaro et al., 2015). The second-generation retinoid acitretin has shown some clinical benefit particularly in high-risk organ transplant recipients. For example, a randomized placebo-controlled trial of 44 renal-transplant patients showed that acitretin at 30 mg daily over a 6-month period reduced new cSCC and AKs compared with placebo (11% vs. 47% and 13% vs. 28%, respectively)(Bavinck et al., 1995). However, in another small trial ($N = 26$) of low (0.2 mg/kg daily) versus high-dose (0.4 mg/kg daily) acitretin, no difference in cSCC was observed (de Sévaux et al., 2003). Acitretin in nontransplant high-risk patients failed to

show benefit over placebo (Kadakia et al., 2012). Although systemic retinoids are used in high-risk patients in practice (Otley et al., 2006), neither acitretin nor any other systemic retinoid is FDA approved. Importantly, use of these agents is limited to the duration they are taken and rapid AKs/NMSC devolvement upon discontinuation can occur (George et al., 2002).

Despite preclinical data supporting the efficacy of COX-2 inhibition and the ornithine decarboxylase inhibitor α-difluoromethylornithine (DFMO), neither agent in randomized placebo-controlled trials met their primary endpoint of reduction in AKs (Elmets et al., 2010) and NMSCs (Bailey et al., 2010), respectively. Nicotinamide (Vitamin B3) at 500 mg twice daily, which is protective against UV damage, was tested in a randomized placebo-controlled trial in 386 patients with a history of ≥ 2 NMSCs (Chen et al., 2015). There was a significant 23% reduction in new NMSC, with a slightly higher reduction in cSCC compared with BCC (30% vs. 20%). Although promising, longer-term safety and efficacy are needed prior to recommending nicotinamide for secondary prevention. Lastly, a phase II randomized placebo-controlled trial of vismodegib, an oral hedgehog inhibitor approved for locally advanced or metastatic BCC, at 150 mg daily showed significant chemopreventive action in patients with the highly penetrant nevoid basal cell carcinoma syndrome, however 54% of patients discontinued treatment due to toxicity (Tang et al., 2012).

Although significant advances in the field of immuno-oncology have changed the prognosis of advanced melanoma, no agent, including vitamin D, NSAIDs, sulindac, and lipid-lowering drugs, has yet been proven to successfully prevent neoplastic melanocytic transformation (Chhabra et al., 2017).

Breast cancer

Chemoprevention approaches in breast cancer focus on preventing breast cancer in high-risk patients. This strategy stemmed from the success of tamoxifen, a selective estrogen-receptor modulator (SERM), in reducing recurrent breast cancer by 40%–50% following definitive therapy for estrogen-receptor (ER) positive breast cancer (Early Breast Cancer Trialists' Collaborative Group (EBCTCG) et al., 2011). Multiple large trials of tamoxifen compared with placebo in both high-risk and average risk women have been conducted since the 1990s. A 2013 meta-analysis revealed that compared to placebo tamoxifen decreased the incidence of invasive breast cancer, primarily as a reduction in ER positive breast cancer risk by 30% (RR 0.70) and a reduction in nonvertebral factures risk by 34% (RR 0.66) but had no impact on breast cancer-specific or all-cause mortality (Nelson et al., 2013). The long-term follow up of the STAR (Study of Tamoxifen and Raloxifene) trial found that the second-generation SERM raloxifene confers 78% efficacy of tamoxifen in breast cancer prevention, however was not associated with an increase in uterine cancer (Nelson et al., 2013; Vogel et al., 2010). Despite the chemopreventive benefits observed, a patient-level meta-analysis of 83,399 patients involved in SERM chemoprevention trials showed that multiple rare but serious risks occur including a slight increase in uterine cancer (105 vs. 63 events, HR 1.56) and thromboembolic disease (375 vs. 215, HR 1.73)(Cuzick et al., 2013). Based on these data, tamoxifen and raloxifene were FDA-approved for the primary prevention of breast cancer in high-risk population (see **Table 1**). High-risk in these studies was defined as women at least 35 years of age with a 5-year predicted risk of breast cancer $\geq 1.67\%$, as calculated by the Gail Model (Rockhill et al., 2001).

Aromatase inhibitors, which have also showed significant benefit over tamoxifen in the adjuvant breast cancer setting in postmenopausal women (Early Breast Cancer Trialists' Collaborative Group (EBCTCG) et al., 2015), have also been evaluated for primary prevention in high-risk patients. Both exemestane (NCIC-MAP3 trial, $N = 4560$) and anastrozole (IBIS-II trial, $N = 3864$) as compared to placebo revealed significant reductions in invasive breast cancer by 50%–65% (Goss et al., 2011; Cuzick et al., 2014). As with SERMs, neither anastrozole or exemestane significantly reduced. Anastrozole and exemestane are not yet FDA-approved for risk reduction.

Despite the minimal negative effect on quality of life reported in the major phase III chemoprevention trials of SERMs and AIs, uptake of these agents in the clinic has been very low. For women aged 35 years or older with increased risk of breast cancer and low risk of adverse effects, the USPSTF provides a grade B recommendation and supports shared and informed decision making when offering tamoxifen or raloxifene. Both agents are effective in pre- and postmenopausal women (Nelson et al., 2013). For high-risk patients who wish to pursue chemoprevention, raloxifene is a reasonable choice if concerns for uterine cancer and thromboembolic disease predominate and tamoxifen if risk of breast cancer prevention predominates. To date, there are no proven therapies to prevent HER2-positive breast cancers, although trials are ongoing targeting anti-HER2 therapy for HER2-positive ductal carcinoma in situ and might provide rational for future chemoprevention studies.

Esophageal and gastric cancer

Esophageal adenocarcinoma (EAC) and esophageal squamous cell carcinoma (ESCC) are the two predominate histologic subtypes of esophageal cancer. Though historically less common, the incidence of EAC has dramatically risen in the US and westernized countries and is suspected to be related to multiple risk factors including obesity and gastroesophageal reflux disease (Zhai et al., 2010; Drahos et al., 2016).

Given the precursor premalignant lesion (Barrett's esophagus) in EAC, secondary prevention utilizing endoscopic screening in high-risk patients as well as local ablative and excisional therapies for established high-grade Barrett's esophagus is the current clinical approach to reduce the risk of progression to EAC. The FDA approved porfimer sodium in conjunction with photodynamic therapy (PDT) in 2003 based on a randomized trial of this combination versus omeprazole alone in 208 patients with high-grade dysplasia (Overholt et al., 2005). Complete ablation of high-grade dysplasia and progression to invasive cancer was improved with porfimer sodium than with omeprazole alone (77% vs. 39% and 13% vs. 28%, respectively), however serious complications

occurred in 12% and strictures in 36%. Radiofrequency ablation with mucosal resection has replaced PDT due to the improved efficacy and safety (Shaheen et al., 2009). A randomized trial of celecoxib in patients with Barrett's esophagus showed no difference in regression of dysplasia as compared to placebo (Heath et al., 2007). A large study of 2500 patients (AspECT trial) comparing aspirin in combination with low or high-dose esomeprazole to esomeprazole alone and has completed accrual and results are eagerly awaited.

In contrast to EAC, ESCC remains prevalent in developing countries and is associated with tobacco and alcohol exposure as well as nutrient deficiencies and exposure to *N*-nitroso compounds. Multiple large randomized chemoprevention studies involving residents of Linxian, China tested the effects of combinations of agents such as retinol, riboflavin, zinc, selenomethionine, and vitamin E without a clear signal of benefit (Blot et al., 1993; Wang et al., 2013; Limburg et al., 2005). A 10-year follow up of the largest trial involving 29,584 patients suggested a 17% reduction in ESCC mortality in those aged <55 years, but an increase of 14% in mortality in those aged ≥ 55 years (Qiao et al., 2009). The interpretation of these studies is made difficult by the use of readily available vitamin supplements in the control arm, blurring potential differences from the treatment arm. This represents an inherent flaw in trials utilizing vitamin supplements and dietary interventions.

Worldwide, *Helicobacter pylori*, a Gram-negative microaerophilic bacterium, are frequently associated with noncardia gastric cancers. Although treatment of *H. pylori* with a combination of antibiotics and a proton pump inhibition ("triple therapy") is clearly effective, data to support a chemopreventive role of such therapy on decreasing gastric cancer occurrence are becoming increasingly realized. One large trial involving 3365 patients randomized patients to amoxicillin and omeprazole for two weeks and showed that at 15 years follow up the incidence of gastric cancer was reduced in those receiving antibiotic therapy (3% vs. 4.6%, odds ratio of 0.61) (Ma et al., 2012). COX-2 inhibition with celecoxib for 24 months was tested alone or following *H. pylori* treatment versus placebo in a randomized trial of 1024 patients with *H. pylori* and advanced gastric lesions (as defined as severe chronic atrophic gastric, intestinal metaplasia, indefinite dysplasia, or dysplasia) (Wong et al., 2012). Interestingly, regression of gastric lesions was increased by both celecoxib and anti-*H. pylori* treatment alone (53% vs. 41% and 59% vs. 41%, respectively), however celecoxib following anti-*H. pylori* treatment showed no benefit over placebo. A meta-analysis of aspirin from cardiovascular disease trials revealed that aspirin was associated with reduction in a variety of cancers including gastric cancer mortality if treated for >10 years (HR 0.42) (Rothwell et al., 2011).

Based on the available evidence, screening and local ablative therapies for high-risk Barrett's esophagus to prevent EAC and treatment of *H. pylori* in high-risk areas is recommended. Although data regarding NSAIDs and aspirin appear encouraging, large phase III studies are needed before firm recommendations can be made.

Bladder cancer

Urothelial carcinoma of the bladder is most commonly attributed to tobacco as well as environmental and occupational carcinogen exposures. Although a number of trials for primary and secondary chemoprevention have been conducted, none have proven effective with the exception of intravesical agents. Only Bacillus-Calmette-Guerin (BCG) and intravesical valrubicin in BCG-refractory patients are FDA-approved (**Table 2**). A comprehensive review of intravesical therapy to prevent recurrence of nonmuscle invasive bladder cancer will not be reviewed here. Instead, the results of major chemoprevention trials of oral agents will be discussed.

Previous studies using retinoids to prevent recurrence in bladder cancer patients have been small and limited by toxicity. Two trials with prolonged low-dose etretinate appeared to have some efficacy. One double-blind, placebo-controlled trial studied the preventive effect of etretinate in 30 patients with superficial bladder cancers (Alfthan et al., 1983). A reduction in recurrence was seen, however a larger multicenter randomized study of 90 patients observed significant toxicity including deaths from myocardial infarction precluding further study of this agent (Studer et al., 1995). Fenretinide, a better tolerated retinoid, failed to show any significant difference in recurrence rates over placebo in two randomized trials (Sabichi et al., 2008; Decensi et al., 2000). Notably, no benefit of retinoids as primary prevention of bladder cancer was observed in the ATBC trial (described in **Lung Cancers** section) or a meta-analysis of six case-control studies (Alpha-Tocopherol, Beta Carotene Cancer Prevention Study Group, 1994; Steinmaus et al., 2000).

A number of other agents including vitamins, selenium, DFMO, and NSAIDs have been studied with largely disappointing results. Pyridoxine (vitamin B6) was hypothesized to counteract the high level of tryptophan metabolites observed in patients with bladder carcinoma. Despite encouraging results from a smaller trial, a larger European Organization for Research and Treatment of Cancer double-blind randomized phase III trial of 291 men with superficial bladder cancer showed no difference between pyridoxine and placebo with regards to recurrence rate or time to first recurrence (Newling et al., 1995). Notwithstanding promising preclinical rational, the phase III Selenium and Bladder Cancer Trial (SELEBLAT) randomized141 patients with noninvasive bladder cancer to selenium-yeast supplementation at 200 μg/day for 3 years and observed no significant decrease in recurrence compared with placebo (Goossens et al., 2016). Similarly, DFMO, a polyamine synthesis inhibitor, at 1 gram daily for 12 months failed to prevent recurrent bladder cancer compared with placebo (Messing et al., 2006). NSAIDs have also failed to show benefit in preventing secondary bladder cancer. In one trial patients were treated with celecoxib 200 mg twice daily for an average of 1.25 years with no difference in recurrence rate compared with the placebo group (Sabichi et al., 2011). Another larger double-blind phase III trial of celecoxib 200 mg twice daily for two years found no difference in recurrent disease and observed an increase in cardiovascular events (Kelly et al., 2015).

Currently, there is no role for any nonintravesical chemoprevention agent in the primary or secondary prevention of bladder cancer.

Cervical cancer

Following the regular implementation of the Papanicolaou (Pap) test for cervical cancer screening, a marked reduction in cervical cancer incidence and mortality in the US and worldwide was observed (Peirson et al., 2013). HPV is the chief etiologic agent for cervical cancer carcinogenesis. Although there are at least 118 HPV types, around 40 are specific to the anogenital epithelium and among these, several high-risk HPV types are considered carcinogenic including HPV types 16 and 18, which account for 70% of diagnoses (de Villiers et al., 2004). Both squamous cell carcinoma and adenocarcinoma of the cervix undergo well-recognized premalignant dysplastic stages (i.e., cervical intraepithelial neoplasia [CIN] 1–3 and adenocarcinoma in situ [AIS], respectively) that are accessible for chemoprevention study.

Primary prevention with HPV vaccination has markedly reduced the risk of cervical cancer and the development of CIN 2 and 3. The FUTURE II trial randomized 12,167 women between the ages of 15 and 26 to three doses of either HPV-6/11/16/18 vaccine or placebo, given at day 1, month 2, and month 6 with a primary composite endpoint of CIN 2 or 3, AIS, or cervical cancer related to HPV 16 or 18. At three years, the quadrivalent vaccine prevented the primary composite endpoint by 98% compared with 44% in the placebo group (FUTURE II Study Group, 2007). In a subsequent randomized trial of 14,215 women aged 16–26, the 9-valent HPV vaccine was equally effective at preventing cervical, vulvar, and vaginal cancers and warts as the quadrivalent vaccine (Joura et al., 2015). Other large trials of the bivalent HPV vaccine also showed similar efficacy in preventing CIN 2 or more severe disease due to HPV infection (Hildesheim et al., 2014). Quadrivalent HPV vaccination of 4065 boys and men aged 16–26 prevented infections with HPV-6/11/16/18 and led to 60% less genital lesions compared with placebo (Giuliano et al., 2011). These data led to the FDA approval of HPV vaccines: Gardasil9 for males and females as well as Cervarix for females (see **Table 1**).

Prior to the development of HPV vaccination, chemoprevention utilizing a variety of agents including interferon, folic acid, β-carotene, DFMO, and retinoids were tested with largely negative results. The efficacies of HPV vaccination along with the improved techniques of cervical screening remain the cornerstone of cervical cancer prevention.

Prostate cancer

The high incidence, long latency, dependence on androgen, and known intermediate biomarkers (high-grade prostatic intraepithelial neoplasia [HG-PIN] and prostate specific antigen [PSA]) of prostate cancer has led to numerous efforts focusing on chemoprevention. The 5-αreductase (5-AR) inhibitors and nutrients including selenium and vitamin E have been best studied.

The Prostate Cancer Prevention Trial (PCPT) was launched in 1993 with its principle endpoint being a reduction of biopsy-proven prostate cancer incidence. This double-blind placebo-controlled trial included 18,882 males aged 55 years and older who were randomized to finasteride, a 5-AR inhibitor, at 5 mg or placebo daily for seven years. The trial was closed early due to meeting the primary study endpoint with a 25% decrease in biopsy-proven prostate cancer, however controversy ensued due to the observed absolute increase in number and proportion of patients with high-grade (Gleason score $\geq$7) prostate cancers (Thompson et al., 2003). At 18 years of follow up, the risk of high-grade prostate cancer remained elevated in patients randomized to finasteride (3.5% vs. 3%) and no between-group difference in the rates of overall or cancer-specific survival was observed (Thompson et al., 2013). In another trial (REDUCE trial) testing the 5-AR inhibitor dutasteride in men with an elevated PSA of 2.5–10 ng/mL and a negative prostate biopsy showed a nearly 25% reduction in biopsy-proven prostate cancer. However, similar to PCPT, higher rates of high-grade prostate cancer were observed (Andriole et al., 2010).

Selenium and vitamin E also had been observed to decrease prostate cancer incidence in several early phase trials. Based on these early phase studies, the National Cancer Institute launched the SELECT trial which tested if selenium 200 μg/day, vitamin E 400 IU/day, both, or placebo in 35,533 men with PSA $\leq$SA 33 menbolenium 200 μg/day, exam (Klein et al., 2011). Study treatment was stopped after a three-year interim analysis suggested futility and vitamin E was noted to increase the risk of prostate cancer (HR 1.17). Similarly, selenium alone or in combination with vitamin E showed no chemopreventive benefit even in those with low selenium status. Importantly, selenium increased the risk of high-grade prostate cancer among those with high selenium status (Kristal et al., 2014).

Currently, the evidence to support any 5-AR inhibitor for prostate cancer chemoprevention is limited due to the potential for increasing high-grade prostate cancer and the lack of any demonstrable impact on mortality. Nutrients including selenium and vitamin E, above the recommended dietary intake, should not be endorsed for the chemoprevention of prostate cancer.

Hepatocellular carcinoma

HBV and hepatitis C virus (HCV) account for the major risk factors for hepatocellular carcinoma (HCC) due to the development of chronic liver disease. HBV-related HCC has declined with the increasing use of the HBV vaccination. In a 20-year follow-up study from Taiwan, where universal vaccination was first implemented in 1984, there was a nearly 70% risk reduction of HCC in vaccinated compared with unvaccinated cohorts (Chang et al., 2009). Although an effective HCV vaccine has yet to be created, observational data of antiviral therapy in the form of interferon or direct-acting antivirals might reduce the risk of HCV-related HCC, particularly those resulting in sustained viral response (Chou et al., 2014; Smith et al., 2012). Studies of retinoids in HCC have been described as well. A prospective randomized trial of 89 patients who were definitively treated for HCC received polyprenoic acid (600 mg daily) or placebo for 12 months. There was a significant decrease in recurrent HCC in the retinoid-treated group (27% vs. 49%) which lasted up to 199 weeks after randomization (Takai et al., 2005; Muto et al., 1996; Chu et al., 2010). Further studies are needed to verify these encouraging results.

Future Directions

Cancer Risk Models

Optimally, treatment of epithelial malignancies should move toward prevention. Since the early 1980s, many patients at high risk for epithelial cancers, mostly those with premalignant lesions or a personal history of epithelial malignancy, have been enrolled in chemoprevention trials (as described earlier). While this accounts for a substantial number of patients, the vast majority of epithelial malignancies arise in patients with no history of either of these risk factors. This particular population is, at present, generally unrecognizable and is therefore most often not entering chemoprevention trials. This highlights the need to develop risk models to define high-risk people from the general population.

Historically, cancer risk models have relied largely on risk factors obtained from population-level data. The Gail Model of breast cancer risk represents a relatively simple example of this and is related to multiple variables accounting for estrogen exposure (Rockhill et al., 2001). Although the Gail Model is validated in breast cancer, similar models for other cancers as well as more refined breast cancer risk assessments ideally require the incorporation of measurable objective biologic data. A simple example of such an objective risk assessment is diagnosing heredity breast and ovarian cancer syndrome via germ-line molecular testing of the BRCA-1 and BRCA-2 genes. This thereby allows identification of a high-risk cohort available for further study. However, for more common non-hereditary cancers it is likely that a combination of histologic, genetic, epigenetic, and proteomic analyses will elucidate those at highest risk. Utilizing transcriptome meta-analysis, scientists found specific gene signatures that drive HCC risk in cirrhosis (Nakagawa et al., 2016). Other studies utilizing novel technologies such as hierarchical gene clustering and computer-assisted imaging analysis (e.g., morphometric signatures) are ongoing (Gann et al., 2013; Ciriello et al., 2015). If validated, such comprehensive tools can be used to select the "highest-risk" patients for chemoprevention trials, thereby avoiding diluting any possible signal of efficacy by inclusion of lower-risk patients.

Summary

The ultimate goal of oncology is to prevent rather than treat morbid invasive cancer. Despite multiple chemoprevention trial failures described earlier, the successes of endocrine therapy in breast cancer primary prevention and HPV vaccinations in cervical cancer provide proof of principle that chemoprevention has the potential to significantly decrease the burden of cancer in society. Ongoing advances in our understanding of the molecular complexities driving carcinogenesis provide a plethora of new avenues to investigate. Current concerted multidisciplinary efforts such as the Precancer Atlas represent a major shift toward better defining the earliest features of neoplasia and exploiting all the technological advances in contemporary science to successfully undertake future precision chemoprevention trials (Spira et al., 2017).

Definition and Classification

Cholangiocarcinoma (CC; ICD-O code: 8160/3; also called bile duct carcinoma and bile duct adenocarcinoma) is a term which encompasses a heterogeneous group of malignant tumors with pathological features of biliary tract differentiation, distinct from gallbladder cancer. It is presumed to arise from the intra- or extrahepatic biliary epithelium (cholangiocytes), although some studies have suggested that it may also arise directly from transdifferentiation of hepatocytes.

Cholangiocarcinoma is classified into subtypes based on its anatomical origin, with, however, some debate and even confusion in the nomenclature.

Traditionally, cholangiocarcinomas were divided into intrahepatic and extrahepatic. However, the boundary between intra- and extrahepatic biliary tree has been somewhat confused in the literature. Still, while the term "intrahepatic cholangiocarcinoma" seems to be well accepted, the use of the term "extrahepatic cholangiocarcinoma" and the nomenclature of the subtypes have been extensively discussed and revised in the past decade, and different terms referring to the same entities can be encountered in both clinical guidelines and in scientific literature.

Intrahepatic cholangiocarcinoma (ICC) is an intrahepatic malignancy with biliary epithelial differentiation. ICC can arise in any portion of the intrahepatic biliary tree, from the segmental and area ducts and their major branches to the smallest bile ducts and ductules. ICC arising from the small intrahepatic bile ducts is often called peripheral ICC but the International Classification of Diseases for Oncology (ICD-O) discourages the use of this term. CC originating from major intrahepatic ducts, including the hilum, has been called hilar CC. However, due to symptoms which are similar to those of extrahepatic CC, it has been classified as an extrahepatic lesion. Hilar tumors arising near the junction of the right and left hepatic duct are traditionally called Klatskin tumors. Current guidelines recommend classifying extrahepatic CC into two subtypes: perihilar and distal CC. However, the term "hilar cholangiocarcinoma" is still widely used. Moreover, one should bear in mind that distinguishing hilar and perihilar CC at advanced stages is usually controversial. All in all, the exact meaning (anatomical scope) of these two terms differs between different specialists.

Presentation and Diagnosis

Early CC symptoms are not specific and so most patients present with advanced disease, with extensive hepatic artery and/or portal vein infiltration by tumor and/or with distant metastases, which makes the definitive treatment impossible. A majority of them

present when jaundice or the sequelae of biliary obstruction appear. The degree of jaundice depends on the extent of biliary involvement. Abdominal pain, weight loss, fever, malaise, and/or hepatomegaly occur in half of the cases, usually in those with the advanced disease. Patients with unrelieved obstruction of large intrahepatic bile ducts may die from complications, such as liver failure or sepsis.

It has been proposed that CC can be diagnosed based on a combination of clinical presentation, blood serum testing, and imaging. However, as many of the criteria lack specificity, a pathological examination is recommended for definitive diagnosis in most patients.

The initial workup in case of suspected CC comprises blood serum testing. Elevated serum bilirubin and alkaline phosphatase (ALP) levels are common in CC patients. However, incomplete obstruction of the right or left hepatic ducts may lead to isolated elevation of ALP. Increased liver transaminase levels and prothrombin time are detected in case of a long-standing biliary obstruction but also cholestatic hepatocellular injury. Increased serum carbohydrate antigen 19-9 (CA 19-9) and carcinoembryonic antigen (CEA) levels are very common (up to 90%) but they are not specific to CC, either.

High-quality cross-sectional imaging plays a key role in the diagnostic process as well as in the preoperative workup. High-resolution contrast-enhanced multidetector computed tomography (MDCT) and magnetic resonance imaging/magnetic resonance cholangiopancreatography (MRI/MRCP) are considered to be the most accurate.

For tissue diagnosis based on brush cytology, both endoscopic retrograde cholangiopancreatography (ERCP) and percutaneous transhepatic cholangiography (PTC) have similar sensitivity and specificity. ERCP with brush cytology is particularly specific for the diagnosis of distal CC and has been the standard diagnostic method for years. However, it has a low sensitivity for some cellular patterns. Various techniques have been investigated to increase sensitivity of cytological testing. In particular, fluorescence in situ hybridization (FISH) has been reported to increase the detection sensitivity to up to 93%.

Endoscopic methods, such as endoscopic ultrasound scan (EUS), intra-ductal ultrasound (IDUS), and cholangioscopy, are used selectively in diagnosing and staging. Cholangioscopy offers direct visualization of biliary strictures and enables targeted biopsies, which increases both diagnostic sensitivity and specificity. IDUS enables detailed imaging of the bile ducts and periductal tissue and has been reported to improve diagnostic accuracy of ERCP. However, stents that are often required to drain obstructed bile ducts make the interpretation of IDUS results difficult. If this is the case, the use of EUS in combination with fine-needle aspiration (FNA) may be preferable. The latter is also useful to detect suspicious regional lymph node involvement. Radiological analyses are necessary for assessing the disease extent (locoregional or distant spread), staging, and resectability.

CCs have a locally aggressive behavior, presenting mainly with infiltration of contiguous structures (liver, hepatic artery and portal vein) and nodal involvement (up to 30% at diagnosis), microscopically invasive spread with neural, perineural and lymphatic involvement, and subepithelial extension. Intrahepatic CCs can be divided into mass-forming, periductal infiltrating, and intraductal growth types. Perihilar CCs can have exophytic (mass-forming) or intraductal macroscopic growth patterns. Over 90% of CCs are well differentiated and mucin-producing adenocarcinomas.

Epidemiology and Risk Factors

Burden

Globally, cholangiocarcinoma is a very rare tumor, accounting for 3% of all gastrointestinal malignancies and less than 1% of all cancers worldwide. However, intrahepatic CC is the second most common primary liver cancer (after hepatocellular carcinoma), with very high mortality rates. The exact incidence of different subtypes is difficult to estimate due to changing nomenclature and coding issues. However, a majority of CCs arise from the intrahepatic upper third of the biliary tract, including the hilum (50%–70% of all tumors). In countries for which incidence trends have been studies, the rates are reported to be rising.

The overall CC incidence shows striking geographical differences, with the highest incidence rates in northeastern Thailand where parasitic infections with endemic liver flukes lead to infestation of the billiary tree. CC occurs with roughly the same incidence in men and women, in most cases after 60 years of age.

Etiology and Risk Factors

Infections with liver flukes (*Clonorchis sinensis and Opisthorchis viverini)*, common in such areas of high CC incidence as Thailand (*O. viverini*) and China (*C. sinensis*), have been shown to be associated with an increased risk of CC, with a high proportion of CC patients being infected. Chronic infection with these parasites causes severe inflammation damage. Moreover, infections with hepatitis B or C virus have been shown to increase the risk of developing intrahepatic CC by contributing to the development of liver cirrhosis.

Several other medical conditions of the gastrointestinal tract have been associated with an increased risk of CC, such as inflammatory bowel disease (in particular chronic ulcerative colitis), primary sclerosing cholangitis, choledocholithiasis, and biliary stone disease. Elevated CC incidence rates have also been reported in patients with congenital anomalies of the intrahepatic and extrahepatic bile ducts (e.g. cysts, congenital dilation of the bile ducts, choledochal cyst, Caroli disease, congenital hepatic fibrosis, polycystic disease, abnormal pancreaticocholedochal junction).

A history of exposure to thorotrast, an alpha-particle emitter that was used as a radiopaque intra-arterial contrast medium between 1930 and 1955 is also a causative factor of CC, with latency period that may range from 25 to 48 years.

Finally, it has also been suggested that tobacco smoking, alcohol consumption and diabetes may contribute to the risk of intrahepatic CC.

Pathology and Genetics

The genetic background of CC is poorly defined. Gains and losses in chromosomal regions containing oncogenes and tumor suppressor genes (e.g., *EGFR*, *ERBB2*, *MAP2K2*/*MEK*) have been linked to the development of CC, while somatic mutations are relatively rare.

Mutations of *KRAS*, *TP53*, and *IDH1* seem to be the most common genetic alterations in intrahepatic CC. The incidence of *KRAS* mutations shows a striking geographical variation, ranging from 4% in Thai patients to as much as 100% in British patients, while Japanese have an intermediate prevalence (about 60%). This may reflect the prevalence of liver flukes. Indeed, the mutational profiles of CCs associated with *O. viverini* infection have been shown to differ from those of tumors not associated with these infections. Moreover, hotspot *KRAS* mutations have been shown to be associated with intrahepatic CC initiation in mouse models and with a proliferation subgroup of intrahepatic patients with poor prognosis. *TP53* mutations do not have any particular hotspot and coexist with *KRAS* mutations in a small proportion of tumors. Mutations in both *IDH1* and *2* have been frequently reported in CC, with some studies suggesting that they are more common in intrahepatic than in extrahepatic tumors. Two identified hotspots: *R132 IDH1* and *R172 IDH2*, promote cholangiocarcinogenesis through repression of hepatocyte differentiation. *IDH* and *KRAS* mutations as well *IDH* and *TP53* mutations seem to be mutually exclusive. Other most frequently altered genes include *ARID1A*, *BAP1*, *KDM6B*, and *SETD2*, interestingly all involved in chromatin remodeling (**Table 1**).

A recent comprehensive analysis of nearly 500 samples has shown that grouping intrahepatic CC patients by classifier mutations in the three most recurrently mutated genes (*TP53*-mutant, *KRAS*-mutant, *IDH1*-mutant, wild-type in the three genes (called "undetermined")) reveals distinct molecular and pharmacogenomic profiles. In *TP53*-driven tumors, G to A transversions were the most prevalent, including the ApT>NpG associated with aristolochic acid. *R249S* was enriched but the aflatoxin signature was not enriched like in hepatocellular carcinoma and, compared to other mutants, *R249S* was not associated with the HBV status or overall survival. C to T transitions were most prevalent in *KRAS*-mutant tumors, with a preference for an upstream purine (G or C), suggesting a role of the APOBEC signature. *IDH1*-mutant tumors were significantly enriched for C to A transversions. These mutations are related to oxidative stress and wild-type *IDH1* has been shown to protect cells from oxidative stress-induced damage. *TP53*-driven tumors were significantly enriched for *PTEN*, *RB1*, and *LATS2* mutations, whereas *BLAF-1* alterations were prevalent in *IDH1*-mutant tumors, *SMAD4* in the *KRAS* group, and *KDM6B* in undetermined tumors. Out of previously identified genes, *ARID1* alterations were present in all the groups except for *TP53*-driven tumors but they were significantly associated only with undetermined tumors. *BAP1* mutations were significantly associated with *IDH1*-mutant tumors. Interestingly, no chromatin

Table 1 Gene loci that are most frequently altered in cholangiocarcinoma

Pathway	*Gene (locus)*	*Alteration type*	*Clinical significance and other comments*
P13K/PTEN/Akt (control of cell metabolism)	*KRAS* (12p12.1)	Point mutations (hotspots)	In up to 12% of intrahepatic CCs
	PTEN (10q23)	Point mutations and deletions	Prevalent in *TP53*-driven intrahepatic tumors
p53 signaling (cell-cycle control)	*TP53* (17p13.1)	Point mutations (scattered)	In up to 20% of intrahepatic CCs; *TP53*-driven molecular signature associated with an in silico sensitivity to some RNA synthesis and mTOR inhibitors
	RB1 (13q14.2)	Mutations	Prevalent in *TP53*-driven intrahepatic tumors
Tyrosine kinase receptors	*FGFR2* (10q26.13)	Fusions	In 6%–15% of CC cases; associated with shorter overall survival
Citrate cycle	*IDH1* (2q34) and *IDH2* (15q26.1)	Point mutations (hotspots)	In up to 12% of intrahepatic CCs; also reported in extrahepatic tumors; mutations associated with sensitivity to dasatinib and PARP inhibitors; *IDH1*-driven molecular signature associated with an in silico sensitivity to microtubule modulators (e.g. taxanes)
Chromatin remodeling	*ARID1A* (1p36.11)	Point mutations, deletions, and insertions	
	BAP1 (3p21.1)	Point mutations, deletions, and insertions	Prevalent in *IDH1*-mutant intrahepatic tumors
	KDM6B (17p13.1)	Point mutations and deletions	
	SETD2 (3p21.31)	Point mutations	
Hippo signaling	*LATS2* (13q12.11)	Point mutations	Prevalent in *TP53*-driven intrahepatic tumors
TGF-ß signaling	*SMAD4* (18q21.2)	Point mutations and insertions	Prevalent in *KRAS*-driven intrahepatic tumors

remodeling genes were associated with the *TP53* group. Both *TP53*- and *KRAS*-driven profiles were associated with a worse overall survival and shorter recurrence-free time. The four molecular signatures were associated with an in silico sensitivity to different groups of anticancer drugs (**Table 1**).

Up to two thirds of all biliary tract carcinomas overexpress ERBB2, while membranous expression of E-cadherin, alpha-catenin, and beta-catenin is downregulated in a majority of intrahepatic CCs and this decreased expression has been shown to correlate with a high grade of intrahepatic CC. Moreover, bile acids have been demonstrated to further activate EGFR and increase the expression of oxidative agents. MET overexpression has also been shown in intrahepatic CCs, correlating with tumor grade (low expression in poorly differentiated tumors) and increased proliferation indices.

Furthermore, bcl-2, an antiapoptotic protein, has been reported to be overexpressed in intrahepatic CC, while telomerase activity is detected in up to 100% of cases. Chronic inflammation which is thought to contribute to tumor development is associated with the release of inflammatory cytokines that induce oxidative stress and DNA damage. These cytokines may also create an immune-suppressive environment that promotes tumor cell survival and proliferation by blocking apoptosis which would normally be induced by DNA damage.

Biomarkers

Early detection of CC is extremely difficult and no reliable screening biomarkers have been identified.

Most CC patients present with advanced disease and have a median survival of less than one year despite treatment with current standard chemotherapy. Even patients who undergo apparently curative resection have poor outcomes due to a high rate of tumor recurrence. The most reliable (statistically significant) prognostic markers include several clinicopathological criteria. Cachexia, poor performance status, serum bilirubin of 9 mg/dL or greater, multifocal disease, hilar or proximal sites, high tumor grade, sclerotic histology, liver invasion, lymph node involvement, and advanced stage have been shown to be significantly associated with a poor outcome. Liver cirrhosis has been associated with an increased risk of recurrence and a reduced survival following resection in intrahepatic CC patients.

The limited ability to reliably acquire tissue samples has resulted in an ongoing quest for CC blood serum biomarkers. In addition to liver-specific testing (see "Presentation and diagnosis"), serum CA 19-9 and CEA levels are used as a part of the diagnostic workup, with increased levels suggesting a gastrointestinal malignancy. However, these two markers are not specific to CC and their sensitivity is also variable. They might be more useful in surveillance for posttreatment recurrence but identifying more reliable and more specific biomarkers remains an urgent need.

Serum IgG4 levels may be used to rule out autoimmune cholangitis during the diagnostic workup of perihilar CC. However, defining clear cut-offs is an on-going challenge. Recently, a new test measuring the IgG4/IgG RNA ratio has been developed. It can, reportedly, distinguish IgG24-associated cholangitis from primary cholangitis and CC. However, its value still needs to be clinically evaluated. Cytokeratin- and mucin-based biomarkers (in particular CYFRA 21-1 and MUC-5) have also been reported to be of potential diagnostic value but they need to be evaluated in larger cohorts.

Management and Therapy

Complete tumor resection with negative margins is the only curative procedure for CC. However, definitive surgery can only be applied to selected patients with well-localized lesions in whom negative microscopic margins can be obtained ("R0 resection") while maintaining adequate liver remnant, vascular inflow/outflow, and biliary drainage. Correct determination of the tumor resectability is a major challenge of the preoperative workup, and requires multidisciplinary and multimodality evaluation.

Imaging plays a decisive role in evaluating tumor resectability. However, it can also lead to confusion due to overlapping appearances with other hepatobiliary diseases, including benign lesions. CT and MRI are commonly used in various combinations with cholangiographic analyses in preoperative planning. When well performed, the accuracy of MRI and CT in predicting resectability exceeds 75%. [^{18}F]-FDG PET-CT seems to have no additional value.

Defining anatomic location and ductal extent of the tumor is an important step in preoperative planning. The Bismuth-Corlette classification is probably the most widely adopted staging system. It classifies perihilar CCs into four subtypes based on their anatomic location within the biliary tree. However, it is mainly informative for surgeons for planning resection type and not to determine resectability since other parameters, such as distant metastases and vascular involvement, are not included. For optimal determination of resectability, patients with potentially resectable CC may undergo staging laparoscopy. However, recent studies question the overall diagnostic yield and accuracy of staging laparoscopy, mainly due to improved imaging techniques.

Since extended liver resections are often required, it is critical to assess the future remnant liver (FRL) preoperatively. CT-volumetric analysis is the standard technique used to this effect. However, as liver volume is not synonymous with liver function and function is not homogeneously distributed in the liver, FRL function assessment is additionally performed. 99mTc-mebrofenin hepatobiliary scintigraphy (HBS) is a validated quantitative dynamic liver function test, with mebrofenin, an iminodiacetic derivative, used as a tracer.

The presence of severe underlying medical comorbidities, distant metastasis, involvement of major vascular structures not amenable to reconstruction, bilateral segmental ductal involvement, unilateral segmental ductal extension with contralateral

vascular inflow involvement, and calculated inadequate future liver remnant (FLR) are generally considered as contraindications to surgical resection. The reported resectability rates show much variability between centers, ranging from 20% to 90%.

Many CC patients present with obstructive jaundice which has a negative effect on liver function, increases the risk of biliary infection and impairs cellular immunity, and may increase the in-hospital mortality by 10%. To improve patient outcomes, preoperative biliary drainage (PBD; biliary stenting) is recommended by many surgical teams. It reduces jaundice, improves liver function and the patient's condition, at the same time improving the ability of the liver to regenerate postoperatively. The impact of these effects is particularly high in patients with an insufficient FLR and preoperative drainage has been shown to improve outcomes especially in patients requiring extended resections. However, the drainage itself may induce severe complications and the optimal drainage method is still a subject of debate. Percutaneous transhepatic biliary drainage (PTBD) had been widely used and has an advantage of a direct access to the biliary duct. However, it has been shown to have no positive effect on postoperative morbidity and mortality and to increase potential risks. Currently, endoscopic biliary drainage (EBD) is the most commonly used in Western countries as having fewer complications and better outcomes, while nasobiliary drainage (ENBD) is favored in many Asian countries. All in all, each method comes with its own set of complications and the potential risks for the patient need to be carefully evaluated against potential benefits when taking a decision whether to perform preoperative drainage at all, with many specialists advocating that it is only recommended if the FLR is small. At the same time, more studies are needed to determine the most optimal drainage method. To avoid the postoperative liver dysfunction resulting from extended hepatic resection (insufficient FRL volume or function), portal vein embolization (PVE) may be used. The use of preoperative radiotherapy has also been proposed in order to prevent seeding metastases following biliary drainage. It has also been reported to have an effect on the tumor size and that it may relieve jaundice in patients without biliary stenting. However, its benefits remain controversial.

R0 resection requires an aggressive surgical approach combining bile duct resection with extended liver resection frequently accompanied with vascular reconstructions, and regional lymphadenectomy. These extended resections are associated with higher morbidity and mortality rates than experienced in liver resections without bile duct resection, probably because of the sequelae of obstructive jaundice. Overall, up to 50% of CC patients suffer from severe postoperative complications. Liver failure is a major complication after extensive hepatectomy and is a major cause of mortality in patients with perihilar CC. Other complications include, among others, biliary leakage, infections, bleeding complications, and cholangitis. The 30-day operative mortality rate may be as high as 25%. Surgical biliary tract bypass may be performed in patients whose tumors are found to be unresectable at operation.

Liver transplantation in CC patients remains controversial. Theoretically, orthotopic liver transplantation (OLT) offers the advantage of resecting all of the structures that may be affected by the tumor, for example the portal vein, bilateral hepatic ducts and atrophic liver lobes. However, it is often not considered appropriate because of the high incidence of local recurrence and no standardized criteria to select patients for transplantation. Generally, transplantation is sometimes considered for selected patients with localized disease. Chemoradiation prior to transplantation has been shown to improve survival, according to some opinions enough to make the transplant meaningful.

Systematic studies on the recurrence rates are scarce and rates from 50% to 100% have been reported. Patients with recurrent disease are not candidates for curative therapy and can only receive adjuvant therapy to improve long-term outcome. Adjuvant therapy has been advocated to reduce the high incidence of local recurrence, but it does not appear to improve survival after curative resection. The role of adjuvant radiotherapy remains unclear. Cholangiocarcinoma is radiosensitive but bile duct tolerance to radiation is limited, with biliary and duodenal stenosis being frequently induced complications.

Chemotherapy, as either first or second-line is of potential benefit. Different regimens in different clinical settings have been and are still being tested in clinical trials. The most recent (February 2018) US National Comprehensive Cancer Network (NCCN) guidelines recommend using fluoripyrimidine- or gemcitabine-based regimens in post-resection CC patients (both intrahepatic and extrahepatic). One of these two regimens, or the gemcitabine/cisplatin combination may be used in unresectable extrahepatic CC patients. The latter is also the treatment of choice for palliative treatment in case of metastatic extrahepatic disease.

Chromatin Dynamics in Cancer: Epigenetic Parameters and Cellular Fate

Daniel Jeffery, Katrina Podsypanina, Tejas Yadav, and Geneviève Almouzni, Curie Institute, PSL Research University, CNRS, Equipe Labellisée Ligue contre le Cancer, Paris, France; and Sorbonne University, UPMC Univ Paris 06, CNRS, Paris, France

Glossary

Centromere Chromosomal region of constriction joining two sister chromatids to which the microtubules of the spindle attach during cell division, via the kinetochore. Coined in 1936 by Cyril Darlington. From Greek *centro-* for "center" and *-meros* for "part."

Chromatin Macromolecular complex of DNA, protein and RNA that makes up the chromosomes of eukaryotic cells. Coined in 1879 by Walther Flemming to describe protoplasm in cell nuclei. From Latinized form of Greek *khromat-* for "color", and the chemical suffix *-in*.

Epigenetics Coined by Conrad Waddington in 1942 in reference to Aristotle's theory of *epigenesis*, proposing that embryos develop progressively from an undifferentiated egg cell. From Greek *epi-*, meaning "over, outside of, around," and *-genetics*, the study of inherited traits. Epigenetic features refer to the "structural adaptation of chromosomal regions to register, signal or perpetuate altered activity states" Bird (2007).

Epigenome The ensemble of modifications that govern the regulation of the genome.

Histone chaperone Histone chaperones are defined mainly as factors that associate with histones and stimulate a reaction involving histone transfer without being part of the final product. In 1978 the term "molecular chaperone" by Ron Laskey was applied to nucleoplasmin, a protein enabling the storage of histones H3–H4 in *Xenopus* oocytes. Later, it has been extended to all factors that prevent incorrect interactions between histones and DNA and facilitate nucleosome assembly.

Histone Five types of basic proteins found in chromatin, namely H1, H2A, H2B, H3, and H4 and their variants. Coined in 1884 by Albrecht Kossel. From Greek *histos-*, meaning "warp, web", and *-one*, meaning "weaker".

Kinetochore complex of proteins associated with the centromere to which the microtubules of the spindle attach during cell division. Coined in 1934 by L.W. Sharp from the Greek *kinisis-* for "movement" and *-choros* for "place, region".

Nucleosome Fundamental repeating subunit of chromatin, made up of DNA wrapped around a single hetero-complex of histones. Coined in 1975 by Pierre Oudet to reflect their nuclear origin and in reference to the "*nu*" bodies described by Olins and Olins (1974).

Oncogene A gene with the potential to transform a cell into a tumor cell. Coined in 1969 by Robert Huebner and George Todaro. From Latinized form of Greek *onco-* meaning "tumor, mass" and *-gene* for "to produce".

Nomenclature

2-HG 2-hydroxyglutarate

Introduction

The Hierarchy of Chromatin Organization: A Versatile Modular Structure

Within the nucleus, eukaryotic genomes are organized as nucleoprotein complexes comprising DNA, RNA, and proteins. This complex, called chromatin, follows a hierarchical organization that ranges from the basic unit, the nucleosome, up to higher-level domains in the nuclear space in interphase and culminates with chromosome compaction in mitosis. Its repeated module, the nucleosome, comprises ~147 bp of double-stranded DNA wrapped around an octamer of histone proteins plus intervening linker DNA. It thus forms periodic arrays giving rise to the nucleofilament or "beads-on-a-string" characteristic observed in early electron microscopy experiments (Fig. 1A). Transcription factors, or various chromatin-associated proteins and RNA punctuate this organization and help in defining specific domains. The nucleofilament undergoes further coiling to give rise to higher-order chromatin structures (Fig. 1B). Notably, DNA can be modified, distinct histone variants can form specific core particles and histones can be modified. These features of chromatin organization in space and time thus define, for a given cell type, an epigenome that corresponds to a cell fate decision. Here, we will refer to epigenetic features as to the "structural adaptation of chromosomal regions to register, signal or perpetuate altered activity states" as defined by A. Bird in 2007. Notably, distinct nucleosome features such as histone composition and modifications along with specific positioning characterize regulatory regions of the genome, such as promoters, enhancers, coding regions, replication origins, telomeres, and centromeres. This versatility of chromatin in space and time allows switching and reversibility, a general characteristic of the modular protein–DNA interactions that constitute chromatin. Thus, chromatin functions as a modular molecular scaffold with epigenetic features that can change and adapt according to cellular states during development and lifetime, and in response to various environmental stimuli.

Epigenetic Regulators: Shaping Chromatin in the Nucleus

Specific chromatin factors, acting at various organizational levels, exert spatial and temporal control over gene expression and are referred to as epigenetic regulators (Fig. 1C).

DNA modifications: Covalent modifications of DNA bases, such as 5-methylcytosine (5mC) and 5-hydroxymethylcytosine (5hmC), play central roles in epigenetic regulation of gene expression. DNA-methyltransferases (DNMTs) are enzymes that catalyze the covalent addition of a methyl group to a cytosine base of DNA. DNA methylation is commonly associated with promoter silencing and transcriptional repression. On the other hand, 10–11 translocation (TET) enzymes, TET1, 2, and 3, sequentially convert 5mC to 5hmC, then 5-formylcytosine (5fC), and 5-carboxylcytosine (5caC). Several additional DNA adducts, such as 8-oxoguanine (8oxoG) and 5-hydroxymethyluracil (5hmU), important for epigenetic regulation should also be considered and the discovery of novel modifications is growing.

Histone choice and chaperones: As key components of the nucleosome, the core histone proteins (H3, H4, H2A, and H2B), along with the linker histone H1, serve as the building blocks of the epigenome. There are multiple forms of the four core histones, called histone variants, originally characterized based on migration properties using Triton Acid Urea gel electrophoresis by S. Franklin and A. Zweidler in 1977. The differences in amino acid sequence for the core histones from their variants range from single residue

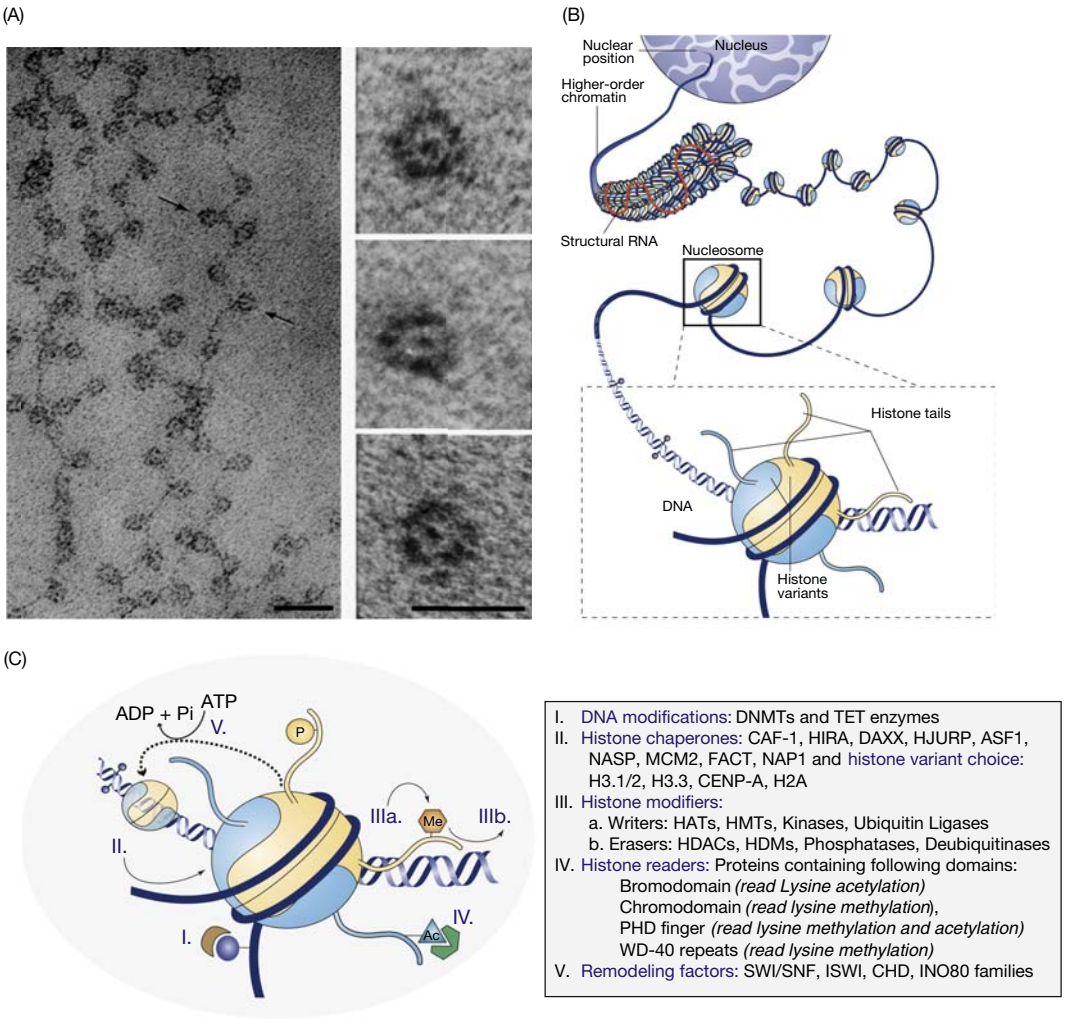

Fig. 1 Chromatin structure and organization: key regulators. (A) Electron micrographs. Left panel: low ionic-strength chromatin spread, the "beads on a string." Scale bar: 30 nm; Right panel: isolated mononucleosomes derived from nuclease-digested chromatin. Scale bar: 10 nm. (B) The hierarchy of chromatin organization—numerous epigenetic factors help organize chromatin in the 4D nucleus: along with the linker histone H1, DNA wrapped around one $(H3–H4)_2$ tetramer capped by two H2A–H2B dimers forms the nucleosome—the fundamental repeating unit of chromatin. DNA and histone tails can be modified. The presence of histone variants adds further complexity. Arrays of nucleosomes fold into higher-order chromatin structures, potentially guided by noncoding RNA. The nuclear localization of a given chromosomal domain represents an additional level of regulatory information. (C) Key chromatin regulators act at each hierarchical level. (A) From Olins, D. E., Olins, A. L. (2003). Chromatin history: Our view from the bridge. *Nature Reviews Molecular Cell Biology* **4**, 809–814—with permission; (B and C) Modified from Probst, A. V., Dunleavy, E., Almouzni, G. (2009). Epigenetic inheritance during the cell cycle. *Nature Reviews Molecular Cell Biology* **10**, 192–206.

alterations to greater than 50% divergence. Within the nucleus, the spatiotemporal dynamics of these various histone bricks are controlled by a specialized group of proteins called histone chaperones (Fig. 2). Thus, histones are never found alone as histone chaperones escort them throughout their cellular life.

Histone modifications—writers, erasers, and readers: While DNA is wrapped around the core histones, the N-terminal tails of histones remain exposed and undergo a variety of posttranslational modifications (PTMs). Individual and combined PTMs constitute what has been called a "histone code" with direct effects on the binding affinity of chromatin-interacting factors as well as DNA accessibility to various cell machineries. To place modifications, a series of enzymes have been identified as "writers," such as histone acetyl- and methyl-transferases (HATs and HMTs), including EZH2, the catalytic subunit of PRC2 (Polycomb repressive complex 2). To remove modifications, a series of enzymes have been identified as "erasers," such as histone deacetylases (HDACs) and demethylases (HDMs) (Fig. 1C). "Readers" that recognize specific chromatin PTMs comprise bromodomain and extraterminal domain–containing proteins (BET), chromodomain-, PHD finger- and WD40-containing complexes. They further recruit or stabilize factors at precise genomic loci to regulate nuclear functions. While a number of modifications are imposed on the nucleosome particle, several of them are also placed on histones before deposition. The dynamics of histone deposition and modifications should also be considered.

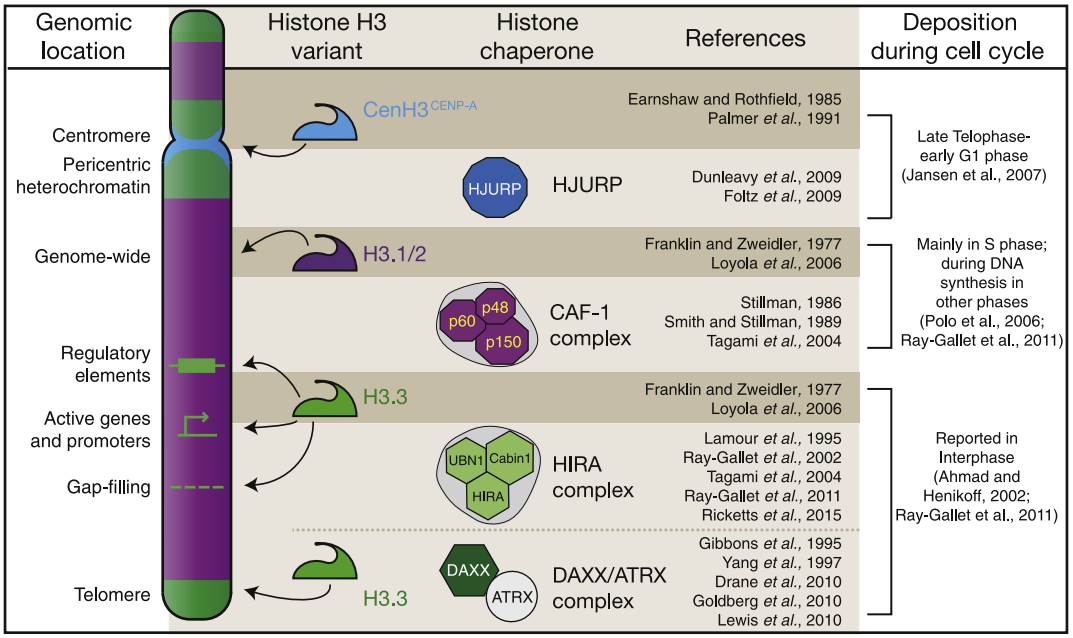

Fig. 2 Histone chaperones dedicated to distinct histone variants help their incorporation into chromatin at particular genomics locations and precise times during the cell cycle. Modified from Sitbon, D., Podsypanina, K., Yadav, T., Almouzni, G. (2017). *Shaping chromatin in the Nucleus: The bricks and the architects*. Cold Spring Harbor symposia on quantitative biology.

Chromatin remodelers and higher order chromatin: Chromatin remodelers are large, multisubunit, ATP-dependent molecular motors that regulate nucleosome structure, positioning and organization (Fig. 1C). These helicases share a common ATPase domain and can be classified into four subgroups based on their divergent domains: SWI/SNF, INO80, ISWI, and Mi2-CHD-NuRD complexes. Factors contributing to higher order structure include transcription factors, insulators, heterochromatin-associated proteins such as HP1, and noncoding RNA, while several others remain to be identified. While we describe the various factors individually, they are often found in combination, for example, a remodeler as a subunit of a larger complex. Also, note that each of the modifiers or remodeler complexes often contain a histone chaperone as a subunit or are associated with one of them.

Connections Between Epigenetic Regulators and Cancer Biology

Importantly, the relationships between epigenetic regulators, nuclear architecture and cancer biology have been stressed in a series of reviews. Indeed, several chromatin factors, such as histone modifiers and chromatin remodeling enzymes are disrupted or altered in cancers, including histone variants and chaperones. With the Cancer Genome Atlas (TCGA) reporting complete genomic and transcriptional data from several thousands of cancer patients and enabling the profiling of somatic tumor mutations, a series of potential chromatin-associated drivers of cancer have been identified. Nearly a quarter of the top 25 mutated genes, ranked by the frequency of alteration across all tumor types, encode chromatin-modifying enzymes—*KMT2C/MLL3*, *KMT2D/MLL2* (Lysine methyltransferases 2C, 2D), *ARID1A* (AT-Rich Interaction Domain 1A), *PBRM1* (Polybromo 1), *SETD2* (SET Domain Containing 2), *CREBBP* (CREB Binding Protein), and *SMARCA4/BRG1* (SWI/SNF-related Matrix-Associated Regulator of Chromatin A4). Indeed, one or more of the 12–15 subunits of SWI/SNF chromatin remodeling complexes are mutated in nearly 20% of all solid malignancies and, hence, represent attractive therapeutic targets. Importantly, individual SWI/SNF mutations vary in frequency in different cancer types, based on TCGA data. In addition to cancer development and maintenance, epigenetic factors have also been shown to correlate with patient response and clinical outcomes to current treatments. For example, specific chromatin regulators, including SWI/SNF chromatin remodelers, can serve as biomarkers for drug response (e.g., *SMARCB4* for docetaxel response or worse prognosis) and the histone chaperone CAF-1 holds prognostic value in renal, endometrial, and cervical carcinomas.

Genetic evidence supports a causal role for histone H3 mutations in aggressive brain cancers in children. Specifically, point mutations of H3 lysine 27 to methionine/isoleucine (H3K27M/I) or glycine 34 to arginine or valine (H3G34R/V) lead to critical changes in the histone methylation status and are found in 35%–80% of pediatric gliomas, depending on the subtype. Recently, recurrent mutations of histone H3 lysine 36 to methionine/isoleucine (H3K36M/I) or glycine 34 to tryptophan/leucine (H3G34W/L) have also been reported in specific bone cancers. Several instances of H1 loss-of-function mutations have been found in diffuse large B-cell/follicular. Although these particular histone mutations are linked to a subset of cancers, changes in histone levels are commonly observed in nearly all types of tumor.

So far, epidrugs have been used mainly in combinations with other cytotoxic treatments with the goal of sensitizing cancer cells as an end point (Table 1). Dynamic changes to the chromatin landscape over time can gradually or acutely influence specific

[a]Target: the epigenetic regulator (molecule(s) or complex(es)) directly affected by the drug.

[b]Epidrugs: all anticancer drugs in the list were selected from the human epigenetic drug database (hedds.org: December 2017) and others with reported epigenetic effects in current literature.

[c]National Clinical Trial (NCT identifier): unique reference from an online database (www.ClinicalTrials.gov) providing details about each trial (start date, study design, current status, etc.).

[d]Current status: the table reports the most advanced clinical trial per cancer type.

[e]Delivery: the administration of the drug as a single agent or in combination with other drugs.

[f]Cancer type: refers to the cancers where the epidrug is tested against a specific tissue/organ tumor, excluding trials for mixed cancer types (except if they use molecular stratification of patients or are the only representative trial for that epidrug).

[g]Molecular selection (biomarker testing) for patient stratification: details about mutations, molecular markers or other physiological features used to select target patients.

genome functions. Importantly, chromatin regulators can also affect the tumor microenvironment and immune system. Understanding the combination of effects and the dynamics of disease progression is of paramount importance. By interfering with specific epigenetic factors with known effects in space and time, in either the cancer cells or cells of the microenvironment, we may be able to alter precise chromosomal territories at defined moments in the cell cycle to adapt the treatment strategy to the type of tumor. This capacity to selectively manipulate genome regulation may provide us with the ability to combat some of the fundamental difficulties of cancer treatment.

Epigenetic Links to the Roadblocks of Cancer Treatment

In the past four decades, advances in the treatment of malignant disease have resulted in growing improvement in overall clinical outcomes. Nevertheless, fundamental problems persist which result in drug resistance, disease recurrence and, ultimately, patient mortality. To name the most critical ones, the roadblocks to patient cure include: clonogenic potential of cancer cells, tumor evolution, tumor microenvironment, inefficient immune surveillance, tumor heterogeneity, and drug-related side effects (Fig. 3A–F). Since multiple chromatin components have been shown to underpin one or several aspects of these pervasive complications, epigenetic targeting represents an important avenue to explore.

Clonogenic potential (Fig. 3A) represents the ability of a single cancer cell to reconstitute the entire tumor as if it were a stem cell. Theoretically, even a single remaining malignant cell following treatment can lead to disease recurrence if it harbors this clonogenic capacity. In fact, the principles of combining chemo- and radiotherapy conceived to combat minimal residual disease are still applied today. However, the "stemness" of residual cancer cells is reminiscent of the pluripotency displayed by normal stem cells. The differences between stem and differentiated cells, supported by changes to chromatin architecture during stem cell differentiation, has to be taken into account for rational drug design. In particular, it is intriguing that the plasticity of transitions between

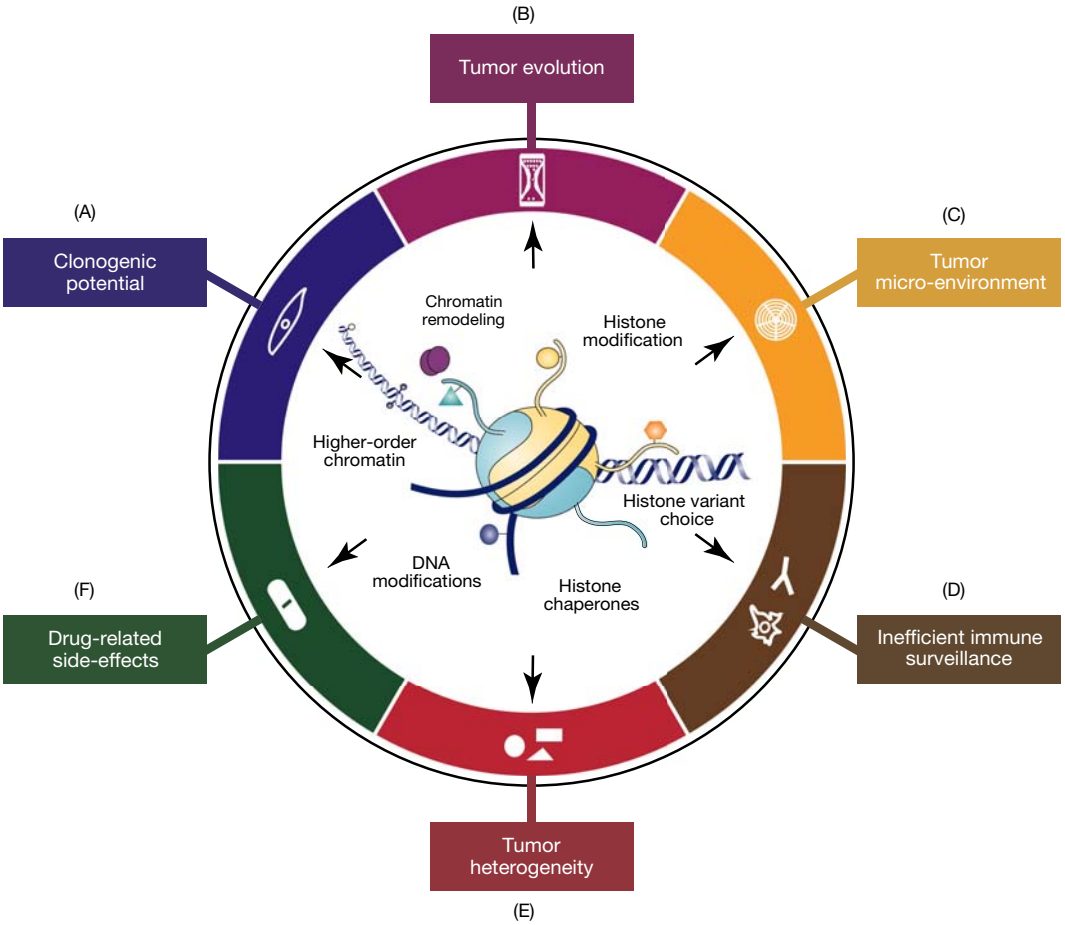

Fig. 3 Epigenetic Links to the Roadblocks of Cancer treatment. Starting from the scheme depicting the hallmarks of cancer, we place the building blocks of chromatin, the nucleosome, and its versatile forms as central players underpinning different roadblocks of cancer treatment (A–F). See section Epigenetic links to the Roadblocks of Cancer Treatment in text for details. Original artwork based on Hanahan, D. and Weinberg, R.A. (2000). The hallmarks of cancer. *Cell* ***100***, 57–70.

differentiated and undifferentiated states shows direct ties to the histone chaperone CAF-1, a chromatin factor found overexpressed in series of aggressive cancers. Indeed, CAF-1 knockdown combined with the modulation of transcription factors improves reprogramming of mouse fibroblasts to induced pluripotent stem cells (iPSCs) by several orders of magnitude and in embryonic stem cells it can enhance totipotency. Therefore, modulation of the expression of CAF-1 may have opposing effects on tumor growth and clonogenicity. Progress in understanding parameters involved in control of stemness at the chromatin level will help shed further light on the problem of residual disease in cancer.

Tumor evolution (Fig. 3B) occurs as the disease progresses from less aggressive to more malignant stages. Cancer cells divide in the context of genetic and *epi*genetic instability. As a result, a tumor is equipped with a vast repertoire of divergent subclones of varying fitness. Continuous tumor growth creates bottlenecks for survival, resulting in selection of individual subclones. As selective pressure mounts during metastasis or administration of treatment, (epi)genetic plasticity provides additional adaptability to the evolving tumor. This form of drug escape may be overcome by modulating the (epi)genome. For example, cancer cells resistant to tyrosine kinase inhibitors (TKI), such as gefitinib, show decreased levels of H3K4me2/3, correlated with poor prognosis. In turn, TKI-resistant tumors become susceptible to KDM5A (H3K4 demethylase) silencing or inhibition of KDM5A-associated HDACs, while the parental tumor cell lines remained unaffected. These results suggest that *epi*genetic factors such as H3K4 demethylase KDM5A likely underlie nongenetic tumor heterogeneity leading to resistance. This example underlines the capacity to exploit chromatin plasticity for overcoming drug resistance linked to (epi)genetic instability and malignant evolution.

The tumor microenvironment (Fig. 3C), a complex network of cells and extra-cellular factors surrounding a developing tumor, functions as the "ecosystem" for an expanding population of cancer cells. These nonmalignant tissues can be co-opted by the tumor to sustain its growth and can also physically block the access of anticancer drugs or the immune system to the tumor. In some instances, marked changes in expression of chromatin factors, such as histone PTMs and DNMTs, have been reported in cancer-associated fibroblasts in contrast to their normal counterparts, despite their nonmalignant genetic status. In breast cancers, these epigenetic changes have been shown to promote tumor invasiveness and malignancy. Increased understanding of epigenetic changes in cancer-associated stroma provides clues for how to overcome this roadblock to cancer treatment. However, the efficacy of currently available epigenetic therapies has not been specifically evaluated in cancer stroma. Describing the metabolic and epigenetic pathways connecting immune, stromal, and cancer cells could provide necessary clues to combat drug resistance linked to microenvironment.

Inefficient immune surveillance (Fig. 3D) is a failure of the immune system to recognize malignant tissue as abnormal or pathological. In the absence of immune recognition, the patient may not present with overt clinical symptoms and there is a paucity of tumor-specific antigens that can generate a proficient antitumor response. Recent experiments studying immune checkpoint blockade (ICB) indicated that tumor-specific effector T-cells are often kept inactive by de novo methylation programs that hinder clonal expansion and diversity of effector T-cells. In this case, an epigenetic strategy to reactivate the T-cell antitumor response could involve reversal of these DNA methylation changes. Indeed, examples of exposure to DNA-demethylating agents, such as decitabine, prior to ICB showed restoration of antitumor CD8 T-cell function, highlighting a role for epigenetic reprogramming in immune surveillance. Other methods could also participate in controlling T cell fate and T cell differentiation. This connection between the immune system and epigenetic regulators offers a number of possibilities that are just beginning to be explored.

Tumor heterogeneity (Fig. 3E) originates from the combined effects of: (1) genetic instability and selection of divergent mutational clones and (2) hierarchical development of a cancer cell population. Epigenetic pathways influence both of these causative factors. For example, aberrant DNA methylation is associated with an increased frequency of cytosine to thymidine (C > T) transitions, initiated by the spontaneous deamination of methylated cytosines, a mutational signature found in all cancer types and most cancer samples. Also, tumors develop as populations of mixed subclones at various stages of lineage commitment. As already mentioned above, factors like the histone chaperone CAF-1 and linker histone H1 are known to regulate lineage specification and cell fate determination. Indeed, cancer-specific chromatin patterns are reminiscent of those in embryonic stem cells and some adult stem cells. This example highlights the ability to manipulate chromatin factors, involved in cell fate decisions, to influence tumor heterogeneity.

Drug-related side effects (Fig. 3F) are commonly associated with cancer therapies, to the extent where patients may even perceive the treatment as being worse than the disease itself. Due to the fact that cancer originates from the host's own cells, classical anticancer drugs target properties that are shared by both tumor and normal cells. Therefore, the therapeutic window can be very narrow and epigenetic manipulation can provide interesting means to help direct a more selective targeting and limit drug-related side effects. For example, the use of the DNMT inhibitor, decitabine, which led to the preferential de-repression of gene promoters silenced only in cancer cells, has been reported as a disease-selective means to avoid affecting noncancer cells. Thus, targeting epigenetic pathways in the future could improve upon the selectivity and specificity of currently available anticancer drugs.

Chromatin Regulators in Cancer: Epi(genetic) Drug Targets

DNA- and Histone-Modifying Enzymes

Drugs inhibiting the enzymatic activities of DNA-modifying enzymes and PTM writers, readers and erasers that can provide cytotoxic effects with a strong potential in cancer therapy are listed (Table 1). Alterations in global DNA methylation levels are linked to aberrant changes in gene expression of oncogenes as well as tumor-suppressor genes. DNMT inhibitors, azacitidine and decitabine,

are cytosine-analogs that cannot be methylated resulting in the sequestration of DNMTs and subsequent global DNA hypomethylation. At high doses, DNMT inhibitors impair DNA synthesis or translation of proteins causing cell death.

Gain-of-function mutations in genes encoding isocitrate dehydrogenases (IDHs) are commonly associated with AML, breast and brain cancers. IDH mutations affect both DNA and histone methylation. *IDH1* and *IDH2* catalyze the production of alpha-ketoglutarate (α-KG), a key cofactor in TET-mediated conversion of 5mC to 5hmC and the HMT function of the Jumonji-C domain-containing family of enzymes. Mutations altering R132 (*IDH1*), R140 or R172 (*IDH2*) enable them to convert α-KG to 2-hydroxyglutarate (2-HG), which competitively interferes with α-KG-dependent epigenetic reactions such as DNA modification and histone-methylation. Thus, therapies targeting these specific chromatin-associated mutations are currently being tested in several clinical trials (**Table 1**).

At the histone level, the presence of acetyl group modifications on the histone tails has generally been correlated with gene activation. Different classes of HDACs catalyze the removal of acetyl groups from a variety of histone and nonhistone substrates. HDAC inhibitors, such as vorinostat, interfere with the active site of the enzyme resulting in hyperacetylated substrates and associated changes in gene expression and posttranslational regulation of nonhistone proteins. However, DNMT and HDAC inhibitors as mono-therapies have demonstrated limited clinical efficacy, especially against solid tumors. It remains unclear if this poor success was due to a lack of informed patient selection based on predictive biomarkers. This highlighted the need to choose patients by careful molecular stratification in future trials.

Careful selection of patient populations for drug testing showed promise in early clinical trials evaluating a new generation of epigenetic drugs, such as targeted inhibitors of BRD4 and its homologs (BET family proteins) or EZH2. BRD4 is a bromodomain-containing reader of acetylated-histones and a transcriptional coactivator, also implicated in DNA replication and repair. *BRD4* fusion with *NUTM1* encodes an oncogenic protein that defines highly aggressive NUT-midline carcinoma (NMC). This fusion leads to oncogenesis by aberrant recruitment of HATs and transcriptional activation of oncogenes, including *MYC*. As well, several lines of evidence demonstrate tumor cell addiction to functional BRD4 activity in acute myeloid leukemia (AML), which harbor translocations or mutations for the gene encoding the MLL1 histone lysine methyltransferase. Another epigenetic target includes the histone methyltransferase EZH2, catalytic subunit of the polycomb-repressive complex 2 (PRC2), which promotes transcriptional silencing and facultative heterochromatin formation. At the molecular level, EZH2 methylates lysine 27 of histone H3 (H3K27) using S-adenosyl methionine (SAM) as a cofactor. EZH2 gain-of-function mutations are associated with non-Hodgkins Lymphoma. At the same time, EZH2 inactivating mutations have also shown oncogenic properties. Thus, understanding the mechanisms of PRC2-mediated gene regulation may help treat patients with *EZH2* mutant cancers.

BET and EZH2 inhibitors are now in Phase II trials in molecularly selected patients, based on criteria described in **Table 1**. Current small-molecule BET inhibitors can be broadly classified as benzodiazepine-derivatives, namely JQ1 and its analog OTX015/MK-8625 (**Table 2**), and quinoline class drugs such as I-BET151 and I-BET762. BET inhibitors mimic acetyl-lysines and serve as competitive inhibitors of BET protein binding to chromatin. EZH2 inhibitors, such as tazemetostat, work as SAM-competitive small molecules that block HMT activity of the PRC2 complex. Moreover, PRC2 shows epigenetic antagonism with specific chromatin remodeling complexes. Hence, these interrelationships suggest that chromatin remodelers may also serve as potent drug targets.

Chromatin Remodeling Enzymes

ATP-dependent chromatin remodeling complexes such as SWI/SNF facilitate the exchange or displacement of nucleosomes. Although at least one alteration in SWI/SNF complexes is directly linked to oncogenesis, few therapeutic agents have been characterized against individual subunits. Currently, ADAADi (Active DNA-dependent ATPase A Domain inhibitor) has shown an ability to interfere with SMARCA4/BRG1, a core catalytic ATPase of the SWI/SNF chromatin remodeling complex. Previously, depletion of SMARCA4 was found to enhance sensitivity toward platinum-based chemotherapy and docetaxel. Despite their overlapping

Table 2 Epigenetic drugs outside of current clinical trials for cancer treatment

Status	*Class of epidrugs*	*Epidrug*
Ongoing and upcoming (noncancer)	DNMTi	Procainamide
	BETi	RVX-208
	HDACi	Resveratrol, sodium butyrate
Previous clinical trials for cancer treatment	DNMTi	Zebularine
	BETi	OTX015/MK-8625
	HDACi	CHR-3996, pivanex
Preclinical only	HMTi	3-Deazaneplanocin A, BIX-01294, CPI360, EI1, EPZ004777, GSK126, GSK343, and UNC0638
	HDMi	Bizine, clorgyline, GSK-J4, JIB-04, KDM5-C70, and pargyline
	BETi	CPI203, I-BET151, and JQ1
	HDACi	Trichostatin A, CG-1521, HC-toxin, ITF-A, and ITF-B
	HATi	C646

molecular functions, various SWI/SNF complexes display heterogeneity in their subunit composition. Synthetic lethal relationships have been reported between independent catalytic subunits such as SMARCA2 and SMARCA4. The loss of either gene is dispensable for viability while their combined loss results in cell death. Interestingly, isolated inactivation of SMARCA2 or SMARCA4 increases cisplatin sensitivity. Similarly, the structural subunit ARID1B is essential for survival of tumor cells lacking its mutually exclusive partner ARID1A. Thus, synthetic interdependencies of intracomplex subunits within chromatin remodeler assemblies provide druggable targets for anticancer therapy.

Importantly, SWI/SNF complexes display interdependent relationships with several pathways involving PRC2, PARP (important for single-strand DNA break repair), and PI3K/AKT (cell cycle regulators). This genetic crosstalk provides additional vulnerabilities in SWI/SNF-mutant tumors. The SWI/SNF chromatin remodeler and PRC2 repressive complexes show opposite effects on target gene expression, such that tumors defective for SWI/SNF subunits display increased PRC2 activation. This results in a PRC2 dependency that is only present when SWI/SNF is compromised. Inhibiting the EZH2 subunit of the PRC2 complex with tazemetostat selectively increased efficacy in patients negative for SMARCA4 or the core SMARCB1/INI1 subunit, in Phase I clinical trials. Although there are currently no ARID1B inhibitors, in preclinical studies ARID1A-deficient cancer cells have shown increased sensitivity to EZH2 inhibitors as well as PARP and PI3K/AKT inhibition. In addition, ARID1A and p53 interact with each other and act as codependent tumor suppressors in certain cancers, providing another example of SWI/SNF interplay with cell cycle regulation.

The increased efficacy brought about by the molecular selection of patients for treatment with epigenetic drugs suggests that educated selection of patients may be essential in the future. Indeed, one reason that the first generation of epigenetic therapies showed limited clinical effects is likely the absence of rational prescreening of patients. However, it is important to consider that while this stratification may need to be tumor-type specific, the characterization of additional biomarkers for these interdependent factors could have widespread applicability. Careful molecular selection would be especially helpful for those situations where the epigenetic targets were deemed undruggable but have demonstrated an interdependent relationship with a different factor for which drugs are already available. This also highlights the opportunity represented in characterizing new vulnerabilities in chromatin regulators that have been shown to play a role in DNA replication and repair or cell cycle progression.

New Potential Targets in Anticancer Therapy: Histones and Chaperones

As the foundation of chromatin structure, nucleosome composition and loading influences many aspects of cancer progression. A wealth of knowledge has identified histone variant-chaperone partnerships critical for DNA replication and repair, gene expression, cell proliferation, and differentiation (Fig. 2).

Histone Variants

To date, eight histone H3 variants have been identified in humans and the identification of homologous variants across species reveals a significant degree of evolutionary conservation. The most widely studied H3 variants (Fig. 2) can be classified based on two modes of incorporation into chromatin: DNA-synthesis coupled (DSC) or DNA-synthesis independent (DSI) pathways. In humans, the highest expression of the replicative variants H3.1 and H3.2 occurs during S phase of the cell cycle, facilitating deposition via the DSC pathway during DNA replication or DNA break repair involving DNA synthesis. Meanwhile, the DSI pathway involves incorporation of the "replacement" variant H3.3, expressed throughout all cell cycle phases. Importantly, the H3.3 variant also plays a significant role in transcription. Expression of CenH3 (histone H3-like centromeric protein A), called CENP-A in humans, is also independent of DNA synthesis. It is incorporated at centromeric sites during late mitosis (M)/early G1 phase while its expression peaks during the G2/M phases. CENP-A is the most divergent H3 variant and has a unique function, acting as the foundation for the constitutive-centromeric associated network (CCAN), which nucleates the kinetochore, and epigenetically determines the sites at which spindle microtubules attach during cell division. Without CENP-A this scaffold for cell division is unable to form and cells fail to segregate their chromosomes appropriately, resulting in cell death. CENP-A acts as one of many examples where specific histone variants play a significant role in the epigenetic control of cellular functions.

The H2A family also contains several different variants found in humans, including H2A.X, H2A.Z, macroH2A1, macroH2A2, H2A.F/Z, and H2A.Bbd. Briefly, H2A.Z is expressed throughout all cell cycle phases and preferentially incorporated at gene promoters and regulatory regions to promote transcription. Two non-allelic genes, *H2AFZ* and *H2AFV*, encode two distinct H2A.Z isoforms: H2A.Z.1 and H2A.Z.2, respectively. H2A.X, synthesized in both S and G1 phases, is a variant directly involved in the DNA double-strand break (DSB) repair pathway as well as several distinct functions involving sex chromosome inactivation, stem cell development, and maintenance of cellular senescence. MacroH2A1 is commonly associated with transcriptionally silent heterochromatin but at a subset of genes it is found near transcription start sites (TSSs) and CTCF-binding sites. MacroH2A1.1 and macroH2A1.2 are two alternatively spliced isoforms originating from the *H2AFY* gene. MacroH2A1.1 is expressed in differentiated cells, while macroH2A1.2 is found in embryonic stem cells and the early embryo.

Histone Chaperones

Histone chaperones escort histones throughout their cellular life. Some of them show very little selectivity and represent "casual" histone partners. In contrast, others associate with and are "dedicated" to a specific variant. They function as a network to ensure the

proper supply of histones in tune with the cellular demand. Dedicated chaperones play a crucial role for the incorporation of distinct histone variants into chromatin at particular locations and times throughout the cell cycle. The histone chaperone CAF-1, dedicated to the replicative H3 variants, deposits histones onto newly synthesized DNA through its association with PCNA, an accessory factor of DNA polymerase. The HIRA complex promotes incorporation of the H3.3 variant, independently of DNA synthesis, at gene bodies, promoters and regulatory elements. DAXX/ATRX ensures accumulation of H3.3 at peri-centromeric heterochromatin and telomeres. Finally, a dedicated chaperone HJURP ensures the timely incorporation of de novo CENP-A at centromeres in late mitosis/G1 in mammals.

The chaperone Asf1 is considered to act as a hand-over chaperone, upstream of other chaperones involved more directly in histone deposition. Asf1 deals with both parental and newly synthesized histones in the DSC and DSI pathways. NASP is another histone chaperone, with lower specificity, that acts as the emergency reservoir for soluble histones H3. Interestingly, MCM2, a DNA replication licensing factor and a component of the DNA helicase at the replication fork, also executes a histone chaperone function by favoring parental histone recycling. FACT is a histone chaperone that acts as a multifunctional heterodimer facilitating transcription, DNA replication and repair. FACT helps deposit the H2A–H2B dimer and $(H3–H4)_2$ tetramer onto DNA and also disrupts core histone–histone and histone–DNA interactions. A coordinated network of chaperones, along with other chromatin regulators, regulates chromatin dynamics during critical cellular processes such as cell differentiation and organism development and is disrupted in various diseases.

Importantly, a number of histone chaperones and variants are overexpressed or mutated in different cancer types. Among histone chaperones: CAF-1 is overexpressed in a series of aggressive cancers. *ASF1b*, one of the two human paralogs of the Asf1 chaperone, is overexpressed in a variety of tumor types. Considering histone variants: the increase in levels of CENP-A or its partner histone chaperone HJURP proves to be a key feature of tumor progression and poor prognosis. Perturbation of these factors to limit tumor growth represents opportunities that remain to be explored.

Changing Chromatin Factor Relationships—A Case of Cellular Adaptability

Experimental CENP-A overexpression is associated with altered genomic localization to the chromosome arms in addition to centromeric incorporation. Importantly, CENP-A and HJURP levels are higher in p53-deficient transformed cells compared to p53 wild-type tumors. Ectopic CENP-A deposition is carried out by DAXX instead of its cognate chaperone HJURP. Although DAXX acts as a casual chaperone for CENP-A in this scenario, it deposits it at locations normally occupied by its variant H3.3 (Fig. 2), namely sites of high histone turnover along the chromosome arms. As previously proposed, this inherent flexibility in chaperone-variant interactions could represent adaptability in the face of transformation-induced stress and cytotoxic chemo- and radiotherapies.

Context of Dosage Perturbation Matters

In p53-null mouse embryonic fibroblasts (MEFs), exogenous induction of HJURP or CENP-A alone does not act as a driver of transformation. Strikingly though, increased CENP-A and HJURP expression plays a critical role in the *maintenance* of the transformed state in p53-null cells. Experimental downregulation of HJURP in fully transformed p53-null cells results in cell death and loss of tumor viability in vivo while p53-proficient cells respond by growth arrest. This "epigenetic" addiction for HJURP in the context of p53-loss suggests that histone variants and their chaperones might act as crucial navigators of the neoplastic process instead of serving as classical drivers or simply passengers.

Targeting Histone Chaperones: The Architects of Chromatin

Given the epigenetic addiction to HJURP in p53-deficient transformed cells, interfering with de novo CENP-A deposition in cycling cells could represent an ideal pharmacological strategy. Since p53-proficient cells tolerated HJURP downregulation, it suggests that there is a therapeutic window for inhibitors of HJURP or its interaction with CENP-A in p53-null tumoral cells compared to non-tumoral quiescent cells (Fig. 4). Essentially, p53-HJURP codependence serves as an example of synthetic lethality due to epigenetic addiction. Several approaches to block HJURP can be envisaged to treat p53-deficient tumors.

These include interfering with:

(1) The N-terminal domain of HJURP that mediates protein–protein interactions with the CENP-A.
(2) Dimerization of HJURP, important for its activity, and potentially required to accommodate a CENP-A-H4 tetramer.
(3) Phosphorylation and DNA-binding of HJURP that is essential for timely CENP-A deposition.
(4) Complex formation with partners CENP-C, a key centromeric factor, or the MIS18 complex (consisting of MIS18BP1, MIS18α, and MIS18β), that are required for proper CENP-A incorporation.
(5) PLK1 kinase-dependent phosphorylation and recruitment of MIS18.

Beyond the example of HJURP, additional histone chaperones would also be worth exploring in future epigenetic therapies. For example, CAF-1, a reliable proliferative marker, acts as a molecular barrier to reprogramming of cell fate. The dual role of CAF-1 in maintaining stemness and promoting cell division may make it an attractive complementary target to existing cytotoxic therapies. The dynamics of CAF-1 posttranslational modifications could provide a means to target its proliferative role in tumors. For example,

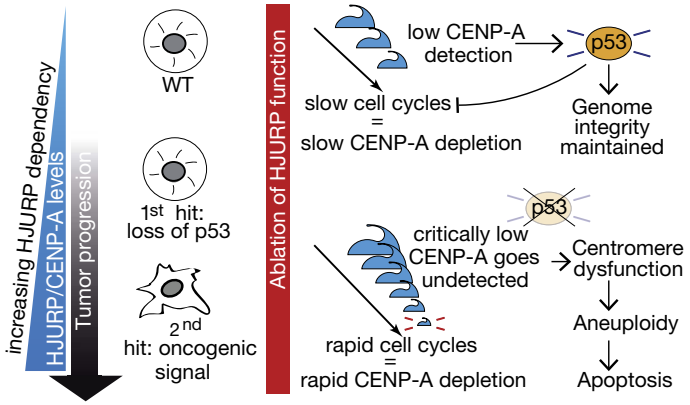

Fig. 4 The unbalance between histone chaperone and variants in p53-deficient tumors: an Achilles' heel in cancer cells. HJURP sustains cellular transformation in cells lacking p53. HJURP and CENP-A levels are increased in cells that lose p53 expression and increase even further following oncogenic transformation. When HJURP is depleted in wild-type cells with functional p53, p53 senses gradual CENP-A depletion and induces cell cycle arrest in order to maintain genome integrity. In cells lacking p53, HJURP depletion results in rapid CENP-A loss at centromeres, leading to centromere dysfunction, aneuploidy, and p53-independant apoptosis. From Filipescu, D., Naughtin, M., Podsypanina, K., Lejour, V., Wilson, L., Gurard-Levin, Z. A., Orsi, G. A., Simeonova, I., Toufektchan, E., Attardi, L. D. et al. (2017). Essential role for centromeric factors following p53 loss and oncogenic transformation. *Genes & Development* **31**, 463–480.

phosphorylation of the large subunit of CAF-1 (p150) by the replication kinase Cdc7-Dbf4 is important for stabilizing its monomeric state and promotes CAF-1 interaction with PCNA. By blocking this modification, CAF-1 function could be modulated during hyperproliferation. While hyperphosphorylation of the p60 subunit keeps CAF-1 inactive during mitosis, in interphase active CAF-1 comprises both hypophosphorylated and/or phosphorylated forms of p60. The phosphorylation of the p60 subunit is regulated by cyclin/Cdk kinase complexes and PP1 phosphatase. Importantly, the phosphorylated form of p60 is preferentially recruited to sites of UV-induced DNA damage. Therefore, therapeutic interference with the regulation of CAF-1 phosphorylation could hinder its nucleosome assembly activity during S-phase and at specific sites of DNA damage in combination with epidrug-treatments.

The proliferation-dependent isoform of the Asf1 histone chaperone, ASF1b, is prognostic of breast cancer outcomes. Thus, interfering with the histone supply function of Asf1 could also be promising. Like aforementioned chaperones, phosphorylation of free Asf1 by Tousled-like kinases (TLK) has been suggested to play a role in S phase progression by regulating Asf1-mediated histone delivery at sites of chromatin assembly. Inhibition of these kinases could potentially interrupt Asf1 activity in targeted cancer types. Furthermore, depletion of Asf1 (both a and b) activates the telomerase-independent telomere maintenance pathway ALT (alternative lengthening of telomeres) in primary and cancer cells. This suggests restoration of Asf1 function could provide a means to suppress the ALT pathway used by immortal cells to maintain their telomeres.

Loss-of-function mutations in the *DAXX* and *ATRX* genes are frequently reported in pancreatic neuroendocrine tumors (pan-NETs) and are also invariably linked to ALT. The ALT pathway is dependent on homologous recombination (HR). Thus, inhibitors against protein kinase ATR, a key regulator of HR, could prove to be effective in ALT-positive tumors carrying mutations in *ATRX* and/or *ASF1*. Considering another histone chaperone complex, FACT is overexpressed in nearly 20% of all breast cancers. FACT recognizes and binds to alternative DNA structures (ADS) leading to p53-activation. As such, curaxin, a FACT-complex anticancer drug that promotes ADS formation, could prove to be efficacious in treating p53-proficient cancers. Additional histone chaperones, such as MCM2, NASP, HIRA, etc., need to be examined for their roles in oncogenesis and tumor development and, thus, their suitability as potential epigenetic targets.

Targeting the Histone Variants: Core Components of Chromatin

Elevated CENP-A levels and recurrent H3.3/H3.1 K27, K36, and G34 mutations are examples of histone variants associated with particular types of cancer. Mutations of H3K27 residues in different histone H3 variants prevent methylation by PRC2 and have been strongly linked with pediatric brain tumors. A recent study, using model and primary patient-derived diffuse intrinsic pontine glioma (DIPG) cell lines, reported PRC2 dependency in H3K27M tumors. Notably, small-molecule EZH2 inhibitors were able to stop these tumor cells from growing. Thus, promising therapeutic opportunities can be envisaged using polycomb complex inhibitors. In addition, a 2014 screen by K. Funato and colleagues demonstrated that inhibitors against Menin, a transcriptional regulator and a member of the trithorax family histone methyltransferase complex, slowed brain tumor growth in mice. These findings highlight Menin as a potential target in patients with gliomas harboring the H3.3K27M mutation. In another study the same year by Hasizume et al. showed that GSKJ4, an inhibitor of H3K27 histone demethylation, extends survival in mice grafted with human H3K27M mutant brain tumors. Thus, pharmacological inhibition of histone K27 demethylation may hold promise in treating K27M pediatric gliomas.

Besides these histone mutants, variants of histone H2A should also be considered. For example, increased expression of H2A.Z isoforms confers poor prognosis in metastatic melanoma. Accordingly, H2A.Z.2 knockdown sensitized melanoma cells to treatment

with doxorubicin, JQ1 or PD325901 (inhibitor of MEK, a MAPK kinase). Expression of macroH2A1.1 decreases in several cancer types and the low macroH2A1.1 to macroH2A1.2 ratio negatively affects patient outcomes. For example, loss of macroH2A has been associated with progression of and osteosarcoma. This is likely due to the antiproliferative roles ascribed to macroH2A1.1 compared to the pro-proliferative role of macroH2A1.2. As well, previous studies have reported that macroH2A1.1 expression reduces PARP-1 protein levels and suppresses growth of lung and cervical cancer cells. This raises the possibility that PARP-1 inhibitors could have therapeutic value in cancers that display decreased macroH2A1.1 expression. In addition, phosphorylation of H2A.X is one of the first events after the occurrence of DSBs, which activates the DNA damage repair (DDR) response. Therefore, interfering with H2A.X could be highly complementary to existing cytotoxic therapies. Lastly, H2A.Z is overexpressed in hormone-resistant cancers. In prostate cancer cell lines, H2A.Z was shown to be downregulated upon overexpression of the histone deacetylase *SIRT1* (Sirtuin-1). Altogether, different histone variants display critical associations with clinical responses and disease progression in specific cancer types. In the future, the connection between histone variants and resistance to anticancer drugs will have to be extensively pursued.

Conclusions and Perspectives

With the advent of epigenetic targeting strategies and advanced knowledge in cancer biology, new therapeutic opportunities and challenges lie ahead. The merits of early pan-cancer interventions against HDACs and DNMTs were overshadowed by the absence of mechanism-based patient stratification criteria. In recent trials using molecularly chosen populations, second-generation drugs against carefully selected targets, EZH2 and BET family proteins, proved more effective. Therefore, a compelling argument can be made for selecting the right tumors in an effort to move away from the pan-cancer type treatments of the past. Understanding how targeting the epigenome could maximally reinforce our current therapies against the pervasive roadblocks of cancer still remains a challenge and there is a need to integrate not only the tumor but also its ecosystem in our therapeutic decisions. Treating carefully selected patient cohorts may also prove to be inadequate unless specific molecular biomarkers are used to choose these patients.

For the development of next generation epigenetic anticancer therapies, there is a pressing need not only to expand our arsenal of epigenetic targets but also to consider novel epigenetic-oncogene interactions (both synergistic and antagonistic). Histone variant-chaperone interplay represents one such druggable epigenetic relationship that needs to be considered. Indeed, histone chaperones could be promising anticancer targets for future pharmacological and clinical efforts. Not only the direct histone variant-chaperone interactions but also the protein–peptide, protein–nucleic acid, and enzymatic control that regulates these interactions in space and time could be targeted. Based on the encouraging example of HJURP-addiction in p53-null tumors, it could be of significant value to characterize additional histone chaperones for interdependencies with tumor suppressor genes and oncogenes. As appears to be the case for EZH2 where both up- and downregulation can have tumor-promoting effects, an important consideration for drug development will be the dosage of chromatin components. Moreover, histone variant choice underlies a key question: is it the means of histone incorporation by a histone chaperone (e.g., HJURP vs. DAXX in the case of CENP-A) and/or the choice of histone variant itself that matters for tumor growth and survival? A detailed examination of the fine-tuned plasticity in chaperone-variant interactions will be necessary to delineate contributions to beneficial adaptation during disease.

Prospective Vision

It has become increasingly evident that the effective treatment of cancer will require the combination of different approaches that counter the different hallmarks of cancer and overcome the roadblocks of current anticancer agents. In parallel, efforts should be made to assess large-scale, tissue-specific genomic, and epigenomic profiling to identify exceptional responders or entire subsets of patients where monotherapy against epigenetic factors will prove to be efficacious (e.g., ARID1B inhibition in ARID1A-deficient tumors). In cases of precancerous conditions, such as Age-related Clonal Hematopoiesis (ARCH), modulating the epigenome could even be considered to prevent progression to malignant neoplasia.

Conventional epigenetic drugs have aimed to block the catalytic activity of enzymatic chromatin modifiers and remodelers. However, noncatalytic domains may also play an important role. For example, compounds that compromise noncatalytic roles of PRC2 subunits, EZH2, SUZ12, and EED, may be required to obtain optimal antitumor benefits in SWI/SNF-defective cancers. Related to this, the "interfacial inhibitor concept" proposes that small-molecules can blockade interacting surfaces within large, macromolecular assemblies, as with topoisomerase enzymes, and unhinge the functional complex, effectively hindering its molecular activity. Similarly, histone chaperones are nonenzymatic factors that could be targeted by interfering with their regulation.

Epigenetic drugs could limit disease progression by crippling the oncogenic machinery of tumors and, potentially, also prevent recurrence in tumors that exploit chromatin pathways to develop resistance to existing therapies. This idea stems from the assumption that the epigenetic modifications responsible for tumor adaptation would remain reversible and sensitive to external manipulation, contrary to genetic changes. For example, loss of DNA methylation before immune checkpoint blockade can boost T cell renewal and enhances disease clearance in mouse models. This approach offers the promise of powerful treatments for chronic infections and cancer. More generally, the therapeutic promise of epigenome modulation could play a role beyond cancer with potential to treat other pathologies linked to defects in DNA metabolism or immunological disorders.

Acknowledgments

We would like to thank Dr. Sophie Postel-Vinay for contributions to the table summarizing epigenetic drugs in ongoing clinical trials and Dr. Iva Simeonova for critical reading of the manuscript.

Chromosome Rearrangements and Translocations

Stefan K Bohlander, Purvi M Kakadiya, and Alix Coysh, University of Auckland, Auckland, New Zealand

Glossary

Chromosome inversion A chromosome segment reversed end-to-end; developed when a single chromosome sustains at least two double strand breaks, followed by rearrangement and repair within itself. Chromosome inversions can either be paracentric (involving parts of a chromosome on one side of the centromere) or pericentric (involving parts of a chromosome either side of the centromere). Inversions can also either be unbalanced or balanced, dependent upon whether there is or is not a gain or loss of genomic content following chromosomal rearrangement.

Chromosome translocation The exchange of chromosomal material when breakage, rearrangement and repair occur between chromosomes (usually involving distinct chromosomes, but sometimes involving different loci within homologous chromosomes). Theoretically, translocations can occur between any loci on any two chromosomes, but many random exchanges produce translocations that are mitotically lethal because they are dicentric (have two centromeres) and cause chromosome breakage, or mitotically unstable because they are acentric (have zero centromeres) and are often lost. A translocation is reciprocal if the exchange of material is bidirectional and reciprocal if it is unidirectional. Translocations can also either be unbalanced or balanced, dependent upon whether there is or is not a gain or loss of genomic material following chromosomal rearrangement.

Chromothripsis The phenomenon where hundreds or thousands of clustered chromosome breaks occur simultaneously causing extremely complex structural rearrangements.

Copy-number alteration Duplications or deletions of chromosome sections resulting in the gain or loss of genetic material, respectively. Copy-number alterations can develop due to errors during both DNA replication and DNA repair, and the specific mechanisms differ dependent on the length of the duplication/deletion. Copy-number alterations can be the result of unbalanced chromosome inversions or translocations.

Cytogenetics A branch of genetics that studies the number, structure, and function of chromosomes; particularly focused on how chromosomes relate to cell behaviors during mitosis and meiosis.

Structural rearrangements A chromosomal abnormality resulting in a change to the normal chromosome structure, including translocations, inversions, duplications, deletions, and chromothriptic events.

Introduction to Structural Rearrangements in Cancers

Cancers and Genome Instability

Cancers are complex diseases that arise as a result of genetic, epigenetic and environmental influences, or a combination thereof, which cause genetic or epigenetic aberrations in cells. When these alterations are pro-tumorigenic (i.e., they provide a survival advantage by fulfilling one of the 10 hallmarks of cancer, they are positively selected for in a manner analogous to Darwinian evolution at the cellular level. Therefore, pro-tumorigenic lesions accumulate over time driving oncogenesis and may eventually lead to cancer.

It is possible for such genetic and epigenetic changes to be acquired in cells because there is a very low level of genome instability in all cells. This instability exists because there is a significant energetic cost to maintaining a stable genome, alongside the fact that it is optimal to have high genome stability for proper functioning and faithful reproduction, but to also have slight genome instability to allow evolutionary changes to occur. Furthermore, genome instability can be increased by the acquisition of mutations followed by selection and clonal expansion of the fittest cells, and in this way a pro-tumorigenic cycle is established.

Structural Rearrangements

Many different DNA alterations can contribute to tumorigenesis, where one class is termed "structural rearrangements." These are genomic abnormalities where the structure of a chromosome is altered and they include, translocations (rearrangements of chromosome segments usually between nonhomologous chromosomes), inversions (reversal of the direction of a chromosome segment within a single chromosome) and copy-number alterations (CNAs) (deletions or duplications of chromosome segments). In addition, although extremely rare there are also complex structural rearrangements that involve more than two DNA breakpoints and the exchange of chromosomal DNA between two or more chromosomes. The most severe complex structural rearrangement is chromothripsis, where hundreds or thousands of chromosomal rearrangements develop in a localized genomic region during a single event.

Structural rearrangements can be respectively described as either unbalanced or balanced, dependent on whether the rearrangement results, or does not result, in the gain or loss of genomic content. For translocations, the descriptors nonreciprocal and reciprocal can be used, respectively referring to whether the translocation of chromosomal material is one-way or bi-directional between two chromosomes. Balanced rearrangements are more common than unbalanced and reciprocal rearrangements are more common than nonreciprocal. Furthermore, it is more common for structural rearrangements to develop within a single chromosome than between chromosomes and between loci with closer spatial proximity in the interphase nucleus.

Structural Rearrangements in Cancer Research and Clinics

Structural rearrangements are mainly identified by cytogenetics, which is concerned with the number, structure, and function of chromosomes as well as how chromosomal variations may affect cell function in health and disease. Studying structural rearrangements has been highly important in cancer research, and in fact, it was the discovery of recurring translocations in chronic myeloid leukemia (CML) and acute myeloid leukemia (AML) patients that was the first evidence to conclusively demonstrate cancers as genetic disorders. Furthermore, the discovery that many nonrandom chromosomal aberrations are frequently associated with driving specific cancers, has shown the importance of structural rearrangements in tumorigenesis, as well as elucidating mechanisms through which they may be generated (i.e., errors during DNA repair or replication) or through which they may function (i.e., fusion proteins and deregulation of gene expression). Moreover, it has enabled structural rearrangements to be important diagnostic, prognostic and disease management indicators, as well as identifying novel targets for cancer therapies. This is particularly true for blood cancers, lymphomas, leukemias and myelomas, where the distinction between critical and irrelevant structural rearrangements is more clear, and consequently it has become routine in clinical practice to perform chromosomal analysis for blood cancer patients. In contrast, it has only become common practice to assess structural rearrangements in very few solid tumors, namely some sarcomas, prostate cancers and lung cancers where often only certain rearrangements are searched for. Hence, the field of cytogenetics and structural rearrangements is much more advanced for hematological malignancies than solid tumors, and thus this article will largely use structural rearrangements in blood cancers as examples, in particular frequently recurring balanced chromosome translocations which are most well researched.

This article will focus on the origin of structural rearrangements, their functional consequences toward tumorigenesis, the methods that enable their detection, and the research and medical advancements that come from studying them.

The Origin of Structural Rearrangements in Cancer

Like other forms of genome aberrations, structural rearrangements develop due to errors during DNA replication and DNA repair. There is a multitude of different mechanisms that can result in structural rearrangements, however the most important mechanisms are those that involve the acquisition of DNA double strand breaks (DSBs). This is because faulty DSB repair is a common cause of all types of structural rearrangements, and in fact, the incorrect repair of two DSBs which happen at close spatial and temporal proximity in the interphase nucleus is the only means through which chromosome inversions and translocations can develop, as well as being the major cause of cancer associated CNAs.

Sources of DSBs

For DNA DSBs to develop, the phosphate backbones of two complementary DNA strands need to break simultaneously. DSBs can originate from both endogenous and exogenous causes.

Firstly, many DSBs occur spontaneously due to a variety of endogenous factors: for example, natural metabolite by-products in cells (e.g., reactive oxygen species), chromosome nondisjunction during cell division, excision of transposable elements, physical or mechanical stress on DNA (e.g., mitotic spindle stress on dicentric chromosomes), and inadvertent action of nuclear enzymes of lymphoid cells (e.g., RAG complex and AID). In addition, intentional cellular processes are an endogenous source of site-specific DSBs, where examples of such processes include homologous recombination to produce gametes, V(D)J recombination in lymphocytes to assemble immunoglobulin antigen receptor genes and T cell receptor genes, and chromatin condensation and expansion via topoisomerases and helicases. Moreover, DSBs can also result from natural DNA impediments that cause DNA replication to pause or stop (e.g., unusual DNA and chromatin structures, transcription machinery, or collisions with DNA binding proteins.

In contrast, major exogenous sources of DSBs include ionizing radiation (IR), cigarette smoke, and anticancer drugs (e.g., cross-linking agents like Cisplatin and Mitomycin C, alkylating agents like Methyl methanosulfonate and Temozolomide), topoisomerase inhibitors like Etoposide, replication inhibitors like Aphidicolin and hydroxyurea, and radiomimetic compounds like bleomycin and phleomycin).

In addition to all of the above, which are direct sources of DNA strand breaks, it is important to note that DSBs can also result when other forms of DNA damage are not repaired properly, such as base mismatches, uracil bases, abasic sites, pyrimidine dimers, and chemically modified bases (e.g., alkyl groups and O-6-methylguanine) or when some DNA lesions are encountered during DNA replication, for example strand cross-links and damaged nucleotides.

Detection and Response to DSBs

Once a DSB is generated, the lesion has to be detected rapidly before it is passed on to daughter cells, because otherwise it could have serious consequences including blood disorders and a range of cancers. Following detection, the cell needs to decide whether the damage can be repaired or whether it is too extensive, because this determines whether the appropriate response would be DNA damage repair, senescence (prevention of further cell cycling in affected cells) or apoptosis (induce programmed cell death in affected cells). It is not yet clear how this decision is made by cells, but it is known that TP53 (Tumor protein p53), RB (Retinoblastoma protein), and other tumor suppressor proteins play an integral role in this process. Furthermore, it is understood that this decision is made very rapidly, typically within a few minutes of DSB generation.

DSB recognition and the subsequent cell signaling are initiated by the two broken ends of a double stranded DNA molecule, because unlike telomeric ends of DNA molecules, broken ends are not hidden by telomeric extensions and telomere associated proteins. As a result, broken ends at DSBs are recognized and attract several proteins that orchestrate the appropriate response, by recruiting additional proteins involved in repair, cell senescence or apoptosis (**Fig. 1**).

Altogether, the signaling cascades from DSB recognition through to completion of the DSB response are very complex. This is because: DSB recognition pathways differ dependent on cell type and DSB origin, there is a great number of proteins that can be involved in the recognition, repair, senescence and apoptosis processes, and there are many different repair mechanisms that can resolve DSBs, where the particular proteins that respond to the broken ends determines which repair pathway will take place.

Some commonalities amongst all repair mechanisms are that significant modifications occur to chromatin, histones and other proteins both at the site of the DSB as well as extending outwards (e.g., poly(ADP-ribosylation), ubiquitination, sumoylation, acetylation, and phosphorylation), and that the gap between the two broken ends is bridged. In some circumstances the DSB may be repaired faithfully without any errors, but in other cases the repair can result in aberrations from the original DNA molecule, with some of the most severe consequences being structural rearrangements.

DSB Repair Mechanisms and Generation of Structural Rearrangements

The mechanisms that produce structural rearrangements from DSBs can be divided into two broad classes, homology-based and nonhomology-based, which respectively do and do not require extensive homology to enable DSB repair. For instance, homology-based mechanisms require homologous template sequences approximately 97% similar to one another, whereas nonhomology-based mechanisms might only require a few to zero base pairs of homology. Consequently, homology-based

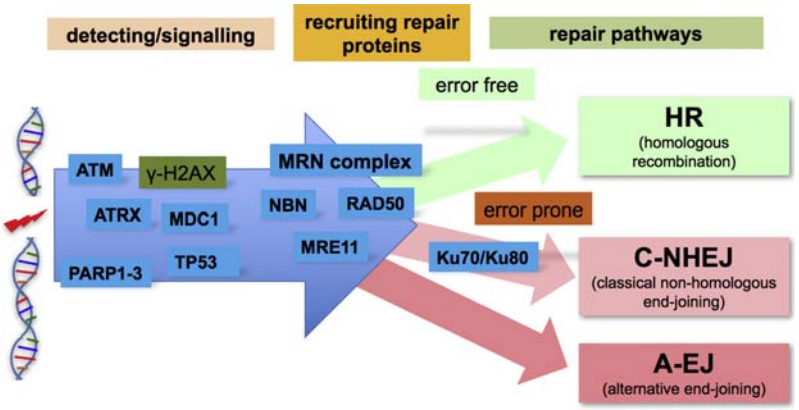

Fig. 1 Detection and resolution of DSBs through different repair pathways. The resolution of DSBs involves the detection of the DSB, protein signaling pathways, recruitment of proteins involved in DSB repair and filling in the gap between the two break points. This example shows these steps and depicts both error-prone (*red*) and relatively error-free (*green*) pathways. The MRN complex is composed of MRE11, Rad50, and NBN.

mechanisms are typically error-free whereas nonhomology-based mechanisms are more error-prone. Respectively, this means that the DSB repair usually produces a DNA sequence that is either identical or different to the original DNA sequence before the DSB occurred. Therefore, it would be more common for nonhomology-based mechanisms to join DSB ends incorrectly and generate structural rearrangements than it would for canonical homology-based mechanisms. Interestingly, in cancers proteins involved in DNA repair mechanisms are frequently mutated and become faulty. Subsequently increasing genomic instability and the acquisition of structural rearrangements. In fact, the mutation of DNA repair pathways is so essential that a two-step model has been proposed for the predisposition of structural rearrangements to tumorigenesis, whereby there must both be an error in DSB repair mechanisms and a failure to initiate cell cycle arrest in order for cancers to develop.

Homology-based mechanisms

Homologous recombination (HR)

HR is a DSB repair mechanism that operates during the S and G2 phases of the mitotic cell cycle in response to DNA damage. This is because HR requires a homologous sister chromatid (second intact copy of the affected chromosome) to use as a DNA repair template, and in mitosis these are more accessible during and shortly after nuclear DNA replication. HR also takes place during the meiotic cell cycle where it occurs in prophase 1 until metaphase 1 to generate crossing overs. Because HR is very cell cycle specific, the cyclin-dependent Kinases that mediate cell cycle progression are important regulators of HR.

HR begins with the MRE11/RAD50/NBN (MRN) complex binding to the broken ends of the DSB. Here MRE11 excises nucleotides from the 5′ ends leaving 3′ single strand DNA overhangs at the DSB break points. Next, the 3′ overhangs are coated with RPA, and then RPA is replaced by RAD51 in a reaction promoted by mediator proteins, such as XRCC2, XRCC3, RAD52, and BRCA2, amongst others. This produces the Rad51-single stranded DNA-nucleoprotein filament which then invades at the homologous site on the double stranded homologous sister chromatid. At this site a Holliday junction develops and the homologous sister chromatid is used as a template to perform DNA repair. Once the Holliday junction is resolved the DNA repair is complete.

Although canonical HR is very efficient, defective HR is known to play a role in the generation of structural rearrangements in disease, such as Downs syndrome (trisomy 21), hereditary breast and ovarian cancers (*BRCA1* and *BRCA2* mutations), Bloom's syndrome (*BLM* mutations), Werner's syndrome (*WRN* mutations), and Rothmund–Thompson syndrome (*RECQL4* mutations).

Mutations in HR genes can contribute to cancers by causing homologous chromatids to misalign during DSB repair, such that the DSB and subsequent Holliday junctions are also misaligned. The subsequent cross over would therefore be unequal as it would occur at nonallelic regions on the homologous chromosomes. This can enable the transfer of genetic material between homologous chromosomes, potentially causing deletion, duplication or inversion of the chromosomal region which may favor cancer development. Secondly, mutations in HR genes can cause nondisjunction to occur where homologous chromatids do not segregate properly during anaphase, resulting in chromosome breakage or aneuploidy (abnormal number of chromosomes in a cell), both of which can contribute to cancer development. For example, mitotic nondisjunction is known to play a role in retinoblastoma when chromosome 13 with wildtype *RB1* is lost through nondisjunction and the remaining chromosome 13 has a mutant *RB1*. Lastly, HR gene mutations can cause HR to be downregulated, consequently increasing the frequency of more error prone DSB repair pathways, which ultimately increases the acquisition of tumorigenic structural rearrangements and genomic instability. Interestingly, the genomic instability caused by mutations in HR genes actually makes cancer cells more susceptible to chemotherapeutic drugs, because these cells have an impaired ability to tolerate the induction of many DSBs at once.

Single strand annealing (SSA)

SSA is an alternate HR pathway which repairs DSBs between two DNA repeats that are less than 25 kbp (kilo base pairs) apart and oriented in the same direction. Unlike the classical HR pathway described above, SSA is unique in that it does not require a separate

homologous chromosome or DNA sequence for the DSB repair. Instead, because SSA only occurs in repeat regions, it merely uses one of the unbroken repeats as a homologous template to resolve the DSB. Because the required template for SSA is always present, SSA does not preferentially occur in any particular part of the cell cycle.

The first step in SSA is to perform single stranded DNA resection at the site of the DSB, generating complementary 3′ overhanging free DNA ends either side of the breakpoint. The overhanging strands are coated by RPA to prevent them adhering to themselves, and then Rad52 assists the alignment of the 3′ overhangs so that the complementary repeat sequences can anneal and form a single repeat. After annealing is complete, any remaining single stranded nonhomologous flaps (remnants from the 3′ overhangs) are reselected by Rad1 and ERCC1. Lastly, DNA synthesis fills in any gaps and ligation produces a continuous double stranded DNA molecule and DSB repair is complete.

Altogether, SSA typically deletes one repeat alongside any sequences between the two repeats, and such deletions cause structural rearrangements and can be tumorigenic. SSA always results in a CNA, and translocations or inversions develop when SSA occurs between two unlinked repeats, but this is highly uncommon due to the requirement for two DSBs to occur at the same time.

Breakage induced replication (BIR) template switching

BIR template switching occurs when the DNA repair machinery from another DSB repair mechanism unexpectedly switches to its homologous chromosome as a template to complete the DSB repair. Therefore, the repair proteins involved depend on the original DSB repair mechanism prior to template switching. BIR template switching is most common when errors occur during the repair of a single DSB, and BIR has not been shown to preferentially occur during any particular phase of the cell cycle.

As in nonallelic HR, because the broken end of the DSB invades a nonallelic region of the homologous chromosome during BIR template switching, it subsequently results in the transfer of genetic material between the respective chromosomes to result in chromosome inversions, translocations and CNAs which can potentially be tumorigenic. Furthermore, in cancers BIR template switching and the subsequent structural rearrangements often increase in frequency due to defective or downregulated cohesins (i.e., because cohesins function to reduce interchromosomal strand invasion).

Nonhomologous-based mechanisms

Nonhomologous end joining (NHEJ)

Classical and alternate NHEJ pathways are the major repair pathways for DSBs in cells, and they are respectively referred to as Classical-NHEJ (C-NHEJ) and alternative end joining (AEJ). C-NHEJ is more efficient than AEJ and C-NHEJ utilizes all of the classical NHEJ factors whereas AEJ lacks one or more NHEJ components as well as utilizing nonclassical factors. These mechanisms also differ in when they predominantly occur during the cell cycle, although it is interesting that NHEJ mechanisms function at least at low levels throughout all cell cycle stages. C-NHEJ is most prevalent in the G1 phase when cells are growing but not yet ready to replicate their nuclear DNA because it does not require an attack template from a homologous sister chromatid. In contrast, AEJ pathways are backup survival mechanisms that occur when C-NHEJ is defective or less active, and AEJ is most frequent during S phase of the cell cycle.

The first step in C-NHEJ is DSB recognition and signaling by the MRN complex, followed by binding of Ku70 and Ku80 to the broken ends to prevent the broken ends drifting apart. Next, the coiled coil domains of Rad50 (component of the MRN complex) extend outwards to connect the broken ends to one another, the MRN complex performs some DNA resection at the broken ends and finally the broken ends are joined together by Lig IV and XRCC4. Other important proteins in C-NHEJ include, DNA-PKcs (functions as a molecular sensor for DNA damage and cooperates with Ku70/Ku80), Cernunnos (may serve as a bridge between XRCC4 and other factors), Artemis nuclease (crucial for processing hairpin structures that form during V(D)J recombination), Metnase (methylates histones to open chromatin to process DNA ends), and BRCA1 (interacts with many DNA repair proteins and is known to be important for certain types of NHEJ, but the specific role of BRCA1 is currently unclear).

In contrast to C-NHEJ, AEJ has a requirement for small regions of microhomology between 5 and 25 bp (Base Pairs), it is more heavily dependent on the MRN complex, it lacks several C-NHEJ factors (e.g., Ku70, Ku80, XRCC4 or LigIV) and it involves several other factors (e.g., PARP1, LigIII, FEN1, and XRCC1, amongst others). The first step of AEJ is the recognition and signaling of a DSB by the MRN complex, followed by the identification of microhomologous sequences upstream or downstream of the DSB. The microhomologous regions are then used as the bases for which to align the strands with mismatched ends, and following ligation of the broken DNA strands hanging ends result. Next, any overhanging nucleotides are resected and finally any missing base pairs are filled in (both by the MRN complex). Because AEJ ligates the DNA strands without checking for homology it causes deletions flanking the original DSB, as it removes any bases required to align the two broken DNA strands.

Because C-NHEJ and AEJ are both error prone they commonly result in structural rearrangements. CNAs almost always result from these repair mechanisms because small insertions and deletions frequently occur during C-NHEJ and always occur during AEJ. Furthermore, these mechanisms can incorrectly repair DSBs to cause chromosome inversions and translocations, where some models suggest that AEJ does this at a higher frequency, but other systems support that C-NHEJ plays a greater role. Furthermore, if any of the NHEJ factors are mutated the propensity of structural rearrangements increases, and consequently mutations in NHEJ are known to cause several conditions, such as hereditary breast and ovarian cancer syndrome (*BRCA1* mutations), LigIV syndrome (*LIGIV* mutations), Cernunnos-Severe Combined Immunodeficiency Syndrome (SCID) (*Cernunnos* mutations), Artemis-SCID (*Artemis* mutations), Ataxia Telangiectasia (*ATM* mutations), and Fanconi anemia (mutations in multiple genes). Additionally, significant upregulation of NHEJ factors is observed in several cancers and thus thought to play a role in tumorigenesis, for example breast cancers (*FEN1 LIGIII* and *MRE11* genes), prostate cancers (*FEN1* and *NBS1* genes), lung cancers (*FEN1* and

XRCC1 genes), stomach cancers (*FEN1* gene), pancreatic cancers (*FEN1* gene) head and neck cancers (*NBS1* gene), squamous cell carcinomas of the oral cavity (*NBS1* gene), Ewing Sarcoma (*PARP1* gene), germ cell tumors (*PARP1* gene), tyrosine kinase-activated leukemias (*PARP1* gene), CML (*LIGIII* gene), multiple myeloma (*LIGIII* gene) and neuroblastomas (*FEN1* and *PARP1* genes). Lastly, it is also known that because C-NHEJ is crucial for V(D)J recombination, somatic recombination and class switch recombination in lymphocytes, dysfunctional C-NHEJ is a major source of structural rearrangements in lymphoid cancers and other disorders (e.g., Nijmegen breakage Syndrome, Fanconi anemia, and Bloom's syndrome).

Breakage fusion bridge (BFB) cycle

The BFB cycle is a mechanism of genomic instability that occurs during anaphase as a result of telomere loss, dicentric chromosome formation, and mechanical and physical mitotic spindle stress.

For instance, if a single chromatid lost its telomeric repeats at one end and the DSB was not repaired prior to DNA replication, then the original chromatid plus its duplicate would both lack telomeric repeats. Without telomeres to prevent chromosome fusion, the two sister chromatids would join to form a single dicentric chromosome. During anaphase of the cell cycle, the two centromeres of the dicentric chromosome would be pulled in opposite polar directions to form a bridge shaped structure until the centromeres were pulled so far away from one another that a DSB resulted. If this DSB does not occur at the exact location where the two chromosomes originally fused, then structural rearrangements would result (e.g., a deletion from one chromosome will result in an inverted duplication on the other). Because the BFB cycle produces two chromosomes lacking telomeres at their broken ends the cycle could continue to produce further duplication, deletion, inversion, and translocation of chromosomal material.

The BFB cycle has been observed to play a role in the production of tumorigenic structural rearrangements in some cancers, where it produces giant abnormal chromosomes (cancer associated neochromosomes) in which oncogenes are highly amplified (e.g., *CDK4*, *HMGA2*, and *MDM2*). Furthermore, sometimes these neochromosomes can have fragments from many different chromosomes stitched together, due to the BFB cycle occurring following chromothripsis events (thousands of simultaneous DSBs). Although BFB-mediated neochromosomes only occur in approximately 3% of cancers, they are very common in certain rare cancers (e.g., in 90% of parosteal osteosarcomas).

Polymerase slippage

Unlike the above nonhomologous-based mechanisms, polymerase slippage is a mechanism of replication errors rather than of DSB repair. Polymerase slippage is most predominant when DNA/RNA synthesis is beginning or when it is stalled and resumed (e.g., following the collapse of a replication fork).

Polymerase slippage occurs when small scale tandem repeats in the genome disrupt DNA/RNA polymerase unclamping and reclamping during DNA/RNA synthesis. Specifically, such repeats may cause the DNA/RNA polymerase complex to reclamp at the wrong position (i.e., shift a few bases backwards or forwards). Respectively, this can cause duplication or deletion of bases in repeat regions and therefore result in small CNAs (where duplications are more common than deletions).

Polymerase slippage can take place in both coding and noncoding regions, and in coding regions it can result in the generation of abnormal proteins. If polymerase slippage occurs in critical conserved regions of tumor suppressor genes or oncogenes, it can play a role in tumorigenesis. For example, it has been shown that RNA polymerase slippage is responsible for the conversion of TGFBR2 between its tumor suppressive form and oncogenic role during colorectal cancer development, by introducing a small frameshift mutation in a microsatellite region that deletes its transmembrane and intracellular kinase domains.

Determining how a structural rearrangement developed

It is possible to determine which DNA repair mechanism was likely responsible for the generation of a structural rearrangement in cancer. Firstly, key DNA repair genes could be sequenced to observe if there are any mutations, and if so the mutated repair gene would implicate a specific repair pathway(s) (e.g., *LIGIV*, Cernunnos, and Artemis mutations correspond to faulty NHEJ). However, if a gene is common to many different repair pathways then its mutation would not be sufficient to implicate a specific pathway (e.g., mutations in the components of the MRN complex).

Another approach is to analyze the DNA sequence at the site of a structural rearrangement and obtain clues from any abnormalities at rearrangement boundaries or from the type of rearrangement present. For example, small insertions or deletions at the boundaries of the rearrangement would suggest that NHEJ had taken place, and in lymphocytes if there are heptamer or nonamer consensus sequences close to the breakpoints it would suggests that NHEJ had occurred as part of somatic recombination. Alternatively, multiple rearrangements or aneuploidies would suggest that multiple rounds of the BFB cycle had happened, whereas evidence of chromothripsis would suggests that replication fork stalling followed by BIR Template Switching may have ensued.

Consequences of Structural Rearrangements

Possible Outcomes of Incorrect Repair of DSBs

Multiple simultaneous DSBs generate free double stranded DNA ends that, regardless of the particular DSB repair mechanism, can either be repaired correctly by rejoining fragments in their original order, or misrepaired by joining fragments together in the incorrect order to produce structural rearrangements. The more DSBs exist locally at any given time, the more DNA free ends will be present (e.g., two DSBs = four free ends, three DSBs = six free ends etc.), and the more complex the potential misrepair outcomes

can be. This is because with an increasing number of DNA free ends, the possible combinations for how DNA fragments can be incorrectly joined together increases in a nonlinear fashion, and with more than two simultaneous DSBs complex structural rearrangements can result. Interestingly, with multiple DSBs, it is much more common for structural rearrangements to be intrachromosomal rather than interchromosomal due to a range of steric constraints restricting the movement of chromosome ends to a radius of approximately 1 μm (e.g., DNA packaging, chromatin packaging, and nuclear chromosome arrangement).

Because it is more likely for two DSBs to occur at the same time in close proximity in the interphase nucleus than three or more DSBs, this article will focus on the outcomes from the misrepair of two concurrent DSBs.

Two DSBs on the same chromosome arm

The misrepair of two simultaneous DSBs on the same chromosome arm can produce either a deletion or an inversion (Fig. 2A). A deletion results when the chromosomal fragment flanked by two DSBs joins end-to-end with the fragment itself producing a circular acentric chromosome, and the two remaining chromosomal fragments fuse to produce a chromosome with an interstitial deletion between the location of the DSBs. Because the acentric chromosome lacks a centromere it will be lost during anaphase when chromosomes are pulled to opposite spindle poles. Alternatively, a paracentric inversion results when the chromosomal fragment between the two breakpoints is inverted and rejoined in the opposite direction to its original position.

Two DSBs on different arms of a homologous chromosome

The misrepair of two simultaneous DSBs on different arms of a homologous chromosome can also produce either a deletion or an inversion (Fig. 2B). A deletion results when the ends of the centromere-containing fragment fuse to one another to produce a ring chromosome, and the two telomere-containing fragments fuse to one another to produce an acentric chromosome. The acentric chromosome will be lost during subsequent cell divisions causing deletions of the two distal fragments. In contrast, a pericentric inversion results when the two distal fragments fuse to the opposite chromosome positions from their original orientation.

Two DSBs on the same arm of two homologous chromosomes

The misrepair of two simultaneous DSBs on the same arm of two different homologous chromosomes will produce translocations that can have either of two outcomes. The first outcome is that a dicentric and acentric chromosome are respectively produced by the two centromere-containing fragments fusing and the two remaining fragments fusing (Fig. 2C). The acentric chromosome will be lost during subsequent cell divisions and result in distal deletions of chromosomal material, and the dicentric chromosome will break during anaphase causing duplications/deletions of chromosomal content if the breakpoint is not exactly where the two chromosome fragments originally fused. The breakage of the dicentric chromosome may also be lethal. Alternatively, the two centromere-containing fragments can fuse to the two distal acentric fragments, but in the incorrect homologous chromosome, producing interstitial deletions or duplications (Fig. 2C).

Two DSBs on two nonhomologous chromosomes

The misrepair of two simultaneous DSBs on two nonhomologous chromosomes can produce translocations with two different outcomes. Again, an acentric and dicentric chromosome may each be produced by fusing of the two centromere containing fragments and acentric fragments resulting in a distal deletion and possibly cell death during cell division. Alternatively, a balanced translocation can result when the two acentric fragments fuse to the centromere containing fragments of the wrong nonhomologous chromosome.

Driver and Passenger Structural Rearrangements

It is now well understood that chromosome inversions, CNAs and especially translocations can all have functional effects toward tumorigenesis. Such structural rearrangements may either be "driver" or "passenger" in nature; respectively, causing or contributing to cancer development, or being produced as a by-product of cancer-related genome instability. However, it is very difficult to determine the driver or passenger status of a rearrangement.

The two main types of driver rearrangements are those that produce a fusion gene and those that lead to the transcriptional deregulation of breakpoint adjacent genes. Passenger rearrangements do not possess tumorigenic functional consequences, and likely candidates are rearrangements that are not recurring, do not produce obvious fusion products and are not in the vicinity of tumor suppressor genes and proto-oncogenes.

Types of tumorigenic functional consequences from structural rearrangements

There are many different types of functional consequences that can result from structural rearrangements in cancers, from gene duplications or gene deletions of tumor suppressor genes or oncogenes, through to complex functional consequences where multiple genes can be impacted at once and novel oncoproteins can be generated. This section will focus on the more complicated functional consequences of structural rearrangements with chromosome translocations as examples, however the same principles can apply for inversions, deletions and complicated rearrangements.

One complex consequence of structural rearrangements is the production of fusion genes that produce tumor promoting fusion proteins. Fusion genes are generated when the translocation breakpoints occur in two gene loci, typically in introns, that result in a translocation of chromosome material between the two loci. Consequently, fusion genes produce a fusion transcript that contains

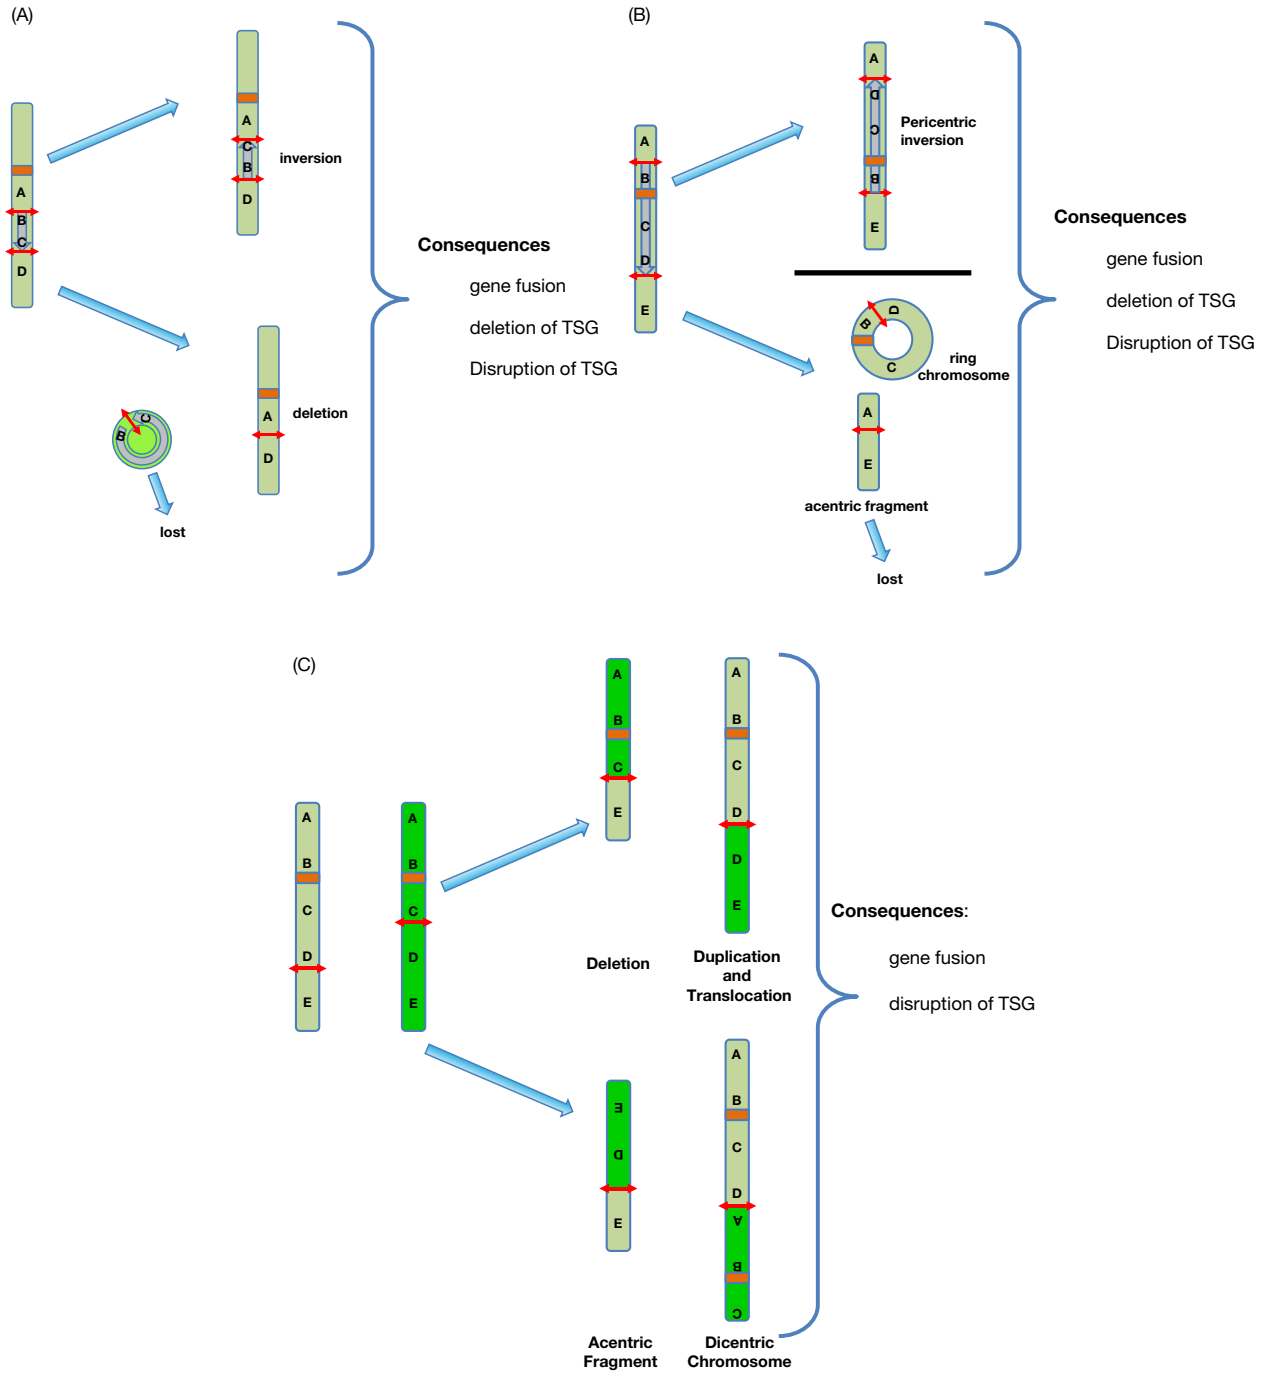

Fig. 2 Possible types of structural rearrangements that can result from the misrepair of two simultaneous DSBs depending on the location of the DSBs. (A) exhibits the possible outcomes (paracentric inversion or deletion and an acentric fragment) resulting from the misrepair of two simultaneous DSBs on the same arm of a homologous chromosome. (B) exhibits the possible outcomes (pericentric inversion or ring chromosome and an acentric fragment) from the misrepair of two simultaneous DSBs on different arms of homologous chromosomes. (C) exhibits the possible outcomes (deletion alongside duplication or a dicentric chromosome and an acentric fragment) from the misrepair of two simultaneous DSBs on the same arm of nonhomologous chromosomes (and these possible outcomes are the same as those from the misrepair of two simultaneous DSBs on different arms of nonhomologous chromosomes—shown in **Fig. 3**). It should be noted that ring chromosomes, dicentric chromosomes and acentric fragments are all frequently mitotically unstable and result in anueploidies.

coding exons from the first gene at the 5′ end and coding exons from the second gene at the 3′ end. Only in-frame fusion transcripts that do not disturb the reading frames for either gene will result in the translation of chimeric fusion proteins, consisting of an N-terminal protein region from the first gene and a C-terminal protein region from the second. For instance, the t(9;22)(q34;q11) translocation (in this case, the derivative chromosome 22 is also known as the Philadelphia chromosome) result

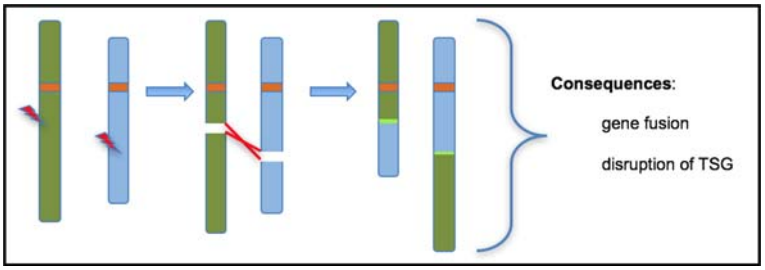

Fig. 3 Possible functional consequences that can result from structural rearrangements. Misrepair of two or more simultaneous DSBs results in the production of structural rearrangements which can have functional consequences. This example shows how two simultaneous DSBs on different arms of nonhomologous chromosomes can produce balanced translocations with either a fusion gene and/or deregulated gene expression as functional consequences.

in a fusion protein of N-terminal BCR and the C-terminal ABL1 (BCR/ABL1) in 90% of CML patients as well as in many acute lymphoblastic leukemia (ALL) patients).

In addition to a single chimeric fusion protein being produced, two reciprocal fusion proteins can be produced from reciprocal translocations. In this case, one of the fusion proteins may be dominant in driving tumorigenesis and the other reciprocal fusion protein is irrelevant, but in other cases both fusion proteins play a role (e.g., PLZF/RARA and RARA/PLZF frequently found in acute promyelocytic leukemiaPML).

Another consequence of a translocation can be the transcriptional deregulation of a gene close to the breakpoint by the juxtaposition of a strong enhancer. Examples of this are the t(8;14)(q24;q32) translocation associated with Burkitt's lymphomas and the t(14;18)(q32;q21) translocation commonly observed in follicular lymphomas. These translocations both involve the IGH intron enhancer and/or locus control regions. Respectively, these translocations result in the overexpression of *MYC* and *BCL2*, causing uncontrolled cell division, increased cell survival, and malignant transformation.

It should be noted that in cases where a balanced translocation leads to the formation of a fusion gene there will always be the disruption of one normal allele of the genes involved in the fusion. Thus, if one or both of the genes have a normal function that suppresses growth it can be speculated that in addition to the formation of two reciprocal fusion genes there will be haploinsufficiency of a tumor suppressor gene. This is, for example, the case in the t(12;21)(p13;q22) translocations in ALL that affects *ETV6* and *RUNX1*. RUNX1 and ETV6 are transcription factors that suppress cell division and encourage cell differentiation in hematopoiesis. Their loss-of-function can be tumorigenic in blood cells.

In addition, it is suggested that tumor suppressor gene functions may be disrupted by fusion proteins which interfere with protein–protein interactions (e.g., fusions between INPP5d and ABL1 caused by t(2;9)(q37;q34) translocations in ALL by altering the protein–protein interactions of the tumor suppressive INPP5D).

Lastly, it should be noted that many of the complex functional consequences of structural rearrangements outlined above may also lead to increased genomic instability (e.g., through upregulation of cell division, production of DSB causing agents like reactive oxygen species, or through knocking out the functions of essential tumor suppressor genes etc.).

Altogether, chromosomal translocation and other rearrangements can either produce fusion proteins, result in deregulation of gene expression or both. Interestingly, it is much more common for structural rearrangements resulting in chimeric fusion proteins to occur in myeloid malignancies and some solid tumors, whereas rearrangements resulting in deregulated gene expression are more typical of lymphoid tumors. Furthermore, for lymphoid cancers the rearrangements generally involve one of the immunoglobulin loci or the T cell receptor loci, as a consequence of faulty somatic recombination (**Table 1**).

Methods for the Detection of Structural Rearrangements in Cancer

Structural rearrangements have been detected and studied for a very long time, since the early 1900s, by observing changes to chromosome structure under light microscopes. However, structural rearrangements in human cancers were not detected until the 1960s and 1970s when a recurrent small chromosome was identified in the leukemic cells from CML patients (named the Philadelphia chromosome after the city where it was discovered). Later with the advent of chromosomal banding techniques the Philadelphia chromosome was determined to be the result of a translocation, the t(9;22)(q34;q11) translocation. Since, the methods for detecting structural rearrangements in cancers have been greatly improved and there are many genetic and cytogenetic techniques that detect different types and sizes of structural rearrangements.

Cytogenetic Methods

Cytogenetics is a branch of genetics that studies the number, structure and function of chromosomes. Cytogenetics is particularly focused on how chromosomes relate to cell behaviors, especially during mitosis and meiosis.

Table 1 Examples of commonly recurring structural rearrangements in different cancer types

Breakpoints	*Functional consequences*	*Frequently associated cancer(s)*
Inv(2)(p21;p23)	Produces an in-frame fusion protein EML4/ALK, constitutive tyrosine kinase signaling and uncontrolled cell proliferation	Nonsmall cell lung cancers
T(2;9)(q37;q34)	Produces an in-frame fusion protein (INPP5d/ABL1), deregulated gene expression through disruption of protein–protein interactions of INPP5D, and cancer transformation	ALL
T(2;13)(q36;q14)	Produces an in-frame fusion protein PAX3/FOXO1, deregulated gene expression through transcriptional activation, increased cell growth, increased cell survival, increased cell motility, and decreased cell differentiation	Alveolar rhabdomyosarcomas
T(6;11)(q21;q23) and T(X;11)(q13;q23)	Produce in-frame fusion proteins (FOXO3/MLL and FOXO4/MLL, respectively), deregulated gene expression through gene transactivation, increased cell stemness, and cancer transformation	Alveolar rhabdomyosarcomas and leukemias
T(8;14)(q24;q32)	Causes juxtaposition of breakpoint adjacent genes (MYC and IGH), overexpression of MYC, uncontrolled cell proliferation, and increased cell survival	Burkitt's lymphomas
T(8;21)(q22;q22)	Produces an in-frame fusion protein AML1/ETO, aberrant recruitment of epigenetic modifiers that regulate myelomonocytic development. Decreased differentiation and increased uncontrolled cell proliferation	AML
t(9;22)(q34;q11)	Produces an in-frame fusion protein BCR/ABL1, constitutive tyrosine kinase signaling, and uncontrolled cell proliferation	ALL, AML, and CML
T(12;21)(p13;q22)	Produces an in-frame fusion protein RUNX1/ETV6, haploinsufficiency of both genes, dysregulation of hematopoiesis, increased cell proliferation, and less influence toward cell differentiation	Leukemias and lymphomas
T(14;18)(q32;q21)	Causes juxtaposition of breakpoint adjacent genes (IGH and BCL2), overexpression of BCL2, uncontrolled cell proliferation, and increased cell survival	Follicular lymphomas
t(15;17)(q22;q21)	Produces two functional in-frame fusion proteins (PLZF/RARA and RARA/PLZF), deregulated gene expression, decreased granulocyte differentiation and uncontrolled cell proliferation	AML and PML

Eleven examples of structural rearrangements found frequently in cancers, with information on their breakpoints, associated genes, functional consequences (fusion genes and/or deregulated gene expression) and associated cancers (mostly hematological malignancies).

Standard cytogenetic methods

Standard cytogenetics uses a variety of chromosomal preparation techniques that determine the karyotype of cells under a light microscope, specifically attention is paid to chromosome number, chromosome length, position of the centromeres and the chromosome banding patterns, as well as any other distinctive characteristics. Karyotyping is achieved through chromosome banding techniques, which use dyes that produce horizontal bands across chromosomes when observed under a light microscope (**Fig. 4**). The banding patterns for a given chromosome pair is unique, enabling chromosomes of otherwise similar size to be distinguished from one another (**Fig. 4**). Alterations to the typical banding pattern of a given chromosome can identify chromosome breakpoints or large translocations, inversions and CNAs. Generally, chromosome banding techniques stain metaphase chromosomes, and typically around 20 cells are analyzed per sample.

Quinacrine banding was the first chromosome banding technique but it is now not as widely used as Giemsa banding. Reverse banding produces the opposite black and white banding pattern from what is seen using quinacrine and Giemsa banding and it is a useful technique for staining the distal ends of chromosomes. High resolution banding is a method that stains chromosomes at prophase or early metaphase when they are not completely condensed, because this produces many more chromosome bands and therefore allows more detailed karyotyping and the detection of less obvious aberrations. However, high resolution banding cannot be achieved in most tumor samples. There are also banding methods that only stain certain chromosomal regions, for instance, C-banding stains constitutive heterochromatin which is typically localized around the centromere, and nucleolar organizing regions banding stains satellites and stalks of acrocentric chromosomes which have centromeres very near one end of the chromosome. In general standard banding techniques have a resolution of only about 5–10 Mbp (mega base pairs). This means that any structural rearrangements smaller than the resolution limit cannot be detected confidently.

Molecular cytogenetic methods

Molecular cytogenetics is a field that combines molecular biology and cytogenetics, by utilizing a series of probe hybridization techniques to visualize one or more specific genomic regions (e.g., fluorescent in situ hybridization (FISH), array comparative genomic hybridization (array-CGH), and single nucleotide polymorphism (SNP) arrays).

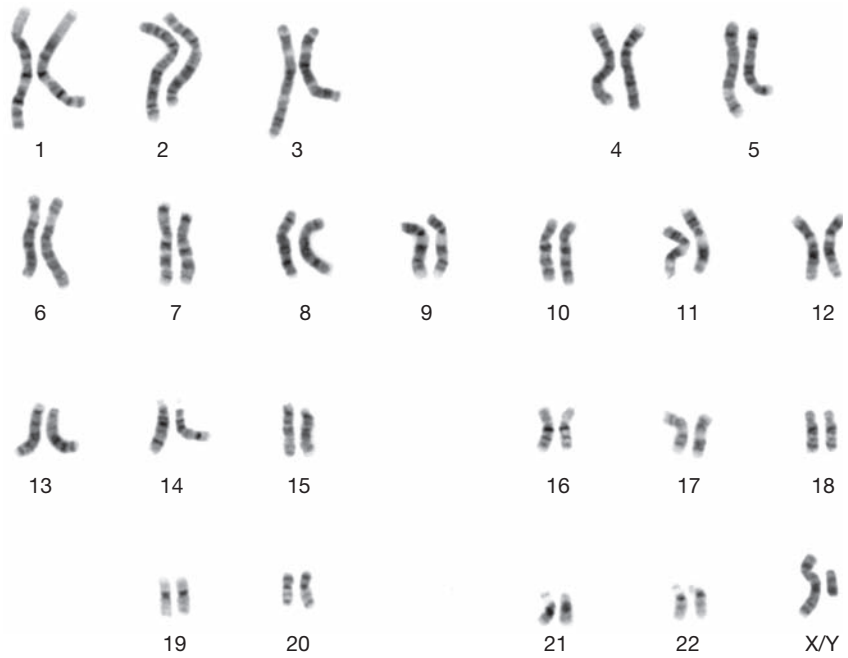

Fig. 4 Karyotype of a healthy human male using Giemsa banding. Twenty-three pairs of Giemsa banded chromosomes from an XY healthy human male, showing the unique black and white banding patterns for each chromosome pair that enables specific chromosomes and chromosome regions to be identified.

FISH uses fluorescently-labeled single stranded nucleotide probes to detect the presence or absence of specific DNA sequences on chromosomes (Fig. 5) or the presence or absence of specific RNA targets in cells. Fluorescence microscopy and computational analysis are used to identify whether any probes hybridized to the sample and if so where they hybridized in the genome or in the cell. Hence, FISH can be used to detect chromosome translocations, chromosome inversions and large CNAs. In oncology, FISH is typically carried out on approximately 100–200 cells to identify tumor cells even in residual disease and to observe the heterogeneity seen in tumors. FISH can be performed with different types of probes, for instance, probes binding the length of a chromosome can detect the gain or loss of whole chromosomes or large chromosomal regions, shorter probes can be used to hybridize more specifically to detect smaller CNAs, inversions or translocations. The extent to which probes overlap can be controlled to alter the resolution at which features can be detected, and different combinations of fluorescent probe colors can produce specific secondary colors. While the resolution of FISH can be as high as a few kbps, but typically is a few 100 kbp, it will only yield information regarding the region that is covered by the probe. Thus a typical FISH experiment will only assay a tiny fraction (less than 0.01%) of the genome and alterations that are outside this region will be invisible to the assay.

Like FISH, array-CGH also uses fluorescently-labeled single stranded nucleotides probes and fluorescence microscopy to detect chromosomal changes. However, in this method the tumor DNA itself is fluorescently labeled in one color and, together with a fluorescently labeled reference DNA, which has a different color, hybridized to an array of probes (e.g., bacterial artificial chromosome clones) that represents the whole genome (Fig. 6). Array CGH is only able to detect CNAs and is blind to balanced rearrangements. Array-CGH can detect alterations across an entire genome (with good coverage) and at a much greater resolution than chromosome banding and FISH, as low as 2 kbp. The resolution is dependent on the size and number of the cloned DNA fragments of the array used. Thus, alterations can be detected in greater detail and the aberrations can be mapped directly onto the genomic DNA sequence.

SNP (single nucleotide polymorphism) arrays are another type of DNA microarray which were originally designed to detect SNPs in the genome only, but can now be used to detect large chromosome abnormalities through identification of CNAs across genomes. SNP arrays involve the fragmentation and fluorescent labeling of sample DNA, followed by application to an SNP array chip. The SNP array chip has approximately a million different probes attached to it, which are roughly 25 nucleotides in length and are designed to bind to a portion of DNA sequence harboring the polymorphic SNP site. Fluorescence microscopy alongside computational analysis systems then detects, reports and interprets the hybridization signals. In this way, the SNPs present in a sample and the subsequent genotype can be determined, and if the intensity of the fluorescent signal for each of these SNPs is compared between multiple samples then CNAs can be inferred. In oncology, SNP arrays are used to detect thousands of CNAs across the genome, and comparisons between tumor and nontumor samples from the same patient can give an indication as to whether a particular CNA is germline-inherited or somatic in origin, as well as detecting loss of heterozygosity and regions of chromosomes that have been duplicated or deleted. Amazingly, SNP arrays have been reported to be over 99.5% accurate in SNP genotyping and CNA detection, with differences in probe and chip design influencing the accuracy and potential of a given SNP array experiment.

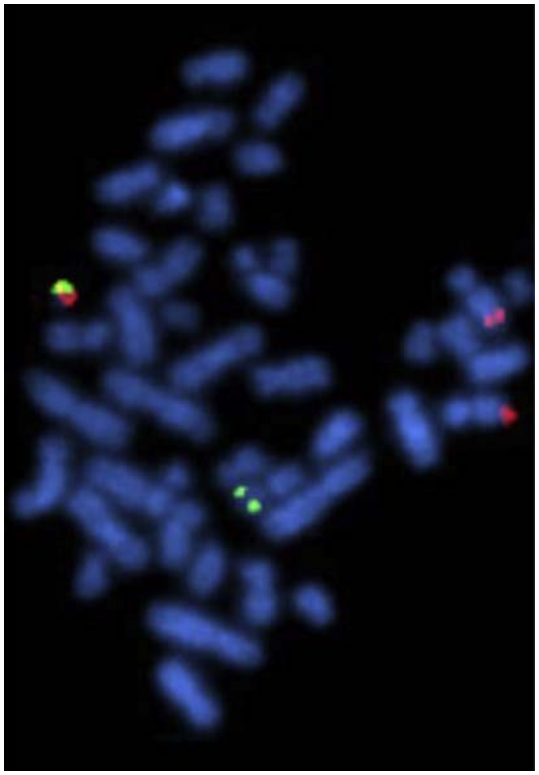

Fig. 5 FISH used to detect the t(9;22) translocation in AML. A metaphase cell positive for the t(9;22)(q34;q11) translocation in the leukemic cells from an AML patient. The chromosomes can be seen in *blue*, and the *green* and *red* spots on chromosome 22 (upper left) indicate a positive result for the BCR/ABL gene fusion.

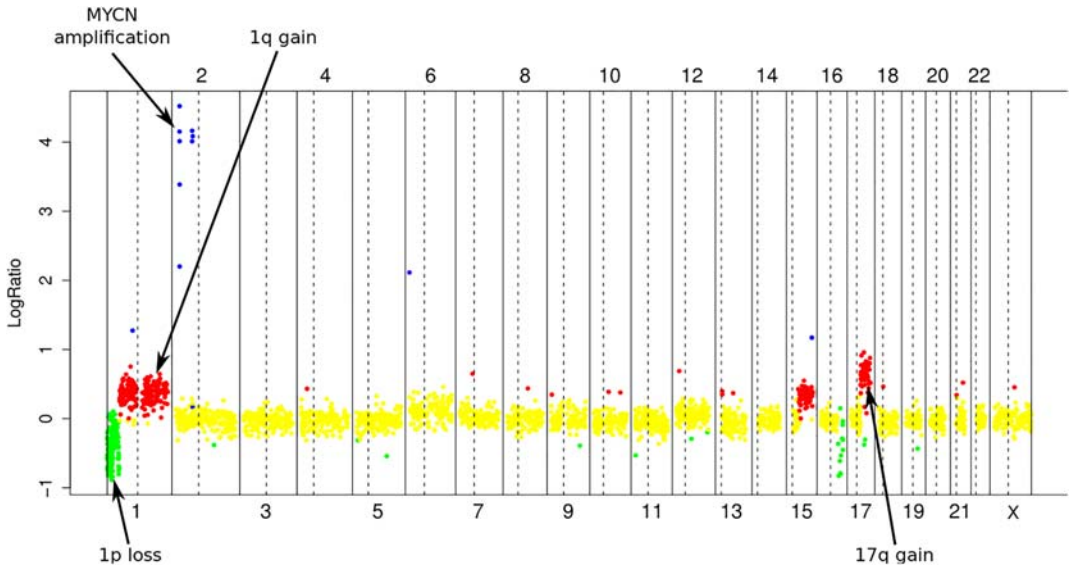

Fig. 6 Array-CGH copy number profile of a IMR32 Neuroblastoma cell line. Differences between the reference and test samples indicate copy number alterations in the IMR32 Neuroblastoma cell line, where regions of green indicate deletions, regions of *blue* indicate duplications and regions of *red* indicate gains and regions of *yellow* indicate copy number neutrality. The top left label shows an amplification of the *MYCN* proto-oncogene, the top right label and the bottom left labels respectively show the gain of chromosome regions 1q and 17q, and the bottom left label indicates a loss of chromosome region 1p.

Advances in the field of cytogenetics are focused on molecular cytogenetics techniques in particular, including automated analysis systems for calculating the results from FISH and other array methods, and improving the resolution of such methods to detect less conspicuous abnormalities.

Genetic Methods

DNA sequencing methods

DNA sequencing techniques determine the precise order of nucleotides in a DNA molecule. Whole-genome sequencing (WGS) uses a number of next-generation sequencing (NGS) methods that sequence entire genomes and they may thus be used to identify structural rearrangements across a genome. For the detection of structural rearrangements, the most efficacious WGS NGS approach is to combine mate pair sequencing and short-insert paired-end sequencing.

In mate pair sequencing, DNA is sheared into fragments of a desired length, often between 2 and 5 kbp. However this poses an issue because it is not feasible to sequence long fragments over 1 kbp using NGS. To combat this, the long fragments are biotinylated at their ends and circularized, and then the DNA rings are fragmented into approximately 400–600 bp. Next the biotin-containing fragments are extracted and the result is fragments short enough to be sequenced which still contain the two ends of the initial long fragment. Because the distance between these two ends was between 2 and 5 kbp depending on the original fragmentation parameters, if they are sequenced and mapped to a reference genome and found to be much closer together or further apart than they should be or even map to different chromosomes, then this indicates that a structural rearrangement has taken place.

In short-insert paired-end sequencing, DNA is fragmented into much shorter insert sizes between 200 and 800 bp, and adapter molecules containing primers are attached to the ends of the fragmented molecules. Because the primers in the adapters are different at each end, this allows bi-directional sequencing of the DNA fragments, which provides greater sequencing accuracy than sequencing from a single end because it generates greater coverage when aligned to a reference genome.
