Introduction

A range of biologic and epidemiologic evidence documents a key role of the hormonal milieu in the etiology of several cancers. Hormones regulate major physiological systems, playing key roles in metabolism, growth and development, reproduction, and neurological function. Produced in and secreted by endocrine glands, hormones enter circulation and target specific organs, where they bind receptors, producing downstream effects. In some cases, secretion may also occur locally, resulting in paracrine or autocrine effects.

Mechanistically, hormones may contribute to carcinogenesis through disruption of normal regulatory action. For example, estrogens and other sex-steroid hormones promote cell proliferation, which increases the opportunity for mutations to occur and can lead to increased tumor growth. Some hormones, including insulin-like growth factor I (IGF-I) and prolactin, have been shown to reduce apoptosis, promoting tumor development. In addition, hormones can affect one another to influence cancer progression; for example, gonadotropins may influence tumorigenesis by stimulating sex-steroid production. Antioxidant properties of certain hormones, such as melatonin, may prevent carcinogenesis. Dysregulation of broader functional processes including circadian rhythm and metabolic control, which is heavily influenced by insulin activity, may increase susceptibility to carcinogenesis through additional mechanistic pathways.

Hormonally related risk factors have long been associated with several cancer types, particularly breast cancer. These established breast cancer risk factors include parity and ages at menarche and menopause. Adulthood obesity is linked to as many as 13 cancer types. This association is mediated, at least in part, through hormonal pathways; for instance, most estrogen production among postmenopausal women takes place in adipose tissue, and obesity is also closely linked to insulin function. Diabetes, defined by insulin resistance, is also a moderate risk factor for several cancers, including breast and endometrial cancers.

Methodologic Considerations

To evaluate the role of hormones in cancer, measurement considerations in epidemiologic studies must be addressed. First, collection of blood or urine (or other tissue) must occur well before the cancer is clinically evident to establish temporality of the association between hormonal exposure and cancer development, given that the tumor and treatments may affect hormone levels.

It is rare for more than one blood or urine sample to be collected per participant in prospective studies, due to logistic and financial constraints. This increases the potential for misclassification of the participant's true long-term hormone levels (generally the exposure of interest), and precludes the ability to evaluate hormonal levels over time. Several hormone measurements show temporal variability, requiring careful consideration in study design and analysis (Fig. 1). However, single blood sample collection has been shown in multiple studies to reasonably reflect long-term hormone levels, with correlations over a 2-to-3-year period ranging between 0.5 and 0.9 for IGF-I, IGFBPs, gonadotropins, and sex-steroid hormones. Phase of the menstrual cycle influences some hormones, and correlations over time for estrogens and progesterone are substantially lower among premenopausal compared to postmenopausal women. Thus, use of a single blood measurement results in some attenuation of relative risk (RR) estimates. Overall, however, for many hormones of interest, reproducibility of hormone measures in blood are similar to reproducibility of serum cholesterol measures, and therefore can likewise be considered consistent predictors of disease.

Whether blood, urine, or both are collected varies based on the study goals and funding limitations. In either case, fasting samples are generally preferred to limit influence of metabolic effects on hormone levels, although exceptions exist, including insulin, where both fasting and nonfasting levels are potentially of scientific interest. Because serum is more proximal to tissues of interest, hormones measured in serum may be a more accurate surrogate marker for tissue exposure compared to urinary levels. Hormone levels tend to remain stable in serum over time, and storage at $-80°C$ or colder is acceptable to prevent degradation or dissociation over time. Urine collection is less invasive, and some urinary hormones are well correlated with serum levels. Urinary analysis is advantageous when breakdown products of hormones are of interest; evaluation of such products may provide insight into mechanistic pathways. However, the concentration of urine varies substantially within and among individuals, and correction for concentration must be considered when measuring urinary products. Moreover, it is less clear whether urine levels are representative of high tissue exposure, or if they simply represent enhanced excretion efficiency, making connections between urine measurements and cancer risk more difficult.

The ability to accurately represent tissue hormone levels via blood or urine measurements is a major consideration, although limited data exist because of challenges in obtaining tissues of interest and measuring hormone levels in these tissues. In a recent study, relatively low correlations were observed between circulating sex hormones and prostate tissue specific levels, while strong correlations were observed between plasma estradiol and expression of estrogen dependent genes in ER+ breast tumors, supporting use of blood biomarkers to evaluate the breast tissue milieu. In addition, external factors, such as exercise, alcohol intake, and

smoking, among others, can influence endogenous hormone production, and thus should be considered in epidemiologic analyses. Despite these concerns, consistency of associations between hormones measured in blood or urine and risk of specific cancers provides evidence for a connection between these measures and actual tissue exposure.

Overview

This article reviews endogenous hormones in relation to incident cancer risk. Data from biologic studies inform mechanistic actions, while data from prospective cohort studies (i.e., "nested" case–control studies) provide the strongest epidemiologic evidence for associations with cancer. The hormones included are sex steroids (estrogen and estrogen metabolites, progesterone, androgens), anti-Müllerian hormone (AMH), gonadotropins, prolactin, insulin/C-peptide, insulin-like growth factors (IGF), adiponectin, and melatonin.

Sex Steroids

Derivatives of cholesterol formed via steroidogenesis, sex-steroid hormones include estrogens, progesterone, and androgens. These hormones bind to their respective receptors, triggering multiple downstream gene pathways. The aromatase enzyme converts androgens to estrogens, representing the primary mode of estrogen production in males and postmenopausal females.

Sex steroids contribute to cancer risk primarily by promoting cellular proliferation, thereby increasing the chance of cellular mutations. Estrogens are thought to influence tumorigenesis via estrogen receptor-mediated transcriptional activation of estrogen-responsive genes, including proto-oncogenes (Fig. 2B). Estrogen also may be tumorigenic through genotoxic mechanisms. Androgens may increase cancer risk by directly influencing proliferation or via conversion to estrogens. Progesterone promotes

apoptotic signaling, and thus may balance the proliferative impact of estrogens; the absence of progesterone underlies the "unopposed estrogen" hypothesis.

Estrogens

Estrogens play an essential role in the development of female secondary sexual characteristics, and contribute to several biological systems, including reproductive, cardiovascular, and neuroendocrine. Major estrogens include estrone (E1), 17-β-estradiol (E2), the most biologically active estrogen, and estriol (E3). In premenopausal women, estrogen is primarily produced in the granulosa cells of ovarian follicles with assistance from follicle-stimulating hormone (FSH), and is produced in smaller amounts in the liver, adrenal glands, breasts, and adipose tissue. Estrone is a primary estrogen in postmenopausal women, produced from conversion of adrenal androgens. In males, estrogen production occurs in the Leydig cells of the testes, through conversion of testosterone to estradiol via the cytochrome p450 aromatase enzyme, and through conversion of androstenedione to estrone. Estrogens affect signaling pathways by binding to and activating one of two estrogen receptors, ER-α or ER-β, in target organs.

Parent estrogens, estradiol and estrone, can be metabolized via 2-, 4-, and 16α hydroxylation pathways. These oxidative metabolites of estrogen have been implicated in carcinogenesis (**Fig. 2A**). Catechol estrogens are formed following irreversible oxidation of estrone and estradiol at the C-2 or C-4 positions, while oxidation at the C-16 position yields 16α-hydroxyestrone. Catechol estrogens can be further methylated to 2-methoxyestrone and 4-methoxyestradiol, 2-hydroxyestrone-3-methyl ether, 4-methoxyestrone, and 4-methoxyestradiol, while 16α-hydroxyestrone can be metabolized to 17-epiestriol, 16-ketoestradiol, and 16-epistriol.

The estrogenic and proposed genotoxic activity of metabolites differs across pathways. The 4- and 16α- pathway metabolites have higher estrogenic activity than estrogen, and as such are thought to increase proliferation in the same manner as estradiol; in contrast, 2-catechol estrogen metabolites may inhibit or mitigate proliferation. These differences may be explained in part by each metabolites' binding affinity to ER: 2- and 4-catechol estrogen metabolites (EMs) bind with a similar affinity as estradiol, while 16α-hydroxyestrone binds with lower affinity, though covalently. Thus, bound 16α-hydroxyestrone results in a constitutively activated ER, whereas 2- and 4-catechol EM can dissociate. 4-Catechol EMs have lower dissociation rates than estradiol, so they tend to upregulate ER-dependent processes. In addition, the metabolism of 4-hydroxy catechols to reactive quinones leads to generation of reactive oxygen species and consequent oxidative damage which may contribute to tumorigenesis. While 2-catechol estrogens are similarly metabolized to quinones, they instead form stable, reversible, DNA adducts. In either case, the methylation of an adjacent hydroxyl group will block formation of quinones.

Women who have traits associated with high cumulative estrogen exposure, such early age at menarche or late age at natural menopause, and long menopausal hormone therapy use, are more likely to develop several cancers, including postmenopausal breast, ovarian, and endometrial cancers, supporting a role for estrogens in carcinogenesis. More recently, evidence has also emerged for estrogen pathways in premenopausal breast, prostate, and colorectal cancers.

Postmenopausal breast cancer

Increasing levels of circulating estrogens are consistently associated with increased risk of postmenopausal breast cancer. A 2002 pooled analysis of nine prospective studies by the Endogenous Hormones and Breast Cancer Collaborative Group included 663 women who developed breast cancer after blood collection and 1765 controls. Positive associations were observed between all measured estrogens and postmenopausal breast cancer (**Fig. 3**), with evident dose–response trends (5th vs. 1st quintile total estradiol relative risk (RR) = 2.00, 95% confidence interval [CI]: 1.47–2.71, p-trend < 0.001; free estradiol RR = 2.58, 95% CI: 1.76–3.78, p-trend < 0.001). Large prospective studies published subsequently confirmed these pooled findings. In a 20-year follow-up within the Nurses' Health Study (NHS), positive associations between estradiol and breast cancer risk were stronger among women with ER+/PR+ tumors (5th vs. 1st quintile RR = 2.8, 95% CI: 2.0–4.0), and for women with more aggressive disease (i.e., recurrent or fatal disease) (RR = 2.6, 95% CI: 1.3–5.1).

In an analysis investigating serum or urinary EMs in postmenopausal breast cancer, including 1298 cases from four studies, an inverse association was observed between 2-hydroxylation pathway metabolites and postmenopausal breast cancer, as well as an inverse association between the ratio of 2-hydroxylation: 16-hydroxylation pathway metabolites.

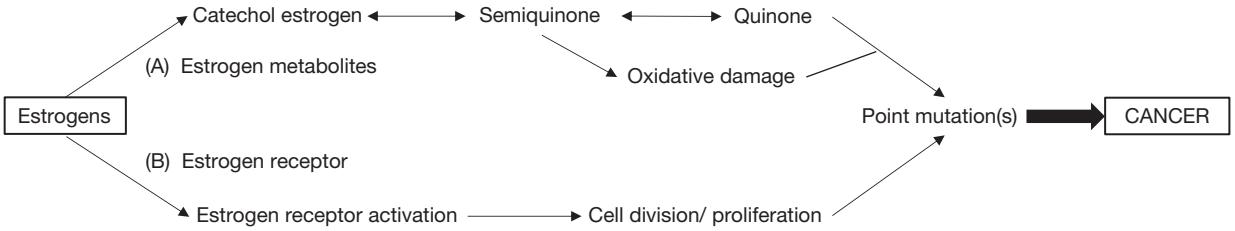

Fig. 2 Mechanisms of estrogens in carcinogenesis. (A) Catechol estrogens form semiquinones and quinones, that may lead to oxidative damage and genetic mutations. (B) Estrogen directly causes increased cell proliferation following ER activation, increasing likelihood of point mutations. Mutations via either mechanism promote carcinogenesis. (2013). Sex hormones and risk of breast cancer in premenopausal women: a collaborative reanalysis of individual participant data from seven prospective studies. *The Lancet Oncology* **14**(10), 1009–1019 (Fig. 1) (premenopausal).

Premenopausal breast cancer

Evaluating endogenous estrogens and risk of premenopausal breast cancer is difficult due to variation in concentrations across the menstrual cycle. A large pooled analysis of seven prospective studies by the Endogenous Hormones and Breast Cancer Collaborative Group evaluated this association with 767 cases and 1699 controls matched on day of menstrual cycle. A doubling of circulating estradiol was positively associated with premenopausal breast cancer risk (RR = 1.19, 95% CI: 1.06–1.35). Similar associations were observed for free estradiol, and estrone (Fig. 3). RRs were suggestively stronger for ER+/PR+ breast cancers, compared with ER−/PR− breast cancers.

While the pooled analysis supports a positive association between circulating premenopausal estrogen levels and risk of breast cancer, opposite associations have been observed with urinary premenopausal estrogens. Within the Nurses' Health Study II (NHSII), a cohort which enrolled majority premenopausal women at baseline, those with higher levels of urinary estrone and estradiol were at lower risk of breast cancer (4th vs. 1st quartile estradiol RR = 0.51; 95% CI: 0.30–0.86), possibly suggesting that higher estrogen excretion decreases risk.

In a large study ($n = 377$ cases) of premenopausal serum 2-hydroxyestrone and 16α-hydroxyestrone, no significant associations were observed with the metabolites or the ratio. However, a suggestive increased risk of ER+ premenopausal breast cancers was observed with a higher 2:16 metabolite ratio (top vs. bottom quartile RR = 2.15, 95% CI: 0.88–5.27). In the NHSII analysis of urinary EMs ($n = 247$ cases), suggestively inverse associations were observed for 2- and 4-hydroxylation pathway EMs, though a significant positive association was observed with a 16-pathway metabolite, 17-epiestriol (4th vs. 1st quartile RR = 1.74, 95% CI: 1.08–2.81).

Endometrial cancer

Strong positive associations of estrone and estradiol with overall endometrial cancer risk were observed in a nested case–control study within the Women's Health Initiative Observational Study (WHI-OS, $n = 313$ cases). The association with unconjugated estradiol was the strongest (5th vs. 1st quintile RR = 6.19, 95% CI: 2.95–13.03), though a positive association with estrone was observed even with adjustment for unconjugated estradiol (RR = 2.70, 95% CI: 1.34–5.45). Nearly all serum estrogen metabolites were associated with a two-to-threefold increased endometrial cancer risk as well. Together with a smaller study with similar findings, the evidence indicates a strong association between circulating estradiol and estrone and endometrial cancer, and potential role of estrogen metabolites in tumorigenesis.

Ovarian cancer

Relatively few epidemiologic studies have examined circulating estrogens and ovarian cancer risk, and results are inconsistent. In a case-cohort study of 67 ovarian cancer cases within the Breast and Bone Follow-up to the Fracture Intervention Trial (B-FIT), neither estrone nor estradiol were associated with ovarian cancer risk. Similarly, no association was observed between any of the 15 measured estrogen metabolites and risk. However, in a larger study of 169 epithelial ovarian cancer cases conducted within WHI-OS, a suggestive association was observed with circulating estrone (5th vs. 1st quintile RR = 1.54, 95% CI: 0.82–2.90), and positive associations were observed for 2- and 4-methoxyestrone metabolites (5th vs. 1st quintile RR = 2.03, 95% CI: 1.06–3.88). For each of these hormones, associations tended to be strongest for nonserous tumors.

Prostate cancer

Polymorphisms of genes in the estrogen metabolic pathway have been associated with prostate cancer risk, and because age is associated with prostate cancer risk this suggests that the natural lowering of the androgen to estrogen ratio with age may be a factor in carcinogenesis. However, a role for estrogen in prostate carcinogenesis is also seemingly paradoxical given the efficacy of estrogen therapy in androgen-dependent prostate cancer.

Despite biologic plausibility and some epidemiologic evidence suggesting an association between estradiol concentration and prostate cancer, the most recent evidence from a pooled analysis ($n = 3886$ cases) suggests endogenous estrogens are not importantly associated with prostate cancers.

Colorectal cancer

Epidemiologic evidence suggests a role of exogenous estrogens in lowering the risk of colorectal cancer among women. However, in an analysis of four prospective cohorts, circulating levels of estrone and estradiol were not associated with risk of colorectal cancer in either men or women.

Progesterone

Progesterone is an ovarian steroid hormone essential in breast and uterine development. Similar to estrogen, progesterone regulates gene transcription through one of two receptor isoforms, progesterone receptor (PR) -A and -B, located in the brain, breast, and reproductive organs. Once progesterone binds to the receptor, it becomes activated, binds to the DNA hormone response elements (HRE) in promoter regions of genes of interest, and, with assistance of coactivators, promotes transcription. Biologic hypotheses for this hormone suggest both pro- and antitumorigenic roles.

One hypothesis for progesterone-specific carcinogenic action in breast cancer is based on the proposed ability of ER+/PR+ cells to stimulate stem cell growth via growth promoters, spurring tumor development in normal breast epithelium. In addition, as most early breast cancer lesions express PR, it has been suggested that PR+ cells directly respond to progesterone to initiate PR-target gene transcription and subsequent proliferation. Progesterone levels are highest in the luteal phase, which corresponds with a period of high breast cell proliferation, suggesting a protumorigenic effect. However, progesterone also is hypothesized to decrease breast cancer risk by slowing estrogen-induced proliferation in breast epithelial cells.

Progesterone is particularly difficult to study separately from growth factors and prolactin in laboratory studies, and because mammary epithelial cells that express PR-A and PR-B also express ERs, the effect of estrogen versus progesterone on carcinoma development in breast tissue is often not easily distinguishable. A few epidemiologic studies have assessed progesterone levels with respect to post or premenopausal breast cancer, and have found null associations overall.

Androgens

Androgens are responsible for formation of male sex traits and play a role in female sexual processes both directly and through their conversion to estrogens. Adrenal androgens function as weak steroids, and include dehydroepiandrosterone (DHEA), produced from cholesterol in the adrenal cortex, dehydroepiandrosterone sulfate (DHEAS), and androstenedione, produced in the testes, adrenal cortex, and the ovaries, all of which can be converted to testosterone. DHEAS is converted to estrone following initial conversion to androstenedione, and is converted to testosterone after intermediate conversion to 5-androstenediol. Conversion of DHEA, DHEAS, and androstenedione to testosterone occurs in certain tissues including brain, skin, fat, and muscle.

Testosterone is one of the most bioactive androgens, produced by the male testes and female ovaries, and is further converted to its metabolite dihydrotestosterone (DHT), in the prostate, liver, brain, and skin; androgen effects are mediated through binding of testosterone or DHT to the androgen receptor (AR). The majority of testosterone is bound to sex-hormone-binding globulin (SHBG), or albumin, with approximately 2% of total testosterone freely circulating. Testosterone can be converted to estrogen via aromatase.

Androgens are hypothesized to increase risk of cancer by either increasing cell proliferation directly, or by their conversion to estrogens via aromatase.

Postmenopausal breast cancer

Approximately 60%–70% of breast tumors express androgen receptor (AR), indicating potential responsiveness to androgens. Moreover, normal and malignant breast tissues contain aromatase to convert androgens to estrogens. In the large pooled analysis of the Endogenous Hormones and Breast Cancer Collaborative Group mentioned above, testosterone concentration was associated with increased risk of breast cancer (5th vs. 1st quintile RR = 2.22, 95% CI: 1.59–3.10), with a similar association with androstenedione. DHEA and DHEAS associations with risk were slightly weaker than those of testosterone and androstenedione, likely due to the requirement of DHEA and DHEAS to be converted to androstenedione prior to estrone conversion. In a subsequent analysis within the NHS ($n = 707$ cases), stronger associations were observed for ER+/PR+ tumors (4th vs. 1st quartile overall RR = 1.5, 95% CI: 1.2–1.9; ER+/PR+ RR = 1.8, 95% CI: 1.3–2.5).

Premenopausal breast cancer

Significant positive associations between testosterone levels and risk of invasive breast cancer in premenopausal women have been consistent across several studies. In the same pooled analysis that examined estrogens and premenopausal breast cancer risk ($n = 750$ cases), androgens were associated with higher risk of premenopausal breast cancer (doubling testosterone RR = 1.18; 95% CI: 1.03–1.35; androstenedione RR = 1.30, 95% CI: 1.10–1.55; DHEAS RR = 1.17, 95% CI: 1.04–1.32).

Ovarian cancer

In vitro evidence suggests that androgens, along with estrogens and progesterone, help regulate the proliferation and invasion of ovarian cancer cells. It is hypothesized that, based on its strong ER-α agonist activity in other cell types, androstenedione may affect epithelial ovarian cancer (EOC) risk via interaction with ER.

In a nested case–control study within the large European Prospective Investigation into Cancer and Nutrition (EPIC) cohort ($n = 565$ cases), no association was observed between testosterone and EOC overall, though suggestively positive associations were observed with low-grade and type I tumors. Null associations were generally maintained across tumor characteristics for DHEAS and androstenedione, although a doubling of androstenedione was associated with higher risk of EOC for type I (RR = 1.99, 95% CI: 1.18–3.35), and low-grade tumors (RR = 1.99, 95% CI: 0.98–4.06). In contrast, in an earlier US study conducted within NHS, NHSII, and the Women's Health Study (WHS) cohorts, an inverse association was observed between androstenedione levels and ovarian cancer risk. Contradictory evidence may be due to differential inclusion criteria, or the heterogeneity of ovarian cancers.

Endometrial cancer

Within the EPIC cohort ($n = 247$ cases), higher risk of endometrial cancer among postmenopausal women was observed with increasing levels of total testosterone (3rd vs. 1st tertile RR = 1.44, 95% CI: 0.88–2.36), and free testosterone (RR = 2.05, 95% CI: 1.23–3.42), which was consistent across the eight included countries. These findings are consistent with smaller prospective cohort studies.

Prostate cancer

Given their critical role in normal growth and development of the prostate gland, androgens are hypothesized to increase risk of prostate cancer. Most prostate tumors initially respond to androgen deprivation therapy, and inhibition of testosterone to DHT conversion reduced incidence of prostate cancer by 25% in the Prostate Cancer Prevention Trial. Despite this plausibility, epidemiologic evidence to date does not support a role for testosterone in risk of prostate cancer. In the pooled analysis of 18 studies ($n = 3886$ cases), no associations were observed between testosterone and prostate cancer risk (5th vs. 1st quintile total testosterone RR = 0.94, 95% CI: 0.82–1.07; free testosterone RR = 1.11, 95% CI: 0.96–1.27). Consistent with this, no associations were observed for DHEA, DHEAS, and androstenedione.

Colorectal cancer

Within the pooled analysis of four male and female prospective cohort studies, higher levels of total testosterone were associated with a lower risk of colorectal cancer in men (4th vs. 1st quartile RR = 0.62, 95% CI: 0.40–0.96), but not women (4th vs. 1st quartile RR = 1.43, 95% CI: 0.82–2.50). The ratio of estradiol to testosterone was also positively associated with colorectal cancer in men (4th vs. 1st quartile RR = 2.63, 95% CI: 1.58–4.36) but inversely associated with risk among postmenopausal women (RR = 0.43, 95% CI: 0.22–0.84). Although in opposite directions in men and women, these results suggest a role for androgens and aromatase activity in colorectal carcinogenesis.

Anti-Müllerian Hormone

Anti-Müllerian hormone (AMH) is a member of the transforming growth factor beta (TGF- β) superfamily. The Müllerian ducts, present in the embryo, are precursors of the fallopian tubes, uterus, and upper vagina. In the fetus, AMH secretion by Sertoli cells of the testes halts Müllerian ducts from further development, whereas a lack of AMH promotes development of the female genital tracts. Postnatally, AMH secretion by granulosa cells of ovarian follicles is a sensitive marker of ovarian reserve. Levels are low in early life, increase during puberty and remain stable until about 25 years of age, and decline until undetectable in menopause, at which point the ovarian reserve is depleted.

The action of AMH binds its primary receptor (AMHR-II), which is present in organs of the reproductive tract, as well as in the breast. AMHR-II then phosphorylates the type I receptor, allowing mediation of downstream signaling. Through this mechanism, AMH activates growth inhibition pathways, and is hypothesized to protect against the development of tumors of the female reproductive tract, with extension to tumors of the breast. It has also been suggested to have a similar protective role against prostate cancer in males. Though animal and experimental studies support this hypothesis, the epidemiologic evidence does not support a protective effect of AMH on carcinogenesis. While the reason for discrepancy is unclear, concentrations of AMH well above normal physiologic levels were used in experimental studies.

Ovarian Cancer

Most ovarian surface epithelial (OSE) neoplasms arise from Müllerian epithelium or Müllerian-like ovarian surface mesothelium; thus, AMH may prevent ovarian cancer development. In animal and experimental studies in ovarian cancer cell lines AMH decreases proliferation, inhibits cell migration, and increases apoptosis. Despite this evidence, epidemiologic studies have consistently found no association between AMH levels and ovarian cancer risk.

Endometrial Cancer

In vitro, AMH inhibits growth in endometrial cancer cell lines, via apoptosis and cell cycle arrest, driven by regulation of proteins responsible for G1-to-S phase transition and cell cycle exit. However, the concentrations of AMH used in most experimental studies were higher than normal biological levels, and findings have not been reproduced in population studies.

In a large study of eight cohorts from the United States, Europe, and China ($n = 329$ cases), no association between AMH levels and endometrial cancer risk was observed (doubling of AMH RR = 1.07, 95% CI: 0.99–1.17).

Breast Cancer

Similar to experimental ovarian and endometrial cancer studies, supra-physiologic concentrations of AMH inhibit growth of breast cancer cells and increase apoptosis in vitro. However, the opposite effect is suggested by indirect epidemiologic evidence, as higher AMH levels are associated with later age at menopause, a known risk factor for breast cancer.

In prospective studies of the association between premenopausal AMH levels and breast cancer risk, positive associations have been observed between increasing AMH levels and incidence of breast cancer. A nearly 10-fold increased risk of breast cancer was observed in an initial epidemiologic study of AMH levels ($n = 309$ cases; 4th vs. 1st quartile RR = 9.8, 95% CI: 3.3–28.9). Two subsequent nested case–control studies ($n = 452$, 539 cases) confirmed the positive association, although the associations were not as strong (90th percentile vs. those with undetectable levels of AMH RR = 2.25, 95% CI: 1.26–4.02; 5th vs. 1st quintile RR = 2.20, 95% CI: 1.34–3.63, respectively). The latter study was conducted within NHSII and included women who were diagnosed with breast cancer prior to menopause, which indicates a biologic role for AMH in breast cancer etiology, and not simply an association that tracks with late menopause. Most recently, a pooled analysis of 2835 cases found a relative risk for breast cancer comparing the top versus bottom quartile of AMH of 1.60 (95% CI: 1.31–1.94).

Prostate Cancer

AMH is produced by the Sertoli cells of the testes in males, and following its initial role in sexual differentiation, AMH controls cell proliferation, differentiation, and apoptosis in normal tissues. Serum levels of AMH decline significantly following puberty and stabilize, remaining detectable throughout the lifespan. TGF-β has been shown to negatively regulate prostate growth through

induction of cellular apoptosis. As a member of the TGF-β growth factor family, AMH has been hypothesized to play a similar inhibitory role in the initial development of prostate cancer. In vitro evidence suggests, as with the cancers of the female reproductive tract, that AMH inhibits prostate cancer through similar mechanisms. However, no association was observed between AMH and prostate cancer risk (4th vs. 1st quartile RR = 1.15, 95% CI: 0.89–1.48) in the Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial ($n = 1000$ cases).

Gonadotropins

The two gonadotropins, follicle-stimulating hormone (FSH) and luteinizing hormone (LH), regulate menstrual cycles in females. These hormones are synthesized by gonadotropic cells in the anterior pituitary gland and their secretion is regulated by gonadotropin-releasing hormone (GnRH). LH and FSH work synergistically to stimulate function within the gonads. LH is primarily responsible for increasing secretion of sex steroids in the ovarian theca cells, inducing ovulation, while FSH is essential for ovarian follicle growth prior to ovulation. Circulating levels of gonadotropins are controlled through a negative feedback loop, as sex steroids induced by LH stimulation inhibit GnRH and, in turn, FSH and LH levels.

The gonadotropin hypothesis posits that gonadotropins stimulate ovarian surface epithelium (OSE) to increase cell proliferation, as observed in vitro, which promotes tumor growth. In addition to proliferative effects, LH and FSH may promote tumorigenesis by increasing cell migration and suppressing apoptosis, through several different signaling mechanisms (e.g., via mitogen-activated protein kinases (MAPKs)).

Ovarian Cancer

Epidemiologic evidence indirectly supports the gonadotropin hypothesis on ovarian cancer risk, particularly given the protective effect of oral contraceptives, which suppress gonadotropin secretion. In addition, increased ovarian cancer risk among postmenopausal women provides support for this hypothesis, given that levels of FSH and LH increase in menopause in absence of ovarian steroid hormone feedback. Coupled with evidence that gonadotropin levels are higher in ovarian cancer patients, these findings support a potential role for FSH and LH in ovarian cancer development. However, among the few prospective studies of prediagnostic circulating gonadotropins on epithelial ovarian cancer (EOC), results have been inconclusive or contradictory to the gonadotropin hypothesis.

For example, while gonadotropin therapy for infertility, usually administered as a high dose of FSH, has been shown to increase risk of ovarian cancer, prospective studies of serum FSH levels have found null or contradictory results. In an analysis of three prospective cohorts, based in the United States, Sweden, and Italy ($n = 88$ postmenopausal cases), no association was observed between circulating FSH and epithelial ovarian cancer (3rd vs. 1st tertile RR = 0.85, 95% CI: 0.36–1.99). In a more recent but similarly small study in the United States and the United Kingdom (67 cases) an inverse association was observed between FSH levels and epithelial ovarian cancer risk (3rd vs. 1st tertile RR = 0.26, 95% CI: 0.10–0.70), that was consistent for both postmenopausal and premenopausal women. In either case, high circulating levels of FSH were not associated with increased ovarian cancer risk.

Null or suggestively inverse associations have also been observed for LH. A nested case–control study within the New York University Women's Health Study (NYUWHS) ($n = 58$ cases), observed an adjusted relative risk of 0.42 (95% CI: 0.09–2.09), comparing the 3rd vs. 1st tertile of LH.

Prolactin

Prolactin (PRL) is a neuroendocrine growth hormone secreted by the lactotroph cells of the anterior pituitary gland. Prolactin's role in breast development and lactation is well-known, though it acts on a variety of biologic pathways and in tissues aside from the mammary glands, including prostate, ovary, and liver tissue. Receptors are also expressed in adipocytes and immune system cells. Prolactin initiates multiple signaling pathways following binding to its receptor, a member of the cytokine receptor family. Signaling primarily occurs through the Janus protein kinase-2/signal transducer and activator of transcription-5 (JAK-2/STAT-5) pathway, which, as a growth promoting pathway, implicates prolactin in carcinogenesis. Supporting its protumorigenic action, prolactin has been shown to increase cell motility, cell proliferation, and tumor vascularization. These functions are particularly relevant in later-stage carcinomas.

Postmenopausal Breast Cancer

Animal and in vitro studies have shown prolactin overexpression accelerates or induces mammary tumor growth. Most epidemiologic studies examining the association between prolactin and breast cancer have correspondingly found increased breast cancer risk among women with higher circulating prolactin levels. However, there have been notable variations with respect to timing of measurement and menopausal status across studies.

In a study within NHS and NHSII ($n = 2468$ cases), a positive association was observed between prolactin levels measured among postmenopausal women and breast cancer incidence, though this was only apparent when prolactin was

measured <10 years prior to diagnosis ($n = 1445$ cases) (4th vs. 1st quartile RR = 1.20, 95% CI:1.03–1.04). The association was stronger among women with ER+ tumors (RR = 1.52, 95% CI: 1.19–1.93) and lymph node positive breast cancers (RR = 1.63, 95% CI: 1.08–2.44). No association was seen for prolactin measured >10 years prior to diagnosis, supporting the hypothesis that prolactin has an important role in later-stage carcinogenesis. A more recent study within EPIC ($n = 1738$ cases) found a similar positive association between prolactin and risk of postmenopausal breast cancer (4th vs. 1st quartile RR = 1.29, 95% CI: 1.05–1.58), although the association was only observed among women using hormone therapy (specifically, estrogen plus progestin).

Premenopausal Breast Cancer

A role for prolactin in premenopausal breast cancer is less clear than in postmenopausal breast cancer, with associations suggestively null overall. Although positive associations were observed in the NHS/NHSII with small case numbers, no association with premenopausal breast cancer was observed in larger subsequent analyses. In a recent study in EPIC ($n = 512$ cases), a suggested inverse association was reported (4th vs. 1st quartile RR = 0.70, 95% CI: 0.48–1.03). However, a positive association was observed in an analysis of in situ cases (3rd vs. 1st tertile RR = 1.49, 95% CI: 0.59–3.74). This finding contradicts the results among postmenopausal women suggesting a consistent positive association.

Prostate Cancer

Prolactin acts on the prostate indirectly by increasing testicular testosterone production through regulation of luteinizing hormone receptors, and directly influences prostate development and neoplasia by initiating signaling pathways after binding to prolactin receptors. As in breast cancer, prolactin may induce proliferation in prostate tumor cell lines and may also have an antiapoptotic effect. Animal studies have shown an influence of prolactin levels on prostate development and induced neoplasia in knockout mice, and prolactin is mitogenic in prostate epithelial cells. In addition, in human prostate tumors, prolactin is positively associated with high tumor grade and aggressive disease.

Despite biologic plausibility, epidemiologic evidence does not support a clear role for prolactin in prostate cancer development. For example, a large prospective study conducted within the Northern Sweden Health and Disease cohort ($n = 144$ cases), found no association between prediagnosis circulating prolactin levels and prostate cancer risk (4th vs. 1st quartile RR = 0.85, 95% CI: 0.49–1.47), agreeing with an earlier analysis combining results from two nested case–control studies, including a total of 320 prostate cancer cases.

Ovarian Cancer

Prolactin is essential for maintaining normal ovarian function, and also is produced in the ovaries, with its receptor expressed in normal ovarian tissues. Studies in ovarian cancer cell lines have shown that, under stressed conditions, addition of prolactin decreases apoptosis, and prolactin has also been shown to promote the growth of ovarian surface epithelial cells in animal models. A nested case–control study of three prospective cohorts in the United States, Sweden, and Italy ($n = 230$ cases) found a suggestive positive association between circulating prolactin and ovarian cancer risk (4th vs. 1st quartile RR = 1.56, 95% CI: 0.94–2.63), that was apparent only among overweight women (BMI ≥ 25 kg/m^2 RR = 3.10, 95% CI: 1.39–6.90).

Insulin/C-Peptide

Insulin, a peptide hormone produced and secreted by the pancreatic β-cells, is essential for maintaining glucose homeostasis, stimulating glucose uptake by insulin sensitive organs, including the liver, muscle, and adipose tissue, and reducing circulating glucose levels. The insulin receptor has two isoforms, α and β, which have distinct biologic functions given differential binding to insulin, and insulin-like growth factors IGF-I and IGF-II. Insulin receptors are ubiquitously expressed, and insulin may play an important role in linking cellular energy balance and cancer energetics.

Insulin is hypothesized to promote tumor development directly, by stimulating the insulin receptor, a member of the tyrosine kinase class, and promoting insulin signaling pathways in tumor cells, such as the MAPK pathway. It also may play an indirect role, increasing bioavailability of active growth factors (e.g., IGFs, described in the following section), and sex hormones, which promote carcinogenesis.

Type II diabetes is defined by insulin resistance, and cancer incidence is modestly increased among those with type II diabetes. Obesity, linked to energy balance and insulin resistance, is an established risk factor for a number of cancers; thus, insulin has been hypothesized as a biologic mechanism for obesity in cancer. Metformin, often used to treat type 2 diabetes, has been related to decreased cancer burden among patients with diabetes, and to reduced insulin-stimulated tumor growth in vivo. Insulin has also been shown to increase proliferation of certain cancer cell lines.

Insulin is initially linked to C-peptide during production as proinsulin; after secretion, insulin and C-peptide exist separately at equimolar concentrations in the blood. Unlike insulin, C-peptide is not metabolized in the liver, and thus measurement of C-peptide is often used to determine circulating insulin levels, as a more accurate representation of initially bioavailable hormone.

Several epidemiologic studies have examined circulating insulin or C-peptide levels in a variety of cancers, including breast, prostate, colorectal, pancreatic, and endometrial cancers.

Postmenopausal Breast Cancer

Indirect evidence for a role of insulin in breast cancer has accumulated, as postmenopausal overweight and obese subjects, and subjects with type II diabetes, have higher risk of breast cancer. Insulin receptor is expressed in breast tumor tissue, and insulin is hypothesized to affect risk by increasing proliferation of breast cancer cells directly or through indirect action described above.

A meta-analysis of prospective studies of circulating insulin or C-peptide and postmenopausal breast cancer risk included six studies of insulin ($n = 1239$ cases), and five studies of C-peptide ($n = 972$ cases). Overall, associations were near-null for C-peptide (summary relative risk (SRR) = 1.26, 95% CI: 0.80–1.96) and suggestively positive for insulin (SRR = 1.59, 95% CI: 0.92–2.74). In two studies that adjusted for BMI, a positive dose–response relationship between insulin levels and postmenopausal breast cancer risk was observed, while no dose–response relationship was apparent in the study that did not adjust for BMI.

Positive associations were observed in two analyses published since the meta-analysis. In the NHS I and II ($n = 796$ postmenopausal cases), C-peptide was associated with increased risk of invasive breast cancer (4th vs. 1st quartile RR = 1.5, 95% CI: 1.1–2.0), adjusting for BMI; the association was unchanged with estradiol adjustment. The association appeared stronger among women with ER− disease (RR = 2.0; 95% CI: 1.2–3.6). In the Cancer Prevention Study II (CPS-II) ($n = 302$ postmenopausal cases), a similarly large association between circulating C-peptide levels and breast cancer risk was observed (3rd vs. 1st tertile RR = 1.63, 95% CI: 1.08–2.45), with slight attenuation after adjustment for BMI. Overall, the current epidemiologic evidence points toward a positive association between circulating insulin and C-peptide and risk of breast cancer among postmenopausal women.

Premenopausal Breast Cancer

Interestingly, adiposity is associated with decreased risk of premenopausal breast cancer, making the investigation into insulin and breast cancer more complex. Several studies in the above-mentioned meta-analysis included premenopausal breast cancer cases; positive, inverse, and null associations between insulin or C-peptide levels and premenopausal breast cancer risk were noted by different studies. In the recent NHS/NHSII analysis ($n = 187$ premenopausal cases), a suggestively positive association was observed between C-peptide levels and premenopausal breast cancer (4th vs. 1st quartile RR = 1.4, 95% CI: 0.79–2.5).

Endometrial Cancer

Endometrial cancer is strongly associated with obesity, and has also been associated with type II diabetes and insulin resistance, even among nonobese women, indicating a potential role for insulin in its development.

In a large prospective study conducted within EPIC ($n = 286$ cases), serum C-peptide was associated with an increased risk of endometrial cancer (4th vs. 1st quartile RR = 2.13, 95% CI: 1.33–3.41), that was modestly attenuated with adjustment for BMI (RR = 1.56, 95% CI: 0.94–2.57). Results from several case–control studies agree with this prospective study.

Prostate Cancer

Insulin is thought to influence prostate cancer through cell proliferation and antiapoptotic functions, supported by in vitro studies in rat cell lines, where insulin has been shown to be mitogenic for both normal and adenocarcinoma prostate cells. While some prospective studies have found null results for overall prostate cancer risk based on C-peptide levels, others have observed differing associations by disease severity, with positive associations generally observed for aggressive disease. In the largest study to date, in the Health Professionals Follow-up Study (HPFS) ($n = 1314$ cases), no association was observed with C-peptide and risk overall prostate cancer (4th vs. 1st quartile RR = 1.05, 95% CI: 0.82–1.34); the null association remained when restricted to aggressive disease. Thus, circulating C-peptide levels do not appear directly associated with prostate cancer risk, and the association between obesity and prostate cancer (particularly aggressive disease) may be through a noninsulin-related pathway.

Colorectal Cancer

Obesity is an established risk factor for colorectal cancer, and insulin resistance has been posited as a potential mechanistic explanation for this association. Several epidemiologic studies have explored the association between circulating insulin or C-peptide and risk of colorectal adenoma, a precursor lesion. The current evidence indicates general agreement for a role of insulin in colorectal cancer development, though data are not entirely consistent.

A meta-analysis including 27 studies measuring either insulin or C-peptide, and risk of colorectal adenoma, found increased risk of adenoma with increasing insulin levels (highest vs. lowest quantile RR = 1.33, 95% CI: 1.12–1.58), and C-peptide levels (RR = 1.44, 95% CI: 1.13–1.83). Among studies adjusting for adiposity, the association was attenuated, though overall summary measures remained positive. In a more recent nested case–control study, in the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial (PLCO) ($n = 273$ cases), no association was observed between serum C-peptide and colorectal adenoma (4th vs. 1st quartile RR = 0.83, 95% CI: 0.52–1.31).

Results from studies of insulin or C-peptide and risk of colorectal cancer have generally been positive. In the Physicians' Health Study ($n = 176$ cases), a strong positive association was observed between plasma C-peptide and colorectal cancer risk (5th vs. 1st quintile RR = 2.7, 95% CI: 1.2–6.2), including adjustment for BMI. A larger study within the EPIC cohort ($n = 1078$ cases) also found a positive association with C-peptide levels (5th vs. 1st quintile RR = 1.56, 95% CI: 1.16–2.09), which remained significant after adjustment for BMI and physical activity. In the WHI-OS ($n = 438$ cases), a positive association was observed between fasting insulin levels and colorectal cancer risk (4th vs. 1st quartile RR = 1.73, 95% CI:1.16–2.57), though the risk was attenuated after adjustment for waist circumference (4th vs. 1st quartile RR = 1.42, 95% CI: 0.91–2.23).

Pancreatic Cancer

In a pooled analysis of four US prospective studies ($n = 197$ cases), prediagnostic plasma C-peptide was positively associated with pancreatic cancer risk (4th vs. 1st quartile RR = 1.52, 95% CI: 0.87–2.64), which was not altered by BMI. Interestingly, the observed risk was attenuated when considering only fasting blood samples (RR = 1.21, 95% CI: 0.66–2.24). Insulin, measured in fasting samples, did not appear to be associated with risk in the same study (4th vs. 1st quartile RR = 1.08, 95% CI: 0.57–2.04).

Insulin-like Growth Factor

Insulin-like growth factors (IGFs, IGF-1 and IGF-2) are peptide hormones produced primarily in the liver that regulate proliferation and act as specific tissue growth factors. IGF-1 and IGF-2 are frequently expressed in neoplastic tissue, along with IGF-1 receptor, which is required for downstream signaling activity. In addition to their endocrine actions, IGFs also have autocrine and paracrine effects. IGF-1 has been shown to increase mitosis and inhibit apoptosis, indicating a procarcinogenic role. In vitro studies have observed positive dose–response relationships between neoplastic cell proliferation and IGF-1 concentration, and tumor progression in vivo has also been shown to depend on IGF-1 levels. In addition, IGFs, like insulin, are involved in signaling pathways that promote cell growth and migration in neoplastic tissue, including Akt and MAPK pathways. Drug candidates that target IGF-1R, either by influencing bioactivity or by blocking downstream signaling pathways, are being tested in clinical trials for response to chemotherapeutics. IGF-2R has not been targeted for such studies, as it exhibits properties of a tumor suppressor, and acts to block IGF-2 binding to IGF-1R, thereby reducing its activity.

Once produced, most IGFs associate with one of six IGF binding proteins (IGFBPs), while a small proportion circulate unbound. IGFBP-3 binds >75% of IGF-1 and IGF-2. In the bound state, IGFs are not available for IGF-I receptor activation. IGF bioactivity has thus been proposed to be a function of circulating levels of IGF, expression of IGF genes on tissues of interest, and protease action to cleave IGBP complexes to their functional form, though additional complexities also must be considered. For instance, most evidence supports an anticarcinogenic role for the binding proteins, particularly IGFBP-3 and IGFBP-1. However, certain binding proteins are also able to enhance the delivery of IGFs to certain tissues. Overexpression of both IGFBP-2 and IGFBP-5 have been associated with increased IGF action, and IGFBP-1, which is closely associated with insulin function, also increases IGF-1 induced DNA synthesis in its dephosphorylated state. Overall, an imbalance of IGFs and IGFBPs may indicate issues in cellular turnover and kinetics, characteristic of carcinogenesis.

Given the biologic plausibility that IGFs are important in carcinogenesis, these hormones, along with IGFBP-3 and IGFBP-1, have been investigated in several cancers to date, including breast, endometrial, ovarian, prostate, colorectal, pancreatic, and lung cancers. Serum measured IGFs and IGFBPs, used in epidemiologic studies, correlate well with tissue levels in murine models, supporting the use of blood-based measures as surrogates for tissue expression.

Postmenopausal Breast Cancer

In a recent pooled analysis combining data from 17 prospective studies in Europe, Australia, and the United States, 15 of which included women who were postmenopausal at blood collection ($n = 2853$ cases), IGF-1 was positively associated with breast cancer risk in postmenopausal women (5th vs. 1st quintile RR = 1.33, 95% CI: 1.14–1.55). Contrary to the idea that IGFBP-3 is inversely related to the bioactivity of IGF, IGFBP-3 levels were also positively associated with breast cancer risk (RR = 1.23, 95% CI: 1.04–1.45). Consistent with evidence from laboratory studies that estrogen and IGF signaling pathways interact in a synergistic manner, risk was only apparent among women with ER+ tumors (for 80% increase in IGF-1 RR = 1.38, 95% CI: 1.14–1.68), with no association noted among ER− tumors (RR = 0.80, 95% CI: 0.57–1.13). However, risk also increased consistently with increasing tertile of estrogen concentration, among women with either low, medium, or high levels of IGF-1, suggesting no clear interaction of effects, though these results were not confined to ER+ tumors.

Premenopausal Breast Cancer

IGF-1 has been associated with mammographic density in premenopausal women, a known risk factor for breast cancer, in a few recent studies. For instance, one study of 783 premenopausal healthy women found high IGF-1 and low IGFBP-3 to be independently correlated with high breast density. In the above-mentioned pooled analysis, 11 of the 17 studies included information on women who were premenopausal at blood collection ($n = 1937$ cases). The association between IGF-1 and breast cancer risk was

similarly positive (5th vs. 1st quintile RR = 1.21, 95% CI: 1.00–1.45). An analysis by age at diagnosis (< 50 years or ≥ 50 years) similarly observed a small, suggestive positive association between IGF-1 and breast cancer among younger women, though circulating IGFBP-3 levels were not significantly associated with breast cancer risk among women premenopausal at blood collection (RR = 1.00, 95% CI: 0.82–1.22).

Endometrial Cancer

A large nested case–control study within EPIC ($n = 286$ cases) examined prediagnostic concentrations of IGFBP-1 and IGFBP-2 and risk of endometrial cancer (the IGF hormones were not examined). No association between IGFBP-1 and endometrial cancer risk was observed (4th vs. 1st quartile RR = 0.76, 95% CI: 0.47–1.21), though there was an inverse association between IGFBP-2 and endometrial cancer risk (RR = 0.56, 95% CI: 0.35–0.90). This finding corresponds with a potential role for the IGF axis in the carcinogenesis of endometrial cancer; though, the null finding for IGFBP-1 suggests that the primary mode through which insulin resistance increases endometrial cancer risk is not through IGF signaling.

Prostate Cancer

A large pooled analysis of 17 prospective studies ($n = 7682$ cases) examined circulating IGF-1, IGF-2, IGFBP-2, and IGFBP-3 with prostate cancer risk (Fig. 4). IGF-1 was associated with an increased risk of prostate cancer (5th vs. 1st quintile RR = 1.29, 95% CI: 1.16–1.43), as was IGFBP-3 (RR = 1.25, 95% CI: 1.12–1.40). IGFBP-1 was inversely associated with risk (RR = 0.81, 95% CI: 0.68–0.96). After mutual adjustment for IGFs and IGFBPs, only IGF-1 remained associated with prostate cancer risk. While experimental evidence suggests that the activation of the IGF pathway is associated with progression of prostate cancer to lethal disease, the association between IGFs and prostate cancer risk did not appear to differ by stage or grade of disease in this pooled analysis.

Colorectal Cancer

Markers of hyperinsulinemia, such as obesity and central adiposity and type II diabetes have been associated with risk of colorectal cancer. Thus, insulin and corresponding IGF signaling pathways have been implicated in colorectal carcinogenesis. IGF-1 receptor is overexpressed in colon cancer cells, and overexpression of IGF-1 in a human CRC cell line resulted in a highly invasive tumor, further supporting a carcinogenic role. IGF-2 is also highly overexpressed in a subset of colorectal cancers. Moreover, CRC patients with low IGFBP-3 or high IGFBP-2 have worse prognosis, suggesting that these binding proteins negatively regulate IGF activity, or act independently, to influence tumor growth. Given the evidence for IGFs and IGFBPs in CRC progression, prospective epidemiologic studies have investigated this association.

A study within the Physicians' Health Study (PHS) examined IGF-1 and IGFBP-3 serum levels and colorectal cancer risk ($n = 193$ male cases). IGF-1 was positively associated with risk of colorectal cancer (5th vs. 1st quintile RR = 2.51, 95% CI: 1.15–5.46), and, correspondingly, IGFBP-3 was associated with decreased risk of colorectal cancer (RR = 0.28, 95% CI: 0.12–0.66). This association was attenuated among obese men, suggesting that obesity also contributes to colorectal cancer through non-IGF related pathways. These findings were supported by an investigation within the Northern Sweden Cohort. In contrast, no association was observed in the EPIC cohort ($n = 1121$ cases) between IGF-1 and CRC, or between IGFBP-3 (total and intact) and CRC. A meta-analysis combining these results with those of nine other prospective studies conducted between 1999 and 2008 ($n = 2862$ cases), found a small positive association between IGF-1 and CRC risk (per standard deviation increase RR = 1.07, 95% CI: 1.01–1.14).

Pancreatic Cancer

Experimental studies have shown the presence of IGF-1 and IGF-1R in pancreatic cell lines, and have demonstrated increased cellular proliferation and decreased apoptosis via signaling through IGF-1R. In the PLCO study ($n = 187$ cases) no statistically significant associations were observed for IGF-1, IGF-2, or IGFBP-3, although associations with IGF-1 (and the ratio of IGF-1/IGFBP-3, which would generally represent the proportion of bioavailable IGF-1) were suggestively positively associated with pancreatic cancer risk (e.g., IGF-1/IGFBP-3 4th vs. 1st quartile RR men = 1.39, 95% CI: 0.69–2.80; RR women = 1.47, 95% CI: 0.58–3.75). Another pooled study from the NHS, HPFS, PHS, and the WHI ($n = 212$ cases), observed no significant association between plasma IGF-1, IGF-2, IGFBP-3, or the IGF-1:IGFBP-3 M ratio and pancreatic cancer risk. Overall, the relatively limited data available to date suggests no substantial association of circulating IGFs and IGFBPs with pancreatic cancer risk.

Lung Cancer

IGF-1 exhibits mitogenic and antiapoptotic effects in lung cancer cell lines, while IGFBP-3 has been shown to inhibit IGF-1R signaling through interference with MAPK and Akt signaling pathways. A recent meta-analysis examining of circulating IGF-1 and IGFBP-3 and lung cancer risk included six nested case–control studies ($n = 1043$ cases). Neither IGF-1 nor IGFBP-3 were associated with increased lung cancer risk. One of the larger studies included found a positive association between IGF-1 and lung cancer risk, though this increased risk was only reported after controlling for IGFBP-3 levels. Overall, current evidence suggests no association between IGF-1 and IGFBP-3 and risk of lung cancer.

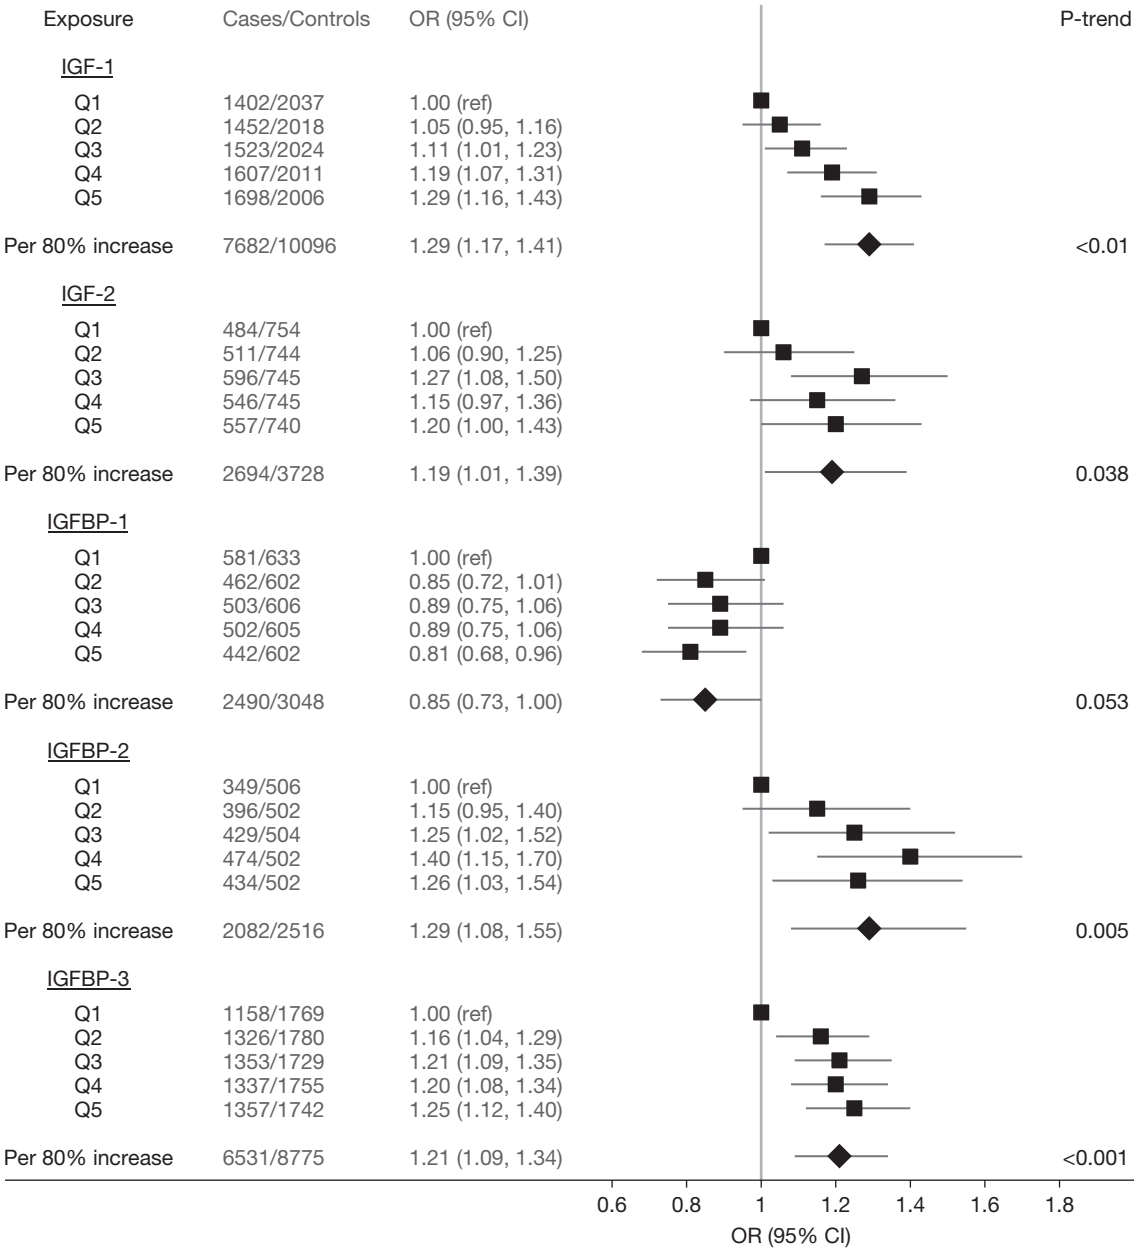

Fig. 4 IGF and IGFBP levels and prostate cancer risk. Odds ratios and 95% confidence intervals for prostate cancer associated with study-specific fifths of IGF and IGF binding protein concentrations. OR estimates from logistic regression conditioned on study-specific matching variables. Adapted from Fig. 1 in Travis, R. C., Appleby, P. N., Martin, R. M., et al. (2016). A meta-analysis of individual participant data reveals an association between circulating levels of IGF-I and prostate cancer risk. *Cancer research***76** (8), 2288–2300.

Adiponectin

Adiponectin is a peptide hormone secreted by adipocytes that acts in both a paracrine and endocrine manner. Adiponectin exists in two forms in circulation, full-length, and globular, both of which have antiinflammatory, antiangiogenic, and antidiabetic properties. Prior to secretion, high molecular weight (HMW) adiponectin is formed; as the dominant form in circulation, this is thought to be most physiologically relevant. Serum adiponectin is inversely associated with both obesity and type II diabetes, and low adiponectin is a sensitive marker for insulin resistance and hyperinsulinemia, independent of obesity.

Adiponectin may influence carcinogenesis via insulin-related pathways, or via a role in inflammation pathways and response. Its anticarcinogenic effect is also apparent at the cellular-level via activation of adenosine monophosphate-activated protein kinase (AMPK), which results in downstream inhibition of cellular proliferation and migration pathways of several key kinases, including phosphatidylinositol-3-kinase/protein kinase B (PI3K/AKT), mammalian target of rapamycin (mTOR), MAPK, glycogen synthase

kinase-3β (Wnt-GSK3β), and JAK/STAT. Overall, the activation of AMPK inhibits tumor growth and survival. Studies have examined the association between circulating adiponectin and breast, endometrial, prostate, colorectal, and pancreatic cancers.

Postmenopausal Breast Cancer

The inverse associations of adiponectin with adiposity and insulin resistance suggest its importance in postmenopausal breast cancer risk, as adiposity is an established risk factor in postmenopausal breast cancer. Experimental evidence also indicates a role for adiponectin in mammary carcinogenesis, with reduced breast cancer cell proliferation and inhibition of growth factor-induced cell migration.

One large prospective study nested within the NHS I and II ($n = 858$ cases) observed an inverse association between adiponectin and breast cancer risk (4th vs. 1st quartile RR = 0.73, 95% CI: 0.55–0.98). Results were similar after adjustment for IGF-I, C-peptide, IGFBP-1, and estradiol, indicating that this association is not simply a derivative of these connected biologic pathways. While this result was expected based on the biologic hypothesis, other epidemiologic studies have found no association between adiponectin and postmenopausal breast cancer risk.

Premenopausal Breast Cancer

In premenopausal women, adiposity is inversely associated with breast cancer risk, though the mechanisms underlying this association are unclear. In the Northern Sweden Health and Disease Cohort, a suggestively inverse association was observed among younger women < 55 years of age ($n = 227$ cases) (3rd vs. 1st tertile RR = 0.56, 95% CI: 0.28–1.11). In contrast, a positive association between adiponectin and premenopausal breast cancer risk was observed in the NHS/NHSII study ($n = 316$ cases) (4th vs. 1st quartile RR = 1.30, 95% CI: 0.80–2.10). This result corresponds with the evidence that obesity/adiposity is inversely related to breast cancer risk in this group.

Endometrial Cancer

Given the role of obesity and type II diabetes in endometrial cancer, adiponectin has been hypothesized to play a role in this disease. Two large prospective studies of adiponectin have shown conflicting results. A study conducted within EPIC ($n = 284$ cases), found an inverse association between adiponectin and endometrial cancer (4th vs. 1st quartile RR = 0.56, 95% CI: 0.36–0.86), which was independent of other obesity-related risk factors. However, a more recent study conducted within NHS ($n = 146$ cases) found no association between adiponectin and endometrial cancer risk (3rd vs. 1st tertile RR = 0.86, 95% CI: 0.53–1.39), which was true for both postmenopausal and premenopausal women.

Prostate Cancer

Both insulin resistance and obesity have been suggested as risk factors for prostate cancer incidence or progression, though the mechanisms underlying this relationship are unclear. Prospective epidemiologic studies do not indicate a role for adiponectin in the development of prostate cancer. Within the PHS ($n = 654$ cases) no overall association between serum adiponectin and prostate cancer risk was observed, though there was a lower risk of high-grade or lethal cancer with higher adiponectin levels (5th vs. 1st quintile RR = 0.25, 95% CI: 0.07–0.87).

Within a French nationwide cohort study (SUVIMAX), prostate cancer risk appeared to increase with increasing adiponectin (4th vs. 1st quartile RR = 1.34, 95% CI: 0.68–2.68), though this result was attenuated after adjustment for other inflammatory markers including high-sensitivity C-reactive protein (hs-CRP), which was strongly positively associated with prostate cancer risk, along with others (4th vs. 1st quartile RR = 1.18, 95% CI: 0.56–2.48).

Colorectal Cancer

In experimental studies, adiponectin inhibits colorectal cancer cell growth through activation of AMPK and consequent downregulation of the mTOR pathway. In addition, the strong link between BMI and colorectal cancer would indicate a potential role for adiponectin in colorectal cancer risk, though epidemiologic studies have not found a clear association. A prospective nested case–control study of Norwegian men ($n = 381$ cases) found no association between prediagnostic adiponectin and colorectal cancer risk (4th vs. 1st quartile RR = 0.8, 95% CI: 0.5–1.4). In another prospective study in EPIC ($n = 1206$ cases), HMW adiponectin was not associated with colorectal cancer risk (5th vs. 1st quintile RR = 1.05, 95% CI: 0.77–1.43), while non-HMW adiponectin was inversely associated with CRC risk (RR = 0.39, 95% CI: 0.26–0.60) with adjustment for BMI and waist circumference. This finding suggests the possibility that the proportion of non-HMW versus HMW adiponectin is important in CRC.

Pancreatic Cancer

Adiponectin's role in mediating insulin sensitivity makes it biologically plausible in pancreatic cancer. Receptors, AdipoR1 and AdipoR2 are expressed on the pancreatic beta cells and pancreatic tumor cells, and serum adiponectin is inversely correlated with

pancreatic tumor growth in mouse models. Plasma adiponectin has been consistently inversely associated with pancreatic cancer risk in prospective epidemiologic studies. A nested case–control study in Finland ($n = 311$ cases) found an inverse association between adiponectin and pancreatic cancer risk (5th vs. 1st quintile RR = 0.65, 95% CI: 0.39–1.07). A study within EPIC ($n = 452$ cases) similarly found higher circulating levels of adiponectin associated with a reduction in pancreatic cancer risk (4th vs. 1st quartile RR = 0.44, 95% CI: 0.23–0.82), though this was only apparent among never smokers. A study using pooled data from five US cohorts again reported an inverse association, with a risk reduction comparable to that seen in the Finnish cohort (5th vs. 1st quintile RR = 0.66, 95% CI: 0.44–0.97), but no modification in this association by smoking status was observed.

Melatonin

Melatonin is produced and secreted by the pineal gland, playing an integral role in the regulation of sleep and wake cycles, known as circadian rhythm. Melatonin production is controlled by a circadian signal from the suprachiasmatic nucleus (SCN), with function controlled through action on its receptors, MT1 and MT2. The SCN neuron firing declines later in the day, stimulating production of melatonin from serotonin conversion to tryptophan, with the majority of secretion taking place during the nighttime. Shift work that involves circadian disruption was identified as a probable human carcinogen in 2007 by the International Agency for Research on Cancer. Thus, melatonin is thought to play a role in carcinogenesis mainly through its regulation of circadian rhythm.

In addition to its pineal production, melatonin is also present in multiple extrapineal tissues such as the skin, reproductive tract, and gastrointestinal tract, where it exhibits antiinflammatory and antioxidant properties. Melatonin is a direct free radical scavenger, and has been shown to protect against ischemic neuronal damage. One pathway of interest for antioxidant activity involves reduction of cAMP and inhibition of the protein kinase A/cAMP pathway, resulting in modulation of antioxidant gene transcription. Melatonin also influences activity of MAPKs, which are involved in transcription and apoptosis, and acts as an angiogenesis inhibitor by targeting hypoxia induced-factor 1α and related genes. Thus, the antioxidant and proapoptotic functions of melatonin in tumor cells suggest it has an anticarcinogenic activity. Increasing evidence further suggests melatonin plays a protective role in carcinogenesis through regulation of the cell cycle and estradiol production.

Breast Cancer

In experimental studies, decreasing melatonin levels increases spontaneous tumor production, and restoration of melatonin prevents breast cancer development. Additionally, melatonin influences aromatase activity to reduce estrogen production and suppress tumor growth, and inhibits breast tumor growth and cell proliferation in vitro. Melatonin has been proposed as a biological mechanism explaining accumulating evidence that night-shift workers are at an increased risk of breast cancer. Epidemiologic evidence thus far indicates melatonin as a potential anticarcinogenic agent in postmenopausal, but not in premenopausal breast cancer.

Postmenopausal breast cancer

A recent meta-analysis of five prospective studies ($n = 1113$ cases), evaluating melatonin's primary urinary metabolite, 6-sulfatoxymelatonin (aMT6s), found an inverse association with postmenopausal breast cancer (4th vs. 1st quartile RR = 0.68, 95% CI: 0.49–0.92). Because melatonin has been associated with suppressed aromatase activity in breast tumors, which represents the primary mode to estrogen production in postmenopausal women, it is possible that melatonin decreases risk through this estrogen-mediated pathway.

Premenopausal breast cancer

In the meta-analysis mentioned above, aMT6s levels were not associated with risk of premenopausal breast cancer (RR = 1.05, 95% CI: 0.71–1.54). A more recent case–control study nested within the NHSII cohort, with approximately 75% premenopausal women ($n = 600$ cases), also found no association with aMT6s (4th vs. 1st quartile RR = 0.91, 95% CI: 0.64–1.28). The association, while remaining null, tended toward a decreased risk when diagnosis was less than 5 years from urine collection, consistent with an earlier analysis, and toward an increased risk when diagnosis was more than 5 years from urine collection, which may be indicative of differences in association by age or menopausal status at diagnosis. Thus, this warrants further study to better understand the issue of timing.

Ovarian Cancer

Melatonin is hypothesized to reduce ovarian cancer risk, based on both the broad argument that melatonin may influence carcinogenesis through circadian rhythm regulation, and biologic evidence suggesting that melatonin and its metabolites inhibit growth of ovarian cancer cell lines. Additionally, melatonin is synthesized in the ovary itself, and as such may influence ovarian function through modulation of luteinizing hormone and progesterone.

Urinary aMT6s levels within the NHS cohorts ($n = 152$ cases) were not associated with risk of ovarian cancer, consistent with studies indicating a null association between night-shift work and ovarian cancer.

Prostate Cancer

Previous epidemiologic studies have shown a positive association between sleep loss and proxies for circadian disruption including light at night and shift work, and prostate cancer, potentially supporting the circadian disruption hypothesis for melatonin action in prostate cancer. There is limited epidemiologic evidence for a role of melatonin in prostate cancer, though a case–cohort study within the Age, Gene/Environment Susceptibility (AGES)-Reykjavik cohort ($n = 111$ cases), found low aMT6s levels associated with increased risk for advanced disease (below vs. above median RR = 4.04, 95% CI: 1.26–12.98). Melatonin was associated with overall prostate cancer risk as well, though the result was not as strong (RR = 1.47, 95% CI: 0.94–2.30), and appeared to be driven by advanced prostate cancer risk.

Colorectal Cancer

Melatonin has been indicated in colorectal cancer, as night-shift work has been associated with increased risk of this cancer. Within the NHS, women who worked >15 years on rotating night shifts had a higher risk of CRC (RR = 1.35, 95% CI: 1.03–1.77) than those who did not work night shifts for this extended period of time. Recent work has also uncovered a role of melatonin in the inhibition of colorectal cancer cell proliferation, which may be suggestive of a potential risk mitigating effect of melatonin in CRC. However, to date there have been no epidemiologic studies of urinary melatonin and colorectal cancer risk.

Induced Pluripotent Stem Cells and Yamanaka factors

Stina Simonsson, Rocío C Viñuelas, Leonie Hartl, and Itedale N Redwan, University of Gothenburg, Gothenburg, Sweden
Joydeep Bhadury, The University of Tokyo, Tokyo, Japan

Glossary

ES cells Embryonic stem cells.
ICM Inner cell mas cells of the blastula.
iPS cells Induced pluripotent stem cells.
Pluripotency Means that the cell can give rise to any cell type in the body. The inner cell mass cells in the blastula and all cells before the blastula stage are considered as pluripotent. Pluripotency is defined as the ability of a cell to differentiate into any cell type of the three germ layers, namely endoderm, ectoderm and mesoderm.
Totipotency Means that one cell can give rise to any cell in the body, extra embryonic tissue and a new individual. The fertilized egg (also called the zygote, and up to the eight-cell stage in humans) is considered to be totipotent.
Zygote Fertlized egg.

Introduction

The challenge to delay aging in order to preserve youth and prolong life is counteracted by devastating diseases such as cancer that drastically shortens the average lifetime. It is tempting to speculate the enormous impact that scientific advancements could have when tweaking our longevity. All humans and other mammals start their life from a single cell the fertilized egg, called the zygote. This one cell replicates in a fast but regulated manner to give rise to a fully developed fetus in the mother's womb during gestation. All cells in our body have the genetic map of how one should look like and perfect regeneration of tissue, organs or limbs should be theoretically possible. Interestingly, a fetus in the mother's womb will not produce scar tissue if surgical procedure is done, but once born that perfect regeneration capacity is lost and scars are formed. One theory is that humans have lost their perfect regenerative capability in order to prevent cancer.

In 2012, Shinya Yamanaka and Sir John Gurdon were honored with the Nobel Prize in Physiology or Medicine for the discovery that mature cells can be reprogrammed to pluripotency. In other words, this meant that mature (differentiated/somatic) cells could be rejuvenated back to pluripotency using Yamanaka's protocol or even to totipotency using Gurdon's protocol. The definition of pluripotent cells is that they can give rise to all cell types in the body, whereas totipotent cells can become not only any cell type in the body but also gives rise to a new individual, the extra embryonic tissue including placenta and umbilical cord. In 2006, Yamanaka along with Takahasi made the landmark discovery of reprogramming differentiated cells into a pluripotent state. First, they succeeded in reprogramming mouse tail-tip fibroblasts into cells similar to embryonic stem (ES) cells. ES cells are in vitro cultured cells that are derived from the inner cell mass cells of the blastula, and are pluripotent. Yamanaka's method involved the retroviral mediated transduction of only four transcription factors to reprogram the differentiated cells into pluripotent cells, which were named induced pluripotent stem (iPS) cells. Their work started back in 2000, when they began analyzing mouse ES cells to identify genes responsible of their inherent characteristics, these are pluripotency and infinite self-renewal capacity. The outcome of these studies was the identification of several ES cell-associated transcripts, such as Nanog, signal transducer and activator of transcription 3 (STAT3), Krüppel-like factor 4 (Klf4), c-Myc, β-catenin, T-cell leukemia/lymphoma protein 1 (TCL1), growth factor receptor-bound protein 2 (GRB2), octamer binding protein 4 (Oct4) and sex determining region Y-box 2 (Sox2), among others. Thus, they elaborated a list of candidate-reprogramming factors that were tested in a system generated by a graduate student in the Yamanaka group. Briefly, this system was based on transducing different combinations of candidate genes into mouse embryonic fibroblasts, and then evaluating their resistance to geneticin. Using this system, they tested the 24 candidates (**Table 1**) and noticed that they got stem cell colonies similar to ES cell colonies, which was narrowed down to only four transcription factors. Recently, Shinya Yamanaka during an event in Gothenburg, Sweden (**Fig. 1**) revealed that it was Takahashi who cleverly excluded one factor at a time to quickly come up with only four factors, the so-called Yamanaka factors, Oct4, c-Myc, Klf4 and Sox2 (**Fig. 2**). A year after the discovery in mouse, human iPS cells were produced with the Yamanaka factors. Approximately at the same time, another group reported deriving human iPS cells with another combination of factors: Oct4, Sox2, Lin28 and Nanog. Currently, both sets of reprogramming factors are used globally.

The iPS cells share many characteristics with ES cells in terms of surface marker expression, morphology, proliferation and gene expression profiles. One of the advantages of iPS cells compared to ES cells is that these cells allow researchers to bypass ethical concerns related to the use of cells from embryos, thus offering amazing opportunities for regenerative medicine, drug discovery and disease modeling applications However, the main advantage of iPS cells is that one rejuvenates the patient cell into the blastula

Table 1 Yamanaka 24 candidate genes that generated ES like cells

Number	*Gene*	*Number*	*Gene*
1	Ecat1	13	Sall4
2	Dppa5	14	**Oct3/4 (Pou5f1)**
3	Fbxo15	15	**Sox2**
4	Nanog	16	Rex1 (Zfp42)
5	Eras	17	Utf1
6	Dnmt3l	18	Tcl1
7	Ecat8	19	Dppa3 (Stella)
8	Gdf3	20	**Klf4**
9	Sox15	21	β-catenin
10	Dppa4	22	**c-Myc**
11	Dppa2	23	Stat3
12	Fthl17	24	Grb2

Final four Yamanaka factors are marked in bold.

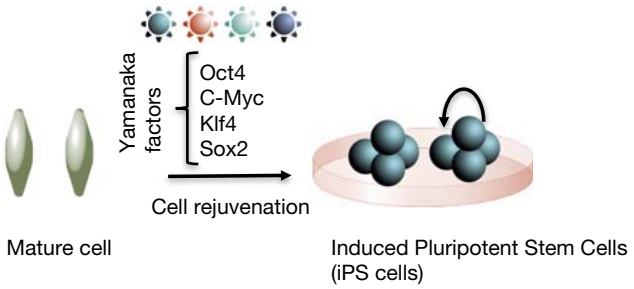

Fig. 2 Induced pluripotent stem cells (iPSCs) can be derived from mature (somatic) cells by expression of various transcription factors and were achieved in murine fibroblasts in 2006 by viral transduction of the Yamanaka factors Oct4, c-Myc, Sox2 and Klf4, and a year later in human fibroblasts. The method results in cellular rejuvenation back to blastula stage of development.

Table 2 Nomenclature of Oct4 and its identified pseudogenes

Gene symbol	*Gene description*
POU5F1	POU class 5 homeobox 1
POU5F1B	POU class 5 homeobox 1B
POU5F1P3	POU class 5 homeobox 1 pseudogene 3
POU5F1P4	POU class 5 homeobox 1 pseudogene 4
POU5F2	POU domain class 5, transcription factor 2

stage of development and can at least in theory attain an unlimited pool of pluripotent cells and these cells can be differentiated into the cell type of interest in any organ or tissue.

In addition to iPS cells, shairing similar properties with ES cells, they share some features with cancer stem cells, such as unlimited self-renewal, multi-lineage differentiation potential, maintenance of the stemness state and in vivo teratoma formation after implantation. Moreover, Yamanaka factors Oct4, Sox2, Klf4 and c-Myc have been identified in cancer cells. However, proteins encoded by the same gene can play very different roles in the cell (e.g., different pseudogenes or differently spliced versions) and the proteins can be modified to a different extent (e.g., glycosylation and phosphorylation, etc.). Therefore, the proteins that have been identified in cancer cells, although having the same name, do not necessarily have the same function in different contexts and further research is required to clarify their exact role. For example, the Oct4 protein is encoded by Pou5f1 and exists in at least five different versions and pseudogenes (Table 2).

Although the molecular mechanism underlying the reprogramming process is still unclear, it has been reported that "reprogramming" involves transcriptional induction that leads to the expression of pluripotency-related genes, therefore re-inducing the cell's capacity for unlimited cell growth. In 2008, Liu and colleagues performed a study to identify the global targets of endogenous Yamanaka factors in mouse ES cells. They found that these factors regulate developmental signaling networks of approximately a dozen signaling pathways to maintain the pluripotency of stem cells, including Notch, transforming growth factor β(TGFβ), Wingless/Wnt, and Hedgehog signaling pathways. Interestingly, they also found that the target genes of Oct4, Klf4, and Sox2 were linked to developmental processes, whereas the targets of c-Myc were mainly related to metabolic processes. Other studies have reported more pathways involved in the reprogramming process, including the overexpression of the Ha-Ras and hTERT oncogenes, inactivation of both the p53 and Rb tumor suppressor pathways by SV40 LT antigen, or the PTEN/PI3K/Akt pathway. Furthermore, it has been shown that the inactivation of p53 improves the efficiency of iPS cell generation. Taking into account that these pathways are considered as a hallmark of cancer and that Oct4, c-Myc, Klf4 and Sox2 are commonly overexpressed in some types of cancers, it seems obvious that cellular reprogramming and tumorigenesis share common features and mechanisms. Unraveling the mechanism of reprogramming could therefore help us to reveal new networks, potential biomarkers, develop cellular models for cancer progression and elucidate molecular mechanisms underlying the pathogenesis of human cancers.

In this article, we will describe each one of the four Yamanaka factors as well as discuss their role in the reprogramming process and relation to cancer (Fig. 3).

The Yamanaka Factor Pou5f1 (Oct4)

Oct4, also known as Pou5f1, Oct3, Otf3 or Oct3/4 (Oct3A, Oct3 B in human) is a member of the POU family of transcription factors and is expressed in the inner cell mass (ICM) of the blastocyst. Oct4 is involved in the initiation, maintenance and differentiation of pluripotent and germline cells during normal development. It is the first transcription factor known to be expressed during early mammalian embryogenesis and can be detected in the two-cell stage in human embryos and in the four-cell stage in mice. Oct4 has been proven to be important for implantation of the fetus in the uterus and was therefore not thought to have orthologues in species other than mammals, although orthologues in xenopus has been described. In mammals, the retention of totipotency has been correlated with the expression of Oct4. In the mouse, Oct4 is expressed from the fourth cell stage and in all of the early-cleavage nuclei of the morula and its expression becomes restricted to the ICM of the blastula. During gastrulation Oct4 is expressed solely in posterior epiblast cells lining the gut and those cells are thought to give rise to the primordial germ cells. These cells migrate using filopodia in the gut and end up where the gonads will be formed. Later, Oct4 expression is only seen in primordial germ cells and finally in oocytes but not in sperm or germ cells that reach the testis. However, Oct4 expression has been detected in primary testicular germ cell tumors and ovarian cancer; and this is associated with poor prognosis. In humans, opposed to mice, the expression of Oct4 has been detected in adult organs, for example Oct4 protein has been detected in numerous tissue/organ (Fig. 4A). Several reports argue that this detection of Oct4 in mature cells are false positive results due to pseudogene transcripts and DNA contamination. As mentioned earlier several versions of this gene exist (several splice variants and pseudogenes) and their different functions needs to be determined. The molecular mechanisms that regulate the first cell fate decisions in the human embryo are not well understood. The role of Oct4 during embryonic development in Oct4 −/− mice was studied and the conclusion was that the ICM formation was impaired. Recently Oct4 function during human embryogenesis was

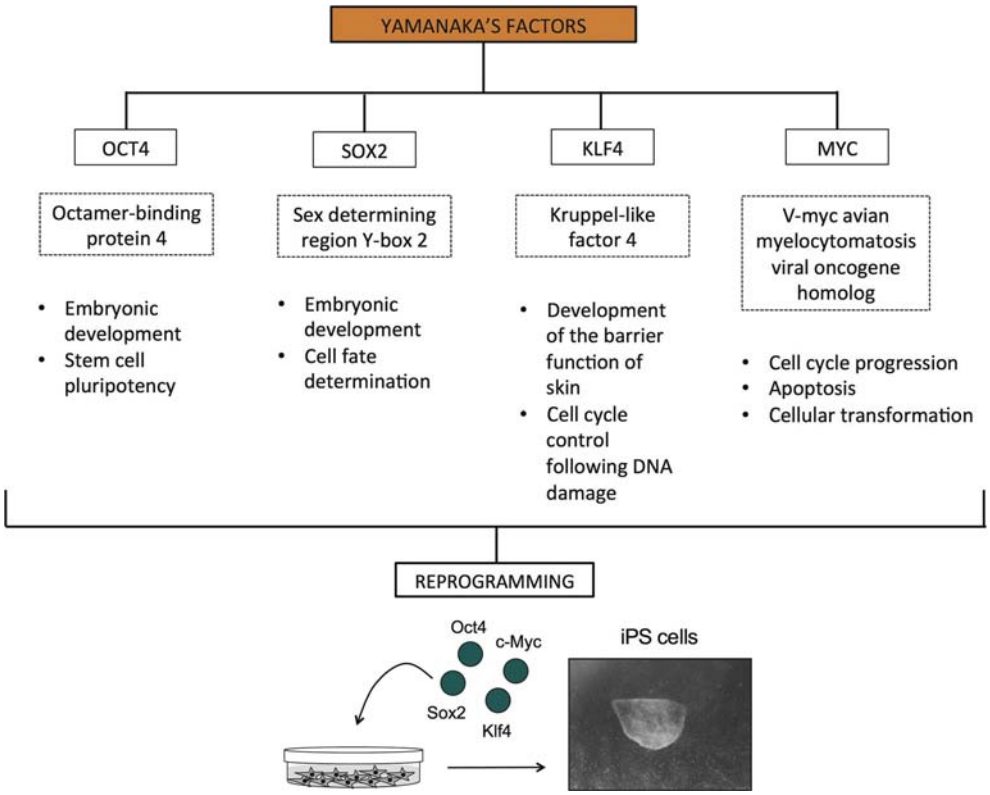

Fig. 3 Schematic picture representing the four Yamanaka factors, their main functions and the process of reprogramming.

investigated by genome editing, using CRISPR/Cas9-system to knock down its expression. Fogarty et al. specifically targeted the gene encoding Oct4 in diploid human zygotes and found that blastocyst development was compromised. Oct4 functions as a transcription factor and can form a heterodimer with Sox2 and function as a transcription activator or repressor. It induces the pluripotency gene Nanog. Oct4 needs to be at a certain concentration in order to maintain pluripotency, as little as a two-fold increase or decrease will cause pluripotent cells to differentiate. Therefore, accurate control of the Oct4 levels are crucial for maintaining pluripotency.

The Yamanaka Factor Myc (c-Myc)

Almost three decades back, the oncogene (v-Myc) from the myelocytomatosis virus (MC29) was traced back to a conserved cellular counterpart (c-Myc). In mammals, Myc has two other paralogs N-Myc (neuroblastoma derived homolog) and L-Myc (lung adenocarcinomas derived homolog). Myc codes for a basic-Helix-Loop Lelix (bHLHZ) domain containing the transcription factor of 439 amino acids and many of the conserved domains are shared with N-Myc and L-Myc. Like most members of the basic/helix-loop-helix/leucine zipper (bHLHZ) family, Myc is an obligate heterodimer. Myc heterodimerizes with Max (Myc-Associated Factor X; another bHLHZ protein) to bind specific DNA sequences (5′-CACGTG- 3′) called canonical *E*-boxes (enhancer boxes) and this interaction in turn activates transcription. On the other hand, binding of this heterodimers to non-canonical *E*-boxes is believed to result in transcriptional repression. Moreover, both N-Myc and L-Myc heterodimers are also known to bind the canonical and non-canonical *E*-boxes to interact with specific DNA sequences. Max is also known to form, self-homodimers to prevent phosphorylation of Max by Casein Kinase II (CKII). Yet, its binding affinity for DNA is extremely weak compared to the Myc-Max heterodimer. On the other hand, Max heterodimerizes with Mad to repress the same set of genes activated by Myc-Max. Furthermore, Myc also binds non- canonical *E*-boxes without Max and has probable Max-independent regulation.

The Myc protein has a half-life of less than ~30 min under normal physiological condition. Myc is typically degraded by tagging the protein for ubiquitin-mediated degradation. The hotspot residues (Serine 62 and Threonine 58) in Myc homology box I (MBI) is the target for ubiquitin ligase Fbw7 and is subsequently degraded by proteasome-mediated pathways (Fig. 5). Not surprising that the T58 residue is one of the most frequently found mutations in Myc. Myc homology box II (MBII) is the most extensively studied Myc domain because of its indispensable role in transcriptional activation, owing to its interaction with a number of histone acetyl transferase and other co-factors. Furthermore, the TAD domain is known to interact with the positive transcription elongation complex (P-TEFB).

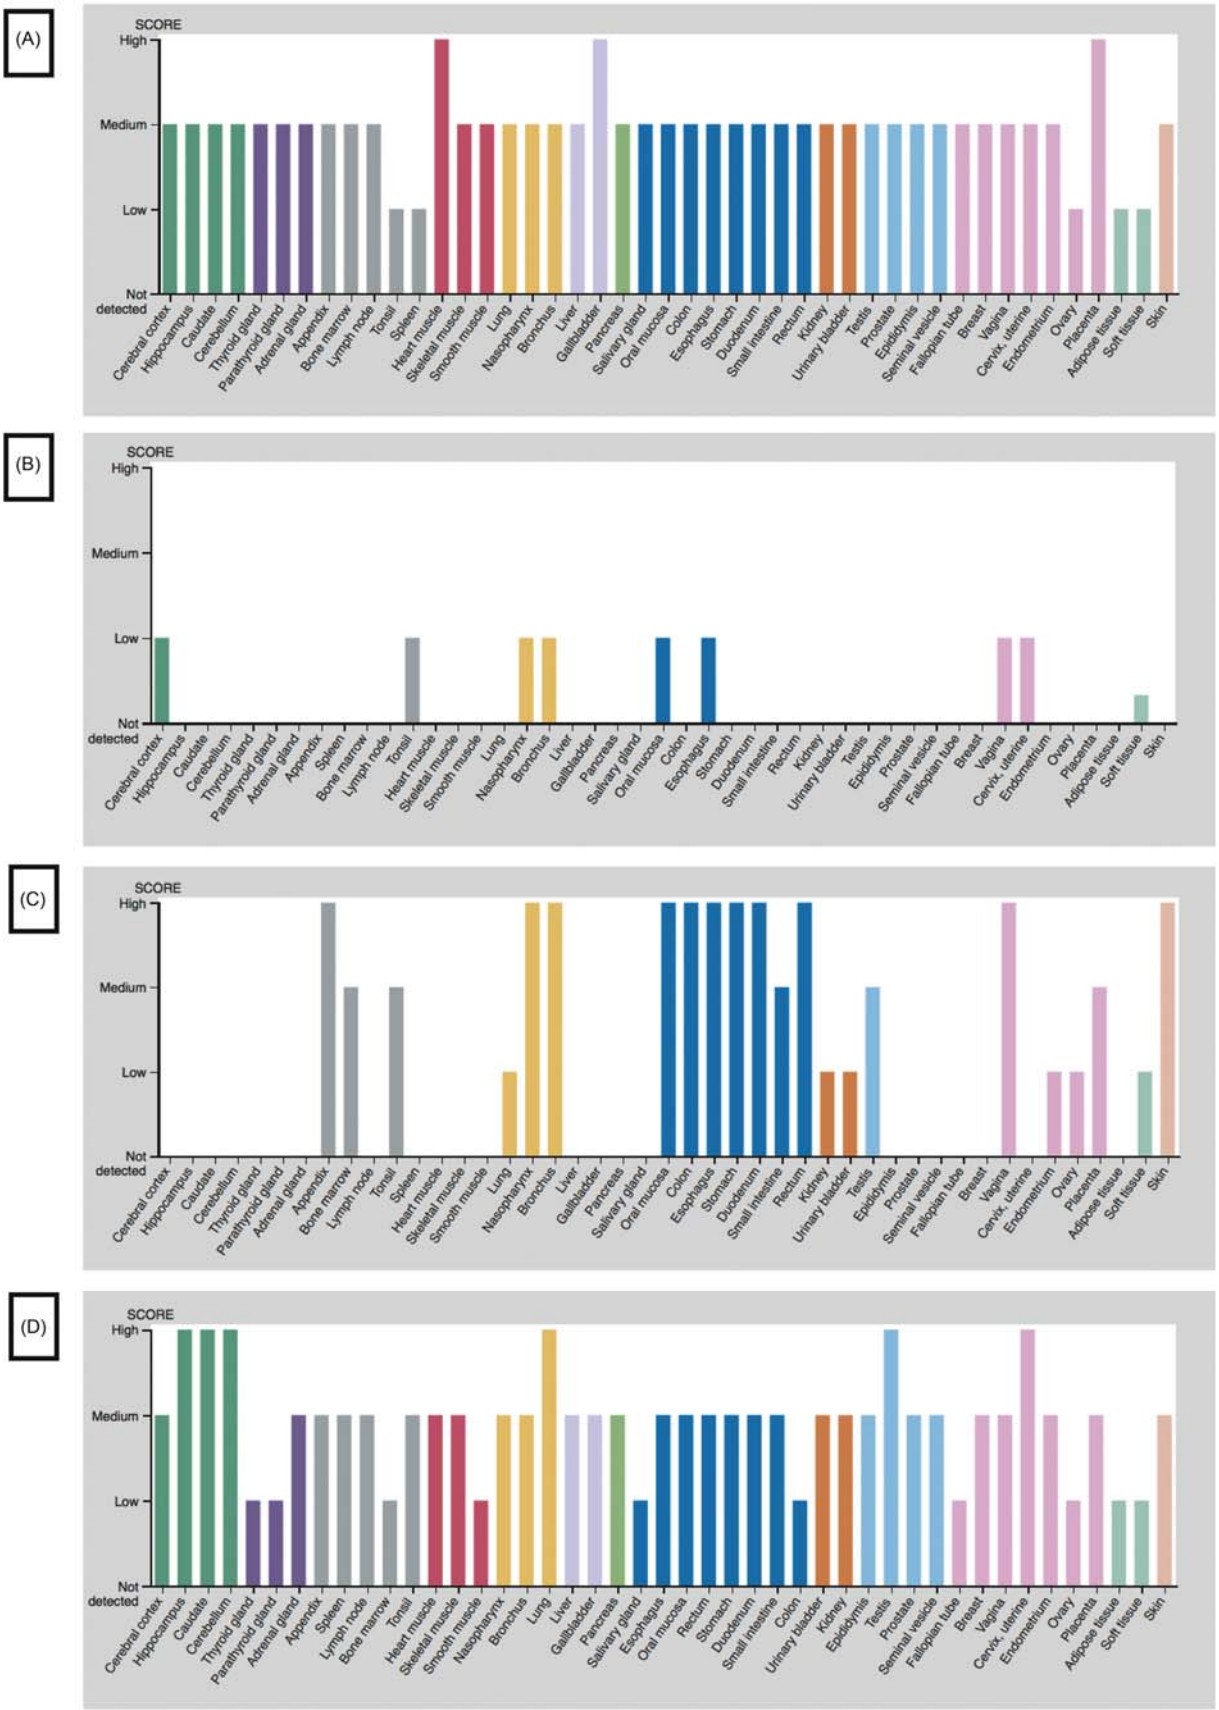

Fig. 4 Bar graph representing the protein levels in the different organs of the body of (A) OCT4 factor, (B) Sox2, (C) KLF4 and (D) MYC. Image obtained and modified from https://www.proteinatlas.org.

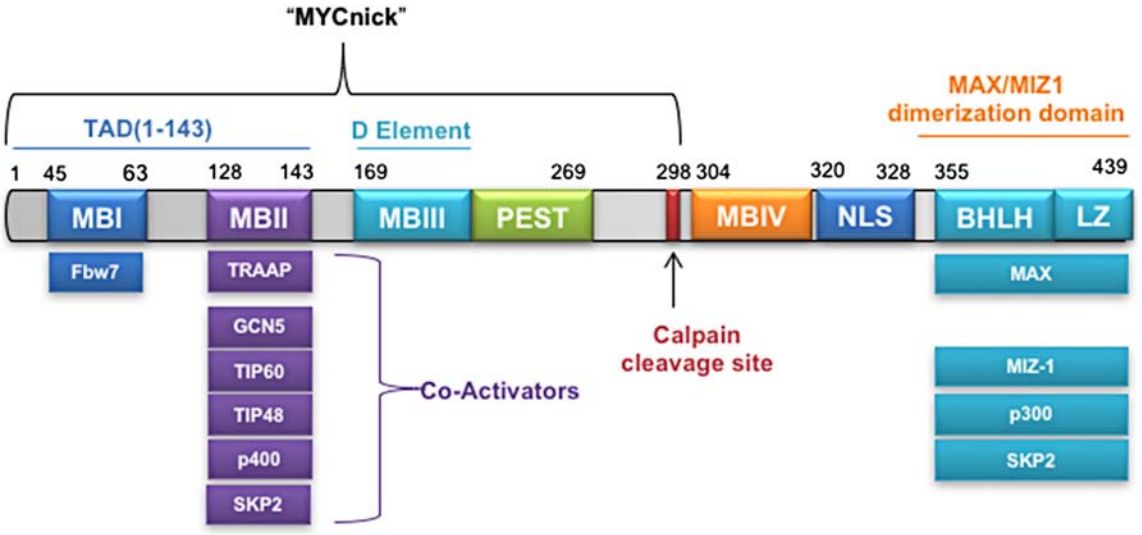

Fig. 5 Myc domains along with the associated factors. Myc contains two Myc boxes (MBI and MBII) in the N-terminal and together this is called a transcriptional activator domain (TAD). The PEST (Proline, Glutamic Acid, Threonine and Proline) domain; two other Myc boxes (MBIII and MBIV) and the nuclear localization signal then follow it. The C-terminal domain of Myc contains the bHLHZ domain. Figure adapted from PhD thesis of Joydeep Bhadury.

Most cells always maintain a delicate equilibrium of Myc levels under normal physiological condition. When deregulated, its level dictates if the cell opts for induction apoptosis or cellular transformation; a characteristic very explicit to Myc. Recently, how varying levels of Myc molecules regulate various Myc dependent functions has been elucidated. Myc regulates a wide range of target genes transcription governed by RNA Pol II by regulating their transcriptional elongation. Moreover, Myc also directly interacts with RNA Pol I and III to stimulate rRNA and tRNA synthesis. Myc not only induces the transcription of target genes but is also known to repress many genes. Despite having an enormous number of target genes, Myc still manages to have its specificity for either activating or repressing genes. YC regulates a wide range of target genes transcription governed by RNA Pol II by regulating their transcriptional elongation. Moreover, MYC also directly interacts with RNA Pol I and III to stimulate rRNA and tRNA synthesis. MYC not only induces the transcription of target genes but is also known to repress many genes. Despite having an enormous number of target genes, MYC still manages to have its specificity for either activating or repressing genes.

Myc is indispensable in embryonic development and only Myc heterozygous mice are born, albeit with not completely normal phenotypes. On the other hand, Myc null rat fibroblasts remain viable in spite of having smaller cell size and slower replication cycles; though the precise molecular mechanism owing to their propagation without Myc remains to be defined. Myc remains to be targeted directly by pharmacological means to date. This is primarily due to its intrinsically disordered protein nature (IDP) and IDPs are in general extremely difficult targets for therapeutic interventions. Indirect targeting of Myc by interfering with the Myc-Max heterodimer is an attractive therapeutic strategy. Among many compounds, 10058-F4 was extensively tested, but could not be used clinically because of its poor pharmacokinetics and bioavailability. Another approach is to use a dominant negative dimerization variant of Myc called "Omomyc", which is known to inhibit Myc function both in vitro and in vivo.

With regard to iPS cells, Myc is dispensable, albeit with significant reduction in the generation of iPS cell colonies. Yamanaka and colleagues had previously shown that either L-Myc or transformation deficient (TD) Myc can be used for iPS cell generation, but is not as efficient as c-Myc. Michael Cole and colleagues first reported the TD-Myc variant. By specifically mutating Myc at W136 to W136E, they showed that this inhibits the binding of Tip49a, a protein known for its role in ATP dependent remodeling of various targets including histones and has numerous other functions. This point mutation only leads to c-Myc losing its transformation capabilities, without significantly effecting its roles in maintaining cell cycle, apoptosis and other functions. Surprisingly, Myc despite being embryonically lethal, seems to be dispensable in maintaining ES cells or the naïve state of pluripotency. Okuda and colleagues have shown that ES cells can self-renew and maintain pluripotency without Max, the obligate heterodimer of Myc. In line with this, Myc transcript level are significantly reduced when ES cells are maintained in two inhibitors (MEK and GSK3-beta inhibitor), the so called 2i condition, a culture condition globally used to derive and maintain ES cells in their naïve or ground state. Finally, Andreas Trumpp and colleagues have recently shown that by transiently inhibiting Myc in mouse embryos, they could induce a diapause-like state. These embryos develop normally when transferred to pseudo-pregnant sows, thus showing a dispensable role of Myc in maintaining pluripotency, at least in the pre-implantation stages. On the other hand, the important role of Myc in mediating cell competition and shaping the developing epiblast during embryogenesis may not be overlooked. Recently, Miguel Torres and colleagues have shown that the ES cells that maintain high levels of Myc stay in naïve state, as compared to Myc low cells, which are found in the primed or epiblast stem cells states. These contradicting roles of Myc being dispensable in ES cells, as compared to the historically observed embryonic lethal phenotypes or its important role in cell competition, to shape the developing post implantation embryo, opens numerous questions. Cell competition is a conventional view of development which

involves elimination of neighboring cells to build an organism. How is Myc dispensable in maintenance of ES cells but still remains a critical factor for cell competition mediated processes of a developing post implantation embryo? Are other members of the Myc family replacing c-Myc during these processes? How are the Myc target genes regulated in absence of detachable Myc protein in ES cells? However, a possible explanation could be as ES cells are retrieved from the ICM cells of the blastula before the formation of epiblast, the embryonic lethal stage when Myc is depleted, post implantation and the cell competition stages. This supports the fact that Myc may be dispensable for reprogramming and in ES cells maintance. (Note: The part of this review partaining to the description of Myc has been adpated and modified with consent from the PhD thesis of Joydeep Bhadury (a co-author in this article). Using genetics to identify epigenetic and signal transduction targets in cancer. http://hdl.handle.net/2077/42347. ISBN: 978-91-628-9850-2 (PRINT); 978-91-628-9851-9 (PDF).)

The Yamanaka Factor Klf4

Krüppel-like factor 4 (Klf4) is a zinc finger-containing transcription factor that belongs to the Krüppel-like factor (Klf) family, and is expressed in various human tissues (**Fig. 4**C). Members of the Klf family possess characteristic carboxyterminal zinc finger domains that allow them to bind specific sites in promoter and enhancer regions of the genes they regulate. These zinc finger motifs at the carboxyterminal end of the proteins are highly conserved from flies to humans.

The Klf family is composed of 17 members, which play crucial roles in different body processes including differentiation, development and programmed cell death. Thus, several human diseases such as cardiovascular disease, metabolic disorders and cancers have been associated with the alteration of the function of these proteins. Specifically, Klf4 is thought to be involved in the normal development of the skin barrier function and consequently, it is involved in the pathogenesis of squamous cell carcinoma. Apart from playing a key role in normal development of the skin barrier, it is also involved in apoptosis, epithelial-to-mesenchymal transition, epithelial differentiation and cell cycle regulation. However, contradictory data exists regarding the regulation of the cell cycle by Klf4. For example, it seems to mediate the G1-to-S transition following DNA damage, by mediating the tumor suppressor gene p53. Also, Klf4 is able to induce cell cycle arrest by mediating p21, thus acting as a tumor suppressor. In fact, a study conducted by Dang and colleagues in 2003 revealed that induced Klf4 expression in cells that do not express endogenous Klf4, resulted in reduced colony formation, cell migration, invasion, and in vivo tumorigenicity. On the contrary, Klf4 can also contribute to tumor progression as it inhibits apoptosis. Furthermore, it has been seen that both Klf4 mRNA and protein are present in a high proportion in breast tumor samples as well as in gastrointestinal tumors. It seems that Klf4 could play different roles – as an oncogene or tumor suppressor - depending on the microenvironment in which it is functioning.

The fact that Klf4 is necessary for the efficient generation of iPS cells could be explained by its role in the maintenance of ES cells pluripotency. Klf4 has been observed to be upregulated by the leukemia inhibition factor (LIF), which maintains pluripotency in mouse ES cells. Additionally, Klf4 enables the maintenance of the self-renewal capacity in iPS cells by its cooperation with c-Myc. In iPS cells, there is a balance between these two factors, in which Klf4 suppress apoptosis induced by c-Myc, and c-Myc neutralizes the cytostatic effect of Klf4, thus maintaining the immortality of iPS cells. Apart from c-Myc, this factor can also cooperate with another member of the Klf family, such as Klf2 or Klf5 in the self-renewal of ES cells, and it is thought to play a crucial role in the ICM development at the blastocyst stage.

Regarding its relationship with the other Yamanaka factors, Klf4 co-occupies a substantial proportion of its downstream genes with Oct4 and Sox2. In fact, when Liu et al. (2008) studied the developmental signaling network in mouse ES cells, they found that Klf4 functioned to enhance Oct4 and Sox2 core factors for developmental regulation. On the other hand, Klf4 was identified as an upstream regulator of a large, feed-forward transcription factor loop that contains Oct4, Sox2, and c-Myc as well as other common downstream factors such as Nanog.

Despite of the fact that the exact mechanism of reprogramming is still poorly understood, new biological and pathobiological roles for Klf factors are continually being discovered. The critical role of Klf4 in important processes such as development, cell cycle, reprogramming or cancer, makes it necessary to study this protein and its pathways further.

The Yamanaka Factor Sox2

Sox2 (sex-determining region Y-box 2) is one of 20 members of the Sox family of transcription factors. Like Oct4, c-Myc and Klf4, it is expressed in embryonic and adult stem cells, where it functions as a master regulator of pluripotency and self-renewal.

During early embryogenesis, Sox2 levels are carefully controlled to inhibit mesendodermal differentiation and to promote differentiation into the neural ectoderm germ layer. Knock-down and knock-out, result in neural deformations and lethality of the developing embryo shortly after the epiblast stage, respectively. Subsequently, Sox2 remains constitutively elevated during neural tube formation and in central nervous system (CNS) progenitor cells until those are fully differentiated. Next to this, Sox2 dictates the branching pattern of the developing bronchial tree as well as differentiation of the airway epithelium. Up- and down-regulation studies show that Sox2 must be tightly regulated at all stages of development. Even a two-fold increase was reported to induce differentiation in mouse ES cells.

In adulthood, Sox2 regulates stemness and homeostasis of basal cells in the tracheal epithelium and the gastric tract; and also, neural stem cells (NSCs) maintain high levels of Sox2. These cells can produce either more Sox2-positive stem cells or differentiated

neural precursors. The high endogenous expression of Sox2 as well as c-Myc by NSCs allows them to be reprogrammed towards pluripotency by the mere addition of Oct4. This decreases the risks associated with the introduction of multiple exogenous reprogramming factors. For most other cell types, at least Sox2 and Oct4 are required to induce pluripotency. However, when reprogramming fibroblasts using small molecule, only Oct4 is required. Sox2 is regulated by LIF (leukemia inhibitory factor) signaling via the Jak/Stat3 (Janus-kinase/signal transducer and activator transcription) pathway activating Klf4 which further activates Sox2. It regulates itself and other pluripotency factors, namely Oct4 and Nanog, as well as developmental genes like FGF4 and is part of a complex network of interacting factors on multiple levels. All members of the Sox family contain the HMG box DNA binding domain (~80 amino acids), named after the highly similar DNA binding domains of High Mobility Group DNA binding proteins. With this domain, Sox2 binds to an eight base-pair DNA motive in the major groove, present in many developmental genes. Yet, Sox2 not only regulates the transcription of developmental genes but also its own by means of positive and negative feedback loops. Additionally, Sox2 has been found to collaborate with Oct4 while possibly also regulating its transcription. Together, Sox2 and Oct4 bind to non-palindromic sequences, the HMG/POU cassette, activating a subset of pluripotency and developmental factors. However, it was found that the HMG/POU cassette of many genes can also be bound by other families of the Sox family, namely Sox4, Sox11 and Sox15, indicating redundancy of Sox2 function. Yet, Sox2 is essential over other Sox protein family members to maintain a pluripotent state. Interestingly, the HMG/POU cassette is also present in the promoter of Sox2 and Oct4 and in at least one of three known Sox2 enhancers, namely SRR2. This implies their ability to regulate themselves and each other, as noted before, and explains why minor changes in Sox2 expression can have such dramatic effects on cell physiology. Together Sox2 and Oct4 might further work as co-activators or co-suppressors, enabling cells to rapidly differentiate during development.

Next to its vital role during nearly all stages of mammalian development, Sox2 has recently been detected in a growing number of cancers. These discoveries have shifted the focus of studies on Sox2 in development towards its involvement with tumor initiation and growth. A PubMed search of "Sox2 in Cancer" yields 2131 results and accumulating evidence of Sox2 upregulation in at least 25 different types of cancers confirms its state as a potent oncogene. Sox2 upregulation relative to healthy tissue is found in many solid tumors but remains low or absent in the surrounding tissue, tightly tying the gene to the disease. Further, enhanced migration and anchorage-independent growth of Sox2 over-expressing cells has been observed in pancreatic cancer, lung and esophageal cell lines and human embryo teratocarcinoma cell lines which links it to metastasis formation. But also in ovarian, skin, esophageal, lung, prostate, breast, and glioblastoma cancers, Sox2 upregulation is found in a number of patient samples. Notably, Sox2 expression is not necessarily uniformly upregulated throughout the tumor tissue but a cancer stem cell (CSCs) subpopulation primarily expresses the gene. Ectopic upregulation of Sox2 in epithelial and mesenchymal breast cancer was shown to enhance cell proliferation and invasion while knocking it down had mitigating effects. The occurrence of Sox2 upregulation in a great number of cancer types has tempted researches to establish a relation between Sox2 levels or Sox2-positive cell count and a possible clinical outcome. Together, these studies motivate the search for possible relations between the percentage of Sox2-positive cells and tumor malignancy in order to ultimately improve clinical diagnoses and patient survival.

However, a number of studies using knock-down and knock-out of Sox2 have brought up contradicting results. For instance, in head and neck squamous cell carcinoma, the knock-down of Sox2 has been related to a five-fold increased recurrence of cancer. The same effect has been observed in ovarian cancer by Wen et al., who found that cancer spheroid formation, proliferation, migration and tumorigenicity decreases under Sox2 knock-down. Although these studies constitute only a small part of the current research on Sox2, they contradict the theory of Sox2-positive tumor initiating CSCs and indicate that Sox2 is not necessarily involved in all types of cancer.

Concluding Remarks

In summary, the invention of iPS cells by Yamanaka and colleagues have led the opening of an entirely new era of research. To date the precise genetic, molecular and epigenetic mechanisms leading to iPS cell generation remains to be fully elucidated. Numerous key discoveries have been made using iPS cells, since its initial publication in 2006, leading to the first clinical trial to treat macular degenerative disease that was first initiated in 2014 and is still ongoing. One of the drawbacks with the iPS cell technology is the random integration of DNA into the genome. This has been an impediment of the iPS cells method for clinical use, and the search for ways to induce pluripotency without causing genetic change has become the focus of intense research. The criteria for the selection of a good manufacturing practice (GMP) grade iPS cell line would be a cell line without any exogenous genomic modifications. For example, iPS cell lines generated by the messenger RNA (mRNA) technology or by using Sendai virus mediated transduction, are known to result in generation of foot-print free iPS cells.

Recently, researchers studied the role of knocking down Oct4 in human embryos and the result is similar but not identical to what has been previously found in mice, which was that the inner cell mass (ICM) cells were absent. Under normal conditions, the ICM cells give rise to the individual. This data supports Oct4 as a key player for the development process and further support earlier findings, that out of the four Yamanaka factors, Oct4 has a primary role in reprograming and as being a totipotent and pluripotent marker. Although, it is important to note that iPS cells generated from murine cells closely resemble the ICM or the naïve state, whereas iPS cell generate using human cells are closer to the epiblast stem cells or primed state. The exact reasons and the factors regulating this difference between the human and murine cells is not fully understood, but several protocols have been developed to convert the human primed state to naïve like state or directly derive naïve state like human ES cells. An imbalance in cellular signaling networks, which are necessary during normal embryonic development, can either result in cancer or birth defects.

However, cancer and birth defects are each other's counterpart since molecules identified to cause birth defects, for example, retinoic acid or thalidomide can be used as cancer drugs. Therefore, in theory all drugs that disrupt normal development are promising candidates for hindering the development of cancer. Scientists hypothesize that the development of certain cancers and embryonic development are closely related events and have particularly been proven for teratocarcinomas. Indeed, the opportunity with the iPS cell technology to rejuvenate cells from patients back to the pluripotent state of development opens up an avenue of experimental approaches. One example is the generation of organoids from iPS cells, to recapitulate development in the test tube, to increase our understanding of human cell biology, genomics and epigenetics that potentially cause a specific devastating disease such as cancer. An additional example is that we have recently made cartilage by 3D bioprinting iPS cells and anticipate this as a future treatment option to repair damaged cartilage in joints. In theory, the strategy of 3D bioprinting iPS cells, followed by differentiation into the desired cell type or tissue, can potentially be used as "tissue patches" that can be stitched into any injured organ. 3D bioprinted tissue-replicas generated from iPS cells are juvenile and if such tissue is proven safe it could be like a perpetual machine and be industrially mass produced.

Inhibitors of Lactate Transport: A Promising Approach in Cancer Drug Discovery

Thomas D Bannister, The Scripps Research Institute, Jupiter, FL, United States

Glossary

α-CHC *alpha* cyano-4-hydroxycinnamic acid, a tool compound MCT inhibitor.
ALL Acute lymphoblastic leukemia.
ASCT2 The glutamine transporter SLC1A5.
CD147 Cluster of differentiation 147, chaperone protein for MCTs.
CLL Chronic lymphocytic leukemia.
CML Chronic myeloid leukemia.
DIDS 4,4′-Diisothiocyano-2,2′-stilbenedisulfonic acid.
GADP Glyceraldehyde 3-phosphate.
GADPH Glyceraldehyde 3-phosphate dehydrogenase.
GLS1 Glutaminase.
HIF1-α Hypoxia-inducible factor 1-*alpha*, a transcription factor.
LAT1 Large neutral amino acid transporter.
LDH Lactate dehydrogenase, family of enzymes that interconvert lactate and pyruvate.
MCF7 The cancer cell line Michigan Cancer Foundation-7.
MCT Monocarboxylate transporter.
MCT1 (aka SLC16A1) Isoform 1 in the MCT superfamily.
MCT2 (aka SLC16A7) Isoform 2 in the MCT superfamily.
MCT3 (aka SLC16A8) Isoform 3 in the MCT superfamily.
MCT4 (aka SLC16A3) Isoform 4 in the MCT superfamily.
NAD Nicotinamide adenine dinucleotide.
NHL Non-Hodgkin's lymphoma.
pCMBS *para*-chloromercuribenzene sulfonate, a tool compound MCT inhibitor.
PET Positron emission tomography.
PI3K Phosphatidylinositol-4,5-bisphosphate 3-kinase.
SLC1A5 A glutamine transporter ASCT2.

Introduction

Altered or deregulated energy metabolism has been widely recognized as a defining characteristic of cancer cells ever since the pioneering work in the 1920s through the 1950s by the German biochemist Otto Warburg. The cancer cell metabolic phenotype arises largely by a preferential dependence upon glycolysis rather than oxidative phosphorylation for energy production, regardless of the availability of oxygen (a reliance termed "the Warburg effect"). The defining components of the Warburg effect are increased glucose consumption, decreased oxidative phosphorylation, and greatly increased lactate production by tumor cells. Here we focus on the roles of lactate in cancer, specifically its transport and utilization.

Why tumor cells rely on glycolysis (i.e., what is the evolutionary advantage gained) has long been a subject of great discussion and debate. Another controversial issue is whether the reliance upon glycolysis is not merely a defining characteristic but rather provides a causal relationship for cancer progression. Recently it has become widely accepted that the glycolytic phenotype does indeed drive both tumorigenesis and cancer progression. Since glycolysis converts glucose into pyruvate and ultimately produces lactate, several biochemical pathways cooperatively maintain the cancer cell metabolic phenotype, including: (1) those that permit increased uptake of nutrient inputs, such as glucose, glutamine, and other amino acids, (2) those that make efficient use of the metabolic intermediates of glycolysis for conducting essential cellular processes, or (3) those that permit lactate utilization and removal. Conversely, targeting glycolysis at various checkpoints are attractive general strategies for cancer treatment. Blocking the influx of nutrients that drive anabolic growth, inhibiting glycolysis pathway enzymes (e.g., lactate dehydrogenase, isocitrate dehydrogenase), and impeding lactate active transport and/or utilization are all areas of very active interest for the development of anticancer therapeutic agents.

High-value biological targets, whether specific proteins or entire pathways, are those that are differentially activated in cancer cells versus normal cells. Targeting cell division processes, for example, historically drove the development of traditional chemotherapy drugs and drug cocktails, relying on a rapid rate of cell growth to achieve a useful therapeutic index. More recently the trend

had been to target proteins and pathways that are more highly specific to cancer cells, defining at the molecular level the characteristics that constitute a unique biochemical fingerprint reflecting one or more of the hallmarks of cancer. Such high-value targets offer the promise of avoiding mechanism-based side effects that limit the usefulness of traditional chemotherapy treatment regimens.

Advances in genomic and metabolomic technologies have helped identify various key proteins and regulatory transcription factors that maintain the glycolytic phenotype and that confer selective advantages to cancer cells, including an uninterrupted growth potential and a high capacity for the evolution of drug resistance. This marks them as potential high-value cancer targets. Protein kinase B (aka AKT kinase), as an example, drives increased glucose uptake. Hypoxia-inducible factor 1-alpha (HIF1α) and phosphatidylinositol-4,5-bisphosphate 3-kinase (PI3K) are proteins that drive the metabolic reprogramming of cancer cells to rely upon glycolysis. The powerful and oft-mutated oncogene RAS has multiple essential roles supporting the glycolytic phenotype. The transcription factors perhaps most relevant to the maintenance of the glycolytic phenotype are the MYC oncoproteins, which are known to directly activate the expression of two isoforms of lactate transporters, which are monocarboxylate transporters known as MCT1 (aka SLC16A1) and MCT4 (aka SLC16A3). MYC also drives the expression of several metabolic genes, including proteins that are involved in glutamine catabolism (e.g., the glutamine transporter SLC1A5 [aka ASCT2] and glutaminase GLS1) and proteins that are responsible for glucose transport. MYC also regulates the biosynthesis of lipids, purines, and pyrimidines. MYC overexpression is sufficient to promote tumorigenesis in mouse models. In humans, high MYC expression levels correlate with aggressive tumor growth and with poor treatment prognosis. Direct inhibition of MYC function by small molecules or by antibodies has often extensively investigated, but to date no MYC inhibitors have translated to clinical use. This is perhaps due to the considerable number of proteins that are unrelated to tumor growth that are also regulated by MYC. Direct inhibition of such an essential transcription factor seems to be an approach that would offer serious complications with respect to therapeutic index. Alternatively, a more attractive means of targeting MYC would be to identify the specific MYC targets that are both necessary and sufficient for driving tumor growth, such as the monocarboxylate transporters (MCTs).

Because cancer cells convert most available glucose into pyruvate and then to lactate, the issue of dealing with the high rate of lactate production, termed the lactate dilemma, is critical for cancer cell survival. An intracellular build-up of lactate would result in cytoplasmic and nuclear pH lowering, adversely affecting a multitude of pH-dependent processes that are involved in cellular homeostasis and cell division. Thus, the active efflux of lactate from intracellular stores to the extracellular matrix is essential for cancer cell survival. Measuring extracellular lactate levels, or as a surrogate, measuring the pH of the tumor's exterior microenvironment, are means to ascertain the glycolytic state of the tumor cells. A lowered extracellular pH, even as low as 6.0, is reflective of increased lactate export from malignant cells by monocarboxylate transporters. While lactate can be considered to be the waste product of energy production via glycolysis, lactate serves other functions that apparently aid tumor survival. The lowered extracellular pH, for example, facilitates the loss of cellular adhesion, thereby aiding tumor migration. The decreased pH also facilitates tumor invasiveness. More recently it has become clear that certain tumor types shift from glycolysis to oxidative phosphorylation, opportunistically using excess lactate generated from glycolysis as a carbon source for energy production through the TCA cycle. For example, when human non small cell lung cancer (NSCLC) patients were infused with ^{13}C-lactate, extensive labeling of TCA cycle metabolites was noted. Surprisingly, lactate's contribution to the TCA cycle is greater than that of glucose in these tumors.

Lactate homeostasis is critical for maintaining the malignant state, either blocking lactate production or inhibiting lactate transport can rapidly compromise the viability of established tumors, stunting growth, preventing metastases, and even eradicating established tumors. As discussed above, in principle all of the glycolytic pathway enzymes are viable targets to impede glycolysis and hence to interrupt lactate production. Many of these targets have been studied and their detailed discussion is beyond the scope of this synopsis, though certain high-value targets are discussed below. The main focus here is on the possibility of controlling the fate of lactate after its production, however. In particular, the strategy of interrupting lactate transport is shown to have significant promise. Such an approach both alters pH homeostasis and precludes the possibility of lactate utilization in the TCA cycle after it is exported. We discuss the therapeutic opportunities, the progress made, and the future translational potential for lactate transport inhibition.

Growth arrest following lactate transport inhibition arises from drastically reducing the internal rather than the external pH of affected cells. Lactate transport inhibitors should also be chemopreventative, since the glycolytic phenotype is manifest even in premalignant cells, as demonstrated for EμMyc premalignant B cells and for many lymphoma cell lines, which show increased expression levels of MCTs prior to their transformation. The transformed cells, in turn, express even higher levels of MCTs. Inhibitors of MCT1 and/or MCT4 should have efficacy as single agents in cells highly expressing that specific transporter. Perhaps more importantly, at least in a clinical setting, MCT inhibitors should augment the efficacy of many other agents, including those that target the glycolytic pathway by other mechanisms, and moreover they should have limited effects on nontransformed cells, which rarely rely upon glycolysis for energy production.

Related Targets in the Glycolytic Pathway

Because lactate is produced from pyruvate as the end product of glycolysis, blocking glucose transporters or blocking any step of glycolysis by inhibiting any of the glycolytic enzymes can be considered de facto means of disrupting lactate homeostasis. Glycolysis enzymes upstream of pyruvate production include hexokinase, phosphoglucose isomerase, phosphofructokinase, fructose 1,6-biphosphatase, aldolase, glyceraldehyde phosphate dehydrogenase, phosphoglycerate mutase, enolase, pyruvate kinase, and the lactate dehydrogenase (LDH), which is a family of enzymes that interconvert pyruvate and lactate, requiring a nicotinamide

cofactor. This step in glycolysis is critical for the recycling of nicotinamide for the continuation of glycolysis, as NAD+ is required in the conversion of glyceraldehyde 3-phosphate (GADP) to D-1,3-bisphosphoglycerate by glyceraldehyde phosphate dehydrogenase (GAPDH). Lactate dehydrogenase plays a key direct role in lactate homeostasis and the reader is directed to reviews describing anticancer efforts relying on selective (ideally) inhibition of the LDH5 isoform. LDH5 has proven to be a difficult target due to the polar and charged nature of its native substrates, pyruvate and lactate. Compounds binding at or near the substrate binding pocket tend to be very polar in nature and thus tend to lack favorable drug-like properties. LDH and many glycolytic pathway enzymes exist in multiple isoforms, some specifically upregulated in various cancers and that thus have been actively targeted in anticancer therapeutics development efforts. The discussion of targeting glycolysis enzymes and LDH is beyond the scope of this review, which rather focuses specifically upon lactate transport.

MCT1 and MCT4: CD147-Associated Proteins That Transport Lactate in Cancer Cells

The SLC16A family of proteins, termed the monocarboxylate transporters (MCTs), are 12-membrane pass cell surface proteins. While 14 MCT isoforms are known, only the MCT1, MCT2, MCT3, and MCT4 isoforms transport lactate. In humans, this transport across plasma membranes is bidirectional and is a proton-linked exchange. Expression profiling studies show that many aggressive tumor types, particularly those linked with activation of the oncogenic transcription factor MYC but also those with elevated expression levels of RAS, PI3K, and HIF-1α, express markedly elevated levels of the MCT1 isoform, the MCT4 isoform, or both.

Fig. 1 shows a modeled structure of the open conformation of the MCT1 transporter (blue and red) shown associated with the type I integral membrane receptor "cluster of differentiation 147" (aka CD147), shown in green. CD147 is a highly glycosylated chaperone protein that is also widely known as basigin or as the extracellular matrix metalloproteinase inducer (EMMPRIN). CD147 is required for proper localization of MCTs in the membrane. In this depiction, MCT1 is bound by the small molecule DIDS (4,4′-diisothiocyanatostilbene-2,2′-disulfonate), which is a strong electrophile and covalently binds to a lysine residue of MCT1.

Directly targeting the chaperone, CD147, rather than MCT1 itself with small molecule inhibitors or with antibodies is a potentially viable strategy for disrupting lactate homeostasis and therefore is an area of high interest for therapeutics development. Agents that target CD147 would compromise the activity of both MCT1 and MCT4 transporters. This would have the advantage of decreasing the viability of: (A) tumors that express both MCT1 and MCT4; (B) tumors that normally express MCT1 but that, under evolutionary pressure, are capable of upregulating MCT4 expression, and (C) tumors that normally express MCT4 but that are capable of upregulating MCT1 expression. The most significant disadvantage of targeting CD147 is perhaps that this protein has

Fig. 1 Calculated molecular structure of the lactate transporter MCT1. From Halestrap and Meredith (2004). *European Journal of Physiology*, **447**, 619–628.

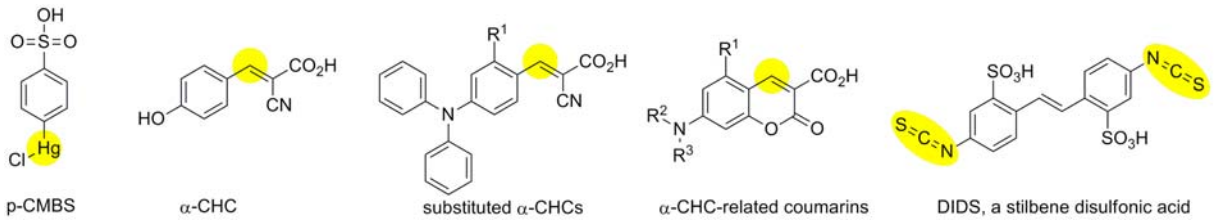

Fig. 2 Purported MCT inhibitors that are cysteine-reactive and that may target CD147 (reactive sites are highlighted in yellow).

a wide variety of biological functions beyond serving as a chaperone for MCTS, functions that are important to nonmalignant cells. As an example, CD147 forms complexes with various matrix metalloproteases. Thus, the blockade of CD147 function has the potential to elicit many dose-limiting side effects, giving a diminished therapeutic index. Perhaps for this reason, a more popular approach has been to directly target MCTs rather than CD147.

Many compounds that have been reported to be MCT inhibitors, especially those that simultaneously inhibit multiple MCTs, apparently interact with CD147 rather than with the associated MCT. This effect was first demonstrated with the organomercurial compound *para*-chloromercuribenzene sulfonate (pCMBS) (see Fig. 2). This compound is highly electrophilic: the mercury atom (highlighted in yellow) binds to sulfhydryl groups on accessible cysteine side chains in proteins. CD147 has several cysteine residues and in a genetic mutation study it was shown that these cysteines, and not those on MCTS, are responsible for the sensitivity of CD147/MCT complexes to pCMBS. Other electrophilic species that are thought to be MCT inhibitors are also cysteine-reactive, typically as Michael acceptors, such as alpha cyano-4-hydroxycinnamic acid (α-CHC). This compound, and related species, can also covalently bind accessible cysteine residues, including those in CD147 (the reactive center is highlighted in yellow in Fig. 2).

Many biological studies have used reactive compounds, especially α-CHC, as tools for MCT inhibition, with implicit assumptions: (1) that the compound has high target specificity; and (2) that any resulting phenotype that results from administering the compound in vitro or even in vivo is driven specifically by MCT inhibition. Care should be taken to establish whether off-target effects could also be important, however, with such broadly reactive species. α-CHC, for example, is also a very potent inhibitor of the mitochondrial pyruvate carrier. Any purported MCT inhibitor that is electrophilic toward cysteine residues, whether reversible or irreversible, might target CD147 rather than the MCTs themselves. Such a compound may have limitations in therapeutic index because of CD147's many roles, as discussed above. It also may target many other cysteine-reactive members of the proteome at large, providing further concerns from a target selectivity and side effect perspective.

This class of electrophilic compounds (i.e., Michael acceptors, like α-CHC) includes potent purported dual MCT1/MCT4 inhibitors that are essentially more highly substituted analogs of α-CHC, as well as closely related coumarin analogs (Fig. 2). Certain compounds among these coumarin inhibitors have properties that appear to be unique among the reactive inhibitors, however. They impede lactate efflux but not lactate influx, even though the MCTs are bidirectional transporters. Thus, if they act by modifying cysteine residues of CD147, the modified complex oddly retains its lactate import function while losing its lactate export capabilities. Certain coumarins also impede MCT1 function to as greater extent than MCT4, suggesting that they either bind to MCT1 directly or that they differentially alter the function of MCT1/CD147 complexes relative to MCT4/CD147 complexes.

Another class of MCT inhibitors are the distilbene sulfonates, which bear two highly reactive isothiocyanate groups. This class of inhibitors is also capable of covalently binding accessible cysteine residues on CD147. However it is also known to be reactive toward lysine side chains, if they are proximally held through other protein–ligand interactions. The distilbene sulfonate DIDS (shown bound to MCT1 in Fig. 1) forms a covalent interaction with a specific lysine residue in MCT1. Unfortunately the high chemical reactivity of isothiocyanates precludes their use as drugs to target MCT1, since a variety of other protein targets would certainly also be covalently modified, conferring unacceptable side effects.

As discussed above, given CD147's many functions, reactive species binding to CD147 may have significant drawbacks. The argument for disfavoring reactive inhibitors in this instance in no way excludes cysteine-reactive species from being useful tool compounds or even drugs; indeed, many recent clinical kinase inhibitors include in their structures appended acrylamide groups that specifically target nearby cysteine residues, for example. Care must always be taken, however, to identify what members of the proteome are targeted by such molecules and, thereby, what therapeutic consequences may result that are unrelated to affecting the intended target. Thankfully recent advantages in proteomics has made target profiling of covalent modifiers trend toward becoming a routine process.

Selective MCT1 Inhibition in Cancer Therapy

For the target selectivity/therapeutic index reasons cited above, directly targeting MCT1, MCT4, or both, preferably with species that are generally unreactive toward other proteins, would seem to be preferable to targeting CD147. Of these modalities, selective MCT1 inhibition has been most extensively reported. Early reports of weak MCT1 inhibitors include the Fig. 2 inhibitors such as pCMBS and α-CHC, but also includes species that are not covalently reactive, including dietary flavonoids and related polyphenols such as phloretin. Such polyphenols have often proved difficult to optimize with regard to their potency and target specificity.

Much more potent MCT1 inhibitors that are also better-suited for therapeutic translation are the structurally related compounds 1–3 (Fig. 3), the pyrrolopyridazinones, fused uracil pyrroles, and fused uracil thiophenes from AstraZeneca. These compounds inhibit MCT1 but not MCT4. They also inhibit MCT2, though the inhibition of the MCT2 isoform should have a negligible effect upon antitumor efficacy, given that the MCT2 isoform has a lesser role than does MCT1 (and MCT4 as well) in human cancers, a finding based upon tumor expression studies for the MCT isoforms. It is apparently very difficult to separate inhibition of MCT1 from MCT2, because these two isoforms have very high sequence homology.

The initial AstraZeneca compounds 1–3 were not ideal for therapeutic translation due to their poor pharmacokinetic (PK) properties. Nevertheless, the probe compound 1 and related analogs have been shown to rapidly block tumor cell growth, leading to cell death ex vivo and to tumor regression in vivo, in the case of both Raji Burkitt lymphoma cells and in the case of estrogen receptor-positive MCF7 breast cancer cells, both of which highly express MCT1 and express very low or undetectable levels of MCT4. Knockdown of MCT1 mRNA and protein in MCF7 breast cancer cells using MCT1-selective siRNA was also shown to impair proliferation, indicating that the antiproliferative activity of the probe compound 1 is due to its on-target effects at MCT1.

The fused uracil thiophene series of probe compounds, related to structure 3, was amenable to further optimization in regions of the molecule where there were specific metabolic and physical property concerns, such as the metabolically labile thioether side chain and the highly lipophilic and extensively metabolized naphthyl group. Changes in these two specific regions of probe compound 3 led to the clinical compound AR-C155858. The changes that apparently improved PK properties are shown in green and in yellow in Fig. 3. Further minor alterations in structure in three areas (see pink shading, Fig. 3) then gave the clinical compound AZD3965, which replaced the previous candidate in 2013. Cancer Research UK has sponsored the clinical studies, which first have been focused on the treatment of advanced solid tumors that express MCT1. Communications from Cancer Research UK have indicated the potential for additional clinical studies versus MCT1-expressing lymphomas and also versus small cell lung cancer (SCLC).

Though the full clinical findings are yet unpublished, some reports of AZD3965's effects, both preclinically and clinically, have appeared. As mentioned, MCT1-expressing tumors are targeted for treatment. In animal models, significant levels of MCT4 expression is associated with the emergence of treatment resistance. The use of MCT4 RNA interference agents in such resistant tumor cell lines restores sensitivity to AZD3965. Not reported, but generally anticipated, is that efficacy may also correlate with the extent of MYC activation, the presence of p53 mutations, and the extent of hypoxia in the treated tumors. In agreement with PK modeling, BID oral dosing of 30 mg of AZD3965 gives 24 h coverage in humans. In animal models, xenografts in mice bearing H526 tumors were treated with 100 mg/kg AZD3965 BID, a relatively high dose, for 7 days, alone or in combination with radiation. Both treatment regimens gave a statistically significant reduction in tumor size, with a more substantial reduction arising from the combination therapy. The compound was generally well-tolerated with respect to maintenance of animal body weight, also without overt effects on animal behavior.

Elevated levels of MCT1 with low levels of MCT4 have been detected in certain neuroblastomas, gliomas, and in certain specific breast, colorectal, gastric, and cervical cancer cell lines. As mentioned above, a potential future clinical application for AZD3965 is targeting MCT1-expressing lymphomas. In general, many hematological malignancies should be sensitive to MCT1 inhibitors that have no anti-MCT4 activity. Table 1, derived from patent data, summarizes the demonstrated or expected efficacy for an MCT1-specific inhibitor versus several clinically relevant hematological cell lines.

It is somewhat unclear what potential toxicities might arise from MCT1 inhibition, including from the clinical use of AZ3965. In an immunohistochemistry study in wild-type mice, MCT1 was found to be expressed in several tissues, including the retina, kidney, heart, stomach, duodenum, and liver. Many of these tissues also express MCT4, often to a greater extent, which might preserve normal function in these tissues should MCT1 be specifically inhibited. MCTs are also highly expressed in red blood cells.

Undesired retinal effects, including abnormal photoreceptor cell function and degeneration, is perhaps the major clinical concern for MCT1 inhibitors, though MCT3 was found to be the most highly expressed MCT in the retinal pigment epithelium and could perhaps compensate for MCT1 inhibition. MCT3 knockout animals display reversibly impaired retinal function. In CD147 knockout mice (all MCTs are effected) retinal tissue sections, especially Müller and photoreceptor cells, had lowered

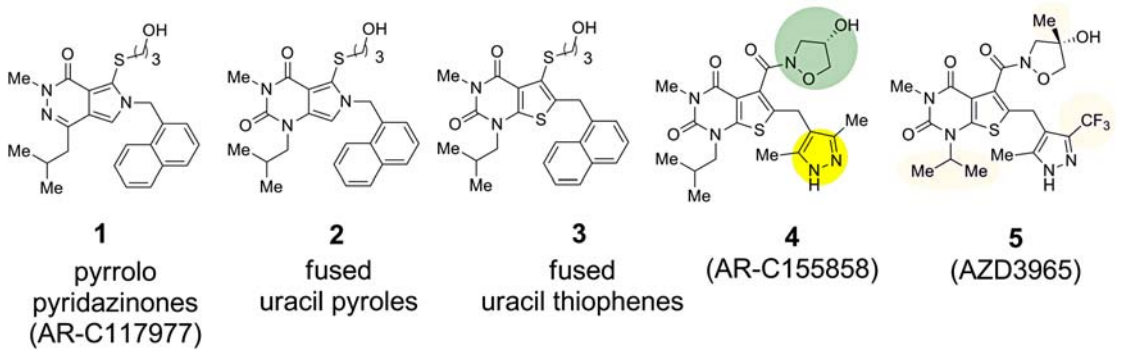

Fig. 3 Potent MCT1/MCT2 inhibitors from AstraZeneca and Cancer Research UK.

Table 1 MCT1 inhibitor-sensitive hematological malignancies[a]

Cell line	*Description*	*MCT1, MCT4 protein levels*
Cell lines highly sensitive to MCT1 inhibitors ex vivo, with $EC_{50} < 10$ nM		
SC-1	B cell non-Hodgkin's lymphoma (NHL)	MCT1 high, MCT4 not detectable
OCI-LY-19	B cell non-Hodgkin's lymphoma (NHL)	MCT1 high, MCT4 not detectable
WSUDLCL-2	B cell non-Hodgkin's lymphoma (NHL)	MCT1 high, MCT4 low
DOHH-2	B cell non-Hodgkin's lymphoma (NHL)	MCT1 medium, MCT4 not detectable
Raji	Burkitt's lymphoma	MCT1 high, MCT4 not detectable
Ramos	Burkitt's lymphoma	MCT1 medium, MCT4 not detectable
Jeko-1	Burkitt's lymphoma	MCT1 medium, MCT4 low
Namalwa	Burkitt's lymphoma	MCT1 high, MCT4 low
K562	CML	MCT1 high, MCT4 not detectable
BV-173	CML	MCT1 medium, MCT4 not detectable
Karpas-231	B cell ALL	MCT1 high, MCT4 low
EHEB	B cell CLL	MCT1 medium, MCT4 not detectable
Cell lines expected to be sensitive, based upon MCT1/4 expression levels		
SUP-B15	B cell precursor ALL	MCT1 medium, MCT4 not detectable
REH	ALL (non-T, non-B)	MCT1 medium, MCT4 not detectable
MEC-2	B cell CLL	MCT1 medium, MCT4 not detectable
HT	B cell NHL	MCT1 high, MCT4 low
SU-DHL-5	B cell NHL	MCT1 high, MCT4 not detectable
SU-DHL-4	B cell NHL	MCT1 high, MCT4 not detectable
Karpas-422	B cell NHL	MCT1 high, MCT4 not detectable
WSU-NHL	B cell NHL	MCT1 high, MCT4 not detectable
KG-1a	AML	MCT1 high, MCT4 low
MOLM-16	AML	MCT1 medium, MCT4 not detectable
OCI-M1	AML & CML	MCT1 high, MCT4 not detectable
KU812	CML	MCT1 high, MCT4 low
Daudi	Burkitt's lymphoma	MCT1 high, MCT4 not detectable
ESKOL	Hairy cell leukemia	MCT1 high, MCT4 low
Jurkat	T-cell leukemia	MCT1 high, MCT4 not detectable
KIT 225	T-cell leukemia	MCT1 high, MCT4 not detectable

[a]All data from Critchlow et al. WO 2010089580 A1 using AZD3965.

MCT1 expression based upon an immunohistochemical study using MCT1 antibodies. Areas to carefully monitor in the clinic thus certainly include retinal function, and if effects are seen, the reversibility of any retinal changes after the cessation of drug treatment.

To lessen the potential for retinal toxicity, or even for other tissue-specific toxicity issues that might arise, it is wise to closely assess the tissue distribution of candidate MCT1 inhibitors. For example, one would choose to advance compounds that have limited retinal exposure relative to the systemic drug levels, and especially relative to intertumoral drug levels. Certain MCT1 inhibitors, including the original AstraZeneca pyrrole pyridazinone probe compound 1 (**Fig. 3**), have been observed to rapidly accumulate in tumors to high levels, a property that could raise efficacy, mitigate potential side effects in normal tissues, and prolong the compound's duration of action, due to low liver exposure and concomitant lower-than-expected metabolism and systemic clearance.

As mentioned above, MCT1 is expressed in the liver, where its primary function appears to be the import of lactate for conversion to glucose (gluconeogenesis) via the Cori cycle. Thus, systemic MCT1 inhibition might be expected to elicit a modest reduction in blood glucose levels. In fact, this effect might well be amenable to therapeutic translation, where MCT1 inhibition could be used for modest glucose lowering in diabetic and/or obese individuals. For long-term use in therapy for diabetes or obesity, however, safety issues must be even more carefully considered. In any event, even in cancer treatment the monitoring of liver function would be advised in clinical trials of MCT1 inhibitors. The kidney, heart, and red muscles are also sites for gluconeogenesis and thus the function of these organs should also be monitored.

As discussed earlier, certain tumors (NSCLC in particular) also use lactate as fuel for entry into the TCA cycle, expanding its metabolic functions in cancer. MCT1, MCT2 and MCT4 are expressed in mitochondria in addition to the plasma membrane. It is unclear if MCT isoform distribution in mitochondria tracks with plasma membrane distribution, but this seems most likely. Thus tumor cells that rely primarily on MCT1, for example, for lactate export also would primarily use MCT1 for lactate flux into the mitochondria. The inhibition of this isoform would have two separate but synergistic effects, upon lactate efflux (driving adhesion and invasiveness, e.g.) and impeding energy production through lactate utilization in the TCA cycle. Similar synergies would exist for inhibitors of other MCT isoforms in tumor types reliant on that isoform for lactate flux.

Immune system responses should also be monitored in the clinical setting. The AstraZeneca probe compound 1 was, in fact, initially identified in a cell-based phenotypic screen for immunosuppressants, with MCT1 inhibition identified as its mechanism of action only a decade later. The AstraZeneca group showed that the inhibition of MCT1 during T lymphocyte activation resulted

in the inhibition of an extremely rapid phase of T-cell division that is believed to be essential for an effective immune response. MCT1 activity, however, is not required for most normal physiological functions of lymphocytes, thus it is unclear if immunosuppression would be a significant concern, especially in an acute treatment regimens that are characteristic of cancer therapy.

Although l-lactate is most often the substrate of MCT1–MCT4, these isoforms also transport other monocarboxylates, including the ketone bodies acetoacetate and β-hydroxybutyrate, as well as branched-chain keto acids. In the colon, MCT1 also facilitates the uptake of short-chain fatty acids. Biological processes dependent upon these species may thus be affected by MCT inhibition. MCTs have also been implicated in the transport of some carboxylate-containing drugs, such as salicylate, valproic acid, atorvastatin, γ-aminobutyric acid (GABA), and nateglinide. Thus MCT inhibitors should be assessed for drug–drug interactions, in particular for their ability to alter exposure of co-administered monocarboxylate drugs.

The emergence of therapeutic resistance is a general concern in the design of antitumor agents, and MCT inhibitors, including MCT1-specific inhibitors, are no exception. Resistance might emerge by at least three different mechanisms: (a) the ectopic induction of the MCT4 isoform, which can then replace MCT1's role in wild-type tumor cells in maintaining lactate homeostasis, (b) mutations to the MCT1 transporter that preserve lactate transport efficiency but that lessen the binding energy of the interactions of the transporter with the inhibitor, and (c) a shift from the reliance upon glycolysis to a reliance on oxidative phosphorylation for energy production, though this can in principle be impeded by inhibition of lactate transport into the mitochondria.

Resistance gained by MCT4 induction would likely be only a minor concern for tumor types that normally express very little MCT4. Tumor genotyping, in particular to ascertain the MCT1/MCT1 expression ratio, is likely to be essential for the successful identification of patient populations that are most likely to respond favorably to MCT1 inhibitors.

The second scenario, mutation to create a functional MCT that doesn't bind to the inhibitor, is perhaps the most problematic. Little is known about what mutations, if any, permit lactate transport while disfavoring the binding of inhibitors. Moreover, the emergence of resistance requires longer-term studies in animals, and preferably in humans. Presumably phase III clinical data on the most advanced MCT1 inhibitors will define the susceptibility for resistance emerging through point mutations in the transporter.

Regarding the third scenario, there is now substantial evidence to suggest that the efficacy of MCT inhibitors can be increased by the co-administration of an inhibitor of mitochondrial complex I, a drug class which includes the biguanides, one of which is the widely used diabetes drug metformin. The added efficacy may be the outcome of thwarting the emergence of resistance that could otherwise arise from a metabolic shift to oxidative phosphorylation. By a yet-unknown mechanism, biguanides seem to disfavor this metabolic shift by tumor cells. MCT1 inhibitor/metformin co-therapy can thus be superior to MCT1 inhibitor therapy alone, with lower doses of the inhibitor needed and with at least short-term resistance averted.

It should also be noted that, because MCTs are bidirectional transporters, antitumor effects may in principle arise via disruption of either lactate export or import. Though some reports attribute effects of MCT1 inhibition to the blockade of lactate import, this seems to be the exception rather than the rule, applying to oxygen-rich tumors relying on oxidative phosphorylation rather than glycolysis for energy production. MCT1-expressing tumor cells treated with MCT1 inhibitors had a decreased level of extracellular acidification, reflective of the blockade of lactate export. The most critical role of MCT1 and MCT4 in tumor cells thus appears to be the export of lactate that has been produced by glycolysis. It is important to keep in mind, however, that nontumor cells that require either the export or import of lactate can be affected.

Proposed Binding Mode(s) of AZ3965 to MCT1

No X-ray structures of MCTs have yet been obtained. Such structures would likely spur structure-based design efforts. Models of how DIDS binds to MCT1 and how AR-C155858 binds to MCT1 have been proposed by Halestrap et al., in both cases based upon extensive site-directed mutagenesis studies, and in the case of AR-C155858 binding, based upon the wealth of reported SAR information from AstraZeneca. The current clinical compound AZ3965 is expected to share the same binding characteristics of AR-C155858, as they are closely related in structure. Interestingly, Halestrap et al. concluded that one binding pose alone for AR-C155858 does not adequately fit the SAR data, and so they have proposed a dynamic model wherein the ligand transiently binds on the cytoplasmic side of MCT1 and then relocates to another, more deeply embedded binding pocket. In the first binding site, the key interactions are with Asn147, Ser264, and Arg306, while in the deeper site the key interactions are with Arg306, Asp302, Phe360, Leu274, Ser278, and Lys38. In aggregate, there are several essential pharmacophore features of this ligand class, as shown in Fig. 4 for AZ3965. The secondary alcohol of the ligand (in yellow) is an H-bond donor to Asp302 in both conformations, and also is an H-bond acceptor to other polar residues in one or both conformations. The A-ring carbonyl group (green) is a hydrogen bond acceptor, and this interaction appears to be the only key interaction involving the core [6,5] ring system of the scaffold. The isopropyl group (blue) fills a hydrophobic pocket in MCT1 that is comprised of lipophilic side chains. Finally, the pyrazole group (pink) makes both hydrophobic and polar interactions with neighboring residues. Presumably the hydrophobic interactions in this region are more important, given that original AstraZeneca pyrrolo pyridazinone inhibitor AR-C117977 (compound 1, Fig. 3) has a highly lipophilic naphthalene ring in this region, but it tightly binds to MCT1. The introduction of polarity in this region likely serves to lower the ligand's lipophilicity, thus conferring improved drug-like properties.

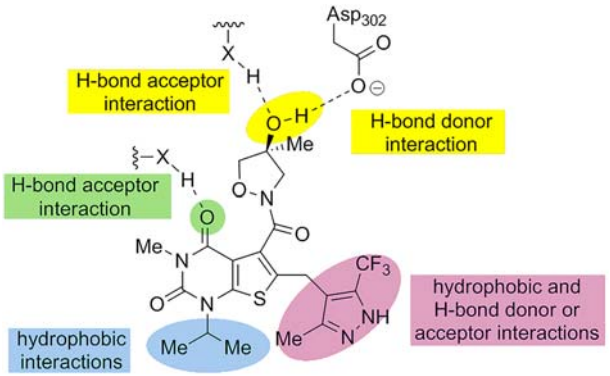

Fig. 4 Pharmacophore model for AZ3965 binding to the lactate transporter MCT1.

Scaffold-Hopping Efforts

The model in Fig. 4 suggests that the core scaffold of AZ3965 (the central 6-5 ring system) makes only one direct interaction with MCT1. The scaffold serves largely as a template for appropriately positioning a hydroxyl-containing group (yellow), a small hydrophobic group (blue) and a heteroaromatic group (pink). This explains the structural diversity allowed in the core scaffolds of the AstraZeneca tool compounds 1–3 (see Fig. 3) and it further suggests that additional scaffold-hopping efforts could identify compounds with groups that can mimic the key binding interactions that are proposed for AZ3965 but that may confer altered physical and/or DMPK properties. This hypothesis is supported by the identification of pteridine dione and pteridine trione MCT1 inhibitors 6–10 (Fig. 5), which have a [6,6] core ring system yet preserve key interactions regarded as essential in the binding model. Compounds in this structural series, such as compound 10, display low nanomolar potency in MTT assays for blocking the growth of the MCT1-dependent Raji Burkitt lymphoma cell line.

Given the activity seen in the pteridine-derived series, one might expect that other [6,6] and [6,5] ring systems might also be well-suited as core scaffolds for MCT1 inhibition. Indeed, in the recent patent literature both chromenones (e.g., compound 11, Fig. 6) and biaryl compounds (e.g., compound 12) have been reported to be potent MCT1 inhibitors. Both of these series, and the pterdinones as well, presumably fit the pharmacophore model shown earlier (Fig. 4) for MCT1 inhibition by AZ3965. While chromenones such as compound 11 share the core structure of dietary flavonoids, this common feature is likely coincidental. Biaryl compounds such as structure 12 have the essential hydroxyl group positioned to bind to MCT1 through a phenyl ring spacer rather than though an amide group, as in AZ3965 (Fig. 4).

Selective MCT4 Inhibition in Cancer Therapy

Much less information is available on the design of potent and selective inhibitors of the MCT4 isoform. Lipophilic statins (but not more hydrophilic statins) have been found to be MCT4-specific inhibitors, though with very low potency (IC_{50} values in the 30–100 μM range, with fluvastatin having the highest affinity for MCT4 among the statins). Such low affinity for relatively large structures offers little promise for optimization to inhibitors with potency at low nanomolar levels.

In 2014 Vettore Bioscience LLP received a Small Business Innovation Research Grant from the NIH to develop MCT4 inhibitors, with an aim of optimizing from a then-undisclosed starting point. A subsequent patent application disclosed an aryl pyrazole lead

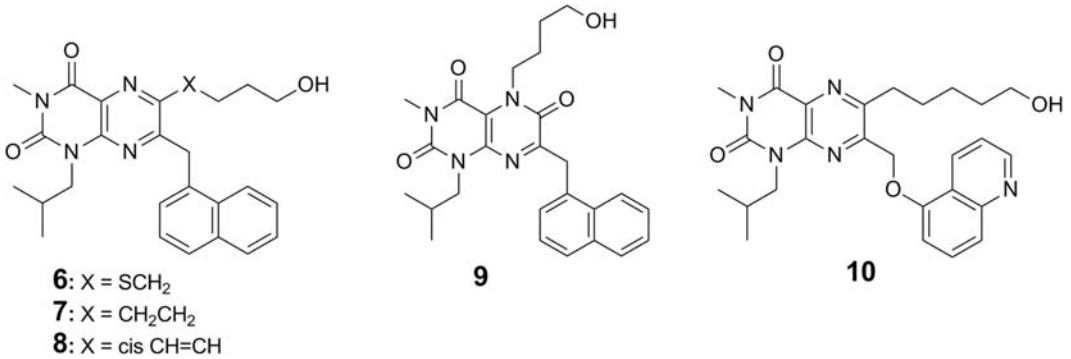

Fig. 5 Pteridine dione/trione MCT1 inhibitors.

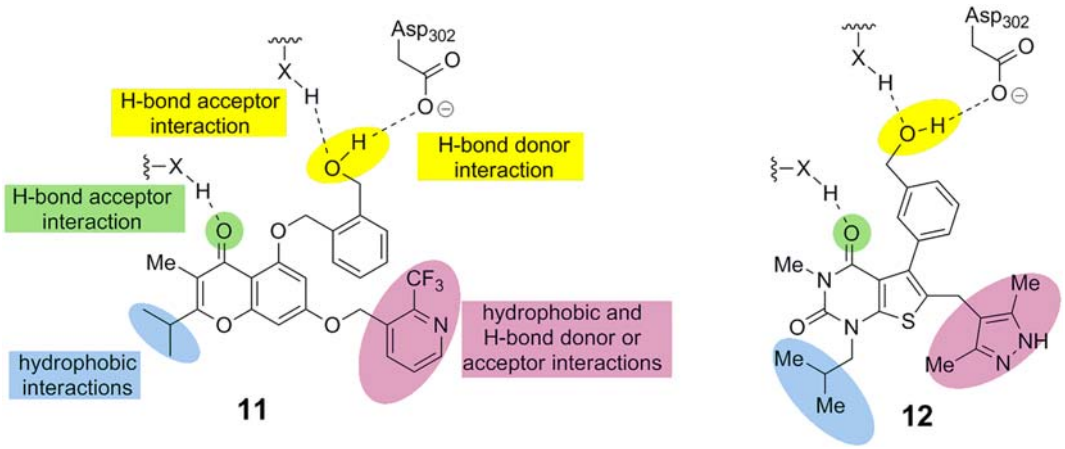

Fig. 6 Chromenone and biaryl MCT1 inhibitors.

series of potently active MCT4-specific inhibitors (Fig. 7). Compound 13 is one of the more potent and highly liver enzyme-stable analogs in the series. In this 2-aryl-*N*-benzyl pyrazole series, the highlighted groups are essential for activity, with some structural variation allowed, as indicated. No binding mode for these compounds to MCT4 had been proposed. Further, no data has yet emerged on the antitumor effects of these compounds in vivo or the side effects of MCT4-specific inhibition, but they should serve as useful tool compounds for making such determinations in animal models.

One might expect a rational design approach would be feasible for designing MCT4 inhibitors, if one might adapt the MCT1 pharmacophore model (Fig. 4) and consider the differences in amino acid sequence for MCT4 versus MCT1, altering the ligand to maximize desired interactions with differing MCT4 residues. To date, however, no MCT4-specific ligands are known to have been identified by such an approach. High-throughput screening presumably led to the Vettore lead MCT4 inhibitors, thus screening other collections might also be expected to give a suitable starting point for selective MCT4 inhibition, perhaps by cell-based screening for reduction in viability of an MCT4-expressing cell line followed by assaying any active compounds for their ability to disrupt the transport of ^{14}C-lactate. This approach could also reveal target binding sites that may be present in MCT4 but absent in MCT1. To date no screening campaigns for identifying MCT4 inhibitors have been reported, however.

Given that small molecule MCT4-specific inhibitors have only recently been disclosed, little empirical evidence has emerged regarding what tumor types they are capable of effectively targeting, though there is enough mounting evidence from other studies that we can anticipate what tumor types would be high impacted. MCT4 silencing by RNA interference was shown to drive clear cell renal cell carcinoma (ccRCC), the most common pathological subtype of kidney cancer, to cell cycle arrest and apoptosis. Other studies have implicated MCT4 as a key mediator of tumorigenicity in various pancreatic cancers, breast cancers (in particular, triple-negative breast cancer), oral squamous cell carcinoma, hepatocellular carcinoma, certain forms of colorectal cancer, and specific forms of prostate cancer. The ability of tumor cell line to express MCT1 would be expected to compromise its sensitivity to MCT4-specific inhibitors, so an analysis of relative expression levels, MCT1 versus MCT4, in tumors is likely to be important to maximizing the potential for therapeutic success.

There are significant mechanism-based safety concerns for systemic MCT4 inhibition, again not based upon reported studies with MCT4 inhibitors but rather based upon proteomics analysis. MCT4 is the major monocarboxylate transporter isoform found in white skeletal muscle and it is essential for muscle homeostasis. Medium levels of MCT4 are also found in all smooth muscles and

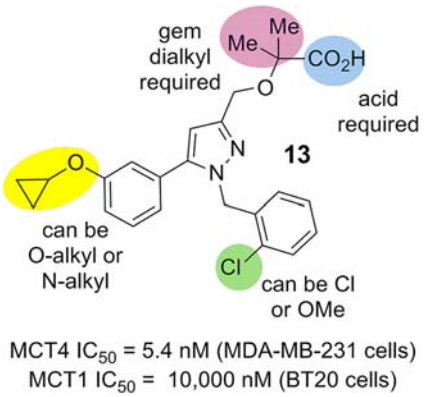

Fig. 7 Vettore's MCT4 inhibitor series.

in the heart. The common phenomenon wherein athletes experience muscle cramps after prolonged periods of heavy exercise is thought to arise from excessive lactate production that overwhelms the capacity of available MCT4s to export lactate. Thus, smooth muscle pain in general is an area of concern in the use of MCT4 inhibitors for treating cancer. Interestingly, muscle pain has been found to be more pronounced in humans taking statins that exercise heavily. As cited above, lipophilic statins are but weak MCT4 inhibitors, thus they likely do not act by direct inhibition. Rather it may arise from the downregulation of MCT4 expression, which has been observed for statins. Statin users might be poor subjects for anti-MCT4 antitumor therapy. There are also elevated levels of MCT4 expressed in the human placenta, in many sections of the GI tract, spleen, testes, and thyroid. Many of these tissues also have moderate or high expression of the MCT1 isoform, which could compensate for MCT4-specific inhibition and thereby prevent unwanted effects from arising. Complicating the analysis further, in a mouse study the expression levels of MCTs was found to differ depending upon whether the animals studied were in a feeding or fasting state, thus clinical studies on MCT4 inhibitors should consider this factor as well.

Dual Inhibition of MCT1 and MCT4 in Cancer Therapy

A few small molecules have been proposed to function as dual inhibitors of MCT1 and MCT4. Many of these species, however, are cysteine-reactive electrophiles (see **Fig. 2**) and thus they may inhibit the function of multiple MCTs by binding to their common CD147 chaperone. Several dietary flavonoids (e.g., quercetin and luteolin) disrupt function of several MCTs, albeit only at high micromolar concentrations. Because these compounds lack a cysteine-reactive warhead, perhaps they indeed do form direct interactions with the MCTs rather than with CD147. Unfortunately, the dietary flavonoids suffer from poor drug-likeness, as multiple metabolically labile phenol groups that are present are also essential for their modest activity. Thus, the series would seem to be ill-suited for substantial potency optimization to the point that physiological effects could be expected after following a reasonable dosing regimen. Dietary flavonoids are also electron transfer agents, with their antioxidant potential contributing to several pharmacological effects that are entirely unrelated to MCT binding.

SAR studies of potent MCT1 inhibitors in multiple scaffolds (**Figs. 3, 5 and 6**) identified no compounds in any series that also potently inhibit MCT4. Conversely, an SAR study of potent MCT 4 inhibitors (**Fig. 7**) also identified no compounds that were also potently active at MCT1. It may be generally true that the significant sequence differences between these two isoforms in their binding pockets will make direct dual inhibition of both MCT1 and MCT4 an elusive goal. Inhibitors of the interaction of CD147 and MCTs could achieve the same result, however. It might also be possible to rationally design dual MCT1/MCT4 inhibitors based upon the binding model for the AstraZeneca MCT1 inhibitors, considering differences in amino acid sequence between the MCT1 and MCT4 transporters and targeting only the common aspects of their respective binding pockets. To date, however, no highly potent dual inhibitors that clearly bind the MCTs directly have been reported.

The dynamic, two-binding site model for interactions of the AstraZeneca MCT1 inhibitors with MCT1 (see **Fig. 4** and associated discussion) may explain why MCT4 cannot be similarly targeted, as perhaps one or both of MCT1's ligand binding sites is much altered or absent in MCT4. A high-throughput screening approach, wherein even alternate binding sites might be occupied, might hold more promise for identifying dual MCT1/MCT4 inhibitors. If tight binding to both isoforms by a single molecule proves not to be feasible, the co-administration of a cocktail of two separate species, an MCT1 inhibitor and an MCT4 inhibitor, might be the most straightforward way to simultaneously block the function of both transporters.

Dual MCT1/MCT4 inhibition could have both significant advantages and disadvantages relative to selectively targeting either MCT1 or MCT4. Because several tumor types express both MCT1 and MCT4, selectively blocking only one transporter is unlikely to impede their growth, as the uninhibited transporter can function to maintain lactate homeostasis. Dual inhibitors should have the advantage of being much more effective versus such cell lines. Dual inhibition may also be advantageous for tumor cell types that, while expressing much more of one of these transporters (MCT1 or MCT4), is also capable of upregulating the other relevant transporter and thereby conferring resistance to any agent targeting only the more highly expressed transporter. In general, dual MCT1/MCT4 inhibitors (or a cocktail containing both an MCT1 inhibitor and an MCT4 inhibitor) are expected be cytotoxic toward wider range of patient-derived tumor cell lines than would either an MCT1 inhibitor or an MCT4 inhibitor.

The drawback to a dual MCT1/MCT4 inhibitor approach would be that side effect risks could also be augmented, given that normal cells that are dependent on *either* MCT1 or MCT4 for either lactate import or export at any stage in their development would be sensitive to dual inhibition. Dual MCT1/MCT4 inhibitors for cancer therapy would be used acutely, however, and perhaps even an extensive side effect profile could be tolerated or managed. The concerns regarding a wider spectrum of potential side effects would also apply to targeting CD147, either by antibody or by small molecule approaches, and perhaps more so, given that CD147 performs other essential physiological functions besides serving as an MCT chaperone.

Additive or Synergistic Effects With Other Drugs

As described earlier, in animal models the administration of mitochondrial complex I inhibitor biguanides, such as the widely used diabetes drug metformin or the related compound phenformin, augments the efficacy of MCT1 inhibitors. In animals receiving AZ3965, radiation therapy was shown to provide a synergistic benefit. Inhibitors of other biological targets that also facilitate glycolysis should also act additively, if not synergistically, with MCT inhibitors. One example is PI3K inhibitors, which cause a significant

decrease in glycolysis by decreasing aldolase activity. MCT inhibitors are likely to also act additively or perhaps synergistically with a variety of other anticancer drugs that act by fully orthogonal mechanisms, such as antiangiogenic compounds, immunologic therapies, and cell cycle disruptors. Now that tool compounds exist for both selective MCT1 and MCT4 inhibition, studies of the potential of such polypharmacological approaches will undoubtedly be thoroughly investigated.

Selective Tissue Targeting

MCT inhibitors can clearly thwart the growth of cell types that rely on the specific MCT isoform being inhibited. Much of the concerns with using MCT inhibitors relate to possible off-target effects at normal cells that at some stage are lactate-producing and that express MCTs. As mentioned earlier, one might fortuitously find small molecules that distribute well to tumors or to the target organ bearing the tumor. A more reliable approach may be to use a mechanism that will very specifically deliver the drug where it is required, that is, in the vicinity of the tumor that is being targeted. Such approaches often provide three important advantages: lower systemic toxicity due to low systemic exposure, prolonged duration of action for the same reason, and improved potency at the site of action due to greatly elevated local exposure.

The emergence of antibody therapies and, more recently, antibody–drug conjugates, has made it clear that tumors can be targeted with high specificity and that small molecule payloads that are highly cytotoxic can also be delivered to tumors, such that the toxic payload has negligible effects on normal cells and devastatingly lethal effects on the tumor. An MCT inhibitor may be a candidate for antibody delivery, although certain conditions much be met. The antibody-MCT inhibitor conjugate must be recognized by the tumor cell, must then be internalized, and then the MCT inhibitor must be released so that it reaches its binding site, near the cytosolic surface of the membrane-spanning transporter. The released MCT inhibitor should then remain in the cell and be neither effluxed nor lost to the cell by diffusion. Thus, while there are significant technological obstacles to overcome, the antibody delivery approach is attractive and warrants further study. To date there have been no reports of antibody-MCT inhibitor conjugates used either in vitro or in vivo.

Antibodies are not the only option for effective tumor targeting. Proteomics studies have identified many active transport systems that are very highly upregulated in numerous tumor types. For example, a folate-tagged small molecule can be delivered to tumors having upregulated folate transporters, meeting the tumor's increased appetite for folate. Tumor cells also aggressively compete for a variety of other nutrients that support the glycolytic phenotype, including glucose, glutamine, and other amino acids. An MCT inhibitor that is a substrate for a glucose transporter, a glutamine transporter (in particular, ASCT2, which is broadly upregulated in tumors), or the transporter for large neutral amino acids (LAT1, which is also highly expressed in tumors) will be internalized by tumor cells through active transport and then can block the function of the MCT.

The strategy of successfully exploiting the upregulation of nutrient transporters has gained substantial validation in the tumor imaging field. The general strategy used is that an imaging group is tethered to, or is part of, a tumor-targeting group. As an example, in ^{18}F-Fluorodeoxyglucose positron emission tomography (PET), tumors are imaged in preference to the background of nonmalignant cells. The extent of imaging contrast arises from the tumor's ability to take up fluorodeoxyglucose (compound 14, **Fig. 8**, also called fludeoxyglucose) via glucose transporters, which are highly upregulated in tumor cells. Similarly, ^{18}F-FBPA (compound 15) is a phenylalanine analog that is taken up preferentially by tumors via LAT1, a transporter for large neutral amino acids (e.g., Phe, Tyr, Leu, Trp, etc.) that is also widely upregulated in tumors. As a third example, gadolinium-containing MRI contrast agents, such as compound 16, have one or more appended glutamine residues. This appended amino acid allows the entire complex to be taken up preferentially by tumors via ASCT2 (aka SLC1A5), a MYC-driven tumor-upregulated transporter for glutamine, a nutrient that is essential for tumor growth.

The sample principles can be applied to the targeted delivery of a therapeutic agent rather than an imaging agent. The LAT1-directed and ASCT2-directed tumor delivery strategies used for imaging agents 15 and 16 have been applied to the targeted delivery of MCT1 inhibitors. Briefly, SAR studies with the AstraZeneca tool compound 1 (**Fig. 3**) revealed that the naphthalene region was open to substitution by even large functional groups without a significant loss of MCT1 inhibitory activity. Thus, a linker group could be attached to the naphthyl ring (or to an isosteric quinoline ring) to permit the attachment of a phenylalanine residue or a glutamine residue, appended as shown in compounds 17 and 18, respectively. The Phe-MCT1 inhibitor and Gln-MCT1 inhibitor conjugates 17 and 18 were designed to be transported by LAT1 and ASCT2, respectively. Since these two amino acid transporters are widely upregulated in tumors (they have even been dubbed "partners in crime" with regard to sustaining tumor growth), the conjugates 17 and 18 are tumor-targeted, displaying higher efficacy versus Raji Burkitt lymphoma cells than compounds lacking a tethered amino acid. Moreover, tumor intracellular drug levels are much higher for the amino acid conjugated compounds, and also for a prolonged duration. No in vivo results using such compounds have yet appeared, but it will be interesting to see if these or other tumor-targeting strategies can be used to widen the therapeutic index of MCT inhibitors.

Prospective Vision

The reliance of cancer cells on glycolysis to meet their energy needs has spurred many efforts to exploit this dependence for cancer therapeutics development. The major impediments to impeding glycolysis with small molecules have been overcoming several potentially toxic side effects and thwarting the emergence of treatment resistance. At the forefront of cancer metabolism mechanistic

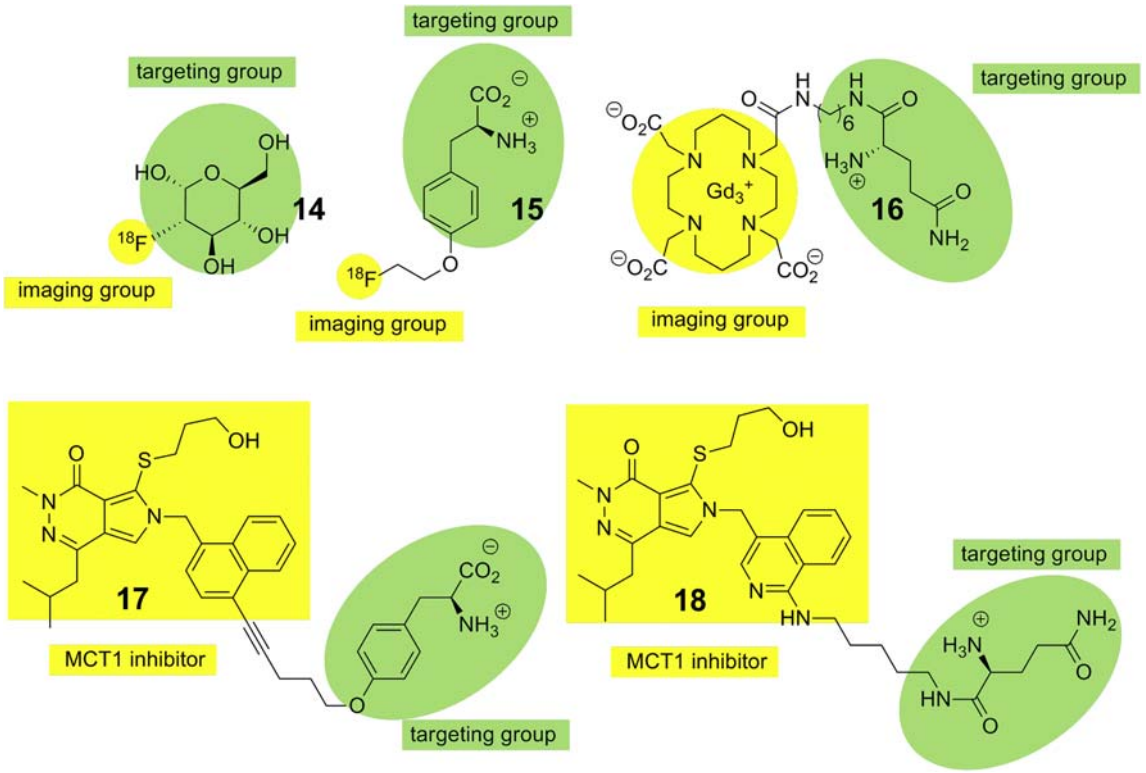

Fig. 8 Tumor upregulation of amino acid transporters can be exploited for the targeted delivery of imaging agents and toxic payloads, such as an MCT1 inhibitor.

targets are the lactate transporters most highly expressed in tumors, MCT1 and MCT4. In recent years potent and drug-like MCT1 inhibitors have emerged and have even reached the clinic. Promising MCT4 inhibitors, while slower to emerge, are now available as tool compounds and possible forerunners of anticancer drugs. We now have the molecular tools necessary allowing researchers to test the idea that MCT inhibition will broadly impede lactate flux in tumors, affecting both the export of lactate and also its utilization, in at least some cases, as an energy source. Controlling lactate flux may be a powerful approach to thwart the growth of many clinically important and otherwise poorly treated tumor types, to evaluate possible treatment synergies, and to address concerns related to the therapeutic index of potent antitumor agents.

Introduction

Understanding the biology of cancer and using this understanding to improve (early) diagnosis, treatment and follow-up of cancer patients is very much a multidisciplinary effort. Clinicians, clinician-scientists and basic scientists work together in what has become known as translational research: results of laboratory studies are translated into new approaches towards diagnosis and treatment and observations in the clinics generate questions for which laboratory studies are necessary. This is exemplified in the well-known metaphor "bench to bedside and back." Pathology is well positioned in this field, as it is considered "the science behind the cure": understanding cancer will eventually lead to earlier and better diagnosis underpinning therapeutic approaches targeting the molecular mechanisms responsible for the development of individual cancers.

Another reason why pathology plays a central role is the availability of biospecimens which are used for detailed molecular mapping of cancer. These biospecimens include tissue obtained through biopsy, cells from bodily fluids, tissue samples from surgical specimens and of late also tumor derived nucleic acids in circulating blood. Such specimens are collected in pathology departments in "biobanks," which have become a cornerstone in cancer research. Detailed questions regarding molecular mechanisms often require in vitro or in vivo (animal) models, which have been refined to closely mimic cancer in man. But invariably, application of new understanding, in terms of biomarkers for detailed therapy-oriented classification or development of new (targeted) therapeutic approaches, will pass through a phase of research on patients or patient samples.

History of Cancer Classification

It is hard to imagine, but as little as 100 years ago there was no standard classification or nomenclature (system of names) for diseases. Case records and causes of death were often recorded using narratives of symptoms. It was only in the second half of the 19th century that attempts were made to get to more systematic classifications of disease. Important groundwork was done not by pathologists or clinicians but by early medical statisticians, notably William Farr (1807–83) and the Frenchman Jacques Bertillon (1851–1922). The latter was instrumental in stimulating the French government to support the first International Conference for the revision of the International Classification of Causes of Death in 1900, which is the predecessor of the WHO International Statistical Classification of Diseases.

Tumor classifications came even later. In 1924 the Health section of the League of Nations decided that disease classifications needed to be revised every 10 years. When the WHO was created in 1947, this responsibility was bestowed upon this organization. In parallel, the Committee on Pathology of the National Academy of Sciences (USA) and the National Research Council of the USA took the initiative to develop the Atlas of Tumor Pathology published by the Armed Forces Institutes of Pathology (AFIP), which rose to fame as the AFIP fascicles. The American Cancer Society (ACS) in 1951 published the Manual of Tumor Nomenclature and Coding (MOTNAC), which consisted of a two-digit code for morphology with a third digit indicating the behavior of the neoplasm. In the 1960s the College of American Pathologists (CAP) decided to develop a classification for all pathologic entities, which evolved into the Systematized Nomenclature Of Pathology (SNOP). Meanwhile, the Union for International Cancer Control (UICC) published in 1952 the "Uniform Technique for a Clinical Classification by the TNM System," of which recently the 8th edition has been published. As of 1956 the International Classification of Disease (ICD) saw the light of day and now its 11th

revision is underway. In 1976 the 1st edition of the International Classification of Diseases for Oncology (ICD-O) was published and presently in use is its 3rd edition dating from 2013.

The role of the WHO in tumor classification started in 1956 when the WHO executive board in 1957 requested the Director-General to explore the possibility that WHO might organize centres in various parts of the world to collect human tissues and their histological classification. The main purpose of such centres would be to develop histological definitions of cancer types and to facilitate the wide adoption of a uniform nomenclature. The first such centre was created in 1958 in Oslo with as task to collect a case set that would underpin a WHO classification of lung tumors and the tangible result came in 1965 with the publication of the first volume of the first edition of the WHO classification of lung cancer. Publication of the 24 volumes of the first edition took until 1980. The second edition was published between 1988 and 2002 in 26 volumes. The third edition was published in 10 volumes between 2004 and 2007 and the publication of the fourth edition in 11 volumes will be completed with the last volume on Tumors of the Eye and Orbita in 2018.

What this brief review of the definition, scientific basis, development and history of classification tells us is that tumor classifications are in constant motion. Understanding of the biology of cancer has improved spectacularly, methods for (early) detection and specific diagnosis become more and more sophisticated, treatment options evolve rapidly and all these need to be taken into consideration in adapting existing classifications to the requirements of the users: patients, their physicians, pathologists, registrars, health care policy makers and (inter)national bodies such as the WHO.

Tumor Classification Now: How and Why?

Disease classification is the process in which signs and symptoms of disease are recognized, differentiated, understood and translated into a universally accepted diagnostic term or disease name, which guides treatment decisions clinicians take, and can be transformed into a universal medical code. These diagnoses and codes are used by health care providers, public health officials, health insurance companies, epidemiologists, registrars etc. among others to decide on therapeutic actions, analyze disease statistics and justify reimbursement.

It is important to emphasize that disease classifications do not develop through a process of deductive but rather through inductive reasoning. In deductive reasoning the starting point is a scientifically verified theoretical framework, within which the consequences of for example, an intervention can be predicted and subsequently experimentally verified. This is the classical model of hypothesis driven experimental studies. Inductive reasoning, on the contrary, starts with a set of observations, which form the basis for discerning a pattern that can be translated into a generalization, a theory or in the context of cancer classification a proposal for a new class or subtype of disease. The result of inductive reasoning can be a new hypothesis, which can subsequently be tested in an experimental approach, using deductive reasoning to establish a logical experimental design.

> "A recent example of this is the birth of the sessile serrated adenoma of the colon. In a well-known context, that of hyperplastic polyps of the colon, pathologists started to recognize lesions that look a little bit different, as they show more architectural disturbance with aberrant crypt shapes and intracrypt differentiation patterns. A set of characteristics was gradually identified, allowing a histological definition of a purported new class of disease. Subsequent clinical-pathological studies linked this new category with an increased risk for the development of colon cancer and molecular studies showed that they are characterized by aberrant gene promoter methylation patterns and *BRAF* mutation. The term sessile serrated adenoma of polyp was finally canonized in the WHO classification of human tumors and earned its own new ICD-O code."

The interplay between inductive and deductive reasoning characterizes translational research: "from bedside to bench and back." The implication of the inductive nature of the evolution of disease classification is the absence of an absolute scientifically verified theoretical framework, like the periodic table. Consequently, new observations might require an established classification framework to be modified. A striking example of the need for adaptation/modification is the emergence of the wealth of "omics" data on cancer, which seriously interrogates the relevance of the anatomo-morphological basis of the current approach to the classification of cancer.

A key characteristic of a scientifically robust classification is that class properties are shared among the members of a class, and new members of a class will share the properties of existing members. Identification of a condition as member of a specific class is of great practical importance, as this instantly conveys important information regarding biological behaviour, possible treatment options and potential outcome. The ideal tumor classification organizes tumors in hierarchical classes, with as basic principle that all members of a class share the same essential characteristics. As we will see, current classifications do not (completely) abide by this rule. Many tumor types occur in several organs, for example adenocarcinomas occurr in practically all parenchymatous organs. This leads to a certain level of redundancy and confusion, as the biological behaviour of an adenocarcinoma of the lung is quite different from that of an adenocarcinoma of the colon. Site can be a more important determinant of behaviour than type. Tumors of the same type at a single site may have different molecular (genetic) characteristics, going along with significant differences in biological behaviour. As a result, the current WHO classification (as all other tumor classifications) has more the character of a standard nomenclature than that of a coherent classification. A list of all entities in the WHO classification does provide a complete taxonomy of cancer, with which then the ICD-O codes can be associated. Using this classification as a tool, pathologists *identify*: they assign a standard diagnostic term from the WHO classification to a tumor using identifying characteristics. In simple

terms "they make a diagnosis." Pathologists also *discriminate*: they recognize features that define sub-types which differ in behaviour. As an example, a class or type would be "adenocarcinoma of the colon" and members of this type can be further subdivided according to anatomical criteria into TNM based stage groups or according to histological characteristics into different morphological subtypes or grades ("low grade" or "high grade").

The current classifications group human tumors according to the following hierarchical characteristics:

- Site
- Tumor category
- Tumor family
- Tumor type
- Tumor sub-type
- Tumor grade

Tumor *site* is usually an organ (e.g., lung, breast, prostate) or system (e.g., hematopoietic system, lymphatic system). Tumor *category* refers to major distinct cancer types, for which over time direction of differentiation homologous to developmental biological concepts were chosen, for example carcinoma (epithelial differentiation), sarcoma (mesenchymal differentiation), lymphoma and leukemia (lympho- and hematopoietic differentiation), and germ cell tumors (germ cell differentiation).

Within these categories, tumor *type* refers to distinct cancer types showing specific patterns of differentiation. For carcinomas typical examples are squamous cell carcinoma, adenocarcinoma or neuroendocrine carcinoma. For sarcomas typical examples are fibrosarcoma, osteosarcoma, chondrosarcoma or angiosarcoma. Tumor types over time segregated into tumor *subtypes*. As an example, adenocarcinoma of the colon has as subtypes cribriform comedo-type adenocarcinoma, medullary carcinoma, micropapillary carcinoma, mucinous adenocarcinoma, serrated adenocarcinoma and signet ring cell carcinoma. The evolution of subtypes was mostly driven by morphological observations, even though their relevance is to a large extent determined by association with differences in clinical behavior and more recently differences in molecular characteristics. The sessile serrated adenoma of the colon, as elaborated above, is an example of this evolutionary pattern of tumor classification.

Tumor *grade* is the final step. Grade refers to the histological similarity of cancer tissue to the tissue type in which the cancer arose. A well differentiated, low-grade adenocarcinoma of the colon shows a histological pattern close to that of normal colon mucosa, while a poorly differentiated high-grade colon cancer has lost many morphological differentiation characteristics. The importance of grading is the association with tumor behavior: high-grade cancers tend to be more aggressive with poorer prognosis than low-grade cancers.

The problem with this approach, used in the World Health Organization classification which list the tumors that occur at different body sites, is that in every organ cell types exist which are organ specific but also cell types not specific for that organ. The colon, for instance, contains a mucosal surface with an epithelial covering which is relatively specific for that organ. Tumors originating in the mucosa are also relatively specific for the colon. However, connective tissue, smooth muscle, fatty tissue, nerves and lymphoid tissue are also components of the bowel wall and give rise to tumors. The list of tumors in the colon therefore does contain, in addition to adenocarcinomas, also fibromas, leiomyomas, gastrointestinal stromal tumors (derived from the interstitial cells of Cajal, the pacemakers of intestinal peristaltic movement), lipomas, neurofibromas, ganglioneuromas, and lymphomas. These all occur in several other sites and henceforth will be mentioned there, which incurs significant redundancy. A comprehensive approach to tumor classification which would avoid such redundancy would be of interest but attempts to this end have not been undertaken.

Tumor Classification in the Post-Genomic Era

In this complex of "moving targets," molecular (genetic) analysis has introduced a whole new layer of complexity. Conceptually, a scientifically validated theoretical framework as a basis for classification should allow new data to be assimilated smoothly within the existing classification structure. New information regarding class members accumulates and/or new class members are identified, and both can be comfortably accommodated within the existing classification: class definitions do not have to be changed. It is now evident that molecular data only partially fit within existing tumor classification approaches and there are several examples of molecular data which have upset them. It is therefore imperative that new approaches to tumor classification are considered.

What would a "second generation" tumor classification accommodating this complex molecular knowledge look like? The following list summarizes some essential features of an ideal tumor classification.

- The classification should be based on biological principles, using features from developmental biology, molecular cell biology and genetics, to segregate tumors into distinct classes, preferably based upon a scientifically valid conceptual framework.
- The classification should be informative in providing basic biological and clinically relevant information regarding the essential characteristics of each class member.
- The classification should be comprehensive (e.g., every human tumor can be easily accommodated within the classification) and based upon consensus: "everyone should speak the same language."
- New subdivisions should be readily accommodated in the classification, allowing for example easy assimilation of the wealth of "omics" data.

- The classification should allow migration of a subdivision to a different class. With the continuous emergence of new molecular data, subtypes might have to be united or repositioned into a different class.
- The classification should allow assimilation of results of basic research with needs of clinicians.
- The classification should be compatible with earlier classifications to allow easy translation of earlier classification results (e.g., pathological diagnoses) into the new classification.

The question arises weather the wealth of molecular genetic data, presently available for almost all human tumor types following the TCGA and ICGC projects, provides a biologically valid basis for a new approach towards tumor classification. If so, the new classification should manage the complexity of voluminous and enormously complex molecular tumor data, allowing elucidation of relationships between different data elements by reclassifying tumors under redefined group hierarchies. Much of the presently available molecular (genetic) data on human tumors represent discriminant analysis within a class, but not necessarily an attempt to reclassify based upon molecular characteristics across the boundaries of existing tumor classifications. Typically, in a gene expression profiling (or genomics) study unsupervised clustering of expression (or genome aberration) data separates the tumors into groups with (partially) shared patterns of gene expression or genome aberrations. To be significant, such new groups will also share specific biologic and/or clinical features (e.g., high propensity for metastasis, response to chemo- or targeted therapy, better prognosis). But this merely represents new intraclass variability, and rarely justifies the creation of a new tumor type. An example is the revised 4th edition of the WHO classification of tumors of the nervous system, "which breaks with the century-old principle of diagnosis based entirely on microscopy by incorporating molecular parameters into the classification of CNS tumor entities" as David Louis states in the introduction. Glioblastomas are now subdivided in *IDH1* wild type and *IDH1* mutated, with differences in biological properties and therapy options, but they are both still considered as belonging to the glioblastoma class.

Some molecular cancer biologists like to convey the impression that we are on the verge of a totally new approach towards tumor classification, based first and foremost on molecular (genetic) information and principles. The question is whether this is indeed the way to go: abandoning presently used principles of tumor classification by reclassifying based upon the presumed primacy of molecular (genetic) data.

Can Human Cancer Be Classified Based Uniquely Upon Molecular (Genetic) Characteristics?

Conceivably, a completely new classification approach might eventually be developed using molecular (genetic) characteristics as dominant ordering principle. Such an effort, however, would face at least four major obstacles.

The Complexity of the "Omics Data"

Molecular (genetic) analysis of cancer has been around for decades. Immunohistochemical studies on gene expression at protein level by immunohistochemistry have become mainstream in diagnostic pathology and for many cancer types this is presently an essential step to arrive at proper classification. Early ground-breaking studies on chromosomal abnormalities in cancer contributed essential new insight, of which the discovery of the Philadelphia chromosome in chronic myeloid leukemia (CML) is the classical example. The recognition of the t9;22 translocation led to the discovery of the *BCR-ABL* fusion gene and subsequently to one of the first success stories of targeted therapy, the tyrosine-kinase inhibitor Imatinib turning CML from a lethal into a manageable chronic disease. Things changed with the arrival of the "omics" era. Cancer is now characterized at exome, whole genome, methylome, transcriptome and proteome level and the end of this revolution is not in sight with exploration of the metabolome and kinome, to name just two. Different "omics" are functionally interrelated and one of the tasks of bioinformatics will be to make sense of this mountain of confusing information. Basing a classification of cancer on one of these "omics" levels does not seem the right way to go. Integration of these levels in experimental biological research has led to a new emerging scientific discipline, that of systems biology. Conceivably, functional integration of these levels of molecular detail will be required to get to more profound understanding as to what exactly determines the behaviour of a tumor. We might therefore see the emergence of "systems oncology." Until then, it is unlikely that the anatomical/histomorphological basis of tumor classification will be replaced by a molecular basis.

The Context Dependency of the Significance of Molecular Characteristics

A further complication is the context dependency of (some?) molecular genetic traits. The same molecular (genetic) aberration may have different functional implications, depending on the tumor type. It is rather likely that integration of the different strata of molecular information, as suggested in the previous paragraph, will eventually explain why. But for the time being this functional inconsistence in the effects of for example, a gene mutation complicates the use of such aberrations as starting point for tumor classification. An example of this problem are the mutations in *BRAF* in a variety of neoplastic lesions: non-Hodgkin lymphoma, colorectal cancer, malignant melanoma, papillary thyroid carcinoma, non-small-cell lung carcinoma, adenocarcinoma of the lung, brain tumors including glioblastoma and pilocytic astrocytomas. Strikingly, sessile serrated adenomas of the colon often harbor the characteristic V600E *BRAF* mutation, even though most of these lesions will spontaneously regress. In contrast, once a colon carcinoma has developed, the same mutation confers aggressive properties to the tumor, which is reflected in poor prognosis. Depending on

the site or histological characteristics of a *BRAF* mutated tumor, it might or might not respond to the BRAF inhibiting molecule vemurafenib. It is clearly not only the mutation as such but also the functionally integrated molecular biological context that determines the influence of an isolated parameter on the behaviour of a cancer. This is a further impediment in using molecular characteristics as guiding principle in tumor classification.

The Need for Complementarity With Existing Tumor Classifications

Any new tumor classification, no matter how biologically relevant, will need to have a clear relationship with existing classification(s). Continuity in cancer registration for epidemiological purposes is essential. Clinicians will have to be able to continue to apply knowledge based upon previous classification systems in giving care to cancer patients. In addition, there is a conceptual dimension: even though a classification might become obsolete, the knowledge gained through its use does not necessarily loose its relevance.

The Spatial and Temporal Heterogeneity of Tumors

Tumors are heterogeneous. To begin with, all tumors are composed of neoplastic cells surrounded by tumor stroma, the generic name for what tumor biologists tend to call the tumor micro-environment. Stromal components are provided by the host, constitute an essential element of the tumor and co-determine tumor behavior. Furthermore, it is not unusual for cancer cells in a tumor to vary in architectural arrangement, size and shape. There may be well differentiated areas, resembling the tissue of origin; other areas may be undifferentiated, having lost identifying morphological characteristics. In some tumors heterogeneous differentiation patterns occur: some lung cancers are partly adenocarcinoma and partly squamous cell carcinoma. Immunohistochemical staining patterns for marker proteins are often heterogeneous. Areas may be strongly positive and others completely negative; sometimes the immunoreactive cells are scattered throughout the tumor tissue. Molecular genetic analyses have shown that tumors are more heterogeneous than earlier assumed and with the advent of next generation sequencing (NGS) we now must face the reality that at all levels all tumor are heterogeneous, with significant implications for diagnosis and treatment.

This heterogeneity is not only spatial but also temporal. Different tumors have different levels of chromosomal instability or genome hypermutability, and both factors continuously introduce new genomic traits over time. Intrinsic "selective sweeps" or external selection, for example chemotherapy affecting responsive tumor cell clones but not those non-responsive, will determine which tumor cell clones emerge over time as dominant clones largely responsible for prognosis.

Does present day practice in molecular analysis reflect tumor heterogeneity?

This is unfortunately not the case. A small endoscopic biopsy of a carcinoma of the colon does not necessarily represent all the clones present in the primary tumor. DNA isolated from the sample is then unlikely to be representative of all different tumor clones. This has immediate practical consequences, as the single maybe 1 cm^2 but 5 μm thin tissue section sample of a colon cancer submitted for determination of *KRAS* mutation status represents an extremely small fraction of all tumor DNA. Small emerging subclones are unlikely to be represented in a small biopsy. This is one of the explanations for the development of secondary resistance to targeted treatment: a small *KRAS* mutated subclone may remain undetected in the analyzed sample but may emerge in a treatment resistant recurrent lesion.

Does molecular heterogeneity affect patient treatment?

To what extent molecular heterogeneity affects patient treatment is not entirely clear yet. We do know that molecular heterogeneity can be found in all tumors but with strikingly different levels between different tumor types or even between different cases of the same tumor. A landmark paper by the Swanton group reported a disturbingly high level of intratumor heterogeneity in renal cell carcinoma but this is not the case in all cancer types. Most colon cancers have a relatively stable genome and driver mutations in the primary tumor also drive (liver) metastases. A notorious exception in colon cancer are mismatch repair and POLE deficient cases, which have a hypermutating genotype. However, most of these mutations are (silent) passengers and do not drive the metastatic lesion. We need more insight in the patterns of molecular evolution/phylogeny of different tumor types. This will allow better understanding which genome alterations are in the trunk of the (phylogenetic) tree, which are in the branches at which level and what drives the development of new branches.

The wealth of molecular data in The Cancer Genome Atlas (TCGA) or the International Cancer Genome Consortium (ICGC) databases only partly allows to address some of these issues. As a rule, in their studies single decentrally collected tumor tissue samples are analyzed, with relatively scanty follow-up data. Despite current NGS deep sequencing and sophisticated bioinformatics analysis, it will require study of multiple samples on large numbers of primary tumors, long term follow-up of the patients with multiple (liquid or tissue) biopsies including from metastatic sites, along with detailed documentation of clinical evolution and treatment response, to answer the most burning and clinically relevant questions.

A New Classification or a New Layer of Complexity in Existing Classifications?

What emerges from the arguments elaborated in the preceding paragraphs is that the present state of knowledge does not justify the creation of a new classification based primarily upon molecular knowledge. A recent TCGA publication on soft tissue sarcomas

provides a striking example of how "omics" data confirms the solid biological basis of existing classifications. Unsupervised clustering of sarcomas based upon genome aberrations nicely put synovial sarcomas and leiomyomas in distinct clusters, confirming the strength of the morphological approach. An interesting finding in this paper is also that nuclear pleomorphism could at least in part be explained by high genome variability. Automated computational analysis of digital pathology images allowed calculating a nuclear pleomorphism score for each case and increased nuclear pleomorphism was found to correlate significantly with genomic complexity. The earlier cited subclassification of glioblastomas according to *IDH1* mutation status is another example: the class remains glioblastoma, but the subtype is based upon molecular characteristics. What emerges as general conclusion is that class definitions in the WHO classification will remain, but that subtypes will be increasingly defined by molecular parameters. Another example is the development of the consensus molecular classification (CMS) of colorectal cancer. Morphologically defined subtypes have had limited clinical impact, apart from the association of carcinomas in the right colon and of medullary or mucinous subtype and mismatch repair deficiency. In contrast, the molecularly defined CMS subtypes differ significantly in behaviour and in the presence of actionable targets.

In clinical perspective extraction of clinically relevant findings from huge amounts of "omics" data is an important issue. This is manageable for pathologists with profound understanding of molecular data interpretation when it comes to testing for a limited set of known cancer associated genome aberrations. However, for exome, RNA and most obviously for whole genome sequencing data expert bioinformatics support is essential. This requires on the one hand pathologists and clinicians sufficiently comfortable with molecular data to communicate effectively with bioinformaticians, and on the other bioinformaticians with good operational knowledge of cancer genomics and its application in a clinical context. Onco(patho)logists need to train bioinformaticians in the pathobiology of cancer and need to adapt curriculum content of their postgraduate education programs to the molecular world. Digital microscopy will gain in importance, in view of its potential in terms of its more objective character, notably for quantitative parameters, and for decision support to be provided by artificial intelligence.

A final important issue is the need for data sharing. TCGA and ICGC data are based upon significant case cohorts, but to document in detail characteristics of emerging subtypes, some of which will be quite rare, it will be important to dispose of very large case collections. While the wealth of data from diagnostic molecular analyses of human tumors will first and foremost serve individual patients, it would be wasteful not to use these data to increase our understanding of the molecular pathobiology of cancer. An obvious way to do this is large scale data sharing. Cancer care centers might form consortia with translational research units, conceivably with participation of industry partners and obviously supervised by a legal and ethics framework to guarantee patient safety and privacy protection. Molecular data are only useful when accompanied by clinical and pathological data and within such consortia optimal data sets can be developed to complement molecular data. To gain support for this approach, onco(patho)logists need to participate actively in campaigns to inform the public at large and intensify productive interactions with patient advocacy organizations.

Conclusions

The cancer research and care providing community is gradually introducing molecular characteristics into cancer classification. This will have significant implications for but will not completely upset present approaches.

1. The current WHO approach to cancer classification will remain a solid basis for the years to come. The definition of main tumor classes will remain histomorphologic. As David Huntsman and Mark Ladanyi put it in the concluding phrase of their introduction to the 2018 Annual Review Issue of the Journal of Pathology: "Thus, oncological pathology's oldest technology remains meaningfully connected with and continues to inform genomic pathology."
2. New cancer subtypes will continue to emerge, of which the definition will be largely or entirely "omics" oriented.
3. Digital microscopy will rapidly complement and gradually replace conventional microscopy. This will provide a higher level of objectivity to cancer diagnostics, notably when it comes to quantitative parameters. Artificial intelligence through machine deep learning might provide decisional support in the future.
4. Pathologists will need to adapt postgraduate training programs to this shift in emphasis in cancer classification. In the 20th century the endpoint of cancer classification was the information a histological section offered. In the 21st century the histological section represents its first phase, providing a solid basis upon which "genomic pathology" will be grafted, and this should be reflected in the curricula. This holds true also for postgraduate education in other oncology oriented clinical disciplines.
5. Bioinformaticians contribute essential competencies to molecular based classification. A new class of "in silico" oncobiologists with profound understanding of cancer biology and its clinical implications needs to be educated to face increasing demand for this type of support.
6. The likelihood that many new "omics" defined subtypes will emerge goes along with decreasing case numbers per subtype. To nonetheless arrive at case collections allowing solid conclusions as to the relationship between molecular characteristics and clinical behaviour including treatment response, data sharing will become imperative. This needs to be supervised by a legal and ethics framework to guarantee patient safety and privacy protection.

Interferons: Cellular and Molecular Biology of Their Actions☆

Dhananjaya V Kalvakolanu, Shreeram C Nallar, and Sudhakar Kalakonda, University of Maryland School of Medicine, and Greenebaum Cancer Center, Baltimore, MD, United States

Introduction

Vertebrates mount two major types of responses to thwart the threat from invading pathogens and progression of neoplastic cell growth: (1) innate (non-specific) immunity and (2) acquired (specific) immunity. The former, an immediate response, sets the stage for the latter, which takes longer time (few weeks) to develop. Cytokines play a central role in both these processes. Interferons (IFNs) are primary responders and drivers of innate immunity, which later continue to collaborate with other cytokines in developing acquired immunity. The name "Interferon" was coined about 59 years back by Isaacs and Lindenmann on the basis of their earliest observation that these cytokines, secreted by virus-infected cells, interfered with virus replication in the neighboring cells. Since their original description, studies on these cytokines provided remarkable insights into anti-pathogen immunity, non-self and self-recognition, cancer biology and signal transduction, gene regulation and many other fundamental processes involved in cellular physiology including RNA stability and translational control of gene expression. As a result IFNs occupy a central place in mammalian biology and continue to provide trailblazing insights. This chapter will provide a bird's eye view of a current understanding of this field.

IFNs—A Family of Cytokines

Although presumed to be a single protein at the time of their discovery, it is now clear that IFNs are a collection of cytokines (α, β, γ, δ, k, ε, λ, τ, ω, ζ). In mammals, there are 13 subtypes of IFN-α, 4 subtypes of IFN-λ and single forms of IFN-β, IFN-γ, IFN-ε, IFN-κ, IFN-δ, IFN-τ, IFN-ω, and IFN-ζ. IFN-κ and IFN-ε are exclusively expressed in the skin keratinocytes and the female secondary reproductive organs, respectively. IFN-δ and IFN-τ are only found in pigs and ruminants, respectively. IFN-τ is expressed only in the trophoblasts. Similarly, one other IFN, Limitin, which downsizes B-cell populations via apoptosis after the initial antigen stimulus, is only found in mice, for which no known orthologues are present in other species. There are 4 IFN-λ subtypes viz., -λ1,-λ2, -λ3 and -λ4 in humans. IFN-λ1, -λ2 and -λ3 were previously known as IL-29, IL-28A and IL-28B, respectively. After realizing their functional equivalence to other IFNs in terms of signal transduction and gene-induction profiles, they were regrouped and named IFN-λ. In the laboratory mouse strains, IFN-λ1 is a pseudogene, whereas all 4 genes are expressed in humans. Some of these IFNs express in a tissue-dependent manner and exhibit as high as 90–100% (e.g., among IFN-α subtypes) and as little as 20% (e.g., IFN-α and IFN-λ) sequence similarity with other members of their family. Despite their significant sequence divergences, most of these IFNs are capable of inducing an anti-viral state in target cells, which unifies them functionally. In humans, the 13 IFN-α, and one of each IFN-β, IFN-ω, IFN-k and IFN-ε genes all are located in a gene cluster on chromosome 9. It is still unclear why 13 different IFN-α subtypes are produced. IFNs are also grouped on the basis of their receptor usage: type I (IFN-α, IFN-β, IFN-ε, IFN-k, IFN-δ, IFN-τ, IFN-ω, and IFN-ζ); type II (IFN-γ) and type III (IFN-λs). All type I IFN genes have no introns, consistent with their activity as first messengers after an active infection, or danger response. It is likely that the lack of introns allows a rapid processing of mRNAs for translation to prevent infections. The IFN-γ gene has 3 introns while IFN-λ genes have 4 introns. All IFNs are produced as 16–18 kDa secretory proteins.

Inducers of IFN Genes

Most IFNs are induced in response to a pathogen or danger signal(s). These signals include viral and cellular antigens, viral genomic nucleic acids or their replication intermediates, bacterial cell wall products such as LPS, lipids, proteins like flagellin, nucleic acids, radiation damage, DNA-damaging drugs like the anthracycline antibiotics, parasite DNAs and their cell constituents, non-DNA-damaging drugs like Imiquimod, and 5,6-Dimethylxanthenone-4-acetic acid (DMXAA) and modified cellular nucleic acids (**Table 1**). Most potent among these are the viral nucleic acids that is, single-stranded (ss) and double-stranded (ds) RNAs, RNA-DNA hybrids (retroviruses), endogenous retroviral nucleic acids, retro-transposon elements, and viral DNAs, along with synthetic nucleic acids like poly I:C and poly dI:dC. The signaling pathways that induce IFN-β have been well worked out using several experimental models (see below). The most commonly shared transducers of these signals are: Tumor-Necrosis Factor (TNF) Receptor-Associated Factor (TRAF) family member-Associated NF-kB activator (TANK)-Binding Kinase 1 (TBK1) and IFN-gene Regulatory Factor 3 (IRF3). Finally, basal IFN-β production under physiological conditions is induced by the commensal microbial flora.

☆*Change History:* August 2016. DV Kalvakolanu, SC Nallar and S Kalakonda has made changes to the entire manuscript, text, figures and tables. They have completely rewritten this chapter and added new sections.
This is an update of Dhananjaya V Kalvakolanu, Ernest C. Borden, Interferons: Cellular and Molecular Biology of Their Actions, In Encyclopedia of Cancer (Second Edition) edited by Joseph R. Bertino, Academic Press, 2002, Pages 511–521.

Table 1 The ligands and effectors of PRRs

PRR	*Ligand*	*Source of Ligand*	*Effector(s) induced*
TLRs			
TLR1	Multiple triacyl lipopeptides	Bacteria	Cytokines
TLR2	Peptidoglycans, Triacyl lipopeptides, Hemagglutinin, Porins	Bacteria, viruses, parasites, self	Cytokines
TLR3	dsRNA, ssRNA, Poly A:U, Poly I:C	Viruses	Cytokines, type I IFNs
TLR4	LPS, Mannan, Envelope proteins	Bacteria, viruses, self	Cytokines, type I IFNs
TLR5	Flagellin	Bacteria	Cytokines
TLR6	Multiple diacyl lipopeptides	Bacteria, viruses	Cytokines
TLR7	ssRNA, Imidazoquinoline	Viruses, bacteria, self	Cytokines, type I IFNs
TLR8	ssRNA, Small synthetic compounds	Viruses, bacteria, self	Cytokines, type I IFNs
TLR9	CpG-DNA, dsDNA	Viruses, bacteria, parasites, self	Cytokines, type I IFNs
TLR10	Bacterial lipopeptides	Bacteria	Cytokines
NLRs			
NOD1	iE-DAP(PGN)	Bacteria	Cytokines
NOD2	MDP(PGN)	Bacteria	Cytokines, type I IFNs
RLRs			
RIG-I	Short dsRNA	RNA viruses, DNA viruses	Type I IFNs, cytokines
MDA5	Long dsRNA	RNA viruses	Type I IFNs, cytokines
LGP2	Unknown	RNA viruses	Reduced IFN-response
CDSs			
AIM2	dsDNA	DNA viruses	IFNs, cytokines
DNA-PK	dsDNA	DNA viruses	IFNs, cytokines
cGAS	dsDNA	DNA viruses	IFNs, cytokines
DHX36	dsDNA	DNA viruses	IFNs, cytokines
STING	dsDNA	DNA viruses	IFNs, cytokines
DHX9	dsDNA	DNA viruses	IFNs, cytokines
DAI	dsDNA	DNA viruses	IFNs, cytokines
IFI16	dsDNA	DNA viruses	IFNs, cytokines
LRRF1P1	dsDNA	DNA viruses	IFNs, cytokines

Abbreviations: AIM2, Absent in melanoma 2; CDS, Cytosolic DNA sensors; cGAS, cyclic-GAMP synthase; CpG DNA: DNA containing unmethylated Cytosine in CG repeates DAI, DNA - dependent activator of IRFs; DHX, DEAH box helicase; DNA-PK, DNA dependent protein kinase; dsDNA, double stranded DNA; dsRNA, double-stranded RNA; iE-DAP,gamma-D-glutamyl-meso-diaminopimelic acid; IFI16, Interferon gama inducible protein 16; LPS, lipopolysaccharide; LRRF1P1, Leucine rich repeat (in FLII) interacting protein 1; MDP, muramyldipeptide; NLR, NOD-like receptor; NOD, nucleotide binding oligomerization domain; PGN, peptidoglycan; PRR, pattern recognition receptor; RLR, RIG-I-like receptor; ssRNA, single-stranded RNA; STING, Stimulator of interferon genes; TLR, *toll*-like receptor.

Signal Transduction Pathways That Induce IFN Genes

At steady state, low levels of IFNs are produced in vivo owing to the microbiome. Autocrine loop of IFN production provides a signal to maintain basal expression of some IFN-stimulated genes (ISGs), for example STAT1. Upon encountering an infection, IFN levels are further induced through *de novo* transcription. Following their synthesis IFNs are secreted into the extracellular environment to suppress the spread of pathogens. Infectious pathogens are surveyed by specific receptors. The pattern recognition receptors (PRRs) monitor extracellular, endosomal and cytosolic compartments for signatures of pathogen-associated molecular patterns (PAMPs), danger-associated molecular patterns (DAMPs) and non-self molecules to activate innate immune responses, which subsequently collaborate with the acquired immune response system to protect the host (**Table 1**). Four major families of receptors, the Toll-like receptors (TLRs), RIG-I like receptors (RLRs), cytosolic DNA sensors (CDSs) and NOD-like receptors (NLRs) act as sentinels to sense the danger. Plasmacytoid Dendritic Cells (pDCs) produce large quantities of type I IFNs upon engagement of TLR7 and TLR9, which detect viral or bacterial RNA and DNA molecules, respectively, that have been endocytosed or sequestered through autophagy. Our current understanding of IFN gene induction primarily comes from the IFN-β gene. The IFN-β gene is regulated by a complex enhancer that binds multiple transcription factors including NF-kB (p65/50), IRF3, c-Jun and ATF2. Of these, IRF3 is the most critical one, which undergoes signal-induced phosphorylation. IRF3 then binds to the critical IFN-gene Regulatory Element (IRE) found in IFN-β gene promoter as a dimer. IRF3 belongs to the IRF family that includes 10 structurally-similar but genetically distinct transcription factors. Virus infection, the most common stimulus, causes the activation of transcription factors NF-kB and IRF3. Following a typical RNA virus infection, the viral genomic RNA is released into the cytosol. Such RNA is readily recognized by the RNA helicases Retinoic acid Inducible Gene-I (RIG-I, also known as DDX58) or Melanoma differentiation antigen-5 (MDA-5, also known as IFIH1). These two proteins with another protein LGP2 (also known as DHX58) comprise the RLRs. LGP2 contains a RNA binding domain but lacks the caspase-recruitment domain (CARD) and is believed to act as a negative regulator of RIG-I and MDA-5 induced IFN synthesis. LGP2 dimerizes with MDA5 in some cells for positively regulating the IFN-β gene. Studies with

Lgp2-/- mice suggest that it may also act as a positive regulator of IFN induction in some tissues. The RLR proteins, RIG-I and MDA5, contain two N-terminal CARDs, a central DEAD box helicase/ATPase domain, and a C-terminal regulatory domain. They are localized to the cytoplasm and are essential sensors of cytosolic RNAs. The RNA-bound RIG-I or MDA-5 then associates with a mitochondrion associated protein MAVS (also known as IPS-1). Following this, MAVS recruits a molecular complex consisting of TRAF3-TANK-NAP1 proteins, which in turn recruits the critical serine/threonine kinase TBK1. TBK1 then phosphorylates IRF3, which forms a dimer that migrates to the nucleus and stimulates transcription of IFN-β gene (Fig. 1). Multiple sites on IRF3 are phosphorylated (S^{385}, S^{386}, S^{396}, S^{398}, S^{402}, T^{404}, S^{405}) that induce its transcriptional activity. A majority of these sites are present in the transcription activation domain (TAD) of IRF3 and are required for optimal transcription.

In the case of other viruses that undergo endosome-mediated internalization and de-capsidation, the viral nucleic acids released into the endosomal lumen are sensed by the resident TLRs viz., TLR3 (binds viral dsRNA), TLR7 and TLR8 (bind viral ssRNA) and TLR9 (viral DNA). These TLRs recruit the intracellular adaptors MyD88, TRIF, TRAM, which then serve as docking sites for TRAF3. The latter then binds and stimulates TBK1. Notably, the endosomal TLRs -7, -8, and -9 preferentially use MyD88, whereas TLR3 employs TRIF as intracellular adaptors. As described above TBK1 phosphorylates IRF3 to stimulate IFN-β gene expression (Fig. 1). Interestingly, the tumor suppressive phosphatase PTEN promotes IRF3 import into the nucleus through a removal of an inhibitory phosphorylation at the S^{97} residue of IRF3.

The non-self or viral dsDNA are sensed by multiple CDSs, amongst which is a nucleotidyl transferase, cGAS, that generates an unusual second messenger, cyclic GAMP (cGAMP), consisting of Guanosine and Adenosine linked by a characteristic 2′-3′ phosphodiester bond. cGAMP binds to an endoplasmic reticulum (ER)-resident protein, STimulator of INterferon Genes (STING; also known as ER IFN Stimulator (ERIS), Transmembrane Protein 173 (TMEM173)). Following cGAMP binding, STING moves into a peri-nuclear endosome, after passing through the Golgi apparatus, where it recruits TBK1 to stimulate IRF3 phosphorylation.

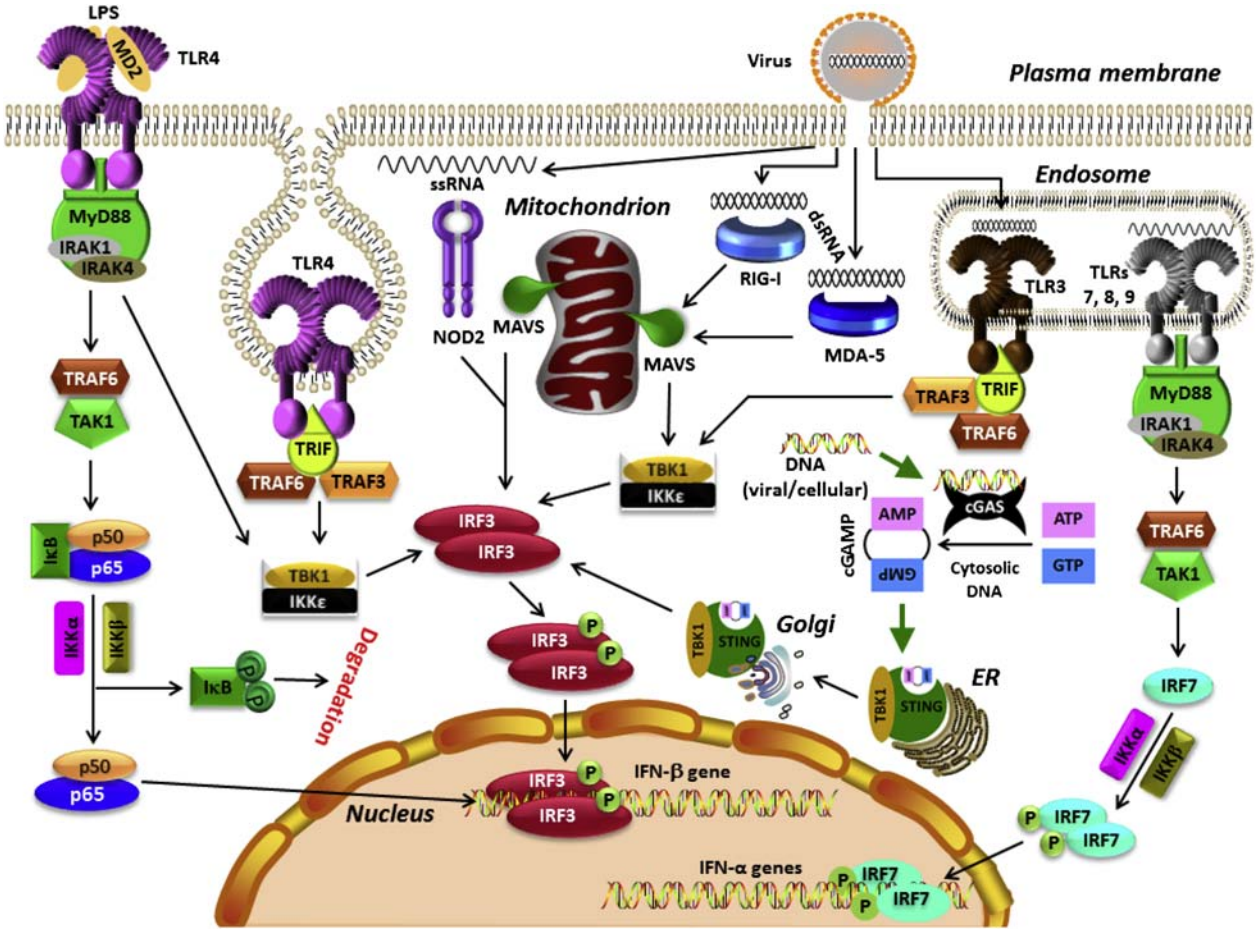

Fig. 1 Signal transduction pathways that induce type I IFNs. A number of exogenous PAMPs are recognized by resident receptors in the plasma membrane, endosome, cytoplasm, non-self nucleic acids (derived from the endogenous retrotransposons) and sensed as danger leading to the upregulation of IFN-β, the first responder cytokine. TBK1 (a signal transducing kinase) and IRF3 (a transcription factor) play a central role in these responses. IRF7 is a major inducer of IFN-α genes. IKK: IkB kinase; LPS: Lipopolysaccharide, a cell-wall phosphoglycolipid synthesized by bacteria; MAVS: Mitochondrial Anti-viral Signaling Protein (also known as IFN-β Promoter Stimulator 1(IPS-1), Virus-Induced Signaling Adaptor (VISA)); NOD2: Nucleotide-binding Oligomerization Domain-containing 2; TRIF: TIR domain-containing adaptor inducing IFN-β.

Apart from cGAS, many other cytoplasmic molecules such as DAI, DDX41 and IFI16 can sense DNA and stimulate STING to activate the TBK1-IRF3-dependent pathway. IFI16 is also an ISG. LRRFIP1 is another molecule that activates IRF3-IFN-β axis in a STING-independent but β-catenin-dependent manner. Two other cytosolic DNA sensors, DHX9 and DHX36, activate IRF7 in a MyD88-dependent manner to induce type I IFNs. Lastly, Ku70, another DNA sensor activates IRF7 and IRF1 to induce type I IFNs (**Fig. 1**).

In the classical TLR4-driven pathway, bacterial LPS binds to the extracellular receptor portion, which recruits the cytoplasmic adaptor molecules MyD88 and TRIF. The former recruits IL-1 Receptor-Associated Kinase-1 (IRAK1), which then activates the NF-kB pathway. The latter activates the TBK1 complex consisting of TRAF3-TANK-TBK1 proteins. TBK1 then phosphorylates IRF3 to stimulate IFN-β gene expression (**Fig. 1**).

The IFN-α proteins are primarily produced by pDCs and macrophages in high quantities. These genes are turned on in response to virus infection through IREs in their enhancers, to which IRF7 homodimers or IRF7: IRF3 heterodimers bind and regulate gene expression. IRF7 is an ISG and it amplifies the initial IFN signal further by inducing transcription of IFN-α genes. IRF7 resides in the cytoplasm at steady state and upon cytosolic RLR stimulation, it undergoes serine phosphorylation at the C-terminus, which permits it migration to the nucleus and induction of type I IFN genes. This is a feed-forward amplifying mechanism that explains the priming effect of IFN on its own synthesis (**Fig. 1**). In contrast to most cell types, pDCs constitutively express IRF7, enabling these cells to rapidly produce high levels of IFN-α and IFN-λ1 following virus infection.

Type III IFNs (IFN-λ) are induced by a number of RNA and DNA viruses. It is generally believed that all type I IFN inducers are capable of inducing these IFNs. However, type III IFNs are expressed in a tissue-restricted manner. Human IFN-λ1 and IFN-β genes are transcriptionally regulated in a similar manner, that is, they are controlled by IRF3, whereas IFN-λ2-4 genes, like most IFN-α genes, are dependent on IRF7. In humans, either IFN-β or IFN-λ1 can prime cells for virus-induced IFN-α and IFN-λ2-4 synthesis by upregulating IRF7 levels.

IFN-γ

The human IFN-γ gene is located on chromosome 12q14. It is expressed and induced only in cells of immune system such as antigen-activated T cells, NK cells, NKT cells and DCs. LPS and certain viral infections induce IFN-γ indirectly. Among cytokines, IL-12 and IL-18 are potent inducers of IFN-γ. Calcium ionophores like ionomycin and phorbol esters are also known to induce IFN-γ. Transcription factors Stat4, Runx3, and T-bet, and epigenetic factors have been implicated in the transcriptional regulation of IFN-γ gene. A constantly low level of IFN-γ is produced by NK cells owing to the action of transcription factors EOMES and T-bet. IL-12 and IL-18 employ STAT4 and NF-kB for inducing IFN-γ gene, respectively. Recent studies show that a long non-coding RNA, *Tmevpg1*, coded by the opposite strand of IFN-γ gene, positively regulates IFN-γ gene expression. However, *Tmevpg1* still requires transcription factors STAT4 and T-bet for inducing IFN-γ. Upon its synthesis IFN-γ forms a dimer. The NLRs upon engaging with bacterial peptidoglycan or viral components form a complex with an adaptor protein ASC and caspase-1. The latter, a cysteine protease, cleaves the inhibitory peptide from IL-18 precursor releasing the mature IL-18.

IFN Receptors

IFNs bind to cell surface receptors for exerting their biological effects. There are three major receptors in mammals: type I, type II and type III. A typical IFN receptor is constituted by two distinct subunits, coded by separate genes. Despite differences in their ligand preferences, genes coding for the subunits of type I (*IFNAR1*, *IFNAR2*), type II (*IFNGR2*) and type III (*IFNLR2* or *IL10RB*) are all clustered on human chromosome 21q22.1, suggesting their common evolutionary origin and a possible functional collaboration. Exceptionally, the *IFNGR1* is located on human chromosome 6q23.3. Almost all cells express functional type I and type II receptors, whereas the type III receptor is most abundantly expressed by epithelial cells. As mentioned above type I IFNs bind to a well characterized heterodimeric receptor that is comprised of a low-affinity IFN-α receptor subunit 1 (IFNAR1) and a high-affinity receptor subunit 2 (IFNAR2). The *IFNAR2* gene codes for three protein isoforms via exon-skipping, alternative splicing and differential usage of polyadenylation sites. The most commonly referred IFNAR2 is derived from the *IFNAR2c* transcript, the longest isoform with an intact intracellular domain and is fully competent to transduce signals. A shorter membrane bound form lacking the intracellular signaling domains is derived from the *IFNAR2b* transcript. A soluble IFNAR2a protein is similar to IFNAR2b but it has additional 11 amino acids in its carboxyl terminus. IFNAR2a and IFNR2b are generally considered as dominant negative inhibitors of type I IFN receptor-driven signaling. The type I IFN receptor is quite plastic as it interacts with nearly 17 different ligands to exert its biological effects. All type I IFNs bind to their receptor as monomers.

The type II IFN receptor (IFNGR) is exclusively used by IFN-γ. It is composed the ligand-binding IFNGR1 and the signal-transducing IFNGR2 subunits. Since IFN-γ exists and binds to the receptor as a dimer, IFNGR is a functional tetramer, that is, two each of IFNGR1 and IFNGR2 subunits. A ligand-induced assembly of the IFNGR complex initiates signal transduction.

The type III IFN receptor (IFNLR) is a very unique heterodimer that is comprised of the ligand-binding IFNLR1 and the signal-transducing IFNLR2 subunits. The latter subunit, also known as IL10RB, is also employed by IL-10, IL-22 and IL-26 for signal transduction. Like the type I receptor, the type III receptor engages with monomeric IFN-λs. Interestingly, even though the receptors and their ligands are structurally and genetically distinct, both the type I and type III IFN receptors engage similar intracellular signal transduction components (see below), suggesting a co-evolution of these molecules. Despite this similarity, neither type I receptor

engages IFN-λs nor type III receptor engages type I IFNs under physiological conditions. Tissue-restricted action of type III IFNs is so far the most important difference between type I and type III IFNs. Expression of IFNLR1 is restricted primarily to epithelial cells and some specific subsets of immune cells, which explains its tissue tropism. Fibroblasts and endothelial cells do not respond to IFN-λs, owing to a very low level of IFNLR1.

IFN-Induced Signal Transduction Pathways

Once engaged with their receptors, multiple ISGs are induced by IFNs with different kinetics. A variety of signaling pathways are employed for inducing ISGs. One of the best understood pathways leading to ISG induction is the Janus tyrosine kinase (JAK)-Signal transducer and activator of transcription (STAT) pathway. JAKs are non-receptor tyrosine kinases characterized by their conserved JAK-homology (JH) domains and two protein kinase domains (JH1 and JH2), only one of which (located in JH1 domain) is enzymatically functional (Fig. 2). The JH2 domain is a 'pseudokinase', for it lacks critical residues required for catalysis. Because of an analogy between two protein kinase domains of JAKs and the mythical two heads of Janus, the Roman god of gateways, these are known as Janus Kinases. A Src homology 2 (SH2) domain, present within JH3 and JH4 domains, allows JAKs to bind specific phospho-tyrosine containing motifs. JH5-JH7 domains form the FERM domain, which target JAKs to membrane-resident receptors. The acronym FERM stands for band 4.1 protein, Ezrin, Radixin and Moesin, respectively, the original four proteins in which this domain was found. FERM domain-containing proteins localize at the interface between the plasma membrane and the cytoskeleton. There are 4 JAKs: TYK2, JAK1, JAK2 and JAK3 coded by distinct genes in the mammalian genome. Through a set of elegant studies that involved derivation of IFN unresponsive cell mutants and genetic complementation, the laboratories of George Stark, Sandra Pellegrini and Ian Kerr provided the first unequivocal evidence for the role of JAKs in IFN signaling pathways. Following this landmark discovery, many labs showed that various cytokines and their receptors utilize various combinations of JAKs to transduce signals. Subsequent to ligand engagement with the receptors, JAKs not only undergo autophosphorylation but also phosphorylate the receptor subunits and the STATs each at a critical tyrosine residue.

STAT proteins constitute a family of 7 structurally-similar but genetically-distinct gene products (STAT1, STAT2, STAT3, STAT4, STAT5A, STAT5B and STAT6) which function as signal transducers and transcription factors. At steady state, these proteins are dormant in the cytoplasm. Following ligand engagement these proteins are tyrosyl phosphorylated at the receptor by JAKs, form dimers, and migrate to the nucleus to stimulate the transcription of target genes. The first evidence for the role of STAT proteins

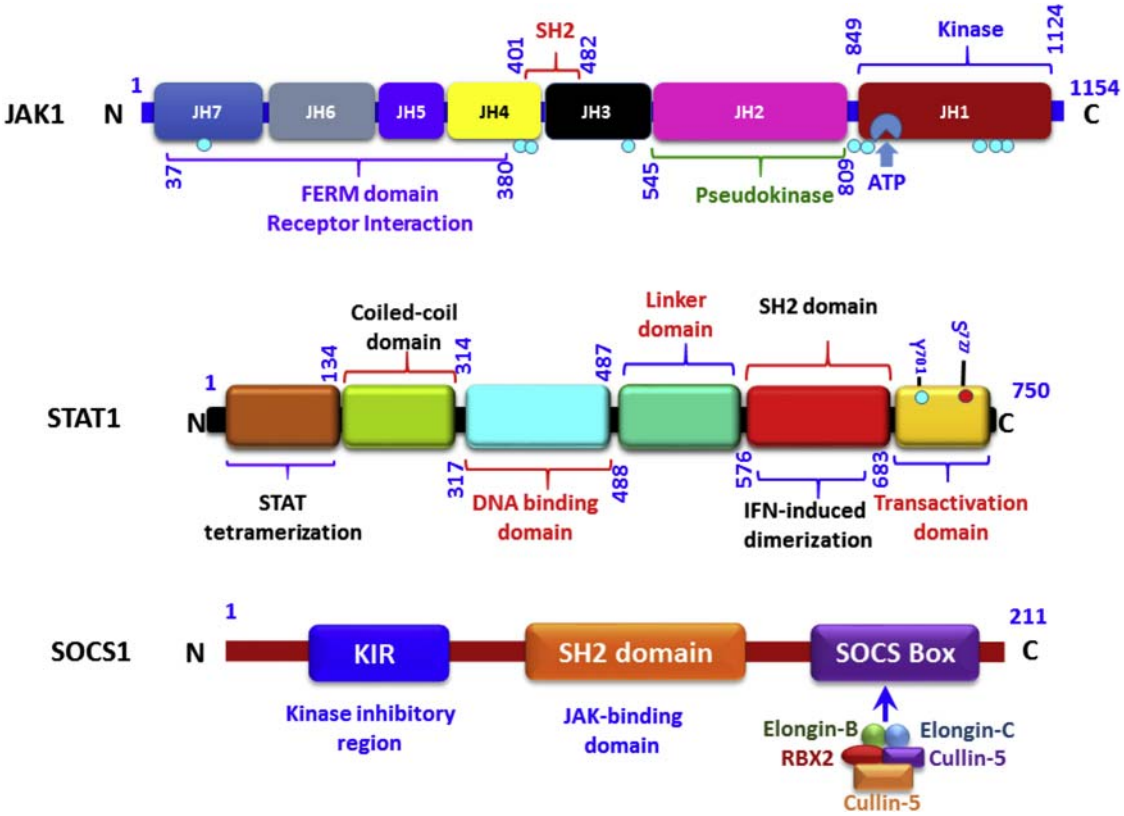

Fig. 2 Modular representation functional domains in JAK1, STAT1 and SOCS1 proteins. N: Amino terminal; C: Carboxyl terminal. Numbers indicate residues in primary sequence. Blue and red circles represent tyrosine and serine/threonine residues, respectively, that undergo phosphorylation.

(STAT1 and STAT2) in IFN signaling pathways came from the laboratory of James Darnell. The critical role of these STATs was established through genetic complementation of IFN unresponsive cell mutants generated by the Stark and Kerr laboratories. These ground breaking studies paved the way for the discovery of the other STATs and their roles in driving responses initiated by ~50 different cytokines and growth factors. A typical STAT (Fig. 2) is characterized by an N-terminal oligomerization domain, a coiled-coil domain, a central DNA binding domain, a linker domain, an SH2 domain and a C-terminal TAD. Sandwiched between the SH2 domain and TAD is a critical tyrosine, which undergoes JAK-induced phosphorylation and allows STAT dimerization. In the case of STAT1 and STAT2 such tyrosine (Y) residues are located respectively at 701 and 690 positions in their primary sequence. In addition to this, STAT1 undergoes phosphorylation at a serine residue (S^{727}) in its TAD, which occurs independently of JAKs but is required for transcriptional activation. Mutation of these critical Y and/or S residues blunts STAT-dependent transcriptional responses. That said, some recent studies show that phosphotyrosine-deficient STAT1 (notated as U-STAT) also activates a set of genes in the steady state.

In the type I and type III IFN signaling pathways (Figs. 3 and 4), TYK2 and JAK1 are essential for driving anti-viral responses and gene expression. In the case of the type I IFN receptor, TYK2 and JAK1 are associated with IFNAR1and IFNAR2 subunits, respectively, in the steady state. Without such pre-association, IFNAR1 becomes unstable on the cell surface. Ligand binding induces dimerization of the receptor subunits and juxta-positioning of TYK2 and JAK1, which permits cross-phosphorylation (required for activation) and then phosphorylation of a critical Y^{466} residue of IFNAR1 (Fig. 3). Phosphorylated Y^{466} serves as a docking site for the SH2 domain of STAT2, which permits the phosphorylation of STAT2 at its Y^{690} residue. Tyrosyl phosphorylated STAT2 then serves as a binding site for the SH2 domain of STAT1 and permits its phosphorylation at Y^{701}residue. The STAT1:STAT2 complex dissociates form the receptor, and the heterodimer migrates to the nucleus to induce transcription of ISGs. In the type I and type III signaling pathways, IRF9 (also known as p48 or ISGF3γ), a non-STAT protein, is also required for DNA binding and transcriptional activation by the STAT1:STAT2 dimer. The STAT1/STAT2/IRF9 complex (popularly known as the IFN-stimulated gene factor 3 or ISGF3) binds to the IFN-stimulated response elements (ISRE) found in the promoters of many ISGs. ISRE, a 15-bp long conserved element with the following canonical sequence 5′-AGGTTTCNNTTTCCT-3′, exhibits remarkable similarity to the IRE (found in the IFN gene enhancers) at its core. As a result, ISRE could drive IRF-driven transcription, independently of the JAK-STAT pathway, under the influence of dsRNA, a known inducer of IFN genes. Such response neither requires IFN synthesis nor IFN receptor. This redundancy allows an efficient management of innate anti-pathogen responses under situations where dysfunctioning of JAK-STAT pathway or the receptors occurs. In some cells, IFN-α also activates the tyrosyl phosphorylation of STAT3. Phosphorylated STAT3 forms a complex a transcriptional suppressor Sin3A, which inhibits induction of direct STAT3 target genes by promoting deacetylation of STAT3 and histones. This mechanism prevents the development of pro-inflammatory diseases, and dampening of IFN-induced anti-viral gene expression.

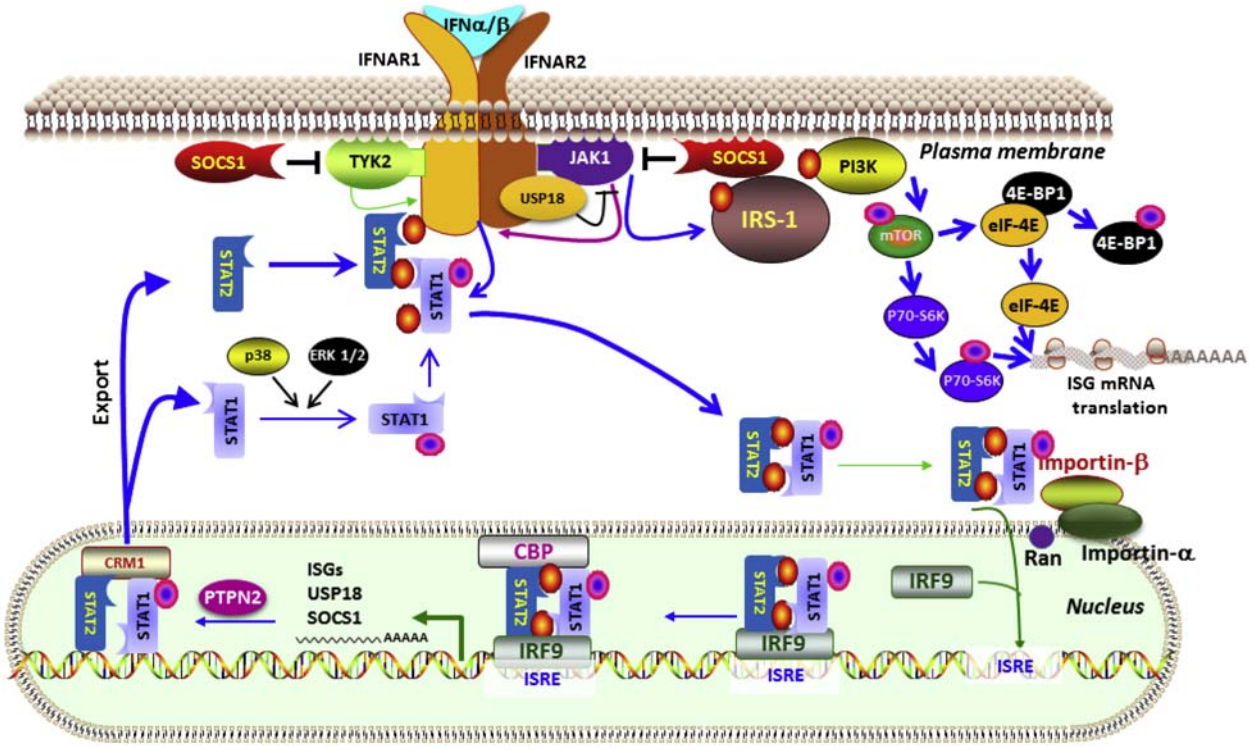

Fig. 3 Type I IFN signaling pathways. CBP: CREB-binding protein (a histone acetyl transferase that serves as a transcriptional co-activator: CRM1: Chromosome Region Maintenance 1 Homolog (also known as Exportin 1).

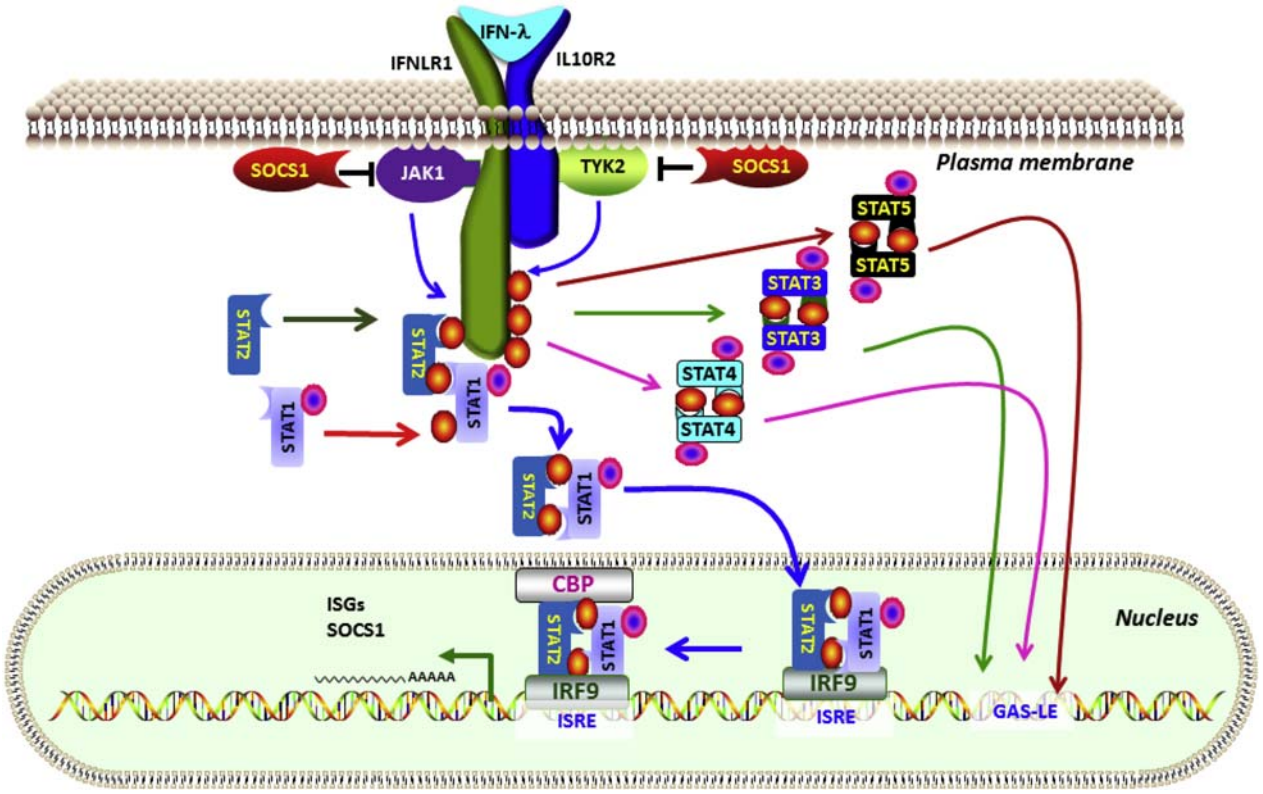

Fig. 4 Type III IFN signaling pathways. GAS: gamma-IFN activated site; GAS-LE: GAS-like elements.

Type III IFN signaling occurs in a very similar manner to that of type I IFN. IFNLR1 and IFNLR2 are pre-associated with JAK1 and TYK2 (Fig. 4). Ligand-induced aggregation of the receptor causes JAK activation and ISGF3 formation as described above. In addition, type III IFNs induce STAT3, STAT4 and STAT5, whose biological relevance is unclear.

IFN-γ-Induced JAK-STAT Signaling

In contrast to IFN-α, IFN-γ binding to its receptor primarily activates STAT1. At steady state IFNGR1 and IFNGR2 subunits of the receptor are pre-associated with JAK1 and JAK2, respectively. Ligand-induced aggregation of receptor leads to JAK activation (JAK2 activating JAK1 first). JAK1 then phosphorylates IFNGR1 on the critical Y^{440} residue (Fig. 5). This then provides a docking site for the SH2 domain of STAT1. STAT1 is then phosphorylated at its Y^{701} residue. This then serves as a docking site for a second STAT1 molecule, permitting its Y^{701} phosphorylation. STAT1:STAT1 homodimers then dissociate from the receptor, translocate to the nucleus and bind to the Gamma-IFN activated sites (GAS) of IFN-γ stimulated genes. Mutant STAT1 lacking theY^{701} residue, cannot translocate to the nucleus when stimulated with IFN-γ. STAT1 dimers are imported into the nucleus via nuclear pores where a GTP-binding protein Ran plays an important role. As already mentioned STAT1 also undergoes S^{727} phosphorylation, catalyzed by different kinases. Depending on the cell type, Mitogen-activated protein kinases (MAPKs) like the extracellular signal-regulated kinase (ERK) and p38MAPK, cyclin-dependent kinase 8 (CDK8) and Ca^{+2}/Calmodulin-dependent kinase II have been implicated in this process. IFN-γ also activates STAT3 and STAT4 proteins under certain circumstances. In fact, the IFN-γ-JAK-STAT4 pathway appears to play an important role in warding off certain viral infections.

Termination of JAK-STAT Signaling

Activated STAT1 is not retained in the nucleus more than 1 h in normal cells. A nuclear phospho-tyrosyl phosphatase TC-PTP has been shown to dephosphorylate STAT1. STAT1 is exported back to the cytoplasm and this terminates STAT1-stimulated gene expression. Two different proteins, one that targets JAKs and another that inhibits STAT1 have been reported. Upon nuclear entry and DNA binding, STAT1 induces several mRNAs. One of these mRNAs codes for SOCS1, the founding member of a large family ($n = 20$ members) of proteins containing Suppressor of Cytokine Signaling (SOCS) box motifs. SOCS1 protein has three functional

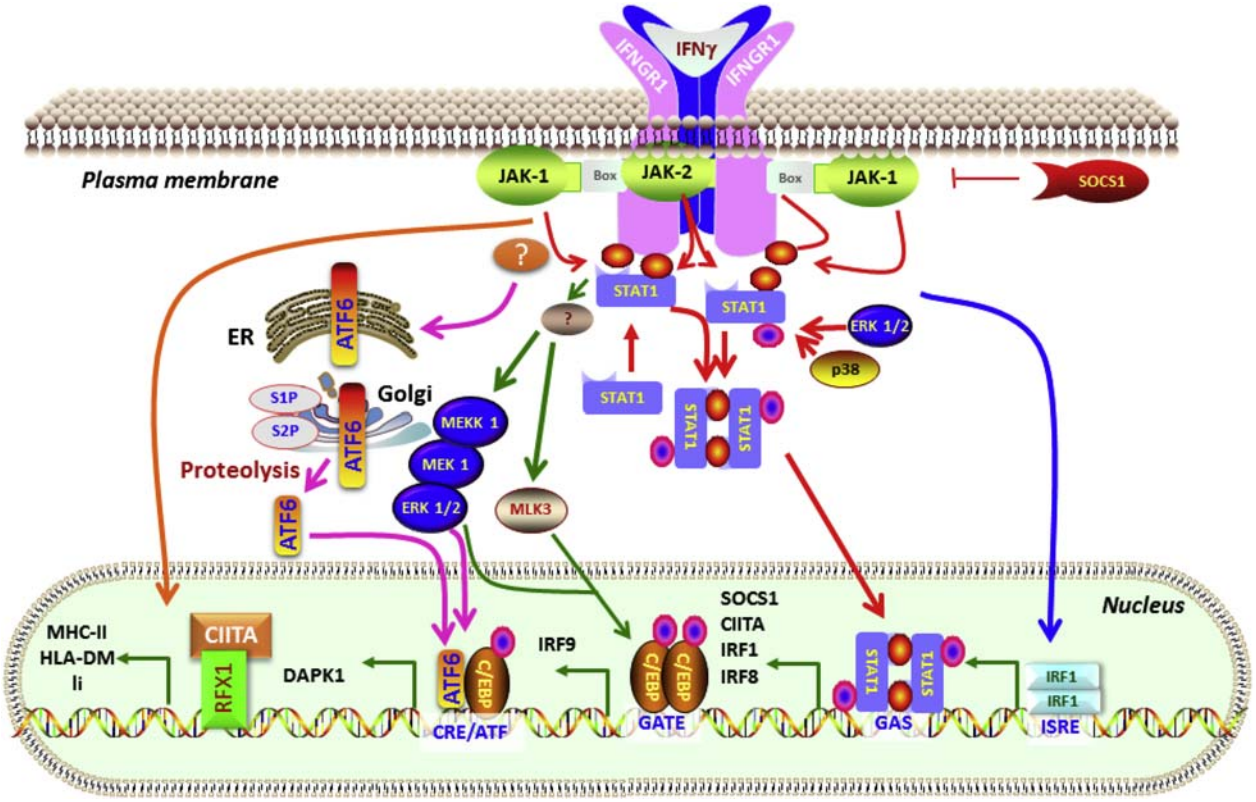

Fig. 5 Type II IFN signaling pathways. GATE: gamma-IFN activated transcriptional element; MLK3: Mixed Lineage Kinase-3; MEKK1: Mitogen-activated protein kinase kinase kinase 1; MEK1: Mitogen-activated protein kinase kinase 1; S1P: Site 1-specific protease; S2P: Site 2-specific protease. CRE: cAMP response element; ATFS: ATF6-binding site; RFX: Regulatory factor X1 (a transcription factor that binds to X-box elements in the MHC class II gene enhancers).

domains (Fig. 2): an N-terminal kinase inhibitory region (KIR), a central SH2 domain and c-terminal SOCS box. The SH2 domain of SOCS protein binds to phosphorylated JAKs, whereas the KIR domain is inserted into the kinase pocket of JAKs to block their protein kinase activity. The SOCS box interacts with a complex consisting of elongin B, elongin C, cullin-5, RING-box-2 (RBX2) and E2 ligase. This allows them to function as E3 ubiquitin ligases and mediate the degradation of proteins that they associate with through their amino-terminal regions. As a result SOCS proteins target the entire cytokine-receptor complex, JAKs and SOCS protein themselves, for proteasome-mediated degradation. Consistent with its negative regulatory role, deletion of *Socs1* resulted in fulminant inflammation and pre-weaning death of mice. Inflammation in kidneys and livers of these mice were found. These phenotypes appear to be a result of uninterrupted IFN signaling, because mice lacking both *Ifng* and *Socs1* genes do not develop such pathologies. SOCS1 also interacts with IFNAR1 to terminate type I IFN-regulated gene expression. A second mechanism that blocks STAT1 activity is the blockade of its DNA-binding function by the Protein-inhibitor of activated STAT1 (PIAS1) via physical interaction. Since, loss of PIAS1 protein resulted in upregulation of a limited number of ISGs, this suggested that it may not be a universal negative regulator of IFN-induced JAK-STAT pathways.

The type I IFN-induced signaling is also negatively regulated by targeting the IFNAR1 subunit to ubiquitin-dependent lysosome-mediated degradation. The E3 ligase complex SCF (Skp1–Cullin1–F-box) initiates IFNAR1 poly-ubiquitylation via both Lys48- and Lys63-linked chains and its degradation. The Casein kinase-1α (CK-1α)-mediated phosphorylation of IFNAR1 at S^{535} residue plays a critical role in recruiting the SCF complex to the receptor. A priming phosphorylation at S^{532} residue by the pancreatic ER kinase is required before S^{535} can be phosphorylated by CK-1α. A second mechanism that negatively regulates IFN-α signaling is the IFN-induced expression of ubiquitin-specific peptidase 18 (USP18 or UBP43) in some cells. ISG15 is an ubiquitin-like IFN-inducible protein. ISG15 is conjugated to a number of cellular proteins, although the exact biological significance is unclear. USP18, an IFN-induced cysteine protease, specifically removes ISG15 from such modified proteins. However, the phenotypic alterations caused by *Usp18* deletion in the mouse have been dissociated from its ISG15-dependent mechanisms. USP18 displaces JAK1 from IFNAR2 subunit to terminate IFN signaling. Both type I and type III IFNs induce USP18 expression, indicating that this protein may also negatively regulate type III IFN receptors. The importance of the JAK-STAT signaling pathway and downstream transcription factors in host defenses against viral infection have been confirmed using gene knockout mice (Table 2).

Table 2 Phenotypes of knockout mice lacking IFN-signaling machinery

Gene	*Defects detected*
Ciita	Loss of antigen presentation, immunodeficiency
Ifnar1	Loss of anti-viral responses
Ifngr1/2	Susceptibility to bacterial infections and carcinogens
Irf1	Immunodeficiency and increased susceptibility to viral infections.
Irf2	Loss of anti-viral effects and B-cell proliferation
Irf5	Loss of anti-viral response; less susceptible to the development of SLE
Irf7	Loss of IFN-α/β expression and susceptible to viral infections
Irf8	Immunodeficiency and increased susceptibility to viral infections
Irf9	Loss of anti-viral responses and immune system defects
Jak1	Post-natal lethality, neuronal development defects
Jak2	Lack of hematopoiesis
Socs1	Death before weaning, fatty degeneration of the liver, hyper response to viral infection
Stat1	Loss of innate immunity and susceptibility to carcinogens
Stat2	Embryonic lethality
Tyk2	Defective NK cell responses

Notes: The complex phenotypes in *Jak1*, *Jak2* and *Tyk2* deficient mice are due to the fact that these kinases participate in signaling pathways driven by other cytokines.

Post-Transcriptional Regulation of Jak-Stat Signaling

MicroRNAs (miRNAs) are small non-coding RNAs processed from their precursor RNAs (200–300 nt). Mature miRNAs (~20 nt) can either induce the degradation of the target RNAs if their sequence matches perfectly to that of target protein coding transcripts or block the translation of the protein from the target RNA, if the homology is not perfect. Two miRNAs, *miR-155* and *miR-29a* block *SOCS1* and *IFNAR1* transcripts, respectively. SOCS1 inhibition increases IFN response, whereas IFNAR1 inhibition down modulates IFN signaling. Since *miR-155* and *miR-29a* can also affect many other targets in the cell, it should be noted that the effects on IFN signaling by these miRNAs can be multi-faceted.

Non-STAT Pathways That Regulate ISG Expression

Apart from the JAK-STAT pathway a collaborative pathway is induced by IFN-α. Activated TYK2 and JAK1 regulate tyrosine phosphorylation of insulin receptor substrate 1 (IRS1), which provides docking sites for the SH2 domains of the regulatory subunit (p85) of phosphatidylinositol 3 Kinase (PI3K). PI3K then activates the protein kinase mechanistic Target of Rapamycin (mTOR) which promotes downstream events leading to the initiation of mRNA translation (Fig. 3). mTOR stimulates ribosomal protein S6 kinase beta-1 (p70-S6K), which phosphorylates ribosomal protein S6 (RPS6), resulting in the initiation of mRNA translation. mTOR also regulates phosphorylation of the translational repressor eukaryotic translation-initiation factor 4E (eIF4E)-binding protein 1 (4E-BP1). Such phosphorylation results in its deactivation and subsequent dissociation from eIF4E, allowing the initiation of cap-dependent mRNA translation and enhances the expression of ISGs. Thus, this pathway appears to be an accessory to the transcription-activating JAK-STAT pathway, described above.

The pro-myelocytic leukemia zinc finger (PLZF) protein, coded by the *Zbtb16* gene, is essential for the expression of certain ISGs involved in anti-viral innate immune responses. PLZF, in contrast to its known gene-repressive function, acts as an inducer of gene expression in this case. PLZF binds to its putative sites in some ISG promoters, such as *Oas1g*, *CXCL10*, *Rsad2* (Viperin) and *Ifit2*. IFN-α failed to induce these genes in *Plzf* $^{-/-}$ mice. PLZF is phosphorylated at its S^{76} residue in a c-Jun N-terminal Kinase (JNK)-dependent manner in response to IFN-α. In contrast, FOXO3, a member of fork-head family of transcriptional regulators, inhibited type I IFN-induced responses by binding to its putative sites in certain ISG promoters and blocking their expression.

IFN-γ induces multiple non-STAT pathways for regulating gene expression. IFN-γ can also induce IRF1 and IRF8-driven expression of certain ISGs in myeloid compartments. The MHC class II gene is an indirect target of IFN-γ signaling. Its expression is dependent on a critical regulatory factor, the Class II Transcriptional Activator (CIITA). CIITA is an IFN-γ inducible gene that binds to the enhancer of MHC class II, HLA-DM and li genes to promote their expression (Fig. 5). CIITA expression is induced by STAT1 and IRF1. Mutations/loss of expression of CIITA causes the 'Bare-lymphocyte syndrome' a severe immunodeficiency in humans.

IFN-γ also induces the expression of the IRF9 gene through a unique element, GATE. Although GATE exhibits some partial homology to ISRE, it does not bind ISGF3 or IRF proteins. Instead it binds C/EBP-β, a member of the CAAAT/enhancer-binding protein (C/EBP) family of transcription factors. In response to IFN-γ, a MEKK1–MEK1–ERK1/2 pathway is activated, wherein the terminal enzymes ERK1/2 phosphorylate the C/EBP-β protein at a consensus motif in the regulatory domain. In addition, orphan MAPK, the mixed-lineage kinase 3 (MLK3) activates a dephosphorylation event at the N-terminal TAD of C/EBP-β, which is also required for optimal transcriptional activation (Fig. 5).

C/EBP-β also collaborates with another protein, activated transcription factor-6 (ATF6). At steady state, ATF6 exists as a precursor in the ER bound by its inhibitor BiP. ATF6 consists two major functional parts: (1) the N-terminal end, which hangs into the cytosol, serves as a transcription factor; and (2) the C-terminal end, which is in the ER lumen senses ER stress. Upon IFN-γ treatment, ATF6 undergoes ASK1–MKK3–p38MAPK-dependent phosphorylation and then migrates from the ER to the Golgi apparatus. In the Golgi it undergoes processing by the resident Site 1-specific protease (S1P) and Site 2-specific protease (S2P), which frees the N-terminal transcriptionally active part (mature form) from the C-terminal portion. The mature ATF6 protein translocates to the nucleus, where it associates with phosphorylated C/EBP-β and forms a transcriptional complex, to drive the expression of the death-associated protein kinase 1 (DAPK1), a major regulator of IFN-induced cell growth, apoptosis and autophagy (**Fig. 5**).

IFN-Inducible Genes

Nearly 5000 genes are induced by IFNs, depending on the type, dose, and cell type, species as identified by several microarray, RNA-seq and proteomic analyses. "Interferome", a web-based database that cures such data, is freely available to all investigators through the Monash University and Hudson Institute for Medical Research, Melbourne, Australia (http://www.interferome.org/interferome/home.jspx). Some of the well characterized genes and their mechanisms of action are shown in **Table 3**. Here, the mechanisms of actions of a few gene products that exert anti-viral effects are described. IFNs induce various ISGs that inhibit virus replication at various stages. The major well-defined anti-viral mechanisms include: (1) degradation of viral RNAs; (2) inhibition of viral protein synthesis; (3) prevention of viral uncoating or blockade of their localization in an infected cell (**Fig. 6**).

Table 3 Mammalian ISGs

Gene	*Function*	*Mechanism*
2′-5′ (A) synthetases	Anti-viral enzymes	Degrade viral RNA through synthesis of 2′-5′ $(A)_n$
ADAR	Inhibits viral replication	RNA editing of adenosine to inosine
APOBEC3C	Inhibits HIV replication	RNA editing cytosine deaminase
APOBEC3G	Inhibits HIV replication	RNA editing cytosine deaminase
β2-Microglobulin	Antigen presentation	Partner for MHC class I protein
CCL2 (MCP1)	Chemoattractant	Recruitment of Monocytes and leukocytes
CCL5 (RANTES)	Chemoattractant	Recruitment of Monocyte/lymphocytes
CH25H	Inhibits at early infectious cycle	Inhibits virus-host membrane fusion
CIITA	Transcriptional co-activator	Induces HLA/MHC Class II genes
CXCL10 (IP10)	Chemoattractant	Monocytes, natural killer and T-cell migration
DAPK1	Tumor suppressor	Induces apoptosis, and autophagy
DDX 60	Suppress viral replication	Increased RLR dependent signaling
FcγR1	Binds to IgG	Opsonization of microbes
IDO	Indoleamine 2,3 dioxygenase	Anti-parasitic/bactericidal
GBP1	Guanylate binding protein	Anti-viral/autophagy
GBP2	Guanylate binding protein	Anti-viral/autophagy
IGTP	GTPase	Anti-toxoplasma
IFI16	Transcription factor	Cell growth inhibition
IFIT1 (ISG56)	Blocks viral infection	Targets eIF3 to block viral IRES mediated translation
IFIT3/RIG-G	Antiviral activity	Protein-protein interaction
IFITM1	Blocks virus entry, e.g., Ebola & HCV	Alters kinetics of endosome acidification
IFITM2	Blocks virus entry, e.g., HIV-1	Increases non-specific protease activity
IFITM3	Blocks virus entry ,e.g., InfluenzaA, HIV-1	Unknown
IFITM5	Blocks virus entry	Unknown
NOS2 (iNOS)	Nitric oxide synthesis	Anti-microbial
IRGM	Macrophage Immunity-Related GTPase	Anti-bacterial/anti-protozoal
IRF1	Transcription factor/tumor suppressor	ISRE-mediated ISG expression, activates IRF3 & 7
IRF5	Transcription factor	Induces IFN-α genes; autoimmune SLE
IRF7	Transcription factor	Increased expression RIG-I and IFN-α genes
IRF8	Transcription factor	Transcription factor
ISG15	Promotes viral replication	ISGylation (Like Ubiquitination)
ISG20	Restricts viral infection	3′-5′ exonuclease activity
LRG47	GTPase	Anti-microbial/Anti-protozoal
MHC class I	Immune response	Antigen presentation
MHC class II	Immune response	Antigen presentation
MNDA	Transcription factor	Cell growth inhibition in association with p53
Mx1 (MxA)	Anti-viral GTPase	Traps incoming viral components
Mx2 (MxB)	Anti-retroviral activity/GTPase	Inhibits chromosomal integration
NOX2 (CYBB)	NAPH oxidase/ROS production	Anti-microbial/microbicidal

(Continued)

Table 3 Mammalian ISGs—cont'd

Gene	*Function*	*Mechanism*
PKR	Anti-viral Protein kinase	eIF2α phosphorylation/translation blockade
RIG-I (DDX58)	Inhibits RNA virus replication	Activates RLR signaling
RNaseL	Anti-viral endoribonuclease	2′-5′ (A) activated/promotes viral RNA degradation
PSCR1	Phospholipid scramblase	Apoptosis induction
PSMA2	Proteasome Subunit, Alpha 2	Protein degradation
PSMB8	Proteasome Subunit, Beta 8	Protein degradation
PSMB9/RING 12	Proteasome Subunit, Beta 9	Protein degradation
PSMB10	Proteasome Subunit, Beta 10	Protein degradation
PSMD8	Proteasome 26S Subunit, Non-ATPase, 8	Protein degradation
PSME1	Proteasome Activator Subunit 1	Protein degradation
SOCS1	Inhibitor of JAKs	Terminates JAK-STAT signaling
TAP1/RING4	Peptide Transporter	Antigen Processing
TGTP	GTPase	Anti-parasitic, anti-bacterial
TNFSF10/TRAIL	Ligand for cell death receptor DR2	Apoptosis
TRIM -5α	Inhibits Virus infection e.g. HIV-1	Disassembly of the capsid shell
TRIM-19 (PML)	Inhibits Virus infection	Ubiquitination, SUMOylation, ISGylation
TRIM-22	Inhibits Virus infection e.g. HIV-1	Ubiquitination, SUMOylation, ISGylation
TRIM-25	Inhibits Virus infection	Ubiquitination, Enhanced RIG-I activity
TRIM-56	Inhibits Virus infection	Ubiquitination, Activation of STING
USP-18	Ubiquitin-specific peptidase	Terminates JAK-STAT signaling binding to IFNAR
Viperin	Anti-viral activity	Alters membrane fluidity
WARS/IFP53	Tryptophanyl-tRNA Synthetase	Protein synthesis

Abbreviations: ADAR, RNA-specific adenosine deaminase; CH25H, cholesterol-25-hydroxylase; DDX, DExD/H box RNA helicase; eIF2α, eukaryotic initiation factor 2α; HCV, hepatitis C virus; HIV, human immunodeficiency virus; IFITM, IFN-inducible transmembrane; IRF, interferon regulatory factor; ISG, interferon stimulated gene; ISRE interferon-sensitive responsive element; Mx, myxovirus resistance; PKR, protein kinase R; RIG-I, retinoic acid inducible gene I; RLR, RIG-I like receptor; RNase L, 2-5A-dependent endoribonuclease latent form; TRIM, tripartite motif.

Notes: IFNs induce more than 5000 genes depending on the cell type. Only the gene products with confirmed biological activities are shown. This list includes both type I and type II IFN stimulated genes. There are no known genes that are regulated by type III IFNs only. Because of the similarity in their signal transduction pathways, it is likely that all type I IFN-induced genes are also type III IFN-inducible. This list does not include IFN-repressed genes. IFIT1, IFIT2 and IFIT3 are related at the sequence level but are functionally distinct. IFITM1, IFITM2, IFITM3 and IFITM5 are not related to IFIT proteins.

Anti-Viral Action Through Targeting Viral RNAs

Two mechanisms contribute to this of type action. In the first, IFN induces the expression of genes coding for a family of enzymes the 2′-5′ Oligoadenylate synthetases (OAS): OAS1 (40/46 kDa), OAS2 (69/71 kDa), OAS3 (100 kDa) and OASL (56/59 kDa). Although all 4 genes are IFN inducible, OASL is also directly induced by viral infection. The OAS1, OAS2 and OAS3 genes are clustered at human chromosome 12q24.1 and OASL at 12q24.2. These enzymes require dsRNA for their catalytic activity (**Fig. 6A**). Monomeric OAS1 protein is catalytically inactive. Upon dsRNA binding (viral RNAs) it tetramerizes to generate a super-activated enzyme that synthesizes an unusual class of oligonucleotides called, 2′-5′ oligoadenylate (2′-5′A) using ATP as substrate. In 2′-5′ A, nucleotides are linked by a 2′-5′ phosphodiester bond unlike the 3′-5′ linkage in DNAs and RNAs. The 2′-5′As then bind to a cognate domain of Ribonuclease L (RNaseL) to activate its nuclease activity. At steady state, RNaseL exists as a dormant monomeric endoribonuclease, with its N-terminal 2′-5′A-binding domain folded over the catalytic C-terminal domain, thus, preventing the ribonuclease activity. 2′-5′A binding to the N-terminus not only releases this inhibitory switch but also allows the dimerization of RNaseL, which dramatically increases its enzymatic activity, leading to the degradation of viral RNAs. RNaseL activity is extinguished by phosphodiesterases (PDEs) that destroy excessive 2′- 5′A, after the initial stimulation. RNaseL also generates additional dsRNA molecules through a destruction of viral RNA replication intermediates, which not only activate the RLR-dependent type I IFN synthesis but also amplifies the OAS-RNaseL loop to sustain the anti-viral effects over a prolonged period. Although RNaseL was classically described as an anti-viral enzyme, recent studies suggest that it also exerts potent anti-bacterial effects, partly through a control of phagocytosis. OAS2 and OAS3 proteins have 2 and 3 OAS domains, respectively, of which only one is enzymatically active in these proteins. These additional domain repeats are believed to recognize larger dsRNA molecules and present them correctly to the enzymatically-active domain. The OASL is unique for it not only lacks the characteristic enzymatic activity of this class but also possesses 2 ubiquitin like domains. As a result it cannot activate RNaseL, but can still exert anti-viral effects though its ubiquitin-like domains, suggesting a novel mechanism of action.

Another IFN-inducible protein that potentially contributes to the anti-viral activity is the adenosine deaminase activated by dsRNA (ADAR). This enzyme, upon activation by dsRNA, edits such RNAs to allow the production of new proteins or make the RNA unstable and target them for destruction (**Fig. 6B**). In the humans, two distinct genes *ADAR* and *ADARB1*, code for proteins with enzyme activity and their expression level is controlled in a tissue-specific manner. The *ADAR* gene, produces two isoforms of

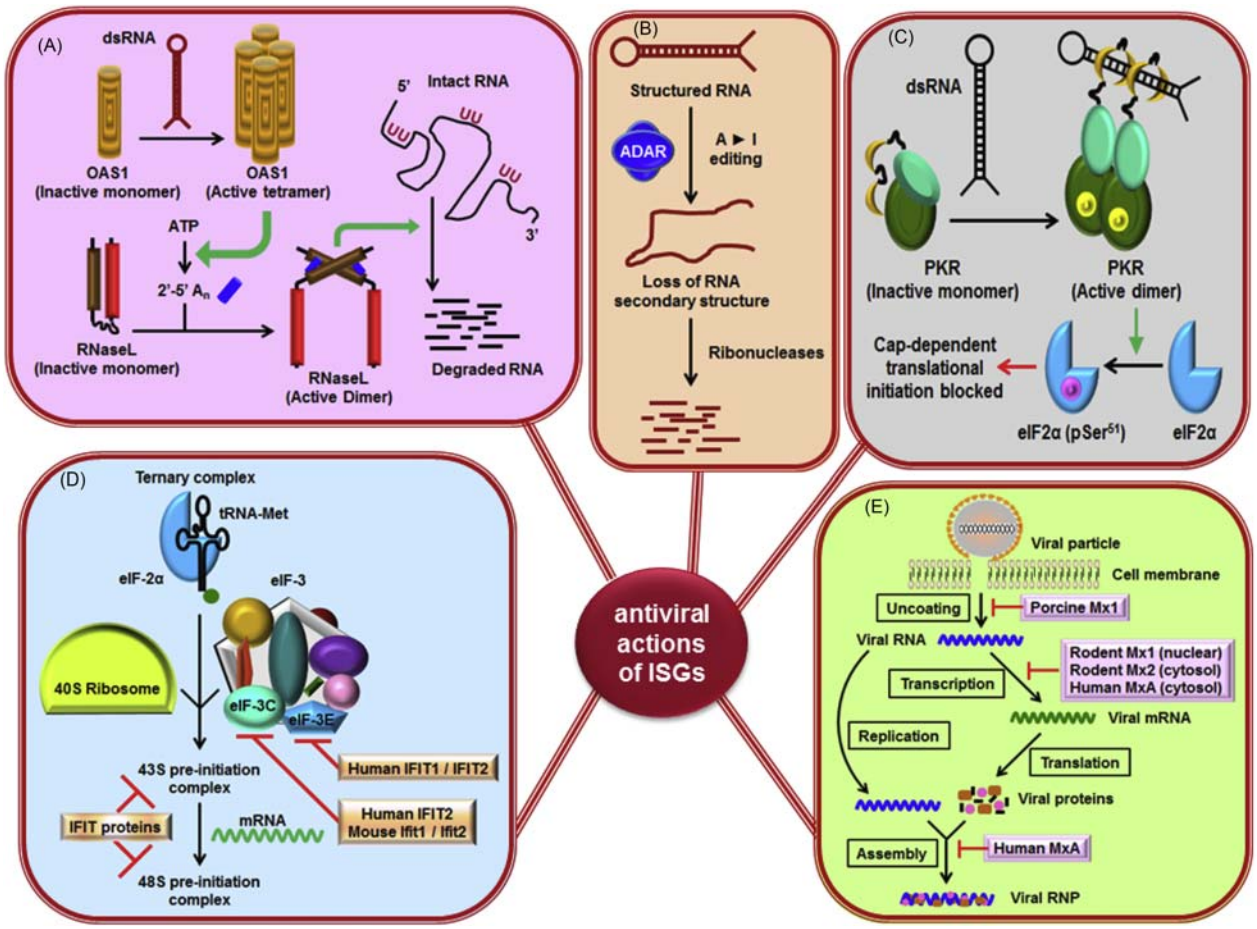

Fig. 6 Anti-viral actions of 5 different ISG pathways are shown. Most of these pathways control viral replication through post-transcriptional and post-translational mechanisms.

110 kDa (house-keeping form) and 150 kDa (IFN-inducible form) due to upstream transcriptional initiation. The 110 kDa isoform is always present in the nucleus as it lacks a nuclear export sequence that is present in the 150 kDa isoform. ADARB1 is known to edit certain host mRNAs to generate proteome diversity as well as regulate splice site choice. ADARs bind to dsRNA through their N-terminal domain. The C terminus catalyzes the Adenosine to Inosine conversion in the target RNA. This enzyme has been suggested to act as an IFN inducer, which amplifies anti-viral activity. Activated ADAR has been suggested to modify viral RNAs, which are sensed as non-self by the RLRs leading to IFN synthesis.

Anti-Viral Action Through Inhibition of Viral RNA Translation

The Protein kinase-RNA-activated (PKR) is an IFN-induced serine/threonine kinase, whose activity is stimulated by dsRNA, a classical co-factor (Fig. 6C). In the native state PKR has little or no enzymatic activity, due to auto-inhibition of its kinase activity by its N-terminal regulatory domain. Upon encountering viral dsRNA or partially dsRNA regions of viral/cellular nucleic acids, the N terminus of PKR binds to them and frees the kinase domain from repression. Two PKR molecules dimerize and autophosphorylate each other on their kinase domains. The eukaryotic translation initiation factor 2 (eIF2) is a heterotrimer consisting of α, β and γ subunits. eIF2 mediates the binding of $tRNA^{met}$ to the ribosome in a GTP-dependent manner. Once the initiation is completed, GDP-bound eIF2 is released from the ribosome as an inactive complex. To participate in another round of translation initiation, this GDP must be exchanged for GTP. Activated PKR phosphorylates the alpha subunit of eIF2 (eIF2α) at specific serine residues at positions 48 and 51. Phosphorylated eIF2α fails to assemble the ternary complex, because it does not exchange GTP to GDP. This aborts viral mRNA translation, and, hence, replication. PKR is also activated by cellular protein, PACT, independently of dsRNA. PKR is also involved in the execution of apoptosis as part of the Fas death receptor-mediated signaling.

The human ISG56 (also known as IFIT1) belongs to a family of structurally similar but genetically distinct proteins called, Interferon Induced proteins with Tetratricopeptide repeats (IFIT). The human IFIT family is constituted by 4 members viz., IFIT1

(ISG56), IFIT2 (ISG54), IFIT3 (ISG60 or IFIT4), and IFIT5 (ISG58) clustered together on chromosome 10. Two other genes *IFIT1B* (uncharacterized) and *IFIT1P1* (a pseudogene) located on chromosome 13, appear to be related members of this family. Human IFIT1 and IFIT2 interact with the 3E subunit of eukaryotic translation initiation factor 3 (eIF3), a protein complex consisting of 13 protein subunits, to regulate translation (**Fig. 6D**). The human IFIT2 and mouse Ifit1 and Ifit2 proteins bind to the eIF-3C subunit to block translation. IFIT1 inhibits protein synthesis by preventing the association of eIF3 with the 43S pre-initiation complex, thus, blunting 5′-cap-dependent viral translation. Alternatively, IFIT1 can directly recognize the type O cap (without 2′O methylation) of certain viral RNAs and prevent the formation of 43S pre-initiation complex. IFIT1 also suppresses hepatitis C virus (HCV) replication by blocking internal ribosome entry site (IRES) dependent translation. Such a translational blockade occurs independently of PKR. The murine *Ifit* family is formed by three characterized members viz, Ifit1 (Isg56), Ifit2 (Isg54) and Ifit3 (Isg49) clustered on chromosome13. *Ifit1c* (Gm14446) is an allelic variant of *Ifit1*. Two additional members of this family with unknown expression patterns and functions include, *Ifit1b* (2010002M12Rik) and *Ifit3b* (I830012O16Rik). Although, the murine Ifit1 and Ifit2 proteins exhibit sequence similarity to human IFIT proteins they are not functionally equivalent. Hence, they should treated as distinct proteins. Importantly, IFN-inducible proteins IFITM1, IFITM2, IFITM3, which are often confused to be IFIT proteins because of the name similarity, are not related to IFIT proteins. They have an unclear mode of action. Among these IFITM3 block the viral entry into cells (see **Table 3**).

The Mx proteins, although originally described as myxovirus-specific inhibitors, can target many other viruses (**Fig. 6E**). MxA, a prototypical member of this family, is a dynamin-like GTPase, whose activity is required for exerting anti-viral effects. Mx proteins form oligomers to exert anti-viral effects. Depending on the virus, different stages of viral life cycle are inhibited by the Mx proteins. Mouse Mx1 inhibits Influenza and Thogoto (THOV) viruses by blocking viral mRNA synthesis catalyzed in the nucleus by the RNA polymerase located in the viral nucleocapsids. Human MxA intercepts THOV nucleocapsids in the cytoplasm and prevents their import into the nucleus, where the virus replicates. MxA also blocks Hepatitis B virus, La Crosse virus (LACV) and other bunyaviruses by sequestering the newly synthesized viral N protein into perinuclear complexes. Human MxB blocks HIV-1 replication by preventing viral uncoating, and nuclear import of the reverse transcribed viral genome. Consistent with their critical role in anti-viral defenses, mice engineered to lack PKR, RNaseL, IFIT1 or Mx proteins are highly susceptibility to viral infections. More importantly, the anti-viral actions of ISGs are blocked by a number of viral gene products to escape from inhibition, testifying their critical role in host defenses (**Table 4**). These mechanisms include a production of soluble receptors, degradation of IRF3, inhibition of the JAK-STAT pathway, blockade of PKR and other ISGs.

Table 4 Viral Resistance to IFNs

Virus	*Component*	*Target*	*Mechanism*
Adeno	E1A protein	IRF3	Competing with IRF3 binding site
Adeno	E1A	ISGF3	Inhibits IRF9 expression/ISGF3 binding to ISRE
Adeno	VAI RNA	PKR	Blocks activation
Coxackie	3C	MAVS and TRIF	Cleavage of MAVS and TRIF
Dengue	NS4B	STAT1	Blocks STAT1 tyrosyl phosphorylation
EMCV	3C	RIG-I	Cleavage of RIG-I
Enterovirus 71	2A	IFNAR1	Cleavage of IFNAR1
Enterovirus 71	3C	RIG - I and TRIF	Sequestration of RIG-I and Cleavage of TRIF
Epstein-Barr	EBNA-2	ISG induction	Inhibits anticellular action
Epstein-Barr	EBER	PKR	Blocks activation
Epstein-Barr	BCRF-1 protein	IFN - γ gene	Inhibits IFN - γ synthesis
Epstein-Barr	BGLF4 protein	IRF3	Decrease amounts of active IRF3
HCMV	pp65 protein	IRF3	Decrease of phosphorylated IRF3, and nuclear translocation and accumulation
Hendra	V protein	STAT1, STAT2	Sequesters STATs to prevent their activation
Hepatitis A	3C protein	MAVS	Cleavage of MVAS
Hepatitis B	TP	ISG induction	Blocks signaling
Hepatitis B	ORF-C	IFN - β gene	Inhibits gene expression
Hepatitis B	X protein	MAVS	Proteasomal degradation of MAVS
Hepatitis C	NS 3-4A	MAVS	Cleavage of MVAS
HIV-1	TAR RNA	PKR	Blocks activation
HIV-1	TAR protein	PKR	Inhibits PKR
HIV-1	Protease	eIF4G,RIG-I	Cleavage of eIF4G, Sequestration of RIG-I
HPIV2	V protein	TBK1	Decoy phosphorylation substrate
HPIV2	V protein	STAT2	Ubiquitination-dependent degradation
HPV 16	E6 protein	IRF3	Direct inhibition of IRF3
HSV	2-5 A analog	RNase L	Blocks activation
HSV	ICP0	IRF3	Blocks nuclear translocation and accumulation
Influenza A	Cellular p58	PKR	Inhibits PKR

Table 4 Viral Resistance to IFNs—cont'd

Virus	*Component*	*Target*	*Mechanism*
Influenza A	NS1 protein	RIG-I	Indirect inhibition of RIG-I
KSHV	LANA-1	IRF3	Competing with IRF3 binding site
KSHV	ORF52	cGAS	Inhibits cGAS activity by direct binding
KSHV	vIRF1	p300 and ISG15	Inhibits type I IFNs by ISGylation
Measles	C protein	IRF3	Nuclear sequestration of IRF3
Measles	V protein	STAT1, STAT2	Prevents nuclear import of STATs
Mumps	V protein	TBK1	Decoy phosphorylation substrate
Mumps	V protein	STAT1	Ubiquitination-dependent degradation
Myxoma	MT2	IFN-γ receptor analog	Neutralizes IFN-γ
Nipah	W protein	IRF3	Nuclear sequestration of IRF3
Nipah	V protein	STAT1, STAT2	Sequesters STATs to prevent their activation
Papilloma	E6 protein	IFN-δ induced genes	Blocks Tyk2
Paramyxo	V protein	MDA5 and RIG-I	Inhibition of MDA5(direct) and RIG-I(indirect)
PIV 5	V protein	TBK1	Decoy phosphorylation substrate
Polio	2A protein	eIF4G	Cleavage of eIF4G
Polio	3C protein	MAVS,TRIF, p65-RelA	Cleavage of MAVS,TRIF and p65-RelA
Polyoma	T antigen	ISG induction	Blocks JAK1
Reo	σ3 protein	PKR	Sequesters dsRNA
Reo	μ2 protein	IRF9	Retains IRF9 in the nucleus and prevents ISGF3 formation.
RSV	?	STAT2	Block type I IFN signaling via STAT2 degradation
Rotavirus	NSP1	IRF3,IRF5, IRF7	Targets IRFs to degradation
Rotavirus	NSP1	STAT1, STAT2	Prevents STAT nuclear migration
Sendai	E6 protein	IRF3	Direct inhibition of IRF3
Simian Virus 5	V protein	STAT1	Ubiquitination-dependent degradation
Vaccinia	SKI	PKR	Sequesters dsRNA
Vaccinia	B19/B19R	Type I IFNs	This secretory protein acts as a soluble IFN-α/β receptor to prevent IFN-action.
Vaccinia	E3 protein	PKR	Inhibits PKR
Vaccinia	K3 protein	PKR	Analog of eIF2-α
Vaccinia	K7 protein	DDX3	Blocks IRF3 mediated IFN-b production

Abbreviations: EBER, Epstein-Barr virus encoded small RNA; EBNA2, Epstein-Barr virus nuclear antigen 2; EMCV, Encephalomyocarditis virus; HCMV, Human cytomegalovirus; HPIV2, Human parainfluenza virus 2; HPV 16, Human papilloma virus 16; HSV, Herpes simplex virus; ICP0, Infected cell protein 0; IFN, Interferon; IFNAR, Interferon alpha receptor; KSHV,Kaposi's sarcoma associated herpesvirus; LANA, Latency associated nuclear antigen; MAVS, Mitochondrial antiviral - signaling protein; MDA 5, Melanoma differentiation-associated protein 5; MT2, Myxoma virus T2 protein; NS, Non-structural protein; ORF, Open reading frame; RSV, Respiratory syncytial virus; TAR, Trans-activation response; TP, Terminal protein; PIV 5, Para influenza virus 5; TBK, TANK-binding kinase; TRIF, TIR-domain-containing adapter-inducing interferon β; TYK, Tyrosine kinase.

IFNs and Microbiota

Resident microbiota influence the homeostasis of the host immune system. IFNsα/β not only influence the host–microbiota interactions but also serve as downstream targets of these interactions, leading to further effects on immune system function. The IFN-inducible inflammatory transcriptional response was severely reduced following the loss of commensals. As a result mononuclear phagocytes from mice lacking commensals were defective at inducing anti-viral responses and failed to activate anti-viral response through NK cells. Loss of type I IFN receptor (IFNAR) in intestinal epithelial cells leads to the proliferation of Paneth cells consequently altering the intestinal microbiota composition. Microbiota-induced production of IFN-β by the resident DCs in the intestine protects mice from experimentally-induced colitis.

Anti-Microbial Actions of IFNs

IFNs acting solely as anti-viral agents is no longer a valid notion. Type I IFNs modulate the effector functions of multiple cell types involved in immune responses against bacteria, fungi, and parasites. However, depending on the duration, quantity and cell type experiencing the IFNs, both anti-microbial and host-detrimental outcomes are possible (**Fig. 7**). During the early phase of a bacterial infection, low levels of type I IFNs promote a beneficial cell-mediated immune response. In contrast, high concentrations of type I IFNs blunt B cell responses and inactivate macrophage-dependent immune responses. It should be noted that these diametrically opposing responses are also dependent on type of the pathogen. Unlike the anti-viral effects, the anti-microbial actions of IFNs sometimes are direct and at other times they are exerted through the production of cytokines. The direct anti-microbial and anti-protozoal actions of IFNs are induced by ISGs such as, inducible nitric oxide synthase (iNOS), indoleamine 2, 3 dioxygenase (IDO) and GTPases like IGTP and TGTP.

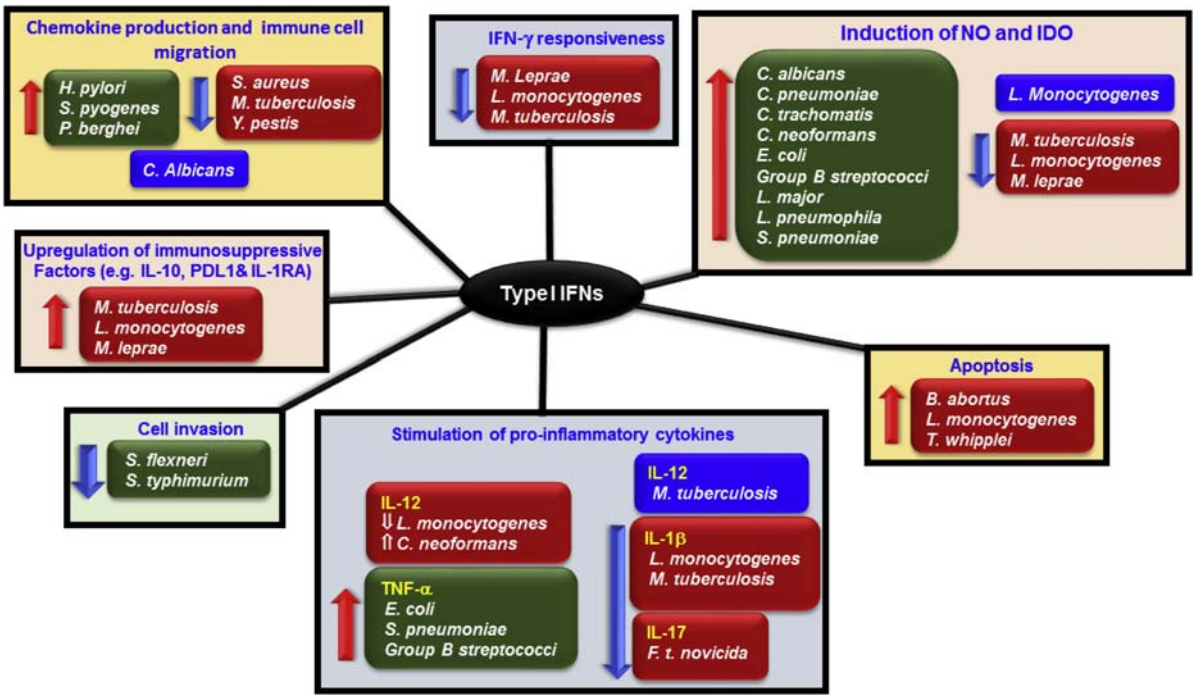

Fig. 7 Effects of type I IFNs on microbial, fungal and protozoal pathogens. Red and blue colored arrows indicate promoting and suppressing effects, respectively, on various immunity-associated processes. Green boxes: host-protective; Red boxes: host-detrimental effects; Blue boxes both host protective and detrimental effects of IFN-α/β. IL, interleukin; IL'1RA, IL'1 receptor antagonist; iNOS, inducible nitric oxide synthase; PDL1, programmed cell death 1 ligand 1; *B. abortus*, *Brucella abortus*; *C. albicans*, *Candida albicans*; *C. neoformans*, *Cryptococcus neoformans*; *C. pneumoniae*, *Chlamydia pneumoniae*; *C. trachomatis*, *Chlamydia trachomatis*; *E. coli*, *Escherichia coli*; *F. t. novicida*, *Francisella tularensis subsp. novicida*; *H. pylori*, *Helicobacter pylori*; *L. major*, *Leishmania major*; *L. monocytogenes*, *Listeria monocytogenes*; *L. pneumophila*, *Legionella pneumophila*; *M. leprae*,*Mycobacterium leprae*; *M. tuberculosis*, *Mycobacterium tuberculosis*; *P. berghei*, *Plasmodium berghei*; *S. aureus*, *Staphylococcus aureus*; *S. flexneri*, *Shigella flexneri*; *S. pneumoniae*, *Streptococcus pneumoniae*; *S. Typhimurium*, *Salmonella enterica subsp. enterica serovar Typhimurium*; *T. whipplei*, *Tropheryma whipplei*; *Y. pestis*, *Yersinia pestis*. Adapted from McNab, F. et al. (2015) *Nature Reviews. Immunology*. **15**: 87–103.

The indirect effects of IFNs include: induction of cellular invasion, production of chemokines or pro-inflammatory cytokines, and induction of apoptosis or upregulation of autophagy. The host-detrimental actions of IFNs involve production of immunosuppressive molecules, promotion of cell invasion, suppression of microbicidal molecules such as iNOS and IDO. IFNs-α/β activate immature committed DCs, by enhancing the cell surface expression of MHC molecules and co-stimulatory molecules, such as CD80 and CD86, which robustly stimulate T cells to block spread of an infection. DCs secrete IL-12, which is critical for promoting T helper 1 (T_H1)-type responses during some bacterial infections. IL-12 induces IFN-γ production by T cells and NK cells. IFN-α down modulates the expression of pro-inflammatory cytokines IL-1, IL-12 and IL-17 during *Mycobacterium tuberculosis* and *Listeria monocytogenes* infections. Strikingly, IFN-α suppresses the beneficial anti-microbial effects of IFN-γ in the case of *M. tuberculosis*, *M. leprae, and L. monocytogenes*.

Anti-Protozoal Parasite Actions of IFNs

There are few studies on the effects of type I IFNs on parasites. As noted with bacterial infections, low doses of IFN-α/β exert a host-protective response, whereas high doses inhibit them during parasitic infections like *Leishmania major*, *Plasmodium berghei* and *P. chaubadi*. In the case of *Leishmania sp*. infections, IFN-α/β exerts a detrimental effect on the host through a blockade of macrophage functions and down regulating neutrophil number. Depending on the species and stage of infection, type I IFNs confer a negative or positive effects on host responses. IFNα/β augment infection by inhibiting $CD4^+$ T cell activity, during blood stages in mouse models of infection with *P. berghei* and *P. chabaudi*. In contrast, IFNs-α/β protect the host during *P. yoelii* infection by inhibiting reticulocytosis, a condition in which immature red blood cells accumulate in peripheral blood. During malaria infection, parasites spread into the central nervous system causing 'cerebral malaria'. IFN-α offers protection against cerebral malaria induced in mice through T_H1 cells. Parasitic RNAs are detected by MDA5 in liver leading to IFN production. Similar positive and negative effects of type I IFNs on host immunity during *Trypanosoma cruzi* infection have been reported. The IFN-induced GTPases (IRGs) viz., IGTP, TGTP, and IRGM acts as deterrents against the protozoan parasite *Toxoplasma gondii* potently inhibiting its multiplication. Some strains of *Toxoplasma* evade the anti-protozoal action of IFN-inducible immunity-related GTPase by secreting the rhoptry kinases (ROP kinases) into the host cell during infection. One such protein kinase, ROP18, phosphorylates

IRG proteins to inactivate their functions, thus, promoting virulence. *Toxoplasma* infection inhibits the expression of IFN-γ – induced secondary response genes, such as CIITA and MHC class II genes, by impairing Brahma-related gene 1 (BRG-1)-mediated chromatin remodeling of their promoters in macrophages. Other studies show that *Toxoplasma*, inhibits both type I and type II IFN-induced gene expression by preventing STAT1 nuclear-cytoplasmic cycling. Strangely, *Toxoplasma* requires IRF3 for its replication, independently of type I IFN production. It induces a Parasite-IRF3 Signaling Activation (PISA) pathway that relies on cGAS – STING – TBK – IRF3 to stimulate certain ISGs to promote its replication. Thus, there is an interesting nexus between *Toxoplasma* and IFN system.

Effects of IFNs on fungal infections

Similar to bacterial infections, IFNs-α/β exert both negative and positive effects on fungal infections. In case of *Candida albicans*, *Saccharomyces cerevisiae* and *Cryptococcus neoformans* infections, IFN-α/β exert a host-protective effect. IFN-α/β signaling is critical for various processes, including inducing the reactive oxygen species that terminate *C. albicans* in phagocytic cells, for maintaining a T_H1 like immune response (high IFN-γ, TNF, iNOS and CXCL10 levels) to *C. neoformans* and for attracting neutrophils to the site of *C. albicans* infection. However, some other models of *C. albicans* showed no effect of IFN-α/β on fungal burden, but instead, promoted a lethal immunopathology. Fig. 7 shows some of the effects of type I IFNs on various microbial infections and outcomes observed in mouse models.

Human IFN-Related Inborn Errors That Increase Infections

A number of compelling studies showed genetic mutations/variations in IFN signaling pathways or downstream products enhances sensitivity to infectious pathogens (Table 5). Earliest studies showed certain humans, who do not display any overt defects in hematopoietic system, were predisposed to infection with attenuated (e.g., BCG) and environmental mycobacteria. Defined now as'Mendelian susceptibility to mycobacterial disease (MSMD)', these rare conditions are due to genetic defects in IFN signaling pathways. Nine of the 18 genes described in MSMD mapped to critical players involved in IFN signaling such as *IFNGR1*, *IFNGR2*, *STAT1*, *IL12B*, *IL12RB1*, *ISG15*, *NEMO*, *CYBB* (codes for the gp91 subunit of the phagocyte NADPH oxidase) and *IRF8*. The MSMD patients do not produce *IL12RB1*, *ISG15*, *NEMO* and *IRF8* owing to defects in *IFNGR1*, *IFNGR2*, *STAT1* and *IRF8* in IFN-γ signaling. Although MSMD patients do not recapitulate all the clinical features, they are also increasingly susceptible to salmonellosis, candidiasis and tuberculosis, and rarely to infections with other intramacrophagic bacteria, fungi, or parasites and some viruses. Genetic defects (heterozygotic) in the human *IRF7* gene are also connected to life-threatening influenza infections. Cells from these individuals do amplify the initial IFN response that leads to the production of IFN-α and IFN-λ. Apart from these, autosomal recessive defects due to *TYK2* loss down regulate IFN-α/β, and IFN-λ, resulting in a hyper-susceptibility to mycobacterial, *Salmonella*, staphylococcal and viral infections. It should be noted that these phenotypes are likely to be more complex given the requirement of TYK2

Table 5 Human inborn errors that dysregulate IFN-signaling pathways and increase susceptibility to infections

Gene	*Inheritance*	*Allele*	*Cytokines*	*Disease Phenotype/Infections*
STAT1	AR	LOF, HPO	IFN-α and IFN-β, IFN-γ, IFN- λ, IL-27	mycobacteria, viruses
	AD[a]	LOF, HPO	IFN-γ	mycobacteria
IFNGR1	AR	LOF, HPO	IFN-γ	mycobacteria
	AD	LOF	IFN-γ	mycobacteria
IFNGR2	AR	LOF, HPO	IFN-γ	mycobacteria
IRF7	*AD*	LOF	IFN-α	Life threatening influenza infections
IRF8	AD	HPO	IFN-γ and others?	Mycobacteria
IL12B	AR	LOF	IL-12, IL-23	mycobacteria, *Salmonella*, CMC
IL12RB1	AR	LOF	IL-12, IL-23	mycobacteria, *Salmonella*, CMC
IKBKG	XR	HPO		multiple mycobacteria
CYBB	XR	HPO		mycobacteria
TYK2	AR	LOF	IFN-α, IFN-β, IFN-λ, IL-6, IL-10, IL-12, IL-23	mycobacteria, salmonella, viruses, *Staphylococci*, atopy[b]
STAT1	AD[a]	HPR	IFN-α, IFN-β, IFN-γ, IFN-λ, IL-27[c]	CMC
IL10RB2	AR	LOF	IL-10, IL-22, IFN-λ	colitis

AR, autosomal-recessive; AD, autosomal-dominant; XR, X-linked recessive; LOF, loss-of-function (null); HPO, hypomorphic; HPR, hypermorphic (gain of function); colitis, early-onset inflammatory colitis; CMC, chronic mucocutaneous candidiasis.

[a]Mutations were found in the DBD and tyrosine phosphorylation domain.

[b]elevated IgE.

[c]STAT1-hyperactive patients lack IL-17 T cells.

Based on Casanova, J.L. et al. (2012) *Immunity*. **36**, 515–428.

for IL-6, IL-10, IL-12 and IL-23 signaling. Patients with autosomal recessive STAT1 deficiency are broadly susceptible to viruses, including herpes simplex virus-1 (HSV-1) infections, which may cause HSV-1 encephalitis (HSE). IL-10R2-deficient patients would be expected to be unresponsive to IFN-λ, for this receptor is not utilized by either IFN-α/β or IFN-γ. Genome-wide sequencing and association studies on chronic mucocutaneous candidiasis have identified mutations in STAT1 (in its coiled-coil domain) in some patients. These mutations were also found in patients with disseminated disease caused by other fungal pathogens such as *Histoplasma capsulatum* and *Coccidioides immitis*. Strikingly, these gain-of-function and dominant mutations promote disease, suggesting a detrimental role for IFN-α/β in fungal infections, possibly through a suppression of T_H17 responses and/or an excessive differentiation of T_H1 cells. Since other cytokines, for example, IFN-γ and IL-27, also employ STAT1 for signal transduction, they may also be responsible for disease promotion.

Anti-Tumor Actions of IFN-Inducible Gene Products

IFNs affect neoplastic cell growth by two major mechanisms: (1) direct induction of anti-tumor gene expression in tumor cells, and (2) development of acquired immune response against a tumor. IFN-induced growth suppressors and the genes that participate in them are shown in **Table 6**. Deletion of *Stat1* increases susceptibility to carcinogenesis in mice. These mice also developed spontaneous $ER\alpha^+/PR^+$ breast tumors at a late age. Indeed, 45% of human $ER\alpha^+$ and 22% of ERα- breast tumors do not express detectable STAT1. STAT1 appears to mediate its anti-tumor effects through an induction of apoptosis. Caspases are proteases with an active cysteine residue that cleave a number of critical cellular proteins during apoptosis. STAT1-deficient cells do not express Caspase-1, Caspase-2 (Ich1) and Caspase-3 (Cpp32). STAT1 also regulates the expression of cyclin-dependent kinase inhibitor, p21. As a result, STAT1-deficient cells become resistant to growth inhibition and fail to undergo apoptosis. Apoptosis is also promoted by cell surface death receptors. Two such receptors Fas and DR4 are essential players in controlling lymphocyte proliferation and death of other neoplastic cells. Fas and TRAIL (a ligand for DR4) are induced by IFNs. In contrast to its known tumor-suppressive actions, STAT1 appears to function as an oncogene in certain forms of endometrial cancers, where it drives the expression of ICAM1 (an adhesion molecule), PDL1 (a molecule that induces T cell apoptosis) and c-Myc (cell proliferation).

JAK1 appears to regulate tumor suppression. In human endometrial cancers, deletions and frameshift mutations have been found in the *JAK1* gene (**Fig. 8**). Such cells fail to upregulate LPM2 and TAP1, both molecules involved in antigen processing and adaptive immune response. This is consistent with the requirement of STAT1 for immunosurveillance. Apart from these *JAK1* truncations were also found in colorectal, lung, skin and kidney cancers. In contrast, JAK2 acts as oncoprotein in some leukemias. Constitutive activation of JAK2 is noted in many myeloid leukemias, for example, polycythemia vera. A number of point mutations, deletions and frameshift mutations in *JAK2* have been reported in human leukemias. The most notable of these is the $V^{617}F$ mutation in the JH2 domain (pseudokinase) that, surprisingly, super stimulates its enzymatic activity in the absence of any cytokine signaling (**Fig.9**). Apart from these other gene translocations of *JAK2*, include a t(9;22) (p24;q11.2) which generates BCR-JAK2 fusion protein containing the N-terminal coiled-coil domain of the BCR (Breakpoint Cluster Region, a member of the Rho family of guanine nucleotide exchange factors involved in cell signaling) gene and JH1 domain of JAK2 in some chronic myelogenous leukemia. ETV6-JAK2 (also known as TEL-JAK2) is another fusion protein found in certain adult T cell leukemias, where a translocation, t(9;12) (p24;p13), between transcription factor TEL/ETV6 and JAK2 produces this fusion. The ETV6 domain in the resultant protein provides an oligomerization interface that brings the JAK2 kinase domains together to produce a constitutively active enzyme and promotes cell growth. A third fusion protein, PCM1-JAK2, is found some atypical chronic myeloid leukemias where the t(8;9) (p22;p24) translocation between the PCM1 (Peri-Centriolar Material 1) gene and JAK2 produces a chimera that possesses constitutive kinase activity. In this case the coiled-coil domain of PCM1 provides an oligomerization domain for JAK2. Based on the JAK2-$V^{617}F$ a number of kinase inhibitors have been successfully developed and implemented as a standard therapy for myeloid leukemias with constitutive JAK2 activity (**Table 7**). Although these inhibitors are developed for treating leukemias, they are also used for treating other autoimmune diseases like rheumatoid arthritis, psoriasis, and systemic lupus erythematosus, where JAK2 activities are elevated.

Table 6 IFN-induced anti-tumor effects and the genes that participate in them

Process	*IFN effects*
Cell cycle arrest	↑ $p21^{WAF1/CIP1}$, $p27^{KIP1}$, IFITM1, pRb dephosphorylation
Growth inhibition	↓ E2F1, CDKs (A, B, D2, D3, E)
	↓ HER-2/neu, c-myc
Apoptosis	↑ Fas, FasL, TRAIL, KILLER/DR5, Caspases (1, 3, 7, 8), XAF1, NO, DAPK1
Angiogenesis inhibition	↓ bFGF, MMP2, MMP9, VEGF
	↑ IP10/CXCL10
Immunosurveillance	↑ LMP2, LMP7, TAP1, TAP2, MHCI, CIITA

NO: Nitric Oxide; Up and down arrows indicate inducing and inhibitory effects of IFNs

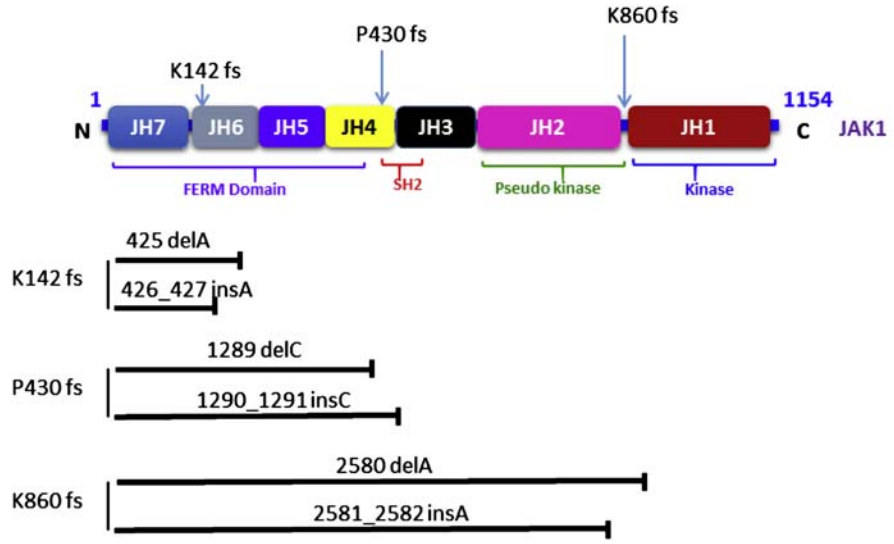

Fig. 8 JAK1 mutations in human tumors. JAK1 protein domains in modular representation and three mutational hot spots are shown on wild-type JAK1. Horizontal bars represent the truncated protein due to frameshift (fs) - mutations arising from deletion (del) and insertion (ins). Numbers indicate the position in protein and/or ORF. Adapted from Ren, Y. et al. (2013) *Science Reporter.* **3**: 3042.

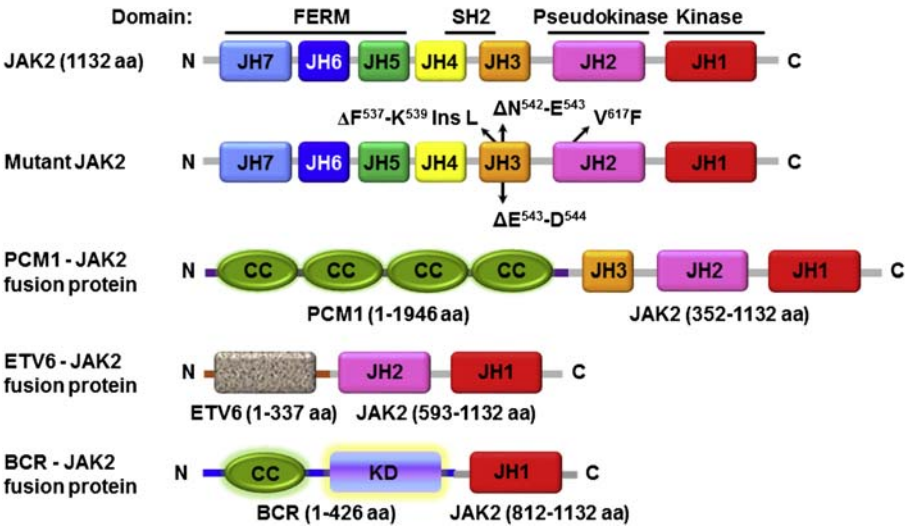

Fig. 9 JAK2 mutations in human tumors. JAK2 protein domains in modular representation showing the region where three mutational hot spots have been documented. Fusion proteins due to chromosomal translocations are also shown. Deletion (Δ) and Insertion (Ins) found in various hematological tumors. Numbers indicate the position in protein. CC: coiled-coil domain. Adapted from Bain, B.J. & Ahmad, S (2014) *British Journal of Haematology*. **166**: 809–817).

The SOCS1 protein is another ISG that acts as a tumor suppressor. SOCS1 is a STAT1-induced ISG, which turns off JAK activities in the IFN-signaling pathway. The E3 ligase activity of SOCS1 plays critical roles in its anti-tumor actions. SOCS1 exerts anti-tumor actions, independently of its anti-JAK function. For example, it associates with tumor suppressor p53 to promote growth suppressive gene expression in certain hepatocellular carcinomas (HCC) and block signaling by receptor tyrosine kinases like EGFR and FGFR3. Interestingly, the cyclin-dependent kinase inhibitor $p21^{Cip1}$ (also known as CDKN1A) a target of p53 and an inhibitor of cell cycle arrest, acts as an oncogene in some cell types. SOCS1 targets CDKN1A to ubiquitination and its proteosomal degradation. The *SOCS1* gene is repressed by hyper-methylation in many cancers, for example pancreatic cancers, myeloid leukemias and HCC.

DAPK1 is a major IFN-inducible tumor suppressor. It was originally isolated using a genetic screen that identified IFN-γ-regulated growth suppressors. DAPK1 codes for a Ca^{+2}-calmodulin dependent serine/threonine kinase that suppresses tumor cell growth and metastasis by causing a cell cycle arrest, apoptosis and autophagy. Other stimuli such as C6-ceramide, inhibition of mitochondrial respiration, unliganded UNC5H2, TGF-β and DNA damage also require DAPK1 for inducing cell death. DAPK1 modulates cytoskeletal remodeling, membrane blebbing and autophagy. Consistent with its multifunctional nature, DAPK1 interacts with several growth-regulatory proteins. DAPK1 phosphorylates multiple substrates depending on the cell type—most notable

Table 7 JAK Inhibitors for treating cancer and autoimmune diseases

Drug	*Targeted JAK*	*Type of cancer*	*Stage of development*
Ruxolitinib	1, 2	Myelofibrosis	III
		Polycythemia vera	II
		Essential thrombocythemia

Based on Kontzias et al. (2012) Jakinibs: a new class of kinase inhibitors in cancer and autoimmune disease. *Current Opinion in Pharmacology*. **12**:464–470.

among these are: Beclin-1 and VPS34 via Protein kinase D (to promote autophagy network), myosin light chain, tropomyosin (to suppress cell contractility), p53 tumor suppressor, p38MAPK (for enforcing apoptosis), interacts with MARKS protein kinase to promote the phosphorylation of Tau (promotes microtubule instability and toxicity) and PAK4-LIM-cofilin (actin remodeling), blocks inflammation-induced NF-kB (promotes growth), Pin-1 (causes chromosomal instability and centrosome amplification) and integrins (metastasis suppression via adhesion) to suppress growth. Lastly, DAPK1 is also involved in translational control of inflammatory gene expression in myeloid cells through a novel IFN-regulated element called GAIT, and NMDA-driven brain damage in stroke. Consistent with its growth-suppressive properties, *DAPK1* expression is suppressed (40-90%) in a variety of human cancers.

cGAS-STING also participates in tumor surveillance. Cellular stress, such as DNA damage, induces NKG2D ligands, which allows damaged cell recognition and destruction by NK and T cells. In certain lymphoma cells the expression of NKG2D ligand, Rae1, is induced by the STING-IRF3 pathway. Expression of Rae1, in tumor cells, aids in NK cell-mediated tumor clearance. The IRF1 and IRF8 proteins are associated with the development of leukemias. IRF1 gene mutations are found in myelodysplasia and other myeloproliferative diseases. IRF8 expression is suppressed in human myelogenous leukemias. Indeed, *Irf8*−/− mice develop a chronic myelogenous leukemia-like disease. IRF7 and the dependent IFN gene signatures are lost in certain forms of human metastatic breast cancers.

In an immunocompetent host, neoplastic cells undergo immunoediting in three distinct phases: elimination, equilibrium, and escape. During the elimination phase, host immune cells (CTLs, type 1 macrophages and NK cells) kill cancer cells to reduce tumor burden. Such killing reaches a phase of equilibrium where tumors enter into a state of dormancy. During dormancy some tumor cells lose tumor antigens, stop expressing MHC molecules, acquire mutations due to genome instability, and reprogram the microenvironment through secretion of immunosuppressive factors like TGF-β, IL-10 and chemokines which recruit and activate type 2 macrophages, immature myeloid-derived suppressor cells, T^{reg} cells, which effectively block any potential immune response and creating paths for the escape of tumor cells from immune scrutiny. IFNs play a major role in shaping the elimination phase of immune response against tumors. The IFN-γ receptor and STAT1 are critical for immunosurveillance of neoplastic cells. Mice lacking these genes are highly susceptible for tumor development. Type I IFNs stimulate CTLs by various mechanisms (**Fig. 10**): (1) promote cross-priming to augment the maturation of DCs, by enhancing their capacity to process and present dead cell-associated antigens, and by promoting their migration towards lymph nodes; (2) by upregulating the expression of perforin 1 and granzyme B, they augment immune effector activity and (3) promote the survival of memory CTLs. Type I IFNs can block the elimination of antigen-activated $CD8^+$ CTLs by NK cells and stimulate the secretion of pro-inflammatory cytokines interleukin-1 beta (IL-1β) and IL-18 by macrophages. Type I IFNs inactivate regulatory T (T^{Reg}) cells, which blunt immune response, through the activation of PDE4 and the consequent depletion of cAMP.

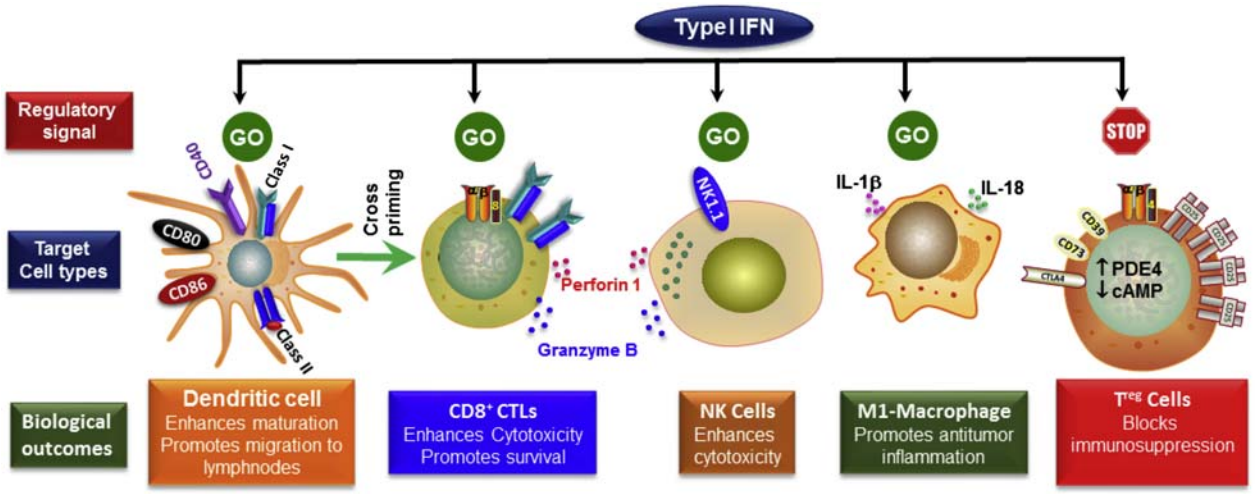

Fig. 10 Type I IFN-stimulated immune mechanisms that contribute to their anti-tumor actions. Various cell types and the effects on them are shown. Granzyme B and Perforin, cytotoxic proteins secreted by $CD8^+$ T cells, kill the target cells. PDE4: phosphodiesterase 4. Adapted from Zitvogel, L., et al. (2015) *Nature Reviews. Immunology*. **15**: 405–414.

IFNs and Autophagy

Autophagy is a type of cellular self-digestion. Although discovered originally as a cell protective mechanism in yeast cells that protects against starvation, autophagy participates in multiple physiological responses including innate immunity against viruses and bacteria, and tumor cell growth regulation. During autophagy, invading pathogens or damaged/superfluous organelle are encased into double membrane vesicles, derived from endoplasmic reticulum, called autophagosomes. These vesicles fuse with lysosome where the cargo is digested out. The resultant peptides are presented to the immune system to generate immune response. DAPK1 promotes autophagy, by phosphorylating multiple targets involved in the autophagic machinery. In addition, transcription factors C/EBP-β and ATF6 are also required for driving IFN-γ-induced autophagy. Mice and cells lacking these factors are increasingly susceptible to intracellular bacterial infections. A cellular protein p62 (also known as SQSTM) serves as a carrier of protein cargo into autophagic vesicles to promote their destruction via lysosomes. Although p62 is dispensable for clearing *T. gondii*, it is essential for generating CTL responses against this pathogen. Autophagy or autophagy-related proteins also contribute to the synthesis of type I IFN as well as to anti-viral IFN-γ signaling. Autophagy directly inhibits the replication of number of viruses. In contrast, HCV inhibits type I IFN production by promoting autophagy. Lastly, autophagy attenuates innate immune response to promote acquired immunity.

Interferon-gene Regulatory Factors (IRFs)

A total of 10 structurally similar and genetically distinct transcription factors constitute this family. These include: IRF1, IRF2 (ISGF2), IRF3, IRF4 (PIP/LSIRF/ICSAT), IRF5, IRF6, IRF7, IRF8 (ICSBP), IRF9 (also known as ISGF3γ) and IRF10. In addition, 4 other IRF-like proteins, vIRF1, vIRF2, vIRF3 and vIRF4, are coded by the human Herpes Virus 8 (HHV8 or KSHV). Mammalian IRFs are characterized by an N-terminal DNA binding domain with several tryptophan-rich (W) repeats, which allow it to fold into a winged Helix-Turn-Helix structure (Fig. 11). Their carboxy termini contain a regulatory domain, which allows IRF-association domain (IAD) and a TAD that permits dimerization among family members and gene induction, respectively. IRF heterodimers can both positively and negatively regulate gene expression depending on the cell type, signal and target gene. The founding member of this family IRF1 was isolated as a protein can regulate IFN-β gene. IRF1, IRF2, IRF3, IRF5, IRF7, IRF8 and IRF9 are intimately involved with the induction of IFNs and ISGs. IRF1, IRF5, IRF7, IRF8 and IRF9 themselves are ISGs, which amplify initial IFN response in various cell types. Some of these proteins, IRF1, IRF3, IRF5, and IRF7 undergo a signal-induced phosphorylation, in their TAD, obligatory for target gene induction. A classic example for this is IRF7. In response to PRR, RLR, dsRNA-driven signals IRF3 is activated, which turns on IFN-β gene. IFN-β produced in this manner turns on the first-round transcription of ISGs, including IRF7. The latter then binds to IFN-α gene promoters and turns on their expression, which then upregulate more ISG expression leading to the amplification of IFN-induced innate defenses. The IRFs are involved in various host-defense and anticogenic processes. For example, the *Irf1*−/− mouse embryonic fibroblasts (MEFs) are readily transformed by the *Ha-ras* oncogene owing a defect in apoptosis. Indeed, aberrations in *IRF1* gene, owing to exon-skipping, are found in human myelodysplasias and certain forms of myeloid leukemia. *Irf1*−/− mice are defective in T_H1 immune response, contain fewer CD8 cells and are highly susceptible to intracellular pathogen infections. IRF2 is required for driving T_H1 and NK cell responses, its loss leads to susceptibility to viral and parasite infections and skin diseases. Loss of IRF3 causes increased susceptibility to viral infections in mice. IRF5 also

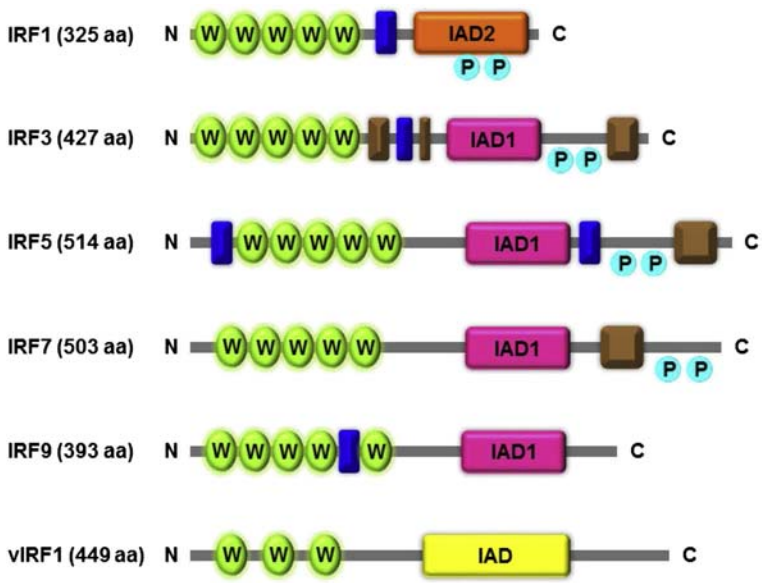

Fig. 11 Modular representation of protein domains in cellular IRFs and viral IRF. All IRFs possess a N-terminal DNA-binding domain (in *green*) characterized by a series of five tryptophan-rich (W) repeats and a C-terminal IRF-association domain (IAD in *orange*, *pink* and *yellow*), a regulatory domain. Some IRFs contain repression domain(s) (in *brown*) and a nuclear localization signal(s) (in *blue*). Phosphorylated residues involved in regulation and/or activity are shown as circles (in *turquoise*).

plays an important role in inducing IFN genes. Loss of IRF5 is associated with reduced responses to IL-6, IL-12 and TLR ligands, and metastasis in human breast cancer. Defective expression of IRF7 and ISGs is associated with metastatic breast cancers. Loss of IRF8 causes immunodeficiency and chronic myelogenous leukemia-like disease in mice. IRF8 promotes T_H1 responses, and differentiation of macrophages and DCs. Indeed, its expression is down regulated significantly in human myeloid leukemia. IRF9 is required for ISG expression and anti-viral defenses. The biological activities of IFN-regulated IRFs and the functional consequences of their loss are shown in Table 8. As mentioned previously, the HHV-8 genome codes for 4 vIRF proteins. The best studied of these, vIRF1, lacks a TAD. Although the exact functions of all 4 proteins in the context of this virus are unclear, cells expressing vIRF1 exhibit defective IFN-α gene expression and ISG expression, owing to its ability to antagonize the transcriptional activity of IRF1 and IRF3 proteins.

Interferonopathies

Although IFNs are generally involved in host-defense against the development of infections and cancers, it is becoming clear in recent reports that excessive type I IFN production, owing to defects in upstream or downstream signaling molecules, leads to several autoimmune diseases. These diseases are now termed as "Interferonopathies" (Table 9). The Aicardi-Goutières syndrome (AGS) is one such childhood interferonopathy that involves hyper-production of type I IFN. The DNA 3′ repair exonuclease 1 (TREX1) degrades short ss and dsDNA molecules generated due the reverse transcriptase activity of endogenous viruses or transposable genetic elements. Patients with AGS possess TREX1 defects, which results in an accumulation of unwanted DNA species, which serve as activating signals for the cGAS and production of cGAMP that turns on constitutive type I IFN via the STING–TBK1–IRF3 pathway. The deoxynucleoside triphosphate triphosphohydrolase with SAM and HD domains 1 (SAMHD1) hydrolyses dNTPs and degrades RNA. SAMHD1 deficiency also leads to elevated levels of IFN through cGAS and may cause AGS. Gain-of-function mutations in STING also induce an interferonopathy. IFN-induced helicase C domain-containing protein 1 (IFIH1 or MDA5) normally senses exogenous viral dsRNA. Hyperactive IFIH1 mutations require a lower threshold of dsRNA for stimulating IFN response and may also contribute to AGS. As ADAR is an ISG, mutations in both IFIH1 and ADAR may also promote the MAVS–TBK1–IRF3 signaling axis owing to their link to cytosolic RNA species. Ribonuclease H2 (RNaseH2), a trimeric enzyme constituted by RNASEH2A, RNASEH2B and RNASEH2C, degrades RNA in RNA–DNA hybrids. Tartrate-resistant acid phosphatase (TRAP, encoded by *ACP5*) a lysosomal phosphatase and PSMB8 encodes the proteasome subunit β5i are also associated with AGS. How mutations in *RNASEH2A*, *RNASEH2B*, *RNASEH2C*, *ACP5* and *PSMB8* promote hyper-IFN induction in a pathological context is unclear at this stage. Depending on the gene involved a number of clinical phenotypes are found in patients. Some of the neurological phenotypes include developmental delays, intracranial calcification, white matter disease, cerebral atrophy, spastic paraparesis, large vessel disease (stenosis, moyamoya or aneurysms) and bilateral striatal necrosis. In other patients skin-related phenotypes such as digital vasculitis and/or necrosis (chilblains); livedo and/or skin mottling, panniculitis, necrotic cheek lesions, and lipoatrophy are reported. Other clinical features of interferonopathies include: recurrent (sterile) fevers, autoimmune features, glaucoma, neonatal

Table 8 Mammalian IRFs and their functions

IRF	*Interacting partners*	*Expression*	*Function (activator or repressor)*	*Key functions*	*Phenotype of knockout mouse*
IRF1	IRF8	(Constitutive) and Inducible	Activator, regulated by phosphorylation	Promotes apoptosis and $T_H1$responses, loss may promote leukemia	Less CD8+ cells and susceptible to bacterial and viral infections
IRF2	IRF8	Constitutive and Inducible	Activator or repressor depending on presence of co-repressors	Antagonizes IRF1 and IRF9, promotes $T_H1$responses and NK-cell maturation	Susceptible to viruses, Leishmania major and skin diseases, Impaired hematopoiesis and B lymphopoiesis
IRF3	IRF3 and IRF7	Constitutive	Activator, regulated by phosphorylation	Induces early type I IFNs in response to viruses and TLR ligands	Susceptible to viruses, impaired IFN-α/β production
IRF5	IRF3, IRF5, and IRF7	Constitutive and Inducible	Activator, regulated by phosphorylation	Induces type I IFNs	Reduced IL-6, IL-12 and TNF production in response to TLR ligands
IRF7	IRF3, and IRF7	Constitutive and Inducible	Activator, regulated by phosphorylation	Induces type I IFNs and promotes macrophage differentiation	Vulnerable to viruses, reduced IFN-α and IFN-β in response to viruses and TLR ligands
IRF8	IRF1, IRF2, IRF4, and PU.1	Constitutive and Inducible	Activator or repressor depending on presence of co-activators	Promotes $T_H1$responses and macrophage and DC differentiation	CML-like syndrome, defective antiviral responses, and susceptible to intracellular pathogens
IRF9	STAT1 and STAT2	Constitutive and Inducible	Activator, depending on presence of co-activators	Induces IRF2 and IRF7, and mediates IFN effects	Defective antiviral responses, impaired IFN-α/β production

Only those IRFs known to function in the IFN-system are shown.

Table 9 Interferonopathies

Gene	*Inheritance*	*Human phenotypes*	*Protein function*
TREX1	AR or AD	AGS, FCL, SLE and RVCL	3′–5′ DNA exonuclease
RNASEH2A	AR	AGS	A catalytic subunit of the RNase H2 that degrades RNA in the RNA–DNA hybrids and removes ribonucleotides embedded in DNA
RNASEH2B	AR	AGS and spastic paraparesis	A non-catalytic subunit of the RNase H2
RNASEH2C	AR	AGS	A non-catalytic subunit of the RNase H2
SAMHD1	AR	AGS, FCL and CLL	dNTP triphosphohydrolase triphosphatase and ribonuclease
ADAR	AR or AD	AGS, DSH, BSN and spastic paraparesis, as well as CNP	adenosine to inosine conversion in dsRNA
IFIH1	AD	Various neuroimmunological and non-neurological phenotypes, including AGS, spastic paraparesis, CNP and SMS	Cytosolic sensor of dsRNA
DDX58 (*RIGI*)	AD	Atypical SMS	dsRNA cytosolic sensor
TMEM173	AD	SAVI (skin and lung)	Cytosolic DNA-sensor
ISG15	AR	MSMD and intracranial calcification (with seizures in some cases)	A negative regulator of type I IFN production by stabilization of USP18
PSMB8	AR	JMP, NNS, JASL or CANDLE (fever, contractures, neutrophilic dermatitis, lipoatrophy and panniculitis)	Part of a multi-subunit protease complex responsible for regulating proteolysis in eukaryotic cells
ACP5	AR	SPENCD, spastic paraparesis and various autoimmune phenotypes (particularly SLE)	Lysosomal acid phosphatase activity

ACP5: Acid Phosphatase 5, Tartrate Resistant (also known as TRAP) AD: autosomal dominant; AR: Autosomal Recessive; ADAR, adenosine deaminase acting on RNA (also known as DRADA, IFI4); AGS, Aicardi-Goutières syndrome; BSN, bilateral striatal necrosis; CANDLE, chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature; CLL, chronic lymphocytic leukemia; CNP, complete non-penetrance; DDX58: DEAD (Asp-Glu-Ala-Asp) Box Polypeptide 58 (also known as RIG-I); dNTP, deoxynucleotide triphosphate; DSH, *dyschromatosis symmetrica hereditaria*; dsRNA, double-stranded RNA; ENU, N-ethyl-N-nitrosourea; FCL, familial chilblain lupus; IFIH1, IFN-induced helicase C domain-containing protein 1 (also known as MDA5); IFN, interferon; ISG15; IFN-stimulated gene 15; JASL, Japanese auto-inflammatory syndrome with lipodystrophy; JMP, joint contractures, muscle atrophy, microcytic anemia, panniculitis and lipodystrophy; MSMD, Mendelian susceptibility to mycobacterial disease; NNS, Nakajo- Nishimura syndrome; PSMB8, proteasome subunit-β type 8; RNASEH2, ribonuclease H2; RVCL, retinal vasculopathy with cerebral leukodystrophy; SAMHD1, deoxynucleoside triphosphate triphosphohydrolase and ribonuclease SAM domain and HD domain 1; SAVI, STING-associated vasculopathy with onset in infancy; SMS, Singleton–Merten syndrome; SPENCD, spondylochondromatosis; TREX1, DNA 3′ repair exonuclease 1; TMEM173: Transmembrane Protein 173 (also known as STING) USP18, Ubl carboxy-terminal hydrolase 18.

thrombocytopenia and/or bone marrow suppression, hypertrophic cardiomyopathy, myositis, enchondromata, lung involvement, chronic lymphocytic leukemia, premature dental loss, aortic calcification and joint contractures.

Systemic Lupus Erythematosus (SLE) is a complex autoimmune disease caused by the hyper-activated immune system in response to nuclear self antigens. One of the characteristics of this disease is the high steady-state serum IFN-α levels and a dysregulated expression of some ISGs. Autoantibodies such as anti-nuclear antibodies (ANA), anti-Ro, anti-La, anti-phospholipid, anti-dsDNA, anti-Smith and anti-nuclear ribonucleoproteins are commonly found in patients. These antibodies deliver self-nucleic acids to endosomal TLRs following F_c receptor-mediated internalization of immune complexes. This leads to hyper-induction of type I IFNs. In fact elevated levels of type I IFN in serum and dysregulated hyper expression of certain ISGs (dubbed as IFN signature) is commonly seen in 50% of these patients. Hyperactivation of IRF5 is commonly seen in this disease. The central region connecting the DBD and the IAD of IRF5 is rich in proline (P), glutamic acid (E), serine (S) and threonine (T) residues and constitutes thus a PEST domain, normally present in proteins that undergo a rapid turnover. The IRF5 gene, located on chromosome 7q32, is regulated in a complex manner by multiple gene promoters and several splice variants of its mRNA. For example a polymorphic 30-nucleotide insertion in the PEST domain produces a high-risk allele. Such IRF5 transcripts and the resultant proteins are highly stable, resulting in a persistent activation of IFN-α genes. IRF5 also activates the expression of IL-12, IL-17, IL-23 and TNF-α in human DCs and high IL-12, IL-17, IL-23 are found in plasma of SLE patients. In mammals, two major types of macrophages, the M1 and M2, mediate inflammatory and tissue repair responses, respectively. The increased cytokine levels polarize macrophages toward the M1 type to enhance inflammatory responses. Indeed, IRF5 is a key transcription factor involved in M1-macrophage differentiation. In addition, IRF5 plays a major role in the differentiation of B lymphocytes into plasma cells (which produce serum antibodies in high amounts) by promoting the expression of B lymphocyte-induced maturation protein 1 (BLIMP1). IRF5 is also involved in class switch of IgG subtypes during pathogenesis in B lymphocytes. Thus, the IRF5 – IFN axis plays a major role in driving SLE pathogenesis. Apart from SLE, IRF5 single nucleotide variations and a 5-bp insertion-deletion are also associated with disease progression in multiple sclerosis (MS), a neurodegenerative disease. Aging-associated cognitive decline is affected by external and internal factors of the brain. The choroid plexus, an interface between the brain and the peripheral blood, of aging mice and human brains expresses a type I IFN signature. In mice, this signature was stimulated by brain-derived signals, present in the cerebrospinal fluid. Neutralization of type I IFN signaling within the aged brain partially restored cognitive function and hippocampal neurogenesis and reestablished IFN-γ-dependent choroid plexus activity, which is lost in aging. Thus, IFNs play a major role in cognition-associated pathologies.

Clinical use of IFNs

The type I IFNs are efficacious in the treatment of malignancies, viral infections and autoimmune diseases (**Table 10**). The efficacy of IFN therapy is dependent on a number of factors including cell types, genetics, immune status, and microbiome etc. (**Fig. 12**). IFN-α plays a role in the management of different neoplasias, particularly those of hematological origin, that is of a myeloid and lymphoid etiology. IFN-β has been shown to have beneficial effects in the treatment of relapsing-remitting MS. IFN-γ is an absolute requirement for resistance against acute infection with *T. gondii* and development of Toxoplasmic Encephalitis during the late stage of infection. Thus, this unique repertoire of biological activities of IFNs has generated considerable interest in its potential for the treatment of viral infections, cancers and immunological disorders. Indeed, administration of IFNs is now the treatment of choice for some cancers, particularly leukemias and Kaposi Sarcoma, MS, rheumatoid arthritis and viral infections such as chronic Hepatitis-B and C (**Table 10**). However, many other types of cancer and viral infections are only partially responsive to IFN therapy. The molecular mechanisms, which determine the anti-viral and anti-proliferative sensitivity or resistance to IFNs, are yet to be fully elucidated.

Type I IFNs and Anti-Cancer Therapies

Some diseases, where IFN is a disease promoter, for example, Lupus, HIV and Interferonopathies, treatment with neutralizing antibodies may alleviate the negative effects (**Fig. 13**). However, the clinical effectiveness of such therapies need to be examined. The STING-activating ligands, and oncolytic viruses are the new IFN-based emerging therapies that have shown some promising. A number of recent reports indicate that the success of conventional chemotherapeutics, targeted anti-cancer agents, radiotherapy and immunotherapy relies on type I IFN signaling. IFNAR1 neutralization abolishes the therapeutic effect of monoclonal antibodies that are specific for human epidermal growth factor receptor 2 (ERBB2; popularly known as HER2/neu) or those specific for epidermal growth factor receptor (EGFR) in mouse models of cancer. Anthracyclines are used for treating a number of human cancers. Recent studies show that these drugs induce type I IFN production. Consistent with these, increased expression of MxA in breast tumor biopsies from patients who received anthracycline treatment predicts a better response to therapeutic response. The efficacy of anthracyclines as anti-cancer agents is suppressed by IFNAR1-neutralizing antibodies.

Radiation therapy induces IFN-β production by the myeloid (not by the tumor) cells in melanoma models. The anti-tumor effect of radiation is lost in *Ifnar1*−/− mice, as well as in mice transplanted with *Ifnar1*−/− hematopoietic cells. Type I IFN signaling is also critical for the robustness of immunotherapies. Imiquimod, a synthetic agonist of TLR7 and TLR8 promotes the IFNAR1-dependent recruitment of pDCs into the tumor bed of skin cancers. pDCs secrete type I IFNs which activate an autocrine loop

Table 10 IFN formulations in clinical practice

Type of IFN	*Chemical modification*	*Structure*	*Source*	*Recommendation*
Lymphoblastoid IFN-α N1	None	Mixture of natural human IFN-α subtypes	Lymphoblastoid cells	Hairy cell leukemia, juvenile laryngeal papillomatosis, condylomata acuminata, chronic hepatitis B or C
Natural human leukocyte IFN-α	None	Mixture of natural human IFN-α subtypes	Human leukocytes	Hairy cell leukemia, multiple myeloma, non-Hodgkin lymphoma, follicular lymphoma, chronic myelogenous leukemia, malignant melanoma, AIDs-related Kaposi's sarcoma, chronic hepatitis B or C
Human IFN-α-Le	None	Human leukocytic IFN-α (1, 2b, 8, 10, 14, 21)	Human leukocyte	Malignant melanoma; treatment of patients who initially respond to recombinant IFN-a, but for whom treatment subsequently fails, most likely as the result of neutralizing antibodies
IFN-α2b	None	165 aa (19 kDa) Arginine at position 23 deletion at position 44	Recombinant *E. coli*	Chronic hepatitis B or C, hairy cell leukemia, follicular lymphoma, condylomata accuminata, AIDs-related Kaposi's sarcoma and malignant melanoma
IFN-α2a	None	165 aa (19 kDa) Lysine at position 23 deletion at position 44	Recombinant *E. coli*	Chronic hepatitis B or C, hairy cell leukemia, chronic myelogenous leukemia
Consensus IFN (IFN-α con-1)	≈ 89% homology with IFN-α and 30% homology with IFN-β	166 aa (19.4 kDa)	Recombinant *E. coli*	Chronic hepatitis C, hairy cell leukemia
Peg IFN-α2b	12-kDa linear PEG covalently linked	165 aa (19 kDa)	Recombinant *E. coli*	Chronic hepatitis C
Peg IFN-α2a	40-kDa branched PEG covalently linked	165 aa (19 kDa)	Recombinant *E. coli*	Chronic hepatitis B and chronic hepatitis C
Peg IFN-α2a	20-kDa linear PEG covalently linked	165 aa (19 kDa)	Recombinant *Hansenula polymorpha*	Chronic hepatitis C
Peg IFN-α2b	31-kDa linear PEG covalently linked	165 aa (19 kDa)	Recombinant *E. coli*	Melanoma after surgery
Albinterferon (Albuferon)	r-Human albumin modified IFN-α2b	165 aa (19 kDa)	Recombinant *Kluyveromyces*	Chronic hepatitis C
IFN-α2b	polyActive technology-based controlled-release recombinant formulation	165 aa (19 kDa)	Recombinant *E. coli*	Chronic hepatitis C
IFN-α2b	MedUSA technology - based recombinant formulation	165 aa (19.4 kDa)	Recombinant *E. coli*	Chronic hepatitis C
IFN-β1a and 1b	None	165 aa (18.5 kDa)	Mammalian cells and Recombinant *E. coli*	Relapsing-remitting Multiple Sclerosis (RRMS)
IFN-γ1b	None	166 aa (18.5 kDa)	Recombinant *E. coli*	Chronic granulomatous disease, Severe malignant osteopetrosis

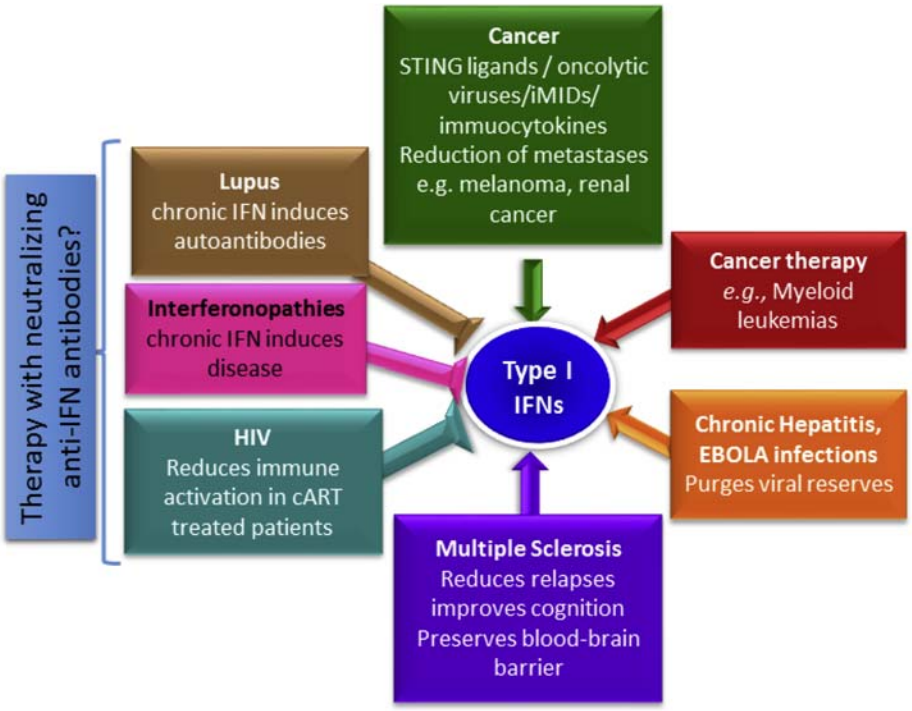

Fig. 13 Current clinical therapies based on type I IFN biology.

that promotes tumor killing by pDCs. iMiDs are immunomodulatory molecules (for example thalidomide, lenalidomide and pomalidomide) approved for the treatment of erythema nodosum leprosum (a complication of leprosy), multiple myeloma and myelodysplastic syndrome. iMiDs promote the expression of IRF7.

Emerging Targeted Type I IFN-Based Immunotherapies

Systemic administration of IFN, although produces strong anti-tumor effects, is associated with side effects such as fatigue, anorexia, hepatotoxicity, flu-like symptoms and severe depression. One approach solve this problem is to deliver the drug into tumor microenvironment. Immuno-cytokines are new therapeutics in development, where anti-tumor cytokines are fused to specific antibodies to achieve effective suppression tumor growth without wide-spread systemic toxicities. IFN-α2b coupled to hL243 (a humanized monoclonal antibody that is specific for HLA-DR) is effective against human myeloma and lymphoma xenografts. Similarly, IFN-β fused to Cetuximab (a clinically approved EGFR-targeting monoclonal antibody) robustly suppresses the growth of EGFR-expressing tumors that failed to respond to unmodified Cetuximab. IFN-α or IFN-β fusion proteins with HER2-specific monoclonal antibody efficiently target HER2-expressing neoplasms better than a therapeutic regimen based on the unmodified monoclonal antibody. Notably, the therapeutic effects of type I IFN-containing immunocytokines targeted to EGFR seem to rely on adaptive immune responses involving CTLs, DCs and IFNAR1. An anti-CD20-IFN-α fusion displays potent biological activity against CD20-expressing lymphoma cells. Other strategies to potentiate IFN-induced therapies are modifying the hematopoietic stem cells with IFN-α/β genes such that they express in differentiated cells such as monocytes, which suppress tumor growth in the microenvironment. The cGAS/cGAMP is another major target for inducing IFN-dependent tumor suppression in cancer models. Recent studies from many labs have reported highly encouraging results, which showed a strong tumor suppressor activity. Another new area that is emerging is the use of oncolytic viruses that exploit mutations in cancer cells to enable their replication. To avoid the growth-inhibitory effects of endogenous IFNs, cancer cells lose the ability to induce IFNs and ISGs. Viruses also use strategies to avoid the IFN-induced anti-viral actions (**Table 4**). Such IFN resistance becomes an Achilles' heel for cancer cells, because oncolytic viruses replicate efficiently in IFN-deficient cells. A number of oncolytic virus-based therapies have shown promising results in experimental models. Recently, the first oncolytic viral product, Talimogene laherparepvec, was approved by the FDA for human cutaneous, subcutaneous and nodal lesions in patients with melanoma recurrent after initial surgery. Thus, oncolytic viruses offer another IFN-based therapeutic strategy for controlling tumor growth.

Conclusions and Perspectives

It is clear that IFNs provided trailblazing insights into various diverse biological processes, such as transcription, post-transcriptional regulation, protein translation, self- and non-self nucleic acid recognition, innate defenses against infectious pathogens, autoimmune diseases, and anti-cancer mechanisms. That JAK-STAT pathways regulate IFN-induced gene expression was a ground breaking discovery, which led to the discovery that about 50 different cytokines, peptide hormones, growth factor receptors employ this system. IFNs act as sentinels in the 'immunosurveillance' of cancer is also well established. Apart from certain viral vaccines, IFNs are the first recombinant biological therapeutics to enter clinics for the treatment of various viral, neurological and neoplastic diseases. The success of IFNs as cancer therapeutics is comparable to those of most chemotherapeutics. Although some target-specific therapeutics such as Imatinib (which blocks the BCR-ABL kinase in CML) and a new small molecule polymerase inhibitor Solvari (HCV) are being increasingly preferred over IFN (because of their severe side effects), clinical resistance to these small molecules is a major concern and it is more likely to occur with these drugs than with IFNs. Pegylated IFNs and 'Immuno-cytokines' (IFNs coupled to specific antibodies) and IFN modulators will alleviate some of the concerns over the side-effects of IFNs. Thus, IFNs will continue to be drugs of choice in the future because of their multi-level effector functions.

Ameloblastoma

Definition

Ameloblastoma is the second most common benign odontogenic tumor following odontoma and generally arises inside bone. The conventional subtype accounts for 80%–85% of cases and has also been designated as solid/multicystic type due to its histologic pattern of growth. Left alone, the tumor grows progressively and expands the gnathic bones which can result in severe facial deformity and a characteristic polylobulated lytic ("soap bubble") appearance in conventional X-rays and CT scans. Desmoplastic ameloblastoma is defined by pronounced desmoplasia and has been considered a separate subtype in the WHO classification of 2005. According to the current classification released in early 2017, however, it is now regarded as a histologic variant of conventional ameloblastoma. Unicystic ameloblastoma is a distinct subtype presenting as a single cystic cavity with or without luminal proliferation (intraluminal vs luminal type) and accounts for 5%–15% of cases. Infiltration of the cystic wall by tumor cells defines the mural variant of unicystic ameloblastoma and there has been considerable debate as to whether this variant should be considered part of the spectrum of conventional or unicystic ameloblastoma. Rarely, ameloblastoma can develop primarily in the soft tissues of the gingiva or edentulous alveolar areas which is classified as extraosseous or peripheral ameloblastoma. Lastly and even rarer, conventional ameloblastoma can metastasize despite appearing completely benign histologically (so-called metastasizing ameloblastoma). Ameloblastic carcinoma is the overtly malignant variant of ameloblastoma and can develop without (primary) or within a preexisting or recurrent ameloblastoma (secondary).

Burden

Odontogenic tumors are very rare in general and epidemiologic data are difficult to gather. For ameloblastoma, an annual incidence of about 0.5 cases per million population has been estimated. Conventional ameloblastoma most frequently develops in the posterior mandible (80%), is uncommon in the first two decades and reaches its peak in the fourth and fifth decade of life. Desmoplastic variants are found most commonly in the anterior mandibular region. Unicystic tumors can occur earlier in life with 50% of cases developing in the second decade. The posterior mandible is again the most common site (80%) and particularly when associated with an impacted tooth, tumors can be indistinguishable from dentigerous cysts or odontogenic keratocysts clinically and radiographically. Malignant ameloblastomas (including metastasizing ameloblastoma and ameloblastic carcinoma) have been estimated to occur with an incidence of 1.79 cases per 10 million population in the United States.

Risk Factors

There are no established risk factors for developing ameloblastoma.

Pathology

Ameloblastoma originates from rests of the dental lamina which can also be found outside bone (and can give rise to peripheral ameloblastoma). All tumors share common morphologic features resembling the enamel organ, including a basal layer of columnar to cuboidal cells with hyperchromatic, palisaded and polarized nuclei and subnuclear vacuolization (also referred to as Gorlin–Vickers criteria). The shift of nuclei away from the basal lamina has been termed "reverse polarity." In the central areas,

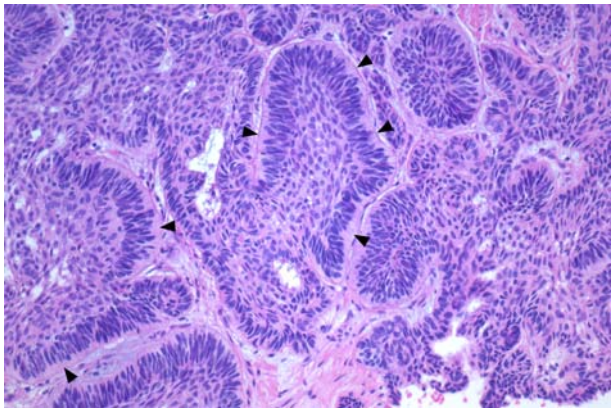

Fig. 1 Ameloblastoma: Interconnected islands of epithelial cells with peripheral palisading and subnuclear vacuoles *(arrowheads)*. The more central parts are less well arranged and resemble the stellate reticulum of the enamel organ.

the tumor cells are loosely arranged and resemble the stellate reticulum (Fig. 1). They can further show spindle, basaloid and granular cell morphology and/or squamous metaplasia and often undergo cystic degeneration. Occasionally, the peripheral cell layer lies on a thick eosinophilic band which is, however, not specific for ameloblastoma.

The conventional subtype (historically also designated as solid/multicystic subtype) primarily shows two patterns of growth: islands or follicles of epithelial cells define the follicular type, complex and continuously anastomosing strands the plexiform type. Both patterns can occur in the same tumor and the epithelial proliferations are generally embedded in a mature fibrous stroma. Although important for the pathologist to recognize, histotyping of growth patterns is of no clinical relevance. In the desmoplastic variant, the stromal component is strikingly rich in collagen fibers and seems to compress the epithelial islands from the outside. The classic Gorlin–Vickers criteria can sometimes be blurred but are usually present at least focally. Myxoid changes of the stromal component can occasionally be observed immediately adjoining the odontogenic epithelium.

Unicystic ameloblastoma presents as a well-defined, often large and generally mono-cystic cavity with a lining that is at least focally composed of ameloblastic epithelium. Commonly, the epithelial layer appears flat and can therefore resemble dentigerous (or other odontogenic) cysts. Secondary metaplasia caused by non-specific inflammatory changes or superinfection can further obscure the defining histologic criteria and render a diagnosis on bioptic material challenging to sometimes impossible. If the tumor appears purely cystic, a luminal variant of unicystic ameloblastoma should be considered, intraluminal projections define the intraluminal variant. Infiltration of ameloblastic epithelium into the cystic wall are diagnostic for the mural variant. Extraosseous or peripheral ameloblastoma is morphologically identical to the conventional subtype and is only defined by its site of origin.

Ameloblastic carcinoma appears cytologically malignant with nuclear enlargement and polymorphism as well as increased nuclear hyperchromasia and mitotic activity. Abnormal mitotic figures, necrosis, perineural and/or vascular invasion may occur but borderline lesions can be difficult to diagnose. In general, the ameloblastic differentiation is still recognizable, at least focally, but nearly undifferentiated spindle cell lesions have been described.

Immunophenotyping is of no diagnostic value in ameloblastoma and individual subtypes.

Molecular Pathology and Genetics

Conventional ameloblastomas are characterized by MAPK pathway and FGFR2 mutations as well as several non-MAPK mutations, including SMO, SMARCB1, CTNNB1, and PIK3CA. The most common alteration is the BRAF V600E mutation which can be identified in roughly 2/3 of cases and is usually confined to mandibular tumors. It is more frequent in patients of younger age. In maxillary ameloblastomas, SMO mutations are the most common aberrations. KRAS, NRAS, HRAS, and FGFR2 (activator of RAS) mutations are generally mutually exclusive to BRAF mutations and have been reported in 2/3 of V600E wild type cases, sometimes in addition to SMO mutations. Taking into account all genes described, somatic mutations in known oncogenes can be detected in roughly 90% of ameloblastomas. Specific BRAF inhibitors (e.g., vemurafenib) have been shown to be effective in ameloblastoma cell lines and in selected patients harboring the V600E mutation. The experience is so far, however, limited to case reports and systematic studies have not been conducted so far. SMO inhibition in hedgehog-driven tumors or antagonizing EGFR signaling which is often overactive in ameloblastoma might be promising alternatives but efficacy has also been demonstrated only in cell lines yet. Data on unicystic ameloblastoma and ameloblastic carcinoma are still limited to small series and case reports but BRAF V600E mutations seem to be the most prevalent alteration in those tumors as well.

Notably, V600E BRAF mutations have been identified also in the epithelial component of other odontogenic tumors, including ameloblastic fibroma and precursor lesions of developing odontoma (ameloblastic fibroodontoma), pointing to common pathway alterations in the molecular pathogenesis of these lesions.

Microenvironment Including Immune Response

There are no established data on the microenvironment of ameloblastoma. On pure morphologic basis, tumor infiltrating inflammatory cells are not a common feature in these tumors.

Staging and Grading

As ameloblastoma is considered a benign tumor, staging is confined to local tumor extent and there is no grading system. Ameloblastic carcinoma is not graded either, staging, however, should be complemented to exclude pulmonary metastases.

Prognostic and Predictive Biomarkers

The single most important prognostic factor in ameloblastoma is the accuracy of surgery aiming for free margins which may be obtained by careful enucleation and curettage for small lesions whereas larger lesions may require more radical treatment. For the same reason it is difficult to appraise biomarker studies in the literature, since early recurrence might not be due to a mutation or an overexpressed marker protein but simply caused by incomplete surgery. BRAF V600E mutations were found to be associated with a favorable outcome but there are conflicting data reported in the literature as well. Whether BRAF and SMO mutations and/or EGFR overexpression might serve as predictive markers in the future has to be elucidated in larger studies.

Odontogenic Myxoma/Myxofibroma

Definition

Odontogenic myxoma is considered the third most common benign odontogenic tumor following odontoma and ameloblastoma and generally arises inside bone (peripheral variants are exceptionally rare). It belongs to the group of benign mesenchymal odontogenic tumors and lacks an epithelial component. Greater amounts of collagens define odontogenic myxofibroma although the distinction is arbitrary and without clinical relevance. The tumors usually present lytic in conventional X-rays and CT scans and cause a painless swelling or asymmetry of the jaws over time. Similar to ameloblastoma, they can be polylobulated resulting in a "soap bubble" or honeycomb appearance with a delicate bony trabeculation. Tumor extent can be difficult to assess radiologically and should include MRI scans. Root displacement is common, root resorption can occur but is rather infrequent ($<10\%$).

Burden

The lesions are rare and account for 2%–5% of all odontogenic tumors. Roughly 2/3 of cases develop in the mandible, tumors of the maxilla tend to infiltrate the maxillary sinus. Most cases are located in the molar and premolar areas. Women seem to be more commonly affected then men (ratio 1.5:1). The age distribution is broad but 3/4 of cases develop within the second to fourth decade of life.

Risk Factors

There are no established risk factors for developing odontogenic myxoma.

Pathology

Odontogenic myxomas are locally aggressive, non-encapsulated and non-metastasizing neoplasms that diffusely infiltrate the marrow spaces. The neoplastic cells are evenly distributed in abundant extracellular ground substance rich in acid mucopolysaccharides and show stellate, spindle-shaped or round cell morphology. Thin cytoplasmic processes interconnect the tumor cells, the cytoplasm is pale to eosinophilic (Fig. 2). In case of odontogenic myxofibroma, the amount of collagen is more pronounced, but the myxoid character of the lesion remains recognizable. The lesional cells can show mild atypia and scattered mitotic figures, occasionally, epithelial remnants can be found within the tumor. Immunohistochemically, the tumor cells express vimentin, orosomucoid 1 and nestin with non of the marker proteins being specific for odontogenic myxoma.

The main differential diagnosis are normal structures. Both the dental papilla and the dental follicle of a developing tooth show evenly dispersed spindle cells within a myxoid stroma that can closely mimic odontogenic myxoma. During development of the dental pulp, the cells in the periphery of the papilla condensate to form odontoblasts and are sometimes lined by a layer of inner enamel epithelium. The follicle surrounding the tooth germ can furthermore become hyperplastic and contain various derivates of the odontogenic apparatus including cementum, dystrophic calcifications and epithelial remnants. Whenever normal structures are identified in close vicinity to tissue resembling myxoma, the differential diagnosis of tissue related to a developing tooth should always be considered. Furthermore, correlation with clinical and radiologic findings is mandatory since odontogenic myxomas are mass-forming lesions that should appear as such and are not diagnosed as incidental findings.

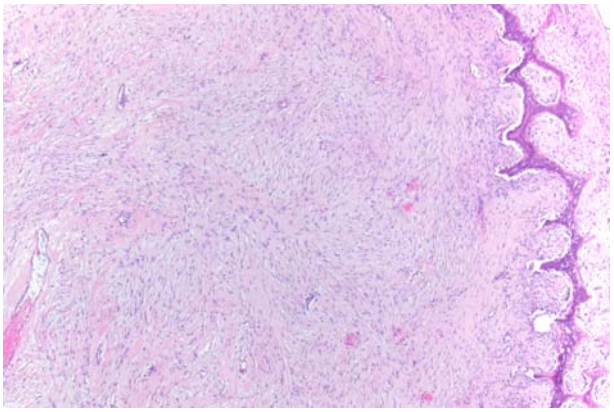

Fig. 2 Odontogenic myxoma: Monomorphic stellate-like spindle cells delineated by a layer of newly formed woven bone *(right side)*.

Molecular Pathology and Genetics

Odontogenic myxoma has been linked to tuberous sclerosis and Gorlin syndrome in single case reports but data on the molecular pathogenesis of the disease is scarce. Mutations in the PRKAR1A gene, which is commonly mutated in cardiac myxomas (both in sporadic cases and in the setting of Carney complex), have been reported in 2/17 odontogenic myxomas. Common oncogenes and tumor suppressors, however, do not seem to play a major role in tumor development, as targeted sequencing of 50 frequent cancer genes did not identify a single (pathogenic) mutation in a set of nine odontogenic myxomas.

Microenvironment Including Immune Response

There are no established data on the microenvironment of odontogenic myxoma. On pure morphologic basis, tumor infiltrating inflammatory cells are not a common feature in these tumors.

Staging and Grading

As odontogenic myxomas are benign neoplasms, staging is confined to local tumor extent which can be difficult to assess due to diffuse infiltration into bone and the surrounding structures. The tumors are not graded.

Prognostic and Predictive Biomarkers

Similar to ameloblastoma, complete resection with free margins is the single most important prognostic factor in odontogenic myxoma. Recurrences are reported to occur in 25% of cases. For small cases with a more fibrous nature, enucleation and curettage may be a therapeutic option.

Osteosarcoma of the Jaws

Definition

Osteosarcoma (OS) is a malignant mesenchymal tumor in which the tumor cells produce bone. Gnathic tumors differ in several aspects from their peripheral counterparts warranting a separate discussion in this article. Symptoms are generally nonspecific and include pain, swelling and loosening of teeth. Radiologically, OS present as mixed radiolucencies reflecting the kind, extent and mineralization of neoplastic matrix formation. Aggressive features such as periosteal reaction and/or cortical permeation are commonly present in high-grade lesions.

Burden

Although OS generally develops in the metaphyses of long bones during skeletal growth, the fourth most common site of origin are the jaws, accounting for approximately 6% of cases. The disease is nevertheless exceedingly rare with an estimated annual incidence of about 1–2 cases per 10 million population. Contrary to the peripheral skeleton, gnathic tumors develop after skeletal maturity and preferentially in the third and fourth decade of life. Men and women are equally affected, there is a slight predilection for the mandible.

Risk Factors

Risk factors are similar to extragnathic OS including prior radiotherapy, M. Paget or several cancer predisposition syndromes (e.g., Li Fraumeni and Retinoblastoma syndrome).

Pathology

Histologically, jaw tumors do not differ from their peripheral counterparts and usually show pleomorphic tumor cells producing a lace-like osteoid matrix (Figs. 3 and 4). The degree of atypia, mitotic activity and necrosis varies but is usually less pronounced compared to extragnathic tumors. Chondroblastic variants are more common in the jaws which can cause diagnostic problems, particularly in core needle biopsies. It therefore needs to be kept in mind that pure chondrogenic tumors (chondroma or chondrosarcoma) are exceedingly rare in the jaws, and diagnosis cannot be made with certainty unless an IDH1/2 mutation has been identified or the complete tumor has been histologically screened for smaller foci of osteoid formation. On the other hand, whenever cartilage is present in a biopsy from the jaws and there is no history of prior fracture with callus formation, an OS should always be within the differential diagnosis.

MDM2 amplification can be found in about 79% of parosteal, 29% of low-grade central and in $<10\%$ of conventional high-grade OS. Immunohistochemical expression of MDM2 can serve as a surrogate but needs confirmation using FISH due to limited specificity. Since parosteal OS is virtually nonexistent in the jaws and data on MDM2 amplification of gnathic OS is lacking, the diagnostic value of MDM2 testing remains unclear. In general, the analysis only helps in case an amplification is detectable but normal copy numbers of the gene do not argue against OS. Additional immunohistochemistry with antibodies directed against SATB2, pro-collagen I and osterix can help to confirm an osteoblastic lineage differentiation but are usually not required and also not specific for the disease.

Molecular Pathology and Genetics

Osteosarcomas generally show highly complex karyotypes with abundant numerical and structural aberrations. Only recently, the tumors have been shown to acquire homologous recombination repair insufficiency as a common trait in the majority of cases ($>85\%$ of cases) that might be therapeutically exploitable by the use of PARP inhibitors. Up to now, genetic analyses of osteosarcoma have been limited to tumors of the peripheral skeleton and have not included gnathic OS. The molecular basis for the differences in biologic behavior and prognosis is therefore still unknown.

Microenvironment Including Immune Response

There are no established data on the microenvironment of gnathic OS. On pure morphologic basis, tumor infiltrating inflammatory cells are not a common feature in these tumors.

Staging and Grading

There are no commonly accepted guidelines for staging procedures in gnathic OS but besides the assessment of local tumor extent, pulmonary metastases should be ruled out by a CT scan of the chest. Grading is generally performed according to tumors of the peripheral skeleton.

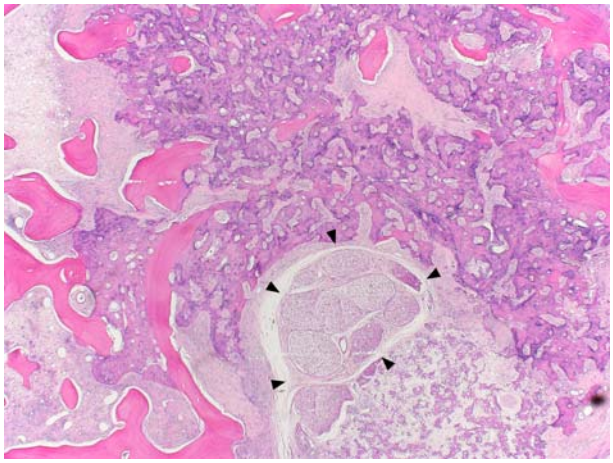

Fig. 3 Osteosarcoma: Neoplastic matrix formation permeating through preexisting bone and encircling the inferior alveolar nerve *(arrowheads)*.

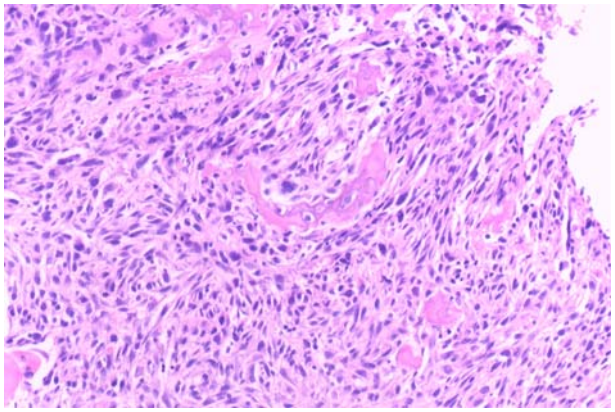

Fig. 4 Osteosarcoma: Pleomorphic and hyperchromatic spindle cells with immature and neoplastic new bone formation.

Prognostic and Predictive Biomarkers

For yet unknown reasons, gnathic OS metastasize far less frequently (6%–21% of cases) and later in the course of the disease compared to OS of the peripheral skeleton, rendering complete resection with clear margins the single most important prognostic factor for affected patients. If achievable, 10-year survival rates exceed 80% and the prognosis remains excellent even if clear margins can only be accomplished after repeated surgery. The role of (neo-)adjuvant chemotherapy is thus still controversial and difficult to investigate systematically due to the rarity of the disease. There are, however, tumors that follow an aggressive course which might not be obvious morphologically. Notably, the favorable outcome of most OS is restricted to tumors developing in the jaws, whereas tumors of the skull or facial bones behave similar to extragnathic tumors.

Craniofacial Fibrous Dysplasia

Definition

Fibrous dysplasia (FD) is a skeletal anomaly caused by a post-zygotic missense mutations of the GNAS gene encoding the activating alpha-subunit of the stimulatory G-protein. The mutation results in the proliferation of undifferentiated bone marrow related stem cells that transform into functionally impaired bone forming progenitors. Marrow spaces are replaced by a fibroblastic spindle cell stroma containing immature trabeculae of woven bone. Fibrous dysplasia might involve single (monostotic) or multiple bones (polyostotic) and can occur together with a range of endocrinopathies and skin lesions (Café-au-lait spots) as McCune Albright syndrome or along with intramuscular myxoma as Mazabraud's syndrome. In the craniofacial bones, multiple adjacent bones are characteristically affected which is still considered as a monostotic involvement and designated as craniofacial fibrous dysplasia (CFD). Symptomatic patients generally notice painless diffuse swellings of the affected region which might cause significant cosmetic deformity and compression/obstruction of vital structures (e.g., the optic nerve or foramina of the skull base). Radiographically, early FD is primarily lytic but develops the characteristic homogeneous ground-glass appearance over time. Lesions are not well defined and gradually blend into the adjacent normal bone. The radiologic and clinical picture is highly characteristic so the diagnosis can often be made without requiring histologic proof (Fig. 5).

Burden

Exact figures on the incidence of FD or CFD are unknown because many patients are asymptomatic. Monostotic involvement is 6–10 times more common than polyostotic disease, craniofacial involvement is frequent (>50% of cases). CFD most frequently involves the maxilla and adjacent bones but can develop in virtually any (craniofacial) bone.

Risk Factors

There are no established risk factors for developing crandiofacial dysplasia.

Pathology

Morphologically, CFD is similar to FD in the peripheral skeleton and reveals a monomorphic and cytologically bland spindle cell stroma containing islands or trabeculae of woven bone. In early stages, the stroma appears immature and richly cellular although mitotic activity is low. Directly evolving from the spindle cells, varying amounts of metaplastic woven formation are recognizable that typically lack osteoblastic rimming. The architecture of the trabeculae can be curvilinear and has been described to resemble

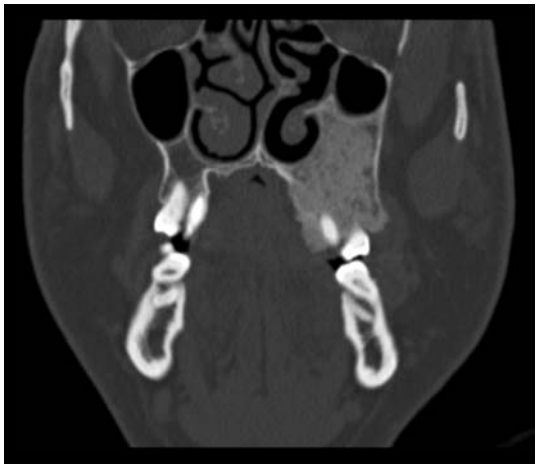

Fig. 5 Fibrous dysplasia: Fibrous dysplasia presenting as an ill-defined expansion of the left maxilla with homogenous ground-glass appearance (CT scan, coronal plane).

Chinese script letters (Fig. 6). Although nonspecific, the kind of matrix formation is almost unique and diagnostic for FD, especially in the hand of an experienced pathologist. Using special stains (e.g., van Gieson), a typical pattern of Sharpey's fibers radiating perpendicularly from the trabeculae into the surrounding stroma can furthermore be seen. Over time, the stromal cellularity decreases and the woven bone matures slowly into lamellar bone that can also show some degree of osteoblastic rimming due to an ongoing remodeling. Occasionally, FD can undergo infarction which can further blur the diagnostic changes and further complicate the histologic diagnosis. Like in other tumors and tumor-like lesions of bone, diagnosis should thus always include the correlation with clinical and radiologic findings, particularly in long-standing disease.

Molecular Pathology and Genetics

Point mutations in the GNAS gene can be detected in the vast majority (>90%) of cases. Over time, however, the lesional cells progressively decrease in number and the amount of mutant gene copies can fall below the detection threshold of the diagnostic method used. Particularly in older or matured lesions, lack of GNAS mutations therefore does not necessarily argue against the diagnosis.

Microenvironment Including Immune Response

There are no established data on the microenvironment of craniofacial fibrous dysplasia. On pure morphologic basis, tumor infiltrating inflammatory cells are not a common feature in these tumors.

Staging and Grading

Fibrous dysplasia is a benign condition and does not require staging procedures besides the assessment of local extent and individual symptoms. There is no grading system either.

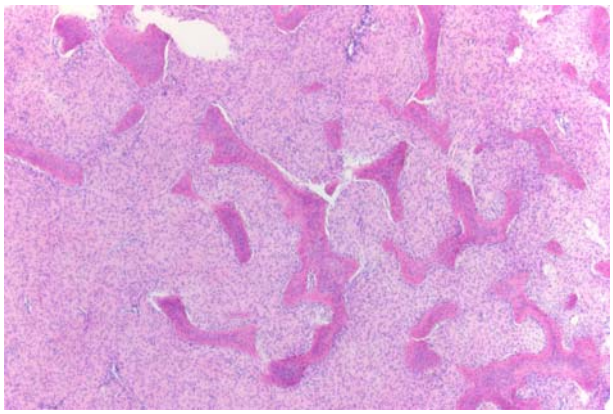

Fig. 6 Fibrous dysplasia: Irregularly shaped woven bone formation embedded in a monomorphous fibroblastic spindle cell stroma lacking atypia.

Prognostic and Predictive Biomarkers

In most patients, CFD stabilizes or even undergoes some degree of remission after skeletal maturity. Surgical intervention should only be considered in severe cases to preserve function and optimize esthetics. Although there is no unified consensus on the exact timing or even the indication for surgery, it is usually postponed until the patient has reached the end of puberty. There are no prognostic or predictive biomarkers to anticipate the clinical course of individual patients. Malignant transformation, most commonly into high-grade OS, is exceedingly rare.

Ossifying Fibroma

Definition

Ossifying fibroma together with (craniofacial) fibrous dysplasia and cemento-osseous dysplasia belong to the descriptively defined group of fibro-osseous lesions of the jaws. Among three variants that can be distinguished, the most common type is the cemento-ossifying fibroma (COF), a tumor of odontogenic origin that exclusively develops in the tooth-bearing areas of the jaws. Juvenile trabecular ossifying fibromas (JTOF) and juvenile psammomatoid ossifying fibromas (JPOF) are rare bone tumors that can develop also in extragnathic sites. All variants generally present as painless intraosseous swellings that can reach considerable and disfiguring dimensions if left untreated. Early lesions are radiologically lytic but over time matrix mineralization increases, resulting in a mixed lytic and sclerotic appearance; usually, a lytic rim remains encompassing the lesion. JTOF and JPOF can grow rapidly and are therefore also designated as juvenile aggressive subtypes, but in general, ossifying fibroma are slowly growing, well circumscribed and expansile lesions that lead to cortical thinning. Aggressive periosteal reactions or wide destruction of preexisting bone are generally not present and are important aspects in the differential diagnosis of osteosarcoma. Occasionally, the lesions are associated with secondary aneurysmal bone cysts.

Burden

Cemento-ossifying fibroma preferentially develops in women in the third to fourth decade of life (female to male ratio = 4:1). Although any tooth-bearing area of the jaws might be affected, the mandible and primarily the molar/premolar region is the most common site of origin. The juvenile variants occur at younger age (8.5–12 years mean age for JTOF and 16–33 years for JPOF) but the age distribution is broad and ranges up the seventh decade. JTOF are most common in the maxilla but can rarely occur also at extragnathic sites, JPOF only infrequently affect the jaws and are more prevalent in extragnathic locations, preferentially in the periorbital frontal and ethmoid bones. All subtypes generally develop as solitary lesions with the exception of multifocal manifestations in the exceedingly rare hyperparathyroidism jaw tumor syndrome. Multifocal involvement of lesions with a similar morphology have also been reported as (familial) gigantiform cementoma.

Risk Factors

There are no established risk factors for developing ossifying fibroma.

Pathology

Ossifying fibromas are characterized by varying amounts and kinds of hard tissue formation embedded in a moderately cellular and fibroblast-like spindle cell stroma. The latter usually appears monomorphic and without significant atypia although hyperchromatic nuclei can be present. Mitotic activity is usually low. In COF, the matrix component consists of woven bone trabeculae with prominent osteoblastic rimming and different stages of maturation (Fig. 7). Additionally, hypo- or acellular cementum-like material can usually be encountered. Over time, the mineralized matrix increases and can coalesce to form more complex structures, that are also visible radiologically as enlarging areas of sclerosis. JTOF can infiltrate into the surrounding marrow spaces and typically demonstrates delicate strands of woven bone that lack evidence of maturation. The matrix and stroma component blend into each other resulting in very immature appearing bone (Fig. 8). In JPOF, spherical and paucicellular matrix deposits reminiscent of psammoma bodies/cementum-like material predominate that can coalesce over time and secondarily induce new bone formation (Fig. 9).

Fibrous dysplasia and particularly cemento-osseous dysplasia can mimic ossifying fibroma histologically, underlining the need for a thorough radiologic and clinical correlation of findings. Cemento-osseous dysplasia is usually not expansile and often occurs multifocally, fibrous dysplasia is less well defined, can affect several adjacent craniofacial bones and typically lacks osteoblastic rimming.

Molecular Pathology and Genetics

Due to the rarity of the disease and the intense mineralization requiring decalcification procedures, molecular and genetic analyses are restricted to few and smaller case series so far. Mutations in the CDC73 gene causes the hyperparathyroidism jaw tumor syndrome and has been detected also in sporadic cases. Recent studies have suggested juvenile ossifying fibromas to represent

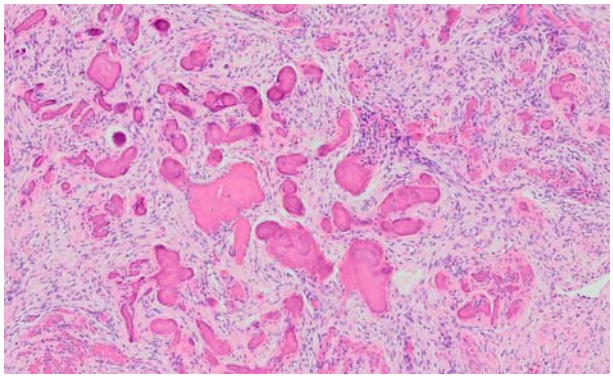

Fig. 7 Cemento-ossifying fibroma: Bony particles of varying size and shape embedded in a monomorphous fibroblastic spindle cell stroma lacking atypia.

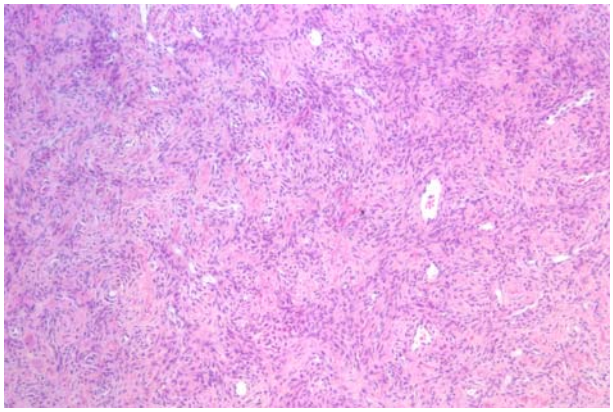

Fig. 8 Juvenile trabecular ossifying fibroma: Immature and slender strands of woven bone directly emerging from and blending into a fibroblast-like spindle cell stroma without atypia.

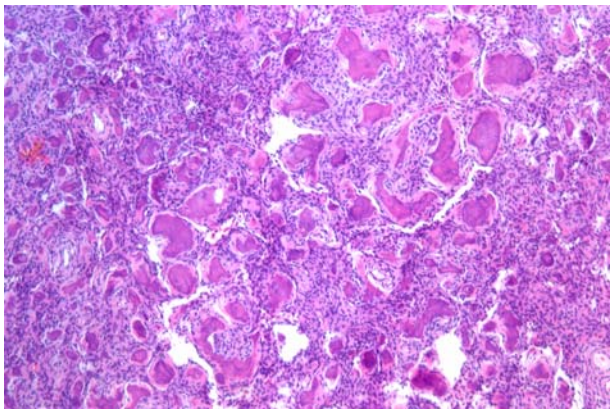

Fig. 9 Juvenile psammomatoid ossifying fibroma: Multiple psammoma-body like ossicles embedded in a cellular spindle cell stroma without significant atypia.

potential precursor lesions of osteosarcoma of the jaws due to an increased amount of MDM2 and RASAL1 templates detected by qPCR, both located on the long arm of chromosome 12. Whereas MDM2 and RASAL1 flank nearly the complete chromosomal arm, the amplification typical for parosteal osteosarcoma and a smaller subset of low-grade central osteosarcoma (approximately 30% of cases) is confined to a very small chromosomal region encompassing the MDM2 and CDK4 genes that are located in close proximity to each other. Although interesting, the data published is not sufficient to conclude a relationship between ossifying fibroma and osteogenic sarcoma or even to consider juvenile ossifying fibroma as a potential precursor of osteosarcoma. GNAS mutations typical for fibrous dysplasia do not occur in ossifying fibroma.

Microenvironment Including Immune Response

There are no established data on the microenvironment of ossifying fibroma. On pure morphologic basis, tumor infiltrating inflammatory cells are not a common feature in these lesions.

Staging and Grading

As ossifying fibromas are uniformly benign, staging is confined to the assessment of local tumor extent. There is no grading system applicable to these lesions.

Prognostic and Predictive Biomarkers

There are no established prognostic or predictive biomarkers in ossifying fibroma. If excised completely, recurrences are rare. Malignant transformation has not been convincingly described.

Central Giant Cell Granuloma

Definition

Central giant cell granulomas (CGCG) are localized and benign but locally aggressive tumors occurring exclusively in the jaws. The majority of lesions grow slowly and present as asymptomatic expansions of bone but one third of patients experience rapid growth, pain, resorption and displacement of teeth, bone errosion (or destruction), and/or soft tissue infiltration. Generally, CGCG are solitary lesions but can occur multifocally, particularly when associated with neurofibromatosis type 1 or Noonan−/LEOPARD syndrome (so-called RASopathies). Radiographically, CGCG appear lytic and polylobulated. They can reach considerable dimensions with cortical thinning and sometimes show central septae of woven bone resulting in a typical honeycomb pattern. Aggressive permeative growth or periosteal reactions are usually absent.

Burden

CGCG represent about 10% of all benign tumors in the jawbones. They occur more commonly in women and usually develop under the age of 20. The anterior mandible is the most frequently affected site.

Risk Factors

There are no established risk factors for developing CGCG.

Pathology

Histologically, CGCG show a lobular proliferation of mononuclear cells with a storiform pattern of growth. The cells appear spindle-shaped or polygonal and lack cytologic atypia (Fig. 10). Mitoses are frequently seen but are not atypical. Intermingled and partly clustered around vascular spaces and hemosiderin deposits, a varying number of rather small multinucleated giant cells

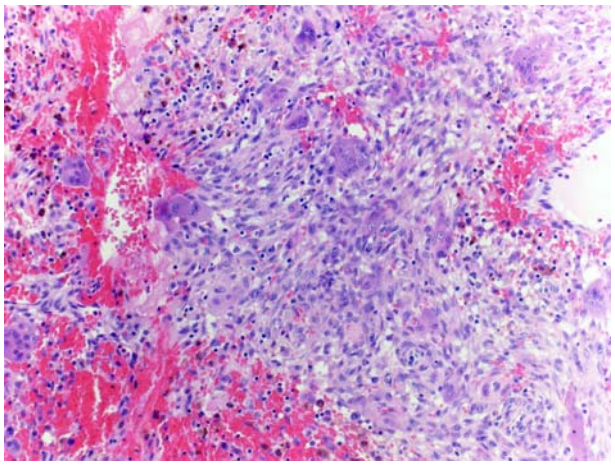

Fig. 10 Central giant cell granuloma: Monomorphic spindle cells arranged in a storiform pattern with intermingled multinucleated giant cells.

(< 15 nuclei per section) can be observed. In some cases, they can be present only focally but they generally do not predominate the histology like in classic giant cell tumor of bone. The lobules of tumor cells are typically incompletely separated by fibrous septae that can contain metaplastic new bone formation.

Brown tumors related to hyperparathyroidism can appear morphologically identical to CGCG so laboratory tests should be complemented to rule out such a condition. The solid variant of aneurysmal bone cyst is another differential diagnosis that can histologically closely mimic CGCG and molecular tests can be useful to exclude these lesions (see below). Conventional giant cell tumors of bone generally do not occur in the jaws with very rare convincing exceptions affecting the condylar process. Syndrome-related giant cell lesions are morphologically identical to sporadic cases but can show a striking predominance of spindle-shaped mononuclear cells. Another syndrome with a similar histologic appearance is cherubism that typically affects all quadrants of the jaws and leads to a marked and sometimes disfiguring expansion of bone.

Molecular Pathology and Genetics

Although the genetic background of sporadic CGCG is still unknown, molecular tests can help to rule out histological mimics. Giant cell tumors of bone typically harbor point mutations in the *H3F3A* gene (p.G34W) which have not been detected in CGCG. These lesions are therefore not only histologically but also molecularly distinct. Primary aneurysmal bone cysts show rearrangements of the *USP6* gene in about 70% of cases that can be detected by FISH analyses. Although a negative FISH result does not exclude the diagnosis, aneurysmal bone cysts usually have larger pseudocystic areas that should make a distinction from CGCG easily possible in the majority of cases.

Microenvironment Including Immune Response

There are no established data on the microenvironment of CGCG. On pure morphologic basis, tumor infiltrating inflammatory cells are not a common feature in these tumors.

Staging and Grading

As CGCG is considered a benign tumor, staging is confined to local tumor extent and there is no grading system.

Prognostic and Predictive Biomarkers

Most CGCG can be cured by local curettage but recurrences occur, particularly in clinically aggressive and syndrome-related lesions. The role of adjuvants including antiresorptive drugs (e.g., RANK ligand inhibitors and bisphosphonates) is currently still unclear and should be restricted to patients in which a complete removal of the lesion is surgically difficult or unfeasible.

Malignant Odontogenic Tumors

The odontogenic tissues occasionally are the source of malignant neoplasms occurring within the jaw bones. They may be epithelial, mesenchymal, or mixed. The following malignant epithelial types (odontogenic carcinomas) are recognized: ameloblastic carcinoma, primary intraosseous carcinoma, sclerosing odontogenic carcinoma, clear cell odontogenic carcinoma and ghost cell odontogenic carcinoma. Mesenchymal malignancies are labeled as odontogenic sarcoma and those of a mixed nature are known as odontogenic carcinosarcoma. Their extreme rarity precludes more extensive discussion; for more information the reader is referred to specialized texts on odontogenic tumors.

Prospective Vision

The field of genetics of odontogenic tumors is yet largely unexplored. It is to be expected that within the near future, elucidation of the pathways involved in these tumors will offer new tools for diagnosis and treatment.

Definition and Classification

Kidney tumors include tumors of the renal cortex and renal pelvis. Approximately 90% of renal tumors are renal cell carcinomas (RCC). Of those, about 80% are clear cell tumors (ccRCC; ICD-O code: 8310/3) which are a heterogeneous group of malignant neoplasms composed of cells with clear or eosinophilic cytoplasm. They have a typical vessel formation and a characteristic molecular background with *VHL* inactivation and the upregulation of *HIF* (see the section "Pathology and Genetics").

Other, less common, variants include papillary (ICD-O code: 8260/3), chromophobe (8317/3), MiT family translocation (8311/3), and Bellini duct (collecting duct) renal cell carcinoma (8319/3). Medullary renal carcinoma (8510/3) is a variant of collecting duct renal carcinoma and was initially described as occurring in sickle-cell trait-positive patients. Renal cancer associated with end-stage acquired cystic kidney disease is regarded as an independent histological subtype.

Presentation and Diagnosis

The two most common renal cell carcinomas are clear cell and papillary type. Clear cell renal cell carcinomas (ccRCCs) are typically sporadic solitary globular tumors protruding from the renal cortex in either kidney. The border with the kidney is usually sharp, with a pseudocapsule. Multifocality and/or bilaterality are rare, and—together with an early age onset—are characteristic for familial cancer syndromes, such as von Hippel-Lindau (VHL) syndrome. Papillary renal cell carcinoma (PRCC) occurs in the renal cortex and may be multifocal. Multiple tumors may occur in association with renal scarring. Multiple and/or bilateral tumors are also characteristic for hereditary disease. PRCC is often well circumvented with a pronounced pseudocapsule and varies in color, depending on the degree of intratumoral hemorrhage. It usually has a friable consistency. Larger tumors may contain fibrosis as well as foci of necrosis and/or cystic degeneration.

The most common RCC symptoms are hematuria and flank pain. However, the classic triad of flank pain, visible hematuria, and palpable abdominal mass is rare (6%–10%) in earlier disease stages. About 60%–80% of kidney tumors are detected incidentally on ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI), many of them at an asymptomatic stage.

Laboratory evaluation includes a complete blood count and a comprehensive metabolic panel which may include serum corrected calcium, serum creatinine, liver function studies, and urinalysis. CT of the abdomen, with or without pelvic CT, and chest x-ray are essential studies in the initial workup. For metastatic evaluation, chest radiography must be performed at the very least,

although chest CT is more accurate than radiograph for chest staging. Abdominal MRI is used to evaluate the inferior vena cava if tumor involvement is suspected, or it can be used instead of CT for detecting renal masses and for staging when contrast material cannot be administered. As the recommended abdominal imaging studies provide high diagnostic accuracy, a needle biopsy is not always necessary before surgery.

Histological diagnosis includes, besides difining the RCC type, an evaluation of the nuclear grade, sarcomatoid features, vascular invasion, tumor necrosis, and invasion of the collecting system and peri-renal fat as well as defining pT and pN categories. A variety of grading systems for renal cell neoplasia have been proposed, the most widely used being the Fuhrman grading system. However, none of these systems has been validated for many of the most recently described renal cell carcinoma morphotypes and using the four-tiered Wolrd Health Organization/International Society of Urological Pathology (WHO/ISUP) grading system is therefore recommended.

Epidemiology and Risk Factors

Kidney Cancer Burden

Kidney cancer is the 13th most common cancer in the world and the 9th most frequent in men. In 2012, 214,000 new cases were reported in men and 124,000 in women. Approximately 70% of cases occurred in countries with high and very high levels of socioeconomic development. Renal cell carcinoma is more frequent in men than in women and is rare in children. With 143,000 deaths from kidney cancer (91,000 in men and 52,000 in women) in 2012, it was the 16th cause of cancer death worldwide (Fig. 1).

Both incidence and mortality rates have been increasing in many countries, across different levels of socioeconomic development. The number of new kidney cancer cases is predicted to rise by 184,064 by the year 2030, and the number of associated deaths by 86,754.

Etiology and Risk Factors

Renal cell carcinoma is more common in men than in women (approximately 2:1), with the peak incidence between 60 and 70 years of age. Approximately 2%–4% of renal carcinomas are hereditary and having a first-degree relative with RCC roughly doubles the risk of developing the disease. Hereditary clear cell RCCs are rare. Chromosome 3p14.2 was suggested as a genomic region containing a kidney cancer susceptibility gene as chromosomal translocations involving this region have been found in

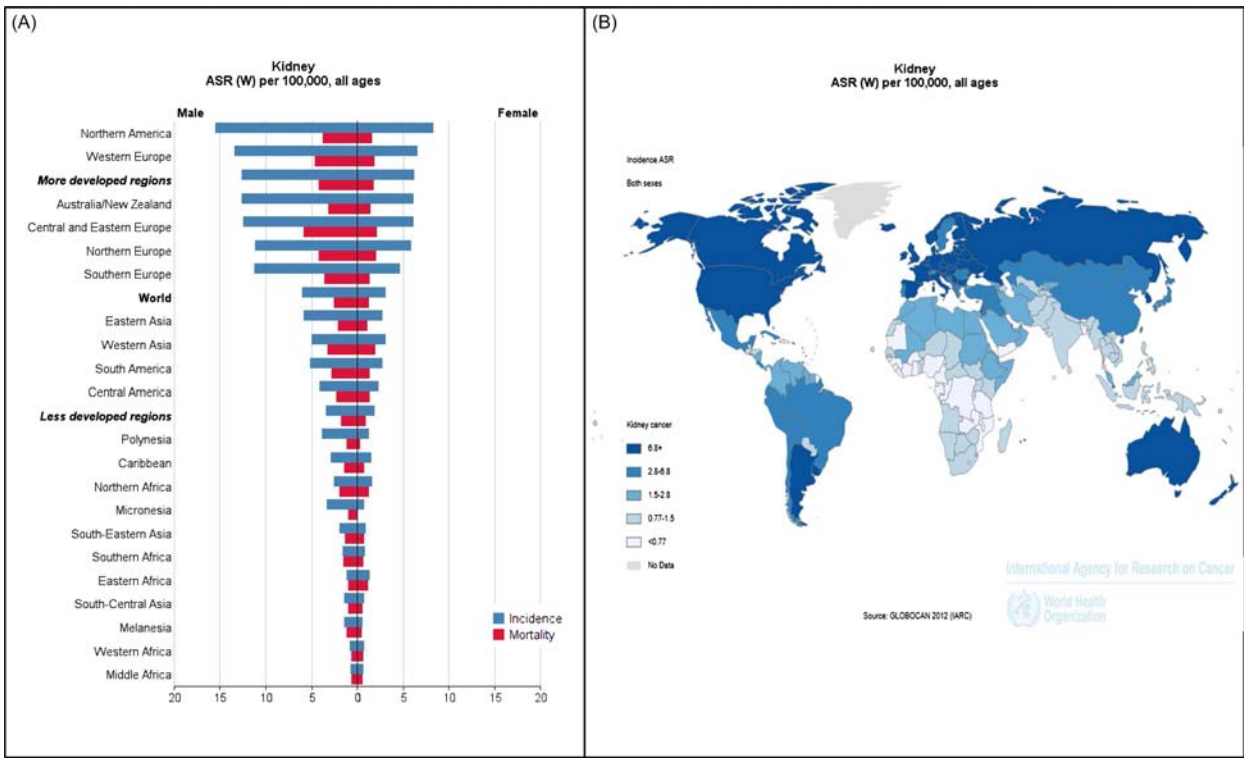

Fig. 1 Incidence and mortality of kidney cancer worldwide. (A) Age-standardized incidence and mortality rates (ASR) by gender and geographical area. (B) Incidence distribution worldwide. Table 1 Risk factors for renal carcinoma

Carcinogenic agents classified by IARC Monographs on the Evaluation of Carcinogenic Risks to Humans (volumes 1–120)	
	Agents of sufficient evidence for kidney carcinogenicity in humans
	Tobacco smoking
	X-radiation and gamma-radiation
	Trichloroethylene
	Plants containing aristolochic acid
	Phenacetin and phenacetin-containing analgesic mixtures
	Agents of limited evidence for kidney carcinogenicity in humans
	Arsenic and inorganic arsenic compounds
	Cadmium and cadmium compounds
	Perfluorooctanoic acid
	Printing processes
	Welding fumes
	Aristolochic acid
Other carcinogenic agents and lifestyle risk factors	
	Obesity
	Hypertension and the use of antihypertensive drugs

a small proportion of families with hereditary renal cell carcinoma (HRCC) and a high prevalence of somatic loss of 3p heterozygosity was identified by tumor studies. However, no causative gene has been identified so far. Several familial syndromes are associated with an increased risk of renal tumors. The most common is the von Hippel-Lindau (VHL) syndrome associated with germline mutations in the *VHL* gene (3p25.3), which predisposes to multiple bilateral renal cell carcinomas and renal cysts. The gene for the hereditary nonpapillary renal cell carcinoma, however, is thought to be different form the *VHL* gene.

Smoking, obesity (body fatness) and hypertension are established risk factors for the development of RCC. The proportion of all renal cancer cases attributable to overweight and obesity in the United States and in European countries has been estimated to be approximately 40%. Hypertension and the use of antihypertensive medication are associated with an increased risk of RCC independently of obesity. Additionally, a number of occupational, lifestyle and health-related exposures have been suggested as potential risk factors for RCC development (Table 1). Finally, the incidence of renal cancer among patients with end-stage acquired cystic kidney disease is reported to be markedly increased.

Pathology and Genetics

The gene which is by far most frequently altered in kidney cancer is the *von Hippel-Lindau* (*VHL*) gene which is a recessive tumor suppressor gene controlling cellular oxygen sensing. Clear cell renal cell carcinoma (ccRCC), the most common type of RCC, is closely associated with *VHL* mutations which lead to stabilization of hypoxia-inducible factors (HIF-1α and HIF-2α) in both sporadic and familial forms. In sporadic ccRCC, this gene has also been found to be inactivated by epigenetic silencing and loss of the 3p chromosome. Overall, this gene is biallelilcally inactivated in a majority of ccRCCs and the loss of the VHL protein function appears to be a critical event in renal carcinogenesis, contributing to tumor initiation, progression and metastasis.

Alterations in genes controlling the maintenance of chromatin states are also frequent in ccRCC. *PBRM1*, a subunit of the PBAF SWI/SNF chromatin remodeling complex has been reported to be mutated in 40%–50% of ccRCCs, whereas *histone deubiquitinase BAP1* and *histone methyltransferase SETD2* in 15% and 12% of cases, respectively. *BAP1*-mutant tumors are typically high-grade and have poor survival.

Whole-exome sequencing of ccRCC tumors from 417 patients has identified 19 significantly mutated genes, with *VHL*, *PBRM1*, *SETD2*, *KDM5C*, *PTEN*, *BAP1*, *MTOR*, and *TP53* being the eight most commonly altered genes.

At the level of chromosome aberrations, deletions of chromosome 3p have been shown to be very frequent in ccRCC (91% of samples in a recent study by the Cancer Genome Atlas (TCGA) Research Network). This locus encompasses all the four most commonly mutated genes: *VHL*, *PBRM1*, *BAP1* and *SETD2*. Arm level losses on chromosome 14q associated with loss of *HIF1A* are also frequent (45% of ccRCCs samples in the recent TCGA study) and have been associated with a more aggressive disease and a worse prognosis. Gains of 5q copy numbers are found in approximately 70% of ccRCC cases. Additional focal amplifications refined the region of interest to 60 genes in 5q35. Focally deleted regions included among others the tumor suppressor genes *CDKN2A* at 9p21 and *PTEN* at 10q23. The PI3K/AKT pathway was also shown to be altered by specific DNA methylation events.

Overall, the most recent data have highlighted the importance of the well-known VHL/HIF pathway, the newly emerging chromatin remodeling/histone methylation pathway, and the PI3K/AKT pathway in ccRCC. The latter presents a strong therapeutic target, supporting the potential value of MTOR and/or related pathway inhibitor drugs for this type of cancer. Of note, despite a proven high intratumoral genetic heterogeneity of renal tumors, the most common gene-level alterations seem to be shared

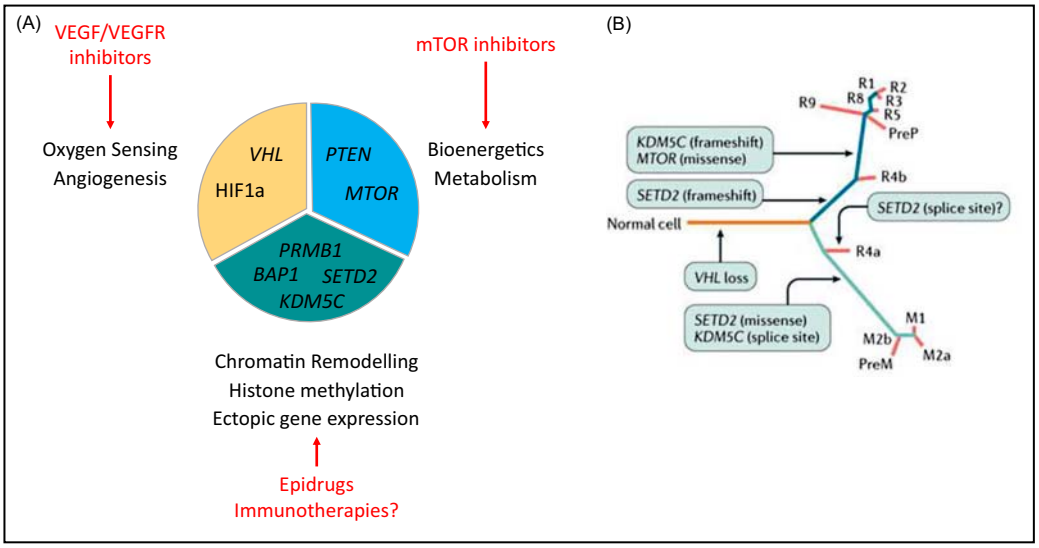

Fig. 2 Genetic alterations in renal cell carcinoma (RCC). The tumor develops by accumulating alterations in three major categories of genes, each of them containing potential therapeutic targets (A). Some alterations (e.g., *VHL* inactivation) occur early in the tumorigenesis and are common to all cells within a tumor. However, further progression results in the development of multiple clones with different alterations and an overall high intratumoral heterogeneity of the tumor (B).

between different areas of the same tumor (Fig. 2). However, studies evaluating the heterogeneity of tumors with regard to specific alterations will be needed to validate their utility as biomarkers or therapeutic targets.

Compared to ccRCC, the genetic background of other, less common, subtypes of renal cell carcinoma is less known. PRCC is typically associated with trisomy and tetrasomy of chromosome 7, trisomy of chromosome 17, and loss of the Y chromosome. Chromosome 7 contains the locus of the *MET tyrosine kinase gene* (7q32) whose heterozygous germline mutations are associated with the hereditary form of PRCC. The *MET* gene may also be altered by other mechanisms—somatic *MET* mutations have been reported in a proportion of sporadic PRCC cases. Moreover, a number of chromosomal aberrations other than the most typical ones have also been shown in PRCCs, with the type 1 and type 2 tumors showing different alterations (Table 2).

Biomarkers

The range of histologies and tumor phenotypes a renal mass can represent is a challenge for the diagnostics and treatment. Renal tumors are genetically diverse with variable prognoses and treatment response rates even within one histological subtype. Therefore, precise molecular differentiation of renal carcinomas would be key to proper treatment. However, while imaging biomarkers (see the section "Presentation and diagnosis") are reliable tools for early detection of kidney tumors, identifying prognostic and predictive biomarkers which would characterize the tumor aggressiveness and metastatic potential on an individual level remains an unmet need. Until now, risk stratification in localized tumors is based on T-category and grading but this does not reliably predict metastases.

Many putative prognostic and predictive biomarkers have been published for ccRCC, including in particular molecules involved in angiogenesis, inflammatory response and the regulation of cell cycle. Baseline serum levels of vascular endothelial growth factor (VEGF) which is key to the angiogenesis of RCC and is targeted by many anticancer drugs have been shown to be prognostic of overall survival in some studies. It has also been suggested it might be a predictive biomarker for sorafenib treatment benefit in RCC patients. High baseline levels of plasma carbonic anhydrase IX (CA-IX), tissue inhibitor of metalloproteinase 1 (TIMP-1), and Ras p21 were shown to be prognostic of reduced overall survival in metastatic RCC patients but not predictive of the sorafenib benefit. Low levels of IL-8, hepatocyte growth factor (HGF), osteopontin and TIMP-1 were all shown to be associated with significantly longer progression-free survival in patients treated with pazopanib. In patients receiving placebo, IL-6, IL-8 and osteopontin were all strong prognostic markers, while IL-6 levels appeared to be predictive of pazopanib treatment benefit. Moreover, Hypoxia-inducible factor (HIF), Ki67 (proliferation), p53, phosphatase and tensin homolog (PTEN; cell cycle), E-cadherin, and other molecules detectable in serum, urine, or circulating free DNA obtained from peripheral blood have also been investigated. However, none of all these biomarkers has been shown to clearly improve the predictive accuracy of current prognostic systems, none has been externally validated, and as of now their routine use in clinical practice is not recommended.

It becomes clear that we need to use molecular signatures rather than single-molecule biomarkers. A 16-gene signature based on the analysis of the expression of genes involved in angiogenesis (*APOLD1*, *EDNRB*, *NOS3*, *PPAP2B*), cell growth/division

Table 2 Gene loci that are most frequently altered in renal carcinoma

Pathway	*Gene (locus)*	*Alteration type*	*Estimate*
–	Loss of chromosome 3p		Up to 91% of ccRCCs
–	Gains of 5q copy numbers		Approximately 70% of ccRCCs
–	Loss of chromosome 14q, associated with *HIF1A* deletion		Up to 45% of ccRCCs
HIF-1 signaling (response to hypoxia)	*VHL* (3p25.3)	Biallelic inactivation by germline or somatic mutations, loss of chromosome, and epigenetic silencing by promoter methylation	Somatic mutations in nearly 40% of all kidney tumors and in 83% of RCCs
Chromatin remodeling/histone methylation	*PBRM1* (3p21.1)	Somatic mutations	40%–50% of ccRCCs
	BRCA1-associated protein *BAP1* (3p21.1)	Somatic mutations	15% of ccRCCs; associated with higher grade and poor prognosis
	SETD2 (3p21.31)	Somatic mutations	12% of ccRCCs
	Lysine-specific demethylase KDM5C (Xp11.22)	Somatic mutations	4%–9% of ccRCCs
P13K/PTEN/Akt: control of cell metabolism	*PTEN* (10q23)	Somatic mutations, deletions	6%–25% of ccRCCs
	MTOR (1p36.22)	Somatic mutations	7% of ccRCCs
C-Met signaling	*MET* protooncogene (7q31.2)	Hyperactivation by point mutations and/or chromosome amplifications	Somatic mutations in approximately 13% of sporadic PRCC cases

ccRCC, Clear cell renal cell carcinoma; *PRCC*, Papillary renal cell carcinoma; *RCC*, Renal cell carcinoma.

(*EIF4EBP1*, *TUBB2A*, *LMNB1*), immune response (CEACAM1, CX3CL1, CCL5), and inflammation (*IL-6*), plus reference genes (*AAMP*, *ARF1*, *ATP5E*, *GPX1*, *RPLP1*) elaborated by Rini and collaborators has been reported to predict renal carcinoma recurrence and reliably stratify patients within disease subgroups by recurrence risk. This assay is particularly promising as there seem to be little intratumoral heterogeneity in the expression of these 16 genes at the RNA level.

Brannon and collaborators have described a gene signature which allows to individually classify ccRCC tumors into two distinct molecular subtypes: ccA and ccB, based on their gene expression profiles which are associated with different clinical outcomes and could potentially be used to guide treatment decisions. The ccA group was shown to relatively overexpress genes associated with hypoxia, angiogenesis, fatty acid metabolism, and organic acid metabolism, whereas ccB tumors overexpressed a more aggressive panel of genes that regulate the epithelial-mesenchymal transition (EMT), the cell cycle, and wound healing. A recent study has validated these signatures as being independently associated with survival, with ccA patients having a markedly better prognosis. Based on these results, a 34-gene classifier (ClearCode34) for assigning ccRCC tumors to the two subtypes has been developed and validated as having an added prognostic value in patients with localized tumors. Combining this molecular profiling with standard clinical tumor evaluation criteria may allow to stratify patients according to the recurrence risk. However, prospective studies with large cohorts of patients will be needed to fully refine the integrated prognostic algorithm. Moreover, a substantial intratumoral heterogeneity so as to these two molecular subtypes has been shown, which implies that multiple biopsies from the same tumor will have to be used to identify clones of poor prognosis. Therefore, the accuracy of the putative prognostic signatures depending on the tumor size and the usefulness of biomarkers based on biopsy material should be evaluated. Finally, the clinical relevance of this model to metastatic tumors has yet to be investigated.

Another group has suggested using the so called total number of aberrations (TNSA) score, a signature of four copy number alterations evaluated using a fluorescence in situ hybridization (FISH) test to identify primary tumors with a high metastatic potential. This putative biomarker has been validated in two independent cohorts and has been shown to independently predict metastasis and correlate with survival. A prospective analysis of a larger multicenter cohort is necessary to define the degree of influence of each specific aberration on the different survival end-points and to develop a multivariate prognostic model for ccRCC, integrating each genomic aberration and well-established prognostic parameters such as T-stages, tumor size, nodal status, and histological grade.

Our knowledge on putative molecular biomarkers in RCC subtypes other than clear cell type is very limited. In papillary RCC, we have to distinguish two subtypes: type 1 with good prognosis and type 2 which is much more aggressive and associated with a shorter survival. Recently, it has been suggested that the aggressive subtype 2 of the PRCC is associated with hypermethylation, 9p alterations, specific miRNA changes and—to some extent—*FH* mutations. However, the development of corresponding prognostic biomarkers remains at an early investigational stage.

Overall, it seems possible to identify aggressive renal cell carcinomas by analyzing the molecular signatures in tumor samples and so stratify patients into groups with different prognosis based on a specific molecular background. However, more studies are needed to validate the putative biomarkers suggested so far and develop clinically relevant algorithms for integrating them into prognostic patient stratification models. In addition, the issue of intratumoral heterogeneity needs to be meticulously addressed. Liquid biopsies containing free nucleic acids as well as extracellular vesicles may help overcome this problem but their utility as prognostic biomarkers in addition to their diagnostic potential also needs to be evaluated.

Management and Therapy

For patients with surgically resectable RCC, the standard of care is surgical excision with a curative intent. For early stage (T1) localized RCC, the treatment of choice is partial nephrectomy (PN). Compared with radical nephrectomy, this nephron-sparing surgery better preserves kidney function and limits the development of metabolic and cardiovascular disorders in a long term. If there is clinical evidence of the adrenal gland invasion, adrenalectomy should simultaneously be performed. In patients with adverse clinical features (a large diameter of the primary tumor or sarcomatoid histological features), extended lymph node dissection (LND) should be considered. Patients with T2 tumors and localized masses not treatable by partial nephrectomy as well as patients not fit for PN for other reasons (e.g., due to the use of anticoagulants) are offered laparoscopic radical nephrectomy.

Elderly and comorbid patients with incidental small renal masses, who have a low risk of RCC-specific mortality and a significant competing-cause mortality risk, may be managed by alternative (nonsurgical) approaches. Active surveillance defined as the initial monitoring of tumor size by serial abdominal imaging (ultrasound, CT, or MRI) should be considered at first, with delayed intervention using ablative therapies (cryoablation or radiofrequency ablation performed laparoscopically or percutaneously) reserved for tumors showing clinical progression during follow-up.

In patients with locally advanced nonresectable tumors, embolization can control symptoms, such as visible hematuria or flank pain. The use of neoadjuvant targeted therapy to downsize tumors is still experimental and cannot be recommended outside clinical trials. In case of clinically positive lymph nodes, lymph node dissection is always justified and can add staging information. LND is also recommended for staging purposes in case of enlarged lymph nodes. However, the extent of lymph node dissection remains controversial.

Tumor resection is curative only if all tumor deposits are excised. For most patients with metastatic disease, cytoreductive nephrectomy (CN) is palliative and systemic treatments are necessary. However, metastatic RCC is often resistant to conventional chemotherapy. Therefore, inoperable or metastatic RCCs are typically managed by systemic treatment with targeted agents and/or immune checkpoint inhibitors. Over the past decade, a number of targeted therapies have been shown to provide a benefit in the treatment of advanced RCC. These therapies include small molecules or monoclonal antibodies inhibiting signaling through the vascular endothelial growth factor (VEGF) and its receptor (VGFR): sunitinib, sorafenib, bevacizumab, pazopanib, axitinib, cabozantinib and lenvatinib. These treatments, as mono-agent or combined regimens, are the current standard of care as first or second-line systemic therapy for advanced RCC. Single-agent treatment with inhibitors of mTOR signaling, such as everolimus and temsirolimus, is an approved second-line treatment.

Current clinical trials are investigating combinations of anti-VEGF therapy with immunotherapy using checkpoint inhibitors, such as monoclonal antibodies against the programmed cell death protein 1 (PD1; e.g., nivolumab, pembrolizumab) and its ligand (PDL1; avelumab, atezolizumab). Another combination under investigation is nivolumab with ipilimumab, an antibody inhibiting the cytotoxic T lymphocyte-associated protein 4 (CTL4). Blocking T-cell inhibitory signals by these antibodies promotes T-cell activation and antitumor response, providing an overall survival benefit in patients who have failed to respond to first- or second-line therapy with small drug inhibitors.

Prospective Vision

In the early 2000s, there were very limited options for the treatment of metastatic kidney cancer and the median patient survival was about 15 months. Introducing small drug inhibitors of VEGF-VEGFR and mTOR pathways in the past decade has caused the median survival to double. Using combinations of these drugs with checkpoint immunotherapies which are being developed is expected to further improve these significant benefits, achieving durable remission in a high number of patients. Progressing towards this objective will, however, require further advances in diagnosing and managing high-risk patients as well as development of systemic therapies. A major gap in the current knowledge is the lack of suitable biomarkers for predicting treatment responses and informing therapeutic decisions. One of the main areas for research to this effect is exploiting the data generated by integrative approaches combining genomics, transcriptomics and epigenomics in order to identify reliable predictive biomarkers that take into account the dynamics of intratumoural heterogeneity. This would enable a better management of off-target effects causing severe toxicities as well as provide biomarker-based rationales for combination regimens allowing to overcome drug resistance.

Laryngeal Cancer: Diagnosis and Treatment

Fernando López Álvarez and Juan Pablo Rodrigo, Asturias Central University Hospital, University of Oviedo, University Institute of Oncology of Asturias (IUOPA), ISPA, CIBERONC, Oviedo, Spain

Glossary

Glottis The glottis extends from an artificial horizontal plane extending bilaterally across the apex of the laryngeal vestibule to approximately 1 cm below the true vocal folds.

Laryngectomy Partial (partial laryngectomy) or complete (total laryngectomy) surgical removal of the larynx, usually as a treatment for cancer of the larynx.

Laryngoscopy A procedure to look at the larynx and pharynx for abnormal areas. A mirror or a rigid or flexible laryngoscope (a thin, tube-like instrument with a light and a lens for viewing) is inserted through the mouth or the nose (fibroscope) to see the larynx. A special tool on the laryngoscope may be used to take samples of tissue.

Supraglottis The supraglottis extends from the tip of the epiglottis to an artificial horizontal plane extending bilaterally across the apex of the laryngeal vestibule, including the epiglottis, the false vocal cords (ventricular bands), the ventricles, the aryepiglottic folds and the arytenoids.

Subglottis The lower part of the larynx between 1 cm below the true vocal folds and the trachea (windpipe).

Tracheostomy The surgical formation of an opening into the trachea through the neck to allow the passage of air. The term "tracheotomy" refers to the incision into the trachea that forms a temporary or permanent opening, which is called a "tracheostomy," however; the terms are sometimes used interchangeably.

Introduction

Cancers of the larynx represents approximately 0.8% of the total cancer risk and is the second most frequent head and neck cancer. The number of new cases of cancer (cancer incidence) is 3.1 per 100,000 men and women per year (based on 2010–14 cases). The American Cancer Society's most recent estimates for laryngeal cancer in the United States for 2017 are that about 13,360 new cases of laryngeal cancer (10,570 in men and 2790 in women) will be diagnosed and about 3660 people (2940 men and 720 women) will die from laryngeal cancer, which is 0.6% of all cancer deaths.

Cancer of larynx is strongly related to cigarette smoking. The role of alcohol in inducing laryngeal cancer remains unclear, although it may be play a role specially in supraglottic cancer.

More than 95% of laryngeal tumors are squamous cell carcinomas (SCC). Other laryngeal malignancies include: verrucous SCC, papillary SCC, nonkeratinizing HPV-positive SCC, spindle cell carcinomas, basaloid SCC, lymphoepithelial carcinomas, acantholytic SCC, adenosquamous carcinomas, salivary tumors and sarcomas, among others.

Glottic, supraglottic, and subglottic cancers represent approximately two-thirds, one-third, and 2% of laryngeal cancers, respectively. Tumors that extend past the ventricle from either a glottic or supraglottic primary are considered transglottic tumors.

Nearly 75% of patients with glottic carcinoma present with hoarseness and often they are diagnosed at an early stage. However, nearly 70% of patients with supraglottic and subglottic laryngeal cancers usually present with advanced disease due to a paucity of symptoms, propensity for local extension, and rich lymphatics resulting in a high incidence of lymph node metastases (mainly supraglottic tumors). Early diagnosis can lead to a reduction in mortality.

Diagnosis

The initial evaluation of patients with suspected laryngeal carcinoma needs to include a detailed medical history to assess clinical risk factors (history of tobacco and alcohol use and environmental exposures) and symptom severity. Moreover, a complete head and neck physical examination should undergo, including examination of all mucosal sites of the upper aerodigestive tract, due to the frequent occurrence of multiple primary tumors in patients with a head and neck tumor. It is advisable an assessment of speech and swallowing function, communication needs, nutrition, health behaviors and availability of social support for what is typically prolonged period of treatment and rehabilitation. Finally, pretreatment dental evaluation is also recommended for patients who will undergo radiation, given the risk of dental infection, damage, and treatment-induced osteoradionecrosis.

Then, if a malignant tumor is suspected, it must be confirmed by obtaining a biopsy of the lesion for histopathological study. Finally, radiologic imaging is performed to obtain precise anatomical details regarding the tumor localization and extension. **Fig. 1** represent an algorithm for diagnostic evaluation of a laryngeal cancer.

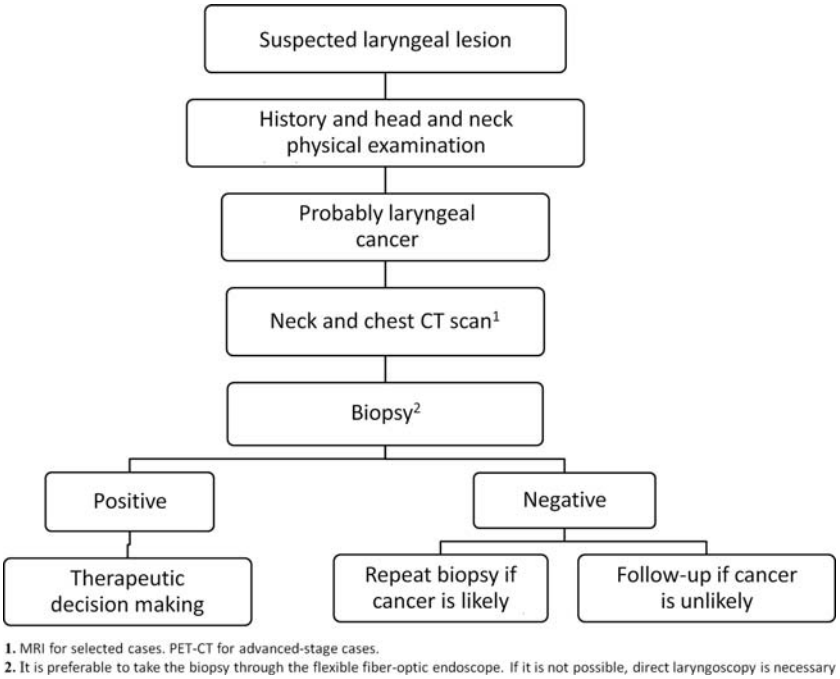

Fig. 1 Algorithm for diagnostic evaluation of a laryngeal lesion. *CT*, computed tomography; *MRI*, magnetic resonance imaging; *PET*, positron emission tomography.

Clinical Evaluation

Patients with primary early-stage tumors arising on the true vocal cords usually present with complaints of dysphonia and hoarseness; sore throat, odynophagia, dysphagia, referred otalgia, pain localized to the thyroid cartilage, hemoptysis, airway obstruction, stridor and neck adenopathy are features of advanced-stage glottic lesions. Early diagnosis is crucial for both improved survival and laryngeal preservation. In general, persistent hoarseness (>15 days) in an adult patient requires endoscopic visualization of the larynx to rule out a tumor.

Supraglottic tumors are usually more advanced than glottic cancer at presentation and patients may experience the following symptoms or signs: discomfort or sensation of a lump in the throat (the most frequent initial symptom), dysphagia, odynophagia, the sensation of something stuck in the throat, occasional respiratory obstruction, hemoptysis, referred pain to the ipsilateral ear (by way of the vagus and auricular nerves) or a mass in the neck; however, hoarseness is not a prominent symptom of supraglottic cancer until the lesion becomes quite extensive.

Primary subglottic tumors are usually asymptomatic at an early stage and they do not present until more advanced in size where dyspnea ad stridor are frequent. Dysphonia is relatively common in advanced subglottic tumors due to the involvement of the true vocal cord or direct extension to the recurrent laryngeal nerve. An emergent tracheotomy is not uncommon in these patients.

Late symptoms of laryngeal cancer include weight loss, dysphagia, foul breath and aspiration.

Physical Examination

After the medical history, a thorough clinical examination using a rigid or flexible fiber-optic endoscope is performed (Fig. 2A). It allows an adequate assessment of the surface extent of the primary tumor, the mobility of the vocal cords and performing an initial tumor staging. Accurate evaluation of the primary tumor prior to initiating treatment is vitally important, especially if any voice-sparing surgical procedure is a consideration. It is advisable to document the lesions of the larynx by a photograph or to depict them on a drawing to describe the site of origin of the primary tumor with its local extension to adjacent sites within the same region of the larynx or from one region to another region. Bulky lesions may extend beyond the larynx into the adjacent base of the tongue, pyriform sinus, or retrocricoid region and this should be assessed. The relation to the anterior commissure is very important in glottic tumors and in lesions involving the laryngeal surface of the epiglottis. Determination of the mobility of the vocal cords is critical because there are subtle distinctions between mobile, partially fixed and fixed cords. Fixation of the vocal cord from laryngeal cancer is caused by invasion or destruction of the vocal cord musculature, invasion of the cricoarytenoid muscle or joint or invasion of the recurrent laryngeal nerve. Ulceration of the infrahyoid epiglottis, fullness of the vallecula or palpation of a diffuse, firm fullness above the thyroid notch with widening of the space between on the hyoid and the thyroid cartilages are indirect signs of preepiglottic space invasion. Retrocricoid invasion may be suspect when the laryngeal click disappears on examination or when the thyroid cartilage protrudes interiorly, producing a fullness of the neck. Pain or tenderness to palpation or a small bulge over the thyroid cartilage is suggestive of thyroid invasion.

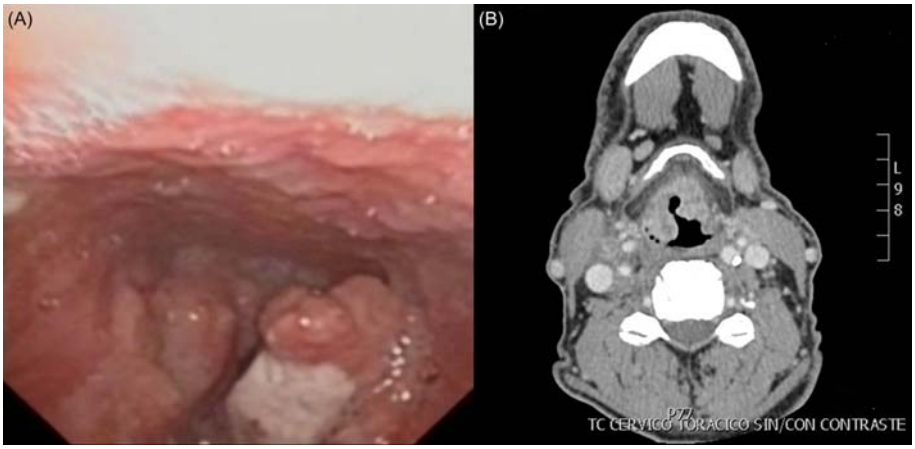

Fig. 2 (A) Endoscopic view of the larynx showing a tumor of the supraglottic. (B) Axial contrast enhanced CT showing an advanced supraglottic carcinoma. Moderately thick lesion arising from laryngeal surface of epiglottis with involvement of preepiglottic space.

Nowadays, apart from the endoscopy with conventional white light, narrow band imaging (NBI) endoscopy should be use in the routine pharyngo-laryngeal examination because it helps to make an early diagnosis of tumors of the larynx. Moreover, it is a useful tool in the postoperative surveillance to detect recurrences. NBI may be used in both flexible fiberoptic or rigid laryngoscopes. NBI is an imaging technique for the depiction of tumor-specific neoangiogenesis. A higher contrast between the mucosal epithelium and blood vessels is achieved in NBI endoscopy using filtered light comparing to white light observations. This allows detection of small suspicious mucosal changes or small tumors, few millimeters in diameter, which are not observable using white light. NBI also allows to define better the extension of tumors, which is crucial for perform targeted biopsy and for determination of resection margins in cancer surgery. NBI is increasingly used for follow-up of patients after treatment for head and neck malignant tumors, when early detection of possible recurrence is crucial.

Other imaging techniques such as auto fluorescence, contact endoscopy and optical coherence tomography (OCT) are increasingly used in ENT practice. However, these techniques have not been reproduced and is consequently not a standardized method.

Sometimes it is necessary to carry out a direct laryngoscopy under general anesthesia. The ventricles, subglottic area, apex of the pyriform sinus and retrocricoid area must be carefully examined when these areas are not well examined by the above techniques and they are at risk of being affected by the tumor. Through the laryngoscope may be introduced rigid telescopes (0, 30,45 or 70 degrees) or microscopic examination can be performed.

A detailed examination of the neck is mandatory whenever a laryngeal tumor is suspected. Regional metastases are the most important negative prognostic factor, decreasing the survival rate by 50%. The subdigastric basin (level II) is the most frequently involved. The submandibular area (level I) is rarely affected and the risk of spinal accessory lymph node (level V) involvement is small. Anterior commissure and anterior subglottic invasion are associated with involvement of the Delphian node. In tumors of the vocal cord, the incidence of clinically positive lymph nodes at diagnosis approaches 0% for T1 lesions and 2% for T2 lesions. This incidence increases from 20% to 65% for T3 and T4 lesions. The supraglottic tumors tend to have a higher rate of lymphatic metastasis and the incidence of clinically positive nodes is up to 60% at the time of diagnosis and 15% are bilateral. Spread to the pyriform sinus, vallecula and the base of tongue increases the risk of lymph node metastases.

The incidence of distant metastases is generally thought to be 10% or less. Although this increases with locoregional extent of disease and is more common with supraglottic (and subglottic) tumors, distant metastases are still found in only a small number of patients diagnosed with laryngeal cancer (15% or less). If spread through the bloodstream does occur, the lungs are the most common site of metastasis, followed by the bones.

Histopathological Diagnosis

Biopsy should be performed at the time of diagnosis, ideally after imaging, but it should not delay the treatment. A correct histologic diagnosis is critical due to the impact on therapeutic approach and prognosis and highlights the need for both a high index of clinical suspicion and adequate representative biopsies. A generous biopsy specimen is taken from the suspicious areas, looking to take tissue samples in depth and avoiding areas of necrosis. The biopsy should be performed through a flexible fiberoptic endoscope or, if this is not possible, by direct laryngoscopy.

Imaging

When malignancy is suspected, computed tomography (CT) scan with contrast enhancement (Fig. 2B) and/or magnetic resonance imaging (MRI) must be performed to define the submucosal extent and deeper margins of the tumor. CT is preferred because it is

Fig. 3 Axial contrast enhanced CT performed in a patient with a tumor invading the anterior commissure and penetrating through the cartilage.

much faster than MRI. Small and superficial mucosal tumors may not be appreciated at CT or MRI and hence, it is mandatory that an endoscopy is done prior to any imaging study. Integration of cross-sectional imaging with endoscopy findings significantly improves the accuracy of T staging. The accuracy of clinical T staging alone for laryngeal cancer to be 57.5%, but as high as 80% when combined with contrast-enhanced CT. CT and/or MRI are valuable to obtain precise anatomical details regarding the tumor localization and extension (preepiglottic and paraglottic space involvement, subglottic extension, cartilage destruction and submucosal and extralaryngeal extension, which may not be obvious on clinical examination) (Fig. 3).

CT and/or MRI of the entire neck provide information on nodal disease that may not be clinically evident. A minimum axial diameter more than 10 mm, round or spherical shape, a necrotic node of any size and a node with indistinct spiculated margins (suggesting extra nodal disease spread) are the generally accepted radiological criteria to diagnose malignant nodes at CT and MRI. The sensitivity and specificity of CT to detect nodal disease using these criteria are 90% and 75% respectively.

It is important to note that imaging should be performed before biopsy so that abnormalities that may caused by the biopsy are not confused with tumor.

The general radiological criteria used for tumor involvement include asymmetric soft tissue prominence or thickening, abnormal contrast enhancement, a bulky mass, obliteration of the normal fat planes and spaces, or a combination of these.

A high-resolution CT scan with contrast enhancement (1–2 mm thick sections through the larynx) is generally preferred. Contrast enhancement helps to outline the blood vessels and the tumor. CT delineates the extent of disease and the presence and extent of lymphatic involvement. CT offers high spatial resolution; discriminates among fat, muscle, bone, and other soft tissues; and surpasses MRI in the detection of bony erosion. Nevertheless, MRI is probably better to define subtle extralaryngeal extension and to assess early thyroid cartilage destruction. MRI has a high sensitivity (89%–95%) but lower specificity (74%–84%) as compared to CT for the detection of cartilage invasion. The negative predictive value of MRI to exclude cartilage invasion is also very high, at around 94%–96%. T2-weighted or postcontrast T1-weighted cartilage signal intensity greater than that of the adjacent tumor is considered to indicate inflammation, and signal intensity similar to that of the adjacent tumor was considered to indicate neoplastic invasion. Supraglottic tumors may arise in the epiglottis or in the aryepiglottic folds and false cords. Epiglottic tumors primarily invade into the preepiglottic space. While the tumors arising from the mobile portion of the epiglottis may spread from the preepiglottic space further into the base of tongue and laterally into the paraglottic space, those arising from the petiole often invade the low preepiglottic space and via the anterior commissure, reach the glottis or subglottis. The primary sign of preepiglottic space invasion at imaging is replacement of the normal fat by abnormal enhancing soft tissue. The sensitivity of CT and MRI to detect invasion of the preepiglottic space is 100% and the corresponding specificities are 93% and 84–90%. Tumors arising in the aryepiglottic folds present as exophytic or infiltrative masses. They expand the aryepiglottic fold and spread into the paraglottic space. They may spread further anteriorly into the preepiglottic space or posteriorly to invade the piriform sinus. Tumors originating in the false vocal cords are lateral masses with a strong predilection for submucosal spread into the paraglottic space. More extensive tumor may destroy the thyroid cartilage and spread transglottically into the glottis and subglottis. Tumor spread to the paraglottic space on CT or MRI is seen as replacement of the normal paraglottic fat by the enhancing tumor tissue. Both CT and MRI have a high sensitivity of about 95% to detect paraglottic tumor spread, the specificity, however, ranges between 50 and 75% as peritumoral inflammation may mimic tumor resulting in false positive assessments.

Glottic tumors commonly arise from the anterior half of the vocal cord and spread into the anterior commissure. Anterior commissural disease is seen on CT or MRI as soft tissue thickening of more than 1–2 mm. The accuracy of CT in predicting anterior commissure involvement is about 75%. From the anterior commissure, the tumor may spread further anteriorly into the contralateral cord and the thyroid cartilage or posteriorly into the posterior commissure, the arytenoids, cricoarytenoid joint and the cricoid. While vocal cord mobility is best assessed at endoscopy, disease in the cricoarytenoid joint and interarytenoid region have been described as imaging correlates for vocal cord fixation. The tumor may spread superiorly to access the preepiglottic space and

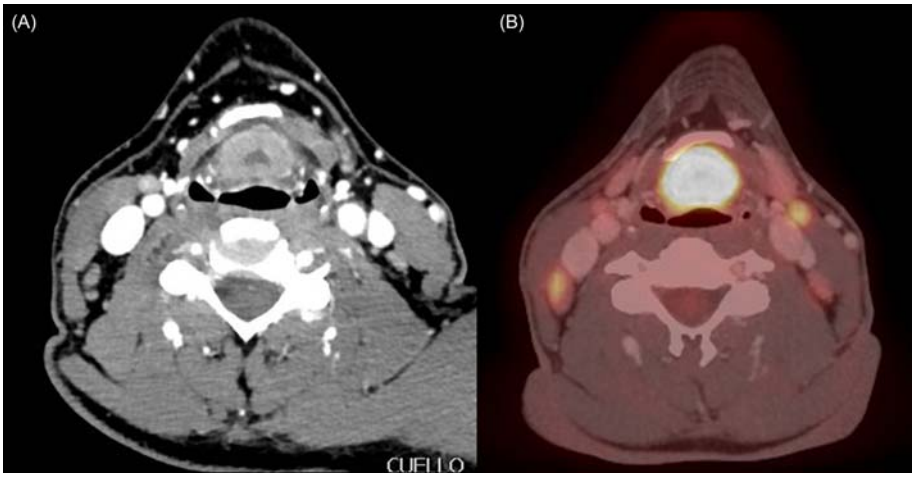

Fig. 4 (A) Axial contrast enhanced CT depicting a supraglottic tumor invading the preepiglottic space. (B) PET-CT showing a hypermetabolic focus of active tumor occupying the preepiglottic space that corresponds to the CT abnormality.

the paraglottic space, or inferiorly to reach the subglottis. Subglottic spread below the anterior commissure is seen as an irregular thickening of the cricothyroid membrane. Tumor may gain access into the extralaryngeal tissues through the cricothyroid membrane.

Subglottic cancer is diagnosed if any tissue thickening is noted between the airway and the cricoids ring. Due to their late presentation, invasion of the cricoids cartilage, trachea and the cervical esophagus with extralaryngeal spread are common findings in these patients at imaging.

Laryngeal tumors encroaching on both, the glottis and supraglottis, with or without subglottic component and when the site of origin is unclear, is termed as transglottic tumor. This tumor spread is frequently through the paraglottic space and is readily identified on CT or MRI. Transglottic carcinoma is frequently accompanied by metastatic lymphadenopathy. Coronal images are particularly helpful in assessing transglottic extension of tumor.

Nowadays, to assess the possibility of diagnosing distant disease and second primary tumors, a chest CT should be routine. Second primary malignancies have been reported in up to 20% of patients with laryngeal cancer.

Moreover, the use of positron emission tomography (PET) scanning with ^{18}F-fluorodeoxyglucose (FDG) and combined CT with PET imaging allow to combine functional and anatomical studies (**Fig. 4**). FDG imaging has the potential to distinguish between benign and malignant processes, grade tumors, identify metastases, and diagnose tumor recurrence. Although standardized uptake values (SUV) of FDG uptake has been used by some authors to identify tumoral tissue, to date, no universally accepted SUV threshold has been determined to differentiate benign from malignant nodal disease. In head and neck cancer, FDG imaging is useful for detecting clinically occult recurrences and for determining residual disease in the neck following definitive radiotherapy. CT-PET can detect occult disease and use alter the treatment plan in up to 30% of patients. CT-PET has a high negative predictive value but the specificity is not very high. The overall accuracy of in identifying nodal disease is higher than that of CT alone, by almost 20%. However, CT-PET is not useful to exclude the presence of metastases in the clinically N0 neck because PET cannot detect very small tumors (<5–7 mm).

Staging

Staging is based on TNM criteria developed by the AJCC/UICC (8th edition) (**Tables 1–4**). This classification incorporates all information available prior to treatment, including the clinical examination, endoscopy, endoscopic biopsy and cross-sectional imaging. The guidelines rely heavily on the use of cross-sectional imaging for the T staging; however, no recommendation is made regarding the preference of one technique over the other. Laryngeal cancer staging is dependent on tumor location and subsite involvement. For supraglottic tumors, the subsites that are important for staging include the suprahyoid and infrahyoid epiglottis, aryepiglottic folds, arytenoids and ventricular bands (false vocal cords). The glottic subsites include the true vocal cords including the anterior and posterior commissure. Other important factors involved in laryngeal cancer staging include the presence of impaired true vocal cord mobility or frank paralysis, base of the tongue involvement, preepiglottic space involvement, paraglottic space involvement and thyroid or cricoid cartilage invasion. It is important to note the fact that a tumor that erodes only the internal cortex of the thyroid cartilage is classified as T3, while if the tumor passes through the cartilage is considered as a T4 tumor.

Those tumors that cause vocal cord fixation, involve base of the tongue preepiglottic or paraglottic spaces, show thyroid or cricoid cartilage invasion, invade tissues beyond the larynx (trachea, soft tissues of the neck, esophagus thyroid gland, strap muscles or extrinsic muscle of the tongue) or are associated with regional lymphatic metastases, are considered as advanced disease. Cancers that invade the prevertebral space, encase the internal carotid artery or extend into the mediastinum are considered incurable with surgery.

Table 1 Primary tumor (T) according to TMN 8th edition

TX	*Primary tumor cannot be assessed*
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Supraglottis	
T1	Tumor limited to one subsite of supraglottis with normal vocal cord mobility
T2	Tumor invades mucosa of more than one adjacent subsite of supraglottis or glottis or region outside the supraglottis without fixation of the larynx.
T3	Tumor limited to the larynx with vocal cord fixation and/or invades any of the following: postcricoid area, preepiglottic space, paraglottic space, and/or inner cortex of thyroid cartilage
T4a	Moderately advanced local disease. Tumor invades through the thyroid cartilage and/or invades tissues beyond the larynx
T4b	Very advanced local disease. Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures
Glottis	
T1	Tumor limited to the vocal cord(s) with normal mobility
T1a	Tumor limited to one vocal cord
T1b	Tumor involves both vocal cords
T2	Tumor extends to supraglottis and/or glottis, and/or with impaired vocal cord mobility
T3	Tumor limited to the larynx with vocal cord fixation and/or invasion of the paraglottics space, and/or inner cortex of the thyroid cartilage
T4a	Moderately advanced local disease. Tumor invades through the outer cortex of the thyroid cartilage and/or invades tissues beyond the larynx
T4b	Very advanced local disease. Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures
Subglottis	
T1	Tumor limited to the subglottis
T2	Tumor extends to vocal cord(s) with normal or impaired mobility
T3	Tumor limited to the larynx with vocal cord fixation
T4a	Moderately advanced local disease. Tumor invades cricoid or thyroid cartilage and/or invades tissues beyond the larynx
T4b	Very advanced local disease. Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures

Table 2 Regional lymph nodes (N) according to TMN 8th edition

	Clinical (cN)	*Pathological (pN)*
Nx	Regional lymph nodes cannot be assessed	
N0	No regional lymph nodes metastasis	
N1	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension	
N2a	Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension	
N2b	Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension	
N2c	Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension	
N3a	Metastasis in a lymph node more than 6 cm in greatest dimension without extranodal extension	Metastasis in a lymph node more than 6 cm in greatest dimension without extranodal extension
N3b	Metastasis in a single or multiple lymph nodes with clinical extranodal extension (skin involvement or soft tissue invasion with deep fixation/tethering to underlying muscle or adjacent structures or clinical signs of nerve involvement)	Metastasis in a lymph node more than 3 cm in greatest dimension with extranodal extension or, multiple ipsilateral, or any contralateral or bilateral node(s) with extranodal extension

Table 3 Distant metastasis (M) according to TMN 8th edition

M0	No distant metastasis
M1	Distant metastasis

Table 4 Stage groups according to TMN 8th edition

Stage 0	Tis N0 M0

Stage IVB	T4b Any N M0
	Any T N3 M0
Stage IVC	Any T Any N M1

Treatment

The primary goal of treatment in head and neck cancer is to achieve optimal oncological outcomes while preserving function and quality of life as much as possible. This is particularly important in the treatment of laryngeal cancer. The larynx has important functions—including breathing, voice making and swallowing, and therefore both the disease and its treatment may significantly affect quality of life. As previously mentioned, 95%–98% of malignant neoplasms of the larynx are squamous cell carcinomas (SCC), so we will only refer to this histological type.

In the treatment of these cancers we have several options available (surgery, radiation therapy, chemotherapy and molecular targeted therapies), which can be used alone or in combination. In general, patients in early stages (I–II) are treated with a single modality therapy, either surgery of radiotherapy. But approximately 40% of laryngeal cancers occur at advanced stages (III–IV) at diagnosis, requiring aggressive treatment that usually involves combining several treatment modalities. Primary treatment decisions may depend on patient desires, tumor extent and location, experience of the treatment team, the adequacy of follow up surveillance, medical comorbidities and long-term voice and swallowing expectations. Since most cases of laryngeal cancer are associated with high consumption of tobacco and alcohol, co-morbidities are common, which not only determine the choice of treatment and compliance, but are an important determinant of overall patient survival.

Treatment of Early Stage (T1–T2) Tumors

Treatment options for T1–T2N0 laryngeal SCC include radiotherapy (RT), transoral laser surgery (TLS), and open partial laryngectomy (see below). Functional results after open partial laryngectomy are usually worse compared to RT and TLS so that this alternative is rarely employed. Given the high probability (>20%) of occult nodal metastasis in supraglottic cancers, even in these initial stages, the neck must be included in the treatment plan of the tumors on this location, and it is usually treated with the same modality therapy (surgery or RT) than the primary tumor.

The decision whether to select RT or TLS (with neck dissection in supraglottic cancers) depends on a number of factors, including the location and extent of the tumor, anatomical circumstances (probability of exposure of the tumor in TLS), the medical condition of the patient, the likelihood of tumor control after treatment, anticipated functional outcome (voice quality), the expertise of the attending physicians and logistical considerations. In this complex decision-making process, we should also include patient preference, after an informed discussion of the pros and cons of each treatment modality.

The likelihood of local control after RT or TLS is equivalent and is approximately 85%–95%. An advantage of RT is that it is applicable to all patients with T1–T2N0 SCCs, whereas TLS could not be used in patients with inadequate exposure of the tumor (due to the location of the tumor or anatomical circumstances). Patients with significant medical comorbidities who are poor candidates for anesthesia may be better treated with RT. On the other hand, in glottic tumors, we must keep in mind that the more of the glottis that is involved with SCC, requiring a wider resection, the poorer the voice quality after TLS. Therefore, RT may be preferred treatment option for patients with more demanding requirements for voice quality. When RT is used, the dose of radiation is from 63 Gy (2.25 Gy/fraction) to 66 Gy (2.0 Gy/fraction) for T1 and 65.25 Gy (2.25 Gy/fraction) to 70 Gy (2.0 Gy/fraction) for T2 disease.

Patients with anterior commissure involvement will provide technical challenges and, even in experienced hands, may have local control rates that are somewhat lower compared with T1–T2 SCCs without anterior commissure invasion. Efficacy of RT is not affected by involvement of the anterior commissure. In addition, voice quality is likely to be worse after TLS in these cases.

One advantage of TLS is that it can be repeated several times in contrast to RT. The ability to repeat TLS may contribute to the fact that the likelihood of laryngeal preservation may be higher when TLS can be offered as initial treatment. Many patients with recurrences after RT will undergo total laryngectomy, although laryngeal preservation may be feasible with salvage open partial laryngectomy or TLS in selected patients after radiation failure.

Another advantage of TLS is the shorter length of treatment. In cases where the neck is not dissected, TLS can be done on an outpatient basis whereas RT is delivered once daily on weekdays over 5–7 weeks. In relation to this, an important point to be taken

into consideration is that TLS is the most cost-effective treatment of early laryngeal SCC, radiation therapy being 2–4-fold more expensive. The presence and extent of a cost differential will vary with the medical system.

Regardless of the modality chosen, physicians should track their own patient's functional and survival data rather than rely on the best reported results from the most experienced institutions. Analysis of outcomes should include tumor control, survival, functional outcomes (quality of voice) and larynx preservation rates.

Treatment of Advanced Stage (T3–T4) Tumors

For years, total laryngectomy (with postoperative radiotherapy in high-risk cases) was the only treatment option for patients with intermediate to advanced laryngeal cancer (T3–T4). In addition, either ipsilateral or bilateral neck dissections should be performed in these cases, based on tumor location and extent of nodal metastasis (if present).

Over the past two decades, great progress has been made in the management of this disease, with multimodality approaches aimed at laryngeal preservation reshaping the treatment landscape. In response to the common use of total laryngectomy, the nonsurgical approaches have often been referred to as "organ preservation" strategies. In many institutions, it appears that there are organ preservation strategies and then there is surgery. In contrast, we think there are both nonsurgical organ preservation strategies and surgical organ preservation strategies (Fig. 5). The key is that in both approaches the goal is to spare the functions of the larynx. A new paradigm has emerged in which both the surgical and nonsurgical approaches have equal value in functional laryngeal preservation. However, in T4 tumors laryngeal preservation rates are much lower and often present complications which compromise laryngeal function. In addition, patients with T4 tumors treated with up-front surgery had superior overall survival than those treated with CRT, and therefore in these cases total laryngectomy continues to be recommended.

Surgical options for functional laryngeal preservation

In addition to the time-honored approaches of vertical partial laryngectomy and horizontal or supraglottic laryngectomy, the options for conservation laryngeal surgery have significantly improved over the past two decades. Transoral minimally invasive surgery and supracricoid partial laryngectomy (SCPL) have emerged as important function-preserving approaches for patients with laryngeal cancer.

After either partial laryngectomy or open resection, absence of adverse features, including extra nodal spread, positive margins, perineural invasion, or lymphovascular invasion, allows for observation of the patient with no need for adjuvant therapy. When these high-risk features are present, adjuvant RT is recommended.

Vertical partial laryngectomy (VPL)

VPL (or vertical hemylaryngectomy) encompasses a spectrum of procedures ranging from laryngofissure with cordectomy to extended hemi-laryngectomy. Common to all these procedures is vertical transection of thyroid cartilage and glottic resection extending into the paraglottic space (Fig. 6). In VPL, vertical incisions are made through the thyroid cartilage near the anterior commissure and just anterior to the posterior edge of the thyroid cartilage. The resulting resection includes the true vocal cord and immediate sub glottis, ventricle, false vocal cord, and arytenoepiglottic fold, and usually crosses just in front of the vocal process of the arytenoid posteriorly. This area can extend around the anterior commissure to involve the anterior one-third of the opposite vocal cord if required. When the anterior commissure is removed, the procedure is termed a frontolateral hemylaryngectomy.

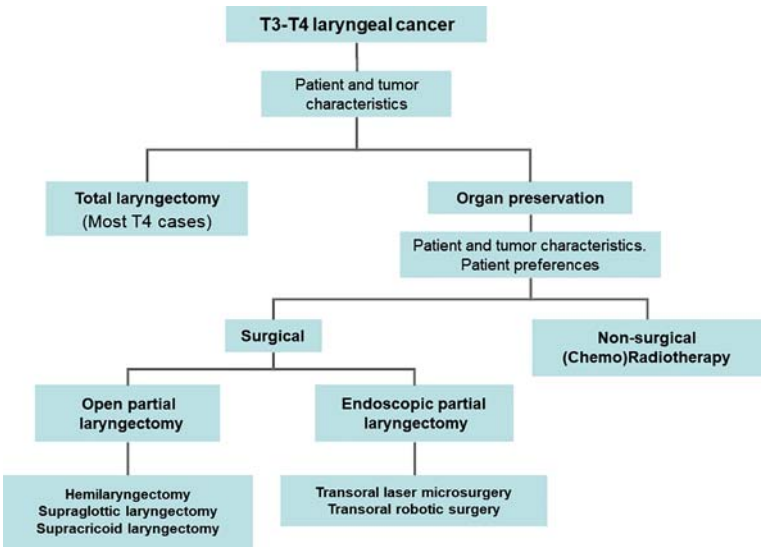

Fig. 5 Algorithm for treatment of advanced laryngeal cancer.

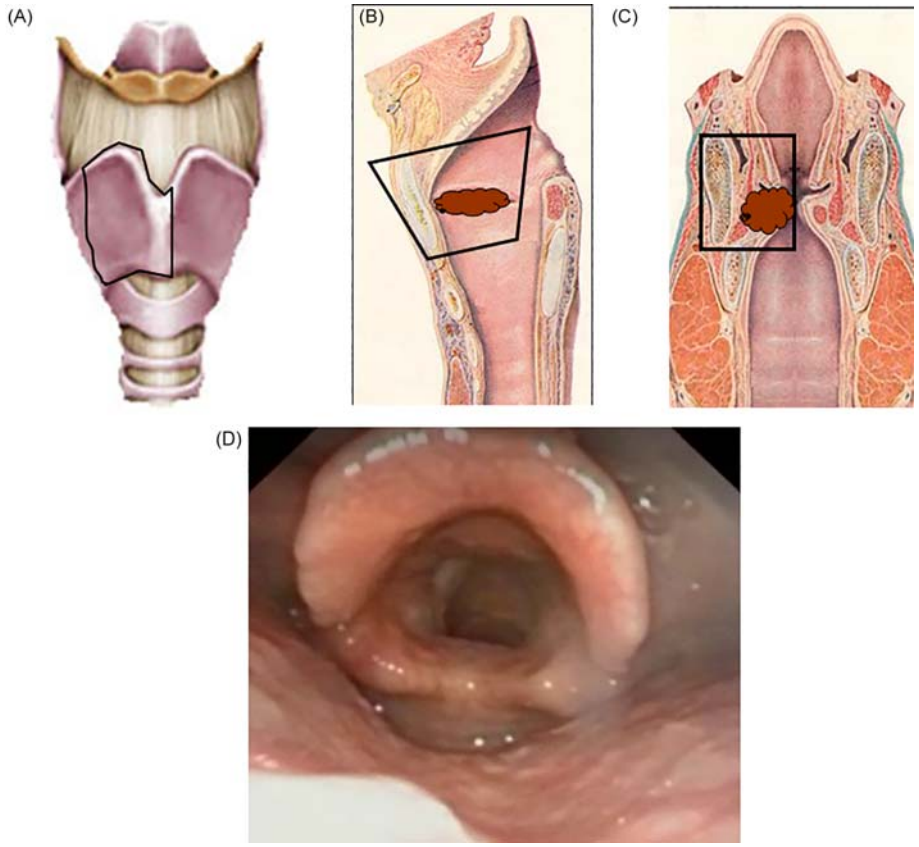

Fig. 6 Vertical partial laryngectomy. (A) Incisions in laryngeal framework. (B) and (C) Sagittal and coronal views showing the resected portions of the larynx. (D) Endoscopic picture of the larynx after a right hemilaryngectomy.

It is a well-established procedure for T1 and T2 glottic cancers. Some authors believe that patients with fixation of the true vocal cord (T3) caused by direct invasion of the cancer into the thyroarytenoid muscle are still candidates for a vertical hemylaryngectomy. However, in patients with vocal cord fixation caused by cricoarytenoid joint invasion a hemilaryngectomy should not be considered. Other contraindications are involvement of the posterior commissure or the thyroid cartilage, and extension superiorly to the aryepiglottic fold.

With this technique overall local control and laryngeal preservation rates, between 82 and 95% have been reported for T1–T2 cases, and 5-year survival rates were greater of 90%. The local control and 5-year survival rates were lower for T3 cases, with reported local control rates between 73% and 85%. These results reflect the continuing value of the VPL in selected cases. However, currently, with the advancement of laser surgery, the role of the VPL is questionable. For most patients with lesions amenable to VPL, laser surgery provides equal local control rates, with superior voice and swallowing function and less complications. And because the relatively high recurrence rates in T3 cases, VPL was replaced by supracricoid laryngectomy for these cases in many centers.

Supraglottic laryngectomy

Supraglottic laryngectomy involves resection of the epiglottis, the false vocal cords, the aryepiglottic folds, the hyoid bone (in most cases), the upper aspect of the thyroid cartilage, and the contents of the preepiglottic space (Fig. 7). The resection can be extended to include one arytenoid, the tongue base or pyriform sinus.

The result is that the patient has a nearly normal voice but a significant challenge in developing normal swallowing caused by the loss of the protective mechanisms of the epiglottis and false cords. Rehabilitation, which involves temporary tracheostomy in all patients and a temporary feeding tube (usually nasogastric), is achieved in most patients within 1 month of surgery with removal of the feeding tube and tracheostomy. The rehabilitative process is complicated by either preoperative or postoperative radiation therapy as well as extension of the surgical resection to include the tongue base, arytenoid cartilage, or pyriform sinus.

Supraglottic laryngectomy is indicated in all T1–T2 supraglottic cancers, but also in patients with T3 and T4 supraglottic tumors that involve preepiglotic space or one arytenoid, or that extend into the pyriform sinus or the tongue base. Massive tumors with cartilage erosion, subglottic extension, or involvement of the lateral wall of the pyriform sinus remain subject to total laryngectomy. In addition, the patient must have adequate pulmonary function to be a candidate for a supraglottic laryngectomy.

Local control was better for those with tumor confined to the endolarynx (>90%), but was over 80% for all sites, and laryngeal preservation rates described are also over 80% cases. Overall five-year survival rates are comparable to that obtained with total

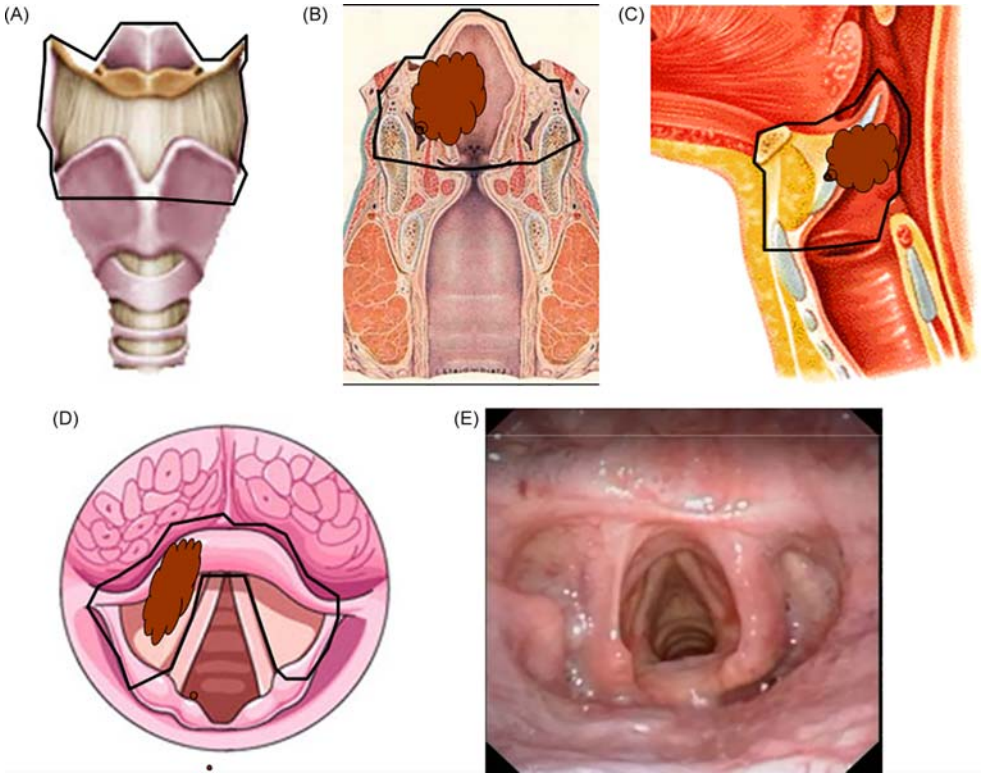

Fig. 7 Supraglottic laryngectomy. (A) Incisions in laryngeal framework. (B–D) Coronal, sagittal, and axial views showing the resected portions of the larynx. (E) Endoscopic picture of the larynx after a supraglottic laryngectomy.

laryngectomy, and range from 67% to 90%. These rates are over 85% for stage I–II tumors, between 75% and 80% for stage III, and between 55% and 70% for stage IV patients. However, in these tumors survival rates depends more from the presence and extension of nodal metastases than the size of the primary tumor.

The laryngeal preservation rates with this technique are very good, with overall reported rates over 85% of patients. However, these rates were lower (60%–80%) in T3–T4 tumors. In addition, functional results were good to fair, with more than 90% of patients achieving decannulation and oral diet.

Nowadays, conventional supraglottic laryngectomy is being replaced by laser supraglottic laryngectomy because the oncological results of transoral laser surgery for early and moderately advanced laryngeal cancer appear to be comparable to those of classic supraglottic laryngectomy, and the endoscopic approach offers functional advantages.

Supracricoid laryngectomy (SCPL)

The SCPL is an alternative to (chemo) radiation therapy, supraglottic laryngectomy, and near total and total laryngectomy in selected cases of supraglottic and transglottic carcinoma. This procedure is a true functional preservation technique and should be considered as a conservative laryngeal technique as it preserves physiological rehabilitation of speech, swallowing, and respiration without a permanent tracheostomy.

SCPL involves resection of the following structures: the true vocal cords, the false vocal cords, the aryepiglottic folds, the epiglottis (to a variable degree), the subglottic to the superior aspect of the cricoid cartilage, the thyroid cartilage, and the contents of the pre- and paraglottic spaces. The resection can include one arytenoid but must preserve the hyoid bone (**Fig. 8**). Two different reconstructions are possible depending on the extent of disease involving the epiglottis. In cases in which only the inferior portion of the epiglottis is involved, the suprahyoid epiglottis can be preserved and used in the reconstruction (cricohyoidoepiglottopexy, CHEP). In cases in which it is not oncologically feasible to preserve the epiglottis, the reconstruction will involve the impaction of the base of tongue/hyoid complex to the cricoid cartilage (cricohyoidopexy, CHP).

Supracricoid laryngectomy with cricohyoidoepiglottopexy (SCPL-CHEP) is indicated in glottic tumors: T2 (especially with anterior commissure involvement), T3 and selected T4 (limited thyroid cartilage invasion). Is contraindicated in cases with fixation of the cricoarytenoid joint, invasion of the posterior commissure, cricoid invasion, extralaryngeal spread of tumor or poor pulmonary function.

Supracricoid laryngectomy with cricohyoidopexy (SCPL-CHP) is also indicated in T2–T4 laryngeal tumors: supraglottic tumors extended onto the vocal cord or anterior commissure and in transglottic tumors. Limitations are the same than with SCPL-CHEP, and also invasion of the hyoid bone.

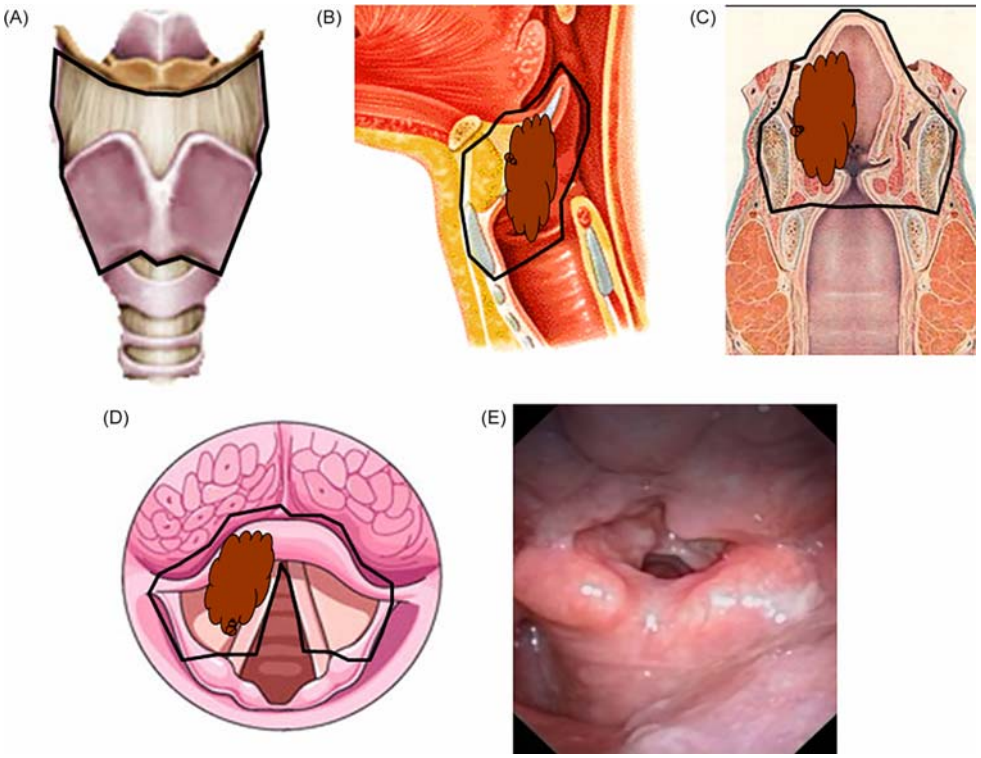

Fig. 8 Supracricoid laryngectomy (with crico-hyoidopexy). (A) Incisions in laryngeal framework. (B–D) Sagittal, coronal, and axial views showing the resected portions of the larynx. (E) Endoscopic picture of the larynx after a supracricoid laryngectomy.

Local control and organ-preservation rates with SCPL as primary therapy in patients with T2 and selected T3 lesions exceed 90% and are comparable with—if not better than—rates seen with chemotherapy and radiation and with total laryngectomy.

With respect to functional outcomes, although speech and swallowing are restored following SCPL, voice quality is substantially different postoperatively, although subjective voice analysis rank voice as globally "acceptable" by the patient and the physician. Restoration of normal swallowing may take several weeks and requires intensive rehabilitation; nonetheless, more than 80%–90% of patients can be expected to have swallowing function restored within the first year.

Transoral laser surgery

Transoral laser surgery (TLS) is minimally invasive and is performed under suspension-direct laryngoscopy, with an operating microscope, microsurgical instruments, and the surgical CO_2 laser. In conjunction with SCPL, this has been one of the two areas of greatest development in conservation laryngeal surgery in recent years.

The approach challenges a basic surgical tenet, as the tumor is transected and removed piecemeal through a laryngoscope. However, transection reveals the depth of tumor penetration and allows for clear visualization of tumor margins during the procedure.

In contrast to open laryngeal surgery, the cartilaginous laryngeal framework and the infrahyoid muscles are preserved during endoscopic resections, which is believed to improve postoperative function. Additionally, the concept of adequate margins is viewed differently for endoscopic resections: the goal is preservation of as much adjacent normal tissue as possible while ensuring a clear margin.

With respect to patient selection, exposure through the laryngoscope dictates which tumors can be managed by TLS. It is a well-established procedure for T1–T2 glottic or supraglottic carcinomas, as previously indicated. Additionally, some authors indicated this technique in selected T3 glottic tumors (fixation of the true vocal cord caused by direct invasion of the cancer into the thyro-arytenoid muscle), T3 supraglottic tumors (with limited preepiglotic space invasion) and also in some T4 cases (limited base of tongue invasion).

Several reports have shown good oncologic results in intermediate and advanced laryngeal cancer. The 5-year local control with laser alone and laryngeal preservation rates are approximately 95% and 98% for T1 tumors, 85% and 95% for T2 tumors, and 70% and 75% for T3 tumors. These results compare well to those of standard supraglottic laryngectomy. Regardless of the surgical technique employed, negative margins are essential in limiting local recurrence. Tumor involvement of the surgical margin after TLS has been associated with higher rates of local recurrence and distant metastasis, lower specific survival rate, and the necessity of salvage surgery.

Functional outcomes following TLS for laryngeal cancers are excellent. By maintaining one valve of the larynx, the airway is protected and voice and swallowing can be resumed with appropriate rehabilitation. Aspiration occurred in most patients soon after surgery, but recovered within 1–6 months, with recovery being faster in partial resections. Functional results depend on the extent of the resection. The return of voice quality also depends on the depth and extent of resection.

The functional results of TLS are generally superior to those of the conventional open approach, in terms of the time required to restore swallowing, tracheotomy rate, incidence of pharyngocutaneous fistulae, and shorter hospital stay. These functional advantages can be attributed to the more conservative nature of the endoscopic procedure, because normal tissues are not disrupted during the procedure. With open procedures, the thyroid cartilage, soft tissues and infrahyoid and suprahyoid muscles are divided, and the hyoid bone is frequently resected. There is invariably airway compromise and a need for a temporary tracheotomy. With endoscopic resection, tracheotomy is almost never indicated. Avoidance of tracheotomy and preservation of the strap muscles may facilitate faster return and ensure improved long-term swallowing function.

Transoral robotic surgery

The concept of robot-assisted surgery is gaining popularity for multiple different specialties, and more recently in minimally invasive head and neck surgery. The overriding advantages from the proponents of robot-assisted surgery are the excellent 3-dimensional visualization and 2- or 3-handed surgery through minimally invasive approaches that are afforded by the instrument. The wider angle of vision and angled lenses increases the range of the endoscopic visual surgical field compared with the "line of sight" visual field gained by microscopes. The 2-dimensional visualization provided by single channel optical systems in current endoscopes lacks the depth perception of 3-D vision provided by the binocular optical systems used in standard microsurgery. The 5-mm robotic endoscope commonly used has a dual-channel optical system coupled with a dual charge-coupled device, which allows for 3-D visualization of the surgical field at the surgeon's console. Another advantage of the technology used in the da Vinci robotic instrumentation is its ability to provide movement at the instrument tip with 7° of freedom and 90° of articulation and motion scaling. This allows the surgeon, who sits at the console with an adjustable arm, support to perform precise tremor-free movement in a deep and confined space, with working angles usually not achievable with nonrobotic instruments.

Weinstein and O'Malley have previously reported on the development and refinement of a novel procedure called transoral robotic surgery (TORS) in preclinical experimental models. These foundational studies established the technical feasibility of TORS to gain access to the oral cavity, oropharynx, hypopharynx, supraglottis, and glottis, and they also introduced basic concepts of patient safety and methods for controlling active bleeding.

Although the present literature reports early findings, without long-term oncologic outcomes, the results are consistently encouraging. Indeed, some institutions have shown that transoral robotic surgery programs can be successfully established yielding excellent clinical results.

Nonsurgical organ preservation protocols

In the 1990s, organ preservation treatment protocols combining chemotherapy and radiotherapy were introduced as an alternative to total laryngectomy with the objective to preserve a functional larynx without compromising oncological outcome.

The effectiveness of concomitant chemoradiation (CRT) as an effective organ preservation strategy was initially established by The Department of Veterans Affairs (VA) Laryngeal Cancer Study Group in 1991. Their conclusions were subsequently confirmed by the GETTEC and RTOG 91–11 trials and two individual data meta-analyses.

According to the different treatment guidelines (European Society of Medical Oncology -ESMO-, National Comprehensive Cancer Network -NCCN-, American Society of Clinical Oncology -ASCO-) the current standard of treatment for patients with T3 laryngeal carcinoma who desire a nonsurgical organ preservation treatment is concomitant radiotherapy with cisplatin, with salvage surgery in cases of persistent disease, or induction chemotherapy followed by definitive radiation/chemoradiation or surgery depending on clinical response. The dose considered standard for cisplatin by most researchers is 100 mg/m^2 administered on days 1,22, and 43 of radiotherapy, and radiation therapy is administered with a conventional fractionation (2 Gy/day to give 70 Gy in 7 weeks). With these treatments, the larynx is preserved in approximately 2/3 of patients.

Although initially not addressed by the VA protocol, it was recognized later that instead of organ preservation, functional preservation is a more relevant outcome. This functional preservation is defined as an "in situ" larynx without need for permanent tracheostomy and permanent gastrostomy at 2 years after finishing the treatment. Despite the various randomized trials that have all confirmed that the CRT approach achieves survival rates similar to treatment with total laryngectomy, none have shown improvement in survival rates with an organ preservation approach. Furthermore, some investigators have been concerned about the long term toxic effects of CRT treatment on laryngeal function and the decreases in overall survival rates with nonsurgical treatment reported more recently from large tumor registries and long-term follow-up of original trials. This raises a critical question of whether the results of a complex multidisciplinary treatment approach developed in controlled clinical trials by skilled investigators can be effectively generalized to standard practice.

Patients specifically included in the pivotal trials were predominantly patients with T3 tumors located at supraglottis, half of them without vocal cord fixation and a small proportion of patients with T4 tumors with minimal invasion to the cartilage, which do not represent the entire spectrum of "advanced larynx cancer." When the results of CRTs were extrapolated and applied in clinical practice and low volume nonteaching centers, selection criteria may not have been applied as strictly as suggested, and many patients who would not have been candidates to receive CRT (most T4 cancers) were included in this type of treatment. There

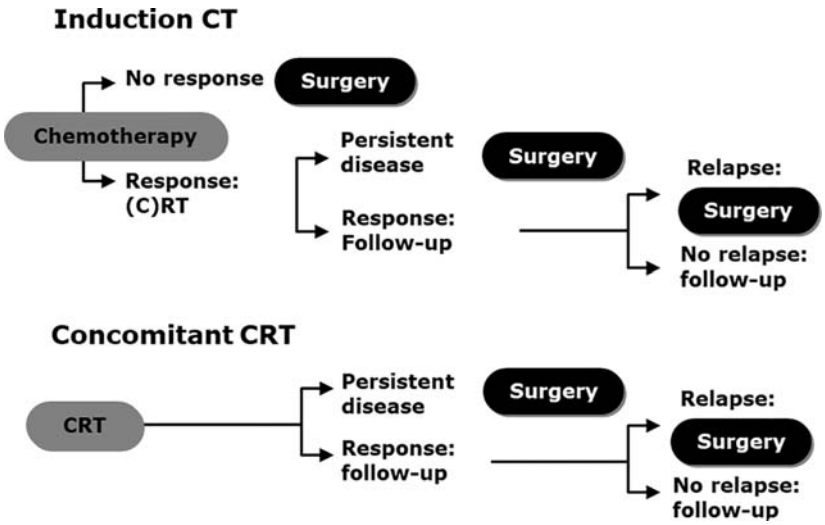

Fig. 9 Role of the salvage surgery in the context of nonsurgical treatment protocols of laryngeal cancer.

are few data about the rate of cartilage invasion or vocal cord fixation in these large cohort studies, but it could be expected to be higher than those reported in pivotal trials.

Therefore, despite state of the art treatment facilities, survival may be decreased due to an incomplete treatment dose, lack of supportive care and treatment of adverse effects of these treatments, loss of follow up, etc. Moreover, if salvage laryngectomy, which is part of an organ preserving strategy (Fig. 9) to obtain comparable survival rates between nonsurgical and surgical treatments, is not offered to patients in case of recurrence, survival is hampered in this patient category. It is highly probable that salvage surgery is not offered due to the lack of organized strategies to assess primary response to CRT, to the delay in the detection of early recurrences, to the lack of surgical experience in resection and reconstruction and for the lack of support from health systems to manage postoperative complications and rehabilitation.

For advanced laryngeal cancers, as laryngectomy is seen as a "mutilating" treatment and organ preservation is an important achievement in treatment, organ preservation protocols will be used more frequently and laryngectomy will be avoided as primary treatment or even when salvage is necessary. In the VA trial, salvage laryngectomy was more frequently done in patients with glottic tumors, vocal cord fixation, and gross invasion of the cartilage and T4 tumors, which indicates early evidence of worse therapeutic response to CRT in these patients. However, CRT was still offered to all patients under the assumption that it will offer better quality of life in comparison with laryngectomy.

There is enough evidence to say that treatment of T4 advanced larynx cancer should consider total laryngectomy since survival outcomes appear better than with CRT in most reports. For patients with T3 tumors, definitive CRT strategies are acceptable on the condition that all resources for the administration of the treatment, follow-up and surgical salvage are available. The entire factors mentioned gives some light to the contradictory results but also offer information for physicians who treat patients with advanced larynx cancer, in order to consider not only the results derived from CRT, but to consider geographical, cultural and socioeconomic conditions before offering the treatment.

The introduction of new systemic therapies should be analyzed carefully before applying them in patients with advanced larynx cancer in order to avoid indiscriminate administration to patients that are not going to get clinical advantages from its use. Customization of treatment is also critically important if overall survival rates are to be improved upon. Future developments of more precise functional imaging capabilities to monitor the response to nonsurgical therapies and possible persistence/recurrence of cancers could allow earlier intervention leading to changes of therapy or salvage surgery which would be expected to enhance survival results. The development of useful biomarkers reflecting disease characteristics such as chemo- or radiosensitivity could be useful in more precise decision making, thereby reducing redundancy of treatments and toxicities.

In summary, decision making for treatment of patients with advanced laryngeal cancer has never been more complex. Primary treatment decisions may depend on patient desires, tumor extent, experience of the treatment team, the adequacy of follow up surveillance, medical comorbidities and long-term voice and swallowing expectations.

Prognosis

Some authors have explored prognostic factors that affect survival in larynx cancer and identified that age, sex, functional status, comorbidities, tumor stage and subsite, type of therapy and treatment of recurrences are closely related with this outcome.

Five-year disease-specific survival is excellent (>95%) in early stage (I–II) patients, and can be considered good (70%–80%) in intermediate stage (III) patients. In advanced disease stages (stage IV) 5-year survival rates drop to 50%–60%. The main cause of death is local-regional recurrence, with distant metastasis being infrequent (less than 10%).

Larynx Cancer: Pathology and Genetics

Nina Zidar and Nina Gale, Faculty of Medicine, University of Ljubljana, Ljubljana, Slovenia

Glossary

Epithelial-mesenchymal transition Process in which epithelial cells change to mesenchymal cells. It is essential in normal embryonal development; in later life, it contributes to wound healing, development of fibrosis and progression of cancer.

Invasion Direct extension and penetration of cancer cells through the epithelial basement membrane into the underlying stroma/lamina propria.

Invasive front Deepest part of the tumor, at tumor-host interface, the most important part of the tumor for invasion and progression.

Precancerosis Lesions with morphologic atypia, associated with an increased risk of cancer development.

Cancer of the Larynx; Pathology and Genetics

Cancer of the larynx is the second most common respiratory cancer, after lung cancer. The vast majority belongs to squamous cell carcinoma (SCC) and its variants. Other carcinoma types are rare and include neuroendocrine carcinomas and adenocarcinomas, particularly adenoid cystic carcinoma and mucoepidermoid carcinoma. They are diagnosed, graded and classified similarly to their counterparts in other organs. Sarcomas are also uncommon, the most important being chondrosarcoma. Malignant lymphomas and malignant melanomas can rarely arise in the larynx, as well as metastases from various primary tumors. Only SCC and its variants will be described in details.

Squamous Cell Carcinoma of the Larynx

Definition

Squamous cell carcinoma (SCC) is a malignant tumor showing evidence of squamous differentiation, e.g., intercellular bridges and/or keratinization. It arises from squamous epithelium or from respiratory epithelium that has undergone squamous metaplasia.

Burden

SCC is the most common malignant tumor of the larynx, accounting for approximately 95% of all malignant tumors at this location. The majority are conventional type SCC.

Laryngeal cancer accounts for 1.6%–2% of all malignant tumors in men, and for 0.2%–0.4% of malignant tumors in women, and for approximately 1.0% of all cancer deaths. Its incidence is on the rise in some countries, particularly in women, presumably related to increased incidence of smoking. It occurs most frequently in the 6th and 7th decades, with a strong male predominance. It rarely occurs in children.

Risk Factors

Cigarette smoking and alcohol consumption, especially in combination, are the most important risk factors in laryngeal cancer. Among them, smoking is more important. Avoiding of smoking and alcohol consumption could prevent about 90% of laryngeal carcinomas. Some other factors, such as gastroesophageal reflux, radiation exposure, diet and nutritional factors have been also related to an increased risk of laryngeal cancer, particularly in patients who lack the major risk factors.

Much attention has been recently paid to the possible role of infection with human papillomavirus (HPV) in the pathogenesis of laryngeal cancer. The results of recent studies, using modern techniques, such as in situ hybridization for HPV E6/E7 mRNA, which enable to detect transcriptionally active, integrated virus, suggest that HPV, particularly type 16, plays a role in the development of 5%–10% of laryngeal SCCs.

Pathology

Macroscopic features

SCC of the larynx may present as a flat lesion with raised edges, as an exophytic lesion frequently with a central ulceration, or an ulcerative endophytic lesion. Most of them occur in the supraglottic and glottic region, while subglottic SCC is very rare.

- Supraglottic SCC arises most commonly in the epiglottis, followed by the false vocal cords, aryepiglottic folds, ventricles and the arytenoids. It tends to spread to oropharynx and pyriform sinus, but it rarely invades the glottis and thyroid cartilage.
- Glottic SCC arises mostly from the anterior half of the vocal cord or from the anterior commissure. Because of poor lymphatic supply, glottic SCC tends to remain localized for a long period. As SCC progresses, it invades the vocal muscle resulting in the fixed vocal cord which is an ominous clinical sign. In late stages of the disease, it may extend to the opposite true vocal cord, to the supraglottis and subglottis; it may also extend through the thyroid cartilage and invade the soft tissue of the neck.
- Subglottic carcinoma involves the region extending 1 cm below the true vocal cord, between the lower edge of the true vocal cord and the first tracheal cartilage (Fig. 1).

Microscopic features

SCC is characterized by invasive growth and variable degrees of squamous differentiation. Invasive growth is manifested by interruption of the basement membrane and the growth of islands, cords or single (dyscohesive) tumor cells in the subepithelial stroma. Large tumors may extend into deeper structures, i.e., muscle, cartilage or bone. Perineural invasion and invasion of lymphatic and blood vessels may be present, which is a reliable proof of an invasive cancer. Squamous differentiation is manifested by intercellular bridges (desmosomes) and/or keratinization, with keratin pearl formation.

SCC is traditionally graded into well-, moderately- and poorly differentiated SCC. The criteria for grading are: the degree of differentiation, nuclear pleomorphism and mitotic activity. Well differentiated SCC resembles closely normal squamous epithelium and contains varying proportions of large, differentiated keratinocyte-like cells and small basal-type cells, which are usually located at the periphery of the tumor islands. There are intercellular bridges and usually full keratinization; mitoses are scanty. Moderately differentiated SCC exhibits more nuclear pleomorphism and more mitoses, including abnormal mitoses; there is usually less keratinization. In poorly differentiated SCC, basal-type cells predominate, with a high mitotic rate, including abnormal mitoses, barely discernible intercellular bridges and minimal, if any keratinization. Keratinization should not be considered an important histological criterion in grading SCC (Fig. 2).

Tumor growth at the invasive front can show an expansive pattern, an infiltrative pattern or both. An expansive growth pattern is characterized by large tumor islands with well defined pushing margins, whereas an infiltrative pattern is characterized by scattered small cords or single tumor cells, with poorly defined, diffusely spreading, infiltrating margins.

Differential diagnosis

The diagnosis of SCC does not usually present a diagnostic problem for pathologists. Nevertheless, well differentiated SCC must be distinguished from pseudoepitheliomatous hyperplasia, which is a benign condition that consists of deep, irregular tongues of epithelium that lack atypia and abnormal mitoses, and is associated with granular cell tumor or infections. Other differential diagnoses include verrucous carcinoma and papillary carcinoma, discussed later.

Poorly differentiated SCC must be differentiated from malignant melanoma, lymphoma, neuroendocrine carcinoma and adenocarcinoma, using immunohistochemistry and special stains for demonstration of mucin production. Melanoma is distinguished

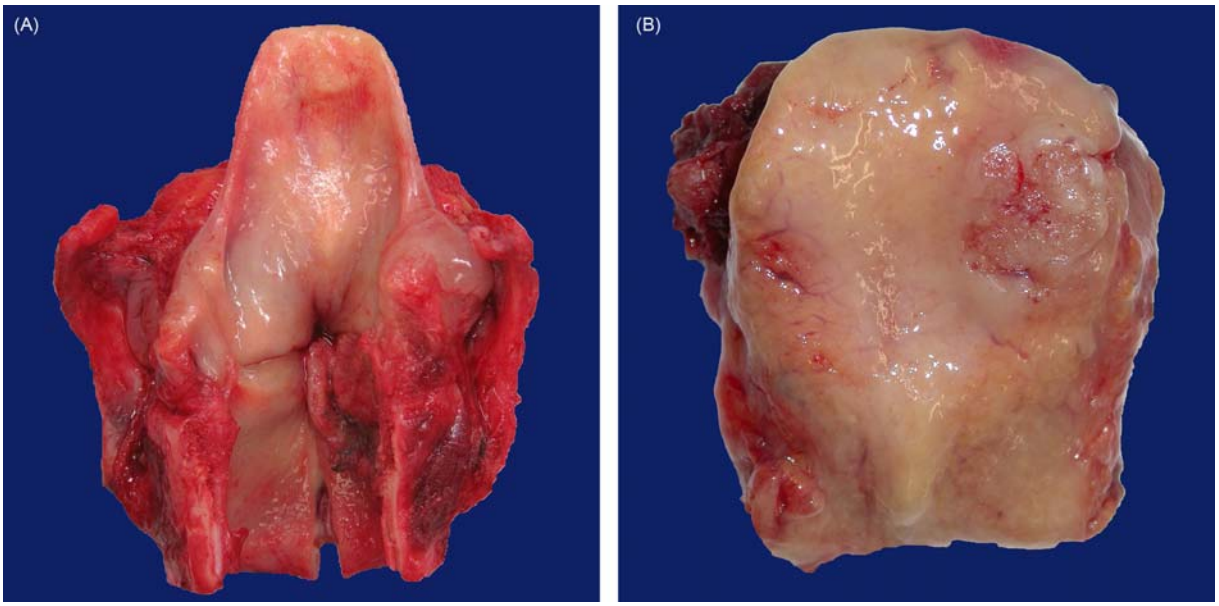

Fig. 1 Squamous cell carcinoma of the larynx. (A) Large exophytic tumor of the glottis extending to the supraglottic and subglottic regions. (B) Small flat tumor of the epiglottis with slightly raised edges.

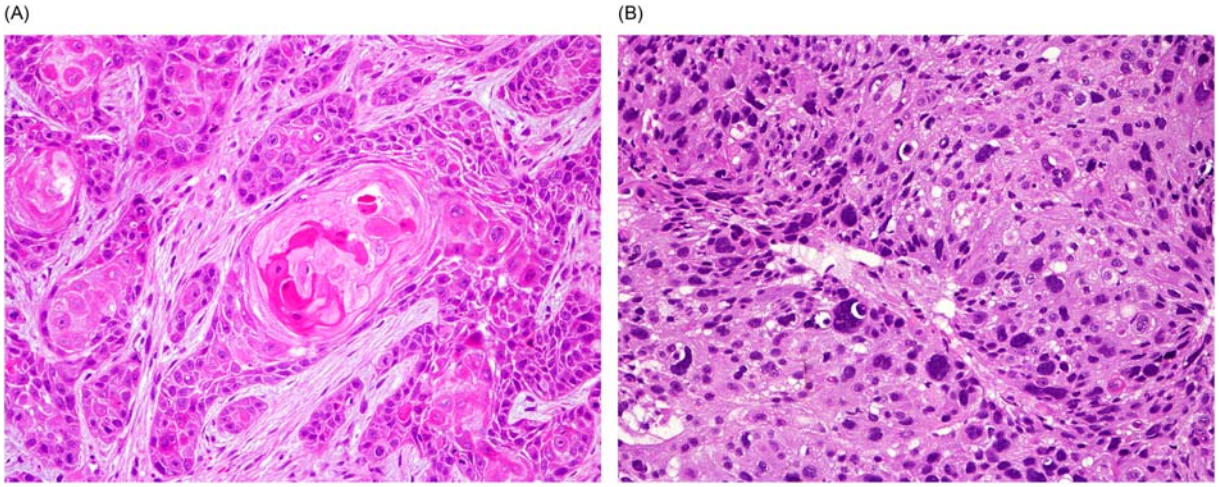

Fig. 2 (A) Moderately differentiated keratinizing squamous cell carcinoma: moderate nuclear and cellular pleomorphism, rare mitotic figures. (B) Poorly differentiated nonkeratinizing squamous cell carcinoma: marked nuclear and cellular pleomorphism, high mitotic rate.

from SCC by expression of S100, HMB45, melan A, MITF. Neuroendocrine carcinoma expresses neuroendocrine markers (synaptophysin, chromogranin, CD56). Lymphoma is distinguished from SCC by the presence of CD45 and markers of B-cell or T-cell differentiation.

Molecular Pathology and Genetics

SCCs of the head and neck including laryngeal SCCs are believed to be among the most highly mutated malignant tumors. Loss of heterozygosity (LOH) and comparative genomic hybridization studies have shown gains of 3q, 5p, 8q, 11q13, and 18p with losses at 3p, 5q, 8p, 9p, 11q23–24, 13q, and 18q.

Cyclin-dependent kinase inhibitor 2A (CDKN2A) and TP53 are among the most commonly affected tumor suppressor genes. Epidermal growth factor receptor (EGFR), vascular endothelial growth factor A (VEGFA), prostaglandin-endoperoxide synthase 2 (PTGS2), phosphatidylinositol-4,5-bisphosphate 3-kinase, catalytic subunit alpha (PIK3CA) and matrix metalloproteinases are among the most commonly amplified and mutated oncogenes.

EGFR, for example, regulates cell growth, migration and survival, and is overexpressed in 80–90% of cases, increasing progressively from precancerous lesions to SCC. Anti-EGFR treatment is now available but has not proven effective in the majority of patients with laryngeal SCC.

P53 is involved in apoptosis and cell cycle regulation. Loss-of-function mutations have been found in laryngeal SILs and SCC. In SCC, the presence of mutations is associated with poor survival and may predict the response to treatment.

PIK3CA plays a role in signaling pathway affecting tumor cell growth, metabolism and survival. Mutations are frequent in SCC of the larynx and is a potential target for treatment with PIK3CA inhibitors.

Much progress has been achieved in our understanding of genetic abnormalities in precancerosis and SCC of the larynx. Hopefully, this will be used in the future as diagnostic criteria for assessing risk of carcinoma development in precancerous lesions and in surgical margins, and the risk of unfavorable course in SCC. Importantly, they are also potential targets for new treatment modalities. Some modern drugs have already been introduced, but patients with head and neck SCC, including laryngeal SCC, respond poorly, and we are still waiting for new targeted drugs to increase survival of patients with laryngeal SCC.

Microenvironment Including Immune Response

Invasive SCC of the larynx is associated with desmoplastic stromal reaction, which consists of proliferation of myofibroblasts, excessive deposition of extracellular matrix and neovascularisation. Together with inflammatory and immune cells, cytokines and other signaling molecules, they constitute tumor microenvironment. It resembles in many ways the processes of inflammation and wound healing and has been compared to a wound which does not heal. The tumor cells and microenvironment are closely related, and the constant interaction between them is complex, playing an important role in the final outcome.

It seems that desmoplastic stromal reaction is present only in invasive SCC and never in precancerosis, regardless of the grade, and may be considered an additional marker of invasion. The desmoplastic stromal reaction tends to be pronounced in well- and moderately differentiated SCC and weak or absent in poorly differentiated SCC, as well as in carcinomas, related to infection with HPV and Epstein–Barr virus (EBV).

Inflammatory cells comprise cells of innate and adaptive immune system. Some of these cells possess antitumoral properties, while others suppress antitumor immunity and are manipulated by the tumor cells to evade the immune system. Recent studies

suggest an important role of regulatory T cells, tumor-associated macrophages and myeloid-derived suppressor cells. There is merging evidence that immune cells mediating host response contribute significantly to the highly variable outcome, providing a clue why some precancerous lesions progress to cancer and others do not, and why some SCCs progress, metastasize and kill the patient and others do not.

Targeting tumor microenvironment to reverse tumor immune escape and induce inhibitory immune cells could represent basis for the development of new treatment modalities in the future.

Staging and Grading

The TNM system (T-tumor, N-node, M-metastasis), established by the International Union Against Cancer (UICC) is widely used for staging laryngeal cancer. The TNM status is based on the extent of the tumor and infiltration of the surrounding structures and organs, and on the presence of regional and distant metastases. The nodal status is assessed on the basis of the number of metastatic nodes, their location and size (expressed as the greatest dimension of the node with metastasis, with cut-off values of 3 and 6 cm) and the presence of extranodal extension. The most common sites for distant metastases are the lungs and bones.

Stage remains the most significant predictor of survival. Consistently, the prognosis varies from excellent for patients with early disease (stage I and II), with more than 90% 5-year survival rate, to poor for patients with advanced disease (stage III and IV), with less than 60% 5-year survival.

Laryngeal SCCs are usually graded as G1 (well differentiated), G2 (moderately differentiated), G3 (poorly differentiated) or G4 (undifferentiated). The criteria and prognostic significance of grading are described elsewhere.

Prognostic and Predictive Biomarkers

Clinical prognostic factors

- Stage is the most significant predictor of survival. Extent of the tumor, depth of invasion and the presence of regional and distant metastases are independent predictors of survival.
- Localization is an important prognostic factor for laryngeal SCC. The most favorable course has been reported for glottic SCC; glottis has a poor lymphatic supply and glottic SCC rarely spreads to the regional lymph nodes. The supraglottic and subglottic regions have a rich lymphatic network, resulting in common metastases in the regional lymph nodes.
- Other factors that may have a significant impact on the outcome of SCC laryngeal include patient age at presentation, comorbidity and performance status.

Histopathological prognostic factors

- Differentiation: the prognostic significance of traditional grading into well-, moderately- and poorly differentiated SCC is controversial and mostly correlates poorly with outcome. The main criticism of this widely used system is related to its subjectivity and lack of objective criteria.
- Invasive front: the growth pattern at the invasive front has prognostic implication: an infiltrative pattern is associated with a more aggressive course and poorer prognosis than an expansive pattern.
- Lymphovascular invasion: tumor cells often invade the thin-walled lymphatic vessels, capillaries and veins. The finding of the penetration of tumor cells in the lymphatic and/or blood vessels is associated with a high probability of lymph node and/or distant metastases, with recurrence and poor survival. However, the presence of lymphovascular invasion should not be considered synonymous with metastasis, because many tumor cells that enter in the lymphatic system and circulation are destroyed (**Fig. 3**).
- Perineural invasion is defined as tumor cells within any of the three layers of the nerve sheath or tumor foci outside of the nerve with involvement of at least 33% of the nerve's circumference. Perineural invasion enables tumor to spread well beyond the extent of local invasion. It is a marker of increased locoregional recurrence rates, a shorter time to recurrence and decreased survival.
- Extracapsular spread (ECS), also termed extranodal extension, in lymph node metastases is defined as penetration of the lymph node capsule by tumor cells, with infiltration of the perinodal fibro-adipose tissue. It can be visible by the naked eye (macroscopic/gross ECS) or on histopathologic examination (microscopic ECS). ECS has been recognized to worsen the adverse outcome associated with nodal metastasis.
- Resection margins: the aim of cancer surgery is to remove as much neoplastic tissue and retain as much healthy tissue as possible. Total surgical removal of the tumor can be proved by clear surgical/resection margins. Margins are considered clear if there is no invasive SCC or carcinoma in situ. Although the concept of clear margins seems straightforward, the definition of adequate margins, i.e., how much healthy tissue around the tumor must be removed, is highly controversial. It is generally believed that a margin of 5 mm is adequate but some believe that even margins of 1–2 mm are adequate, particularly in glottic cancer.

Resection margins clear of tumor are associated with a lower recurrence rate and better survival. However, up to 22% of patients with histologically negative margins undergo treatment failure. In these cases, relapse may be due to a minimal residual disease or to field cancerisation, the latter being related to the presence of genetically damaged cells in microscopically normal mucosa. It has

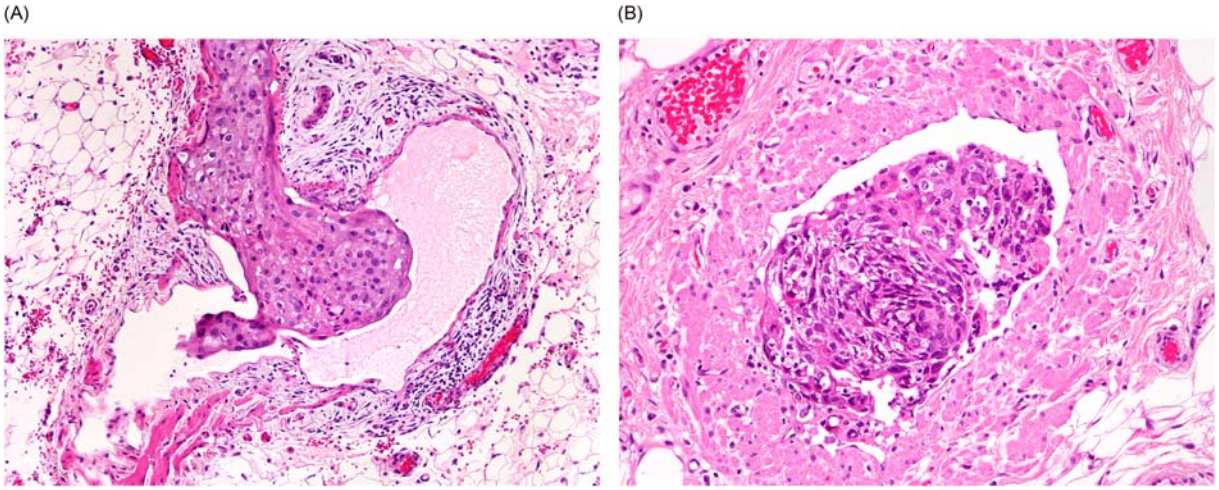

Fig. 3 (A) Lymphatic invasion: carcinoma cells in a thin-walled lymphatic vessel. (B) Vascular invasion: carcinoma cells within a small vein.

therefore been proposed to introduce novel molecular assays to detect these genetically damaged, phenotypically normal mucosal cells in resection margins. This form of margins has been termed "molecular margins." Some studies reported promising results using various genetic alterations including TP53 mutations, loss of heterozygosity, promoter hypermethylation, eIF4E proto-oncogene overexpression, mitochondrial DNA mutations etc. Nevertheless, there is no clinical experience with these methods and no consensus on how to use them in routine work.

Precancerous Lesions of the Larynx

Transition from normal laryngeal epithelium to precancerous lesions and SCC is a stepwise process, in which genetic changes progressively accumulate, followed by architectural and cytologic abnormalities. The entire spectrum of morphologic changes in this process has been referred to as dysplasia or squamous intraepithelial lesions (SILs). Several classification systems are used worldwide. Aiming to harmonize the various concepts of different classifications, the new edition of the WHO classification of head and neck tumors proposed a two-tiered system, classifying these lesions as low-grade or high-grade dysplasia (SILs). Some authors believe that carcinoma in situ must be defined as a separate category. Dysplasia (SILs) is associated with an increased risk of progression to SCC, from 1.6% for low-grade dysplasia to 12.5% for high-grade dysplasia, and up to 40% for carcinoma in situ (Fig. 4).

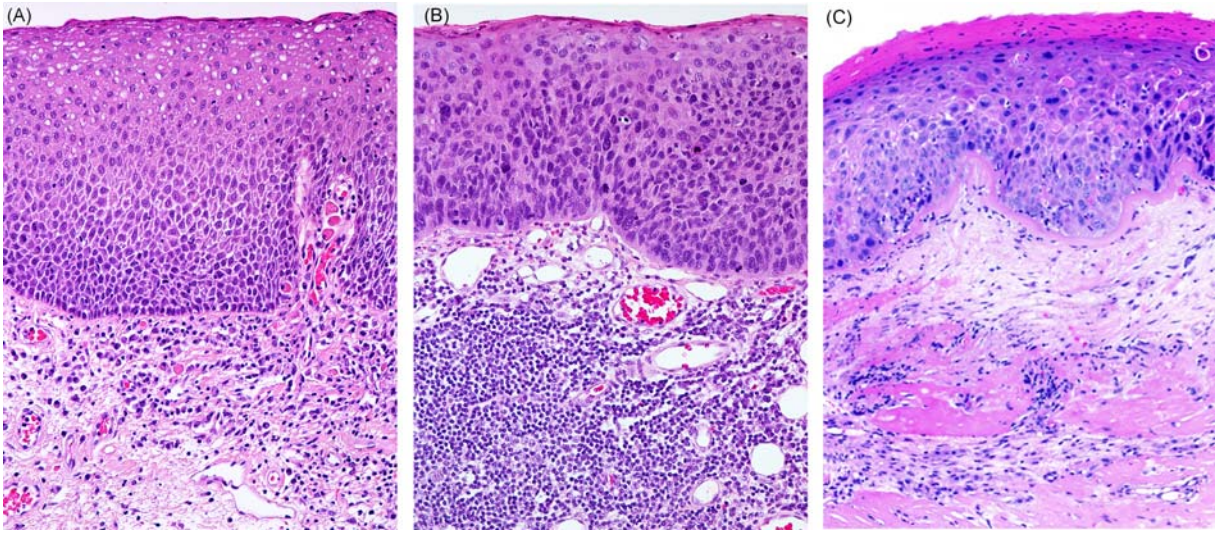

Fig. 4 (A) Low-grade dysplasia (squamous intraepithelial lesion): hyperplastic squamous epithelium with augmented basal-type cells, occupying lower half of epithelial thickness, with rare mitotic figures and no atypia. (B) High-grade dysplasia (squamous intraepithelial lesion): hyperplastic squamous epithelium with augmented basal-type cells, occupying almost the entire epithelial thickness, with marked atypia and high mitotic rate. (C) Carcinoma in situ: epithelial cells show severe atypia, with frequent mitoses, architectural disorder and preserved basement membrane.

Subtypes of Squamous Cell Carcinoma of the Larynx

Several variants of SCC in the larnyx have been described in the WHO Classification of the head and neck tumors, including verrucous carcinoma, basaloid SCC, papillary SCC, spindle cell carcinoma, adenosquamous carcinoma and lymphoepithelial carcinoma. Most of them are true clinico-pathologic entities with important prognostic implications. Their recognition also helps to distinguish them from other tumors.

Variants of SCC are rare and together account for 5%–10% of laryngeal malignant tumors. Similarly to conventional SCC, they mostly occur in the 6th and 7th decades, more frequently in males, and are often associated with alcohol abuse and tobacco.

Verrucous Carcinoma

Verrucous carcinoma (VC) is a variant of well differentiated SCC which grows slowly but can cause extensive destruction. Pure VC is believed to be unable to metastasize. The possible relation of VC to HPV infection has been controversial. Recent studies using highly sensitive and specific molecular methods suggest that VC is not related to infection with HPV.

Macroscopically, VC presents as an exophytic, broad based tumor with a warty surface.

Microscopically, it consists of thickened, club-shaped filiform projections with prominent surface keratinization and blunt stromal invaginations lined by thick, well differentiated squamous epithelium, composed of a few layers of basal cells and multiplied, voluminous spinous cells lacking cytologic criteria of malignancy. Mitoses are present only in the basal layer. The tumor invades the subjacent stroma with a well defined, pushing margin. Approximately 10% of VCs of the larynx contain foci of conventional SCC. They are referred to as hybrid (mixed) tumors and have the potential for metastasis (Fig. 5).

VC is characterized by a high frequency of initial misdiagnosis. An adequate, full-thickness biopsy specimen must be taken, when a clinician suspects VC; moreover, multiple biopsies may be needed to rule out a conventional SCC component in a VC.

Differential diagnosis includes verrucous hyperplasia, well differentiated SCC, papillary SCC and squamous papilloma. Invasion below the level of the basal cell layer of the neighboring normal squamous epithelium distinguishes VC from verrucous hyperplasia. Lack of atypia helps to rule out conventional SCC and papillary SCC. VC also lacks the well formed, wide papillary fronds of a squamous cell papilloma.

Molecular pathology and genetics of VC are largely unknown.

Pure VC has a significantly better prognosis than conventional SCC and doesn't affect overall survival of the patients when properly treated. Patients with hybrid carcinoma must be treated aggressively as if they had conventional SCC.

Basaloid Squamous Cell Carcinoma

Basaloid squamous cell carcinoma (BSCC) is a biphasic tumor composed of neoplastic basaloid cells and foci of SCC. In the larynx, BSCC is not associated with HPV infection.

Macroscopically, BSCC does not show any characteristic features, distinguishing it from conventional SCC. It usually present as slightly elevated tumor with a central ulceration and elevated edges.

Microscopically, it consists of a SCC component and basaloid cells. The SCC component can present as foci of conventional SCC or as dysplastic changes in the surface epithelium. Basaloid cells are small, with hyperchromatic nuclei without nucleoli and scant cytoplasm. They grow in a solid nests which are closely packed, with a jigsaw-puzzle pattern. Stromal hyalinization between and within the tumor nests is a characteristic feature. Large central necroses of comedo type and prominent peripheral palisading are

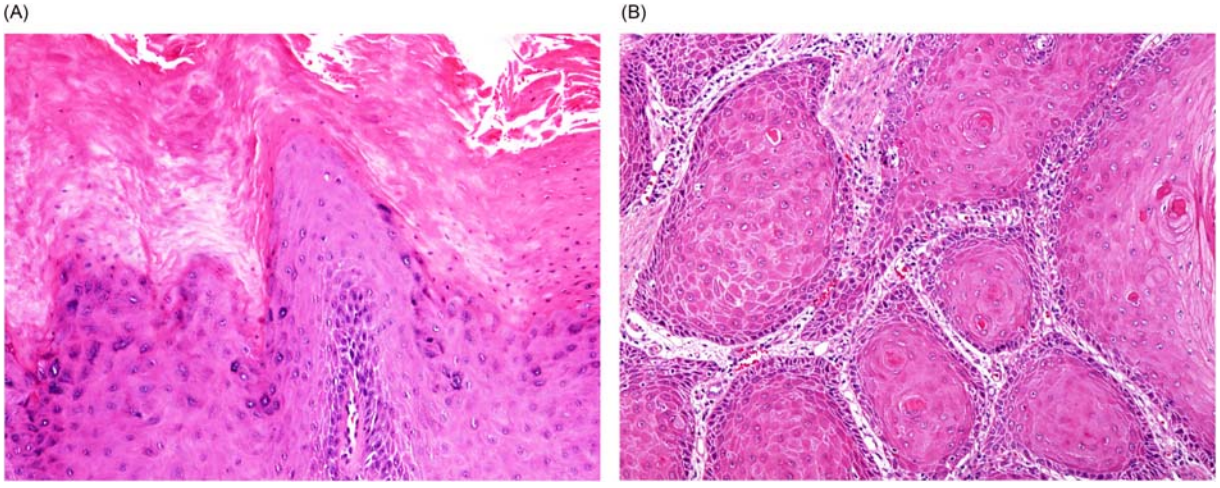

Fig. 5 Verrucous carcinoma. (A) Filiform projections of well differentiated squamous epithelium with prominent surface keratinization, with no atypia. (B) Tumor invades the subjacent stroma with well defined, pushing margins.

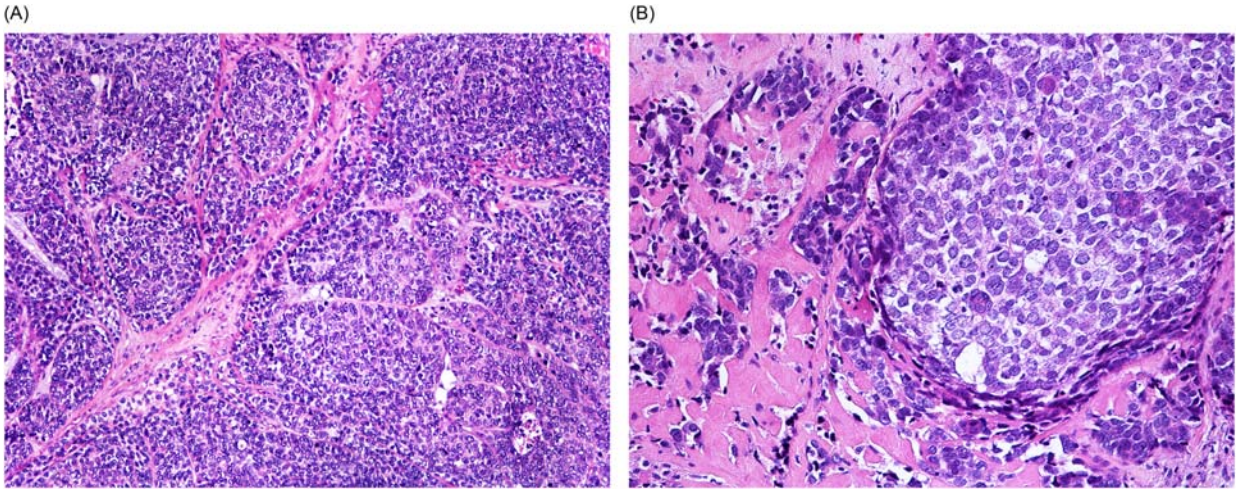

Fig. 6 Basaloid squamous cell carcinoma. (A) Islands of closely packed small cells with hyperchromatic nuclei without nucleoli and scant cytoplasm. (B) Stromal hyalinization between and within the tumor islands.

usually present. Distinctive features of basaloid SCC are small cystic spaces mimicking gland formation, containing PAS-positive material. BSCC may occasionally lack the SCC component (Fig. 6).

Immunohistochemically, BSCC expresses high-molecular-weight cytokeratins, p63 and p40, but it does not express neuroendocrine markers.

The most important differential diagnosis includes adenoid cystic and neuroendocrine carcinoma. The former lacks squamous differentiation and usually expresses S100, vimentin and focally p63. Neuroendocrine carcinoma is distinguished from BSCC by positivity for neuroendocrine markers, e.g., synaptophysin, chromogranine and/or CD56. In large tumors extending to the oropharynx, HPV-positive SCC must be considered; it is characterized by immunohistochemical overexpression of p16 and the presence of HPV16/18.

Molecular pathology and genetics of BSCC of the larynx are largely unknown.

There is some controversy regarding the prognosis of basaloid SCC. Some studies suggested that it has a worse outcome than conventional SCC, whereas others suggested that prognosis in both tumor types is similar when matched for site and stage.

Papillary Squamous Cell Carcinoma

Papillary squamous cell carcinoma (PSCC) is characterized by an exophytic, papillary growth pattern and a good prognosis. In the larynx, it is rarely associated with HPV infection.

Macroscopically, PSCC presents as exophytic, friable, soft tumors.

Microscopically, they are composed of papillary projections, which consist of a central delicate fibrovascular core covered by neoplastic squamous epithelium. The covering epithelium is nonkeratinizing or minimally keratinizing, it may be composed of immature basaloid cells or may be more pleomorphic resembling carcinoma in situ. Stromal invasion is often difficult to demonstrate in biopsy specimens (Fig. 7).

Differential diagnosis includes squamous papilloma and verrucous carcinoma. Papilloma and VC share similar architecture with PSCC, but PSCC is differentiated from both VC and papilloma by the presence of atypia of the squamous epithelium covering the papillae.

Molecular pathology and genetics of PSCC of the larynx are largely unknown.

PSCC is generally believed to have a better prognosis than conventional SCC, though recurrences are frequent.

Spindle Cell Carcinoma

Spindle cell carcinoma (SpCC), also referred to as sarcomatoid carcinoma, is a biphasic tumor composed of conventional SCC and malignant spindle cells. The characteristic spindle cell phenotype of the neoplastic cells in SpCC is the result of epithelial-mesenchymal transition. Similar to conventional SCC, SpCC has been etiologically related to cigarette smoking and alcohol consumption. It has been suggested that SpCC may develop after radiation exposure; however, some authors believe that this is not a major etiologic factor.

Macroscopically, SpCC can present either as an exophytic, polypoid lesion or as a flat, ulcerated tumor.

Microscopically, the SCC component may be well-, moderately- or poorly differentiated, keratinizing or nonkeratinizing, and transition between the two components may be abrupt or gradual. The spindle cell component usually forms the bulk of the tumor. Spindle cells are often pleomorphic, with large hyperchromatic nuclei, prominent nucleoli, and numerous mitoses. Sometimes,

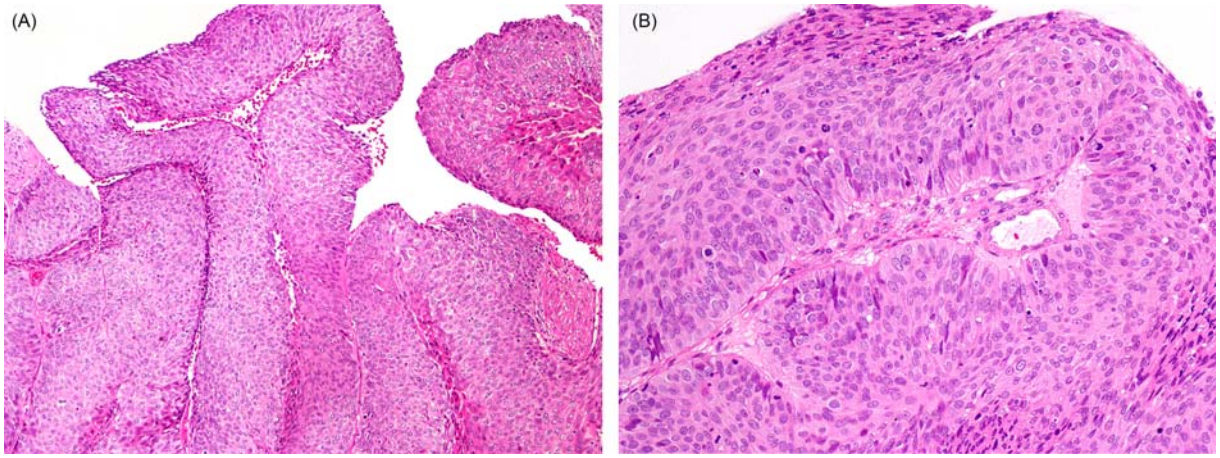

Fig. 7 Papillary squamous cell carcinoma. (A) Exophytic tumor, consisting of papillary projections, covered by nonkeratinizing squamous epithelium and fibrovascular cores. (B) The epithelium covering papillae shows nuclear and cellular atypias and increases mitotic activity.

only spindle cells are present. If such tumors are less cellular, they may mimic benign reactive lesions. Foci of osteosarcomatous, chondrosarcomatous or rhabdosarcomatous differentiation may be present, particularly in patients who had previously been treated by radiotherapy (Fig. 8).

Immunohistochemically, tumor cells in SpCC often express epithelial and mesenchymal markers. Cytokeratin and vimentin coexpression has been observed in individual tumor cells. Cytokeratin expression can be demonstrated in spindle cells in 40%–85% of cases. The most sensitive/reliable epithelial marker for SpCC seems to be keratin (AE1/AE3, K1) K1, K18 and EMA. Spindle cells always express vimentin and often other mesenchymal filaments, such as myogenic markers (smooth muscle actin, muscle specific actin, desmin).

A diagnosis of a SpCC is based on demonstration of an invasive or in situ SCC and a malignant spindle cell component. However, when a SCC component cannot be demonstrated, the diagnosis is more difficult and SpCC must be distinguished from a number of benign and malignant processes, such as spindle cell sarcomas, nodular fasciitis, inflammatory myofibroblastic tumor and malignant melanoma. In the larynx, true sarcomas (with the exception of chondrosarcoma) and benign mesenchymal tumors are very rare. It is therefore the general view, that a malignant spindle cell tumor in the mucosa of the larynx tract is probably a SpCC and not a sarcoma. A negative reaction for S100 protein and HMB45 helps to distinguish SpCC from malignant melanoma.

Molecular pathology and genetics of SpCC is complex and is similar to poorly differentiated SCC. SpCC also shows features of epithelial-mesenchymal transition, e.g., up-regulation of transcription repressors (Snail, Slug, SIP and Twist etc.) and down-regulation of microRNAs implicated in the induction of epithelial-mesenchymal transition.

Prognosis of the laryngeal SpCC is controversial, but it seems to be favorable for patients with no history of radiation, glottic location and polypoid appearance of the tumor.

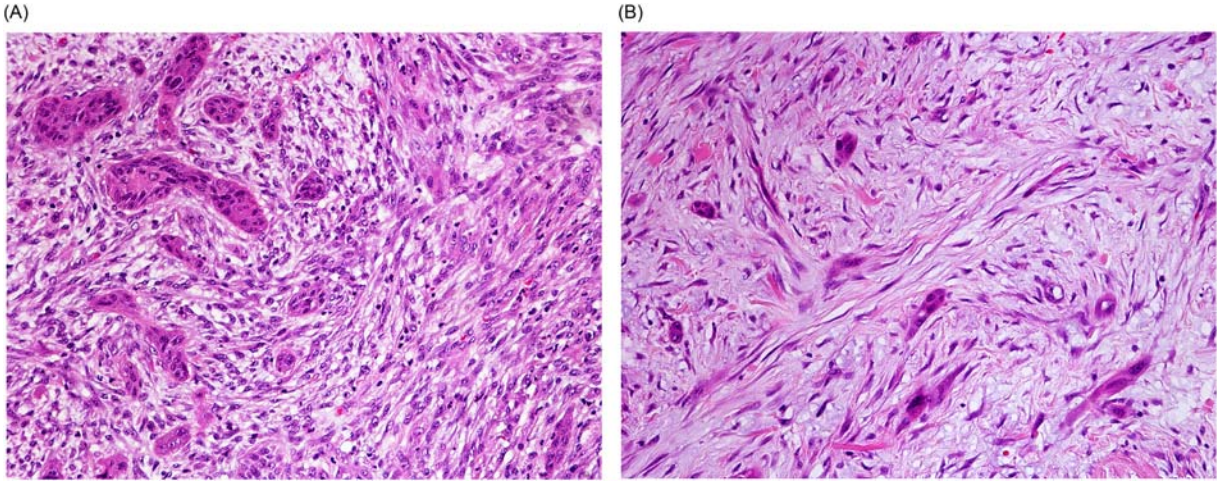

Fig. 8 Spindle cell carcinoma. (A) Small islands and cords of squamous cell carcinoma and dense proliferation of neoplastic spindle cells. (B) Spindle cell carcinoma with abundant edematous, myxoid stroma.

Adenosquamous Carcinoma

Adenosquamous carcinoma (ASC) is a malignant tumor that arises from the surface epithelium and shows both squamous and glandular differentiation.

Macroscopically, ASC cannot be distinguished from conventional SCC.

Microscopically, the two components occur in close proximity but are generally distinct and separate and are not closely intermingled as in mucoepidermoid carcinoma. The SCC component can present either as in situ or as invasive SCC, and the adenocarcinoma component is usually located in the deeper parts of the tumor, consisting of tubular, alveolar or ductal structures (Fig. 9).

Immunohistochemistry shows distinctive staining patterns in the two components: positive staining for CEA and low-molecular-weight cytokeratins, such as K7 and CAM5.2 in the adenocarcinomatous component and positive staining for p63, K5/6 and K7 in the SCC component. Both components express high-molecular-weight cytokeratins.

Molecular pathology and genetics of ASC of the larynx are largely unknown.

Differential diagnosis includes mucoepidermoid carcinoma, adenoid SCC and conventional SCC invading the normal salivary glands. It is important to differentiate ASC from mucoepidermoid carcinoma because ASC has a worse prognosis. Features favoring a diagnosis of ASC are separate and distinct areas of SCC and adenocarcinomatous components and the involvement of the surface epithelium, exhibiting either atypical hyperplasia, carcinoma in situ or invasive SCC.

The presence of mucin in the true glandular spaces helps to distinguish ASC from adenoid SCC. Conventional SCC invading or entrapping the normal salivary or mucoserous glands can be confused with ASC, especially in small biopsy specimens. In such cases, preservation of the lobular gland architecture and lack of significant atypia are observed, helping to distinguish conventional SCC from ASC.

In general, ASC has a more aggressive course than conventional SCC, with a tendency for early lymph node metastases, frequent local recurrences and dissemination.

Lymphoepithelial Carcinoma

Lymphoepithelial carcinoma (LC) is a poorly differentiated SCC or undifferentiated carcinoma, associated with a dense lymphocytic stromal infiltration. It is morphologically similar to nonkeratinizing nasopharyngeal carcinoma, undifferentiated subtype. It is extremely rare in the larynx. In contrast to nasopharyngeal LC, laryngeal LC is rarely associated with EBV infection.

Macroscopically, LC cannot be distinguished from conventional SCC.

Microscopically, LC is composed of small clusters or large syncytial masses of cells with oval or round vesicular nuclei and prominent nucleoli, and poorly defined, sparse cytoplasm. The stroma is densely infiltrated by T lymphocytes, occasionally admixed with plasma cells, follicular dendritic cells and eosinophils. Immunohistochemically, LC expresses cytokeratins distinguishing it from other malignant neoplasms, e.g., malignant melanoma and lymphoma (Fig. 10).

Molecular pathology and genetics of LC of the larynx are largely unknown.

LC is more aggressive than conventional SCC, with a higher incidence of cervical lymph node metastases and a propensity for distant metastases.

Prospective Vision

A step towards a unique classification of precancerous lesions has been made in the last WHO edition of Classification of head and neck tumors.

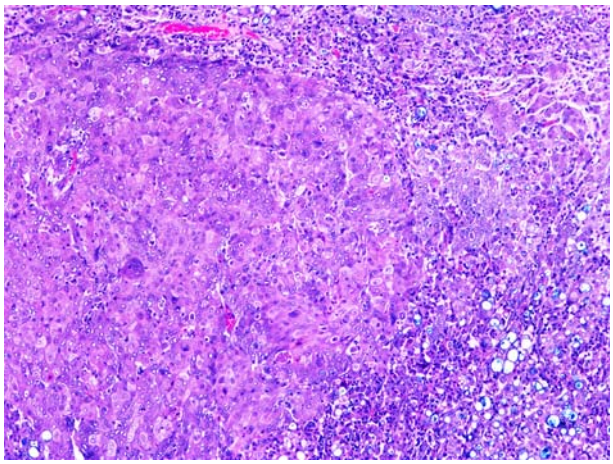

Fig. 9 Adenosquamous carcinoma. Two components, clearly separated: squamous cell carcinoma component on the left, and adenocarcinoma component on the right, with mucin production within the cytoplasm of tumor cells.

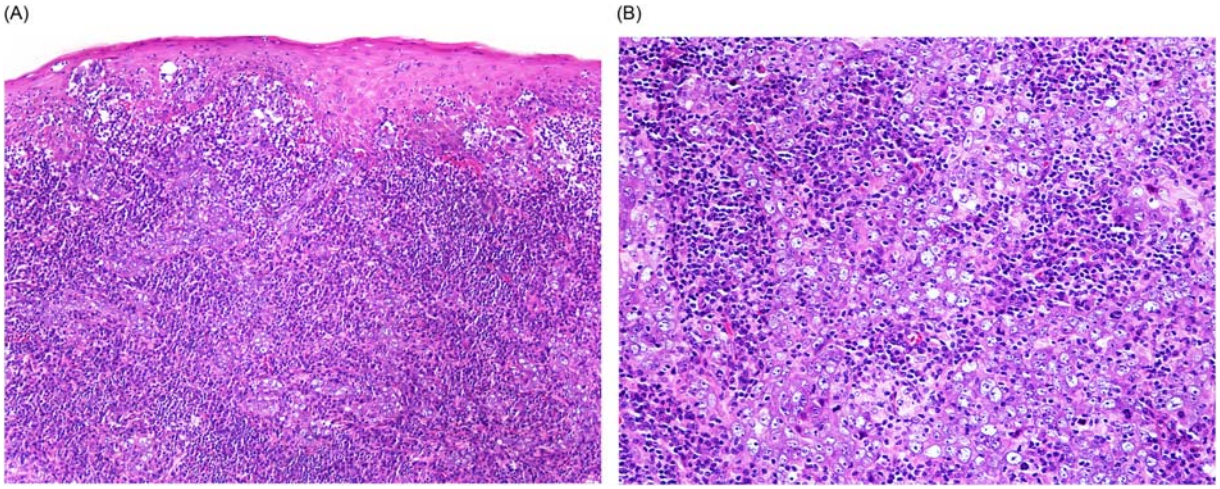

Fig. 10 Lymphoepithelial carcinoma. (A) and (B) Islands of poorly differentiated carcinoma beneath the surface epithelium, with stroma densely infiltrated by lymphocytes and occasional plasma cells.

In contrast to oropharyngeal carcinoma, no significant progress has been achieved in the understanding of etiology, pathology and treatment of laryngeal carcinoma.

Early diagnosis of precancerous lesions, proper classification and optimal choice of treatment is therefore essential for better outcomes of patients at risk for laryngeal cancer.

It is now clear that a small proportion of laryngeal SCC is related to high-risk HPV, but clinical significance of this finding, if any, is yet to be determined.

Discovery of new targets and treatment modalities are needed, possibly targeting not only tumor cells, but also other constituents of the tumor microenvironment.

Li–Fraumeni Syndrome☆

Orli Michaeli and David Malkin, The Hospital for Sick Children, Toronto, ON, Canada; and University of Toronto, Toronto, ON, Canada

Glossary

Familial cancer A form of cancer that occurs in various members of the same family at a far higher rate than would be expected to occur by chance or that would be attributed to shared environmental conditions, for example, Li–Fraumeni syndrome.

Germline mutation A mutation which occurs in the germ cell and is therefore propagated to every cell in the body and can be inherited, in contrast to somatic mutations which are acquired.

Li–Fraumeni syndrome (LFS) A familial cancer syndrome associated with occurrence of a wide spectrum of cancers that typically develop at significantly earlier ages than their sporadic counterparts. These include breast carcinomas, soft tissue and bone sarcomas, leukemia, and brain tumors among others. For families at risk, the probability of developing some invasive form of cancer by age 30 is close to 50%.

p53 A tumor suppressor protein encoded by the *TP53* tumor suppressor gene whose primary function is to activate maintenance of genome integrity. Somatic *TP53* mutations occur in over 50% of human cancers; germline *TP53* mutations occur in ~80% of LFS patients.

Sporadic cancer Nonhereditary malignancy.

Trp53 (transgenic) mice Mice that have been genetically engineered either to be devoid of functional p53 or to express mutant alleles that compromise wild-type p53 function.

Tumor suppressor gene A gene whose protein product, when inactivated, can contribute to the malignant transformation of a normal cell to a tumor cell.

Introduction

Inherited mutations in "cancer genes" pose the most potent and penetrant oncogenic influence in human carcinogenesis, exceeding the effects of such environmental factors as ionizing radiation, tobacco, and occupational carcinogens. Hereditary cancers have been reported to occur in autosomal dominant, recessive or X-linked patterns of inheritance, and for some (most notably breast and colon) at least two different hereditary forms exist, distinguished by their clinical features. Different genetic events are thought to influence the respective phenotypic associations. Some neoplasms such as acute myelogenous leukemia occur only rarely in a familial form, whereas others such as retinoblastoma occur in the heritable form almost as frequently as in the sporadic form. There tends to be a wide degree of penetrance of the susceptibility to tumors arising among family members for each particular gene. Furthermore, the number of different types of cancer varies from family to family. For example, the only well-documented second tumor in the context of hereditary retinoblastoma is osteosarcoma. However, members of a Li–Fraumeni syndrome (LFS) family are at risk for a wide spectrum of tumors, including, but not limited to, carcinomas of the breast, lung and adrenal cortex, soft tissue sarcomas, osteosarcoma, leukemia, and a spectrum of brain tumor subtypes. Studies of hereditary cancers have identified a class of genes that is critical to both carcinogenesis and normal development. The identification of these genes facilitates the identification of increasing numbers of individuals (with or without cancer) who harbor them, as well as opportunities for development of novel therapeutic options. These advances have generated both rays of hope as well as significant challenges both for families and clinicians.

History and Definition

In 1969, Li and Fraumeni reported the results of a survey of 280 medical records and 418 death certificates of childhood rhabdomyosarcoma (RMS) patients diagnosed in the United States. In five families in whom siblings or cousins had a childhood sarcoma,

☆*Change History*: May 2018. O Michaeli and D Malkin updated all text and added new text.
This article is an update of David Malkin, Li–Fraumeni Syndrome, in Encyclopedia of Cancer (Second Edition), edited by Joseph R. Bertino, Academic Press, 2002, Pages 21–29.

 https://doi.org/10.1016/B978-0-12-801238-3.96122-1

a high concentration of cancers of diverse types was noted on the ancestral line of one parent. Soft tissue sarcomas and breast carcinomas, as well as acute leukemias, brain tumors, carcinomas of the lung, pancreas, and skin frequently occurred in first- and second-degree relatives, and adrenocortical carcinomas were often seen in siblings.

This family cancer syndrome came to be known as the Li–Fraumeni Syndrome (LFS). A subsequent prospective analysis of more than 50 similarly affected families defined the list of cancer phenotypes in affected members to include osteosarcoma, brain tumors, leukemias, and adrenocortical carcinomas, in addition to the originally described component tumors, namely soft tissue sarcomas and breast cancer (**Fig. 1**).

It was suggested in the original reports that the familial occurrence of neoplasms originating at discordant sites might represent a counterpart of the tendency for a single individual to develop multiple primary tumors. Indeed, neoplasms in LFS tend to develop in children and young adults, often as multiple primary cancers in affected individuals. Although LFS shares with other hereditary cancer syndromes the tendency for tumors to develop at unusually early ages at multiple sites, the constellation of tumors is quite distinct.

"Classic" LFS families include one member diagnosed with a sarcoma before age 45, a first-degree relative with cancer before age 45, and another first- or second-degree relative in the same ancestral line with any cancer diagnosed under 45, or a sarcoma at any age.

It was recognized that the identification of a defective gene or genes conferring a predisposition in carriers within these families would assist in clarification of the definition of the syndrome. Although LFS had been characterized in both a statistical and a classical genetic manner, identification of the gene that yielded this striking cancer predisposition remained elusive until 1990. Recognition of the limitations placed on standard linkage analysis suggested that the candidate approach to isolating the responsible gene might be productive. The class of genes most strongly associated with familial neoplasms has been the tumor suppressor genes. Of those genes known at the time, *TP53* was most likely to be linked to LFS, and indeed was found to be its cause.

Subsequent to the initial report of *TP53* mutations in classic LFS families, numerous cases were reported of individuals who did not fulfill the classical LFS definition but who either had an extensive familial history or who carried a germline *TP53* mutation. These families were termed "LFS variants" or "LFS like" with several somewhat different definitions that, in general, broadened the classic criteria. For example, the Eeles (1995) definition of LFS like families include individuals with any childhood cancer or sarcoma, brain tumor, or adrenocortical carcinoma diagnosed under 45 years of age, with one first or second degree relative, with typical LFS cancer (sarcoma, breast cancer, brain tumor, leukemia, or adrenocortical carcinoma) diagnosed at any age, plus one first or second degree relative in the same lineage with any cancer diagnosed under age 60.

In 2001, a wider set of criteria were proposed by the French LFS consortium that expanded referral opportunities for individuals for genetic testing for *TP53* mutations. The original "Chompret criteria" included the following (Chompret et al., 2001):

1. Proband affected by one of a narrow spectrum cancer (see below) before 36 years and at least one first or second degree relative affected by a narrow spectrum tumor (other than breast cancer if the proband is affected by breast cancer) before 46 years or multiple primary tumors.

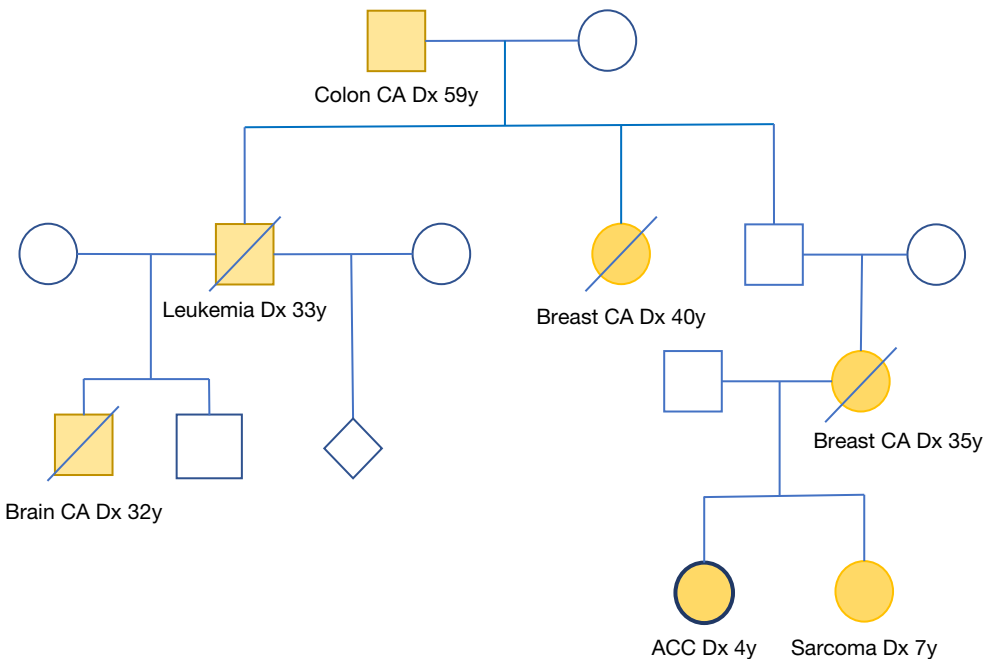

Fig. 1 Li–Fraumeni syndrome "classic" pedigree.

Table 1 Criteria for referral for TP53 mutation analysis (based on "revised Chompret criteria")

Familial presentation	Proband with tumor belonging to LFS tumor spectrum before age 46 years, AND at least one first/second-degree relative with LFS tumor (except breast cancer if proband has breast cancer) before age 56 years or with multiple tumors
Multiple primitive tumors	Proband with multiple tumors (except multiple breast tumors), two of which belong to LFS tumor spectrum and first of which occurred before age 46 years
Rare tumors	Proband with one of: adrenocortical carcinoma, choroid plexus carcinoma, anaplastic rhabdomyosarcoma, very early-onset breast cancer (<31 years), hypodiploid acute lymphoblastic leukemia, medulloblastoma (SHH subtype), irrespective of family history (at any age unless specified)

LFS tumor, premenopausal breast cancer, soft tissue sarcoma, osteosarcoma; *CNS tumor*, adrenocortical carcinoma.
CNS, central nervous system; *SHH*, Sonic Hedgehog; *LFS*, Li–Fraumeni syndrome.
Based on "2015 Version of Chompret Criteria", in: Bougeard, G. et al. (2015). Revisiting Li–Fraumeni syndrome from *TP53* mutation carriers. *Journal of Clinical Oncology* **33**(*21*), 2345–2352.

2. Proband with multiple primary tumors, two of which belong to the narrow spectrum and the first of which occurred before 36 years, whatever the family history.
3. Proband with adrenocortical carcinoma whatever the age of onset and family history.

The "narrow spectrum of tumors" includes soft tissue sarcoma, osteosarcoma, brain tumor, breast cancer, and adrenocortical carcinoma.

These criteria were further revised in 2009 (Tinat et al., 2009) and again in 2015 (Bougeard et al., 2015) (**Table 1**). These criteria can now be expanded even more, as recently several other cancers have been added to the list for whom gene testing is highly suggested (see "**Diagnosis and TP53 Germline Prevalence in Selected Cohorts**" section). The current criteria that should be generally used to guide *TP53* gene testing is depicted in **Table 1**.

The *TP53* Tumor Suppressor Gene

Alterations of the *TP53* gene or its encoded protein are the most frequently observed genetic events in human cancer; more than 50% of sporadic cancers harbor somatic *TP53* mutations and p53 is functionally dysregulated in more than 80%. The human gene, located on chromosome 17p13, encodes a 53-kDa nuclear phosphoprotein. p53 binds specific DNA consensus sequences and is a transcription factor that regulates the expression of other growth regulatory genes.

Structural analysis suggests that several highly conserved amino acids contact the minor or major grooves of the DNA helix. p53 function may be inactivated through sequence changes at these or other codons that alter the conformation of the protein and prevent it from forming tetramers or activating transcription.

Activation of p53 is the consequence of various stress signals to the cell: oncogene expression, DNA damage, hypoxia, nutrient deprivation, oxidative stress, replication defects, and more. Activation of p53 induces several downstream effects, including cell cycle arrest, senescence, apoptosis or DNA repair, through modulation of numerous genes. The exact effect will be determined according to the type of stress, the specific cell type, and other factors.

Inhibition of growth is achieved by blocking progression at a checkpoint control site prior to G1/S and at the G2/M restriction point. p53, commonly referred to as the "guardian of the genome" is important in maintaining the fidelity of DNA repair, particularly in response to double-stranded (ds) DNA breaks induced by ionizing radiation or certain chemotherapeutic drugs. Wild-type p53 mediates apoptosis when overexpressed in cultured cells in the absence of appropriate differentiation or proliferation signals.

Transcriptional targets of p53 are many and include Mdm-2 which is involved in a negative regulatory system that terminates the response of a cell to DNA damage; GADD45, a DNA repair protein; CDKN1a, which is critical for G1 cell-cycle arrest and cell senescence; PUMA and NOXA, mediators of apoptosis; and miR34, a microRNA which regulates genes that promote apoptosis, cell-cycle progression and differentiation.

In a cell with normal p53, levels of the protein rise in response to DNA damage, and the cell arrests prior to the G1/S transition, where genomic repair or apoptosis ensues with the mechanism being determined by the transforming oncoprotein(s). In a cell in which p53 is inactivated, G1 arrest does not occur and damaged DNA is replicated. During mitosis, the presence of damaged DNA results in mutation, aneuploidy, mitotic failure, and cell death.

As "the guardian of the genome" the functions of p53 are therefore very complex. Indeed, p53 has additional roles that involve autophagy, modulation of reactive oxygen species levels, ferroptosis and metabolism, as preventing tumorgenesis can be achieved by controlling aberrant cellular metabolism. Moreover, *TP53* alterations are necessary but not sufficient, for the ultimate cancer that arises from these malignant clones, as other genetic events are clearly required. While the scope of this chapter focuses on germline TP53 mutations and LFS, we suggest further reading of *TP53* tumor suppressor gene itself.

Germline *TP53* Mutations

In 1990 (Malkin et al., 1990), five LFS families were studied to determine whether *TP53* played any role in the occurrence of cancer in affected family members. Base pair mutations were identified in the germline of affected members in each of the five families

studied. Although the missense mutations were initially observed between codons 252 and 258 in exon 7, within one highly conserved region of the gene, further analysis of one family revealed a 2-bp deletion at codon 184 in exon 5 instead of the codon 252 mutation. The wild-type allele was deleted in tumors of affected individuals. Several unaffected relatives were mutant gene carriers, suggesting that they might be at risk to develop cancer at a later date.

Since that original report, germline *TP53* mutations were reported in additional LFS families, with other constitutional mutations in the same region of the gene, as well in different ones.

However, while most LFS families harbor a *TP53* alternation, there is a lack of 100% concordance with the "classic" LFS phenotype. In fact, only 60%–80% of "classic" LFS families harbor germline *TP53* mutations. The other clinical criteria as mentioned above are broader and less specific; therefore, only approximately 40% of "LFS-Like" families and 30% of individuals meeting the 2009 version of the Chompret criteria, carry mutations. This genotype–phenotype discordance, in which not even all "classic" LFS exhibit *TP53* mutation, may be explained in several ways. These include posttranslational p53 alterations, endogenous undetected promoter defects leading to aberrant expression of the *TP53* message, complete *TP53* deletion, effects of modifier genes, or alterations of other genes that may influence the phenotype generated by the presence of a specific germline *TP53* mutation.

Nevertheless, the high frequency of germline *TP53* mutations in LFS families together with the tight association of tumor formation in *Trp53*-deficient or *Trp53*-mutant mice (see "**Animal Models of Li–Fraumeni Syndrome**" section) do confirm a causal association of germline *TP53* alterations and cancer predisposition.

Currently, hundreds of germline *TP53* mutations have been reported. For the most part, these correspond to the somatic mutations and can be found across the gene. However, the most common mutations include those found in the original hotspots along with several additional ones, located in the highly conserved DNA binding domain of the gene, in exons 5–8 (**Fig. 2**). According to the recent version of International Association for Research on Cancer (IARC. R18, April 2016), the most common mutation hotspots, excluding a unique one at codon 337 (see below), are at codons 248, 273, 175, 245, 282, 213, 125, and 158, in decreasing order of frequency. Point mutations are the most prevalent (70%–96%), specifically missense mutations. Other, less common alternations are splice site and nonsense mutations that encode a truncated p53 protein, as well as rare frameshift mutations, intragenic deletions, in-frame insertion/deletions, and also intronic mutations.

Animal Models of Li–Fraumeni Syndrome

Transgenic animals carrying distinct deregulated oncogenes develop tumors that appear to be cell-type specific. To better study p53 in vivo, mice have been created that either lack functional p53 or express dominant-negative mutant alleles that inhibit wild-type p53 function.

In one of the early studies by Donehower et al. (1992), homozygous knockout mice with a germline *Trp53* null mutation ($p53^{-/-}$) were created. These mice were highly susceptible to malignant lymphomas and sarcomas, which occurred in >75% before 6 months of age. Tumor development, primarily sarcomas, was delayed in heterozygotes mice ($p53^{+/-}$); however, by 18 months of age, 50% of them develop tumors. Multiple primary tumors were noted in ~30% of tumor-bearing $p53^{-/-}$ mice, while virtually none of the $p53^{+/+}$ mice had developed tumors by 18 months. The heterozygous mice are a closer genetic model for LFS, since affected LFS individuals are heterozygous for mutant p53 rather than homozygous, and a substantial fraction of the germline mutations are functionally null for p53. Developmentally, the mice were normal, implying lack of crucial function of p53 in the evolving embryo. In a different study, the $p53^{-/-}$ state was again compatible with normal development. However, the yield of $p53^{-/-}$ offspring varied from 16.6% to 23%. The apparent increase in fetal loss is related to presence of fetal exencephaly, although increased fetal loss is not seen in human LFS families.

The genetic background of mice (C57BL/6 mice vs. 129/Sv), determined by strain-associated modifier genes, was shown in the aforementioned study to influence the tumor spectrum in the setting of p53 functional deficiency. The importance of genetic background in influencing the tumor type is as well exemplified by the occurrence of unusual cancers, including pineoblastomas and islet cell tumors in $p53^{-/-}$ mice crossed with mice heterozygous for an *RB1* mutation. In a study by Kuperwasser et al. (2000), which looked at female mice and breast carcinomas, high rate of mammary tumors developed in p53-deficient mice in a BALB/c background, but not in other genetic backgrounds (C57Bl/6 or 129/Sv). Notably, BALB/c-$p53^{-/-}$ mice did not develop high rates of mammary tumors, but this was likely due to early death from other tumors, especially lymphomas. Indeed, when mammary glands of BALB/c-$p53^{-/-}$ female mice were transplanted into wild-type (BALB/c-$p53^{+/+}$) hosts, 75% developed mammary tumors.

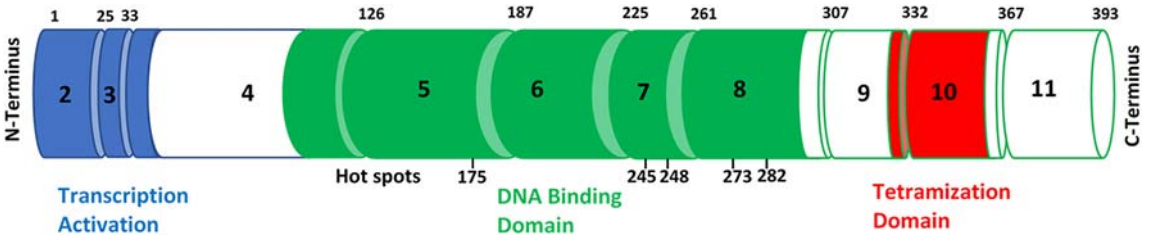

Fig. 2 Structural organization of p53.

Mice deficient for p53 are more sensitive to the effects of certain carcinogenic agents. $p53^{+/-}$ mice exposed to dimethylnitrosamine developed liver hemangiosarcomas more rapidly than treated $p53^{+/+}$ animals. $p53^{-/-}$ mice treated with an initiator, dimethylbenzanthracene, and a promoter, 12-*O*-tetradecanoyl-phorbol-13-acetate, show a more rapid rate of malignant progression of skin papillomas to carcinomas. These studies help distinguish whether p53 mutations play rate-limiting or tissue-specific roles in the tumor progression pathway. p53-deficient and p53-Tg mice (mice carrying mutant transgene) exposed to sublethal doses of γ-irradiation develop tumors, usually sarcomas, earlier than in untreated animals. This susceptibility is associated with a twofold increase in the accumulation of radiation-induced dsDNA breaks compared to that seen in $p53^{+/+}$ animals. These studies confirm that p53 prevents the accumulation of cells sustaining radiation-or chemically induced DNA damage.

More than 80% of the *TP53* germline mutations in humans are missense mutations in the conserved regions of the p53 DNA binding domain, whereas only few are nonsense mutations that result in no p53 or a truncated p53 protein. Therefore, it was crucial to test missense mutations in mice, and not only null p53 models. A model by Liu et al. (2000) looked at heterozygous mice with *TP53* R172H mutation ($p53^{R172H/-}$), which corresponds to the *TP53* R175H hotspot mutation in human cancers, and demonstrated different spectrum of tumors. Although mice with this mutation expressed low levels of mutant p53, there was high prevalence of metastatic disease compared to heterozygous null mice ($p53^{+/-}$). Notably, most of the tumors from these mice had an intact *TP53* allele, suggesting that loss of wild-type *TP53* was not important to tumor development.

Actually, in LFS patients, approximately 40% of tumors retain an intact wild-type *TP53* allele, in contrast to sporadic tumors, in which mutations or loss of both *TP53* alleles occur more frequently. In humans with germline missense *TP53* mutation, when p53 is functionally null, all the tumors will show LOH (loss of heterozygosity), meaning loss of the wild-type allele. In mouse models, however, tumors from mice with one null *TP53* allele ($p53^{+/-}$) were analyzed, and over half were found with an intact, wild-type *TP53* allele, which was functionally active.

Provocative studies have tested whether the tumorigenic activity of a mutant p53 is altered by the presence or absence of wild-type p53 in vivo. Mice carrying the 135Ala > Val mutant transgene were crossed with p53-deficient mice. The mutant p53-Tg accelerated tumor formation in $p53^{+/-}$, but not in $p53^{-/-}$ mice, suggesting that this loss-of-function mutation had a dominant-negative effect with respect to tumor incidence and cell growth rates. Although the tumor spectrum was similar in transgenic and nontransgenic mice, the transgenics showed a predisposition to lung adenocarcinomas. Thus, a given p53 alteration may have distinct tissue specificity with respect to tumorigenic potential.

The dominant-negative effect, by which mutant p53 functionally inactivates the wild-type p53 allele, was demonstrated by Chène (1998) in a mouse model with two types of mutations. The first, Arg175His, is a structural mutation, which affects the global configuration of the p53 protein, hence interfering with its ability to bind DNA. The p53 protein is active as a tetramer. When wild-type p53 forms a tetramer with such a mutant protein to form heterotetramers, that heterotetramer does not bind DNA due to its defective configuration. The second, Arg248Trp (and similarly-Arg 273Leu), is an active site mutation, which affects the actual site of DNA binding on the p53 protein, and not its configuration. This is also a dominant negative mutation: the complete lack of ability to bind DNA causes the wild type subunit of the heterotetramer to act improperly so that all parts of the heterotetramer cannot bind DNA. However, a different kind of mutation, which does not allow any tetramerization with the wild type protein, (e.g., Arg175His; Leu330Ala) will not cause such a dominant negative effect. Likewise, an active site mutation which causes low affinity of DNA binding but does not completely preclude it (e.g., Arg273His) also do not cause such dominant negative effects, since some binding is possible.

The role of those two different types of point mutations were examined in study by Olive et al. (2004). *Trp53* R270H is a missense mutation which corresponds to the *TP53* R273H mutation in humans and is an active site mutation. A different mutation, *Trp53* R172H, corresponds to the *TP53* R175H in humans. Heterozygous mice ($p53^{R270H/+}$ and $p53^{R172H/+}$) developed different tumor spectra when compared to $p53^{+/-}$ mice, to each other (in the same genetic background) and to $p53^{-/-}$ mice. Tumors arising in $p53^{-/-}$ mice were primarily carcinomas (specifically lung adenocarcinomas), most of which were metastatic or invasive, as well as B cell lymphomas. In contrast, $p53^{R172H/+}$ mice showed a higher incidence of sarcomas—particularly osteosarcomas, with frequent metastatic disease. Thus, at least in mice, different genotypes produce different phenotypes.

Lang et al. (2004) also created $p53^{R172H/+}$ mice. These mice developed osteosarcomas and carcinomas but with a much higher frequency of metastases than $p53^{-/-}$ mice. Importantly, both studies demonstrated the "gain-of-function" effect common to many p53 missense mutations, meaning that the mutant p53 exhibits additional inherent tumorigenic activity. Both also highlighted possible tumor suppressor roles of p63 and p73. These other p53 "family members" were functionally inactivated by the mutant $p53^{R172H/+}$ in mouse embryonic fibroblasts, providing an explanation for their role in the "gain of function" effect.

Owing to the fact that p53 has several functions, one can speculate that different mutations will cause distinct altered functions. An interesting study evaluated mice harboring a R172P mutation, which corresponds to the human R175P. This mutant retains cell cycle arrest while abrogating initiation of apoptosis. Consequently, cells of mice with a homozygous mutation ($p53^{R172P/R172P}$) were able to induce cell-cycle arrest and maintain a stable genome. Notably, the mice had delayed tumor onset compared with homozygous null mice ($p53^{-/-}$). This finding suggests that delayed cell-cycle arrest contributes to tumor suppression.

These mouse models and many others shed light on the critical functions of p53 and the phenotypic manifestations of different *TP53* mutations. The continuing expansion of our knowledge through these models is still crucial to further understand the phenotype: genotype correlations in LFS. However, although mice are powerful models with which to study various aspects of p53 biology, they are still somewhat imperfect representations of LFS and cannot be entirely relied upon to explain the clinical and genotype associated phentoypes of the human disease.

Clinical Aspects and Epidemiology of Li–Fraumeni Syndrome

Prevalence

Currently, more than 700 families have been reported in the database of the International Association for Research on Cancer (IARC). However, estimations of the actual prevalence of the syndrome are much higher, until recently estimated at approximately 1:5000, as awareness of cancer predispositions is increasing and many cases are not reported. In addition, newer ways of determining the prevalence are emerging (i.e., by surveying genetically larger cohorts and through the use of next generation sequencing technologies) which suggest that the *TP53* mutation population carrier rate may be as high as 1:500.

Penetrance

Penetrance is thought to be very high, although it is challenging to determine as cancer development in an individual is not entirely dependent on the specific mutation. As genetic tests are becoming more prevalent, more and more people are identified with *TP53* germline mutations without having a rich familial history or even having cancer. Some are identified by the occurrence of cancer in a family relative. Moreover, others are discovered incidentally, for instance by genetic testing which was performed for reasons other than a cancer diagnosis.

Studies have demonstrated a high penetrance rate with estimates of a lifetime cancer risk of 93% in females and 75% in males. Some reports attribute 100% penetrance by the age of 70 years.

This cancer risk is determined by various variables including gender and age. Hwang et al. (2003) looked at 56 carriers of germline *TP53* mutations and found that 12%, 35%, 52%, and 80% developed cancer by ages 20, 30, 40, and 50 years, respectively. In comparison, Bougeard et al., 2015 found an earlier age of onset, with 22% of carriers diagnosed with a cancer by age 5 years and 41% by age 18 years. While these differences are attributed to different cohorts with different inclusion criteria, it is notable that cancer risk is substantially higher than the general population. Notably, risk of cancer begins from infancy, as one of these studies reports that 4% of participants developed a malignancy during the first year of life.

Tumor Spectrum

LFS is a cancer predisposition syndrome with no other phenotypic features. The cancer spectrum is vast and virtually any cancer can occur. However, the "core cancers" that were included in Li and Fraumeni's original report are indeed more prevalent. In the report by Bougeard et al., 2015, 322 affected carriers were described. The five core cancers were the most frequent, with breast cancer more prevalent than any other, occurring in 60% of females. Soft tissue sarcoma and osteosarcoma followed, affecting 27% and 16% of patients, respectively. ACC and brain tumors affected 13% of individuals each. IARC reports 1644 tumors in *TP53* carriers, of which 27% are breast cancers, 13% STS, 12% brain cancers, 11% are adrenal and 10% involve the bones (**Fig. 3**).

Other cancers that occur in *TP53* carriers with some frequency are leukemia, lymphoma, embryonal cancers, various carcinomas, other kinds of sarcomas, neuroblastomas, and more. Interestingly, several tumor types that frequently harbor a somatic *TP53* mutation are less common among individuals with LFS, though when they do occur, they tend to happen at a lower age of onset than

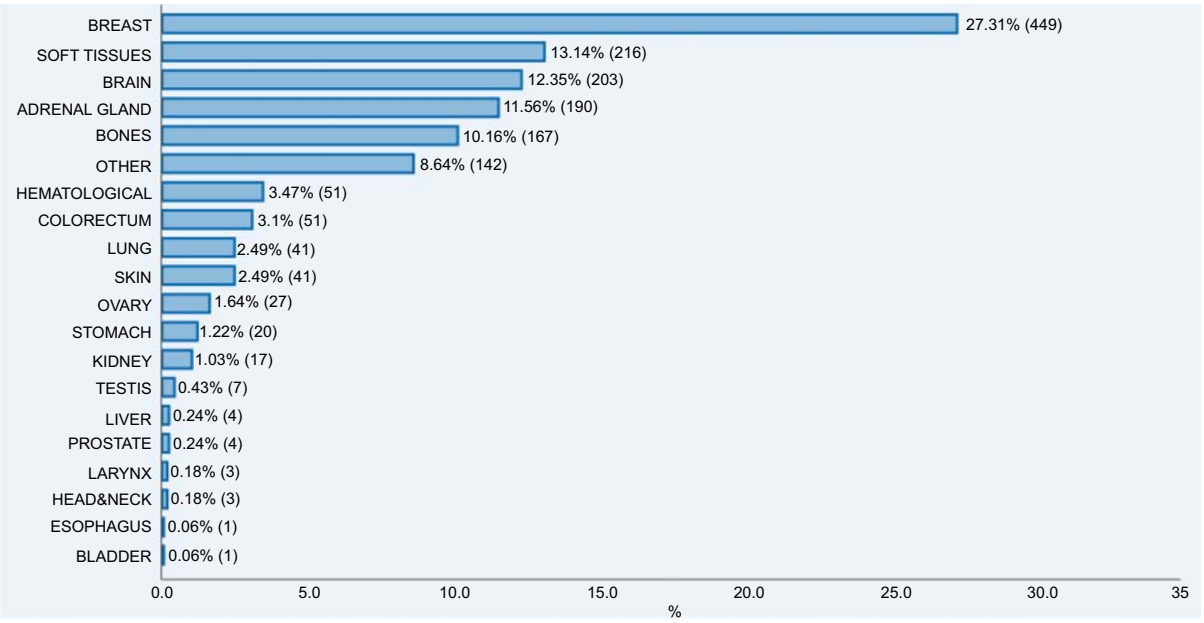

Fig. 3 Tumors associated with *TP53* germline mutations ($n = 1644$).

their sporadic counterparts. For example, colorectal cancer occurred in only 3% of *TP53* carriers, though on average at least two decades earlier than the median age of onset for sporadic CRC.

Type of cancer naturally changes in relation to age. Although adults with LFS are more commonly affected by breast cancer and soft tissue sarcomas (STS), in adolescents the most common tumors are osteosarcomas and young children are noted for adrenocortical carcinoma (ACC), brain tumors, and STS.

In regards to gender differences, since LFS is an autosomal dominant disorder, males and females have an equal chance of carrying the affected gene. However, penetrance differs and women appear to have a higher chance of developing cancer. This difference is attributed in part to the relative abundance of breast cancer, although several studies report that additional factors are involved. In a study by Olivier et al., 2003, among 494 tumors in individuals with germline *TP53* mutations, there was an excess in males of brain tumors, hematopoietic cancers, and stomach cancer. Excess of females was observed for skin cancer and adrenocortical carcinoma. This distribution is in concordance with gender predilection in sporadic tumors, though the excess of females with ACC is exceptional. Males and females were equally affected by soft tissue and bone sarcoma, lung cancer, and colorectal cancer. Mai et al. (2016) report that among females, the cumulative incidence rates by age 70 years were 54% for breast cancer, 15% for STS, 6% for brain tumors, and 5% for osteosarcoma. Among males, the incidence rates were 22% for STS, 19% for brain tumors and 11% for osteosarcoma.

Females not only have a greater chance for cancer, but also tend to be affected at an earlier age. A difference of 11 years between median age of cancer onset was reported among females (28.0 years) and males (17.0 years). This difference was still present after excluding breast cancers, though it was narrowed to 4 years—tumor onset in females was 13 years, compared to 17 years in males.

Multiple Cancers

A striking feature in LFS kindreds is the high frequency of affected members who develop multiple primary neoplasms. One multicenter study demonstrated germline *TP53* mutations in leukocyte DNA from 4 of 59 patients (6.8%) who had survived second cancers but did not have family histories compatible with the LFS.

The increased risk for multiple cancers is pronounced in patients who had their first cancer at a young age or were previously treated with radiation. While early studies state a relatively low incidence of second primaries, more recent studies report a higher incidence, perhaps due to different inclusion criteria, differences in treatment, and survival. For example, in a study by Hisada et al. (1998) among patients diagnosed between 1968 and 1986, the incidence of second, third and fourth primary cancers were 15%, 4%, and 2%, respectively. Notably, 71% of the multiple cancers developed were the LFS core tumors. In contrast, Mai et al. (2016) report in 2016 that almost 50% of LFS patients develop second primary tumors after a median of 10 years following their initial cancer. Breast cancer was the most commonly occurring second malignancy, followed by STS and brain and lung cancer. Interestingly, females had a higher risk of second cancer when compared with males, but lower risk of death. Similarly, Bougeard et al., 2015 reported multiple primary tumors in 43% of mutation carriers, metachronous presentation being more common than synchronous.

This higher chance of multiple primary cancers cannot be attributed solely to therapy, as the incidence is also increased when compared to patients with a history of sporadic cancers. According to a study by Hwang et al. (2003), there is 12-fold higher risk to develop a second primary cancer among carriers, when compared to the general population. In this report, among LFS patients the second cancer occurred at a median of 9.3 years after the first malignancy, which is longer than the median time for treatment-related secondary malignancy in noncarriers in this cohort.

As survivorship increases and surveillance is implemented (see "**Management**" section), more instances of patients surviving multiple cancers are reported, several of which are quite remarkable with documentation of up to 17 primary cancers in a single patient. As mentioned, the estimates of second cancer risk will continue to evolve as more data from cases of *TP53* carriers becomes available, mostly of individuals that do not fulfill the classical LFS criteria, or have any familial history of cancers.

Germline *TP53* Aberrations and Phenotype: Genotype Correlations

Understanding genotype: phenotype correlations in individuals with LFS can aid clinicians in determining more precise estimates of the likelihood of occurrence of specific tumors according to age group, gender, and genotype. Ideally, surveillance and management can be tailored according to those characteristics. Although not fully understood, several important correlative associations have been described.

One important observation is that dominant-negative *TP53* missense mutations within the DNA-binding domain are associated with the highest cancer risk and young age of onset. Such mutations were detected most commonly in pediatric cases of LFS with brain tumors, osteosarcoma and rhabdomyosarcoma (RMS). In contrast, the majority of pediatric cases with adrenocortical carcinoma (ACC) harbor other types of alterations. Other studies have noted that gain of function mutations were associated with younger age of onset when compared to loss of function mutations.

A unique association between genotype and phenotype is described for the germline *TP53* mutation R337H. This mutation is abundant in Brazil, where this founder mutation results in a high prevalence of LFS. The specific mutation (c.1010G > A) is located at codon 337 in exon 10, within the oligomerization domain of the p53 protein. Interestingly, the pH level is a determinant of the mutant protein's function, so that only in the physiological pH range (up to 7.5), does the protein form normal oligomers. At higher pH, and higher temperatures, the mutant protein is unable to dimerize and therefore does not assemble into a functional protein.

The *TP53* R337H mutation is estimated to be present in 0.3% of residents of the South/Southeastern regions of Brazil, resulting in estimate of more than 300,000 carriers. The spectrum of cancers is similar to that observed with other mutations; however, there is a greater than 15-fold increase in childhood ACC in the Brazilian population. In addition, there is high occurrence of papillary thyroid cancer, renal cancer, and lung adenocarcinoma. The age of tumor onset is somewhat older so that the penetrance in the younger age group is lower: cancer occurs before age 30 in only 15%–20%, compared with 50% in carriers of other *TP53* mutations. The lifetime penetrance is, however, as high as in "classic" LFS.

The phenotype: genotype correlations are complicated by various alterations that modify the function of p53. One example are specific *TP53* polymorphisms, such as a duplication within intron 3 (PIN3). When this duplication is found in a *TP53* R337H mutation carrier, the malignancies are more likely to appear at a later age, compared to carriers of the same *TP53* mutation that do not harbor the PIN3 duplication. PIN3 also confers a higher susceptibility to breast and colorectal cancer.

Another genetic modifier is a specific polymorphism of MDM2, an important regulator of p53. MDM2 ubiquinates p53 so that it is targeted for degradation. Bond et al. (2004) found that a T>G substitution at nucleotide 309 (SNP309) in the promoter of the first intron of MDM2 leads to increased levels of MDM2 and hence accelerated degradation of p53. As a result, it is associated with a higher rate of tumor formation in *TP53* mutation carriers and was shown to correlate with younger age of tumor onset. This higher risk is augmented when, in addition to the MDM2 SNP309 polymorphism, the *TP53* mutation carrier also harbors a *TP53* polymorphism at codon 72Pro (Arg72Pro). If a 72Arg variant of the p53 protein exists instead of 72Pro, a higher affinity of p53 to MDM2 will be achieved, causing greater degradation of p53 and younger age of cancer.

A different mechanism of functional modification of *TP53* is through differential methylation of other targets. One example are the microRNAs (miRs), short noncoding RNA molecules that modulate protein expression by promoting RNA degradation and inhibiting mRNA translation. miR-34a is a regulatory microRNA of p53. It was found that miR-34a promotor is hypomethylated in *TP53* mutation carriers, thus making it more active as a "cover" mechanism for the absent p53 tumor suppressor activity. On the other hand, hypermethylation of miR-34a, which decreases its function, is associated with decreased overall survival. This finding was demonstrated in choroid plexus carcinomas (CPC), a typical LFS tumor. Investigators found increased hypermethylation across three CpG sites of the miR-34a promoter, when compared with wild type *TP53* CPCs. Moreover, patients with CPCs that harbored miR-34a promoter hypermethylation had a lower median survival, a finding consistent with the fact that *TP53* mutant CPCs are known to have a more clinically aggressive course, with poorer survival.

An additional microRNA that was found to modify the LFS phenotype is miR-605, which regulates the p53–MDM2 loop. MDM2 as mentioned is a cellular inhibitor of p53, and is correlated with earlier age of tumor onset when increased. A variant of miR-605 gene, the G allele, was shown to be associated as well with an earlier age of tumor onset in LFS patients, in almost all tumor types. In vitro, when nucleofected as pre-miR 605 plasmids to RMS cell lines, the G allele showed decreased processing from its precursor form to its mature form, as compared to the "normal" A allele. Furthermore, in the context of mutant p53, overexpression of miR-605 resulted in a significant reduction in cell viability and oncogenic properties, including cellular proliferation and migration potential.

An intriguing genotype: phenotype phenomenon in LFS is anticipation, wherein successive generations manifest with earlier onset of malignancies. While the exact mechanisms remain unknown, there is probably a role for accelerated telomere attrition. Tabori et al. (2007) compared the telomere length in peripheral blood leukocytes of *TP53* mutation carriers and noncarriers. Carriers who were affected with cancer had shorter telomeres than unaffected carriers or healthy controls. The same was true when comparing affected children with cancer in comparison to their unaffected family members.

Excess DNA copy number variation (CNV) was also found to be one of the characteristics of the LFS phenotype. In a study by Shlien et al., 2008, of individuals with LFS compared the general population, *TP53* mutation carriers had a significant increase in CNVs across their genome, particularly if they had a family history of cancers. This is postulated to be the consequence of the underlying genomic instability caused by the mutant p53. In addition, some LFS individuals had only a few CNVs but of exceptionally large deletions or duplications. Subsequently, large deletions that encompass the entire *TP53* gene, appear to be associated with a distinctive phenotype of congenital anomalies without a predisposition to cancers.

While such genetic modifiers continue to be explored, it is now acknowledged that phenotype: genotype correlations are the result of complex genetic interactions including genetic modifiers within and outside of *TP53* itself.

Diagnosis and *TP53* Germline Prevalence in Selected Cohorts

LFS can be defined as an inherited form of cancers caused by germline mutations of the *TP53* gene; therefore, its diagnosis is best confirmed by the identification of a pathogenic variant in the gene. However, prior to the genetic test, the diagnosis in most cases has to stem from a high index of suspicion.

The revised Chompret criteria described above should aid in the decision of which cancer patient should be referred for genetic testing. As mentioned, these criteria are broad and more sensitive for identifying individuals with LFS who do not have familial cancer. In fact, estimations of de novo mutation frequency in LFS patients range between 7% and 20%, though the number might be even higher as more individuals are now being referred for genetic testing. In particular, the revised criteria focus also on specific cancer diagnoses which confer high risk of *TP53* germline mutation, regardless of the familial history. For instance, 9% of children diagnosed with RMS harbor germline *TP53* alterations. This fraction increases to 23% for patients younger than 4y and up to 73% of children with RMS with diffuse anaplasia. The incidence of *TP53* germline alternations in other sarcomas vary according to specific

type; for example, up to 10% of children with osteosarcoma harbor germline *TP53* mutations. Among children with ACC, about 50% have *TP53* germline alterations, and newer estimates range as high as 70%. However, in adult ACC patients, germline *TP53* mutations are exceedingly rare.

Two studies of patients with CPC found that about 40% carry *TP53* mutations. This rate is increased when cohorts focus on patients with somatic *TP53* mutation or on patients with a familial history of cancer. More than 10% of children with the Sonic Hedgehog (SHH) subgroup of medulloblastoma (SHH-MB) harbor *TP53* germline mutations, though the number increases to 30% when children between 8 and 17 are studied. Furthermore, 56% of children with the subgroup SHH/TP53-MB (SHH-MB with somatic *TP53* mutation) carry such a mutation.

While most patients with childhood acute lymphoblastic leukemia (ALL) do not have cancer predisposition, an uncommon subset of them with hypodiploid ALL, have substantial risk to harbor *TP53* germline mutation. Studies show that 19%–43% of such children are in fact carriers.

The prevalence of *TP53* germline carriers among breast cancer patients substantially changes with age. At older age they represent a minority. However, up to 10% of very early onset breast cancer (< 30 years of age) have LFS, similar to the rate of *BRCA 1/2* mutations in this population.

While all of these types of malignancies do confer high risk of underlying constitutional *TP53* mutation, it is important to bear in mind that for all of these cohorts, ascertainment bias is likely to lead to an overestimation of tumor risk in individuals with LFS. Regardless, germline testing is still recommended in these clinical contexts.

Suspicion of an underlying predisposition for cancer should also be raised with other features of a given malignancy. For instance, detection of specific tumor signatures should promote germline testing. In a report by Rausch et al., 2012, the phenomenon of chromothripsis—massive genomic rearrangements—was associated with *TP53* germline mutations in SHH MB. When looking at medulloblastomas, the vast majority displayed low numbers of single nucleotide variant (SNV) per chromosome. However, 13 of 98 tumors showed high number of SNVs, consistent with chromothripsis. Eleven of these thirteen were SHH-MBs, of whom 10 harbored *TP53* mutations, whereas none of the wild-type SHH-MBs showed this phenomenon. Therefore, the finding of chromothripsis in medulloblastoma, should raise the suspicion of an underlying *TP53* germline mutation. Likewise, comparing SNV rate in a given tumor to the expected SNV rate in the same "reference" sporadic tumor, can point to the need of germline testing.

All these features of a specific cancer diagnosis should advance the suspicion for an underlying predisposition. Other "universal criteria" that should raise suspicion of LFS include multiple primary tumors (synchronous or metachronous) and familial history of cancer, though not necessarily as depicted in the "classic" LFS criteria.

In an era of increasing genetic tests, many individuals are being diagnosed without even being affected. Individuals can be identified following a family member's diagnosis of LFS or incidentally.

Once a referral for genetic testing has been made, the type of genetic testing is determined according to the indication. A known familial variant usually leads to testing for this variant only. Where the mutation is not known, single gene testing by Sanger sequencing is often the initial test of choice with the addition of copy number analysis for intragenic deletions/duplications as well as examination of the intron/exon borders. This however may not identify certain types of variants (e.g., deep intronic variants).

Updated data regarding the different variants, including their interpretation as pathogenic or not, can be found in the website of the International Agency for Research on Cancer (IARC) *TP53* mutation database (listed below). It compiles *TP53* mutation data that have been reported in the published literature since 1989, and is updated annually. In addition to somatic *TP53* mutations, it includes the largest datasets on individuals carrying a sequenced *TP53* germline mutation or affected by cancer and belong to an "LFS family."

Management

Surveillance

Implementation of a surveillance protocol for germline *TP53* mutation carriers enables the presymptomatic detection of malignancies. Such early tumor detection can potentially allow definitive localized treatment approaches that may obviate or minimize exposure to systemic or radiation treatment.

In 2011, and later in 2016, Villani et al. (2016) first reported feasibility and potential survival benefit of a comprehensive surveillance strategy in patients with LFS. This surveillance protocol, termed the "Toronto Protocol," consisted of regular physical examinations together with scheduled imaging and biochemical studies, and was later proven to be beneficial in terms of survival. Among the initial cohort of 59 patients who chose to undertake this surveillance protocol, 40 neoplasms were detected pre-symptomatically in 19 patients, over a median follow-up period of 32 months. Two additional cancers were diagnosed between surveillance assessments in one patient. In contrast, 61 neoplasms presented clinically in 43 of 49 patients who did not undergo surveillance. Furthermore, 25 of 40 neoplasms on the surveillance "arm" were low grade or premalignant at the time of detection, suggesting that early detection through surveillance may identify lesions before malignant transformation. Five years OS was 88.8% in the surveillance arm, versus 59.6% in individuals not undergoing surveillance. Several other studies have since suggested improved clinical outcomes for *TP53* mutation carriers with intensive screening, specifically with the utility of WBMRI.

Table 2 Recommended LFS screening protocol

Adults
General assessment
• Complete physical examination every 6 months
• Prompt assessment with primary care physician for any medical concerns
Breast cancer
• Breast awareness (age 18 years onward)
• Clinical breast examination twice a year (age 20 years onward)
• Annual breast MRI screening[a] (ages 20–75)
• Consider risk-reducing bilateral mastectomy
Brain tumor (age 18 years onward)
• Annual brain MRI (first MRI with contrast; thereafter without contrast if previous MRI normal)
Soft tissue and bone sarcoma (age 18 years onward)
• Annual WBMRI[a]
• US of abdomen and pelvis every 12 months
Gastrointestinal cancer (age 25 years onward)
• Upper endoscopy and colonoscopy every 2–5 years
Melanoma (age 18 years onward)
• Annual dermatologic examination
Children (birth to age 18 years)
General assessment
• Complete physical examination every 3–4 months, including blood pressure, growth curve, Cushingoid appearance, signs of virilization, and full neurologic assessment
• Prompt assessment with primary care physician for any medical concerns
ACC
• US of abdomen and pelvis every 3–4 months
• In case of unsatisfactory US, blood tests[b,c], may be performed every 3–4 months: total testosterone, dehydroepiandrosterone sulfate, and androstenedione
Brain tumor
• Annual brain MRI (first MRI with contrast; thereafter without contrast if previous MRI normal and no new abnormality)
Soft tissue and bone sarcoma
• Annual WBMRI

WBMRI, whole-body MRI; *US*, ultrasound; *ACC*, adrenocortical carcinoma.

[a]Breast MRI/US of abdomen and pelvis to alternate with annual WBMRI (at least one scan every 6 months).

[b]The efficacy of biochemical surveillance for detection of adrenocortical carcinoma has not been shown.

[c]Serial specimens obtained at the same time of day and processed in the same laboratory.

Kratz, C.P., Achatz, M.I. and Brugières, L. (2017). Cancer screening recommendations for individuals with Li–Fraumeni syndrome. *Clinical Cancer Research* **23**(*11*), e38–e45. http://clincancerres.aacrjournals.org/content/23/11/e38.

In 2016, international consensus surveillance recommendations were generated for individuals carrying a pathogenic *TP53* variant, and those fitting the classic clinical definition of LFS. These were based on the "Toronto protocol" with slight modifications and is depicted in **Table 2**. Based on prediction of timing of cancer initiation for the various tumor types, the surveillance approach is proposed according to age groups. Also considered are adverse effects of "over" surveillance including use of contrast, risks from invasive medical procedures or anesthesia, and false positive or false negative results. The importance of regular thorough physical examination and targeted history is emphasized, as well as the prompt assessment of any medical concern.

For early identification of ACC, ultrasound is recommended until 18 years of age, with or without ACC-specific blood tests every 3–4 months. Given its low incidence in adults, there is no need for specific ACC surveillance after childhood. The lifelong brain tumor risk justifies annual brain MRI in all age groups. In order to minimize the potential risk for gadolinium accumulation in individuals undergoing multiple enhanced MRIs, if the initial MRI performed with a gadolinium-based contrast agent (GBCA) shows normal results, the following MRIs may be conducted without GBCA unless an abnormality is seen. For solid tumor surveillance, specifically the lifelong risk of sarcoma, an annual rapid whole body MRI (WBMRI) including limbs, is recommended to all individuals. In addition, abdominal and pelvic ultrasound is recommended annually in adults (while children will have such imaging every 3–4 months as above). The adult abdominal imaging should be every 6 months—alternating between WBMRI and ultrasound. The annual WBMRI cannot replace dedicated brain MRI, as was demonstrated by Ballinger et al. (2017) in a meta-analysis, and it is generally suggested that the two examinations should alternate. In adults, as the risk for gastrointestinal cancers increases, a dedicated periodic exam (colonoscopy/upper endoscopy) is indicated starting at age 25. Annual dermatology exams should start no later than at 18 years of age, as are breast cancer prevention strategies.

While this protocol is currently widely accepted, changes will evolve with more universal uptake and as more experience is reported. Specifically, genotype: phenotype correlations will be clarified, permitting differential recommendations by specific organ risk and disease penetrance.

Treatment of Malignancies in the Context of LFS

In multiple tumor types, somatic *TP53* mutation was proven to confer poorer prognosis in comparison to wild type. Likewise, the prognosis of some specific tumors was reported to be worse among *TP53* germline carrier in comparison to the same tumors when occurring sporadically.

Since the key role of p53 is in response to DNA damage, one could make an argument of the need to minimize exposure of these patients to radiotherapy and some chemotherapy. Indeed, the deleterious effect of radiation in animal models of LFS is well established. Data among LFS patients is not vast, yet is growing. There are several case reports and small case series that integrate a growing volume of evidence suggesting an increased risk of second malignancies in the radiation field of patients with LFS. For example, Bougeard et al. (2015) reported development of tumors within the radiotherapy fields in 30% of mutation carriers. Hisada et al. (1998) studied 200 LFS patients of whom 30 had multiple primary cancers. Nine of those 30 had radiation in the past, in six of which the secondary tumor was within the radiation field. Hence, trying to avoid radiation therapy when feasible, especially in high dose and large volumes, is recommended. However, it should be noted that in the context of treatment discussions for large or high-grade malignancies, omitting radiation may not be a viable therapeutic option. More knowledge of the effects of radiation as well of chemotherapy and other agents in this setting is needed.

An exciting new direction in treatment options for LFS patients is coming from studies of specific treatments aimed at restoring the function of p53. PRIMA-1 (p53 reactivation and induction of massive apoptosis) and its derivate, APR-246 (PRIMA-1^{MET}), were studied for their ability to restore some of the functions of mutant p53. In various tumor cell lines they were shown to convert p53 to its active conformation, inhibit proliferation and promote apoptosis. Antitumor activity has been demonstrated in several xenograft models and the first human studies showed a good safety profile. Other promising agents such as pyrazoles (e.g., PK7088) bind to specific p53 mutated proteins, and restore their conformation and activity to some extent. Zinc-metallochaperones can transport zinc to specific zinc-deficient p53 mutant proteins, so that the protein's folding and function are restored.

Metformin, a commonly used antidiabetic drug, was shown to impact several pathways in cancer, one of which is p53. Metformin is known to inhibit mitochondrial respiration, which is essential to cancer progression. Wang et al. (2017) took mice with a known *Trp53* germline mutation and generated an additional mutation in their mitochondria, causing a decreased oxygen consumption rate. These mice had increased cancer free survival as compared to the other *Trp53* mutated mice. Metformin was given to the mutant mice leading to the same effect on mitochondria as the double mutant ones, of reduced oxygen consumption and induction of antiproliferation signaling cascade. Metformin given to LFS (human) patients, resulted in decreased oxygen consumption rate in mononuclear cells, with decreased mitochondrial activity and similar anticell proliferation signaling. These are all examples of the evolving approach to make p53 a targetable genetic lesion, that will hopefully change the current treatment of LFS specifically, and cancer in general.

Ethical and Psychological Considerations

The potential ethical and psychosocial impact of being able to predictively screen unaffected family members or children for disease predisposition raises a number of complex issues.

While this article is not meant to discuss these in detail, one would be remiss to ignore their significance. Predictive testing for germline *TP53* mutations (or any other disease-predisposing gene) must be based on theoretical principles of respect for the autonomy of the patient and freedom from coercion, benefit to the patient, universal accessibility and freedom from discrimination, and maintenance of confidentiality of results. In the evolving flood of disease and cancer-predisposing genes that are being made available for mutation screening, guidelines addressing the following issues must now be established using *TP53* testing as a model: (1) who is to have access to the information, (2) what safeguards are to be established to protect employees and others from discrimination, (3) at what stage in the development of these genetic tests should mass screening be advocated, and (4) when might mandatory genetic screening be acceptable practice?

For several reasons, testing cannot at present be offered to the general population. Even within the general cancer population the carrier rate is demonstrably low. However, mass screening can be considered in populations that carry a high mutation rate. Such an exceptional example is the southern Brazilian population. Indeed, in a Brazilian study, neonatal screening for the p.R337H mutation followed by surveillance in mutation carriers led to the detection of lower stages of ACCs. The sensitivity and specificity of screening methods to identify mutations are yet not well known and both false-positive and false-negative results have been encountered. The sequence-confirmed presence of a base pair alteration itself must be interpreted carefully to ensure that its protein product has significance in that in some way it inactivates normal p53 function.

Furthermore, effective ways must be developed to provide informed consent to those being screened for a *TP53* germline mutation, about potential beneficial and harmful psychologic and social sequelae. Multidisciplinary services should be incorporated, including oncology, psychiatry, psychology, genetic counseling, medical ethics, and molecular and medical genetics. Such services require skills in communicating risk information and how to motivate adherence to cancer prevention and early detection.

Yet ethical considerations should be taken into account: Is there an obligation to inform family members of individuals who are identified as having such a genetic susceptibility? How aggressively should people at genetic risk for cancer be recruited into surveillance protocols, or clinical trials?

The issue of prenatal testing is also challenging. Risks for future children in the family should be addressed, and discussion with families should include options for preimplantation genetic diagnosis, prenatal diagnosis or testing of infants after birth. The

potential to reduce risk of losing a child or young adult makes prenatal testing compelling to some families. For other parents, prenatal diagnosis will not change the fate of the pregnancy but can be beneficial in term of very early initiation of surveillance protocol. Furthermore, the option of preimplantation genetic diagnosis (PGD) is also a possible with the use of in vitro fertilization (IVF) techniques, and should be discussed when feasible.

The psychological burden of the identification of a cancer predisposition syndrome has to be taken into consideration. While some individuals who are de novo carriers do not have personal of familial experience of cancer, others are very familiar with malignancies and their outcomes. The perceptions are hence different. While some individuals will prefer to disregard such diagnosis, other advocate for a more active route. Although surveillance confers physical, psychosocial, and financial challenges, and sometimes increased anxiety, many individuals believe in the value of this approach. In fact, some of the patients going through surveillance report enhanced sense of control, security, and empowerment facing this very poor prognostic syndrome.

Concluding Remarks

Decades after its first description, and years after the identification of its cause, our knowledge of Li–Fraumeni syndrome has expanded dramatically. However, the prognosis for individuals with LFS is still grim. Comprehensive data of the molecular causes, clinical manifestations and better understanding of genotype: phenotype interactions will allow for better prediction of disease. Improving surveillance, which in turn will allow for earlier detection of tumor will greatly influence the longevity and quality of life of the patient. Most importantly, discovering ways to make p53 a drugable target will make the most substantial contribution. Not only will we be able to treat premalignant lesions in the setting of germline mutations, the impact on all cancers, sporadic and predisposed, will be enormous.

Lipid Metabolism

Fatima Ameer, Rimsha Munir, and Nousheen Zaidi, University of the Punjab, Lahore, Pakistan

Introduction

This is widely recognized that tumors display an increased ability to synthesize lipids, and that this lipogenesis is tightly coupled to glucose metabolism. The endogenously synthesized lipids fuel membrane biogenesis in rapidly proliferating cancer cells. Lipids may also play substantial role in cell signaling, operating as second messengers and hormones. Changes in lipid metabolism may also affect cell growth, proliferation, differentiation, and motility. Major lipid synthesis pathways include *de novo* fatty acid synthesis pathway and mevalonate pathway; that leads to the synthesis of cholesterol and isoprenoids. The significance of these pathways in tumorigenesis is widely reported.

De Novo Fatty Acid Synthesis Pathway

De novo fatty acid synthesis or *de novo* lipogenesis is a coordinated series of enzymatic reactions that moderates the flow of carbons from different sources to fatty acids (Fig. 1). The first step of *de novo* lipogenesis is the conversion of cytoplasmic citrate to acetyl-CoA by ATP-citrate lyase (ACLY). The resulting acetyl-CoA is carboxylated to malonyl-CoA by acetyl-CoA carboxylase (ACACA). Acetyl-CoA and malonyl-CoA are then coupled to the acyl-carrier protein domain of the rate-limiting enzyme fatty acid synthase (FASN).

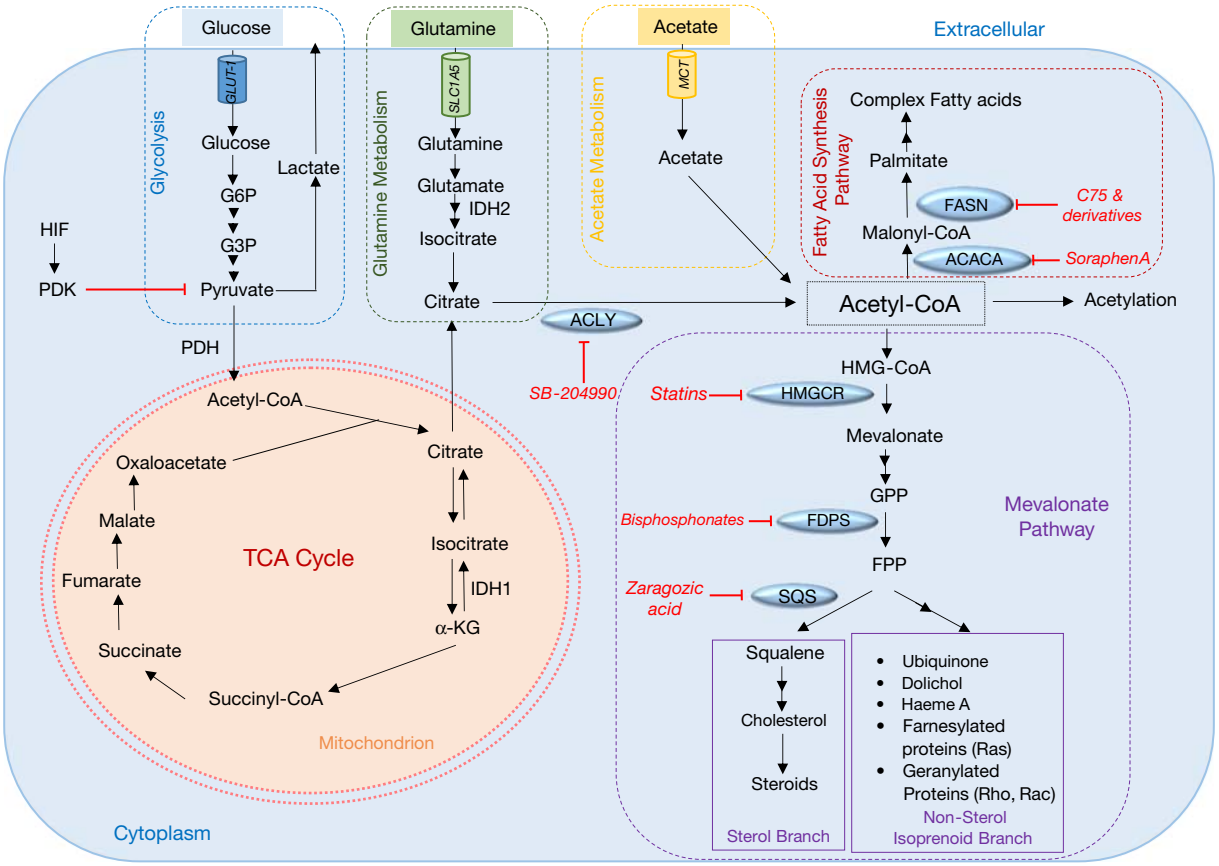

Fig. 1 Overview of cellular lipid metabolism. *De novo* lipogenesis and mevalonate pathway are fueled by acetyl-CoA derived from glucose, glutamine and/or acetate. Intermediates of these pathways yield diverse biosynthetic precursors for macromolecule production necessary for cell proliferation and survival. Key metabolic enzymes known to be upregulated during cancer are represented in blue. Some of the common pharmacological inhibitors of these pathways are indicated in *red*. Many reactions and their ability to be reversed are omitted for simplicity. Abbreviations used: *α-KG*, α-ketoglutarate; *G3P*, glyceraldehyde-3-phosphate; *G6P*, glucose-6-phosphate; *HIF*, hypoxia-inducible factor; *MCT*, monocarboxylate transporter; *IDH*, isocitrate dehydrogenase; *ACACA*, acetyl-CoA carboxylase; *ACLY*, ATP-citrate lyase; *FASN*, fatty acid synthase; *HMGCR*, 3-hydroxy-3-methylglutaryl (HMG)-coenzyme A (CoA) reductase; *FDPS*, farnesyl disphosphate synthase; *FPP*, farnesyl pyrophosphate; *GLUT*, glucose transporter; *PDH*, pyruvate dehydrogenase; *PDK*, pyruvate dehydrogenase kinase; *SLC1A5*, solute carrier family 1 member 5; *TCA*, tricarboxylic acid.

Repeated condensations of acetyl groups generate palmitic acid (16:0)—a basic 16'carbon saturated fatty acid. Palmitic acid is further elongated and desaturated to generate complex fatty acids (e.g., stearate).

Cancer cells are shown to display up-regulated *de novo* lipogenesis, whereas most nonmalignant counterparts preferentially acquire fatty acids from exogenous sources. Certain types of nonmalignant cells/tissues—including adipocytes, hepatocytes, hormone-sensitive cells and fetal lung tissue—also display active *de novo* lipogenesis. However, in general *de novo* lipogenesis is suppressed in most nonmalignant cells.

Several lines of evidence suggest that activation of the *de novo* fatty acid synthesis pathway is required for carcinogenesis. Chemical or RNA interference-mediated inhibition of the key enzymes involved in fatty acid synthesis, including FASN, ACACA and ACLY, has been shown to attenuate cancer cell growth and to induce cancer cell death. Moreover, enhanced expression of FASN is correlated with poor prognosis in cancer patients.

The mammalian cells have a limited ability to synthesize polyunsaturated fatty acids *de novo*, because they lack the Δ12 desaturase—an enzyme which introduces a second *cis* double bond into monounsaturated fatty acids. Therefore, enhanced *de novo* lipogenesis enriches the cancer cell membranes with saturated and/or mono-unsaturated fatty acids. As these fatty acids are less prone to lipid peroxidation than polyunsaturated acyl chains, *de novo* fatty acid synthesis is suggested to make cancer cells more resistant to oxidative stress-induced cell death. Moreover, as saturated lipids pack more densely, the increased lipogenesis also alters lateral and transverse membrane dynamics that may limit the uptake of drugs, rendering the cancer cells more resistant to therapy. The altered saturation index of cancer cell membrane also affects fundamental cellular processes including signal transduction, gene expression and ciliogenesis. Furthermore, *de novo* fatty acid synthesis may also regulate the formation and composition of membrane structures that orchestrate signal transduction and motility (e.g., lipid rafts, invadopodia, and blebs). Lipogenesis can also control biosynthesis of lipid signaling effectors implicated in cancer genesis and progression, including phosphatidylinositols, lysophosphatidic acid, and prostanoids.

In nonmalignant cells fatty acids are also used to supply energy via a highly regulated process-lipolysis. Three lipases—adipose triglyceride lipase (ATGL), hormone sensitive lipase (HSL) and monoacylglycerol lipase (MAGL)—act in a stepwise series of reactions in order to generate diacyl glycerol (DAG), monoacylglycerol (MAG), and glycerol respectively, with subsequent release of three fatty acids. Free cytoplasmic fatty acids are then activated, by coupling to coenzyme A followed by exchange of acyl chain to carnitine via carnitine acyltransferase, to be transported into the mitochondrial matrix. Repeated rounds of this process (known as β-oxidation) guarantees the balance between lipogenesis and lipid digestion in nonmalignant cells. Certain types of tumors, including prostate tumors, display increased dependence on β-oxidation of fatty acids as their main source of energy. Human leukemia cells are also shown to require β-oxidation for their proliferation and survival.

Mevalonate Synthesis Pathway

The mevalonate pathway leads to the synthesis of sterols and isoprenoids that are shown to be crucial for tumor-growth. Multiple enzymes of this pathway are recognized to be essential for proliferation and survival of various types of cancer cells. The first committed step of the mevalonate pathway is conversion of 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) to mevalonic acid (mevalonate) by HMG-CoA reductase (HMGCR) (**Fig. 1**). In the next step of the pathway mevalonate is metabolized to isopentenyl pyrophosphate (IPP) and dimethylallyl pyrophosphate (DMAPP). Farnesyl pyrophosphate synthase catalyzes sequential condensation reactions of DMAPP with two units of IPP to form farnesyl pyrophosphate (FPP) and geranylgeranyl pyrophosphate synthase catalyzes yet another condensation reaction to form geranylgeranyl pyrophosphate (GGPP). FPP is the branch point for several pathways leading to various end-products including cholesterol, steroid and dolichols. Additionally, FPP can also be converted into geranylgeranyl pyrophosphate (GGPP) by GGPP synthase. Squalene synthase catalyzes the first reaction of the pathway committed exclusively to cholesterol biosynthesis and plays a crucial role in directing intermediates to either sterol or non-sterol branches of this metabolic pathway.

The oncogenic potential of the mevalonate pathway has also been investigated. Mevalonate pathway is shown to induce proliferation in primary leukemia cells. HMGCR is also suggested to be a candidate metabolic oncogene. It was shown that ectopic expression of HMGCR accentuates growth of transformed and non-transformed cells and cooperates with RAS to drive the transformation of primary mouse embryonic fibroblasts cells. Moreover, direct administration of mevalonate via miniosmotic pumps into mice harboring breast cancer cell line xenografts resulted in increased tumor-growth. Higher expression of different genes of the mevalonate pathway has also been correlated with poor prognosis in breast cancer patients.

As mentioned above the mevalonate pathway generates various metabolites that are implicated in carcinogenesis. For instance, cholesterol is shown to be involved in cancer cell proliferation and protection of cancer cells against immune surveillance as well as various therapeutic agents. In addition to that cholesterol serves as the precursor for synthesis of steroid hormones and oxysterols that are suggested to play various roles in cancer progression.

Farnesyl-diphosphate and geranylgeranyl-diphosphate are respectively involved in farnesylation and geranylgeranylation of a variety of proteins. Farnesylation and geranylgeranylation are required for the ability of Ras and Rho proteins to induce malignant transformation, invasion, and metastasis. Dolichol is an essential component of the N-glycosylation of nascent polypeptide. Protein N-glycosylation is often altered in cancer and may contribute in tumor formation progression. On the other hand, complex branching of N-glycans also leads to tumor-suppressive properties in some cancers. Coenzyme Q is crucial for ATP production in cancer cells that rely on oxidative phosphorylation to produce energy.

Therapeutic Targeting

Studies on significance of *de novo* lipid synthesis pathways in cancer progression suggest that the enzymes involved in these pathways would be rational therapeutic targets for cancer treatment. Multiple studies on therapeutic targeting of *de novo* fatty acid synthesis pathways mainly focused on pharmacological inhibition of FASN (Fig. 1). The effects of FASN-inhibitors have been examined in diverse preclinical tumor models. These inhibitors are effective in chemoprevention of breast cancer in HER2/neu transgenic mice. They also reduce incidence of chemically induced lung tumorigenesis. Several studies have shown that inhibition of other key enzymes involved in fatty acid synthesis pathway—including ACACA and SCD—limit the growth and proliferation of cancer cells. Silencing of ACLY has also been reported to prevent cancer cell growth both in vivo and in vitro.

The significance of inhibitors of the mevalonate pathway as antitumor agents has also been investigated. Statins—potent competitive inhibitors of HMGCR—have been shown to induce growth arrest and apoptosis in cancer cells both in vitro and in vivo. Moreover, bisphosphonates—inhibitors of FPP synthase—are also approved for the treatment of multiple myeloma breast and prostate cancer. Zaragozic acid A—inhibitor of squalene synthase—attenuates proliferation and induces death of prostate cancer cells. Table 1 provides a list of pharmacological inhibitors of *de novo* lipid synthesis in clinical or preclinical trials.

Lynch Syndrome

Päivi Peltomäki, University of Helsinki, Helsinki, Finland

Glossary

Epigenetic change Heritable alteration in the function (expression) of a gene without a change in DNA sequence. Epigenetic mechanisms include DNA methylation, histone modification, and noncoding RNA (e.g., micro-RNA)-based gene regulation.

Gene penetrance The proportion of individuals with a particular variant (genotype) that express an associated trait (phenotype).

Haploinsufficiency Half of the normal level of the protein product of a gene (as a result of a heterozygous mutation, for example) is insufficient for normal function.

Loss of heterozygosity (LOH) The absence of one of the two parental alleles in tumor tissue from an individual who is constitutionally heterozygous for the marker used to measure LOH. LOH can expose a mutant tumor suppressor gene in the remaining allele.

Microsatellite instability (MSI) The number of repeat units of a microsatellite repeat is different in tumor DNA compared to normal DNA from the same individual, resulting in a difference in the microsatellite length between normal and tumor tissue. During replication, DNA polymerase may slip from the DNA strand at the repeat region, causing deletion or addition of repeat units, and the errors remain if postreplicative mismatch repair is defective.

Abbreviations

CIMP CpG island methylator phenotype
CMMRD Constitutional mismatch repair deficiency
EMAST Elevated microsatellite alterations at selected tetranucleotide repeats
FCCTX Familial colorectal cancer, type X
LLS Lynch-like syndrome
LS Lynch syndrome
MMR DNA mismatch repair
MSI Microsatellite instability
MSI-H High-degree MSI
MTS Muir–Torre syndrome
TCGA The Cancer Genome Atlas
TS Turcot syndrome

Lynch Syndrome: Definitions and Phenotypes

Lynch syndrome (LS) is an autosomal dominant disorder caused by a defect in one of the DNA mismatch repair (MMR) genes. The syndrome is characterized by the development of colorectal carcinoma, endometrial carcinoma, and other cancers. Three main sets of clinical criteria have been formulated to select families suspected of having LS for molecular and other studies (Table 1). These include the stringent Amsterdam criteria I and II and the less stringent Bethesda criteria.

Absent MMR protein(s) and DNA microsatellite instability (MSI) serve as tumor markers for LS. These are not, however, specific for LS since similar abnormalities occur in 15% of sporadic cancers as well. A panel of five microsatellite markers, the so-called Bethesda panel (BAT25, BAT26, D2S123, D5S346, and D17S250) has been recommended for screening purposes. Instability at two or more microsatellite loci indicates high-degree MSI (MSI-H) (see section "MMR Gene Dysfunction and MSI").

Table 2 summarizes the clinical and genetic features of LS and its variants. The identification of a pathogenic germline mutation in one of the DNA MMR genes *MLH1* (MutL Homolog 1), *MSH2* (MutS Homolog 2), *MSH6* (MutS Homolog 6), or *PMS2* (post-meiotic segregation increased 2 (*S. cerevisiae*)) is required for LS diagnosis. The genetic definition of LS covers the Muir–Torre syndrome, where sebaceous gland tumors co-occur with LS-type internal malignancy. Rare individuals who inherit defective alleles from both parents in a recessive manner resulting in homozygosity or compound heterozygosity for predisposing mutation have constitutional mismatch repair deficiency (CMMRD). Clinical presentation is severe and includes childhood cancers such as hematological malignancies and brain tumors, and early-onset colorectal cancer. Germline mutations in MMR genes may also be responsible for Turcot syndrome (TS), in which primary brain tumors, usually glioblastomas, are accompanied by multiple colorectal

Table 1 The Amsterdam I and II and revised Bethesda criteria for the clinical diagnosis of LS

Amsterdam criteria I
There should be at least three relatives with colorectal cancer (CRC); all the following criteria should be present:
(1) One should be a first-degree relative of the other two
(2) At least two successive generations should be affected
(3) At least one CRC should be diagnosed before age 50
(4) Familial adenomatous polyposis should be excluded
(5) Tumors should be verified by pathological examination
Amsterdam criteria II
There should be at least three relatives with a Lynch syndrome-associated cancer (colorectal cancer (CRC), cancer of the endometrium, small bowel, ureter, or renal pelvis): all of the following criteria should be present:
(1) One should be a first-degree relative of the other two
(2) At least two successive generations should be affected
(3) At least one should be diagnosed before age 50
(4) Familial adenomatous polyposis should be excluded in the CRC case (s) if any
(5) Tumors should be verified by pathological examination
Revised Bethesda criteria
The criteria can be used to select individuals for MSI analysis. Individuals that meet one of these criteria are suspected of having Lynch syndrome.
(1) Colorectal cancer diagnosed in a patient $<$50 years of age
(2) Presence of synchronous, metachronous colorectal, or other Lynch syndrome-related tumors[a], regardless of age
(3) Colorectal cancer with MSI-H phenotype diagnosed in a patient $<$60 years of age
(4) Patient with colorectal cancer and a first-degree relative with a Lynch syndrome-related tumor, with one of the cancers diagnosed under age 50 years
(5) Patient with colorectal cancer with two or more first-degree or second-degree relatives with a Lynch syndrome-related tumor, regardless of age

[a]Lynch syndrome-related tumors include colorectal, endometrial, stomach, ovarian, pancreas, ureter, renal pelvis, biliary tract, and brain tumors, sebaceous gland adenomas, keratoacanthomas, and carcinoma of the small bowel.

Table 2 Lynch syndrome and related phenotypes

Syndrome	*MIM no.*[a]	*Predisposing genes and their relative shares of all mutations*[b]	*Mode of inheritance*	*Clinical features*
Lynch syndrome (LS)	120436 120435	*MLH1* (40%) *MSH2* (34%) *MSH6* (18%) *PMS2* (8%)	AD	Colonic and extracolonic cancers of a defined spectrum (Amsterdam criteria II), occurring earlier than in the average population (at ~40–60 years of age)
Muir–Torre syndrome (MTS)	158320	*MSH2* > *MLH1* > *MSH6*	AD	Multiple sebaceous gland adenomas co-occurring with visceral malignancies, such as colorectal carcinoma
Constitutional mismatch repair deficiency (CMMRD)	276300	*PMS2* > *MSH6* > *MSH2, MLH1*	AR	Childhood cancers, mainly hematological malignancies and/or brain tumors, combined with early-onset colorectal cancers
Turcot syndrome (TS)	276300	See CMMRD	AR (AD)[c]	Primary brain tumors co-occurring with multiple colorectal adenomas

AD, autosomal dominant; *AR*, autosomal recessive.
[a]Mendelian Inheritance in Man (www.omim.org/).
[b]The designation *A* > *B* indicates that mutations in gene *A* are more frequent than in gene *B*.
[c]TS arising as a variant of CMMRD shows recessive transmission. TS may also be associated with germline mutation of the Adenomatous Polyposis Coli (*APC*) gene (MIM no. 175100), in which case it is dominantly inherited.

adenomas. TS is a variant of LS if associated with a heterozygous MMR gene mutation, CMMRD if associated with a homozygous or compound heterozygous MMR gene mutation, and familial adenomatous polyposis if associated with a heterozygous mutation of the gene for adenomatous polyposis coli (*APC*).

LS is among the most prevalent hereditary cancer syndromes in man. It accounts for 1%–3% of unselected colorectal or endometrial carcinomas and some 15% of those with MSI or absent MMR protein. The population incidence of LS is around 1:400.

LS Genes and Their Functions

Postreplicative DNA Mismatch Repair

LS genes are conserved in evolution (Table 3). The postreplicative MMR system in *E. coli* includes three main proteins: MutS (recognizes the mismatch), MutH (marks the nascent strand by making a nick), and MutL (couples mismatch recognition to the

Table 3 Lynch syndrome genes in evolution and phenotypes resulting from germline mutations

E. coli	S. cerevisiae	H. sapiens	*Phenotype resulting from germline mutation*
MutS	Msh2	*MSH2*	LS, MTS, CMMRD[a]
	Msh6	*MSH6*	LS, CMMRD[a]
	Msh3	*MSH3*	Attenuated adenomatous polyposis/CMMRD[a]
	Msh1	Not identified	N/A
	Msh4	*MSH4*	No Lynch syndrome-associated mutations known
	Msh5	*MSH5*	No Lynch syndrome-associated mutations known
MutL	Mlh1	*MLH1*	LS, MTS, CMMRD[a]
	Pms1	*PMS2*	LS with reduced penetrance, TS/CMMRD[a]
	Mlh2	*PMS1*	No Lynch syndrome-associated mutations known
	Mlh3	*MLH3*	LS?
MutH	Not identified	Not identified	N/A

LS, Lynch syndrome; *MTS*, Muir–Torre syndrome; *CMMRD*, constitutional mismatch repair deficiency; *TS*, Turcot syndrome; *N/A*, not applicable.
[a]Biallelic germline mutations.

downstream events). MMR acts on the newly synthesized strand; therefore, a mechanism of strand discrimination is necessary. In *E. coli*, a methyl group on the template strand directs MutH to make a nick on the opposite strand. Thus, hemimethylated DNA is corrected on the unmethylated strand and the methylated strand serves as a template.

Multiple homologues of MutS and MutL exist in eukaryotes. In humans, five MutS homologues (MSH2, MSH6, MSH3, MSH4, and MSH5) and four MutL homologues (MLH1, PMS2, PMS1, and MLH3) have been identified and at least six of them play a direct role in MMR (**Table 3**, **Fig. 1**). MSH4 and MSH5 are necessary for meiotic (and possibly mitotic) recombination but do not participate in MMR. The role of human PMS1 in MMR is unclear (see later).

The MMR proteins form heterodimers in different combinations and have different substrate specificities (**Table 4**). The main mismatch-binding factor is hMutSα, consisting of MSH2 and MSH6, which recognizes single-base mispairs and insertion–deletion loops (IDLs). Another mismatch-binding heterodimer is hMutSβ, formed by MSH2 and MSH3, acting mainly on IDLs. According to

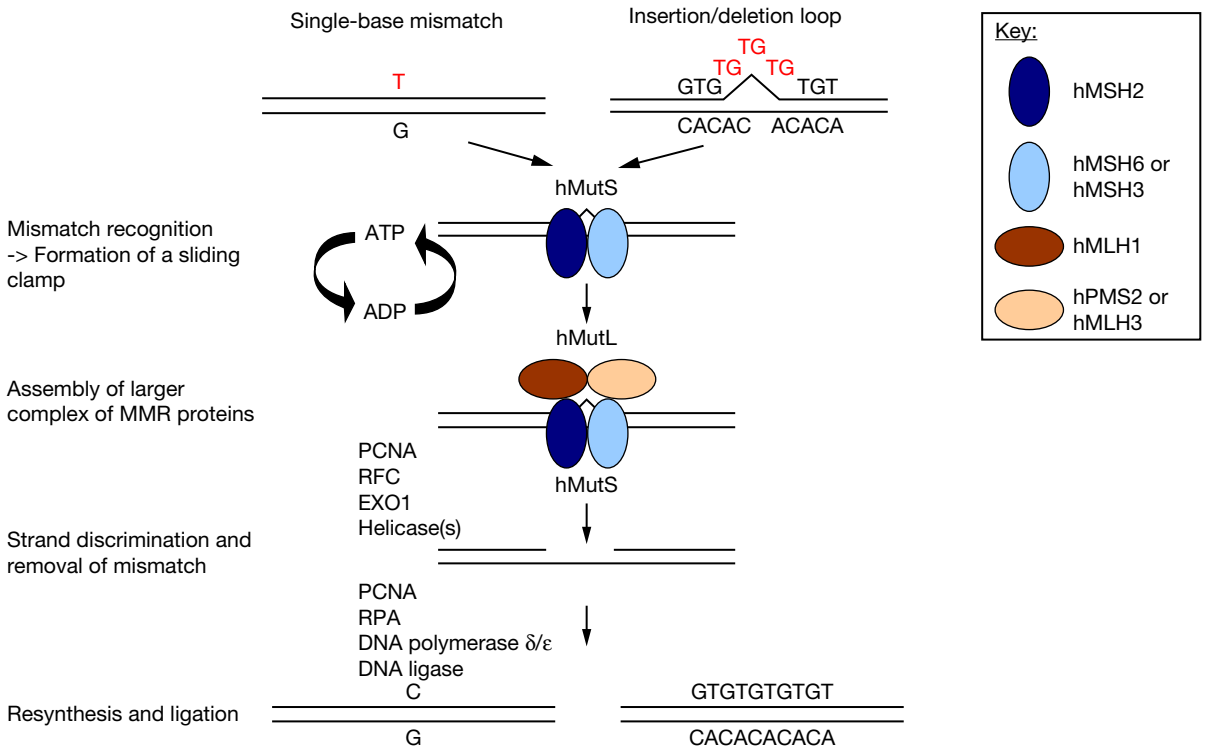

Fig. 1 DNA mismatch repair. The main biochemical steps necessary for the correction of replication errors, single-base mismatches, and insertion/deletion loops in the newly synthesized strand (*red*), are shown. *PCNA*, proliferating cell nuclear antigen; *RFC*, replication factor C; *EXO1*, exonuclease 1; *RPA*, replication protein A.

Table 4 Complexes of human MMR proteins and their substrate specificities

Heterodimer	*Components*	*Type of mismatches repaired*	*Predominant type of MSI (defective gene)*
hMutSα	MSH2 + MSH6	Single-base mismatches, ins/del loops	MSI-H (*MSH2* or *MSH6*)
hMutSβ	MSH2 + MSH3	Ins/del loops	MSI-L/EMAST (*MSH3*)
hMutLα	MLH1 + PMS2	Single-base mismatches, ins/del loops	MSI-H (*MLH1* or *PMS2*)
hMutLβ	MLH1 + PMS1	?	?
hMutLγ	MLH1 + MLH3	Single-base mismatches, small loops	MSI-L/EMAST or MSI-H (*MLH3*)

the "molecular switch" or "sliding clamp" model, the hMutS heterodimer binds to mismatched DNA in an ADP-bound form. Mismatch binding induces an ADP to ATP exchange that allows the hMutS complex to convert to a sliding clamp. The purpose of the sliding clamp that diffuses away from the mismatch is thought to be to empty the mismatch site for the loading of additional hMutS clamps and to recruit the hMutL heterodimer and the necessary downstream factors to the site of repair. The hMutL heterodimer coordinates the interplay between the mismatch recognition complex and other proteins necessary for MMR. The main hMutL complex is hMutLα, consisting of MLH1 and PMS2 and responsible for single-base mismatch and IDL repair. Alternative hMutL heterodimers are hMutLγ (MLH1 and MLH3), which may predominantly contribute to IDL repair, and hMutLβ (MLH1 and PMS1), which does not appear to participate in MMR.

When one of the component proteins (e.g., MSH2) is absent, its pair in the heterodimer (MSH6 in hMutSα) becomes unstable as well, whereas the expression of components belonging to other heterodimers (MLH1 and PMS2) is unaffected. Defined patterns of absent MMR proteins in immunohistochemical evaluations of tumor tissues can help prioritize individual MMR gene(s) for germline mutation screens in suspected LS.

No MutH homolog has been identified in yeast or mammalian cells, and two main alternative mechanisms for strand discrimination have been proposed. First, nicks that separate Okazaki fragments on the lagging strand may mark the nascent strand during replication. Second, MutLα has a proliferating cell nuclear antigen-dependent endonuclease activity that allows strand-specific cleavage.

The predominant role of *MLH1* and *MSH2* as LS predisposition genes (**Table 2**) is easy to understand given that their protein products are obligatory components in all types of heterodimers (**Table 4**), followed by *MSH6* and *PMS2*. *MLH3* mutations are rare (the protein is functionally redundant with PMS2). No LS-predisposing heterozygous germline mutations are known for *MSH3* (functionally redundant with *MSH6*); however, biallelic (homozygous) mutations may cause susceptibility to attenuated adenomatous polyposis. No convincing LS-associated germline mutations are known for *PMS1*, *MSH4*, or *MSH5*.

MMR Gene Dysfunction and MSI

Substrate specificities of the individual MMR proteins are reflected in different MSI phenotypes in tumors (**Table 4**). MSI-H is detected with the Bethesda panel of two mononucleotide repeats (BAT25 and BAT26) and three dinucleotide repeats (D2S123, D5S346, and D17S250); at least two unstable markers indicate MSI-H. (If only one marker or none is unstable, a tumor is said to have low-degree MSI (MSI-L) or be microsatellite-stable (MSS), respectively.) It has been suggested that the mononucleotide repeat markers BAT25 or BAT26 alone are sensitive and specific indicators of MSI-H. *MSH2* and *MLH1* mutations are associated with MSI-H involving mononucleotide and dinucleotide (and other short tandem) repeats. The same is true for *PMS2* mutations. In the case of *MSH6* mutations mononucleotide repeats are predominantly affected. In tumors from *MLH3* mutation carriers, mononucleotide repeats may be less informative than dinucleotide and tetranucleotide repeats and MSI phenotypes may range from MSI-high to the absence of MSI.

Loss of *MSH3* function may underlie a distinct form of MSI called EMAST (elevated microsatellite alterations at selected tetranucleotide repeats). EMAST and MSI-L are likely to be the same. EMAST can be frequent as an acquired defect in colorectal cancers or result from rare biallelic germline mutations in *MSH3* associated with polyposis predisposition. While no consensus definition for EMAST exists to date, a commonly used definition is 1–2 tetranucleotide repeat markers mutated out of 5 or more markers examined.

Other Functions of MMR Genes

Genomic instability is an "enabling characteristic" that, by generating genetic diversity, expedites the acquisition of the fundamental hallmarks of cancer that are prerequisites for tumor growth and metastasis. Apart from the correction of replication errors, MMR proteins have replication-independent (so-called noncanonical) functions whose failure may play important roles in conferring selective advantage on subclones of mutant cells. MMR proteins recognize diverse types of endogenous and exogenous damage, such as heterocyclic amine (e.g., PhIP) DNA adducts and damage induced by oxidation or alkylation. If possible, the lesions are corrected; otherwise, MMR proteins signal DNA damage to cell cycle arrest or apoptosis. In these processes, MMR proteins interact with other players of the DNA damage response pathway, including ATM and ATR, protein kinases involved in apoptosis and cell cycle regulation.

Recombination between DNA sequences that are related but nonidentical (homeologous) generates mismatches that act as substrates for the MMR pathway. MMR proteins correct mismatches occurring in recombination and suppress recombination between homeologous sequences. If recombination-related mismatches are not corrected, gene conversion is reduced in mitotic cells and "postmeiotic segregation" (PMS) is increased in meiotic cells (*S. cerevisiae*).

The MMR system can also promote mutations when appropriate. For example, MSH4 and MSH5 facilitate meiotic crossover between homologous chromosomes. MMR proteins also promote somatic hypermutation and class switch of antibody genes.

LS Genes and Knudson's Two-Hit Hypothesis

Generally, both gene copies of a given MMR gene need to be inactivated for a phenotype in agreement with Knudson's two-hit hypothesis for tumor suppressor genes. As a consequence, protein expression of the affected MMR gene is absent in tumor tissue and microsatellite repeats become unstable (Fig. 2, upper panel). The frequencies of immunohistochemical aberrations and especially MSI display some organ-specific variation (Fig. 2, lower panel), which is discussed in greater detail in the section "**LS Tumor Spectrum and Its Molecular Basis**."

In LS, the first hit inactivating one allele of the responsible MMR gene is inherited, whereas the second hit inactivating the remaining wild-type allele occurs in, and is restricted to, the somatic cancer progenitor cell in a target tissue. Either one of the two hits, or both of them, may be genetic or epigenetic. Both hits are usually genetic in LS-associated cancer and consist of a point mutation or a large rearrangement for the first hit and loss of the wild-type allele (loss of heterozygosity, LOH), gene conversion, or point mutation for the second hit (Fig. 3). Occasionally, promoter methylation of a MMR gene (*MLH1* or *MSH2*) provides the first hit (see section "**Constitutional Epimutations Predisposing to LS**"). Promoter methylation can also provide the second hit, although this is relatively rare.

In sporadic tumors with MSI, two inactivating hits, one in each allele of a MMR gene, occur somatically prior to tumor initiation. In the most common situation, the two hits are epigenetic and consist of biallelic methylation of *MLH1*. In approximately half of MMR-deficient tumors without germline mutations or promoter methylation, two somatic mutations of a MMR gene, or a somatic mutation and LOH, explain the MMR deficiency (Lynch-like syndrome (LLS), see section "**Differential Diagnosis of LS**").

Although MMR genes are typically recessive on cellular level, a single allele is sometimes sufficient to initiate tumorigenesis (haploinsufficiency). MMR gene dosage makes a clear difference regarding phenotypic consequences. Heterozygosity versus homozygosity for the predisposing mutation causes drastically different constitutional phenotypes (LS vs. CMMRD, Table 2). In somatic target tissues, the amount of available MMR protein may regulate tumorigenesis in a function-specific manner. For example, it has been shown that DNA damage signaling requires higher dosage of the MLH1 protein than DNA MMR. Furthermore, MLH1 haploinsufficiency in sporadic cancers and cell lines (such as pancreatic and renal cell cancers) prone to *MLH1*-LOH has been reported to cause a distinctive form of genomic instability involving increased rates of insertion/deletion mutations without

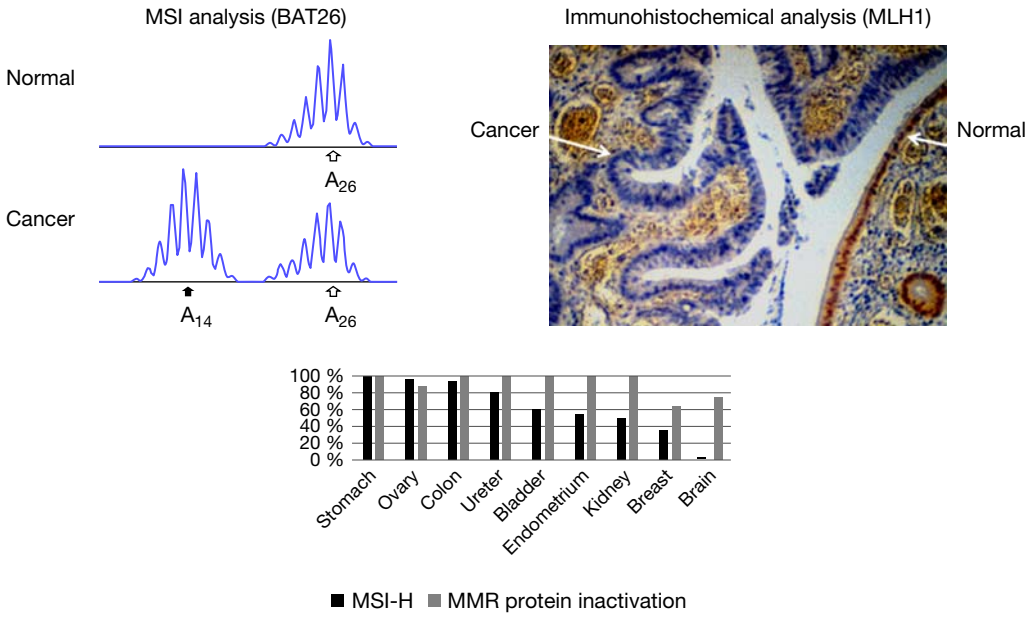

Fig. 2 Microsatellite instability and absent MMR protein as hallmarks of LS tumors. *Top left*: BAT26 includes a stretch of 26 consecutive adenine nucleotides (A_{26}); shortened alleles (A_{14} in this example) indicate MSI. *Top right*: Staining with an MLH1 antibody reveals absent MLH1 expression (*blue color*) in colorectal carcinoma cells from an *MLH1* mutation carrier, whereas MLH1 is normally expressed (*brown color*) in the patient's non-neoplastic mucosa. *Bottom*: The frequencies of LS tumors with MSI and MMR protein inactivation show organ-specific variation.

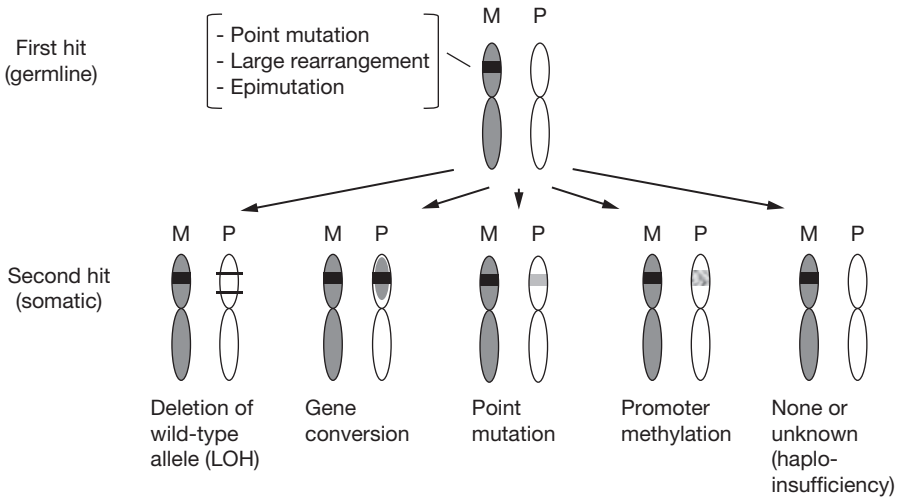

Fig. 3 Mechanisms of two-hit inactivation of MMR genes in LS (see text). M refers to the maternal and P to the paternal allele (the maternal allele was randomly chosen as the target of the first hit).

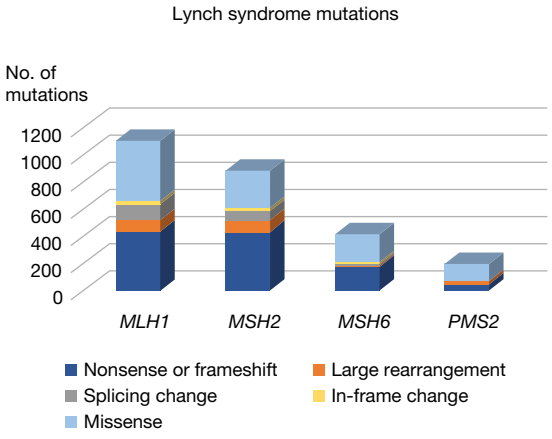
conventional MSI. The truncating insertion/deletion mutations can inactivate tumor suppressor genes and thereby drive sporadic tumor development.

Germline Mutations Predisposing to LS

The International Society for Gastrointestinal Hereditary Tumors (InSiGHT) has collected information of LS-associated MMR gene mutations in a public database established in 1994. *MLH1*, *MSH2*, *MSH6*, and *PMS2* account for 40%, 34%, 18%, and 8%, respectively, of the over 3000 unique germline sequence variants of MMR genes deposited to the database to date (Fig. 4, left, and www.insight-group.org). Mutations are scattered throughout the genes. Most *MLH1* and *MSH2* mutations and an important proportion of *MSH6* mutations are truncating nonsense or frameshift mutations. Missense changes, which lead to single amino acid substitutions without altering the reading frame, also account for a significant share (30%–60%) of the known mutations in all four genes.

It was precisely the abundance of missense-type changes that prompted a recent large-scale effort by InSiGHT to classify each MMR gene variant according to pathogenicity (Fig. 4, right). The classification is based on variant, family, and tumor characteristics



Classification for pathogenicity

InSiGHT class	Examples of variants	Predictive testing	Surveillance of variant carriers
5 (Pathogenic)	Nonsense, frameshift, large rearrangements, missense with proven pathogenicity	Yes	Full high-risk guidelines
4 (Likely pathogenic)	Splicing aberrations (untested)	Yes	Full high-risk guidelines
3 (Uncertain)	Missense, small in-frame changes	No	Tailored for each family
2 (Likely non pathogenic)	Intronic and synonymous variants	No	Treat as no mutation detected
1 (Non pathogenic)	Polymorphisms	No	Treat as no mutation detected

Fig. 4 Mutations predisposing to LS and translation of mutation information to clinical recommendations. *Left*: Based on information deposited in the InSiGHT database, the number of unique mutations discovered for each main LS susceptibility gene is shown, along with a breakdown into five mutation types within each gene. *Right*: An individual variant can be assigned a pathogenicity class from 1 (non-pathogenic) to 5 (pathogenic) on the basis of evaluation criteria formulated by the InSiGHT. Typical examples of changes representing each category are given. Possibilities for clinical use in predictive testing of at-risk relatives or regular surveillance of variant carriers vary according to the class of pathogenicity.

on the one hand and a variety of functional assays on the other hand. It is linked to clinical recommendations as follows. Classes 5 and 4 indicate a "pathogenic" and "likely pathogenic" variant, respectively, implying that a causative mutation was detected. Surveillance according to full high-risk guidelines is warranted and predictive testing of at-risk relatives should be made available. Nonsense and frameshift mutations constitute a majority of class 5 and 4 variants. Class 3 comprises variants of unknown significance (VUS), predominantly missense changes. Clinical management has to be tailored case by case. Classes 2 and 1 indicate a "likely nonpathogenic" and "nonpathogenic" variant, respectively, suggesting that no causative mutation was found. Carriers of class 2 and 1 variants should be clinically treated as "no mutation detected." Intronic variants and synonymous (silent) variants with no associated RNA aberration are typical representatives of category 2 and variants with frequency $\geq 1\%$ in the general population (polymorphisms) of category 1.

Most MMR gene mutations are inherited from either parent and de novo mutations are rare. A majority of MMR gene mutations are unique (specific to a single family). Nevertheless, some prevalent recurrent mutations are known and may arise de novo or represent founder mutations. Founder mutations originate from a single ancestor, revealed in present-day carriers by shared haplotypes of various sizes depending on the age of the mutation. Founder mutations are enriched in isolated populations, such as the Finns, Newfoundland population, or Ashkenazi Jews.

A genetic point mutation is the main type of germline mutation in MMR genes. Analysis of LS cohorts from different geographic locations indicates a frequency of 15% for large genomic rearrangements. Mutations typically abrogate one or several capabilities necessary for a functional MMR system, such as MMR protein expression, transport to the nucleus, heterodimer formation, DNA mismatch binding, and ATP–ADP cycling (Fig. 1). In a small but significant percentage of LS-suspected families with MMR-deficient tumors and negative for point mutations and large rearrangements, the predisposing defect is regulatory and consists of a constitutional epimutation in an MMR gene. The latter mechanism is discussed in more detail in the next section.

Constitutional Epimutations Predisposing to LS

Constitutional epimutation can be defined as constitutional hypermethylation at the promoter of one allele of a given (nonimprinted) gene leading to silencing of expression from that allele in all main somatic tissues. If induced by a genetic alteration (usually located *in cis*), epimutation is secondary and otherwise primary. Primary and secondary epimutations of *MLH1* have been described (Fig. 5A and B). The only known type of constitutional epimutation of *MSH2* is a secondary epimutation caused by deletions of the 3′ end of the *EPCAM* gene (Fig. 5C). After removal of stop codon, transcription of *EPCAM* reads into the

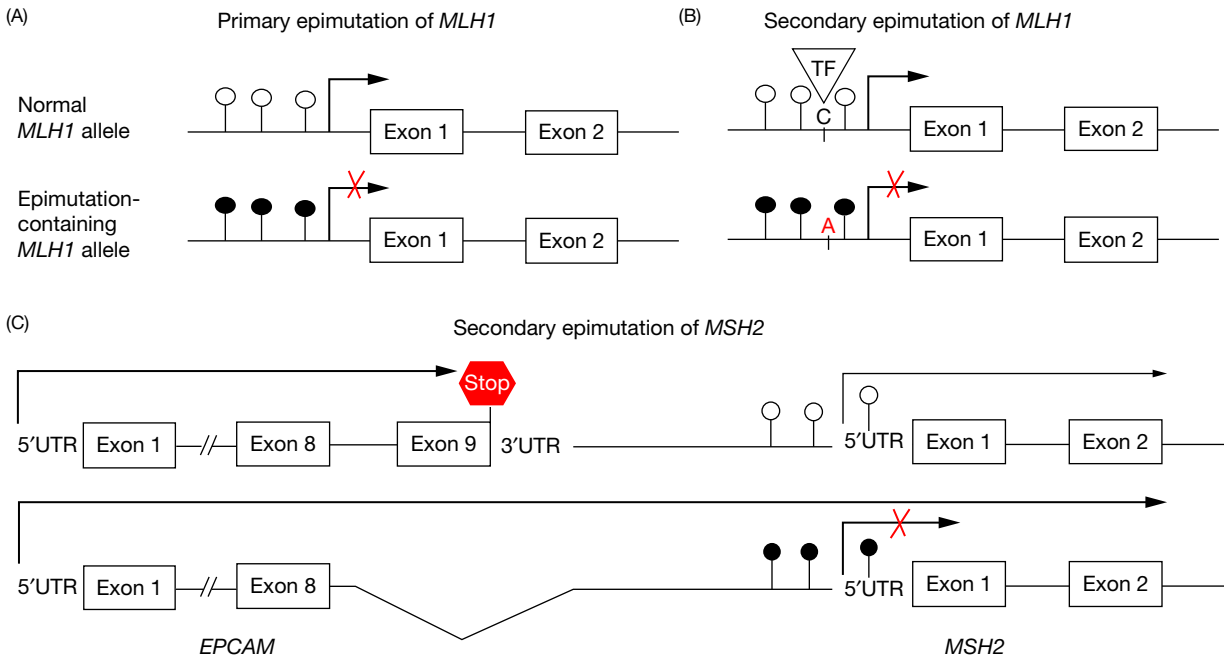


Fig. 5 Mechanisms of constitutional epimutations in MMR genes. In *A* to *C*, the upper allele is normal (open lollipops denote unmethylated CpG sites and an arrow depicts active transcription) whereas the lower allele contains an epimutation (methylated CpG sites and transcriptionally inactive). (A) CpG sites at the promoter of an epimutation-containing *MLH1* allele are methylated (*black lollipops*) blocking transcription from that allele (*crossed arrow*). No apparent reason (e.g., a genetic change) for methylation can be identified, which is why the epimutation is designated primary. (B) A single nucleotide polymorphism (C to A) abolishes transcription factor (TF) binding and leads to secondary methylation at the *MLH1* promoter. (C) Owing to a genomic deletion, the stop codon of the *EPCAM* gene is lost and transcription continues into the adjacent *MSH2* gene, causing secondary methylation of the structurally normal *MSH2* promoter.

adjacent, structurally normal *MSH2* gene inducing promoter methylation of *MSH2*. In tumor tissues of constitutional epimutation carriers, the remaining wild-type allele is inactivated by a genetic or epigenetic mechanism according to Knudson's two-hit hypothesis (Fig. 3).

Carriers of constitutional epimutations of *MLH1* or *MSH2* are clinically indistinguishable from carriers of conventional (structural) MMR gene mutations (Table 5). However, family features and segregation patterns make a distinction. Epigenetic changes are erased on passage through the germline, preventing regular transmission from parent to child. Therefore, primary constitutional epimutations segregate in a non-Mendelian manner and are seldom associated with any remarkable family history of cancer (the revised Bethesda criteria may be fulfilled, Table 1). Examination of the families of primary epimutation carriers has revealed variable patterns of transmission, including apparent heritability, mosaic epigenetic inheritance, and reversion of the methylated allele to normal active state. Importantly, it has been shown that asymptomatic low-level somatic mosaicism for a *MLH1* epimutation in a parent can produce a nonmosaic constitutional epimutation in the offspring, resulting in early-onset colorectal cancer. Such observations make genetic counseling of *MLH1* epimutation carriers and their families quite challenging. In contrast, secondary epimutations of *MLH1* or *MSH2* give rise to classical LS families and regularly cosegregate with their *cis*'acting genetic changes in a dominant Mendelian fashion. Nevertheless, the mechanism of transmission may display distinct features compared to that of a genetic mutation. Secondary epimutation of *MLH1* has been shown to undergo a complete but transient reversion in the germline, being erased in spermatozoa but reinstated in somatic cells of the next generation.

To date, more than 50 index cases with primary or secondary constitutional epimutation of *MLH1* are known. Constitutional epimutations may explain 1%–10% of mutation-negative Lynch-suspected families with silenced MLH1 expression in tumors (Table 5). A comparable number of index cases with *EPCAM* deletion-induced *MSH2* epimutation have been described. Their share of Lynch suspected families without conventional germline mutations and with absent MSH2 protein in tumor tissues ranges between 0% and 40% depending on possible founder effects.

Tumorigenesis in LS

Precursor Lesions

Colorectal tumorigenesis in LS is traditionally considered to follow the adenoma–carcinoma sequence, which forms the rationale of using colonoscopy screening and removal of adenomas as an important means of cancer prevention in MMR gene mutation carriers. In sporadic colorectal tumorigenesis, the complete adenoma–carcinoma sequence can take 15 years or more. The presence of one defective copy of the predisposing MMR gene in every cell of LS individuals may shorten the process to only a few years or less. MMR genes are "caretaker" genes which when mutated, may accelerate tumor progression in particular, while the incidence of polyps is not markedly different from the average population. This is in contrast to "gatekeeper" genes such as *APC* that accelerate tumor initiation and underlie polyposis syndromes. Compatible with the underlying MMR defect, adenomas in LS often show aggressive features such as villosity and poor differentiation (high grade). Additionally, tumor-infiltrating lymphocytes (TILs) are common because of neoantigens resulting from mutant proteins.

Recent evidence suggests that adenomas in LS may not always be easily detectable or may not exist prior to colorectal carcinoma development. For example, a report from a prospective LS database based on 10 centers from Europe and Australia

Table 5 Constitutional epimutations of *MLH1* and *MSH2* in LS predisposition

	MLH1	MSH2
Type of epimutation	Primary or secondary	Secondary
Gene defects associated with secondary epimutation reported in the literature	• Genomic deletion of *MLH1* exons 1–2 • Genomic deletion of *MLH1* exon 1 • Duplication of *MLH1* and flanking regions • c.-27C > A in the *MLH1* promoter	• Deletions of *EPCAM* removing stop codon
Tumor phenotype	MSI Lack of MLH1 (and PMS2) protein	MSI Lack of MSH2 (and MSH6) protein
Clinical phenotype	May present as a sporadic case (primary epimutation) or as a classical Lynch syndrome family (secondary epimutation). Age at onset and tumor spectrum are similar to Lynch syndrome. Atypical phenotypes (e.g., increased number of polyps) are possible	Presents as a classical Lynch syndrome family. Colorectal cancer risk is high. Endometrial cancer risk is increased with deletions extending close to the *MSH2* promoter
Pattern of transmission	Variable, from apparent lack of heritability (primary epimutation) to autosomal dominant (secondary epimutation)	Autosomal dominant
Share of LS[a]	1%–10%	10%–40%

[a]Estimated from Lynch-suspected cases with MMR-deficient tumors and negative screens for conventional germline mutations in MMR genes.

(http://LScarisk.org) shows that colorectal cancer is surprisingly frequent despite colonoscopic surveillance with 1–3-year intervals. Furthermore, a long-term (mean 56 months) follow-up analysis of close to 900 MMR gene mutation carriers enrolled in the Colorectal Adenoma/Carcinoma Prevention Program 2 (CAPP2) surprisingly reveals that aspirin exhibits delayed protection against colorectal cancer without reducing adenoma incidence. These observations imply that colorectal carcinomas in LS may arise from lesions other than adenomas. Such possible alternative lesions remain to be identified and defined histologically and molecularly.

Endometrial cancer, the most common extracolonic cancer in LS, is thought to develop via endometrial hyperplasias as precursor lesions. Accordingly, endometrial cancer prevention in LS is based on screening for endometrial hyperplasias by regular endometrial biopsies. Epidemiological studies suggest that atypical and complex hyperplasias are associated with increased risks of malignant transformation. According to the current knowledge, ovarian carcinomas of endometrioid and clear cell types, the predominant histological types of ovarian carcinoma in LS, also arise from endometrial epithelium, with atypical endometriosis as a recognized precursor. The fact that the abovementioned precursor lesions of endometrial and ovarian carcinoma share many genetic and epigenetic characteristics of the corresponding malignancies, such as MMR defects, tumor suppressor promoter methylation, and mutations in *ARID1A*, *PIK3CA*, or *PTEN* strongly supports their malignant potential.

Somatic Mutations in LS Tumors

Owing to defective MMR, LS tumors belong to the "hypermutated" category defined by The Cancer Genome Atlas (TCGA) for unselected colorectal, endometrial, and other cancers. Whole-exome sequencing of MSI colorectal tumors by the TCGA network has revealed somatic nonsynonymous mutation rates above 12 per 10^6 bases, with a median number of ~700 mutations per tumor. This is 10–100-fold compared to MMR-proficient tumors (median 58 mutations per tumor). The profiles of mutant genes differ in hypermutated and nonhypermutated tumors. For example, frameshift mutations in coding repeats within *ACVR2A*, *TGFBR2*, and other genes are characteristics of MSI tumors. The karyotypes are usually diploid and copy number changes are relatively rare. Molecular features typical of MSI tumors broadly apply to LS tumors as well. Additionally, certain universal signatures of tumor types, such as mutations in the adenoma–carcinoma progression sequence genes *APC*, *KRAS*, and *TP53* in colorectal tumors and *ARID1A*, *PIK3CA*, and *PTEN* genes in endometrial and nonserous ovarian cancers, are largely preserved in LS tumors, although mutation frequencies of individual genes may vary.

The *BRAF* oncogene is an important exception to the generally similar patterns of mutant genes between sporadic and LS tumors with MSI. Analysis of large cohorts of colorectal cancers indicates that *BRAF* V600E mutation occurs with a frequency of 1.4% in tumors from MMR gene mutation carriers (LS), compared with 5% in MSS cases and 63% in sporadic MSI colorectal cancers. *BRAF* V600E mutation coincides with *MLH1* promoter "C region" methylation and strongly argues against LS. *BRAF* V600E mutation can therefore be utilized as a biomarker for predicting MMR-negative mutation status in MSI colorectal cancers.

Epigenetic Alterations in LS Tumors

The MMR system can influence the epigenetic machinery and vice versa. For example, deficient MMR can induce mutations in genes with key roles in epigenetic regulation (such as *ARID1A* and other chromatin regulator genes), therefore having the potential to alter epigenetic modifications. Coding repeats, common targets of frameshift mutations in MMR-deficient tumors, are part of several epigenetic regulator genes and can be one reason why epigenetic regulation is commonly affected in LS and sporadic cancers with MSI. Conversely, MMR genes can be epigenetically regulated by promoter methylation (*MLH1*) and micro-RNAs (*MSH2*, *MSH6*, and *MLH1*). Moreover, the histone mark H3K36me3 is required to recruit hMutSα to chromatin in the process of MMR. In light of this interplay, it is not unexpected that apart from somatic mutations, coordinated methylation of CpG islands that are normally unmethylated (CpG island methylator phenotype, CIMP) and global hypomethylation (with the long interspersed element 1, LINE-1, as a surrogate marker) are integral parts of LS tumorigenesis. CIMP has the potential to silence hundreds of tumor suppressor genes per cancer cell. DNA hypomethylation in turn can activate oncogenes and increase chromosomal instability via LINE-1 retrotransposition.

Sporadic MSI colorectal cancers with *MLH1* promoter methylation typically display high CIMP phenotypes. More or less the same loci are involved in LS-associated colorectal cancers, but the frequencies of tumors with methylation are lower. Promoter methylation appears early and increases along with tumor progression. Promoter methylation of *SFRP1* and *SLC5A8*, established tumor suppressor genes of colorectal carcinogenesis, has been shown to be significantly elevated in normal mucosa from MMR gene mutation carriers previously diagnosed with colorectal carcinoma, as compared to mutation carriers of a comparable age with no prior colorectal carcinoma diagnosis, suggesting that methylation changes may form cancer-prone "fields" in histologically normal mucosa. Moreover, methylation increases with histological dysplasia, with 0% of normal mucosae, 15% of adenomas with low-degree dysplasia, 23% of adenomas with high-degree dysplasia, and 50% of carcinomas from LS individuals reported to display CIMP-high with established marker genes.

Analogous observations are available from endometrial tumorigenesis, except that different tumor suppressor genes (e.g., *RASSF1* and *CHD13*) are preferentially affected given the tissue-specific nature of epigenetic regulation. Retrospective examination of serial endometrial biopsy samples from a long-term follow-up of LS mutation carriers has revealed MMR defects and elevated promoter methylation at tumor suppressor gene loci up to 12 years before endometrial carcinoma development. Furthermore, promoter methylation of CpG islands associated with tumor suppressor genes and microRNA genes stratifies endometrial lesions into a low-methylator group (normal endometrium and simple hyperplasia) and a high-methylator group (complex hyperplasia

with and without atypia and endometrial carcinoma) suggesting that increased methylation accompanies endometrial tumorigenesis. The findings apply to both LS-associated and sporadic endometrial lesions emphasizing their universal nature.

The highest levels of global hypomethylation occur in sporadic MSS colorectal cancers. Extensive hypomethylation is not a feature of LS-associated colon cancers; however, when present, LINE-1 hypomethylation has been reported to be associated with a worse prognosis compared with LS patients without significant hypomethylation. In line with observations from LS colorectal cancers, LS-ovarian carcinoma shows a significantly higher average number of methylated tumor suppressor genes and lower degree of LINE-1 hypomethylation compared with the corresponding sporadic disease, which may contribute to the favorable prognosis of LS-ovarian cancer (see section "**Molecular Profiles in Tumors Versus Disease Outcome**").

Temporal Relationship Between MMR Deficiency and Other Tumorigenic Events

MMR defects are among the earliest detectable alterations in cancer-prone target tissues of LS individuals. Intestinal resections for small or large bowel cancer from LS mutation carriers display lesions termed MMR-deficient crypt foci with a frequency of one focus per 1 cm^2 of nontumorous mucosa, as compared to none in non-LS control patients. MMR protein is absent and MSI is present in such lesions, indicating biallelic MMR gene inactivation. The abundance of MMR-deficient crypt foci contrasts with the low number of adenomas or carcinomas observed in LS and suggests that most lesions do not progress to malignancy. In colorectal polyps from MMR gene mutation carriers, the prevalence of MMR deficiency increases with the size and dysplasia of adenomatous polyps, from 67% in adenomas with low-degree dysplasia to 100% in adenomas with high-degree dysplasia; the latter frequency is similar to colorectal carcinomas. Hyperplastic polyps from LS individuals rarely ($<5\%$) display MMR defects and their malignant potential is considered low. In analogy to colorectal tumorigenesis, the prevalence of MMR defects increases with endometrial tumor progression in LS. Decreased MMR protein expression has been reported to occur in 7% in normal endometrium, 40% in simple hyperplasia, and $\sim 100\%$ in complex hyperplasia with or without atypia and likewise in endometrial carcinoma; the frequencies of MSI are somewhat lower.

The observations of abundant MMR-deficient crypt foci without progression to visible tumors on the one hand and adenoma development without biallelic MMR gene inactivation on the other hand imply the need of other oncogenic events besides MMR deficiency. As mentioned earlier, DNA methylation changes can be early events in tumorigenesis. Promoter methylation of *SFRP1* and *SLC5A8* may form field defects in histologically normal colonic mucosa from LS individuals. Studies on sporadic cases has revealed frequent hypermethylation of *SFRP1* and *SLC5A8* promoters in aberrant crypt foci, the earliest detectable morphological lesions of colorectal tumorigenesis that usually lack *APC* mutations, and methylation is accompanied by decreased expression of the corresponding proteins. The repair gene *MGMT* encoding O^6-methylguanine DNA methyltransferase is a further gene whose loss of expression, usually by promoter methylation, can form field defects in normal mucosa from LS and sporadic cases. The resulting failure to process mutagenic methyl adducts may trigger cellular transformation by inducing mutations in cancer-related genes such as *KRAS* or by inactivating the MMR genes by mutations or promoter methylation. It has been postulated that methylation tolerance due to *MGMT* field defects may initiate sporadic or LS-associated MSI-colorectal cancer prior to MMR deficiency. As, however, no such studies are available that would have examined the earliest lesions (aberrant crypts) for both MMR and methylation abnormalities, it remains unsettled which aberrations come first.

Mutations of *APC*, an important gatekeeper of colon tumorigenesis, are known to occur early in colon tumorigenesis; therefore, this gene has been used in studies addressing the temporal relationship between MMR defects and other molecular events. Investigations on mice heterozygous for the *Apc* Min mutation and knockouts for selected MMR genes (*Min*/+, *Msh2* −/− and *Min*/+, *Mlh1* −/− mice) demonstrate that MMR deficiency changes the spectrum of somatic *Apc* alterations from LOH, the usual second hit, to point mutations, suggesting that deficient MMR exerts its effect before *Apc*. On the other hand, comparison of the *APC* mutation spectra in sporadic MSI and MSS colon cancers has failed to identify in the former tumors any clear excess of changes characteristic of MMR defects, such as preferential involvement of repeat sequences, suggesting that MMR deficiency occurs after *APC* mutations. Taken together, studies conducted to date have remained conflicting or inconclusive in an attempt to determine the chronological order of MMR defects relative to other molecular events in multistep tumorigenesis.

Molecular Profiles in Tumors Versus Disease Outcome

Evidence from a prospective LS database (http://LScarisk.org) on MMR gene mutation carriers without previous cancer and under regular surveillance shows that the 10-year survival after the first cancer is excellent: 91% for colorectal cancer, 98% for endometrial cancer, 89% for ovarian cancer, and 87% for any cancer. Although early detection probably plays a role, LS cancers are additionally likely to have intrinsic factors that contribute to the favorable outcome compared to cancers arising in the general population.

Early studies already found that despite aggressive histological features (poor differentiation) of LS-associated colorectal carcinoma, LS patients experience a definite survival advantage over average colorectal carcinoma patients. Since the same applies to unselected colorectal carcinoma with MSI, it is logical to reason that MMR deficiency offers a plausible explanation. Increased mutational load triggering apoptosis of tumor cells can be one possible mechanism. The favorable effects of deficient MMR may also be related to the generation of neoantigens that can elicit strong antitumor immune responses. Multiple genes encompass coding microsatellite repeats prone to insertion/deletion mutations, resulting in neopeptides with altered carboxy-terminal sequences that are recognized as foreign by the immune system. Some peptides derived from mutant genes (*TGFBR2*, *AIM2*, *HT001*, and

TAF1B in one study and *ASTE1*, *HNF1A*, and *TCF7L2* in another study) have been identified as especially immunogenic and may help develop vaccination-based immunotherapy in LS. Pronounced immune responses provoked by various neopeptides may eliminate MMR-deficient crypt foci present in nontumorous mucosa of LS individuals. Progression and metastasis of tumors that have already developed may be prevented by similar mechanisms. Furthermore, the active immune microenvironment is counterbalanced by immune inhibitory signals, resulting in overexpression of several immune checkpoint molecules, such as PD-1 and PD-L1. This may make metastatic MMR-deficient cancers particularly susceptible to pembrolizumab and other immune checkpoint inhibitors.

Ovarian carcinomas arising in LS individuals are mainly of nonserous histology (endometrioid and clear cell type) and well or moderately differentiated early-stage tumors at diagnosis, as opposed to sporadic ovarian carcinomas, a majority of which are serous and advanced at presentation. Although the abovementioned clinicopathological differences are likely to contribute to differential disease outcomes, the 5-year survival of LS patients with even stage III or IV ovarian cancer is 59% compared to 28% in sporadic cases. A novel molecular profile for LS-associated ovarian carcinoma has been described, consisting of normal p53 expression, lack of *KRAS* mutation, MMR deficiency, significantly higher rate of methylated tumor suppressor genes and lower degree of LINE-1 hypomethylation compared to sporadic endometrioid and clear cell ovarian cancers. This markedly different overall molecular profile compared to sporadic ovarian cancers may in part explain the surprisingly high survival rates of LS-associated ovarian carcinoma.

Genotype-Phenotype Correlations in LS

Cancer Risks Associated With Germline Mutations in MMR Genes

The life-time risks of cancer vary according to the mutant gene, which may reflect the degree of functional redundancy of the corresponding proteins in MMR (**Table 4**). *MLH1* and *MSH2* mutations have high penetrance, with 60%–80% of mutation carriers developing some form of cancer during their lifetime. The mean age of onset is ~45 years for colorectal cancer and ~45–55 years for other cancers. *MSH6* and especially *PMS2* mutations have lower penetrance, 25%–54% for *MSH6* and ~20%–30% for *PMS2*. The mean age at onset is 55–60 years for colorectal cancer and 54 years for endometrial cancer in *MSH6* mutation carriers. Heterozygous carriers of *PMS2* mutation have a mean age at onset of around 50 years for colorectal and other cancers. The type (truncating vs. missense) or location (relative to different functional domains) of MMR gene mutations is poorly correlated with clinical phenotype.

LS Tumor Spectrum and Its Molecular Basis

The Amsterdam II criteria (**Table 1**) acknowledge cancers of the colon and rectum, endometrium, small bowel, ureter, and renal pelvis as LS-associated cancers, because these are significantly more frequent in LS compared to the average population. Since the Amsterdam II criteria were formulated, significantly increased standardized incidence ratios have repeatedly been reported for cancers of the stomach, ovaries, and pancreas as well as for certain other cancers (footnote in **Table 1**), which combined with molecular profiles characteristic of LS, such as MMR protein loss and MSI, justifies their inclusion in the LS spectrum. Recently, breast cancer and prostate cancer have also been suggested to belong to the LS tumor spectrum, based on MMR deficiency in tumors from MMR gene mutation carriers, in addition to some published evidence of increased risk in LS compared to the average population. While confirmation from additional study series is still warranted for reliable conclusions, a recent investigation compared the rate of MMR deficiency in breast carcinomas from proven mutation carriers versus noncarriers from the same families, resulting in frequencies of 65% versus 0% ($P < 0.001$). Moreover, the age at onset of breast carcinoma in mutation carriers was earlier if the tumor was MMR-deficient, suggesting that MMR deficiency does play a role in breast cancer development in LS.

Why MMR gene mutation carriers are predisposed to a narrow spectrum of cancers, considering that they carry one defective copy of a given MMR gene in all their cells, is not well understood. Some possible mechanisms of organ selectivity are depicted in **Fig. 6**. First, the individual MMR genes may be associated with different tumor spectra. For example, the risk of extracolonic cancers has been suggested to be higher in *MSH2* than *MLH1* mutation carriers. As another example, female carriers of *MSH6* mutations are at a higher risk of endometrial than colorectal cancer.

Second, the dosage of the MMR gene or protein is important for phenotype. As discussed earlier (**Table 2**), homozygosity or compound heterozygosity for germline mutation results in a separate syndrome, CMMRD. At present, ~150 cases with CMMRD are known. Childhood cancers of the hematological system and brain, signs of neurofibromatosis type 1 (café-au-lait spots), and coexistence of colorectal and brain tumors (TS) are common manifestations of CMMRD. The distinct tumor spectrum may reflect the sensitivity of neural and hematological progenitor cells to MMR deficiency via specific somatic target genes, such as *NF1*. In contrast to LS with heterozygous MMR gene mutations (**Fig. 2**, upper right), CMMRD patients lack expression of the MMR protein(s) in question not only in cancer tissue but in normal tissue as well. Despite biallelic MMR gene inactivation, MSI is not usually detectable by standard methods in peripheral blood lymphocytes because of clonal heterogeneity; however, immortalized lymphoblastoid cells, which are oligoclonal, can reveal MSI. Another line of evidence to support the significance of MMR gene or protein dosage for phenotypic consequences comes from observations of haploinsufficiency in somatic cells (see section "**LS Genes and Knudson's Two-Hit Hypothesis**"). Different organs may have different requirements for MMR gene dosage or

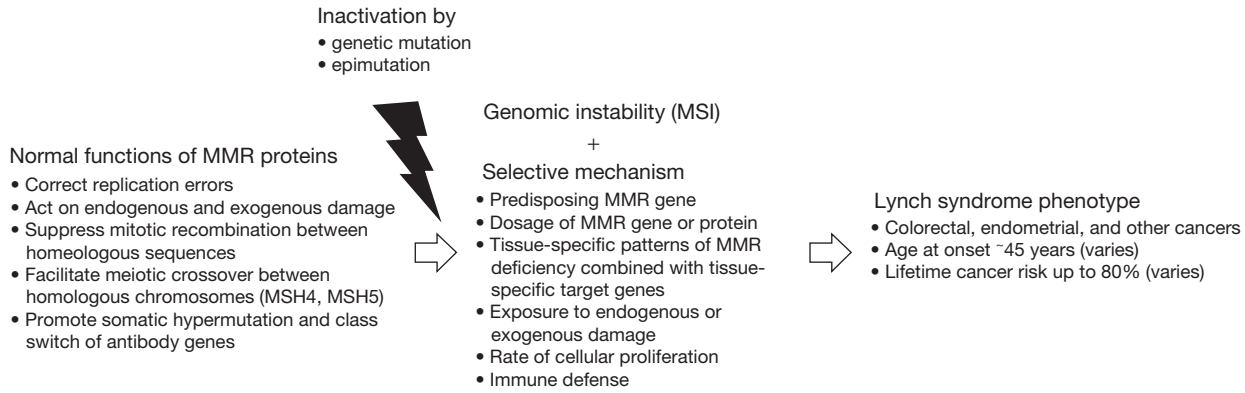

Fig. 6 Possible mechanisms that may lead to organ selectivity in LS. MMR gene inactivation by genetic or epigenetic mechanisms (see **Fig. 3**) abrogates normal functions of MMR proteins and results in genomic instability (see **Fig. 2**), which together with various selective mechanisms can target specific organs for tumor development and contribute to the overall LS phenotype (see text).

protein, which may affect their susceptibility to tumor development. For example, analysis of second hits in *MLH1* mutation carriers shows that deletion of the wild-type *MLH1* allele is more common in colorectal than endometrial cancer.

Third, tissue specificity for MMR deficiency and genes targeted by failing MMR may be a factor behind organ selectivity. In LS, immunohistochemical analysis of cancers regularly demonstrates absent MMR protein corresponding to the gene mutant in the germline, but the frequency of MSI-high varies from 80% to 100% (stomach, ovary, colon, and ureter) to ~50% (bladder, endometrium, and kidney) and even less (35% for breast and 0% for brain tumors) (**Fig. 2**, lower panel). Clonal heterogeneity is a feature of LS and sporadic MMR-deficient tumors and can partly explain the different frequencies of MSI between tumor types. Observations of *BAT* markers showing shorter allelic shifts in endometrial than colorectal cancers from LS patients offer another indication of tissue-specific patterns of clonal growth. Genes with coding repeats are preferential targets in MMR-deficient cancers (see earlier) and different genes confer selective advantage for different cancers, such as the *TGFβ* superfamily for gastrointestinal cancers and *PTEN* for endometrial cancers. Organ-specific differences in the manifestation of MMR deficiency can therefore contribute to LS tumor spectrum via tissue-specific target genes with mutation-prone sequences.

Fourth, exposure to endogenous and exogenous damages can have serious consequences when the ability of the MMR system to repair such damage is compromised due to inherited mutations. Such damage can be exogenous (many heterocyclic amines are of dietary origin) or endogenous (such as inflammation-induced oxidation). The accumulation of damage could facilitate cancer development in exposed organs, such as the gastrointestinal tract and endometrial epithelium. Western-style diet has been shown to increase colorectal adenomas in LS mutation carriers and colon adenomas and carcinomas in *Mlh1*+/− mice. Likewise, tobacco smoking appears to increase colorectal adenoma risk in LS mutation carriers. Such observations imply a reduced capacity of MMR gene mutation carriers to repair dietary and tobacco-associated damage.

Fifth, tumors initiated by unrepaired mutations or carcinogen-derived adducts may show differential progression rates in different tissues depending on cellular proliferation. Colon and many other epithelial cells have fast turnovers, and short cell cycles may allow less time to repair errors. Stem cell divisions in the epithelium continue throughout life. Hematopoietic tissue, which is likewise highly proliferative, may be less cancer-prone because of fewer stem cell divisions during lifetime. Proliferation rates may explain why a majority of LS-associated tumors are epithelial and why MMR deficiency can occasionally (in CMMRD) cause predisposition to hematological malignancies.

Finally, immunological processes may play a role in organ-specific tumor susceptibility. MMR deficiency induces frameshift mutations that can have differential effects on the immune system. Cell surface proteins responsible for antigen processing and presentation may lose expression as a consequence of frameshift mutations of genes encoding them and this may make it possible for tumor cells to escape from immune surveillance. For example, mutations in the *B2M* gene coding for beta 2 microglobulin can abrogate HLA class I antigen expression on the surface of tumor cells, allowing evasion from the attacks by cytotoxic T cells. Mutations in other types of genes such as *ACVR2* or *TGFBR2* may result in the formation of neoantigens and induce a strong immune response against cancer cells. High levels of TILs in colon, gynecological, and other tumors from LS patients are indicators of active immune surveillance. Differential manifestation of MMR defects (see earlier) combined with possible variations in the inherent efficacy of immune surveillance in different organs may contribute to organ selection in LS.

Differential Diagnosis of LS

A suspicion of LS typically arises because of a family history of LS-spectrum cancers or because of MSI and/or immunohistochemical loss of MMR protein in tumor tissue. Starting from family or tumor studies, a number of alternative diagnoses are possible and need to be considered in differential diagnosis (**Fig. 7**, **Table 6**).

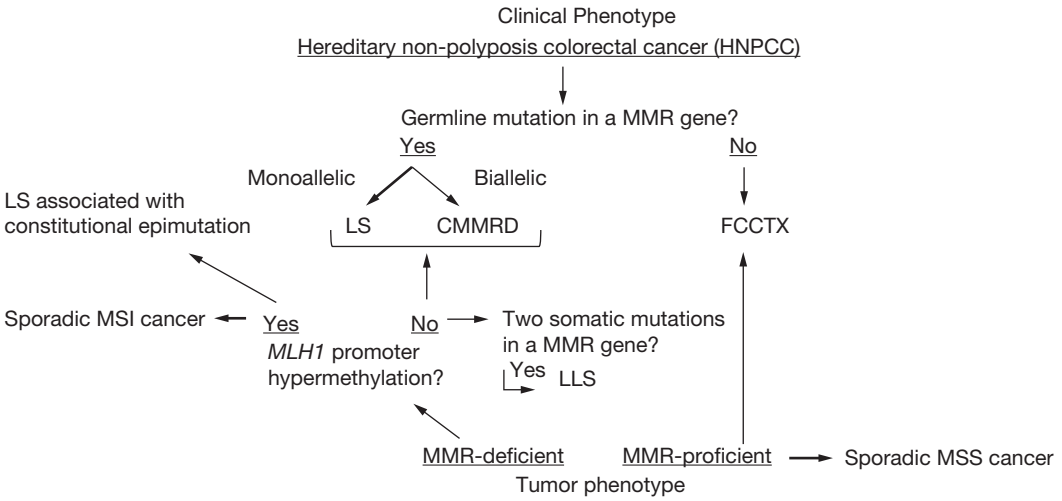

Fig. 7 Differential diagnosis of LS. Clinical and tumor phenotypes are common starting points for molecular evaluation to differentiate LS from overlapping conditions (see **Table 6**). When two options exist, a *thick arrow* denotes the most likely alternative.

Table 6 Syndromes that overlap with or mimic LS

Syndrome	*Share among unselected CRCs (%)*	*Responsible gene*	*Family features*	*Tumor characteristics*
Familial colorectal cancer type X (FCCTX)	~2	Mostly unknown	Hereditary/familial	No MMR defects in a family that fulfills the Amsterdam criteria
Sporadic MSI	~15	*MLH1*	Sporadic	MSI-H or absent MLH1 protein due to *MLH1* methylation
Lynch-like syndrome (LLS)	2.5	*MLH1*, *MSH2*, *MSH6*, or *PMS2*	Sporadic (some familial clustering reported)	MSI-H or absent MMR protein not explained by methylation of *MLH1* or germline mutation of MMR genes. Attributable to two inactivating somatic events of MMR genes
POLE/*POLD1*-associated hypermutability	1–2	*POLE* or *POLD1*	Sporadic or hereditary	Rate of nonsynonymous mutations comparable to that caused by MMR defects, but MSI-H is absent. Somatic mutations result in "ultramutated" tumors, whereas germline mutations predispose to polymerase proofreading-associated polyposis (PPAP)

CRC, colorectal cancer; *MSI-H*, high-degree of microsatellite instability.

Familial Colorectal Cancer Type X

Before the discovery of the LS genes in the 1990s, the Amsterdam Criteria (**Table 1**) were used to identify families with a presumably inherited form of colorectal carcinoma. Families that meet these clinical criteria were called hereditary non-polyposis colorectal cancer (HNPCC). Molecular analyses have revealed that in about half of such families, MSI or absent MMR protein in tumors or a germline MMR gene defect cannot be identified. Such families are referred to as familial colorectal cancer "type X" (FCCTX), because the genetic basis of this disease is largely unknown. FCCTX forms the MMR-proficient subset and LS with pathogenic germline mutations in MMR genes, the MMR-deficient subset of HNPCC. FCCTX families show site-specific (mainly distal) colorectal cancer, as opposed to colonic (mainly proximal) and extracolonic cancers seen in LS; furthermore, the mean age at cancer onset is 10 years higher (55 years in FCCTX vs. 45 years in LS). A number of novel candidates for FCCTX susceptibility genes have recently been identified, including *GALNT12*, *BMPR1A*, *RPS20*, *SEMA4*, and *FAN1*. The genes function in different biological pathways and each seems to be restricted to a small number of families.

Colorectal carcinomas from FCCTX families display a remarkably low LINE-1 methylation (i.e., strong LINE-1 hypomethylation) as a common denominator. As low LINE-1 methylation is also a feature of normal mucosae from FCCTX patients, it may represent a field defect or a constitutional alteration. The mechanistic basis of FCCTX-associated hypomethylation remains to be uncovered by future studies.

Sporadic MSI-H Colorectal Cancer Associated With MLH1 Promoter Methylation

If a colorectal cancer is MMR-deficient, the main subgroup (~15% of all colorectal cancers) to be considered is sporadic colorectal cancer with acquired biallelic methylation of the *MLH1* promoter. Like LS-associated colorectal cancer, sporadic colorectal cancer with *MLH1* methylation preferentially affects the proximal colon; however, the age at onset is higher (~70 years) compared to LS and, for reasons that remain to be clarified, there is a clear female predominance. The presence of *BRAF* V600E mutation combined with *MLH1* promoter methylation identifies the sporadic MSI-H subgroup of colorectal cancers. A comparable (or even higher, up to 30%) share of unselected endometrial carcinomas may be MMR-deficient because of biallelic *MLH1* methylation. While *BRAF* V600E mutation is absent in LS-associated endometrial carcinoma in analogy to LS-colorectal cancer, *BRAF* mutations are so infrequent in endometrial carcinomas in general that *BRAF* V600E testing has no role in differentiating sporadic MMR-deficient endometrial carcinoma from LS-associated disease.

Lynch-Like Syndrome

Approximately 2.5% of all colorectal cancers are MMR-deficient in the absence of promoter methylation or causal germline mutations, which is referred to as LLS. In half of the cases, two somatic events that inactivate *MLH1*, *MSH2*, *MSH6*, or *PMS2* are detectable. These events can consist of two point mutations or a point mutation and LOH. The mean age at onset of colorectal cancer and predominant location in the proximal colon resemble LS. Unlike LS, LLS is an acquired disease, although some family clustering by unknown mechanisms has been reported.

The profiles of molecular alterations in MMR-deficient tumors may depend on the underlying defect. While hypermutability with repeat sequences as preferential targets is a feature common to all tumors with MMR deficiency, the CIMP phenotype combined with *BRAF* mutation is a particular characteristic of sporadic MSI colorectal cancers with *MLH1* methylation, as discussed earlier. Preliminary evidence suggests that *BRAF* mutations are absent LLS colorectal carcinomas, thus resembling LS tumors. More frequent mutations in *PIK3CA* may distinguish LLS colorectal and endometrial tumors from LS tumors.

POLE or POLD1-Associated Hypermutability

Hypermutability without MSI-H in tumors can result from proofreading mutations of the replicative DNA polymerases Pol ε and Pol δ (the polymerases are depicted in MMR in **Fig. 1**). Somatic *POLE* proofreading domain mutations occur in 1%–2% of colorectal cancers and 7%–12% of endometrial cancers (somatic *POLD1* mutations are rare). Germline mutations affecting the *POLE* and *POLD1* proofreading domains predispose to polyposis that is often relatively mild (polymerase proofreading-associated polyposis). Interestingly, faulty proofreading owing to somatic or germline mutations in *POLE* or *POLD1* can induce mutations in MMR genes and thereby explain some LLS cases with MSI-H.

Prospective Vision

The fact that LS cannot be diagnosed on the basis of clinical or tumor phenotype alone emphasizes two important aspects, first, that the syndrome serves as a general model for common cancers and second, that LS and related phenotypes are breaking down to separate subsets by modern molecular methods.

At present, germline mutations in MMR genes are detectable in up to 88% of LS families fulfilling the Amsterdam criteria and showing MSI in tumors. Smaller or atypical families and families not prescreened by MSI or immunohistochemical analyses of tumor tissues show mutation frequencies of 10%–40% depending on the method of ascertainment. Deep sequencing by targeted gene panels and whole exomes or genomes, which will be replacing current single gene-based approaches, is likely to increase the fraction of LS with detectable predisposing mutations and to unravel the genetic basis of colon cancer families unrelated to MMR defects.

The complex phenotype of LS is associated with multiple puzzles that remain to be solved by future investigations. Why does the penetrance of MMR gene mutations vary so much even between individuals with identical predisposing mutations? Related to the former question: what is the relative contribution of genetic versus nongenetic factors to LS phenotype? What is the clinical and functional significance of MMR gene variants of the VUS type? Which tumors are unequivocal components of the LS tumor spectrum and by which mechanisms? With a better understanding of the pathogenesis of LS, will cancer eventually become preventable in a large fraction of mutation carriers?

Apart from defining the spectrum of genes and mutations predisposing to LS, genome-wide screens (as opposed to previous targeted approaches) can identify low-penetrance alterations that may modify the LS phenotype. Comprehensive genetic, epigenetic, and expressional profiling of tumor tissues may define tumorigenic mechanisms in LS and identify clinically actionable somatic alterations in analogy to efforts on sporadic cancers (TCGA). One in ten carriers of MMR gene mutations may never develop cancer during their lifetime and identification of possible protective factors, inherited or acquired, would be of particular interest. Clinical and molecular studies need to be combined with epidemiological investigations to explore the impact of environmental and lifestyle factors on LS phenotype—an area that is a largely uncharted in LS compared to sporadic cancer. By integrating clinical, molecular, and epidemiological information, a complete picture of LS can be built, which is likely to advance cancer research and facilitate the management of LS individuals.

Malignant Sweat Gland Tumors

Malignant sweat gland tumors comprise the largest group of skin adnexal carcinomas. They are classically subdividing according to their behavior into low- and high-grade carcinomas. Low-grade tumors may show locally destructive growth with risk for local recurrences and rare metastasis to loco-regional lymph nodes while disseminated metastasis and disease-related mortality is a complication of high-grade neoplasms. Morphologically, sweat gland carcinomas frequently mimic adenocarcinomas of visceral primary sites, especially of the breast. They should not be mistaken for cutaneous metastasis but reliable separation is often difficult requiring careful clinical correlation and work-up.

Low-Grade Sweat Gland Carcinomas

Primary Cutaneous Cribriform Carcinoma

Primary cutaneous cribriform carcinoma is a rare tumor of indolent behavior. No local recurrences or metastases have been described to date and it is unclear whether this tumor should be regarded as a true carcinoma. It presents as slowly growing nodules of few centimeters with a preference for the lower extremities of middle-aged adults. Females are twice as commonly affected as males. Complete removal is curative.

Histological features: The tumors are well circumscribed and situated in the dermis without connection with the overlying epidermis (Fig. 1A). They are composed of interconnecting strands of medium-sized cuboidal tumor cells with florid duct

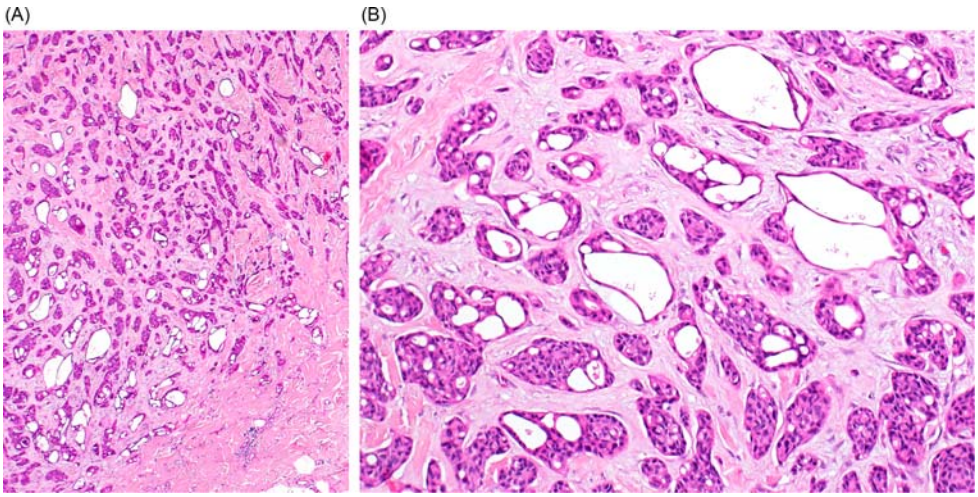

Fig. 1 Primary cutaneous cribriform carcinoma. This well circumscribed but unencapsulated nodular tumor is located within dermis and composed of interconnecting epithelial nests and strands separated by a loose fibrous stroma (A). Extensive ductal differentiation leads to its cribriform appearance. The tumor cells are cuboidal without significant cytological atypia (B).

formation, resulting in a cribriform architecture (Fig. 1B). The mitotic activity is low and there is no nuclear pleomorphism or tumor necrosis. Focal decapitation secretion may be found.

Immunohistochemistry: Expression of cytokeratins AE1/3, MNF116, Cam5.2, and CK7 is present. EMA and CEA staining illustrates luminal differentiation. No myoepithelial cell layer is present.

Differential diagnosis: Primary cutaneous cribriform carcinoma may resemble tubular adenoma. These benign tumors show a tubular growth pattern with intervening stroma. They lack the cribriform architecture and show a preserved myoepithelial layer. Separation from the more aggressive adenoid cystic carcinoma is of greater importance. Cutaneous adenoid cystic carcinoma is characterized by a diffusely infiltrative growth, and the cribriform architecture is due to mucinous pseudocysts rather than true duct formation.

Endocrine Mucin-Producing Sweat Gland Carcinoma

Endocrine mucin-producing sweat gland carcinoma (EMPSGC) is a rare disease, closely related to solid papillary carcinoma of the breast or endocrine ductal carcinoma in situ. The tumors may arise in association with and may represent a precursor of mucinous carcinoma. EMPSGC presents as a solitary, slowly growing lesion in the periorbital region or cheek, with a strong predilection for the eyelids. The patients are elderly adults (median: 70 years) with a female predilection (F:M = 2:1). Local recurrence following complete excision is a rare event and no metastases or disease related mortality have been described.

Histological features: EMPSGC is a well-circumscribed and lobulated dermal based tumor with solid, cystic and papillary differentiation in varying proportions (Fig. 2A). The solid tumor lobules are composed of monomorphous, medium-sized round and oval cells with a pale eosinophilic cytoplasm that may contain mucin (Fig. 2B). The nuclei are placed centrally and show stippled chromatin. Cytological atypia is limited and nuclear pleomorphism is rare. Mitotic activity is noted. The presence of extracellular mucin with the formation of mucinous pseudocysts is a characteristic finding (Fig. 2B). True cystic structures are present in varying amounts and may show decapitation secretion. A subset of tumors shows transition to invasive mucinous carcinoma with small tumor islands suspended in large mucin lakes. Tumor necrosis is usually not a feature.

Immunohistochemistry: The tumor cells express neuroendocrine markers (synaptophysin, chromogranin, neuron-specific enolase, CD57) and low molecular cytokeratins (Cam5.2) and CK7. Epithelial membrane antigen (EMA) highlights luminal differentiation. EMPSGC also expresses estrogen and progesterone receptors. The tumor cells are negative for CK20 and S100. No myoepithelial differentiation is found.

Differential diagnosis: Mucinous carcinoma is less circumscribed with invasion of deeper tissues. Mucin filled lakes containing scattered epithelial islands dominate the histological pattern. Cutaneous metastases from a visceral primary, particularly of breast origin, are an important differential diagnosis, which requires clinico-pathological correlation. The adenoid-cystic variant of basal cell carcinoma contains more pronounced cytological atypia, shows peripheral palisading and lacks duct differentiation. Merkel cell carcinoma is characterized by a sheet-like or trabecular architecture and clearly infiltrative growth. It lacks mucin and is cytokeratin 20 positive.

Primary Cutaneous Mucinous Carcinoma

Mucinous carcinoma arising primarily in the skin is a rare sweat gland tumor that affects the scalp and face, especially the eyelids of elderly adults (median: 76 years) with a predilection for females. The nodular tumors grow slowly and often show a violaceous discoloration. They are of low-grade malignant potential with local recurrence rates of 20%–26% but low risk for metastases, mainly

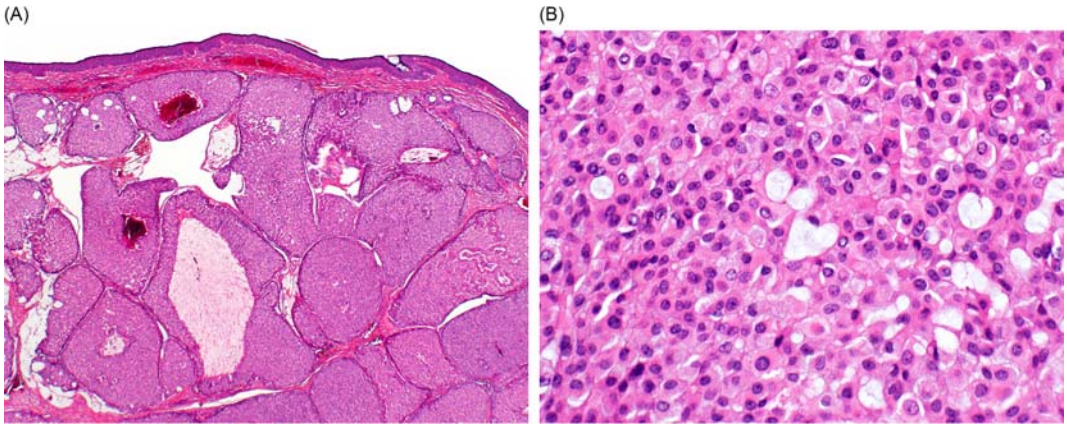

Fig. 2 Endocrine mucin-producing sweat gland carcinoma. This multilobular dermal based tumor shows a basophilic appearance (A). It is composed of medium sized round to polygonal cells containing eosinophilic cytoplasm and centrally located nuclei with indistinct nucleoli. Intracytoplasmic mucin droplets and extracellular mucin pools are also present (B).

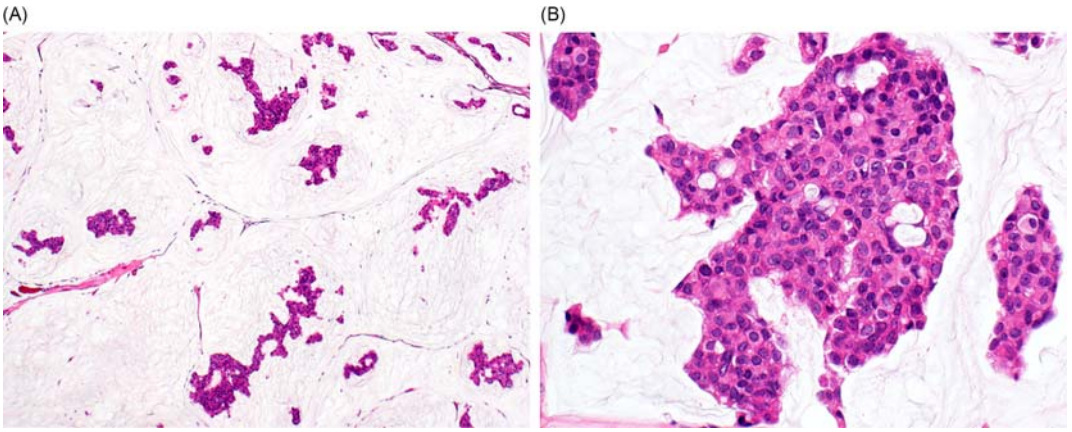

Fig. 3 Primary cutaneous mucinous carcinoma. The tumor is composed of nests and strands in an abundant mucinous matrix separated by thin fibrous septa (A). The tumor cells are polygonal and contain eosinophilic cytoplasm and irregular vesicular to hyperchromatic nuclei (B).

to loco-regional lymph nodes. Disseminated spread and disease related mortality is exceptional. Importantly, the diagnosis requires an investigation for a possible underlying mucinous adenocarcinoma of visceral sites, especially the breast, ovary, gastrointestinal and genitourinary tract.

Histological features: The tumors show an invasive growth in dermis and subcutaneous fat. They are lobulated showing fine, delicate fibrous septa and are composed of irregularly shaped epithelial islands and strands embedded in pools of mucin (Fig. 3A). The tumor cells are cuboidal containing eosinophilic cytoplasm occasionally with mucin droplets (Fig. 3B). Nuclear pleomorphism is variable. Areas of cribriform as well as solid growth are present in some tumors. Glandular structures with papillary projections and decapitation secretion may also be seen.

Immunohistochemistry: The tumor cells are positive for cytokeratins AE1/AE3, Cam 5.2., CK7, and estrogen (ER) and progesterone receptors (PR). Duct differentiation is highlighted by EMA and CEA staining. They are negative for CK20.

Differential diagnosis: Primary cutaneous mucinous carcinoma needs to be distinguished from cutaneous metastases from visceral primaries. Tumors of colonic origin can be distinguished by the presence of so-called "dirty" necrosis and expression of CK20. Visceral primaries of other sites, especially breast, require careful clinic-pathological correlation and work-up.

Microcystic Adnexal Carcinoma

Microcystic adnexal carcinoma (MAC, syringomatous carcinoma, malignant syringoma, sclerosing sweat duct carcinoma) is a rare carcinoma that usually affects adults in their 5th and 6th decade without gender bias. It typically involves the face, especially the nasolabial and periorbital regions. Other sites are rarely affected but it may be related to infiltrating syringomatous adenoma of the nipple. The tumors present as slowly growing, poorly circumscribed plaques measuring several centimeters. They are locally destructive and show high local recurrence rates of around 30%–40%. Metastasis to regional lymph nodes and systemic disease are exceptionally rare. Wide local excision or Mohs surgery are the treatment of choice to ensure complete removal and prevent against local recurrence.

Histological features: The tumor is located in the dermis and is characterized by a diffusely infiltrative architecture with invasion of subcutaneous fat, skeletal muscle, fascia and rarely bone (Fig. 4A). Morphologically it shows both follicular and sweat duct differentiation. The tumor consists of solid cords and strands of small to medium sized basaloid cells in a dense fibrotic stroma (Fig. 4B). Cytological atypia is minimal and mitoses are rare. Superficially, keratocysts and dystrophic calcifications are present. Ductal differentiation is most evident in the deeper parts of the tumor (Fig. 4C). Perineural infiltration is commonly present.

Immunohistochemistry: The tumor cells express pan-cytokeratins. EMA and CEA highlight duct differentiation.

Differential diagnosis: MAC may resemble syringoma, desmoplastic trichoepithelioma, infiltrative basal cell carcinoma and desmoplastic squamous cell carcinoma. Separation from syringoma and desmoplastic trichoepithelioma is important as these are benign skin adnexal tumors. Both tumors are confined to the superficial and mid dermis and lack the diffusely infiltrative and deep growth of MAC. Reliable separation is often challenging and may be impossible on superficial biopsies. In these cases, a deeper repeat biopsy or complete excision is recommended for a definitive diagnosis. Sclerosing basal cell carcinoma and squamous cell carcinoma lack ductal differentiation and show more pronounced cytological atypia.

Primary Cutaneous Adenoid Cystic Carcinoma

Primary cutaneous adenoid cystic carcinoma (PCACC) is rare. It affects middle-aged to elderly adults (median: 62 years) without sex predilection. It presents as slowly growing nodules and plaques, often measuring multiple centimeters. There is a predilection for the head and neck area, especially the scalp, but the anatomic distribution is wide, also including the genital area, in particular the

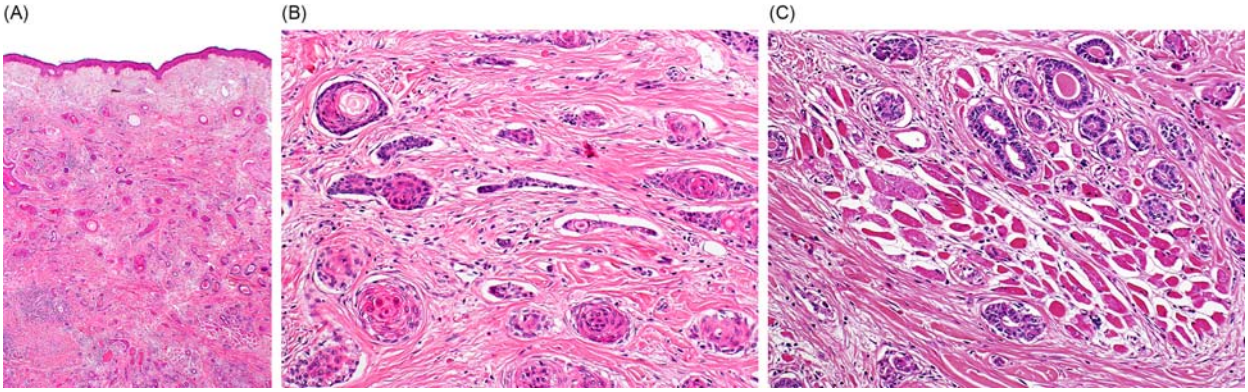

Fig. 4 Microcystic adnexal carcinoma. The tumor is characterized by a diffusely infiltrative growth within dermis (A). It consists of cords and strands showing hair follicular differentiation in a sclerotic stroma. Small keratocysts are also present (B). In the deeper aspects, ductal differentiation is evident. The tumor invades skeletal muscle (C).

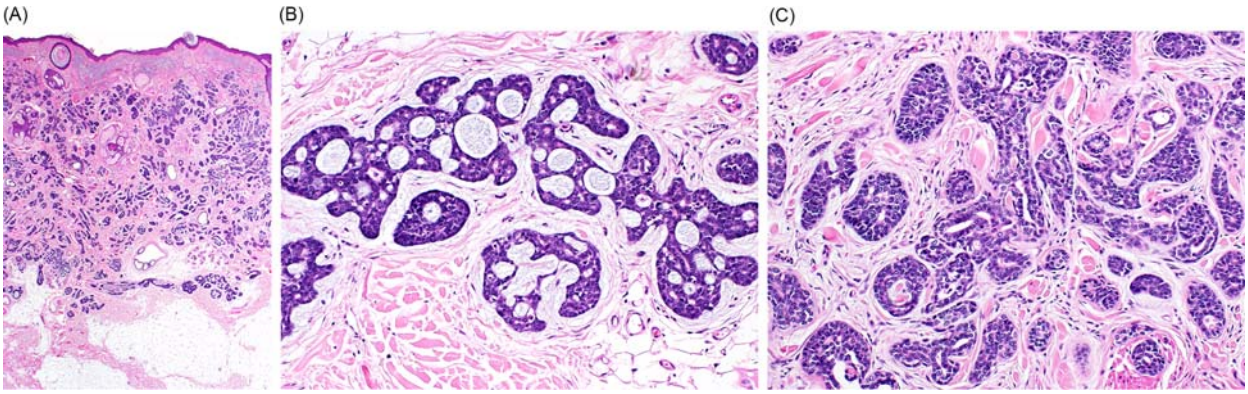

Fig. 5 Primary cutaneous adenoid cystic carcinoma. This basophilic tumor is poorly circumscribed and shows an infiltrative growth within dermis with invasion of subcutaneous adipose tissue (A). The tumor cells are medium sized without marked nuclear pleomorphism. Mucin filled pseudocyst give rise to the typical cribriform architecture (B). Ductal differentiation is a focal finding (C).

vulva. In contrast to its visceral counterparts the behavior of primary cutaneous tumors is less aggressive, characterized by locally destructive growth and risk for local recurrence. The risk for metastatic spread and mortality is however low.

Histological features: The tumor is poorly demarcated with an infiltrative growth in dermis and subcutaneous fat (Fig. 5A). It is composed of variably sized and shaped nests, tumor lobules and cords and strands of basaloid epithelioid cells with little cytoplasm and hyperchromatic nuclei. Cytological atypia is mild to moderate but mitotic activity is readily identified. The individual tumor islands are surrounded by stromal mucin leading to the formation of mucinous pseudocysts and the characteristic cribriform appearance (Fig. 5B). Ductal differentiation is focally present and perineural infiltration is usually seen (Fig. 5C).

Immunohistochemistry and genetics: The tumor expresses cytokeratins AE1/3 and Cam5.2. Myoepithelial differentiation is present and highlighted by SMA, SOX10 and S100 staining. Most tumors show positivity for CD117. Ductal structures stain with CEA and EMA.

The t(6;9)(q22-23;p23-24) translocation leading to the MYB-NFIB fusion gene and resulting in MYB overexpression characteristic of visceral adenoid cystic carcinoma has also been found in primary cutaneous tumors.

Differential diagnosis: Primary cutaneous tumors need to be distinguished from cutaneous extension or metastasis from visceral adenoid cystic carcinoma. This requires careful clinico-pathological correlation and work-up as the histological, immunohistochemical and genetic features are identical. Adenoid cystic basal cell carcinoma can be differentiated from PCACC by the presence of palisading of tumor cells, the stromal cleft artifact and lack of duct differentiation.

Squamoid Eccrine Ductal Carcinoma

Squamoid eccrine ductal carcinoma is a rare and likely under-recognized entity, closely related if not identical to adenosquamous carcinoma of the skin. The tumor mainly affects the head and neck area of elderly males. It presents as solitary and often ulcerated nodules and plaques. The tumors are characterized by local recurrence rates of 25% and occasional metastasis to regional lymph nodes. Systemic disease and mortality are rarely reported events.

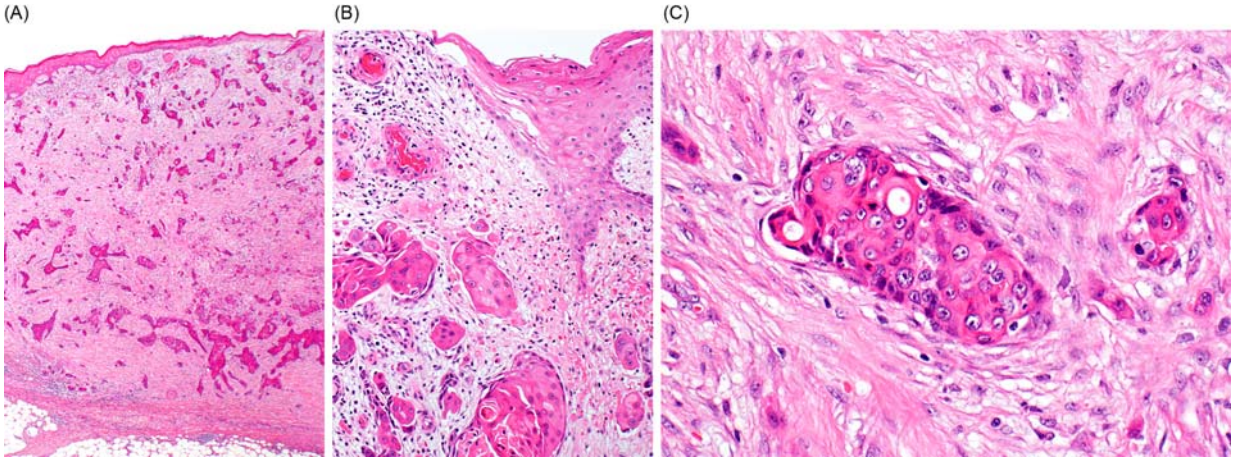

Fig. 6 Squamoid eccrine ductal carcinoma. The tumor is situated in the dermis, is poorly circumscribed and shows a diffusely infiltrative growth invading subcutaneous fat (A). In the superficial aspects of the tumor squamous cell differentiation is typical and may be morphologically identical to squamous cell carcinoma. A connection with the overlying epidermis is often present and there may be surface ulceration (B). Eccrine ductal differentiation is found in the deeper reaches of the tumor consisting of irregular cords and strands of pleomorphic cuboidal cells in a desmoplastic stroma. Mitotic activity is high (C).

Histological features: The tumors are situated in the dermis with a diffusely infiltrative growth, frequently invading subcutaneous fat, skeletal muscle and fascia (Fig. 6A). They are characterized by a dual differentiation towards squamous cell carcinoma in the superficial aspects and eccrine ductal carcinoma in the deeper reaches. A connection with the overlying epidermis is often present and there may be surface ulceration. The tumors are indistinguishable from squamous cell carcinoma superficially (Fig. 6B). In the deeper areas, they are composed of irregular cords and strands of pleomorphic cuboidal cells in a desmoplastic stroma (Fig. 6C). Mitotic activity is brisk and ductal differentiation is present. Tumor necrosis, perineural infiltration and lymphovascular invasion may be present.

Immunohistochemistry: Duct differentiation is highlighted by immunohistochemistry for CEA and EMA.

Differential diagnosis: Squamoid eccrine ductal carcinoma may be mistaken for squamous cell carcinoma on superficial biopsies. Eccrine porocarcinoma may show focal squamous differentiation but lacks the zonation. Microcystic adnexal carcinoma also shows duct and squamoid differentiation but lacks the pronounced cytological atypia.

High-Grade Sweat Gland Carcinomas

Porocarcinoma

Porocarcinoma (malignant eccrine poroma) affects elderly people in their 7th and 8th decade without gender bias. It is typically found on the lower limbs but can also be seen on the trunk, head and neck area and upper extremities. Risk factors include trauma, burning, radiotherapy and potentially also immunosuppression. Porocarcinoma presents as long-standing solitary verrucous tumors, polypoid nodules or plaques measuring several centimeters. Ulceration is common. The behavior is similar to squamous cell carcinoma if adjusted for tumor thickness. The risk for local recurrences is 17% with potential for lymph nodes metastasis. Although rare, the presence of distant metastatic spread is an adverse prognostic factor associated with high mortality rates.

Histopathological features: Porocarcinoma is a poorly delineated dermal based tumor showing multifocal epidermal connection and epidermal ulceration (Fig. 7A). Its borders may be pushing or diffusely infiltrative and invasion of subcutis and deeper structures may be present. A preexisting benign poroma is noted in 11% of cases. The tumors are composed of irregularly shaped and interconnecting strands and islands of polygonal epithelioid cells with varying degrees of cytological atypia and nuclear pleomorphism (Fig. 7B). The identification of duct differentiation is a prerequisite for the diagnosis (Fig. 7C). Tumor necrosis, perineural infiltration and lymphovascular invasion may also be present. Other rare features include squamous or clear cell change and sarcomatoid differentiation. The tumors can be pigmented by melanocytic colonization.

Immunohistochemistry: The tumor cells express pancytokeratins. P16 is overexpressed in most porocarcinomas as is p53. Duct differentiation is highlighted by EMA and CEA staining.

Differential diagnoses: Squamous cell carcinoma can be separated by the absence of duct differentiation. Squamoid eccrine ductal carcinoma shows a zonation with areas indistinguishable from squamous carcinoma and eccrine ductal carcinoma. When adjusted for tumor thickness the behavior of porocarcinoma, squamous cell carcinoma and squamoid eccrine ductal carcinoma is similar.

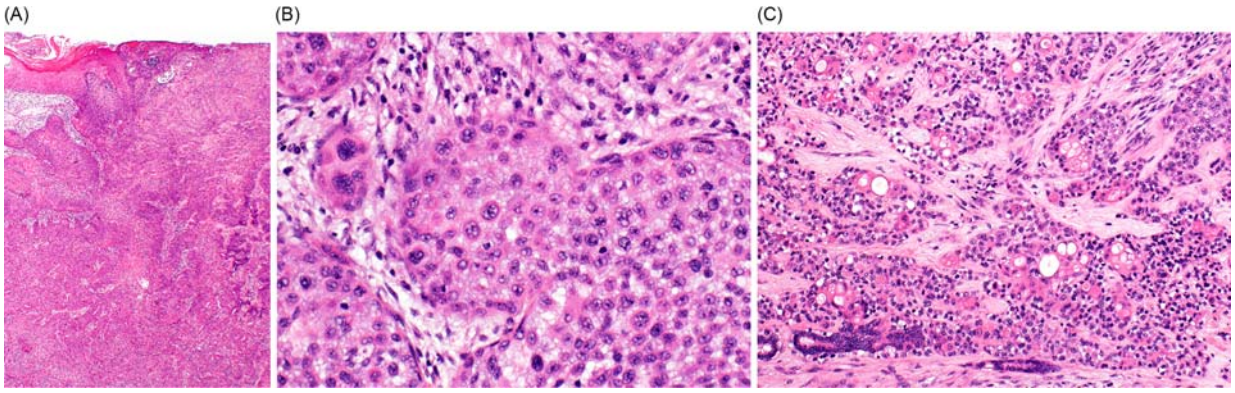

Fig. 7 Porocarcinoma. This large dermal based tumor shows ulceration and connection with the overlying epidermis (A). It consists of solid nests and islands of poroid polygonal cells with varying degrees of cytologic atypia (B). Ductal differentiation is invariably present and its identification is necessary for the diagnosis (C).

Hidradenocarcinoma

Hidradenocarcinoma (clear cell hidradenocarcinoma, malignant hidradenoma) is a rare tumor with a wide anatomic distribution and a predilection for adults. The face and the extremities appear to be most frequently affected. The tumors have potential for aggressive behavior with high local recurrence rates (50%–75%) and a high potential to metastasize to lymph nodes, lung and bone. Wide local excision is the treatment of choice. No clear guidelines exist regarding sentinel lymph node biopsy. The possibility should be considered and discussed on an individual basis.

Histopathological features: Hidradenocarcinoma is located in the dermis as a multinodular tumor with an infiltrative growth and invasion of deeper structures (Fig. 8A). The tumor lacks an epidermal connection and is composed of polygonal epithelioid cells with eosinophilic cytoplasm and variable nuclear pleomorphism (Fig. 8B). Clear cell change and squamoid features may also be present. Duct differentiation or cystic elements are invariably seen and their recognition is necessary for the diagnosis (Fig. 8C). In addition, mitotic activity, tumor necrosis, perineural infiltration and lymphovascular invasion may be seen. A preexisting benign hidradenoma is observed in a small subset of tumors.

Immunohistochemistry and genetics: The tumor cells express cytokeratin and frequently Her-2/neu. Ductal differentiation is demonstrated by EMA and CEA stains. Immunohistochemical overexpression of P53 is seen in the majority of tumors despite low frequency of mutations in the TP53 gene. The translocation t (11;19) can be detected in some hidradenocarcinomas analogous to hidradenoma.

Differential diagnoses: Morphologically low-grade tumors are a particular diagnostic challenge and need to be separated from hidradenoma. Tumors with infiltrative margins and cytological atypia need to be regarded with care and require complete excision. In this context, it is also important to be aware that morphologically and biologically benign hidradenomas may rarely show lymphovascular invasion and even lymph node deposits. Morphologically high-grade tumors require separation from cutaneous metastases from visceral primaries by careful clinical correlation, work-up and imaging techniques.

Apocrine Carcinoma

Apocrine carcinoma is a rare adenocarcinoma mainly affecting the axilla of adults with a mean age of 60 years and no significant gender predilection. It presents as solitary, slowly growing erythematous or violaceous nodules. The disease course can be aggressive

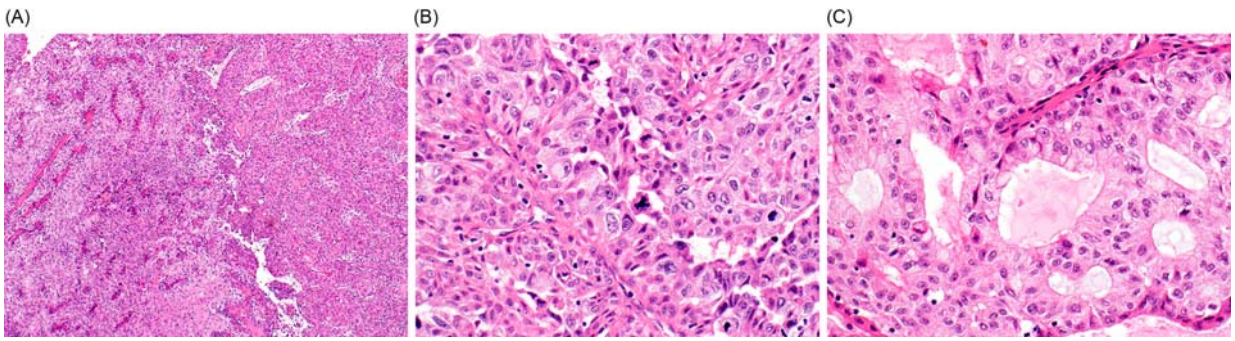

Fig. 8 Hidradenocarcinoma. The tumor shows a solid growth and arises from a preexisting hidradenoma seen on the right-hand side (A). Marked cytological atypia, nuclear pleomorphism and mitotic figures are present (B). In areas duct differentiation is appreciated (C).

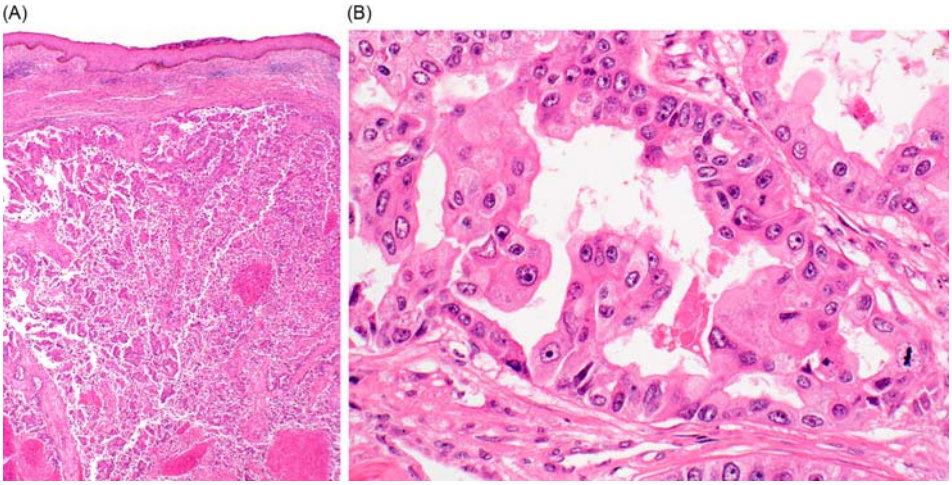

Fig. 9 Apocrine carcinoma. This dermal-based tumor shows a mixture of cystic and papillary elements (A). It is composed of large epithelioid cells with abundant eosinophilic cytoplasm containing vesicular nuclei and prominent eosinophilic nucleoli. Mitotic activity is identified (B).

with metastatic disease to lymph nodes and distant organs (lungs, liver, bone) and associated mortality. Histological grading appears to be a good predictor of outcome. The treatment consists of wide local excision.

Histopathological features: Apocrine carcinoma is lobulated and located in the dermis, frequently also invading subcutaneous fat (Fig. 9A). It is poorly circumscribed with infiltrative borders. The tumor cells are polygonal containing abundant eosinophilic cytoplasm and vesicular nuclei with prominent nucleoli. Cytological atypia and mitotic activity are variable and tumor necrosis may be seen (Fig. 9B). The growth pattern may show solid, tubular and cystic structures in a dense fibrotic stroma. Papillary structures are also frequently seen and decapitation secretion is consistently present. Adjacent apocrine glands are usually found close to the tumor. The tumors can be graded according to the modified Bloom Richardson grading system, which correlates with outcome.

Immunohistochemistry and genetics: The tumor cells express CAM5.2, AE1/AE3, EMA, CEA, GCDFP-15, mammaglobin, ER and PR. They are negative for HER2/neu and adipophilin.

Differential diagnosis: Apocrine carcinoma needs to be differentiated from metastatic adenocarcinoma, especially of breast origin. This differential diagnosis is challenging due to the morphologic overlap and presentation in the axilla. It requires careful clinical correlation. In addition, an immunohistochemical panel of ER and PR, HER2/neu, adipophilin, CK5/6, mammaglobin may be helpful: cutaneous apocrine carcinoma is likely to be adipophilin and Her2/neu negative, ER and PR positive and also shows a strong positive staining with CK5/6 and mammaglobin.

Digital Papillary Adenocarcinoma

Digital papillary adenocarcinoma is a rare but distinctive sweat gland carcinoma with a narrow anatomic distribution and a marked male predominance. The tumor shows a strong predilection for the distal extremities, particularly the digits. It presents as small erythematous or brown nodules, ranging from few millimeters to multiple centimeters. A wide age range is affected, including children and adolescents. The tumors have potential for aggressive behavior independent of the histological degree of differentiation. The local recurrence rates are high (20%–40%) and metastatic disease is seen in approximately 15%, mainly to lymph nodes and lung. Wide local excision or amputation is the recommended treatment. It may positively influence the disease course with reduced local recurrence and distant metastatic rates.

Histological features: Digital papillary adenocarcinoma shows a wide histological spectrum ranging from bland and innocuous appearing tumors to poorly differentiated examples with high-grade morphology. The majority of tumors are well-circumscribed and located in the deep dermis and superficial subcutaneous adipose tissue (Fig. 10A). They are solid and cystic with additional papillary, micropapillary and tubular growth patterns (Fig. 10B and C). The tumor cells are cuboidal basaloid cells with varying degrees of cellular atypia and nuclear pleomorphism, ranging from mild to severe. Mitotic figures are usually present. A second myoepithelial cell layer is present. Tumor necrosis and a more infiltrative growth are rare additional findings (Fig. 10C).

Immunohistochemistry and genetics: Tumor cells express cytokeratins. The luminal differentiation can be highlighted by EMA and CEA staining. S100, p63, podoplanin, SMA and calponin staining demonstrates a second myoepithelial cell layer.

Differential diagnosis: In view of the bland histological features and the preserved myoepithelial cell layer digital papillary adenocarcinoma may easily be mistaken for benign skin adnexal tumors, especially apocrine cystadenoma, hidradenoma and tubular adenoma. Apocrine cystadenoma is exceptionally rare on acral sites and this diagnosis should be made only after careful consideration. In reality, the vast majority of cystic and papillary tumors thought to be apocrine cystadenomas are in fact digital papillary adenocarcinomas. Hidradenoma shares many of the histological features with digital papillary adenocarcinoma. Papillary differentiation is usually not a prominent finding and the presence of any cytological atypia should be a warning sign. Tubular adenoma is

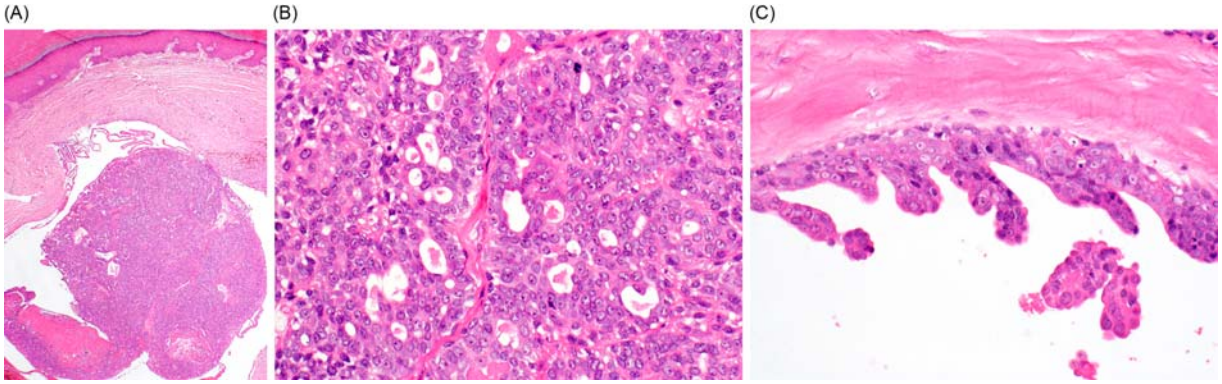

Fig. 10 Digital papillary adenocarcinoma. The tumor is well-circumscribed and situated in the dermis with a solid and cystic architecture (A). In areas duct formation and a tubular growth are noted (B). The cystic structures show micropapillae and a second myoepithelial cell layer can be seen (C).

characterized by a striking tubular growth with intervening stroma. A solid growth component is not observed. Metastases from papillary adenocarcinomas of visceral origin can be excluded by the demonstration of the myoepithelial differentiation.

Malignant Neoplasms Arising from Preexisting Spiradenoma, Cylindroma or Spiradenocylindroma

These rare tumors are defined by the presence of a malignant component arising in the background of a preexisting spiradenoma (spiradenocarcinoma), cylindroma (cylindrocarcinoma) of a hybrid spiradenoma-cylindroma. They present as solitary nodules with a preference for the head and neck and the extremities of elderly adults without gender bias. A long-standing history with recent enlargement may be given. The tumors may develop in association with the autosomal dominant Brooke Spiegler syndrome. The syndrome is characterized by the development of multiple adnexal neoplasms, especially cylindroma, spiradenoma, spiradenocylindroma and trichoepithelioma. The Brooke Spiegler syndrome is linked to mutations resulting in the inactivation of the tumor suppressor gene CYLD.

Morphologically the tumors arising from preexisting spiradenoma and cylindroma are divided into low- and high-grade, which correlates with outcome. Low-grade carcinomas have a 20% risk of local recurrence but distant metastasis and disease-related mortality is seen almost exclusively in high-grade carcinomas.

Histological features: These multinodular tumors are located in the deep dermis and subcutis and often show pushing rather than diffusely infiltrative borders. Recognition of a preexisting spiradenoma, cylindroma or hybrid tumor is essential for the diagnosis. Morphologically low-grade tumors show a similar architecture to spiradenoma on low power examination (Fig. 11A). They are composed of a monotonous population of uniform basaloid cells with mild to moderate cytological atypia and increased mitotic activity (Fig. 11B). A hallmark feature is the lack of the dual cell population, typical of spiradenoma and cylindroma. Additional findings include clear cell change and the formation of squamous eddies. Tumor necrosis and ulceration may also be observed. Morphologically high-grade tumors show a wide range of histological features. They are characterized by high-grade cytological atypia and nuclear pleomorphism and atypical mitoses, resembling poorly differentiated carcinoma or adenocarcinoma, NOS (Fig. 11C). Necrosis is a frequent finding.

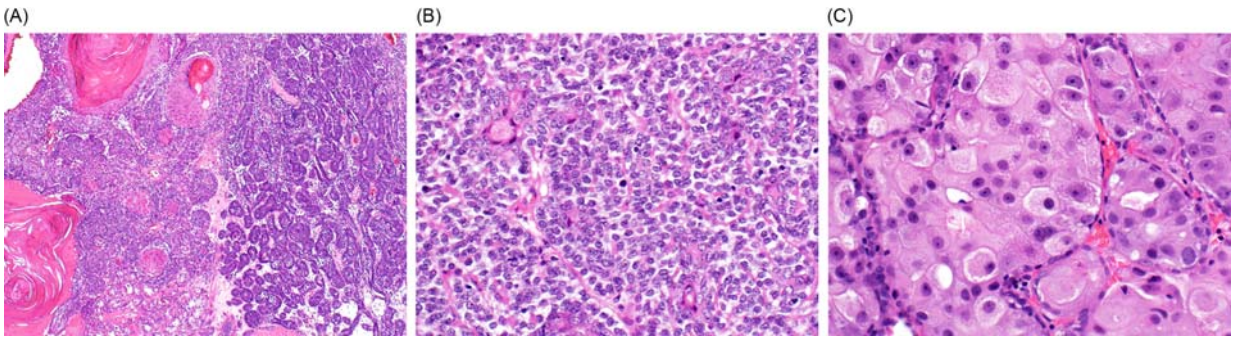

Fig. 11 Spiradenocarcinoma. The malignant nodular tumor (on the left-hand side) arises in association with a preexisting benign spiradenoma (on the right-hand side) (A). Morphologically low-grade tumors show a monotonous proliferation of uniform basaloid cells with mild to moderate degrees of cytological atypia and increased mitotic activity. The dual cell population characteristic of benign spiradenoma is lost (B). Morphologically high-grade spiradenocarcinoma is characterized by marked cytological atypia and resembles poorly differentiated adenocarcinoma (C).

Immunohistochemistry and genetics: The tumor cells express cytokeratins, duct differentiation is highlighted by EMA or CEA staining. Immunohistochemical overexpression of MYB is used as surrogate marker for the t(6;9) translocation seen in benign spiradenomas and cylindromas. MYB expression is lost, at least in the low-grade malignant tumors and serves as a helpful diagnostic marker to distinguish these tumors from their benign counterparts. Adnexal neoplasms arising in patients with Brooke Spiegler syndrome are likely to show mutations in the CYLD gene mapped on chromosome locus 16q12–13.

Differential diagnosis: The separation of morphologically low-grade spiradenocarcinoma from benign spiradenoma is particularly challenging. It requires careful examination with recognition of loss of the dual cell population, the presence of cytological atypia and mitotic activity. Immunohistochemical loss of MYB expression is helpful in this setting. High-grade tumors resemble metastases from visceral primaries. The recognition of a benign precursor is essential for the correct diagnosis.

Extramammary Paget's Disease

Extramammary Paget's disease (EMPD) is a rare adenocarcinoma. The majority of tumors develop primary to the skin which is subject of this article. Less commonly, EMPD presents secondary to the skin as cutaneous spread of an underlying visceral carcinoma, especially of the rectum, the urogenital tract, endocervix and stomach. Primary cutaneous EMPD develops in areas rich in apocrine sweat glands, especially in the vulva and perianally. Other sites include the penis, scrotum, axillae, umbilicus, and very rarely the face, scalp, trunk and extremities. It shows a predilection for females in their sixth to eighth decade of life. EMPD presents as erythematous, pigmented or erosive plaques accompanied by pruritus or pain. Early lesions can resemble eczema. In late stages nodules and ulceration are noted.

Primary cutaneous EMPD is usually diagnosed in the intraepidermal state (carcinoma in-situ). It shows a high risk for local recurrences but the overall prognosis is excellent. In contrast, invasion is seen in approximately 10% of EMPD and is associated with potential for aggressive behavior with regional and distant metastasis resulting in disease related mortality. Treatment for localized disease includes radical excision and radiotherapy. In-situ disease may also respond to photodynamic therapy and local immunomodulators (imiquimod).

Histological features: Primary cutaneous EMPD presents as an intraepidermal carcinoma in most cases. It is composed of medium-sized to large round to epithelioid cells arranged singly and in clusters (**Fig. 12**A). The tumor cells are scattered throughout the epidermis and may also involve hair follicular epithelium and sweat ducts. They contain abundant cytoplasm and vesicular nuclei showing variable pleomorphism. Intracytoplasmic mucin may be seen. Signet ring cell and glandular differentiation have been described. The involved epidermis may be hyperplastic and ulceration may be a feature. An invasive component is present in approximately 10% of cases. The invasive component shows a diffusely infiltrative growth involving dermis and deeper structures. It may be solid or nested and can show single cell infiltration. Signet ring or acinar differentiation may also be evident (**Fig. 12**B).

Immunohistochemistry: The tumor cells are PAS-positive and express low molecular weight cytokeratins (CAM5.2) and cytokeratin 7. Tumor cells are also positive for EMA, CEA, GCDFP-15 and mucicarmine 1. Androgen receptors and Her-2/neu are variably positive.

Differential Diagnoses: Most importantly, an epidermotropic metastasis of an internal adenocarcinoma needs to be excluded. Metastasis from colonic carcinoma is usually positive for both CK20 and CDX-2 in contrast to EMPD. Melanoma in situ and superficial spreading melanoma may show morphological similarities but can be distinguished by staining for melanocytic markers (S100, MelanA, HMB45). Clear cell squamous cell carcinoma is negative for GCDFP-15 and CEA but positive for p63.

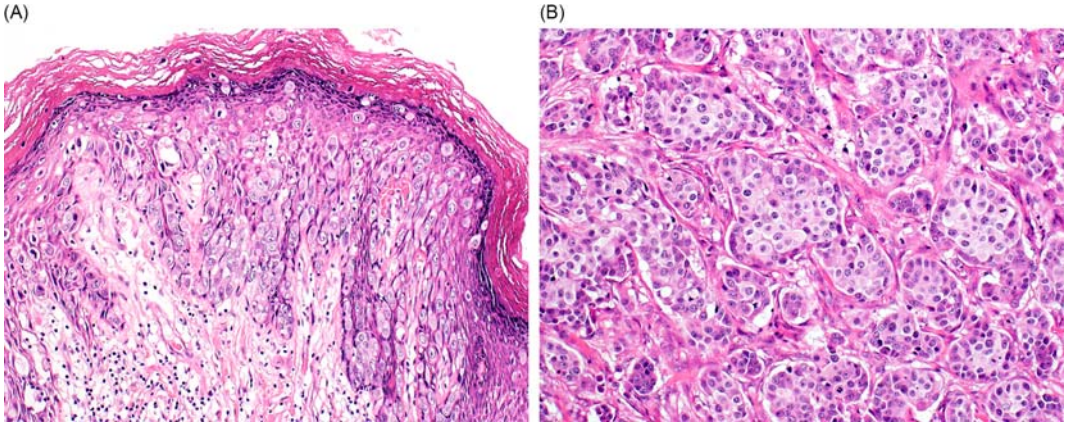

Fig. 12 Extramammary Paget's disease. The epidermis is diffusely infiltrated by medium sized tumor cells with abundant eosinophilic to clear cytoplasm and vesicular nuclei containing prominent eosinophilic nucleoli. The tumor cells are arranged singly and in small clusters, there is surrounding epidermal acanthosis (A). The invasive component consists of irregular nests of tumor cells. The invasive tumor cells are morphologically identical to the intraepidermal cells. Mitoses are readily spotted (B).

Eccrine Ductal Carcinoma NOS

Eccrine ductal carcinoma (eccrine adenocarcinoma) NOS is a diagnosis of exclusion. These rare tumors do not fit with any of the entities described above, and there are no systematic studies in the literature. Histologically they may be identical to metastases from visceral primaries, particularly of breast origin. Their diagnosis is only possible after a visceral primary has been excluded by clinical work-up and imaging studies. The tumors present as firm erythematous nodules involving a wide range of anatomical locations, especially of middle aged and elderly adults. The disease course is aggressive with high recurrence, metastasis and mortality rates.

Histological features: Eccrine ductal carcinoma is located in the deep dermis and may invade subcutaneous fat and deeper structures (Fig. 13A). The tumors are poorly circumscribed and consist of nests and strands of pleomorphic cuboidal cells with prominent ductal differentiation in a sclerotic stroma (Fig. 13B). Mitotic activity is brisk and tumor necrosis may be present. Perineural infiltration and lymphovascular invasion are common features.

Immunohistochemistry: The tumor cells express cytokeratins and CEA. Hormone receptors, GCDFP-15 and S100 are variably positive.

Differential diagnosis: Eccrine ductal carcinoma is morphologically identical to cutaneous metastasis from adenocarcinomas of visceral sites. The diagnosis of eccrine ductal carcinoma is one of exclusion requiring a careful clinical work-up and imaging of the patient.

Malignant Tumors with Follicular Differentiation

Pilomatrix Carcinoma

Pilomatrix carcinoma (malignant pilomatricoma, matrical carcinoma) is a rare neoplasm of low-grade malignancy and a predilection for male adults. The tumor presents as nodules of a few to multiple centimeters with a wide anatomical distribution. The head and neck area and the back are most commonly involved. Local recurrences are common but loco-regional and distant metastases are rare.

Histological features: Pilomatrix carcinoma is a multinodular dermal based tumor and may show invasion of subcutis, skeletal muscle and fascial tissues (Fig. 14A). The irregularly shaped and sized tumor lobules are composed of basophilic tumor cells with varying degrees of cytological atypia and a brisk and atypical mitotic activity. In addition, the tumor shows the distinctive hair matrix keratinization with ghost or shadow cell differentiation (Fig. 14B). Confluent necrosis, perineural infiltration and lymphovascular invasion may be present. Occasionally, colonization by melanocytes is seen.

Immunohistochemistry and genetics: Pilomatrix carcinoma is associated with mutations in beta-catenin that have also been identified in pilomatricoma, its benign counterpart. By immunohistochemistry, the tumor cells show nuclear expression of beta-catenin and cyclin D.

Differential diagnosis: Differentiation from the benign pilomatricoma is challenging. An infiltrative growth pattern, the presence of cytological atypia and tumor necrosis are the most reliable differentiating features. Basal cell carcinoma with matrical differentiation shows a peripheral palisade and a stromal cleft artifact.

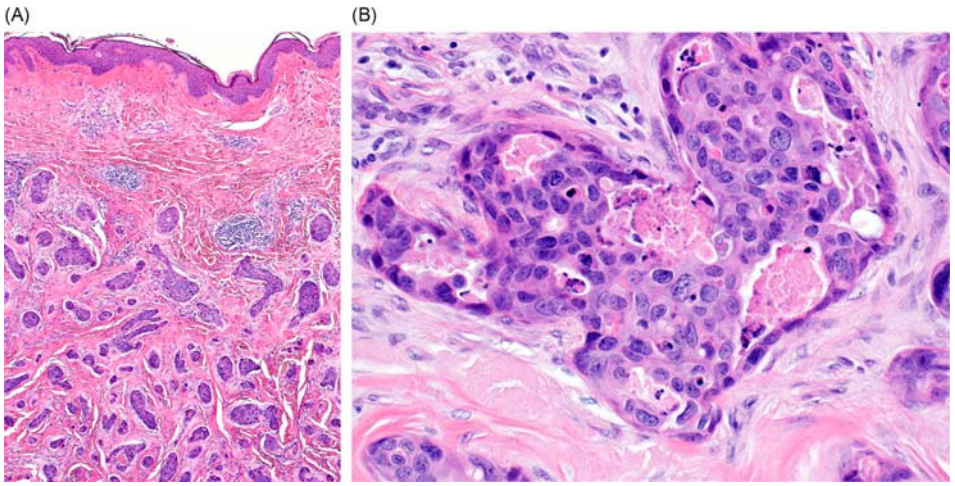

Fig. 13 Eccrine ductal carcinoma, NOS. The dermal based tumor is composed of irregularly shaped basaloid nests and lobules (A). There is marked nuclear pleomorphism and prominent duct differentiation. A desmoplastic stroma surrounds the tumor nests (B).

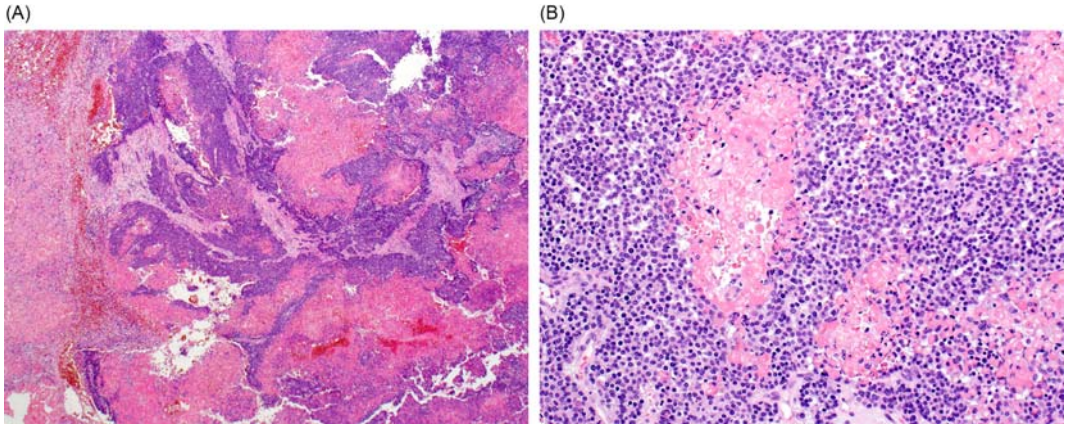

Fig. 14 Pilomatrix carcinoma. This large tumor is composed of irregular lobules containing sheets of basophilic cells and keratin (A). The tumor cells show a monotonous growth pattern and keratinization with ghost- or shadow-cell differentiation (B).

Trichilemmal Carcinoma

Trichilemmal carcinoma is a rare carcinoma of low-grade malignancy. It affects sun-exposed skin, particularly of the face, scalp, neck and hands of the elderly with a mean age of 71 years. The tumors are solitary erythematous nodules and plaques that may ulcerate. After complete excision trichilemmal carcinoma recurs very rarely. Regional lymph node metastases and systemic disease are rare events, but have been described, especially in immunocompromised patients.

Histopathological features: Trichilemmal carcinoma is a dermal based tumor with pushing borders composed of irregular tumor lobules, nests and strands (Fig. 15A). A diffusely infiltrative architecture is rarely observed. The tumor may extend into deep dermis and invades subcutaneous fat. A multifocal connection with the overlying epidermis or with hair follicles is typically present and there may be epidermal ulceration. The neoplastic cells show trichilemmal characteristics with clear to palely eosinophilic cytoplasm. Trichilemmal keratinization is invariably present either in the form of intracytoplasmic hyaline droplets, in form of small horn cysts or as large confluent areas (Fig. 15B). Cytological atypia and nuclear pleomorphism are variable and range from mild to severe. Nuclear palisading may be seen in the periphery of tumor lobules with surrounding hyaline basement membrane material. Mitoses are often numerous including atypical forms. Tumor necrosis may be an additional finding.

Immunohistochemistry: The tumor cells express cytokeratins and the cytoplasm is PAS-diastase positive. With rare exception, there is no expression of EMA and CEA.

Differential diagnoses: Differentiation from clear cell squamous cell carcinoma is difficult. The trichilemmal keratinization and hyaline basement membrane material as well as EMA negativity are diagnostic clues. Basal cell carcinoma with outer root sheath differentiation shows palisading of peripheral cells and retraction artifacts between tumor lobules and tumor stroma. Porocarcinoma and hidradenocarcinoma are separated by the presence of ductal differentiation.

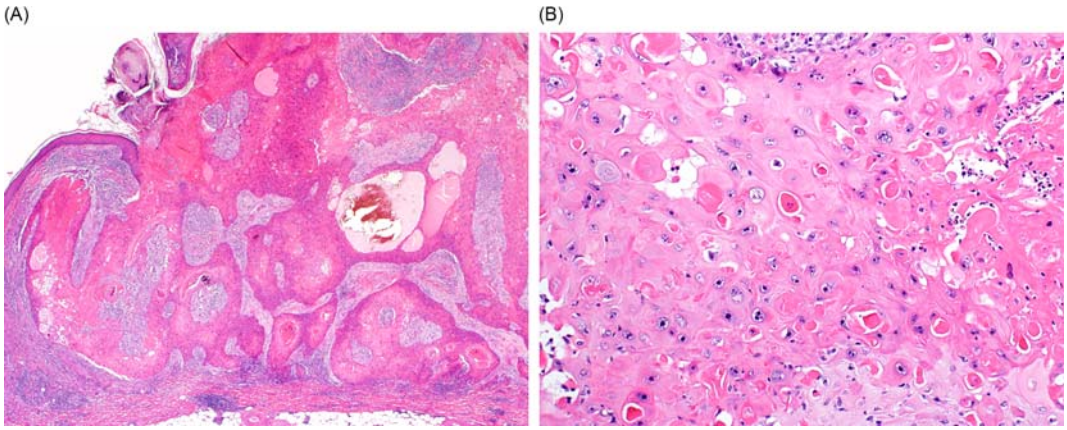

Fig. 15 Trichilemmal carcinoma. The tumor is connected with the surface epithelium and shows a multinodular growth pattern with pushing borders (A). It consists of large epithelial cells with abundant palely eosinophilic cytoplasm and trichilemmal keratinization. Nuclear pleomorphism is marked (B).

Proliferating Pilar Tumor

Proliferating pilar tumor (PPT) is a rare neoplasm that shows a predilection for elderly women. The tumors are usually located on the scalp. Other locations include eyelids, face, neck, vulva, trunk and extremities. PTT presents as slowly growing subcutaneous nodules measuring several centimeters. The majority of proliferating pilar tumors is benign. Local destructive growth and metastases to regional lymph nodes and distant organs is rare and seen in tumors with adverse histological features as listed below.

Histopathological features: The tumor has a multinodular growth pattern in deep dermis and may extend into the subcutaneous fat, skeletal muscle and fascia (**Fig. 16**A). It shows solid and cystic differentiation composed of large epithelioid cells with palely eosinophilic cytoplasm, vesicular nuclei and prominent trichilemmal keratinization (**Fig. 16**B). The periphery of tumor lobules is composed of smaller, more basophilic cells that may show palisading and an outer hyaline basement membrane. The presence of marked cytological atypia, atypical mitotic activity, an infiltrative growth pattern, tumor necrosis, perineural infiltration and lymphovascular invasion confers risk for more aggressive behavior.

Immunohistochemistry: Immunohistochemistry plays no role in the diagnosis of these tumors.

Differential diagnosis: Squamous cell carcinoma and trichilemmal carcinoma are characterized by an epidermal connection. They both lack the classical solid and cystic multilobular growth pattern characteristic of proliferating pilar tumor.

Sebaceous Carcinoma

Sebaceous carcinoma is a rare neoplasm that is classically divided into periocular (sebaceous carcinoma of the eyelids) and extraocular sebaceous carcinoma.

Periocular sebaceous carcinoma affects the elderly and appears to be more common in Asia. It has potential for aggressive behavior with local recurrence rates of 30%–40% and metastases to regional lymph nodes and distant organs in up to 25%. Metastatic disease is associated with high mortality and poor 5-year survival.

Extraocular sebaceous carcinoma is rare. It is mainly found in the head and neck area of elderly adults and presents with erythematous and often ulcerated nodules and plaques. The presentation outside the head and neck area, young age at presentation and multiple sebaceous neoplasms raise suspicion for the Muir-Torre-Syndrome (MTS), a variant of hereditary nonpolyposis colorectal cancer syndrome (Lynch syndrome). The behavior of extraocular sebaceous carcinoma is thought to be similar to that of periocular tumors. Treatment of choice is complete excision and long-term follow-up.

Histological features: Sebaceous carcinomas are circumscribed and multinodular or diffusely infiltrative dermal based tumors, often invading underlying subcutaneous tissues (**Fig. 17**A). They may show multifocal epidermal connection and ulceration (**Fig. 17**B). The tumor cells are epithelioid with basophilic cytoplasm and vesicular nuclei. Admixed in varying proportions are pale staining tumor cells with a vacuolated cytoplasm and indented nuclei (**Fig. 17**C). Poorly differentiated tumors show a predominance of the basaloid cells and sebaceous differentiation is difficult to appreciate on histology (**Fig. 17**D). There may be marked cytological atypia and nuclear pleomorphism. Mitoses are numerous and tumor necrosis is frequently seen. Lymphovascular or perineural invasion may be present. An intraepidermal growth with florid pagetoid spread is a feature seen particularly in the periocular tumors.

Immunohistochemistry: Tumor cells are positive for cytokeratin 7, p63 and p40. Sebaceous differentiation is highlighted by staining for EMA and adipophilin. The immunohistochemical demonstration of sebaceous differentiation may be difficult in poorly differentiated tumors.

Differential diagnosis: Sebaceous carcinoma needs to be distinguished from basal cell carcinoma, basaloid squamous cell carcinoma and Merkel cell carcinoma. The demonstration of sebaceous differentiation on morphology and immunohistochemistry is the clue to the correct diagnosis. In contrast to basal cell carcinoma sebaceous carcinoma does not show palisading of peripheral

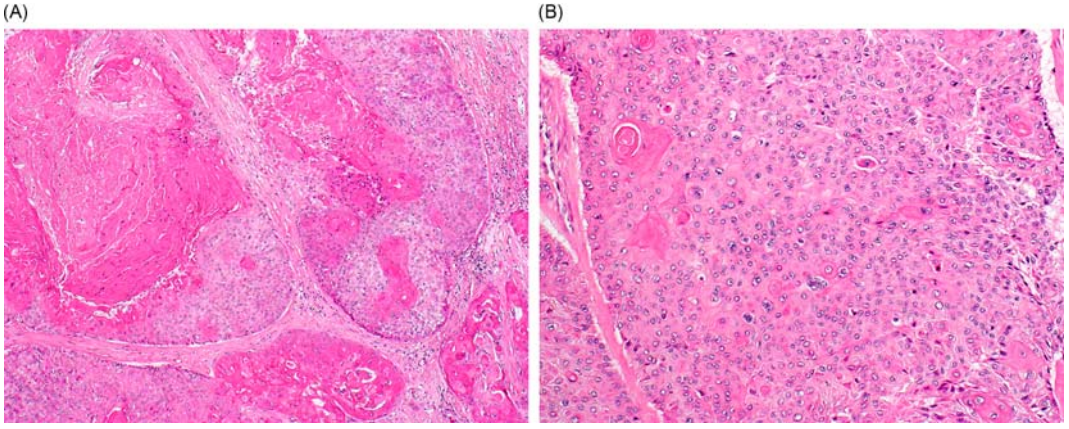

Fig. 16 Proliferating pilar tumor. The lobulated tumor is composed of solid epithelial elements and abundant trichilemmal keratinization (A). There is cytological atypia and numerous mitotic figures are present (B).

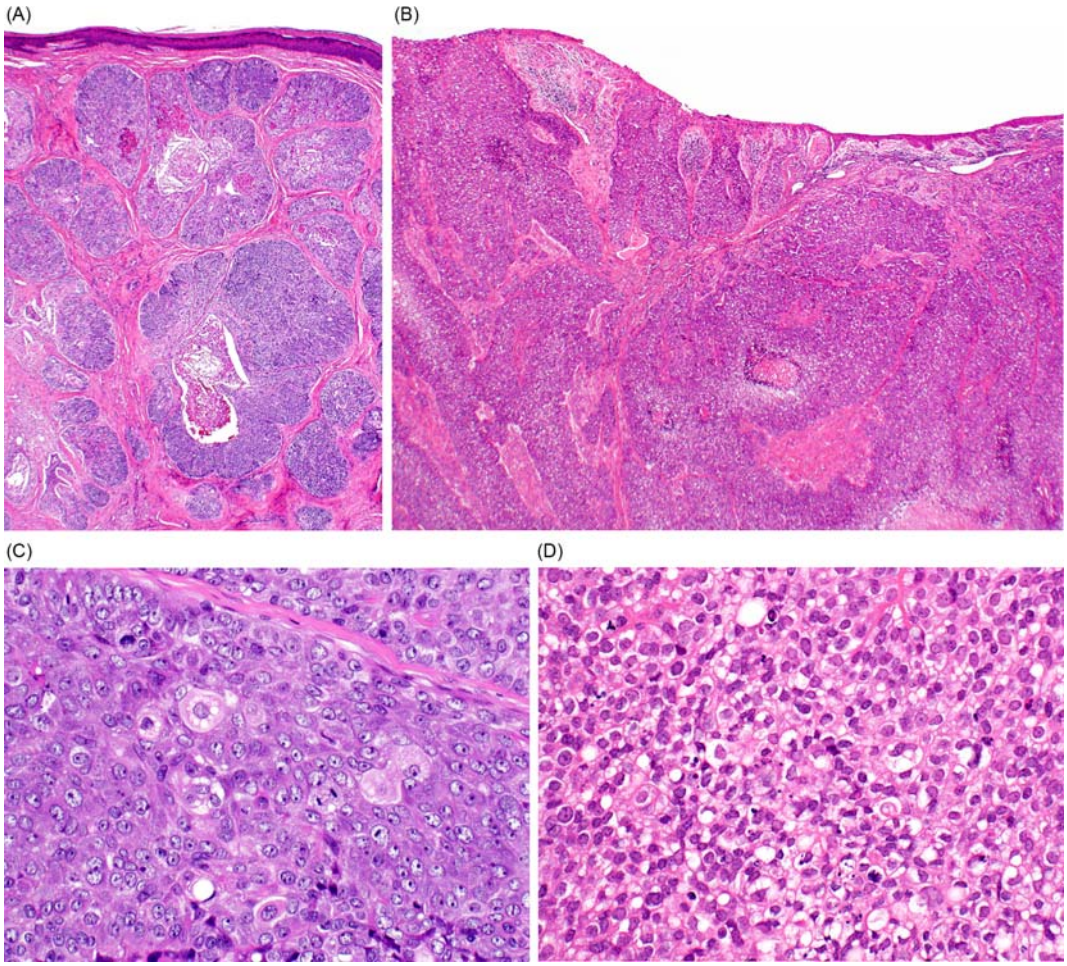

Fig. 17 Sebaceous carcinoma. This basaloid tumor is characterized by a multinodular growth within dermis (A). Multifocal epidermal connection and ulceration are present (B). The tumor is composed of basaloid cells with cellular atypia and admixed pale staining cells with a vacuolated cytoplasm (C). Sebaceous differentiation is difficult to appreciate in poorly differentiated examples (D).

cells, no retraction artifacts and is usually BerEp4 negative. Merkel cell carcinoma expresses CK20 which is consistently negative in sebaceous carcinoma.

Prospective Vision

Insight into the clinical behavior and underlying molecular events of skin adnexal carcinomas is still limited. Larger and more comprehensive studies with genetic analysis are necessary to better define these tumors and develop novel targeted therapeutic options, especially for disseminated disease.

Malignant Tumors of the Eye, Conjunctiva, and Orbit: Diagnosis and Therapy

Laurence Desjardins, Nathalie Cassoux, and Alexandre Matet, Curie Institute, Paris, France

Primary Intraocular Malignant Tumors

Uveal Melanoma

Diagnosis

Uveal melanoma is the most frequent primary intraocular tumors of adults. The age at diagnosis is around 60 years. For most patients, conservative management by proton beam therapy, plaque brachytherapy or transcleral resection is possible with equal survival than enucleation. Metastasis occurs in 50% of the patients mostly in the liver and survival with liver metastasis is short. For many years, there has been little progress in the management of metastatic disease but there is now increasing research and interest in many centers.

Blue and green eyes are more frequently involved and uveal melanoma is very rare in melanodermic patients. Usual visual symptoms include scotomas, phosphenes, loss of vision if the tumor is involving the macula or if the central retina is detached. Large peripheral tumors can cause visual field defects. Diagnosis relies mainly on fundus examination. Location of the tumor is very variable from ciliary body to posterior pole. Small ciliary body masses are often asymptomatic at first. They can invade the iris angle but are only visible with dilated pupil. Most tumor appears as a choroidal or ciliochoroidal mass with variable amount of pigmentation (sometimes very dark, sometimes amelanotic). The typical shape is the mushroom shape due to rupture of Bruch's membrane. Orange pigment can be present on the surface representing lipofuscin deposits. Serous retinal detachment is often associated sometimes visible only on OCT, sometimes clinically visible and associated to inferior exudative retinal detachment. Useful ancillary test are ultrasonography of the eye and fluorescein angiography. MRI can be useful when there is invasion of optic disk or suspected extra scleral extension. Ultrasonography usually shows typical attenuation of ultrasounds due to the very dense tumor tissue. The tumors appear hypoechogenic at the base with frequent choroidal excavation. On fluorescein angiography, it is possible to see a typical double circulation in achromic tumors in the early phase. Later tumors all show hyperfluorescence with surface pin points.

In the absence of appropriate treatment, uveal melanoma can invade the sclera and grow in the orbit. Extrascleral extension can be detected by ultrasonography or MRI. MRI is also helpful to verify the absence of optic nerve invasion for tumors invading the optic disk. If extrascleral extension is detected it can be treated by brachytherapy or proton beam but large extrascleral extension requires enucleation followed by external beam radiation.

Differential diagnosis includes choroidal naevi and other benign pigmented lesions such as melanocytomas and congenital hypertrophy of the retinal pigment epithelium, choroidal metastasis, choroidal hematomas, choroidal hemangiomas and choroidal osteomas. The most difficult and frequent situation is to differentiate between suspicious choroidal naevi and melanoma. The risk factors for a nevus to grow into a melanoma have been extensively described by JA Shields and CL Shields. They are diameter of >7 mm, thickness of >2 mm, orange pigment, subretinal fluid, visual symptoms, absence of drusen and location close to the optic disk. In studies performed with fluorescein angiography it has been shown that the presence of pin points is a significant risk factor. Risk for growth increases when the number of risk factors increases. The decision to treat depends on the number of risk factors, the location of the tumor and age of the patients. Decision should always be made with informed consent of the patient.

Unique metastasis can sometimes be difficult to differentiate from achromic melanoma. Choroidal metastasis can be seen in all cancer but more frequently in breast cancer and lung cancer. In lung cancer, metastasis is the first symptom of the disease in many cases. It is recommended to perform thoracoabdominal CT in all patients with achromic fundus mass.

Prognosis

Clinical risk factors for metastatic disease are well known: largest tumor diameter and anterior tumor location are important. Histological risk factors are the presence of epithelioid cells, mitotic count, vascular loops and presence of intravascular tumor cells. Largest tumor diameter should be correlated with histological and cytogenetic studies.

There has been a lot of progress in the understanding of genetics of uveal melanoma during the past 10 years. Since the first papers on genetic abnormalities based on karyotype, chromosome comparative genomic hybridization (CGH) and fluorescent in situ hybridization (FISH) analyses monosomy 3 has been recognized as bad prognostic factor. Other chromosomal imbalances, especially gain of 8q, have been reported as important events for metastasis. Molecular techniques such as CGH- and single nucleotide polymorphism (SNP)-arrays, and multiplex-ligation-dependent probe arrays (MLPA), has made it possible to reliably assess the status of genomic markers of prognostic value. These studies have highlighted genetic heterogeneity with isodisomy on chromosome 3. For others gene expression profile is the most precise way to predict the prognosis of uveal melanoma. All these advances were made possible thanks to the collaboration of ophthalmologist oncologists and geneticists in multidisciplinary teams.

Local treatment

The treatment of uveal melanoma by radiotherapy was popularized by Stallard who initiated the use of cobalt plaque brachytherapy in the 1950s with encouraging results. In the 1970s Zimmerman and colleagues showed that enucleation of the eye does not prevent metastatic dissemination compared to conservative management of uveal melanoma. Since then treatment by brachytherapy or

 https://doi.org/10.1016/B978-0-12-801238-3.65323-0

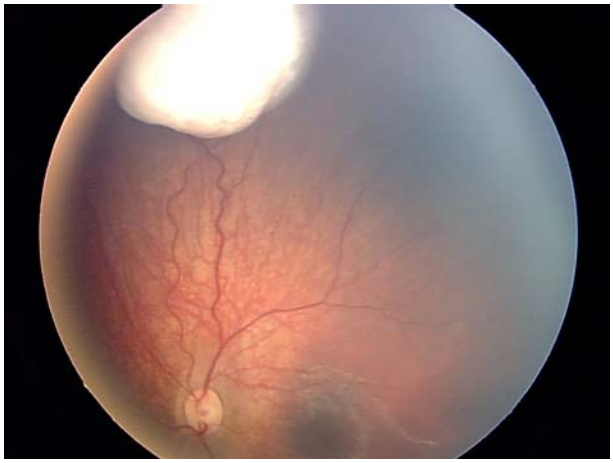

Fig. 1 Uveal melanoma (fundus).

accelerated heavy particles has been used extensively. Compared to brachytherapy and to fractionated stereotactic radiotherapy, proton beam therapy has the advantage of delivering a homogenous dose of radiation to the entire tumor. This is due to the physical properties of accelerated proton beam which deliver the dose precisely with sharp decrease after the delivery point called the Bragg peak (Fig. 1).

The first step to treat uveal melanoma with proton beam is radiological spotting of the tumor by clip positioning. During a surgical procedure, tantalium rings of 2.5 mm in diameter with two holes in the middle are sutured to the sclera around the tumor base that has been visualized by transillumination of the globe. Proton beam therapy is planned and performed 2 weeks after surgery. Head immobilization during radiotherapy is ensured by a custom-made thermoplastic mask associated with a bite block. All the data collected during surgery (axial length, clip measurements, tumor diameter, tumor thickness) are sent to the physicist in charge of the planning of therapy. It is mandatory to have good pictures of the fundus, ultrasonography of the eye and biometry. EYEPLAN software is used for dosimetry based on three-dimensional (3D) reconstruction of the eye, including the tumor. The irradiated volume is the tumor volume plus a safety margin of 2.5 mm around the tumor. The standard dose delivered is 60 Grays in four fractions. During treatment, patients are seated on a robot chair facing the beam and are asked to aim at small target light placed at a known angle adopted during the treatment planning process.

Local control is excellent. The local recurrence rate at 10 years is usually around 5%. Secondary enucleation is performed in 10% to 15% of patients either for complications or for local recurrence. Complications include retinal detachment, maculopathy, papillopathy, cataract, glaucoma, vitreous hemorrhage, and dryness can occur. The most severe complication that usually leads to secondary enucleation is neovascular glaucoma and it is encountered after irradiation of large to extra-large tumors. The toxic tumor syndrome was recently described. It is supposed to result from the residual tumor scar producing proinflammatory cytokines and VEGF, leading to intraocular inflammation and neovascular glaucoma. Additional treatments after proton beam such as TTT (trans pupillary thermotherapy), endoresection of the tumor scar or intravitreal injections of anti-VEGF antibody may reduce the rate of these complications.

Plaque radiotherapy is the best option when proton beam therapy is not available, when the patient's general health precludes proton beam, for small anterior tumors or for tumors situated anteriorly in the superior and external quadrant (where the dose at the entrance of proton beam can cause lacrimal gland atrophy). Iodine 125 seeds can be used. This is a low gamma energy radiation emitting isotope and this radiation can be stopped by heavy metals such as gold or lead. Gold or lead plaques (12–20 mm diameter) are prepared with iodine 125 seeds and sutured on the sclera at the location of the tumor. The usual calculated dose is 90 Grays at the apex of the tumor. The time duration is calculated by the physicist and the plaque is then removed surgically. Ruthenium is a Beta emitting isotope with less penetration and less diffusion. Plaques are already prepared and can be used for multiples applications. It is recommended to avoid the use of ruthenium for tumor with a thickness of >6 mm.

Role of biopsy at the time of local treatment

Ocular oncologists have recently changed their approach to uveal melanoma in most centers. During many years, it has been considered that biopsy was not necessary in the management of uveal melanoma. Diagnostic techniques were reliable enough to allow performing conservative treatment by radiotherapy without histopathological confirmation of diagnosis. More recently it has become evident intraocular biopsies at the time of local treatment are needed to better characterize the disease at cell and molecular level. The techniques of transcleral and transvitreal fine needle aspiration biopsies were published on large series of patients, with very few side effects. Today most centers are able to offer fine needle aspiration biopsies for cytogenetic studies despite in principle risk of tumor dissemination, vitreous hemorrhage and retinal detachment; On the other hand, the benefits for the patient are still

limited as there is still a lack of efficient chemotherapy to prevent metastasis in high-risk patients. Others benefits of genetic studies are the possibility of entering a closer follow-up protocol to detect early liver metastasis and to participate to adjuvant therapy protocols.

Management and follow-up

Besides genetic studies of the primary tumor, the presence of circulating tumor cells could be an indicator for metastatic risk and is currently under evaluation. A few centers have started to use adjuvant therapy protocols. In the past, there has been three published studies on adjuvant therapies in uveal melanoma, one randomized with DTIC, one nonrandomized with interferon and one with intraarterial fotemustine. None of these trials gave statistically significant results. There have been a lot of controversies on how to follow patients that have been treated for uveal melanoma. Early detection of metastasis by repeated liver ultrasonography can allow the surgical resection of localized metastasis and therefore increase survival. Some of the new targeted therapies are active in 10% of metastatic patients. Ultrasonography of the liver every 6 months is usually recommended. Liver MRI is useful, in particular to confirm liver metastasis but TEP scan are sometimes not detecting metastasis from uveal melanoma though they are very sensitive in the case of cutaneous melanoma.

Oncologists have become recently more interested in this disease and many new drugs or protocols are already under trial for metastatic disease. Chemoembolization is employed for the liver but is not useful when the patient has other localizations of the metastatic disease. Vaccine protocols are available in HLA2 patients, with limited success but there is still ongoing work. Current research is investigating the prognosis and predictive significance of transcriptomic analysis. Proteins involved in the migration of tumor cells from the eye to the liver and adhesion and proliferation of the metastasis are being studied.

Other primary intraocular malignancies in adults are very rare. Some rare cases of adenocarcinoma of the pigmented epithelium have been published. Oculocerebral lymphoma is a rare disease due to large cells lymphomas. The vitreoretinal lymphoma is associated generally with central nervous system lymphoma. A typical retinal infiltrate is associated with the presence of abnormal cells in the vitreous. Diagnosis can usually be made by vitreous cytology or more rarely by biopsy of the cerebral lesions. Treatment must be performed in reference centers.

Retinoblastoma

Diagnosis

Retinoblastoma is the most common malignant intraocular tumor in children with an estimated incidence of 1/20,000 live births. Retinoblastoma is the first tumor for which a genetic origin was demonstrated. According to the Knudson hypothesis, retinoblastoma carcinogenesis is dependent upon inactivating mutation on the two alleles of the *RB1* tumor suppressor gene located on chromosome 13q14.2.2. The tumor can arise in a child carrying a germline mutation on one of the two alleles. A second hit mutation of the other allele in a precursor cell is responsible for the appearance of a retinal tumor. This predisposition can be transmitted by a parent carrying the mutation (familial form) or can occur as a de novo event. In this setting, retinoblastoma is usually bilateral or unilateral multifocal and the child is at risk of developing other extra ocular tumors (soft tissue sarcoma, osteosarcoma, carcinoma, high-grade glioma, malignant melanoma). Treatment must take into account the risk of developing second tumors, which can be increased by treatment with mutagenic agents (chemotherapy), X-rays, and radiotherapy. Retinoblastoma occurs almost exclusively in children under the age of 15 years and the median age at diagnosis is lower for the bilateral form (<12 months) than for the unilateral unifocal form (24 months). Early diagnosis is a priority, as it allows the child to be cured with preservation of almost normal vision in at least one of the two eyes. However, despite well-known clinical signs, retinoblastoma is still often diagnosed at an advanced stage, requiring aggressive therapy with a high-risk of enucleation of the affected eye in unilateral forms and of the two eyes in bilateral forms.

The clinical presentation of retinoblastoma is well known. Leukocoria is the presenting sign in 60% of cases, but is often a late sign. At the beginning, leukocoria can be intermittent, only visible in specific direction of gaze or with specific light. If no diagnosis is made, leukocoria become more and more visible and permanent. It can easily be detected on photos with flash especially if the anti-red eye system is disconnected. The second most common early sign of retinoblastoma is strabismus, generally related to a macular tumor. Provided that strabismus is not confused with accommodative strabismus, treatment can be curative and allow preservation of the eye. Less common clinical presentations may also be encountered, generally indicating advanced forms (buphthalmia, neovascular glaucoma, orbital inflammation, phthisis bulbi, etc.), which generally do not allow globe-conserving treatment. The clinical presentation varies according to the stage of the disease and the presence of one or several tumors in either or both eyes, with symmetrical or asymmetrical lesions. The tumor is visible as a white retinal mass with a variable blood supply depending on the size of the tumor and may present calcifications. The tumor (or tumors) may present as an endophytic form, in which the tumor extends into the vitreous, an exophytic form, associated with retinal detachment and subretinal infiltration; or a mixed form, comprising vitreous involvement and retinal detachment. Diffuse infiltrating retinoblastoma is a rare form of retinoblastoma with infiltration of the retina without tumor mass. Examination shows vitreous infiltration and sometimes hypopyon (**Fig. 2**).

Retinoma (or retinocytoma) is a spontaneously arrested or spontaneously regressive form that resembles treated retinoblastoma with a grayer color, intense calcification, and a zone of atrophy around the lesion. These lesions can be detected on ocular fundus examination of a parent of a child with retinoblastoma or in a child consulting for leukocoria or strabismus. These lesions must be carefully monitored in young children, as they can progress to active retinoblastoma (**Fig. 3**).

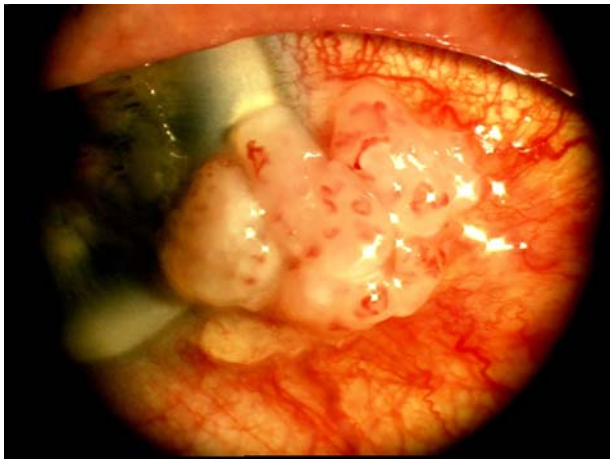

Fig. 2 Leukocoria.

Fig. 3 Retinoblastoma (fundus).

Prognosis

There are also several well-known differential diagnoses (Coats disease, persistent hyperplastic primary vitreous, medulloepithelioma, uveal melanoma in children, retinal detachment due to other causes, *Toxocara canis* infection, etc.). Examination in a reference center and modern imaging comprising duplex Doppler ocular ultrasound and magnetic resonance imaging (MRI) allow confirmation of the diagnosis in the vast majority of cases.

Several classifications have been proposed to address various issues, but none of them are fully satisfactory. The first classification proposed by Reese-Ellsworth was developed in the age of external beam radiotherapy to evaluate the chances of globe-conserving radiotherapy. The second classification, the International Intraocular Retinoblastoma Classification (ABC classification), was developed by Murphree in 2005 in the age of systemic chemotherapy. This classification, ranging from A to E, can be used to estimate the possibility of preserving the eye by systemic chemotherapy in combination with local therapy. This classification remains widely used. The new TNM classification (eighth American Joint Committee on Cancer TNM classification) estimates survival and the chances of preserving the eye by taking into account clinical risk factors (cT), histological risk factors (pT), the presence or absence of a germline mutation (H), and of course the presence of lymph node (N) or distant metastasis (M). Modern MRI imaging is also used for intraorbital and central nervous system staging.

The treatment of retinoblastoma was very much improved during the past 30 years. The cure rate in developed countries is closed to 100%. Radiotherapy has been the treatment of choice until early 1990s but has now been phased out because of the risk of second cancer in the field or radiation that can be as much as 30% in patients carrying RB1 mutation. Chemotherapy is now the treatment of choice. The combination of intravenous carboplatin, vincristine and etoposide found to be active on metastasis is also very efficient on intraocular retinoblastoma. Depending on the severity, patients with bilateral retinoblastoma can be treated with a combination of two to three drugs. More recently the use of intraarterial chemotherapy with melphalan, topotecan, and carboplatin has allowed very impressive regression of the tumors. Chemotherapy can also be injected directly in the vitreous cavity in selected cases. Disseminated metastatic disease or cerebral involvement (pinealoma or metastases via the optic tract) requires intensive chemotherapy with autologous bone marrow transplantation. Cerebral involvement is associated with a poorer prognosis.

The second factor that has improved survival and eye preservation rates is the use of local therapy. Most teams specialized in the treatment of retinoblastoma agree that chemotherapy alone cannot ensure perfect control of intraocular disease but must be combined with local therapy (diode laser transpupillary thermotherapy, laser, cryoapplication, brachytherapy). Early diagnosis, as a result of information campaigns directed to the general population, healthcare professionals, and ophthalmologists, allows ablation of small tumors exclusively by local therapy or a combination of carboplatin and transpupillary thermotherapy. Local therapies can also be also used as second-line treatment for local relapse.

Another important factor for improved patient survival is the establishment of specialized centers comprising multidisciplinary teams composed of ophthalmologists, oncologists, pediatric oncologists, radiation physicians, radiologists, geneticists, anesthetists, and so on. This high level of multidisciplinary competence allows tailored treatments based on the findings of the initial ophthalmological examination, which must be performed under general anesthesia. In centers treating retinoblastomas, genetic information concerning the parents of an affected child and patients treated for retinoblastoma during childhood is essential and germline mutation screening must be systematically proposed, with due consideration to mosaicism.

Chemotherapy

Various drugs are used for intravenous, intraarterial, subconjunctival, or intravitreal chemotherapy depending on the team (most commonly carboplatin, vincristine, etoposide, topotecan, melphalan). Intravenous chemotherapy alone cannot cure retinoblastoma but chemoreduction with intravenous chemotherapy followed or combined with local therapy is still widely used by many teams with recognized efficacy and acceptable systemic toxicity. The intraarterial route of administration developed by Kaneko, using melphalan or topotecan or carboplatin alone or in combination, allows drug administration directly into the ophthalmic artery, thereby limiting systemic distribution of chemotherapy and its adverse effects. Consequently, local administration cannot be used to treat micrometastases in advanced forms of the disease. This route of administration is not devoid of local toxicity on the choroidal and retinal blood supply and must be performed by an experienced team of neuroradiologists. In a large meta-analysis based on 208 publications on the subject, only 28 articles with sufficient follow-up could be analyzed. Most of these studies were retrospective and noncomparative. Enucleation was avoided in 66% of cases and 20 cases of metastases were reported. These cases of metastases probably occurred in the context of treatment of advanced retinoblastoma. Nevertheless, this treatment is very effective in unilateral forms with visual potential (*c*T2 or group C or D). Some authors also use intraarterial chemotherapy to treat bilateral forms. The place of this treatment remains controversial in advanced unilateral forms (*c*T3 or V) regardless of the subgroup in the absence of visual potential. No clear consensus has been reached, as the indications for intraarterial chemotherapy vary from one team to another. No multicenter prospective studies comparing intraarterial chemotherapy and systemic chemotherapy are available and the published studies are all too often retrospective and present excessive bias to allow reliable scientific results.

There is also insufficient follow-up concerning the sensitivity of bone and soft tissues to repeated exposure to low doses of X-rays necessary for catheter positioning by radiologists: these doses are not negligible in the context of constitutional alteration of the *RB1* gene, associated with an increased risk of second tumor (essentially sarcoma) in the irradiated field.

Intravitreal administration of melphalan or topotecan is particularly effective treatment for vitreous seeding. A rigorous technique is essential due to the risk of tumor cell dissemination along the needle track. Some cases of extraocular tumor spread have been described. This phenomenon is probably rare, but several cases that have been reported to the author and have never been published. Compliance with the most commonly accepted doses (20–30 μg of melphalan) is important to avoid major complications, including phthisis bulbi for doses higher than 50 μg.

Radiotherapy and other local therapies

External beam radiotherapy (EBRT) is now rarely used due to the risk of local complications and the major risk of sarcoma in the irradiated field. The incidence of second cancer in the irradiated field, but also outside of the irradiated field, was estimated to be 51% at 50 years by a team in New York on the basis of a very large series. Brachytherapy is generally used for peripheral tumors, usually as second-line treatment. Orbital brachytherapy using rows of iodine 125 plus a plaque can be used instead of EBRT after enucleation in the presence of extraocular tumor spread or positive optic nerve resection margins (pT4), in combination with systemic chemotherapy. Other focal Treatments include triple freeze-thaw cryotherapy with freezing as far as the tip of the tumor for peripheral tumors inaccessible to laser ablation not exceeding a thickness of several millimeters. Laser thermotherapy is used as an adjuvant to chemotherapy or alone for small tumors or localized relapses. We use a diode laser (810 nm) with continuous wavelength delivered via an operating microscope or via the indirect ophtalmoscope. The laser is absorbed at the level of the pigment epithelium and produces energy and hyperthermia of which is synergistic with carboplatin (chemothermotherapy). Duration and intensity is adapted to the size of the tumor and degree of pigmentation (5–20 min, 400–800 mW). A complete ophthalmological assessment, including bilateral dilated ocular fundus examination under general anesthesia, MRI, and a pediatric assessment, is essential before any treatment decisions and should be done in emergency.

Genetic information is essential in familial forms. Prenatal diagnosis is possible if the mutation is identified. Embryo selection and in vitro fertilization of embryos not carrying a constitutional alteration of the *RB1* gene is possible in some countries. Parents must be informed about this possibility. A child born to a parent with a history of retinoblastoma must be examined during the first week of life and, in the absence of visible tumor, must be examined at least monthly under general anesthesia. Small *c*T1a tumors detected on clinical examination or optical coherence tomography can be treated by transpupillary thermotherapy alone.

Retinoblastoma survival is around 95% in high-resource countries but is much less in low-resource countries where diagnosis is often made at late stage and access to care constrained. Programs to improve retinoblastoma care are ongoing in many countries. In low-resource countries the rate of ocular conservation is improving but careful evaluation is needed for treatment, balance of benefits and risk, side effects and long term results and metastatic rate.

Medulloepithelioma

Medulloepitheliomas are very rare, almost always unilateral congenital tumors arising from the ciliary epithelium usually becoming symptomatic between 2 and 4 years of age. They are most often localized in the ciliary body. They often are slow growing but some of them can be very aggressive with possible orbital recurrence or metastasis.

Malignant Conjunctival Tumors

The conjunctiva is the outermost layer of the ocular surface, above the sclera, and also forms a continuous membrane with the innermost layer of the eyelids behind the tarsal plane. Anatomically these regions are described as bulbar and tarsal conjunctiva, and they merge in the conjunctival fornices. Histologically, the conjunctiva is composed of an epithelium, overlying a basal membrane that separates it from the conjunctival stroma, that is densely vascularized, innervated, and contains immune elements. This structure has clinical consequences since most primary conjunctival neoplasia develop initially within the epithelium, and may become invasive when they progress into the stroma, where there is a risk of local spread and distant metastases.

Conjunctival invasive squamous cell carcinoma

Invasive squamous cell carcinoma is a continuation of the spectrum of conjunctival intraepithelial neoplasia (CIN), a minimally aggressive lesion localized to the conjunctival epithelium. Severe CIN, also termed in situ squamous cell carcinoma, can progress through the basement membrane, invade adjacent tissues and become malignant. Invasive squamous cell carcinoma can also metastasize (in $<2\%$ of cases), usually to the regional and cervical lymph nodes. Therefore, CIN is a major risk factors for invasive squamous cell carcinoma. Other identified factors include UV-light exposure, human papillomavirus infection (especially HPV-16, that may be associated to a better prognosis), immunosuppression, especially by human immunodeficiency virus (HIV), associated to more aggressive tumors, and conditions that predispose to epithelial malignancies, such as atopic eczema and xeroderma pigmentosum, a rare genetic skin disorder characterized by an extreme sensitivity to UV light. The reported incidence of invasive squamous cell carcinoma ranges from 0.02 to 3.5 per 100,000, and the disease seems more frequent in men (estimated male–female ratio, 3:1) and in elderly subjects (Fig. 4).

The main diagnostic challenge is the similar appearance of CIN and invasive squamous cell carcinoma, which are sometimes difficult to differentiate clinically. Both lesions develop in the interpalpebral region of the conjunctiva, often adjacent to the limbus, with part of the lesion overlapping the cornea, and can more rarely extend to the conjunctival fornices. Although most frequently affecting elderly Caucasian males, they can be diagnosed at all ages, in both genders, and in patients of all ethnicities. While CIN

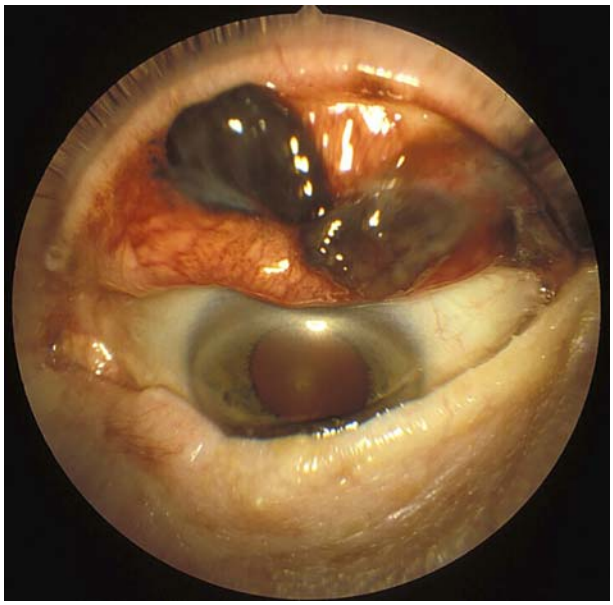

Fig. 4 Conjunctival invasive carcinome.

presents as a fleshy, with moderate elevation and a sessile base, invasive squamous cell carcinoma can have multiple presentations, from a localized gelatinous mass to a large elevated, papillomatous lesion. It is often associated with dilated conjunctival feeder vessels. A frequent feature is the multilobular aspect of the lesion.

Variants of squamous cell carcinoma need to be recognized. The diffuse form, flat and poorly demarcated, may be underdiagnosed. Two aggressive forms, the mucoepidermoid and spindle cell variants (< 5% of conjunctival squamous cell carcinoma) carry a more severe prognosis. The mucoepidermoid form may progress intraocularly with the development of large supra-uveal mucinous cysts. Spindle cell carcinoma is more aggressive locally with a higher risk of distant organ metastases.

Diagnosis should rely on pathological examination after primary complete surgical excision. The characteristic histological features include abnormal keratin-producing epithelial cells with mitotic activity. A small proportion of cases are poorly differentiated with atypical pleomorphic giant cells and dyskeratosis. The main characteristic is that the tumor extends beyond the basal conjunctival membrane into the subepithelial connective tissue. The mucoepidermoid form harbors an epidermoid component with vacuolated cytoplasms and variable mucin accumulation. The spindle cell variant presents with pleomorphic spindle cells of epithelial origin. Differential diagnoses, besides CIN, include all nonpigmented conjunctival malignancies may resemble invasive conjunctival squamous cell carcinoma. Notable entities include amelanotic conjunctival melanoma; mucoepidermoid and spindle cell carcinoma, detailed above; conjunctival basocellular carcinoma, a very rare entity; and diffuse conjunctival extension of eyelid sebaceous carcinoma, that carries a higher metastasis and mortality rates than invasive squamous cell carcinoma and should be recognized.

The local prognosis is related to the risk of local recurrence, which is globally quite high (40%), in the absence of neoadjuvant treatments, such as irradiation, as detailed below. The systemic prognosis is generally favorable and related to the risk of developing metastases. Although rare in invasive squamous cell carcinoma, metastatic disease is conditioned by tumor size, the depth of local invasion, and presence of immunosuppression (especially HIV infection). According to these factors, locoregional extension should be explored at regular intervals by ultrasound exploration of head and neck lymph nodes (for lower risk cases) or Positron Emission Tomography (for higher risk cases).

Regarding treatment, a schematic drawing or preferably a color photograph of the lesion at diagnosis, before any therapeutic intervention is mandatory. Initial management consists in a surgically complete excision, that should be performed with a "no touch" approach similar to pigmented lesions (avoiding direct contact of instruments with the lesion, and replacing instruments for conjunctival suture/reconstruction), given the possibility of presumed epithelial malignancy to be eventually identified as amelanotic melanoma upon pathological analysis. For the same reason, surgery is preferably performed under general anesthesia to avoid orbital seeding. Cryotherapy of tumor margins combined to excision contributes to reduce the risk of local recurrence. If pathological examination confirms the diagnosis of squamous cell carcinoma (or other malignant epithelial tumor), neoadjuvant radiotherapy of the tumoral site by either conventional external radiotherapy, plaque brachytherapy or proton beam irradiation should be performed, according to the initial tumor topography. These treatments allow to reduce dramatically the recurrence rate from 40% to 2%, and their major adverse effect is the acceleration of cataract formation. Topical chemotherapy by mitomycin C eyedrops is indicated as neoadjuvant therapy for CIN. The initial recommended dose is 0.02%, four times daily, two 2-week cycles. In case of relapse, the same treatment at the higher dose of 0.04% is indicated. Interferon eyedrops, administered four times daily for 6 months, are an alternative to mitomycin C, in patients with severe corneal alterations or in those with limited disease.

With adjuvant, topical chemotherapy having widely improved local control and recurrence rates, future developments rely in the higher integration of treatment approaches. In a near future, advances in diagnosis techniques, for instance by impression cytology, and by tumoral genome detection, may improve management of conjunctival epithelial malignancies by allowing their detection and referral to tertiary centers at earlier stages.

Conjunctival melanoma

Conjunctival melanoma is a rare, malignant invasive melanocytic tumor, affecting the bulbar conjunctiva, and more rarely the conjunctival fornices or the palpebral conjunctiva. Its incidence increased with age, and is higher in individuals in their 50–60s or older. It only rarely occurs in subjects younger than 30 years. There seem to be a recent increase in the incidence of conjunctival melanoma, according to data from the United States and Northern Europe. Conjunctival melanoma has a variable, but usually aggressive course, characterized by a tendency to recur often after simple surgical excision. It therefore requires adjuvant treatments to optimize local control. Moreover, conjunctival melanomas frequently metastasize. This tumor is composed by variably pigmented malignant melanocytes (**Fig. 5**).

Commonly recognized risk factors for conjunctival melanoma include lighter skin (although it has been scarcely studied in black-skinned subjects), exposure to UV light (this explains the preferential localization to exposed parts of the conjunctiva, nasal and temporal to the limbus, but does not account for the possibility of melanoma localized in the conjunctival fornices), primary acquired melanocytosis (75% of conjunctival melanoma arise from primary acquired melanocytosis) and conjunctival nevi (25% of conjunctival melanoma arise from conjunctival nevi).

At clinical presentation, conjunctival melanoma usually consists in a nodular pigmented elevation, most often located close or adjacent to the limbus, with possible extension over the corneal epithelium, and usually surrounded by a fine, planar, granular pigmentation of the conjunctiva. Usually sharply demarcated, the borders of the pigmented tumor may be ill-defined, taking the appearance of diffuse of multiple nodules, which often occurs in cases arising over areas of primary acquired melanocytosis. It can occasionally develop in the conjunctival fornices or palpebral conjunctiva, in which case it may remain undetected until the diagnosis is made when the tumor is advanced. Conjunctival melanoma can also be nonpigmented (amelanotic), making it

Fig. 5 Conjunctival melanoma.

difficult to distinguish clinically from malignancies of the conjunctival epithelium. In addition, seeding of the palpebral conjunctiva by continuous contact with a bulbar lesion may occur.

Diagnosis relies on histopathological evaluation after surgical excision, identifying the morphology of malignant melanocytes, that may vary from low-grade spindle cells to epithelioid cells. It affects the basal conjunctival epithelium at early stages, and secondarily invades the stroma. Morphological evaluation may be challenging, for instance in purely fusiform or amelanotic presentations. Immunostaining can be used to identify S-100 protein (sensitive but not specific), HMB-45 or melan-A (more specific), SOX10 (very sensitive and specific), and other proteins expressed by melanoma cells. Ki-67 labeling evaluates the depth of the proliferative activity and help differentiate malignant from naevic pigmented lesions. The pathological evaluation also recognizes preexisting naevi or primary acquired melanocytosis.

Differential diagnoses include conjunctival nevus, primary acquired melanocytosis (with are also risk factors and may coexist with melanoma), ethnic conjunctival melanocytosis in dark-skin subjects, squamous cell carcinoma (difficult to differentiate from completely amelanotic melanomas), ciliary or very peripheral choroidal melanoma with extrascleral extension, conjunctival foreign body (especially long-standing metallic elements progressively surrounded by a brown halo due to perilesional oxidation), and most other benign or malign conjunctival tumors that may harbor variable pigmentation.

Prognosis is hampered by the difficulty to locally control the tumor due to frequent recurrences and the tendency to spread by simple contact, and by the high rate of metastasis (up to 40% 10 years after diagnosis). Preferred sites of metastasis are regional lymph nodes, and follow-up by serial ultrasonography of cervical lymph nodes is mandatory. The particularity of conjunctival melanoma is the serious risk of aggravating the prognosis in cases of mismanagement, especially by improper steps during surgery. Contact of surgical instruments with the tumor itself must be avoided, and new forceps and scissors must be used after excision for repair of the conjunctival defect by either direct suture, or amniotic membrane graft for wider defects. To date, intraorbital disease is treated by orbital exenteration, illustrating the catastrophic course that may result from improper surgical management. Although difficult to estimate, the overall mortality related to conjunctival melanoma is close to 25% at 10 years.

Regarding treatment, as for epithelial malignancies, a color photograph of the lesion at diagnosis, before any therapeutic intervention, is mandatory. The treatment of conjunctival melanoma consists in removing surgically the malignant tissue, and is associated to additional multidisciplinary treatment modalities to limit the risk of recurrence. Surgical excision of the whole tumor with safety margins is the first step. Due to the tendency of melanoma cells to disseminate and develop in seeded tissues, the excision of any pigmented or nonpigmented conjunctival tumors (due to the possibility of amelanotic melanoma resembling spindle cell

carcinoma) should be performed using "no touch" technique under general anesthesia to avoid orbital seeding by local anesthesia infiltration. The tumor should be totally removed, with 2-mm security margins macroscopically devoid of any tumor. In order to limit tumor spread, biopsies must also be avoided, except for diagnostic confirmation of advanced cases requiring orbital exenteration. Additional cryotherapy can be performed on tumor margins to destroy microscopic lesions or invisible primary acquired melanosis. A double freeze-thaw process is recommended, but overtreatment should be avoided due to the destructive effect on underlying ocular structures, and the inflammatory conjunctival reaction. Adjuvant irradiation by plaque brachytherapy or proton beam therapy is performed for invasive forms of conjunctival melanoma. Adjuvant topical chemotherapy by 0.04% mitomycin C (four times daily, two 2-week cycles) aims at treating primary acquired melanosis lesions.

The recent advent of neoadjuvant therapy after surgical excision seems to dramatically reduce recurrences of conjunctival melanoma. Radiotherapy by either proton beam irradiation or plaque brachytherapy has provided ocular oncologists with an unprecedented tool to treat conjunctival melanoma and reduce the rate of recurrences. With now a few years' follow-up, topical adjuvant chemotherapy by mitomycin seems efficient in controlling primary acquired melanocytosis, a major predisposing risk factor that also favors recurrences. Finally, progress remains to be made in the search for efficient treatment strategies for metastatic disease, a frequent course of this aggressive conjunctival neoplasia.

Caruncular malignant tumors

Due to the particular histological origin of the caruncle, an evolutionary remnant of the third eyelid still present in certain species of birds or reptiles, it harbors cutaneous elements such as hair follicle and sebaceous glands, and can be affected by tumors types usually found on eyelids or conjunctiva.

Sebaceous gland carcinoma is a rare malignant tumor arising from sebaceous glands of the caruncle, similarly to eyelid sebaceous gland carcinoma that arises from sebaceous glands of the eyelids. A purely conjunctival variant also exists that develops insidiously as a flat diffuse "pagetoid" lesion at the surface of the conjunctiva. Both forms may pose diagnostic dilemmas. The caroncular/palpebral form may be initially mistaken and managed as a chalazion (a benign meibomian gland cyst), and the diffuse conjunctival form as an ocular surface inflammation (such as chronic conjunctivitis or episcleritis). Histologically, the lesions are composed of pleomorphic cells with prominent nucleoli. A characteristic but not systematical aspect consists in disseminated malignant cells within the conjunctival epithelium, termed "pagetoid infiltrate." If advanced, this infiltrate can replace completely the normal epithelium (in situ carcinoma). Sebaceous gland carcinoma is aggressive and can metastasize, with an estimated mortality of 25% at 5 years. Local treatment relies on surgical excision, that must be complete, and additional cryotherapy or mitomycin C topical chemotherapy.

Caruncular melanoma presents as variably pigmented, noncystic solid lesions. They are diagnosed and managed similarly to conjunctival melanoma. Due to the high risk of seeding into the lacrimal drainage system, because of the proximity of the caruncle to the lacrimal ducts, lacrimal plugs may be employed.

Malignant Orbital Tumors

The orbit is a circumscribed anatomical region where skeletal, muscular, vascular, and neural elements coexist. A wide array of lesions can produce orbital masses, including inflammatory syndromes, thyroid-related extraocular muscle dilation, and benign or malignant tumors of muscular, skeletal, vascular or neural origin. Although rare, malignant orbital tumors should be recognized and appropriately managed. Three of the most important malignancies localizing to the orbit will be detailed in this section.

Rhabdomyosarcoma represents the most frequent orbital malignancy in childhood and teenage. Median age at diagnosis is 8 years but the tumor can develop during the first two decades of life. This tumor derives from skeletal muscle. It is favored by local irradiation, which is of particular importance for the follow-up of children previously irradiated for retinoblastoma, a common treatment modality until the early 1990s. These patients are at higher risk of developing secondary tumors, including rhabdomyosarcoma, with devastating consequences.

Clinical manifestations are nonspecific and result from the orbital volume occupation by the developing tumor. They include proptosis, lateral or vertical globe displacement in primary gaze position, variable eye movement limitations, ptosis of the superior eyelid, eyelid or conjunctival swelling, pain and detection of a palpable protruding mass in most advanced cases. Most often, the mass is localized in the superonasal part of the orbit and the globe is displaced inferiorly and temporally.

Diagnosis relies on radiological suspicion and pathological confirmation. Imaging by computed tomography (CT) scan shows an irregular, moderately demarcated mass generally not involving the extraocular musculature. Magnetic resonance (MR) imaging reveals on T1 an hypointense lesion, as compared to extraocular muscles, and a hyperintense T2 images, enhanced after gadolinium injection. If accessible to biopsy, rhabdomyosarcoma may harbor different cell morphologies, the most frequent being the embryonal type, and the more aggressive the alveolar type. Embryonal type displays skeletal muscle cells at different stages of embryogenesis. The alveolar type displays separated cells with septae resembling pulmonary alveolar structures. Differential diagnoses include anterior or posterior orbital cellulitis, nonspecific orbital inflammation, capillary hemangioma, lymphangioma, rupture dermoid cyst, and any orbital may present as an orbital space-occupying process and should be differentiated from rhabdomyosarcoma.

Prognosis depends on the presence of metastases in distant organs, such as lung or lymph nodes. The local long-term prognosis may also be influenced by the treatment strategy, with patients receiving radiotherapy to the facial and orbital region in their childhood or teenage years at higher risk of developing secondary neoplasias of skin, bone, or soft tissue.

Regarding treatment, initial management is surgical and consists in a biopsy of the orbital mass for diagnosis conformation. When possible, the entire tumor should be removed. Once the diagnostic is ascertained by histopathological evaluation, the treatment relies on radiotherapy and chemotherapy, alone or combined, according to guidelines.

The optimization of irradiation treatment strategies (total dose, dose fractioning, irradiation modality) will hopefully reduce the burden of secondary tumors arising years or even decades after successful management. Progresses in chemotherapeutic approaches may contribute to reduce partially or totally the amount of radiation administered.

Malignant tumors of the lacrimal gland

Approximately 10% of orbital lesions involve the lacrimal gland. Malignant lesions of several histological type can affect the lacrimal gland, associated with different prognosis. Primary epithelial tumors arise from epithelial structures of the lacrimal gland. Nonepithelial neoplasia include inflammatory, infiltrative, lymphoid lesions. Adenoid cystic carcinoma, pleomorphic adenocarcinoma and primary ductal carcinoma are the most frequent epithelial malignant tumors affecting the lacrimal gland, among several histological diagnoses, and will be detailed in this section.

Lacrimal gland malignancies do not have any gender or ethnic predilection. They occur more frequently in middle-aged individuals, with the exception of adenoid cystic carcinoma that showing incidence peak in childhood. The clinical presentation of all tumor types is very similar, reflecting the space-occupying orbital process located superiorly and temporally. The main sign is a progressive, unilateral proptosis, with medial and inferior displacement of the eyeball, possibly associated with pain in the more aggressive types due to local sensitive nerve invasion. Frequently, patients experience progressive diplopia. Posterior neural invasion induces cutaneous hypoesthesia in the territory of the 5th cranial nerve (upper cheek, periocular area).

Diagnosis relies on imaging by CT scan and MRI to visualize a round or oval-shaped mass, located in the superior temporal orbit, possibly displaying irregular contours. Bone erosion is visible on CT scan in case of large, aggressive tumors. These imaging modalities provide certain features suggestive of malignancy, like intralesional calcifications, but cannot distinguish between pathological types. MRI show lesions with low T1 signal, high T2 signal, and moderate enhancement by contrast agents. Diagnosis also requires pathological examination after ultrasound-guided or surgical biopsy, or preferably whole lesion removal. Each histological type harbors distinctive features. Adenoid cystic carcinoma can be cribriform (a pattern described as "Swiss cheese"), sclerosing, basaloid (associated to a worse prognosis), tubular or comedocarcinoma. Pleomorphic adenocarcinoma harbors a proportion of malignant epithelial cells within a benign pleomorphic adenoma. Ductal carcinoma presents proliferative epithelial cells within lacrimal ducts, resulting in cystic dilation. Differential diagnoses include symptoms and signs related to malignant tumors tend to progress more rapidly than in benign lesions. Pain is also more frequently associated to malignant than benign lesions, due to neural invasion. Benign lacrimal gland lesions include pleomorphic adenoma, also termed "benign mixed tumor," and ductal epithelial cysts, also termed "dacryops."

Epithelial malignant neoplasia of the lacrimal gland are aggressive tumors. Prognosis depends mostly on histological subtype, the main factor influencing local invasiveness and the tendency for distant metastases. Treatment includes Irradiation, chemotherapy, and in most advanced cases exenteration.

Improvements in the care of rhabdomyosarcoma patients rely on two major axes. First, better screening of at risk individuals, namely those previously treated for another malignancy in childhood, is needed. Prolonged and sustained follow-up in tertiary centers with standardized imaging protocols will improve the detection of new tumors, and the understanding of risk factors and progression patterns of these secondary tumors. Second, current improvements in therapeutic modalities by mini-invasive or endoscopic orbitofacial surgery, brachytherapy, optimized external irradiation, and pharmaceutical approaches may hopefully improve the local and systemic prognosis of these aggressive tumors.

Orbital metastases

The tumors that have the higher propensity for seeding metastases to the orbit are carcinomas of the breast, lung, kidney, prostate, and gastrointestinal system. Recognizing orbital metastases is of importance since in 20% of cases patients have no history of cancer and orbital metastasis is the revealing manifestation of the primary neoplasia. Orbital metastases follow the age distribution of solid organ tumors and are more common in elderly subjects. They are very rare in children. They manifest with the classical signs of orbital space-occupying lesions, with a very rapid onset and progression, and frequent pain. Paradoxically, certain tumors induce endophthalmos rather than proptosis, like breast or gastric neoplasia, that tend to induce tissue contraction.

Regarding diagnosis, some primary cancer types have preferential localizations within the orbit, visible on imaging. For instance, breast cancer localizes to soft orbital tissue and prostate cancer tends to localize to bone. Several cancer types generate demarcated, oval-shaped orbital metastases that resemble benign lesions. A biopsy is mandatory to ascertain the nature of an orbital mass and its benign or malign characteristics. The final diagnosis is made by the pathologist (or cytologist, when only needle aspiration is feasible instead of surgical biopsy), who identifies the histological nature of the primary neoplasia. Differential diagnoses include all intraorbital lesions and should be explored by cytological, or preferably histological analysis. Ultrasound-guided biopsy for cytological analysis is a diagnostic option for lesions not accessible surgically, or for patients unfit for invasive orbital surgery. Certain metastases from epithelial tumors in distant organs pose a diagnostic challenge because they may lack specific histological features to distinguish them from orbital, conjunctival or eyelid epithelial neoplasia.

Orbital metastases indicate advanced metastatic disease and are classically associated to a poor prognosis. They are frequently associated to brain metastases. Nonetheless, advances in chemotherapy, especially drugs modulating the immune system, seems to

improve the survival of metastatic patients. Treatment involves irradiation, chemotherapy, or hormone treatment are possible management strategies for orbital metastases, depending on the primary tumor type, stage and general status of the patient.

Progress in fine-needle, ultrasound-guided biopsy techniques should improve diagnostic procedures. Novel chemotherapeutic agents may bring new possible treatment lines for advanced metastatic disease in many different primary neoplasia, variably effective on metastatic disease. However, despite of the rich vascularization of the orbit supplying the eye and extraocular musculature, intraorbital spaces are moderately accessible to oral or intravenous drug administration. Progress in drug delivery to the orbit will improve the management and prognosis of orbital metastases.

Glossary

Radial growth phase (RGP) An atypical melanocytic proliferation that enlarges along the radii of an imperfect circle and is limited to epidermis and superficial dermis. Clinically, the lesion tends to be relatively flat with oval or circular borders. Clark used the term RGP to describe the clinical peripheral enlargement of melanoma, but not the growth direction of melanocytic cells, as they may grow upward in the epidermis, downward into the papillary dermis, or peripherally, determining enlargement of the margins. Melanoma in situ and invasive melanoma that has not yet metastasized, are in the radial growth phase.

Vertical growth phase (VGP) An atypical melanocytic proliferation that expands as a spheroidal nodule in the dermis and is associated with the risk of subsequent metastatic disease. Clark used the term VGP to describe the focal appearance within the radial growth phase of a new clone of melanocytic cells, which is characterized by a distinct expansive growth preference, similar to that of a metastasis.

Nomenclature

AKT AKT serine/threonine kinase
ALK ALK receptor tyrosine kinase
ARAF A-Raf proto-oncogene, serine/threonine kinase
ARID2 AT-rich interaction domain 2
ATM ATM serine/threonine kinase
BAP1 BRCA1 associated protein 1
BRAF B-Raf proto-oncogene, serine/threonine kinase
BRCA1 BRCA1, DNA repair associated
BRCA2 BRCA2, DNA repair associated
CCND1 Cyclin D1
CDH1 Cadherin 1
CDH11 Cadherin 11
CDK4 Cyclin-dependent kinase 4
CDKN2A Cyclin-dependent kinase inhibitor 2A
CHEK2 Checkpoint kinase 2
CIMP CpG island methylator phenotype
CM Cutaneous melanoma
CN Congenital nevus
CRAF Raf-1 proto-oncogene, serine/threonine kinase
CSD Cumulative solar damage
CTNNB1 Catenin beta 1
CYSLTR2 Cysteinyl leukotriene receptor 2
DDX3X DEAD-box helicase 3, X-linked
EGFR Epidermal growth factor receptor
EIF1AX Eukaryotic translation initiation factor 1A, X-linked
ERBB1 Erb-B2 receptor tyrosine kinase 1
ERBB2 Erb-B2 receptor tyrosine kinase 2
ERK Extracellular signal-regulated kinase
EZH2 Enhancer of zeste 2 polycomb repressive complex 2 subunit
FBXW7 F-box and WD repeat domain containing 7

FoxP3 Forkhead box P3
GAB2 GRB2 associated binding protein 2
GDP Guanosine diphosphate
GNA11 G protein subunit alpha 11
GNAQ G protein subunit alpha q
GTP Guanosine triphosphate
HER2 Human epidermal growth factor receptor 2
HRAS HRas proto-oncogene, GTPase
IDH1 Isocitrate dehydrogenase (NADP+) 1, cytosolic
IDO Indoleamine-2,3-dioxygenase
IκB Inhibitor of kappa B
KDR Kinase insert domain receptor
KIT KIT proto-oncogene receptor tyrosine kinase
KRAS KRAS proto-oncogene, GTPase
LM Lentigo maligna
LMM Lentigo maligna melanoma
MAP2K1 Mitogen-activated protein kinase kinase 1
MAPK Mitogen-activated protein kinase
MBN Melanoma arising in blue nevus
MC1R Melanocortin-1 receptor
MCN Melanoma arising in congenital nevus
MEK MAPK/ERK kinase
MET MET proto-oncogene, receptor tyrosine kinase
MITF Microphthalmia-associated transcription factor
mTOR Mechanistic target of rapamycin kinase
NF1 Neurofibromin 1
NFKBIE NFKB inhibitor epsilon
NF-κB Nuclear factor kappa-light-chain-enhancer of activated B cells
NGS Next-generation sequencing
NM Nodular melanoma
NMSC Nonmelanoma skin cancer
NRAS NRAS proto-oncogene, GTPase
NTRK1 Neurotrophic receptor tyrosine kinase 1
NTRK3 Neurotrophic receptor tyrosine kinase 3
PALB2 Partner and localizer of BRCA2
PDGFRA Platelet derived growth factor receptor alpha
PD-L1 Programmed death ligand 1
PI3K Phosphatidylinositol 3-kinase
PIK3CA Phosphatidylinositol 4,5-bisphosphate 3-kinase catalytic subunit alpha
PIP2 Phosphatidylinositol 4,5-bisphosphate
PIP3 Phosphatidylinositol 3,4,5-trisphosphate
PLCB4 Phospholipase C beta 4
POT1 Protection of telomeres 1
PPP6C Protein phosphatase 6 catalytic subunit
PREX2 Phosphatidylinositol-3,4,5-trisphosphate dependent Rac exchange factor 2
PTEN Phosphatase and tensin homolog
PTPN11 Protein tyrosine phosphatase, nonreceptor type 11
RAC1 Rac family small GTPase 1
RAD50 RAD50 double strand break repair protein
RAF1 Raf-1 proto-oncogene, serine/threonine kinase
RB1 RB transcriptional corepressor 1
RET Ret proto-oncogene
RGP Radial growth phase

RICTOR RPTOR independent companion of MTOR complex 2
ROS Reactive oxygen species
ROS1 ROS proto-oncogene 1, receptor tyrosine kinase
RTK Receptor tyrosine kinase
SF3B1 Splicing factor 3b subunit 1
SNX31 Sorting nexin 31
SOS1 SOS Ras/Rac guanine nucleotide exchange factor 1
SPRED1 Sprouty related EVH1 domain containing 1
SSM Superficial spreading melanoma
STK19 Serine/threonine kinase 19
TACC1 Transforming acidic coiled-coil containing protein 1
TCGA The Cancer Genome Atlas
TERT Telomerase reverse transcriptase
TET Tet methylcytosine dioxygenase
TME Tumor microenvironment
TP53 Tumor protein p53
UM Uveal melanoma
UV Ultraviolet
VEGFR2 Vascular endothelial growth factor receptor 2
VGP Vertical growth phase
WT Wild-type
WT1 Wilms tumor 1

Introduction

The approach to the classification of melanoma has evolved from the traditional clinicopathologic to a novel molecular classification. Based on recent knowledge, it is generally agreed that melanoma definition cannot be exclusively confined to the cytoarchitectural morphology observed under light microscope, since melanoma molecular features are much more intricate, and genetics has a remarkable clinical impact for effective systemic therapy. Cutaneous melanoma is the malignant tumor with the highest mutation load and a prevailing cytosine to thymine nucleotide transition signature, which is attributable to UV radiation. While such a signature has been found to be a characteristic of melanoma arising on sun-exposed skin, acral and mucosal melanomas have been shown to have structural changes and mutational signatures not related to UV radiation damage. The most significantly mutated genes in cutaneous melanoma are BRAF, NRAS, CDKN2A and TP53, in acral melanoma NRAS and NF1, in mucosal melanoma SF3B1, and in 80%–90% of uveal melanomas GNAQ or GNA11, whose mutations are mutually exclusive and happen early in the pathogenesis.

Overall, the most frequent mutations are those in noncoding DNA sequences and involve the TERT promoter. The TERT gene encodes the catalytic subunit of telomerase, and its transcriptional regulation is usually the limiting step in telomerase activity. Telomerase activity is usually silenced in normal tissues, causing telomeres to shorten with each successive round of cell division. The expression of telomerase is considered a hallmark of tumorigenesis, as over 90% of human cancers express the enzyme, including melanoma. TERT mutation results in cell immortalization by extension of the replicative lifespan of cells, allowing them to avoid replicative senescence in response to critical telomere shortening.

In addition, whole-genome sequencing of melanoma has unveiled how different mutational pathways are implicated in melanoma pathogenesis contributing to the development of targeted therapies.

The molecular perspective has developed as a reinterpretation of the clinicopathological classification on the basis of genotype–phenotype correlation. As proposed by Bastian, the taxonomy of melanocytic neoplasia is structured according to a dichotomous approach that differentiates lesions that originate from intraepithelial melanocytes, and are variably associated with UV radiation damage, from those lesions arising from nonintraepithelial melanocytes that can be uveal or nonuveal (brain, visceral organs, and proliferation in the dermis). While the first type of lesion is correlated with patient's age, the second type does not show strict correlation with age distribution, with the exception of melanoma on congenital nevus, which occurs primarily in children.

Melanomas can be considered as a group of biologically distinct categories showing differences in age and ethnic distribution, clinical and histological features, pattern of metastasization, etiopathogenetic role of UV radiation, primary oncogenic mutations, somatic alterations, and pathways of mutational mechanisms. Furthermore, analysis of The Cancer Genome Atlas (TCGA), mainly in metastatic melanoma dataset, has indicated that, independently of the oncogenic mutations (BRAF, NRAS, NF1), melanomas with immune signature have a better survival than those without immune signature. According to presence or not of an immune

signature, two major subsets of melanomas characterized by the presence or absence of a gene expression profile indicative of a pre-existing T cell-inflamed tumor microenvironment (TME) have been described. The T cell-inflamed subset of tumors is characterized by a type I Interferon transcriptional profile, the presence of T cell transcripts, T cell recruitment through chemokines and macrophage activation markers. Accordingly, immunohistochemistry confirms the positivity for CD8+ T cells, macrophages, and some B cells and plasma cells. While a subset of T cells specific for tumor antigens is present in tumor microenvironment, functional analysis indicates various degrees of dysfunction of these T cells due to immune suppressive mechanisms acting at the level of the TME. Transcripts encoding IDO, PD-L1, and FoxP3 and positivity for PD-L1 and IDO protein expression, and also nuclear FoxP3 + CD4+ cells by immunohistochemistry, are present within T cell-inflamed melanomas in the same region as CD8+ T cells. This immune adaptive resistance feature represented a clinical challenge recently addressed by the adoption of immune checkpoint inhibitors, which unleash the immune system against melanoma.

Genetic Features

Cutaneous melanoma originates in melanocytes, whose biology and role in melanin production have been well studied and characterized. Melanin plays a role in the dispersion of UV radiation and in the absorption of reactive oxygen species (ROS); physiologically, the protein product of the TP53 gene plays a crucial role in melanocytes for the control of cell response to DNA damage related to increased UV exposure and ROS levels. In particular, the damage to DNA induced by UV rays determines specific mutational signatures, many of which are driven by TP53, which therefore define the frequent events of melanomagenesis in the skin. Considering data from TCGA and the results of the main initial studies with screening approaches based on mutational analysis of the entire exome/genome by next-generation sequencing approaches, cutaneous melanoma has been shown to possess a very high prevalence of somatic mutations, both in primary lesions and—at an even higher level—in metastatic lesions (Fig. 1). The mean mutation rate of cutaneous melanoma, calculated by TCGA from whole-exome sequencing of 318 primary and metastatic melanomas originating from nonglabrous (hair-bearing) skin, has been estimated ranging from 18 to 21 mutations per megabase, which is among the highest rates reported for any type of cancer, with the exception of colorectal cancer carrying deficient mismatch repair (MMR) mechanisms. Approximately three-fourths (range, 69%–82%) of these genomic variations are represented by C>T substitutions, which is associated with another small fraction (about 4%–5%) of CC > TT transitions; all these variants were strictly dependent on a mutagenic effect of UV rays and typically cause the so-called *UV signature*. Overall, the mutation rate in melanomas

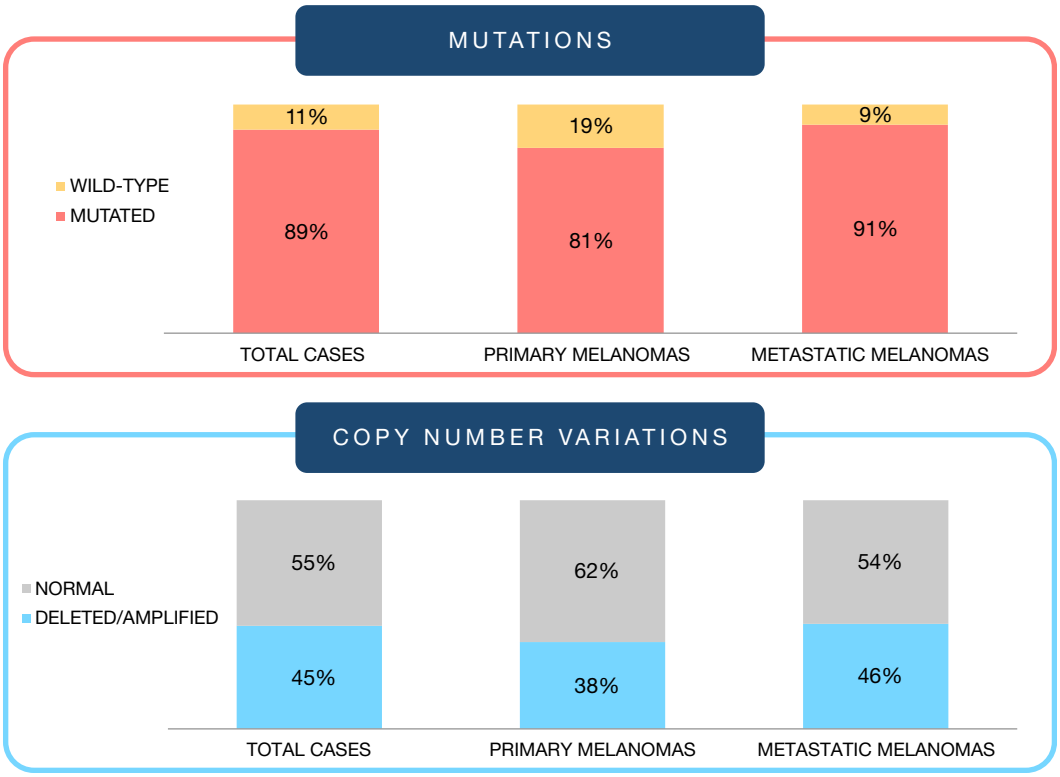

Fig. 1 Mutations and copy number variations in primary and metastatic melanomas. Nine out of ten melanomas are genetically mutated. Copy number alterations are present in 45% of cases. The frequency of mutations and copy number variations increases significantly from primary to metastatic lesions; indeed, metastatic melanomas have a higher mutation burden.

arising on chronically sun-exposed skin was approximately five times higher compared to those on skin not subject to chronic damage by the sun. Finally, UV signature appears to be slightly more prevalent in metastatic lesions (about 85% of the total amount of detected mutations) than primary tumors (about 75%).

About 10% of melanomas occur in families with increased recurrence of the disease, sometimes associated with the presence of other neoplastic diseases (such as pancreatic carcinoma or brain tumors). Approximately, 40% of these familial melanomas are due to hereditary transmission of mutations in high penetrance susceptibility genes, including *cyclin-dependent kinase inhibitor* 2A (CDKN2A; the most frequently mutated gene for predisposition to melanoma, located on chromosome 9p21), *cyclin-dependent kinase 4* (CDK4; 12q14), *breast cancer gene 1 (BRCA1)-associated protein 1* (BAP1; 3p21), *telomerase reverse transcriptase* (TERT; 5p15), *protection of telomeres 1* (POT1; 7q31), and *microphthalmia-associated transcription factor* (MITF; 3p13—susceptibility is quite exclusively associated with the intermediate risk variant pE318K). Carriers of BAP1 mutations show an intermediate risk for cutaneous melanoma (CM), which becomes much higher in families with coexistence of CM cases and uveal melanoma (UM): 3% in UM cases (population based), 15% in CM families, and 28% in CM–UM families. Overall, carriers of germline mutations in CDKN2A/CDK4 and BAP1 genes may present an increased predisposition to either cutaneous melanoma (for BAP1, also to other melanoma subtypes such as UM; for CDKN2A/CDK4, also to higher prevalence of atypical melanocytic nevi), either to an increased incidence—though with a penetrance markedly lower than melanoma—of other types of cancer (particularly, pancreatic and renal carcinoma, brain tumor and mesothelioma). In about 60% of families with melanoma recurrence, the predisposition to the disease is probably due to the combination of variants—both mutations and functional polymorphisms (the latter often associated with specific environmental exposure conditions)—in susceptibility genes with a lower penetrance. In other words, the increased predisposition to melanoma would seem to be linked to the inheritance of specific patterns of genetic alterations rather than mutations in single, stronger susceptibility genes (hence, the difficulty encountered so far in identifying additional melanoma-predisposing genes).

In addition to the model of dominant inheritance described above, melanoma may represent a subordinate malignancy in the context of other tumor syndromes. Members of families with rare hereditary syndromes—such as Cowden syndrome (due to mutations in PTEN), Li Fraumeni syndrome (TP53 mutations), Lynch syndrome (inactivation of genes controlling DNA mismatch repair mechanisms) and xeroderma pigmentosum (mutations in multiple predisposing genes)—or relatively more common genetic conditions, such as hereditary breast and ovary cancers (mainly, mutations in BRCA1–2, but also mutations in ATM, CDH1, CHEK2, PALB2, PTEN, RAD50, TP53), present a poorly defined but higher risk of melanoma.

All these observations strongly support the hypothesis that the pathogenesis of melanoma is complex and involves both genetic and nonhereditary or extrinsic factors.

Molecular Pathways

Summarizing the data generated by the main NGS analyses on the whole-exome/genome, the molecular pathways involved in the melanoma pathogenesis depend on the following genes: BRAF (able to activate the pathway downstream, which includes two effector proteins MEK and ERK), NRAS (whose activation is able to promote the activity of downstream pathways: BRAF-MAPK and PI3K-AKT), NF1 (able to induce the activation of NRAS), CDKN2A (able to activate the pathways dependent on the two proteins encoded by this tumor suppressor gene: $p16^{CDKN2A}$-CDK4-RB and $p14^{CDKN2A}$-MDM2-p53 pathways), and PTEN (activating the PI3K-AKT-mTOR pathway). From a therapeutic point of view, besides BRAFV600, there are no alterations currently considered relevant in clinical decision making. Testing for NRAS or NF1 mutations is largely a matter of identifying patients who are potential candidates for clinical trials. Preliminary evidence supports the importance of CDKN2A and/or PTEN inactivation as mediators of acquired resistance to BRAF inhibitor-based therapy, but these alterations cannot be currently considered routinely in clinical decision making.

BRAF

The RAF kinase family consists of three proteins (ARAF, BRAF, and CRAF), all of which are part of the signal transduction cascade named mitogen-activated protein kinase (MAPK) pathway. In melanoma, the BRAF gene is mutated in 45%–50% of cases; the most prevalent mutation (about 90% of cases) is represented by a substitution of a valine with glutamic acid at codon 600 ($BRAF^{V600E}$). The remaining BRAF mutations often occur at the same codon (V600-K/D/R); therefore, mutations in codons other than V600 are not very common (among them, K601 is the most prevalent). The constitutive oncogenic activation of BRAF—through a process of phosphorylation of MEK and ERK, the effectors immediately downstream of the MAPK pathway—promotes a continuous, uncontrolled stimulation of cell proliferation. There is an inverse relationship between BRAF mutation prevalence and age-decade. The majority of patients <30 years and 25% ≥ 70 years harbor a BRAF-mutant melanoma. Among BRAF-mutant melanomas, the frequency of non-V600E genotypes (including V600K) raises with increasing age. Non-V600E genotypes have been found in <20% of patients <50 years and >40% in those ≥ 70 years. A higher degree of cumulative sun-induced damage correlates with V600K but not V600E melanoma. Melanomas that carry BRAF mutation are characterized by an enrichment of alterations in PTEN, corroborating the frequent coexistence of BRAF and PTEN mutations in melanoma. At the same time, a large fraction of melanomas with mutated BRAF exhibits a reduced or absent expression of $p16^{CDKN2A}$ or p53 proteins, due to the coexistence of mutations inactivating the corresponding genes (CDKN2A and TP53, respectively). The demonstration that BRAF is mutated

in a large fraction (65%–80%) of common nevi suggests that its oncogenic activation is a necessary but not sufficient condition for the development of melanoma (in fact, it is considered an initiation event in melanocyte transformation). Therefore, the onset of alterations in other genes able to cooperate with BRAF seems to act as the main mechanism underlying the transformation and neoplastic progression in the melanocytic lineage. It has finally been demonstrated that some genetic variants of the *melanocortin-1 receptor membrane receptor* (MC1R) are not able to adequately stimulate the production of melanin protecting the skin from the damage of UV rays. The combination of the presence of such variants of MC1R and exposure to UV rays (especially, when intermittent) was also considered responsible for the oncogenic activation of BRAF in this specific subgroup of melanomas.

RAS

The products of the RAS family are composed of three tissue-specific isoforms: HRAS, KRAS and NRAS. NRAS mutations are found in 20%–25% of melanoma cases; again, they occur almost exclusively in a single gene codon (Q61, about 90% of cases); in the remaining 10% of cases, the mutated codon is G12 or G13. The oncogenic stimulation of RAS is able to activate specific cytoplasmic downstream proteins with kinase function: RAF and *phosphatidylinositol 3-kinase* (PI3K).

RAS mutations have been demonstrated to be mutually exclusive with BRAF mutations in nearly all cases (coexistence of the two genes mutated in a constitutive manner are reported in a fraction of cutaneous melanomas, $<2\%$–3% of cases). It has been observed that, in the presence of NRAS activation (both for the acquisition of mutations or functional oncogenic induction), the translation of the mitogenic signal in the MAPK pathway can be switched to CRAF, which therefore acquires a key role in maintaining cell proliferation stimulation in this subset of melanomas. Interestingly, an increased activation of CRAF, as well as the presence of NRAS mutation, have been described as responsible for the acquired resistance to BRAF inhibitors.

In addition to BRAF, genetic alterations (mutations and gene copy number changes) in other important components of pathways downstream of RAS that control cell proliferation and survival—including PIK3CA (altered in 5% of cases) and AKT3 (8%)—occur at lower frequency. In fact, a vast majority of the PI3K-PTEN/AKT genes downstream of RAS are functionally silenced in melanoma. In this pathway, an exception is represented by a markedly higher frequency of mutations (about one fifth of melanomas in NGS studies) in the PREX2 gene regulating PTEN.

A limited fraction of melanomas that are not mutated in BRAF and RAS may carry activating mutations in KIT, a tyrosine kinase receptor of the cell membrane, resulting in a continuous induction of cell proliferation, through functional stimulation, mainly of the MAPK pathway. In particular, KIT mutations have been described in acral melanomas (about 10% of cases) and in those from chronically sun-exposed skin areas (5% of cases) among cutaneous melanomas, showing, however, the highest prevalence in mucosal melanomas, particularly in anal melanomas (15%–20% of cases).

NF1

Germline mutations in NF1 cause an inherited multisystem genetic disorder, neurofibromatosis type 1, which is characterized by changes in skin coloring pigmentation, as well as the growth of both benign and malignant tumors. In preclinical models, NF1 mutation suppresses BRAF-induced senescence in melanocytes, promoting melanocyte proliferation and enhancing melanoma development. The Cancer Genome Atlas has also identified a subset of melanomas (approximately 15% of cases) in which activation of the MAPK pathway is due to inactivating mutations of the NF1 gene. Physiologically, NF1 encodes for neurofibromin, a RAS-GTPase-activating protein, which negatively regulates *RAS* signaling by facilitating hydrolysis of RAS-GTP to the RAS-GDP-inactive form; therefore, mutations functionally silencing NF1 result in RAS activation. In this perspective, the activation of several RASopathy genes—such as SOS1, PTPN11, RAF1, and SPRED1—appears to occur more frequently in subtypes of melanomas with NF1 mutations. At the same time, these data are a clear demonstration that NF1 cooperates with other RASopathy genes in melanomagenesis. Although the mutations of NF1 are the most prevalent alterations in the group of BRAF and RAS wild-type melanomas (about two-fifths of these cases, which, however, represent 4%–5% of the total cutaneous melanomas), they are present at almost the same frequency in BRAF- and RAS-mutated melanomas (3%–4% of cases). NF1 is a key driver of melanoma, and this is suggested by three biological features: (i) a high frequency of nonsilent exonic mutations, (ii) a low frequency of synonymous or intronic mutations, (iii) it occurs in a considerable portion of studied melanoma specimens.

Melanomas with NF1 mutations generally occur on chronically sun-exposed skin or in elder individuals and show a high mutation burden. Additionally, NF1 mutations characterize certain clinicopathologic melanoma subtypes, specifically desmoplastic melanoma. Unlike BRAF-mutated melanomas, those with the NF1 subtype have a stronger correlation with the UV-induced mutagenesis. Overall, occurrence of mutations in NF1, alone or associated with BRAF or RAS mutations, induces a higher mutational load and, consequently, a greater probability of generating neoantigens. Due to this increased antigen capacity, tumors with mutations in NF1 and/or constitutive activation of RASopathy genes are thought to be addressed to immunotherapeutic treatment with immune checkpoint inhibitors.

In several melanoma cell lines, there is evidence that NF1 ablation decreases the sensitivity of melanoma to BRAF inhibitors. NF1 mutations are present in BRAF-mutant tumors intrinsically resistant to BRAF inhibitors, as well as in melanomas of patients showing resistance to BRAF inhibitors. Correspondingly, NF1/BRAF-mutant murine tumors are resistant to BRAF inhibitors but sensitive to combined inhibition of MAPK/ERK and mTOR pathways.

Triple Wild-Type Melanomas

According to TCGA classification, cutaneous melanoma can be categorized into four genetic subgroups on the basis of MAPK driver mutations: BRAF, RAS (N-H-K), NF1 (lacking a BRAF p.V600 or RAS p.G12, G13 and Q61 hotspot mutation) and *Triple wild-type* (*WT*) melanomas.

Triple wild-type melanomas represent a genetic distinct entity for several reasons: (i) only ~30% of *Triple WT* melanomas harbor a UV signature compared with over 90% considering the other three molecular subtypes; (ii) somatic copy number analysis shows that *Triple WT* melanomas comprise a significant number of cases with copy number amplifications; amplicons include the 4q12 minimal common region containing KIT, PDGFRA and KDR (also known as VEGFR2), as well as amplifications in loci encompassing TERT, CDK4 and CCND1; (iii) *Triple WT* melanomas have more complex structural rearrangements and candidate fusion drivers, although few recurrent fusions have been described so far.

CDKN2A

The CDKN2A gene encodes two proteins: $p16^{CDKN2A}$ and $p14^{CDKN2A}$. It acts as tumor suppressor gene in a recessive manner; inactivation of both alleles is necessary for the development of melanoma. In patients with melanoma familiarity, 20%–40% of probands may carry germline mutations in CDKN2A. At the somatic level, about two-thirds of melanoma patients instead present a CDKN2A gene inactivation; these melanomas seem to be resistant to BRAF inhibitors, or to BRAF and MEK inhibitors. In particular, activation of the downstream CDK4-RB effectors through inactivation of $p16^{CDKN2A}$ seems to be correlated with disease progression; indeed, its prevalence significantly increases during transition from primary tumors to metastatic melanomas and melanoma cell lines. Similarly, the inactivation of $p14^{CDKN2A}$ causes the reduction of the p53 protein levels, with consequent impairment of the cell-cycle progression control and inhibition of the apoptosis, contributing to increase the aggressiveness of tumor cells and their refractoriness to therapy. Activation of the CDKN2A-dependent pathway may also be associated with the amplification of the CyclinD1 (CCND1) gene, which is generally found in melanomas negative for BRAF and NRAS mutations. However, in a fraction (about 15%) of mutated BRAF melanomas, the coexistence of CCND1 amplification seems to confer resistance to BRAF inhibitors.

PI3K-PTEN

In addition to MAPK, the second cell regulating pathway—mainly dependent on RAS activation—consists of the PI3K protein pathway which is characterized by signal transduction through the PTEN, PI3K, and AKT (in particular, the AKT3 isoform in melanoma) protein cascade. Oncogenic activation of the PI3K pathway can occur through several mechanisms, including: mutation and/or amplification of genes encoding RTKs (e.g., EGFR (*ERBB1*) and HER2 (*ERBB2*)), subunits of PI3K (e.g., p110α, p110β, p85α, and p85β), AKT (*AKT1*), or activating isoforms of RAS. Within the PI3K/AKT/mTOR pathway, AKT plays a major role, being at the crossroad and implicated in the oncogenic mutation, the immunotolerance, and the developing of de novo and acquired treatment resistance in various tumor types treated with targeted therapies. Furthermore PTEN (encoding phosphatase and tensin homolog, the major PIP3 phosphatase) is frequently mutated.

In physiological conditions, the phosphatase activity of the PTEN protein reduces the intracellular level of the PIP2 and PIP3 phosphoinositoles, which are produced by the activation of PI3K, in order to regulate the activation level of downstream AKT and its mTOR substrate, thus modulating the synthesis of proteins involved in apoptosis and cell survival. In melanoma, the PTEN gene is deleted in about a third of cases, with complete loss of expression of the corresponding protein in 10%–20% of primary melanomas; the level of this loss increases during neoplastic progression, up to 40%–50% in melanoma cell lines. The combined effect of the PTEN loss and the PI3K-AKT pathway activation results in aberrant growth of melanoma cells and increased survival capacity with the acquisition of apoptosis resistance.

All of these findings clearly indicate that there are distinct molecular subtypes of melanoma; the well-characterized ones are summarized in **Table 1**. From a practical point of view, the characterization of these subtypes becomes extremely important for an increasingly correct therapeutic approach and an appropriate definition of clinical–biological behavior in patients with melanoma.

Epigenetic Events

Alongside the genetic alterations, data are emerging that increasingly support a role of epigenetic events in the development and progression of melanoma. The latter are defined as inheritable alterations in gene expression without a change in the DNA sequence. Main epigenetic modifications include:

- posttranslational modifications of histones and remodeling of nucleosomal complexes;
- methylation of cytosine–guanine (CpG) dinucleotides from accessible DNA;
- gene silencing by noncoding RNAs, either short or long, whose expression can in turn be directly regulated through epigenetic modifications of the corresponding genes.

Table 1 Main molecular subtypes of melanoma: frequent mutations and rearrangements

Subtype	*Most frequently mutated genes (≥ 10%)*	*Less frequently mutated genes (< 10%)*	*Rearranged genes*
BRAF mutant	TP53, CDKN2A, PTEN, ARID2	PPP6C, NF1, MAP2K1, RAC1, IDH1, DDX3X, SNX31, TACC1, CTNNB1, PREX2, PIK3CA, STK19, EZH2, FBXW7, RB1, WT1	CDKN2A-del, CCND1-ampl, PTEN-del, MITF-ampl, TERT-ampl
RAS mutant	CDKN2A, TP53, ARID2, NF1, PPP6C	DDX3X, RAC1, IDH1, PTEN, MAP2K1, RB1, TACC1, PREX2, CTNNB1, FBXW7, PIK3CA, STK19, WT1	CDKN2A-del, PTEN-del, CCND1-ampl, TERT-ampl, MITF-ampl, KIT-ampl, CDK4-ampl
$BRAF^{neg}/RAS^{neg}$ mutant	NF1, TP53, ARID2, RAC1	KIT, CDKN2A, PTEN, IDH1, MAP2K1, RB1, SNX31, PPP6C, PIK3CA, STK19, EZH2, WT1, PREX2	CDKN2A-del, CCND1-ampl, PTEN-del, TERT-ampl, CDK4-ampl, KIT-ampl, MITF-ampl

del, gene deletion; ampl, gene amplification.

A particularly interesting result is given by the fact that the CpG island methylator phenotype (CIMP) is able to stratify patients with melanoma. The CIMP defines tumors that have a higher level of overall DNA methylation associated with a state of hyper-methylation of the CpG islands. The CIMP, initially observed in colorectal carcinoma, has been described in various other types of cancer, including melanoma. The TCGA highlighted the occurrence of a hyper-methylation status in both primary and metastatic melanomas (in some cases, as for CDH11, gene transcription is active only in the lymph nodes and not in the primary tumor). Hyper-methylation seems to be associated with mutations in most of the genes mainly involved in melanomagenesis (the RAS-mutated subtype is associated with CIMP to a greater extent than the BRAF-mutated subtype). Somatic mutations of the ARID2 and IDH1 genes, both involved in chromatin remodeling, appear to be significantly associated with the CIMP cluster. In particular, IDH1 (located on chromosome 2q33) encodes an enzyme that converts isocitrate into α-ketoglutarate (also known as 2-oxoglutarate). The loss of the IDH1 function results in a reduction in the production of α-ketoglutarate, which is a necessary co-substrate for the TET family enzymes—composed of TET1, TET2 and TET3—essential for the DNA de-methylation pathway. TET2 catalyzes the oxidation steps on the methyl group of 5-methylcytosine to produce 5-hydroxy-methylcytosine, 5-carboxyloxosine and 5-formylcytosine, and ultimately cytosine. This newly discovered pathway has a role in controlling methylation levels and maintenance of the DNA epigenetic fidelity; this led to the definition of the TET genes as the "guardians of the epigenome."

Overall, melanoma is even more heterogeneous than expected from the molecular point of view. Complexity of the disease is thus given by a combination of driver somatic mutations (both genetic and cytogenetic) and epigenetic modifications able to negatively and/or positively induce expression aberrations and even genomic changes.

Classification of Melanoma

Considering the molecular approach, once a melanoma has been diagnosed, it is relevant to know which primary mutation that melanoma harbors. Primarily, BRAF, NRAS, HRAS, KIT, GNAQ and GNA11 mutations should be tested and, hence, the lesion classified. As mentioned above, these mutations are typically mutually exclusive, and each is more or less frequently associated with a different UV-related clinical scenario. The diagnosis of melanoma still relies on histopathological examination, however, the clinicopathological classification proposed by Clark and McGovern can be integrated in a molecular multidimensional reclassification where nine main melanoma classes with distinct mutational pathways have been identified:

Pathway I. Low-CSD Melanoma/Superficial Spreading Melanoma (SSM)
Pathway II. High-CSD Melanoma/Lentigo Maligna Melanoma (LMM)
Pathway III. Desmoplastic Melanoma
Pathway IV. Malignant Spitz Tumor
Pathway V. Acral Melanoma
Pathway VI. Mucosal Melanoma
Pathway VII. Melanoma arising in Congenital Nevus
Pathway VIII. Melanoma arising in Blue Nevus
Pathway IX. Uveal Melanoma

Considering the causative role of UV radiation, a distinction can be made between melanomas originating on sun-exposed skin in susceptible individuals and associated with cumulative solar damage varying from low (Low-CSD Melanoma/SSM) to high (High-CSD Melanoma/LLM and Desmoplastic Melanoma), as observed on clinical–histological ground, and melanomas arising on sun-shielded skin or sites without consistent association with UV exposure (Malignant Spitz Tumor, Acral Melanoma, Melanoma arising in Congenital Nevus, Melanoma arising in Blue Nevus, Mucosal Melanoma and Uveal Melanoma) (**Fig. 2**). In cutaneous biopsies, signs of sun damage are denoted by solar elastosis which consists of ribbon-like basophilic fibers produced by injured fibroblasts.

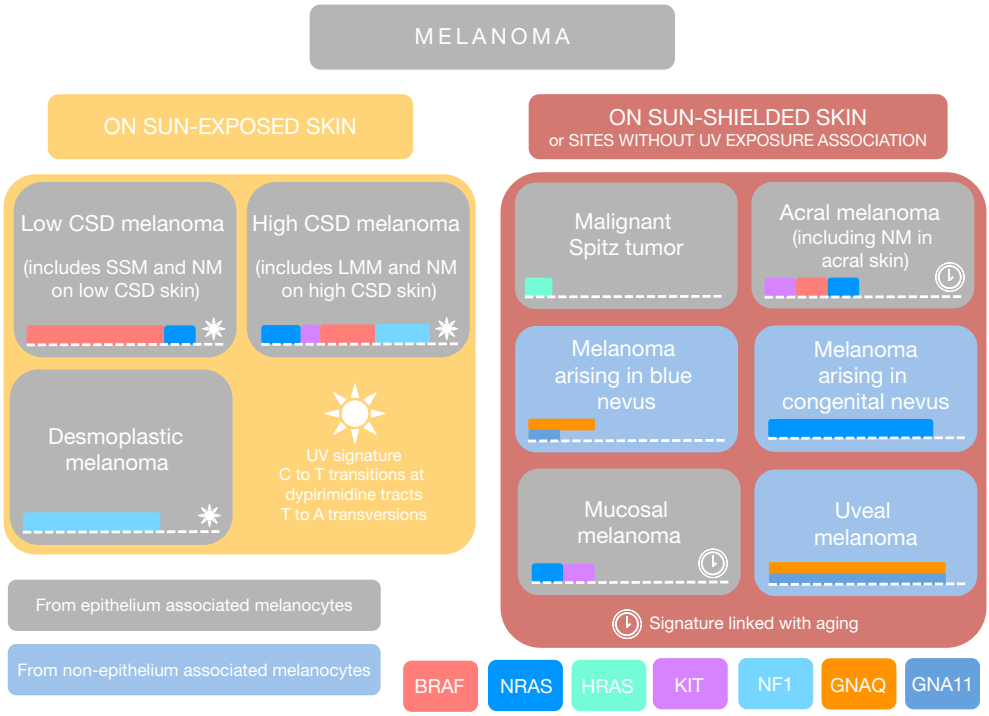

Fig. 2 Classification of melanoma integrating genotype–phenotype correlation. The heterogeneity of melanoma has been postulated for years, until a taxonomy based on molecular pathways emerged.

Such detail is referred to as a measure of cumulative solar damage (CSD); unfortunately, this criterion has limitations in diagnostics of doubtful cases, as most melanomas arise on low-CSD skin that has been intermittently exposed to sun, rather than chronically and severely sun-damaged skin.

Low Cumulative Solar Damage Melanoma

Low-CSD melanoma arises on intermittently sun-exposed skin of trunk and extremities (except palms, soles and nails) in young individuals (third to sixth decade) with a high number of nevi and fewer NMSC. Increased risk is determined by recurrent sunburns in childhood and the use of tanning beds. It is typically a SSM that shows radial growth phase (RGP) and often intense pigmentation, in the absence of marked solar elastosis. Compared to other melanoma mutational pathways, this category is most frequently affected by BRAF mutation (predominantly V600E) in 50%–70% of cases.

Such peculiarity is relevant for the possibility of treating patients showing BRAF-mutated metastatic melanoma with BRAF and MEK inhibitors. Among the primary oncogenic mutations, NRAS is also frequently mutated (15%–20%), while KIT mutation is rarely described (1%). Loss-of-function mutations include CDKN2A, TP53 and PTEN. Chromosomal aberrations are common and involve gains of chromosome 6p, 7 (copy number increases that favor mutant BRAF allele), 8q, 1q, 20q and 17q, and losses at chromosome 9, 10 (driven by PTEN), 6q and 8p. TERT promoter mutations play a role in melanoma pathogenesis via alteration in the regulation of telomere protection. Remarkably, Hayward and colleagues demonstrated that TERT promoter mutations in melanoma determine shorter telomere length. Low-CSD melanoma class includes a subset of nodular melanoma (NM) that might originate as vertical growth phase (VGP) on RGP, the latter being displaced by the rapid nodular growth, and rare variants that recognize similar molecular pathways: Melanoma in BAP1 Inactivated Naevus, Melanoma in Deep Penetrating Nevus, Melanoma in Pigmented Epithelioid Melanocytoma.

High Cumulative Solar Damage Melanoma

High-CSD melanoma develops on chronically sun-exposed skin of the head and neck region, dorsal surface of the forearm, and lower legs in elderly people, and is frequently associated with NMSC. Long-standing occupational solar UV exposure is a risk factor. This category includes LMM and NM in high-CSD skin. In contrast to low-CSD melanoma that can originate from nevus, high-CSD melanoma can develop from melanoma in situ (LM). In up to 30% of cases, loss-of-function mutation of the tumor suppressor NF1 can be found, without, at the present, any therapeutic implication in clinical decision making. It is also characterized by mutually exclusive activating mutations of NRAS (20%–25%), BRAF (more frequently V600K) or KIT (1%–10%). Loss of CDKN2A is typical of the VGP of these tumors, while TERT promoter mutations emerge earlier in the progression, in the intraepithelial lesion.

Desmoplastic Melanoma

Desmoplastic melanoma is a rare tumor that typically arises on the head and neck region. The lesion is characterized by intradermal proliferation of atypical spindled melanocytes that are generally poorly pigmented, often making the diagnosis difficult, and by marked tropism for neural structures, which determines increase of recurrence risk. A lentiginous-pigmented component is often associated. Indeed, desmoplastic melanoma more commonly arises as the VGP of a melanoma in situ LM type on CSD skin. It may also present de novo, or more rarely as the progression of another lentiginous type melanoma that can be acral or mucosal melanoma. Desmoplastic melanoma shows a high mutation load (median of 62 mutations per megabase) that ranks it, like high-CSD melanoma, among the most highly mutated cancers. NRAS and KIT are rarely mutated, while in 55%–93% of cases there are inactivating mutations of NF1, mainly represented by truncating mutation or homozygous deletion. Such genetic (predominantly NF1 mutated) and clinical (primarily head and neck localized) features define the uniqueness of desmoplastic melanoma. In addition, TP53 is mutated in 48% of cases. Gain-of-function mutation of NFKBIE have been identified in 14.5%. Interestingly, as NFKBIE mutated desmoplastic melanomas, NFKBIE mutated nondesmoplastic melanomas show neither BRAF nor NRAS mutations. NFKBIE encodes IκBε, one of the three traditional IκB proteins, whose function is that of inhibiting NF-κB signaling pathway by promoting cytosolic sequestration of NF-κB dimers in unstimulated cells, thus preventing transcription.

Malignant Spitz Tumor

Malignant Spitz Tumor or Spitz melanoma is a cancer morphologically composed of large spindled and/or epithelioid melanocytes. It may be indistinguishable from Atypical Spitz Tumor. CSD is typically absent or minimal. Compared to other melanomas, the Malignant Spitz Tumor tends to be less aggressive and present at a younger age. This melanoma subtype is defined by characteristic genetic alterations that comprise mutation of HRAS on chromosome 11, BRAF mutation with loss of BAP1 and, above all, mutually exclusive tyrosine kinase fusions in ALK, ROS1, RET, NTRK1, NTRK3, BRAF and MET genes that have been found in 39% of cases. The identification of chromosomal translocations with expression of fusion proteins, although having no role in distinguishing Spitz nevus from Spitz melanoma, is relevant to the understanding of the molecular pathogenesis of melanocytic lesions and broadens the treatment of these neoplasms to targeted therapies.

Acral Melanoma

Acral melanoma, once referred to as "acral lentiginous melanoma," is localized on glabrous acral skin, that is, the palms, soles and nail apparatus. It shows a peculiar ethnic distribution, being the most common melanoma subtype among Asian, Hispanic and African populations. Trauma may represent a risk factor. Delayed diagnosis correlates with poor prognosis. Earlier lesions in the RGP typically show lentiginous proliferation that progresses in the VGP, characterized by spindled and desmoplastic atypical melanocytes. Compared to other melanoma subtypes, acral melanoma has a low mutational load, characterized mostly by genomic rearrangements and multiple high level amplifications of CCND1, CDK4, GAB2, RICTOR and TERT loci. KIT mutations occur in 15%–40% of cases, NRAS in 15%–20% and BRAF in 15%. Loss-of-function mutations occur in NF1 and CDKN2A.

Mucosal Melanoma

Mucosal melanomas are rare tumors that arise in mucosal membranes. They can be found in the nasal cavity and sinuses, along the gastrointestinal tract (from the oral cavity to the anorectum), along the genitourinary tract (especially vulvar and vaginal region) or in the tarsal conjunctiva. As they originate on mucosa, the causative role of solar UV exposure is absent. Genomically, they show similarities to acral melanoma. Compared to cutaneous melanomas on sun-exposed skin, mucosal melanoma has a considerably lower mutational load, characterized by the presence of frequent copy number variations and structural changes. BRAF mutation is generally absent. 20%–40% of cases are KIT mutated, 15%–20% NRAS mutated. It is interesting to note that there are mutations that occur more frequently in some mucosal localizations than others, suggesting that mucosal melanomas are a group of distinct molecular lesions: up to 43% of vaginal melanomas are NRAS mutated, 25% of anorectal melanomas are KIT mutated. For this reason, there have been attempts to subdivide melanomas arising on mucosa, but they are rare and, therefore, it is difficult to make statistically significant studies.

Melanoma Arising in Congenital Nevus

Congenital nevi are benign melanocytic proliferations that are already present at birth as they arise in the fetus. They are classified according to their dimension in small (<1.5 cm), medium (1.5–20 cm), large (20–40 cm) and giant (>40 cm). The size corresponds to the largest diameter that can be expected in adulthood (predicted adult size or PAS) because congenital nevi extend in proportion to the child's growth. Risk factor for the development of melanoma is the lesion size: in giant congenital nevus, the risk increases up to 10%–15%. In pre-pubertal patients with large congenital nevus, the risk for the development of melanoma is 1%–2%, which is ten-thousand times more frequent than same-aged general population. Large congenital nevi have a 2%–42% risk of malignant transformation and a 6%–14% lifetime risk of developing melanoma. MCN presents as a nodular growth in the context of congenital nevus, though rapidly growing nodules are more often mimickers of melanoma, including atypical

proliferative nodules, as they have a benign behavior. MCN arises within the cutaneous lesion intradermally or subcutaneously before puberty, at the dermo-epidermal junction in adulthood. Gain-of-function somatic mutation in NRAS at codon 61 with the substitution of glutamine by lysine (Q61K) or by arginine (Q61R) have been found in >90% of large and giant CN, and 70% of small and medium CN. In contrast to large-giant CN, small-medium ones harbor in 30% of cases $BRAF^{V600E}$ mutation.

Melanoma Arising in Blue Nevus

Blue nevus is a frequent dermal melanocytosis. The name derives from the color blue that results from the Tyndall effect. The two most important variants are common blue nevus and cellular blue nevus. The common blue nevus consists of an exclusively dermal proliferation and it most frequently arises on the dorsal surface of the hands, albeit ubiquitous. The cellular blue nevus is a proliferation of spindled melanocytes arranged in bundles involving reticular dermis and hypodermis. MBN usually arises on the cellular blue nevus variant and appears as a dermal proliferation of large atypical spindled and/or epithelioid melanocytes with moderate to severe cytologic atypia and necrosis. MBN has conceptual affinity with uveal melanoma, as both originate from melanocytes that are not intraepithelial, and it is not a coincidence that their genetic mutations extensively overlap. Indeed, melanomas arising on blue nevus show GNAQ and GNA11 gain-of-function mutations (Q209 in Exon 5).

Additional mutations have been described in SF3B1 and BAP1. Chromosomal aberrations, such as gains in chromosome 6p and/or 8q, monosomy of 3, and loss in 1p, are similar to those described in uveal melanoma mutational pathway.

Uveal Melanoma

Uveal melanoma, the most common intraocular tumor in adults, arise from melanocytes in the uvea, the middle vascular layer of the eye consisting of three parts: iris, ciliary body, and choroid. Uveal melanomas are not related to sun exposure, as demonstrated by the absence of UV signature. The mutation load is lower than CSD cutaneous melanoma. In 80%–90% of uveal melanomas, there are GNAQ or GNA11 mutations which are mutually exclusive and happen early in the pathogenesis. Other mutations involving the Gαq pathway include PLCB4 and CYSLTR2. BAP1 mutation, which affects up to 50% of cases, SF3B1 (18%), and EIF1AX occur while the tumor progresses, and correlate with different risks of metastasis. Chromosome 8 and 3 can be studied via FISH for additional information on prognostication, since monosomy of chromosome 3 and isochromosome 8q correlate with poor prognosis with higher risk of liver metastasis.

Prospective Vision

Melanoma research is now moving toward a holistic vision, defining melanoma with specific histopathologic and genetic features in a unique and complex individual, aimed at achieving the most effective treatment and the best outcome. Genotype–phenotype correlation is a key lever in that sense. The efforts in cataloging the genomic architecture of different subtypes of melanoma have led to the study of a distinct set of genetic alterations, even in noncoding regions, and such developments open new frontiers in our understanding of melanoma pathogenesis. High-throughput technologies have revolutionized melanoma research, and will continue to do so, especially in defining the genetic progression of melanoma subtypes from their precursors, as well as characterizing metastatic melanoma polyclonality.

Metastatic Signatures—The Tell-Tale Signs of Metastasis

Christina Ross and Kent Hunter, National Institutes of Health, Bethesda, MD, United States

Introduction

Metastasis is defined as the spread of a disease from one organ, or "primary site", to another non-connected "secondary site". In the context of cancer, metastasis refers to the process of a single cell leaving the original "primary" tumor, traveling through the circulatory or lymphatic system, and invading into a distant organ to create a second tumor or metastasis. For a cancer cell, this is an incredibly challenging multi-step feat that most cannot achieve. Indeed, while millions of cells are shed from a tumor every day, very few clinically detectable metastatic colonies are usually formed. Briefly, the steps of metastasis are as follows:

1. Cells separate from the primary tumor
2. Tumor cells invade through the basal membrane into a blood or lymphatic vessel.
3. Tumor cells intravasate into the circulatory or lymphatic system
4. Tumor cells travel throughout the body as circulating tumor cells (CTCs) until halting at a distant organ, at which point they are referred to as disseminated tumor cells (DTCs)
5. Tumor cells extravasate from the vessels into the secondary organ and re-initiate proliferation

Early Work Defining the Metastatic Process

Metastases have been observed in mummies estimated to be around 2400 years old, and have been described in manuscripts as far back as 200 CE. However, the term metastasis was not coined until 1829 by French surgeon Joseph Récamier. It was taken from the Greek meaning removal, migration, change or revolution. At the time, very little was understood about cancer, but Récamier was considered an expert on breast malignancy. In his book "Sur le traitment de cancer," one of the earliest medical texts on oncology, he describes the suffering of cancer patients of the day and in particular, several breast cancer patients with metastasis to the brain. In his text, Récamier was the 1st to propose that metastasis was due to the translocation of cells by local infiltration at the primary site, invasion of the veins, and distant growth in the brain.

The theory of metastasis continued to take shape through the 1800s with the work of Rudolf Virchow, who in 1858 suggested that metastatic tumor dissemination to secondary sites was determined largely by mechanical factors. More specifically Virchow hypothesized that circulating tumor cells somewhat randomly became arrested at a distant organ because they were stuck in the vasculature. However, in 1889 Stephen Paget proposed a slightly different theory in his Lancet paper "Distribution of secondary growths in cancer of the breast". Paget, who is now referred to as the father of metastatic theory, analyzed 735 fatal cases of breast cancer and argued the distribution of metastases could not be due to chance alone. The patterns he observed did not simply follow blood flow distribution as suggested by Virchow. Instead Paget's theory referred to tumor cells as "seeds", and stated that their distribution throughout the body must be understood by studying the properties of the "soil" of distant organs. Paget drew parallels with botany, stating that seeds can only live and grow if they fall on congenial soil. While this theory is currently widely accepted, it was challenged as recently as 1928 by James Ewing who theorized that location of metastases was primarily determined by the anatomy of the vascular and lymphatic channels that drain the primary tumor.

These theories were ultimately merged and supplemented by several metastasis studies published by Isaiah Fidler. His groundbreaking studies demonstrated that metastasis occurred in a series of sequential steps that involve cancer cells with different metastatic capabilities. Dr. Fidler suggested that different "seeds" interact with their microenvironment, leave the primary tumor, and ultimately either land in a "congenial soil" or perish. Dr. Fidler's work also showed that tumor cells could leave the primary tumor by entering the bloodstream or the lymphatics. This theory of the metastatic process took into account Virchow, Paget and Ewing's work and suggested that successful cancer clones metastasized in a stochastic manner. It also hinted at the notion that while many cancer cells leave the primary site, very few are successful at creating a metastasis, as cells with differing characteristics are selected for or lost along the way. Today's current understanding of the metastatic process is built upon the observations and studies of clinicians and researchers going back centuries, and while considerable strides have been made in the last few decades, metastatic disease remains an incredible challenge to treat.

Current Clinical Observations and Challenges in Treating Metastasis

Metastasis is the primary clinical challenge in the treatment of cancer as it is unpredictable in onset and it exponentially increases the clinical impact to the patient. It is a key element in cancer staging systems such as the tumor/node/metastasis (TNM) staging system, where metastasis places a cancer in Stage IV. The possibilities of curative treatment are greatly reduced, or often entirely removed, when a cancer has metastasized. For example, in breast cancer approximately 20–50% of patients diagnosed at an early stage are expected to develop metastatic disease, and because the treatment of primary tumors is quite good, around 90% of breast cancer deaths in the U.S. are instead due to untreatable metastases. It remains a major challenge to eliminate, identify, or remove metastases, and there are several factors that have led to this disparity in curative treatments between localized and metastatic tumors.

 https://doi.org/10.1016/B978-0-12-801238-3.65027-4

Metastatic cancer is multifaceted and therefore complex to study and treat. Firstly, not all cancers metastasize, but those that most commonly do - lung, breast, skin (melanoma), colon, kidney, prostate, pancreas, and liver – don't all metastasize to the same distant organs. For example, breast cancer usually spreads to the brain, bone, or lungs, yet colorectal cancer will primarily spread to the liver. Furthermore, the sensitivity of clinical imaging techniques cannot always expose small metastatic lesions. Another key characteristic that confounds treatment is the drug resistance often observed in metastatic lesions. The current treatments available target the biology of the primary tumor, for which ample patient tissue is available for study. Metastatic tissue is often not resected from patients and therefore not widely available to study; because of this the current therapies are often unable to eliminate the metastatic cells which can be significantly altered during the metastatic process.

Finally, another major challenge in the treatment of metastatic cancer is cancer cell dormancy. Once shed from the primary tumor, dormant cancer cells cease dividing but survive in a quiescent state, often in the bone or other organs, waiting for appropriate environmental conditions to trigger proliferation again. This period of quiescence can last from months to many years. Dormancy creates a large hurdle for treatment as individual dormant cells cannot be detected in the clinic and most therapies target proliferating cells. Furthermore, the creation of drugs to target cells in this state is incredibly difficult as the outcome of effectively targeting dormant cells may not be measurable for upwards of 10 years and may only be recognized as the absence of further metastasis.

Ultimately, in order to improve patient outcomes, clinicians must be able to identify the spread of cancer or a patient's potential for metastasis early in their disease. The identification and use of such "metastatic signatures" will be described in this chapter.

Tumor-Intrinsic Signatures of Metastasis

Gene Expression Profiling of the Primary Tumor

Molecular profiling of tumors following patient surgery has enabled oncologists to categorize tumor types beyond the organ of origin to several subtypes, ultimately guiding physicians' prognoses and treatments. A major factor in this subcategorization has been the assessment of somatic gene mutations, amplifications, and tumor-specific gene expression patterns. Interestingly, epidemiological studies combining the genetic analysis of patient tumors with patient outcomes has also revealed which subtypes, and which genetic alterations in the primary tumor, are likely to result in metastatic disease.

The categorization of breast cancers into subtypes based on gene expression is a prime example of using primary tumor characteristics to predict patient outcomes. Breast cancer subtypes have been extensively categorized by the expression levels of the estrogen and progesterone hormone receptors, and cell surface marker HER2. The 4 major subtypes of breast cancer are Luminal A which expresses both hormone receptors but is negative for HER2, Luminal B which expresses the hormone receptors and either HER2 or Ki-67, Triple negative/Basal-like which is hormone-receptor negative and HER2 negative, and finally HER2-enriched tumors which are hormone-receptor negative but HER2 positive. Analysis published by the American Society of Clinical Oncology has revealed that the Luminal A type has the lowest rate of metastasis, while Luminal B HER2 positive has the highest. When metastasis does occur, subtypes can also be used to predict patterns of metastatic spread. For example, high rates of brain metastases are seen among HER2-enriched, basal-like, and Triple negative types, whereas brain metastases are less frequently seen in the luminal/HER2 groups. Interestingly, bone is the predominant site of metastasis for the luminal/HER2 groups but the least common site for the basal subtype.

In addition to using the expression of specific markers, primary tumor metastatic propensity can be evaluated by different gene expression programs. With recent advances in technology, it has become possible to compare gene expression patterns between primary tumors and metastases. Over the last decade microarray and RNA sequencing studies of patient tissue, mouse metastasis models, and cell lines have informed numerous biomarker panels that can be used to predict metastasis and patient outcome. Several cancer gene signature tests are used clinically to guide personalized treatment decisions for breast, colon, or prostate cancer. Such panels can typically assess expression of 10–70 genes that span cellular pathways critical for cell adhesion, migration, cell-cell signaling, differentiation, and metabolism. As well as creating robust biomarker panels that can direct treatment for individual cancer types, there is also an ongoing effort to create multi-cancer gene expression biomarker panels for cancer metastasis.

Many studies have demonstrated that microRNAs, and the altered expression of specific microRNAs, may play essential roles as either promoters or suppressors of metastatic progression. By altering the expression of networks of genes, microRNAs can be powerful determinants of pathway activation and cellular phenotype. For example, by down regulating a specific network of target transcripts, miR-155 promotes the dissolution of tight junctions via TGFβ-induced cell plasticity and RhoA suppression, ultimately increasing cell migration and metastasis. In addition, sustained expression of miR-155 through positive feed-back of TGF-β signaling has been associated with dysregulation of cell polarity in solid tumors. Conversely, miR-29b has previously been reported as a metastasis suppressor. miR-29b targets transcripts encoding prometastatic effector molecules involved not only in angiogenesis and collagen remodeling such as VEGFA, ANGPTL4, PDGF, and MMP9, but also in differentiation and plasticity such as ITGA6, ITGB1, and TGF-b. miR-29b is enriched in luminal breast cancers and loss of miR-29b increases metastasis and promotes a mesenchymal phenotype. As well as contributing to each tumor cell's metastatic capacity, microRNAs can also function to induce tumor cell non-autonomous alterations. In section "**Systemic Signatures of Metastasis**" of this chapter we will discuss, microRNA involvement in the preparation of the distant pre-metastatic niche.

Somatic Mutations of the Primary Tumor

Several high-quality genomic studies have explored the genetic relationship between primary and metastatic lesions in order to understand metastatic evolution. It is now well accepted that metastases arise from a clone of unique cells within the primary tumor. DNA copy number analysis of metastatic prostate cancers has indicated a common clonal origin in most cases, although sub-clonal alterations have also been observed in metastases. Whole-genome sequences of a basal-like primary breast tumor and corresponding brain metastases have consistently shown that while copy number alterations and overall mutational spectra within the genome are not significantly different, specific mutations revealed a subset of cancer cells from the primary tumor were preferentially enriched in metastatic lesions. Genomic sequencing analyses of pancreatic cancer lesions also suggested that metastatic lesions are clonal in nature, but also likely require additional driver mutations that are not found in the primary tumor.

Phylogenetic analysis of metastatic progression in breast cancer using somatic mutations and copy number aberrations (CNAs) has shed yet further light on the timing of the evolution of metastases. In agreement with earlier studies, descent of metastases from a common origin was observed in patients diagnosed with early stage breast cancer, however multiple seeding events from the primary tumor were observed in patients diagnosed with advanced stage disease. Interestingly, the number of late single nucleotide variants and CNAs increased as distant metastases evolved and can therefore give an indication of the time elapsed since they diverged from their common ancestor. Not surprisingly, there is a correlation between overall patient survival and the phylogenetic branch lengths of the metastases. This phylogenetic analysis ultimately revealed that metastases from patients with longer cancer histories are genetically more distant from their primary tumor tissue of origin than those of patients with a shorter cancer history.

Despite a large number of studies into the evolution of metastatic tumor cells, no specific driving mutations of metastasis have been identified. However, there are several tumor progression-promoting genetic alterations that often result in more aggressive and metastatic disease. In the case of metastatic colorectal cancer, associations have been made between mutational activation of the KRAS, BRAF, PIK3CA, and NRAS oncogenes and metastatic patterns in patients. The presence of a KRAS mutation is associated with decreased liver metastases and increased lung, brain, and bone metastases. BRAF mutation, a poor prognostic factor, is associated with decreased liver-limited metastasis and increased peritoneal and distant lymph node metastases. Conversely, PIK3CA and NRAS mutations do not clearly affect outcomes in the metastatic setting, although PIK3CA is associated with concurrent KRAS mutations. Our expanding understanding of how somatic mutations correlate with metastatic patterns contributes to the clinical care of patients by focusing treatment and guiding surveillance strategies for metastasis.

Inherited Predisposition to Metastasis

The inherited basis for many cancers has been thoroughly studied. For example, inherited predisposition to breast and ovarian cancer with a BRCA1 mutation is commonly assessed in the clinic. However, the inherent diversity in the host genetic background has also been shown to influence metastatic risk. In 1998, a pioneering study showed that an identical oncogenic event in the mammary tissue of mice with different genetic backgrounds led to the development of mammary tumors with similar primary tumor properties but with distinct propensity for metastasis. Linkage analysis has further mapped several genomic loci that modify metastatic potential in mice. With recent advances in global transcript analysis, several studies have now demonstrated the influence of germline polymorphisms and gene networks on the susceptibility to metastatic disease.

Inherited predisposition to metastasis often impacts metastasis in a manner specific to cancer type and subtype. However, recent work suggests that inherited variants can function to modify metastasis by tumor cell-autonomous and non-autonomous mechanisms. Consider that while a patient may have inherent specific expression of genes that benefit tumor cell proliferation or survival, they may also harbor variants in immune surveillance or metabolism pathways that alter the tumor cell's road to the secondary site. In a series of genetics studies in mice, several inherited tumor-intrinsic factors have been identified as metastasis modifiers. One such factor is human circadian rhythm gene Arntl2, for which polymorphisms associated with its expression correlate with metastatic prognosis of ER- breast cancer patients by a tumor intrinsic mechanism. Ultimately, future and ongoing studies will extend this area of research to human patients with the application of genome-wide association study (GWAS) methods. The goal of such studies is to enable early screening of patients for inherited metastatic modifying genes, and develop targeted therapies for specific groups.

Epigenetic Signatures of Metastasis

The study of genetic lesions alone has been unable to explain the complexity of the aberrations that arise in a cancer cell. It is now recognized that cancer is both a genetic and an epigenetic disease. Epigenetics is defined as the inheritance of changes in gene activity that are independent of DNA sequence. The two main epigenetic events involved in gene regulation, development, and carcinogenesis are histone modifications and DNA methylation. In cancer cells, the fine control of epigenetic mechanisms is lost and the disruption of epigenetic patterns promotes the expression of the tumoral phenotype. The alteration of epigenetic marks on the genome is a key tool in successful metastasis, as these marks are reversible and allow the cell to adapt as it travels to the metastatic site. A noteworthy example of such a phenomenon is the *E*-Cadherin gene, which is silenced in some human cancers due to DNA hypermethylation. It has been shown that in some primary tumors displaying E-cadherin hypermethylation, the corresponding metastases are unmethylated at the E-cadherin gene and regain gene expression at this locus. Demethylation of E-cadherin and re-expression are thought to be indispensable for the incorporation of metastatic cells into their new cellular environment.

Recent work in metastatic pancreatic cancer has provided tremendous insight into the epigenetic changes that arise in metastases that seed different sites. Using matched primary and metastatic samples, researchers revealed differences in epigenetic reprogramming within subclones of the primary tumor that seeded local (peritoneal) and distant (liver and lung) metastases. Differences in the epigenetic reprogramming between local and distant metastatic lesions were also observed. Interestingly, no significant changes were seen in the tumors of patients whose cancer spread only locally. However, tumors from patients with distant metastases showed substantial epigenetic changes both in the distant metastases and in the subclone of the primary tumors from which they arose. The genes impacted by these epigenetic alterations in lung metastases were associated with oxidoreductase activity as well as DNA damage, rendering corresponding cell cultures resistant to oxidative stress and chemotherapy. Also, genes encoding epithelial and mesenchymal identity were reciprocally expressed between the local and distant metastases, such that peritoneal metastases were epithelial and lung metastases were poorly differentiated. This work suggests that epigenetic regulation by metastatic cells is paramount to reaching and growing secondary tumors in specific organs. It also highlights the complexity of metastatic cancers and the multifaceted treatment strategy that must be implemented to eradicate it.

Metabolic Changes in Metastatic Cells

It has long been appreciated that metabolism is altered in cancer cells. In 1955, Otto Warburg presented his work showing the nuanced manner in which cancer cells utilize glucose and oxygen. Since this discovery, metabolism in cancer has been thoroughly studied and the conditions to which tumor cells can adapt and thrive by metabolic modifications is wide and varied. In recent years, further specialization of metabolic changes has been observed during tumor cell dissemination into the circulation and establishment of metastatic lesions.

The dissemination of malignant cells is an integral characteristic of advanced stages in transformation. While contributions of peroxide signaling to metastasis may be context-dependent, elevated levels have been found to mediate metabolic changes that facilitate anchorage-independent survival and consequent metastatic spread. The mitochondria generate reactive oxygen species (ROS), which are required for KRAS-induced anchorage-independent growth through regulation of the ERK/MAPK signaling pathway, resulting in the transduction of a survival signal. The peroxide signal underlying anchorage-independent expansion has now been tied to ATP generation, which is increased to satisfy energy requirements for cells that lose contact with the substratum. The elevation of peroxide levels must be tightly regulated however, as intracellular ROS can be limiting to cell survival. This is just one example of the specific metabolic changes wielded by tumor cells to aid in the process of dissemination from the primary tumor.

Interestingly it has also been revealed that the tropism of metastatic cells may in part be dependent on their ability to adapt to the metabolic environment of the secondary organ. For example, the liver is largely hypoxic with uneven glucose levels due to competing hepatocytes. Both glucose and oxygen are key substrates in both glycolytic and oxidative metabolism and therefore metastatic cells in the liver are forced to adapt. It has been observed in patients with colon cancer that metastatic cells are able to escape this potential metabolic stress by capitalizing on the higher levels of creatine in the liver, which is synthesized and secreted by hepatocytes. Through the modulation of miRNAs these cells are able to upregulate and secrete Creatine Kinase B (CKB) into the extracellular space. Once secreted, CKB catalyzes phosphocreatine from ATP and creatine. Phosphocreatine can then be imported back into the tumor cells through specific upregulated transporters, and used to regenerate ATP. Through this mechanism the cells bypass glycolytic and oxidative metabolism pathways and essentially scavenge energy from the secondary organ's extracellular environment. Pharmacological inhibition of CKB has been shown to substantially decrease the level of liver metastasis in mouse models and may be a useful therapeutic strategy in the clinic.

Signatures of Metastasis in the Tumor Microenvironment

Tumor Vasculature

Not only is tumor vasculature important for tumor growth, it is also key in tumor cell dissemination in the initial steps of metastasis. It is well established that tumor vasculature is distinct to that of healthy tissue, and these distinctive qualities can influence the spread of tumor cells into the circulation. Normal vasculature is maintained through a careful balance of pro- and anti-angiogenic factors and is composed of a hierarchical distribution of arterioles, capillaries, and venules. In contrast, tumor vasculature lacks this hierarchical structure and is mainly composed of immature differentiated and undifferentiated vessels with high permeability. Undifferentiated tumor vessels frequently present with either collapsed or an absent lumen, and consequently tumor vasculature is inefficient in carrying blood flow. Due to this phenomenon, and despite increased intra-tumoral microvessel density, the tumor microenvironment is often hypoxic when compared to healthy tissue. This hypoxia can promote the generation of new vessels and also induce metastasis. Tumor blood vessels can form by the common processes of neovascularization, but often also through alternative mechanisms. "Vascular mimicry" or VM is one such alternate process and involves the creation of tumor cell-lined channels for fluid transport independent of typical endothelial cell-driven angiogenesis. It is this process of VM that has most recently become the focus of attention as a signature of metastatic cancer.

The initial morphological, clinical, and molecular characterization of VM was performed using human melanoma as a model. These tumor cells were shown to express endothelial, embryonic/stem cell, and tumor markers; they were also shown to form channels, networks, and tubular structures rich in laminin, collagens, and heparin sulfate proteoglycans and contain plasma as well as

red blood cells. Since these initial characterizations in the late 1990s VMs have been hypothesized to function as "escape routes" for metastatic cells, and indeed several studies have demonstrated that VM is implicated in poor patient clinical prognosis. In a 2015 study, Wagenblast and colleagues showed VM can indeed pave a way for breast cancer metastasis. Using a polyclonal mouse model of breast tumor heterogeneity and a systems genetics approach, they identified discrete clones within the primary tumor that displayed phenotypic specializations and their corresponding gene expression profiles. Clones that efficiently entered the vasculature expressed two secreted proteins, Serpine2 and Slpi, which are necessary and sufficient in programing tumor cells for vascular mimicry. This study suggests that vascular mimicry drives the ability of breast tumor cells to contribute to distant metastases. Furthermore, this study also revealed that in the clinic SERPINE2 and SLPI are overexpressed preferentially in patients that have lung-metastatic relapse. Thus, these two secreted proteins, and the VM phenotype they promote, may be a relevant signature of metastatic progression in human cancer.

Tumor-Associated Immune Cells

A substantial amount of clinical data has indicated that tumor infiltration of certain immune cell types correlates with poor prognosis of cancer patients. Inflammation in the tumor microenvironment can contribute to the initiation, promotion, and progression of malignant disease by fostering a nurturing environment for tumor progression and metastasis. Specifically, chronic inflammation modifies the transformed tissue by providing an abundant source of growth factors, cytokines, chemokines, prostaglandins, and reactive oxygen species, which promote angiogenesis and metastasis. As a result, the tumor microenvironment is frequently rich with immune cells including innate immune cells, such as mast cells, tumor-associated macrophages (TAMs), and myeloid-derived suppressor cells (MDSCs), as well as adaptive immune cells including T and B lymphocytes and dendritic cells that can have tumor and metastasis-promoting properties. Accumulating evidence has indicated that myeloid cells, such as TAMs and MDSCs, contribute to early steps of metastasis by promoting tumor cell migration and invasion into blood vessels.

Macrophages are considered to be highly plastic cells and have distinct functions in response to environmental signals. Accumulating data suggest that the tumor microenvironment polarizes recruited macrophages from a potentially tumor-reactive state to a tumor-promoting state. These 'tumor-educated' macrophages influence the early steps of the metastatic cascade by promoting tumor cell invasion of the surrounding tissue and intravasation into the circulation. Research has shown that in breast cancer mouse models the ablation of macrophages inhibits tumor angiogenesis, suggesting that TAMs promote metastasis by increasing the density of leaky blood vessels that provide pro-tumorigenic and pro-invasive factors, as well as a route of escape for tumor cells. TAMs have also been found to secrete factors such as epidermal growth factor (EGF), which activate tumor cell receptors and enhance invasion and motility by increasing invadopodium formation and matrix degradation. Along with this, TAMs also secrete many cytokines that recruit tumor cells to the blood vessels and remodel the extracellular matrix. Interestingly, intravital imaging has also revealed that perivascular TAMs aid in tumor cell invasion of surrounding tissues by directly associating with tumor cells as they intravasate. In the clinic, breast cancer patients are given a 'tumor microenvironment for metastasis' (TMEM) score, which is an indication of the number of TAM, endothelial cell, and tumor cell interactions observed within a tumor. A high TMEM score, and thus high number of interactions, is a signature associated with an increased risk of metastasis.

Tissue Rigidity and Metastasis

Mechanical properties of the extracellular matrix (ECM) have become increasingly recognized as functionally important during tumor progression. In particular, tissue rigidity has emerged as an important factor during metastasis. Briefly, recent work shows that mesenchymal-like tumor cells enhance ECM remodeling through deposition of additional ECM molecules, which alters the local ECM, increases the pool of available growth factors, and potentiates the mesenchymal phenotype. Tumor cells have also been shown to hijack the normal functions of stromal cells to facilitate ECM remodeling. Take for example cancer-associated fibroblasts, which can drive matrix stiffening through collagen crosslinking. Force mapping of human and mouse breast tumors revealed invasive tumors have heterogeneous mechanical properties. More specifically, when compared to the tumor core, the periphery is relatively stiffer which is consistent with the observation that cells from the invasive front of tumors are prone to be more mesenchymal before dissemination. While research continues into this phenomenon, such a finding does suggest that local mechanical properties of a niche may control the movement of tumor cells. Indeed, studies in 3D culture systems and mouse tumor models have shown that increased tissue rigidity has a functional role in driving tumor invasion and malignancy. More notably, in breast cancer patients, increased tissue rigidity due to dense clusters of collagen fibers and fibroblast at the tumor site correlates with metastatic recurrence and poor patient survival.

In 2011, Conklin et al. performed a thorough study of the relationship between the long-term survival rate of human patients and the tumor-associated collagen signature 3 (TACS-3). TACS-3 is defined as bundles of straightened and aligned collagen fibers that are oriented perpendicular to the tumor boundary which specifically increase matrix stiffness through increased collagen deposition and matrix alignment. In this study, the presence of TACS-3 was evaluated in tissue biopsies from 196 breast cancer patients. Remarkably, the presence and extent of TACS-3 observed in primary tumor samples was confirmed as a prognostic indicator regardless of tumor grade or subtype. In this study, even the presence of small TACS-3 sites, and therefore only niche regions of stiffness, carried an increased risk of long-term relapse. This study produced strong statistical evidence for poor survival in patients with TACS-3, and showed that routine TACS assessment can be performed with clinical histopathological samples. Ultimately, while much is

left to ascertain about the role of ECM and tissue stiffness in metastasis, it is clear that TACS-3 is a strong biomarker for the prediction for breast cancer survival.

Systemic Signatures of Metastasis

Tumor-Secreted Factors

Cancer is able to grow and spread by implementing unique survival and proliferative pathways. This subsequently results in the production and release of specific metabolic, hormonal, and exosomal signatures. With recent advances in blood and liquid biopsies, many different tumor-secreted factors have been identified within the peripheral blood of cancer patients. By using liquid biopsy, many of the unique signatures produced by tumors can now be observed serially – a current limitation – and without invasive tissue biopsies. While tumors produce specific factors distinct from other organs, they also have signatures unique to their type and even molecular subtype. Not surprisingly, tumors undergoing metastatic spread have also been shown to produce measurable factors indicative of unique metastatic characteristics such as preferred metastatic site or "organotropism", and therapeutic sensitivity or response. The specific ways in which tumor-secreted factors are being used as signatures of metastatic spread are discussed in the following sections.

Hormones and metabolites

For some cancer types, the use of circulating metabolites and hormones as biomarkers for diagnosis has become common in the clinic. One example of a cancer prognosis marker is Prostate-specific antigen (PSA), for which serum levels are used to screen for prostate cancer in older male patients. Another serum test in early clinical use is a three protein signature indicative of glioblastoma for which the levels of CRP, LYAM1, and BHE40 are assessed. Recent work has also revealed that some metastatic tumors can be identified by changes in circulating metabolites and hormones. Currently this is a young field, however with the increasing use of liquid biopsy in the clinic, the number of metabolite and hormone-based serum screens for metastasis will likely continue to grow.

In several cancer types, including breast, lung, and prostate cancers, Parathyroid hormone-related protein (PTHrP) has been identified as a bone metastasis-specific serum biomarker. In normal physiology PTHrP is widely expressed in embryos and is critical to organ development. PTHrP is also critical during lactation, where it is secreted from the mammary tissue into the circulation to mobilize skeletal calcium for milk production. PTHrP also contributes to the pathophysiology of several cancers, and its production by disseminated tumor cells in the bone microenvironment has been shown to promote osteoclastic activity and contribute to osteolytic bone metastases. PTHrP appears to also play a central role in cancer-associated hypercalcemia. Thus the serum levels of PTHrP and calcium are together very important biomarkers for bone metastasis of several cancers. As well as a biomarker, PTHrP inhibitors have attractive prospects for clinical treatment. Two small nucleotide analogs have been reported to inhibit production of PTHrP by tumor cells and reduce bone lesions with higher survival rates in animal models, but are not yet in use for human patients.

Cell-free nucleic acids

Due to advances in nucleotide sequencing, along with a better understanding of tumor and metastasis mutational signatures, the assessment of circulating DNA and RNA has recently become an exciting new tool for the diagnosis of cancer and metastasis. Circulating, cell-free DNA (cfDNA) are fragments of DNA found in the blood. cfDNA was first described in 1948, but cfDNA fragments originating from tumor cells (ctDNA) were not characterized until the 1980s. The origin of ctDNA has not been well defined yet, but is thought to result from cell death. Nucleosomes play essential roles in the fragmentation of DNA during programmed cell death and genome-wide nucleosome mapping has shown that ctDNA fragments can be distinguished from non-tumor derived cfDNA by distinct patterns of nucleosome spacing.

ctDNA as a prognostic biomarker is currently used for several different types of cancers, including melanoma, colorectal cancer, cervical cancer, and pancreatic cancer. Through the assessment of ctDNA, somatic oncogenic Ras, p53 and other metastasis-related gene mutations, plus epigenetic signatures can be detected. As well as providing insight into metastasis promoting genetic changes occurring in tumors, the relative abundance of ctDNA can also be used as a prognostic marker. It was recently shown that ctDNA is found at a relatively high concentration in the peripheral circulation in patients with metastatic cancer compared with localized disease: ctDNA detection in patients with no radiographic evidence of metastasis varies between 49 and 78%, compared with 86–100% in metastatic disease.

Circulating RNAs (cf-RNA) in human cancer patients were first described in the 1990s in patients with different types of cancers. As mRNA is critical in intracellular protein translation, extracellular mRNAs provide a rare glimpse into the status of the intracellular processes. Non-coding RNAs which largely function to regulate gene expression also make up a large percentage of cf-RNAs. While the majority of research to date has focused on circulating microRNAs and long non-coding RNAs, the number of studies of other RNA classes has recently grown. Interestingly, despite the unstable nature of RNA and the presence of RNA degrading factors in the blood, cf-RNA is stable enough for use as a biomarker. This is likely because tumor derived cf-RNA is often released in vesicles from tumor and apoptotic cells.

cf-RNA is used as a biomarker in several ways. In serum obtained pre-surgically from patients with early stage colorectal cancers, a panel of 6 circulating miRNAs can predict cancer recurrence. Similarly, changes in cf-miRNA patterns within the same patients can be monitored over time to assess response to therapy. In addition, several studies have indicated the usefulness of cf-RNA as a marker of host response to treatment. In terms of metastatic cancer, cf-RNA is currently evaluated to reflect the gene expression within the

primary tumor, and as such its use in the prognosis of metastatic disease is limited by the current understanding of cancer spread. Essentially, cf-RNA is screened for distinct primary tumor gene expression signatures indicative of metastatic spread. As the use and study of cf-RNA increases, it is likely that the nuances of metastatic disease will be further revealed in circulating nucleotides, increasing their use in the clinic for metastatic prognosis.

Tumor-secreted exosomes

Exosomes are spherical or cup-shaped nanovesicles 40–100 nm in diameter that are secreted by many cell types and can be found in most body fluids such as urine and blood. They are end-products of the recycling endosomal pathway which involves endocytosis, formation of early and late endosomes, multivesicular bodies, and secretion with the help of specific cellular pathways. Exosomes are distinct from other secreted lipid entities such as microvesicles and ectosomes, which are microvesicles derived from neutrophils or monocytes and apoptotic bodies. The basic makeup of exosomes consists of a lipid bilayer containing transmembrane and non-membrane bound proteins and nucleic acids. Each of these components give insight into the state of the cell of origin, and, not surprisingly, exosomes released from tumor cells have been found to contain proteins involved in cancer pathogenesis such as mutant KRAS. Interestingly, exosomes can transfer their constituents and cargo to neighboring or distant cells, and it is in this way that tumor exosomes are thought to aid in tumor cell invasion of local stroma, immune cell suppression, and preparation of the metastatic site for colonization.

As a signature of metastasis, exosomes can be evaluated to determine organotropism of tumor cells. In a seminal study published in 2015, David Lyden's group showed that exosomes and their contents play a large role in determining the secondary site of metastasis. In their study, exosomes from lung-, liver- and brain-tropic tumor cells were shown to fuse preferentially with resident fibroblasts and epithelial cells at their predicted destinations. In addition, by taking up tumor-derived exosomes, the organ-specific cells were altered to create a pre-metastatic niche (section "**The Premetastatic Niche**"). This was revealed when treatment of mice with exosomes from lung-tropic models redirected the metastasis of bone-tropic tumor cells to the lung. Assessment of the protein signatures within exosomes from different organotropic tumors revealed distinct integrin expression patterns. Specifically, exosomal integrins $\alpha6\beta4$ and $\alpha6\beta1$ were associated with lung metastasis, while exosomal integrin $\alpha v\beta5$ was linked to liver metastasis. Ultimately this study reveals a new tool for predicting and monitoring the site of cancer recurrence, as exosomal integrin signatures can be used to predict organ-specific metastasis.

Circulating Tumor Cells

The hypothesis that circulating tumor cells (CTCs) are an essential prerequisite to metastasis was first proposed by the Australian pathologist Thomas Ashworth in the mid-19th century. Today, the identification and molecular characterization of CTCs in cancer patients remains key to further understanding the metastatic process and developing new therapeutic targets for treatment. Fortunately, recent advances in technology have provided a means to reliably identify and isolate tumor cells in the peripheral blood stream of cancer patients, opening up new avenues of research into their biological significance.

Release of CTCs into the circulation is frequently termed shedding. A study using a single rat model reported that CTCs are shed from solid tumors at a daily rate of 3.2 to 4.1×10^6 per gram of tissue. However, this cell loss via blood comprised about 10% of the tumor weight and resulted in a CTC count of approximately 20,000 CTCs/mL blood, a rate much higher than that observed in human cancer patients. Clinical data published in 2016 suggests a much lower rate of tumor cell shedding in humans at around 3–5 CTCs/7.5 mL blood for breast, prostate cancer, and colon cancer patients. To date, the majority of clinical studies have focused on CTC enumeration in guiding prognosis in metastatic cancer patients. This work aims to use CTC number as a signature to discriminate which patients are more likely to benefit from adjuvant treatment, as well as a method to monitor the efficacy of therapy.

CTC number surveillance, as a marker of metastatic potential, is also predicted to detect relapse at a much earlier stage than current clinical or radiological tests. Pioneering studies in breast, prostate, and colorectal cancer have shown that higher CTC number predicts for worse prognosis, and a change in number following initiation of therapy can be predictive of survival outcome. Essentially, the characterization of CTCs from a 'simple' blood test could serve as a non-invasive 'real-time tumor biopsy' permitting an up-to-date snapshot of a patient's tumor biology. In this case, molecular characterization of CTCs will also be essential for understanding the status of treatment.

The characterization of CTCs on a molecular level is also useful is determining the course of treatment for recurrent and metastatic disease. For example, HER2 is a targetable factor in breast cancer and the expression of HER2 has been detected in CTCs of metastatic breast cancer patients in cases where primary tumors were negative at the original diagnosis. Subsequent clinical studies have shown that despite a HER2-negative status of the original tumor biopsy, patients with HER2-positive CTCs do benefit if treated with HER2-specific therapy to target CTCs and consequent metastatic lesions. Similarly, acquired genetic mutations can be detected in CTCs, and as next generation sequencing and whole cell proteomics become more accessible, the signatures associated with metastasis will likely become more obvious. The recent advances in isolating and evaluating CTCs are exciting and have greatly accelerated progress in understanding, treating, and monitoring metastasis.

Disseminated Tumor Cells

As described in the previous section, tumors are able to shed cells into the circulation in large numbers. However, simply entering the blood stream alone is not enough to initiate metastasis. A fraction of CTCs are also capable of entering distant sites and

persisting as DTCs. Interestingly, research has revealed that the presence of disseminated tumor cells can be observed before the detection of a primary tumor, suggesting that shedding and colonization of distant tissues can occur at very early stages of the disease. DTCs are currently of great interest to the metastasis research community, as they can remain dormant for many years before initiating growth of a metastasis. However, the exact "trigger" that pushes DTCs from dormancy to metastatic outgrowth is still unclear.

The use of DTC characteristics as a prognostic indicator, or even a sign of likely metastasis, is also in its infancy for several reasons. Firstly, the study of DTCs is difficult because their isolation in the clinic invariably requires invasive procedures. Current strategies are limited to isolating DTCs from tissue that is convenient to collect and lacks common epithelial tumor markers, such as lymph nodes or bone marrow. Markers such as cytokeratins and proliferation-associated Ki67 are then used to detect epithelial cells foreign to that tissue. As new markers are identified and verified, they are increasingly being applied in a multi-marker fashion. Detection of DTCs in lymph nodes and bone marrow is primarily used before and after therapy, however their use as an indicator for relapse remains weak. Despite DTCs predicting adverse outcomes, the majority of DTC-positive patients do not develop metastases. This suggests that the ability to take up residence in bone marrow or lymph node is not sufficient to initiate the growth of a metastatic lesion. The presence of DTCs in these tissues also does not indicate which other organs may also be occupied. Rather, it is thought that a change in the microenvironment of these cells must also occur to initiate the switch from dormant to proliferative state. Furthermore, as well as the technical caveats in analyzing DTCs, the timing of dissemination remains a confounding factor in their use as biomarkers for relapse or sensitivity to therapy. Regardless, the study of such cells with more refined detection, isolation, and characterization technologies has the potential to make DTCs clinically useful in metastatic disease management and also as therapeutic targets.

The Premetastatic Niche

As described in section "**Current Clinical Observations and Challenges in Treating Metastasis**" of this chapter, the "seed and soil" hypothesis of metastasis was proposed by Paget in the late 1800s. Modern research continues to expand on this concept, with a rapidly growing emphasis on the "soil". Today, the "soil" of metastasis describes not only the distant organ but also a suitable microenvironment for metastatic growth, often referred to as the premetastatic niche. The microenvironment within distant organs is critical in the initiation of metastatic growth, as the dissemination of tumor cells alone is not sufficient for metastasis (section "**Disseminated Tumor Cells**"). First described by Kaplan and colleagues in 2005, the premetastatic niche is conceived to form before tumor cells arrive in the tissue. It is populated with bone marrow-derived cells (BMDCs) that promote the chemoattraction and attachment of disseminated cancer cells, as well as numerous other cell types that together impact cancer cell extravasation, survival, colonization, and aggressive growth. Revolutionary work by the Lyden group has revealed that tumor-derived exosomes, which are described in section "**Tumor-secreted exosomes**", initiate the formation of the premetastatic niche by reprograming stromal cells and determining organ specificity. Further work has found that a premetastatic niche can also be further enhanced in a tumor-independent manner by tissue damage or systemic physiological changes such as pregnancy. The unique features of the premetastatic niche can change surrounding tissue remarkably, revealing several signatures of possible metastatic development.

There are various key alterations that have been shown to prime tissue for the growth of metastatic lesions. One of the first observed phenomena is the recruitment of BMDCs to the premetastatic niche by a myriad of tumor secreted factors that can both mobilize the BMDCs from the bone marrow and attract them to specific sites. One example is primary tumor STAT3 signaling which induces secretion of factors such as IL6 and IL10 from tumor cells. This secretion results in widespread STAT3 activation in distant organs. In premetastatic lungs, STAT3 activation stimulates fibroblasts to produce fibronectin (FN) and induces the clustering of a specific BMDC type, the myeloid-derived suppressor cells (MDSCs), which together create a favorable site for metastatic growth. Interestingly, MDSCs are not the only immune cell found in the premetastatic niche, however there is widespread heterogeneity among research model systems. Neutrophils, macrophages, T-Cells, and MDSCs are all reported to infiltrate premetastatic tissues, and contribute to the favorable conditions for growth.

As well as the recruitment of several foreign cell types, the premetastatic niche is also prepared by the reprogramming of resident stromal cells. In bone tissue, senescence is induced in osteoblasts which results in their elevated secretion of IL6 and other factors that promote NFATc1-driven osteoclastogenesis. Osteoclasts function to remodel bone, a process that creates osteolytic lesions and provides a suitable environment for metastatic growth. Yet another example can be found in the premetastatic lung. Normal lung fibroblasts express the miR-30 family of microRNAs to limit MMPs and stabilize vasculature. Cancer cells, however, secrete exosomes whose contents can reprogram miR-30 family expression in lung fibroblasts, resulting in elevated MMPs and ultimately increased vascular permeability and metastasis.

Vascular permeability is key to the establishment of metastasis (section "**Tumor Vasculature**") and is targeted by exosomes for tumor-derived adaptation in preparation of the premetastatic niche. Specifically, tumor-secreted exosomes can promote dissemination of CTCs by transporting regulators of the vascular endothelial barriers to distant tissues. This modulation of the blood vessels in the premetastatic niche is key, as they directly control the arrest and extravasation of CTCs into the tissue. For example, brain metastasis by breast cancer cells is partially facilitated through the secretion of exosomes carrying miR-181c, which modulates actin to promote systemic vascular leakiness and the destruction of the blood-brain barrier.

Metabolic manipulation within target tissues of metastasis is another specific form of tumor-induced stromal cell reprogramming. Upon dissemination into a distant site, cancer cells must compete with the surrounding tissue for nutrients to establish a metastatic colony. Breast cancer cells have been shown to secrete exosomes containing miR-122, which reprograms lung

fibroblasts to decrease their glucose consumption by suppressing pyruvate kinase. By decreasing glucose consumption of resident cells, the cancer cells have increased glucose availability, which facilitates their proliferation and survival.

Finally, alterations in ECM are observed early in the formation of the premetastatic niche. One such change is the accumulation of FN, which can be induced by primary tumor-secreted factors. Hypoxia in the primary tumor has been shown to induce the secretion of FN and lysyl oxidase (LOX), which colocalize in the lung premetastatic niche to recruit myeloid cells in the lung. LOX can also mediate collagen cross-linking, which in turn increases MMP2 activity to also recruit myeloid cells. This phenomenon functions as a positive feedback loop because myeloid cells break down collagen IV, releasing it into the blood to function as a chemoattractant to draw yet more myeloid cells to the niche. Activated fibroblasts are another cell within the premetastatic niche that also excretes LOX, which results in collagen deposition and ECM stiffening to promote metastatic cell survival and engraftment.

The majority of premetastatic niche characteristics have been observed in the laboratory and are not routinely assessed clinically as they would require potentially unnecessary invasive procedures. However, several biomarkers of premetastatic niche formation can be identified by non-invasive blood biopsy. Current focus is being placed on circulating exosome contents, as tumor- secreted exosomes play a large role in adapting the distant stromal cells at the site of metastasis. By analyzing tumor-secreted factors clinicians may be able to determine the likelihood of metastatic spread, the organ of metastasis, or target mediators of premetastatic niche development.

Prospective Vision

Early detection and the interruption of metastasis pathways holds promise for the treatment of cancer patients with, or at risk of, metastatic disease. Target discovery efforts are currently focused on blocking metastasis at several steps, as the degree of metastatic progression in patients often cannot be determined. The obstacles that must be overcome for a tumor cell to achieve metastasis provide several vulnerabilities to exploit. The ability to enter the circulatory system, evade immune surveillance, extravasate into distant tissues, switch from dormancy to growth phase once disseminated, and establish a premetastatic niche are all essential steps of interest to target therapeutically. Detection and screening for metastatic pre-disposition are also important aspects of the current efforts in treating patients. The use of liquid biopsies continues to improve physicians' abilities to predict secondary site location and measure treatment response. In addition, studies of inherited predisposition have potential to begin early screening of cancer patients to determine their likelihood of developing secondary tumors. Finally, as new drugs are tested pre-clinically and in patients, researchers have begun to consider a specific shift in the end points of clinical trials for metastasis therapeutics. Preclinical metastasis therapies often provide a significant delay in the development of metastases rather than reducing the size of established lesions. It is thought that "time to new lesion" end points will be more beneficial in the prevention of an initial metastasis, or additional metastases. In summary, with sights focused squarely on improving detection and treatment, creative minds and the advancement of technology continues to accelerate our grasp of the nuanced biology of metastasis.

Glossary

AMPK 5′ AMP-activated protein kinase or AMPK is an enzyme that plays a role in cellular energy homeostasis. It is expressed in a number of tissues, including the liver, brain, and skeletal muscle. The net effect of AMPK activation is stimulation of hepatic fatty acid oxidation, ketogenesis, stimulation of skeletal muscle fatty acid oxidation and glucose uptake, inhibition of cholesterol synthesis, lipogenesis, and triglyceride synthesis, inhibition of adipocyte lipolysis and lipogenesis, and modulation of insulin secretion by pancreatic beta-cells. Recently AMPK is emerging as a possible metabolic tumor suppressor and target for cancer prevention and treatment. Activation of AMPK has been found to oppose tumor progression in several cancer types and offers a promising cancer therapy. AMPK activity opposes tumor development and progression in part by regulating inflammation and metabolism.

IGFs Insulin-like growth factors I (IGFs) are important mediators of growth, development, and survival. They are synthesized by almost any tissue in the body, and their action is modulated by a complex network of molecules, including binding proteins, proteases, and receptors, which all comprise the IGF system. IGFs may promote cell cycle progression and inhibition of apoptosis either by directly associating with other growth factors or indirectly by interacting with other molecular systems which have an established role in carcinogenesis and cancer promotion. In addition, increased serum levels of IGFs and/or altered levels of their binding proteins are associated with increased risk for developing several malignancies.

MAPK A mitogen-activated protein kinase (MAPK or MAP kinase) is a type of protein kinase that is specific to the amino acids serine, threonine, and tyrosine. MAPKs are involved in directing cellular responses to a diverse array of stimuli, such as mitogens, osmotic stress, heat shock, and proinflammatory cytokines. They regulate cell functions including proliferation, gene expression, differentiation, mitosis, cell survival, and apoptosis.

mTOR The mammalian target of rapamycin is a kinase that in humans is encoded by the MTOR gene. mTOR is a member of the phosphatidylinositol 3-kinase-related kinase family of protein kinases. mTOR functions as a serine/threonine protein kinase that regulates cell growth, cell proliferation, cell motility, cell survival, protein synthesis, autophagy, and transcription. Furthermore, mTOR also promotes the activation of insulin receptors and insulin-like growth factor 1 receptors.

REDD1 The protein regulated in development and DNA damage response 1 (REDD1) is a protein that in humans is encoded by the DDIT4 gene. REDD1 acts as a negative regulator of mTOR, and its clinical interest is based primarily on its effect on mTOR, which has been associated with aging and linked with diseases such as diabetes and cancer.

Introduction

Metformin is an orally administrated drug commonly used to lower blood glucose concentrations in patients with type II diabetes mellitus (T2DM). There is intense interest in the cancer prevention research community regarding the potential use of metformin (1,1-dimethylbiguanide) to decrease cancer incidence or cancer-related mortality. A series of recent metaanalyses confirmed the association of diabetes or prediabetes (impaired fasting glucose and/or impaired glucose tolerance) with an increased risk of cancer. Such metaanalyses have estimated a relative risks (RR) of 1.1–2.5 for cancer risk at various organ sites in patients with T2DM, as shown in **Table 1**.

Insulin-resistance and hyperinsulinemia are the principal conditions associated with T2DM. Various mechanisms have been reported to explain the relationship of T2DM with cancer incidence. In particular, insulin can exert its oncogenic effect through the stimulation of growth factors, such as insulin-like growth factor-I (IGF-I), and the concomitant reduction of the binding proteins (BPs) for these growth factors.

Metformin reduces gluconeogenesis and hepatic glucose production and improves insulin sensitivity by increasing peripheral glucose uptake. Thus, it does not increase the circulating insulin, and it is a relative safe drug with a good pharmacokinetic profile and mild toxicity that is usually well tolerated. The most common side effects are nausea and diarrhea, usually self-limited and transient. The only potential major adverse event during therapy is lactic acidosis, but a direct association between this condition and metformin use has not yet been clearly demonstrated. Moreover, this disease is rare and primarily confined to patients with concomitant renal and hepatic disorders.

Despite many epidemiological studies and metaanalyses showing an association between metformin use and reduced cancer incidence and mortality (fully discussed later), only a minority of these associations have a robust supporting evidence without suggestion of bias. In particular, time-related biases have been recently recognized as a major potential source of error in some epidemiologic studies, imposing a reevaluation of the literature linking metformin use to reduced cancer incidence, and indicating the need to conduct properly designed randomized clinical trial. The chapter summarizes the scientific evidence of metformin use to

reduce cancer incidence and mortality, from putative mechanisms of action through critical evaluation of observational studies and the limited data on clinical trials.

Molecular Mechanisms of Metformin in Cancer and Diabetes

Despite being introduced clinically in the 1950s, the exact mechanism of action of metformin has not been fully elucidated. This applies not only to its antihyperglycemic and antihyperinsulinemic effects but also to its anticancer properties. Two major mechanistic categories are relevant to the anticancer action of metformin: an indirect and a direct mechanism, not mutually exclusive and converging on the same molecular pathways.

Indirect Mechanisms

This category involves "endocrine-type effects" related to its insulin-lowering activity. Metformin acts on the liver to inhibit hepatic production of glucose, antagonizing glucagon-mediated effects that lead to hyperglycemia in diabetics. To a lesser extent metformin increases insulin-mediated uptake of glucose in skeletal muscle, though not by increasing insulin levels, as the drug actually decreases the hyperinsulinemia that is seen in diabetes. Since high insulin levels are known to stimulate proliferation of some common cancers, this decrease in insulin levels may slow tumor proliferation in hyperinsulinemic patients.

Direct Mechanisms

In this category metformin exerts its effects directly on the target cells by an insulin-independent mechanism that leads to suppression of ATP production via metformin's inhibition of mitochondrial complex I. NADH-ubiquinone oxidoreductase (Complex I) plays an essential role in biosynthesis and redox control during proliferation, resistance to cell death, and metastasis of cancer cells. Both routes of metformin activity converge on the mTOR (mammalian target of rapamycin) pathway resulting in inhibition of its proproliferative activity.

Table 2 Possible pathways involved in the anti-cancer effects of metformin

Mechanism	*Function*
AMPK-dependent	Inhibition of cell mitosis and proliferation Upregulation of the p53 axis DNA synthesis Growth inhibition Cell apoptosis
AMPK-independent	REDD1 mediates cell cycle arrest Induced apoptosis
Suppression of mTOR	Inhibition of cell growth Induction of apoptosis Induction of autophagy Inhibition of tumor promotion Suppression of HER2 overexpression
Suppression of IGF signaling	Prevention of IGF-1R upregulation Reduction of cell proliferation and invasion Reduction of circulating insulin and IGF-1 Arrest of cell growth and proliferation
The MAPK signaling pathway	Arrest of tumor cells migration and invasion Inhibition of cell growth, colony formation Induction of cell cycle arrest Survival signals blockade

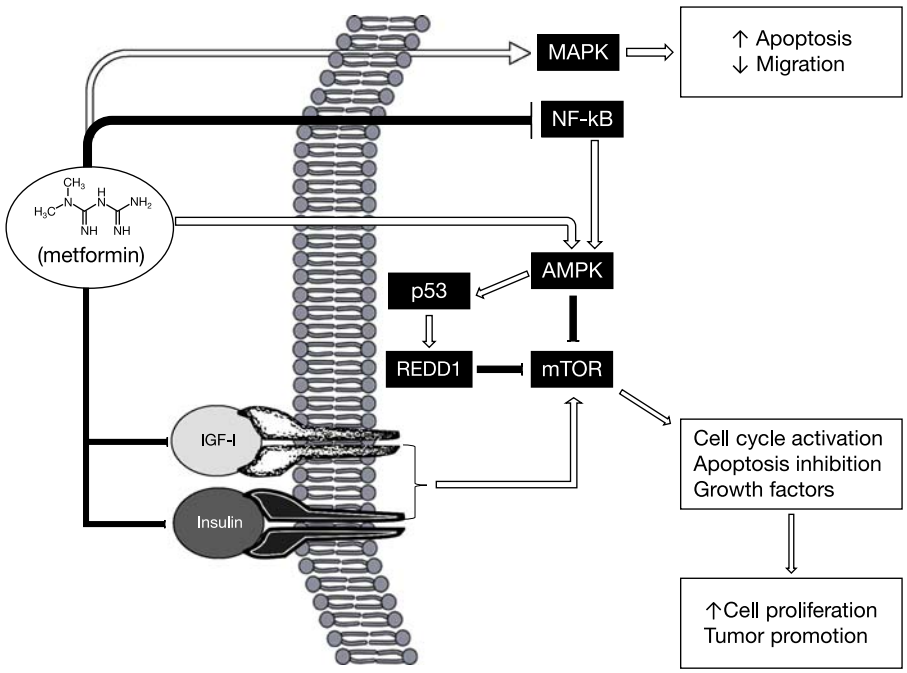

Fig. 1 Main signaling pathways involved in the anti-cancer effects of metformin.

Table 2 and Fig. 1 show some possible signaling pathways involved in the anticancer effects of metformin. Some effects are mediated by the activation of adenosine monophosphate protein kinase (AMPK), an intracellular energy sensor whose activation inhibits cell mitosis and proliferation by directly influencing the dynamics of cell division. Metformin stimulates AMPK through upregulation of the p53 axis. However, certain antitumor effects of metformin are independent of the AMPK signaling pathway. Metformin directly influences mTOR in a p53-dependent manner through an AMPK-independent mechanism increasing the level of REDD1, a negative regulator of mTOR, thus contributing to the cell circle arrest. mTOR regulates cellular energy homeostasis by modulating protein synthesis and autophagy, and exerting significant positive effect on cell proliferation and tumorigenesis. An imbalanced activation of mTOR is associated with malignant tumor progression, drug resistance, and a worse prognosis. mTOR metformin-induced inhibition of the mTOR pathway has been demonstrated in different types of cancer and through AMPK-dependent and -independent pathways.

The suppression of IGF signaling is another possible mechanism of action: insulin and IGFs are key regulators of metabolism and cancer progression by activating signaling pathways associated with cell growth and proliferation. There are two subtypes of IGF, IGF-1 and IGF-2, which are both mitogenic and antiapoptotic. IGF-1 receptor (IGF-1R) binds to the ligand IGF-1, IGF-2, or insulin to promote autophosphorylation of tyrosine at its kinase domain and with a consequent activation of signaling through the phosphatidylinositol-3-kinase PI3K/Akt/mTOR and RAS/RAF/mitogen-activated protein kinase (MAPK) pathways.

Emerging evidence suggests that metformin decreases IGF-1 by indirectly downregulating insulin and insulin-binding proteins to reverse hyperinsulinemia.

Metaanalyses of Observational Studies and Randomized Controlled Trials Examining the Effect of Metformin on Cancer Incidence and Mortality

Multiple metaanalyses of observational studies have reported the use of metformin is associated with a decrease in cancer incidence ranging from 14% to 40%, along with a decrease in mortality in the same range (Table 3). Organ sites include the breast, colon, liver, pancreas, prostate, endometrium, and lung, among others. However, these studies have a multitude of study designs, from cohort and case-control studies through randomized controlled trials. As the level of scientific evidence increases with the study design, the effect of metformin on cancer incidence appears to decrease. Thakkar et al. showed that while cancer incidence was decreased by 30% in cohort studies and 10% in case-control studies, there was no clear effect in randomized controlled trials. Gandini et al. performed a metaanalysis with particular attention to biases and confounders and also found that the risk reduction for cancer incidence decreased from 31% for all studies to 29% for prospective studies to 5% for randomized clinical trials.

Several authors suggested that the existing metformin literature might be subject to important sources of time-related bias, which potentially overestimate cancer-reducing effects. Time-related bias is a form of differential misclassification bias that can be avoided by appropriate accounting of follow-up time and exposure status in the design and analysis of studies. There are different types of time-related biases: (i) immortal time bias, when unexposed time is misclassified as drug-exposed time; (ii) time-window bias, when there are differential exposure opportunity time windows between exposed and unexposed subjects; (iii) time-lag bias, when there's a comparison of treatment given during different stages of the disease. Immortal time bias refers to a period of cohort follow-up time during which a cancer event (that determines end of follow-up) cannot occur. Immortal time bias can arise when the period between cohort entry and date of first exposure to metformin, during which cancer has not occurred, is either misclassified or excluded and not accounted for in the analysis. In particular this is frequently found in studies that compare "ever users" against "nonusers" and do not take into account, in the analysis and in the study design, of time of use (when patients' start and stop metformin). Caution should be used also when analyzing cohort studies where a first-line therapy with metformin is compared with second- or third-line therapies. Patients are unlikely to be at the same stage of diabetes, which can induce confounding of the association with an outcome (e.g., cancer incidence) by disease duration. An outcome related to the first-line therapy may also be attributed to the second-line therapy if it occurs after a long period of exposure. Such a situation requires matching on disease duration and consideration of latency time windows in the analysis.

In the metaanalysis performed by Gandini et al., time-related biases were taken into account, resulting in a diminution of the protective effect on cancer incidence. The risk reduction in cancer incidence at all sites decreased from 30% to 10%, albeit still statistically significant. When focusing on specific organ sites, metformin use was significantly associated with decreased breast cancer incidence, but the magnitude of the effect was not clinically relevant. For colon cancer, 8% decrease in incidence was calculated. For prostate and pancreatic cancers, metformin use was not associated with a statistically significant protective effect. For lung cancer, examination of all studies showed a 18% decrease in cancer incidence. Adjustment for time-related biases decreased this protective effect to a statistically significant 12%, but adjustment for smoking, which is by far the most relevant lung cancer risk factor, resulted in no association between metformin use and cancer incidence. Similarly, the strong protective effect of metformin use against liver cancer became nonsignificant when only unbiased studies were examined. It should be emphasized, however, that the total number of studies and patients was rather small for the liver cancer associations, and thus these results should be interpreted with caution. Notably, a very recent metaanalysis of studies using metformin as a reducer for liver cancer risk in diabetic patients reported that metformin use reduced the ratio of liver cancer by 48% compared with nonusers. The protective effect was validated in all the exploratory subgroup analyses, except that pooled result of post hoc analyses of two randomized controlled trials found no significant difference between subjects with metformin and those without. After adjusting for hepatitis B/C virus infection, cirrhosis, obesity, behavioral factors, and time-related bias, the association was stable, pooled OR ranged from 0.42 to 0.75.

Another potential source of confounding that is often not adequately explored in the existing literature is the effect of obesity and its surrogate, body mass index (BMI). Obesity is intimately linked to increased risk of multiple cancer types. Potential mechanisms include both direct and indirect effects of obesity on insulin, IGF-1, sex hormones, adipokines, and inflammation, many of which are directly impacted by metformin. Metformin, unlike several other antidiabetic agents, is associated with weight loss. Furthermore, a recent clinical trial showed that metformin affected breast cancer proliferation differentially according to insulin resistance status and BMI, with a trend toward inhibiting proliferation only in women with insulin resistance or high BMI.

Gandini et al. examined BMI as a potential confounder and found that adjustment for BMI decreased the protective effect of metformin for all-cancer incidence from 31% to 18%, which was still statistically significant. For breast cancer, adjustment for BMI revealed a borderline association of metformin use with cancer incidence. For colon and prostate cancer, there was no statistically significant association between metformin use and cancer incidence. Other organ sites could not be assessed due to a small number of published studies with adjusted estimates. It should be noted, however, that BMI is dynamic and therefore adjusting for a single BMI assessment might be inadequate to account for confounding by BMI dynamics over time. Furthermore, Gandini et al. were unable to assess the effect of BMI and time-related biases simultaneously due to inadequate numbers of studies that controlled for both factors.

The effect of metformin on cancer mortality is influenced by a limited literature and thus Gandini et al. were unable to determine the effect by cancer sites. However they found that metformin use was associated with a 34% decrease mortality that remained significant when the analysis was limited to prospective studies. Adjustment for BMI maintained the magnitude of the effect although adjustment for time-related biases, limited to only three studies, resulted in loss of statistical significance. Different mechanisms may be responsible for effect of metformin on cancer mortality compared with cancer incidence. Several retrospective analyses have suggested that diabetics treated with metformin during chemotherapy have longer survival than individuals treated with other antidiabetic agents. A previous mouse xenograft study showed that metformin targets breast cancer stem cells and synergizes with doxorubicin to prevent relapse. Increasing the effectiveness of chemotherapy could result in improved survival.

Taken together, these results point out the limitations of the current literature regarding the association between metformin use and cancer incidence and mortality. While all the studies, including metaanalyses, suggest that metformin use is associated with a reduced risk of cancer and death, the effect may be far smaller than previously believed.

Published Clinical Trials of Metformin in Cancer

Table 4 summarizes the main characteristics of the completed clinical trials (mainly phase II) in cancer patients with metformin. Two studies examined various doses of metformin given for 3–6 months to women after therapy for breast cancer. Goodwin et al. phase II study (2008) examined women with breast cancer who completed adjuvant therapy and whose plasma levels of insulin were at least 45 pmol/L. Metformin decreased circulating insulin levels by 22.4% significantly. Campagnoli et al. study (2012) enrolled women with breast cancer, who had completed adjuvant therapy but had elevated testosterone, and compared two different doses of metformin. The higher dose (1500 mg/day) significantly reduced serum testosterone levels and free androgen index compared to the lower dose. In 2015, Goodwin and colleagues analyzed 492 patients enrolled in the NCIC Clinical Trials Group MA.32 phase III trial (metformin vs placebo effect on invasive disease-free survival and other outcomes in early breast cancer) to explore whether metformin may improve metabolic factors (insulin, glucose, leptin, highly sensitive C-reactive protein [hs-CRP]). At 6 months, decreases in weight and blood variables were statistically significantly greater in the metformin arm (vs placebo) in univariate analyses: weight – 3.0%, glucose – 3.8%, insulin – 11.1%, homeostasis model assessment – 17.1%, leptin – 20.2%, hs-CRP – 6.7%. There was no statistically significant interaction of change in these variables with baseline BMI or insulin. Five trials examined the short-term effects (1–4 weeks) of various doses of metformin on cell proliferation (Ki-67) in women awaiting surgery for breast cancer (presurgical, window of opportunity trial). Hadad et al. (2011) found a 3.4% reduction in Ki-67 in the metformin arm, but 29% of the patients on metformin withdrew due to gastrointestinal side effects. Bonanni et al.

Table 4 Completed phase II–III clinical trials of metformin in cancer patients

First Author (year of publication)	*Phase*	*Organ*	*Number of patients*	*Patients Characteristics*	*Treatment*	*Endpoint*	*Results*

Abbreviations: *MET*, Metformin; *AMPK*, Phospho-adenosine monophosphate-activated protein kinase; *HD*, High dose; *LD*, Low dose; *HOMA-IR*, Homeostasis model assessment-insulin resistance; *IGF-1*, Insulin-like growth factor-1; *TUNEL*, Terminal eoxynucleotidyl transferase dUTP nick end labeling; *HOMA*, Homeostasis model assessment; *hs-CRP*, Highly sensitive C-reactive protein; *IGFBP-3*, Insulin-like growth factor binding protein 3; *BMI*, Body mass index; *CRP*, C-reactive protein; *Ps6*, Phospho-ribosomal protein S6; *pS6K1*, Phosphorylated S6 kinase; *IGFBP-7*, Insulin-like growth factor binding protein 7; *ERK1/2*, Phospho-extracellular signal-regulated kinase 1/2; *ACF*, Aberrant crypt foci.

(2009) performed a larger double-blind, placebo-controlled study, where metformin effect on Ki-67 change relative to placebo was not statistically significant, with a mean proportional increase of 4.0%. Women with a HOMA index (Homeostasis Model Assessment, used to quantify insulin resistance) >2.8 had a nonsignificant decrease of 10.5% while women with a HOMA index <2.8 had a nonsignificant increase of 11.1%. The interaction between HOMA index and metformin on Ki-67 was statistically significant; a similar trend was seen with BMI although the interaction was not statistically significant. Niraula et al. (2012) in a single-arm trial reported a 3% decrease in Ki-67 ($p = 0.016$) after a median of 18 days of treatment, and a recently completed study (Kalinsky et al., 2014) showed no reduction in Ki-67. Two studies have been reported in women with early-stage endometrial cancer. Endometrial cancer prevention is of particular interest because of its relationship with obesity and the use of metformin for treatment of polycystic ovary syndrome, a condition associated with increased endometrial cancer risk. In the Laskov study (2011), 11 newly diagnosed, untreated, nondiabetic patients with endometrial cancer received metformin 500 mg tide from diagnostic biopsy to surgery. Ki-67, pAMPK, and pS6 immunohistochemistry staining were performed on the endometrial cancer before and after metformin treatment, and they were compared with a control group of 10 women with endometrial cancer who did not receive metformin. Mean plasma insulin, IGF-1, and IGFBP-7 were significantly reduced after metformin treatment. A clear reduction in Ki-67 and pS6 expression was observed by both conventional light microscope analysis and digital image analysis with a significant mean reduction in percentage of cells staining for Ki-67 and pS6. In the untreated control group expression of ki-67 was similar between the biopsy and the surgical specimens. Mitsuhashi et al. trial (2014) reported that increasing the dosage from 750 mg QD to 1500 mg or 2250 mg for 4 weeks of metformin resulted in a 44.2% decrease in Ki-67. Three additional studies in other organ systems (Barrett's esophagus, colon, and prostate) have been published. A study in Barrett's esophagus (Chack et al., 2015) showed no significant change in phosphor-serine 6 kinase (pS6K), cell proliferation, or apoptosis. Hosono et al. (2010) study examined change in the number of aberrant crypt foci (ACF, a putative precursor of colon cancer) in individuals with preexisting ACF, randomizing participants to a very low dose of metformin (250 mg/day) or no treatment for one month. A significant decrease in ACF from 8.78 ± 6.45 to 5.11 ± 4.99 was observed in the metformin arm but not in the control group. Additionally, proliferation was significantly decreased in the metformin group. Recently, Hirugashi et al. (2016) in a phase III trial reported that the administration of low-dose metformin (250 mg/daily) for 1 year to patients without diabetes after colorectal polipectomy has shown to be safe and to reduce the prevalence and number of metachronous adenomas or polyps. In the trial published by Joshua et al. (2014), men with prostate cancer were treated with metformin for 4–12 weeks prior to surgery. The primary endpoint, change in Ki-67, was statistically significant, with an absolute decrease of 1.44%. In a per patient and per tumor analyses, metformin reduced the Ki67 index by relative amounts of 29.5% and 28.6%, respectively.

Ongoing Phase III Trials With Metformin in Cancer Patients and Prevention

Table 5 summarizes the main characteristics of ongoing phase III clinical trials in cancer patients with metformin. NCT01864096 trial aims to see if metformin can delay the time to progression in men with low-risk prostate cancer when compared to a placebo. NCT01101438 is looking at whether metformin can decrease or affect the ability of breast cancer cells to grow and whether metformin will work with other therapies to keep cancer from recurring. NCT02614339 trial wants to identify the effect of adjunctive metformin on recurrence of nondiabetes mellitus stage III colorectal cancer. This trial is open-label randomized controlled study, and the primary endpoint is to compare the 3-year disease-free survival between metformin group and nonmetformin group. The secondary endpoint is to compare the 5-year overall survival and disease-specific survival between two group, to identify the safety of metformin, and to compare the recurrence rate of polyps after polypectomy between two groups. NCT01697566 study analyzes the effects of metformin and/or a program called "lifestyle intervention" on the endometrium in postmenopausal women who are also obese (both risk factors for endometrial cancer). Lifestyle intervention is made up of a series of in-person sessions with a coach to discuss strategies for losing weight and ways to increase physical activity. NCT03184493 is a prospective trial to compare the role of celebrex alone, metformin alone, and celebrex plus metformin in preventing hepatocellular carcinoma recurrence after hepatic resection. NCT02065687 is a randomized phase II/III trial to investigate how well paclitaxel, carboplatin, and metformin hydrochloride works and compares it to paclitaxel, carboplatin, and placebo in treating patients with endometrial cancer that is stage III–IV. The hypothesis is that metformin may help paclitaxel and carboplatin to work better by making cancer cells more sensitive to the drugs. NCT02040376 is a placebo-controlled, double-blind crossover trial of metformin in 30 children treated with radiation for medulloblastoma, the most common malignant brain tumor. Tests of thinking and learning and brain imaging techniques will be used to examine whether metformin can enhance cognition or promote brain repair following radiation-induced brain injury. NCT01905046 tests whether metformin is able to get rid of atypia (early cell changes that are thought to be a marker of breast cancer risk) in women at increased risk for breast cancer. A total of 300 patients with atypia (Masood Score 14–17) on random periareolar fine needle aspiration (RPFNA) at baseline are expected to be randomized between Metformin and placebo control arm. The randomization will be stratified for known BRCA mutation (BRCA1 or BRCA2 mutation vs no mutation), prior excisional biopsy (atypical epithelial hyperplasia, atypical lobular hyperplasia, flat epithelial hyperplasia vs DCIS vs LCIS), and baseline fasting insulin levels. The primary objective is to test for the presence or absence of cytological atypia in RPFNA bilateral aspirates after 12 and 24 months.

Table 5 ClinicalTrials.gov Search Results 07/14/2017

NCT number	*Recruitment*	*Conditions*	*Interventions*	*No. of patients*	*Study designs*	*Primary endpoint*
NCT01864096	Recruiting	Prostate cancer on active surveillance	Metformin versus placebo	408	Randomized; double blinded	Time to progression
NCT01101438	Active, not recruiting	Breast cancer	Metformin versus Placebo	3649	Randomized; double blinded	Invasive disease-free survival
NCT02614339	Active, not recruiting	Stage III colorectal cancer Nondiabetic	Metformin versus control	593	Randomized; open label	Disease-free survival
NCT01697566	Active, not recruiting	Healthy women; BMI $\geq$ 30	Metformin versus placebo	100	Randomized; double blinded	Ki-67
NCT03184493	Recruiting	Liver cancer	Metformin plus celebrex versus Metformin versus cerebrex	200	Nonrandomized	1-year tumor recurrence
NCT02065687	Recruiting	Endometrial cancer	Metformin plus paclitaxel and carboplatin versus paclitaxel and carboplatin	540	Randomized; double blinded	Overall survival
NCT02040376	Recruiting	Children with cranial-spinal radiation for medulloblastoma	Metformin versus placebo	30	Randomized; double blind; crossover	Fostering brain repair
NCT01905046	Recruiting	Breast ADH; BRCA1/2 mutation carrier; DCIS; LCIS	Metformin versus Placebo	400	Randomized; double blinded	Presence of atypia in RPFNA

Abbreviations: *NCT*, Number of clinical trial; *ADH*, Atypical ductal hyperplasia; *DCIS*, Ductal carcinoma in situ; *LCIS*, Lobular carcinoma in situ.

Conclusions

The emerging data from preclinical, epidemiologic, and clinical studies suggest that there is a signal for cancer-preventive potential with metformin use. There is biologic plausibility for a cancer-preventive effect given the multiple ways that metformin can interfere with cancer-promoting signaling pathways. However, both animal and epidemiologic studies have shown somewhat mixed effects. Further, the epidemiologic literature reviewed presented results that regard mainly individuals with diabetes and the effect is of lesser magnitude than previously reported once the appropriate adjustments to avoid bias and confounding are made. It remains to be determined whether a similar protective effect on cancer risk and mortality can be confirmed in nondiabetic individuals by properly designed studies. Multiple ongoing clinical trials are addressing which cancer patient cohorts are most likely to benefit from metformin.

Although the long history and clinical experience with metformin make it a very attractive candidate for drug repurposing, general recommendations about its use, particularly in nondiabetic populations, need to await the results of the ongoing studies.

Glossary

Aceto(acetyl)-CoA Acetyl CoA is formed from pyruvate in the final stages of glycolysis and is also a metabolite from fatty acid catabolism (beta oxidation) and a precursor of ketone bodies, which are accumulated in a status of hunger. Addition of an acetyl-residue results in aceto(acetyl)-CoA, a substrate for enzymes of the upper mevalonate pathway.

Bisphosphonate Also named diphosphonates, group of chemical compounds which contain two phosphonate groups, this group of drugs is known to inhibit osteoclasts.

GTPases A large family of hydrolase enzymes that can bind to and hydrolyze guanosine triphosphate (GTP). The GTP binding and hydrolysis takes place in the highly conserved G domain, which is common to all GTPases.

NAD(P)H Nicotinamide adenine dinucleotide phosphate, abbreviated $NADP^+$, is a cofactor on anabolic reactions, which require NAD(P)H as a reducing agent. $NADP^+$ differs from NAD^+ in the presence of an additional phosphate group on the 2′ position of the ribose ring that carries the adenine moiety.

Prenylation The addition of hydrophobic molecules to a protein or to a chemical compound. It is assumed that prenyl groups (3-methyl-but-2-en-1-yl) facilitate attachment to cell membranes.

RHOA and RHOB A family of small (~21 kDa) signaling G proteins. The members of the Rho family have been shown to regulate many aspects of intracellular actin dynamics and metabolic processes.

Squalene A 30′carbon unsaturated oily liquid hydrocarbon and an important metabolite in cholesterol biosynthesis.

Sterol regulatory element-binding protein (SREBP) SREBPs are transcription factors that bind to the sterol regulatory element DNA sequence TCACNCCAC.

Statin A class of drugs that reduce the levels of lipids in the blood by altering the enzyme activity of 3-hydroxy-3-methylglutaryl-CoA reductase (HMGCR).

Sterol isoprenoids Basically, isoprenoids are a class of organic compounds composed of two or more units of hydrocarbons, with each unit consisting of five carbon atoms arranged in a specific pattern. These compounds include certain sterols, oxysterols, farnesol, and geranylgeraniol, as well as the diphosphate derivatives of isopentenyl, geranyl, farnesyl, geranylgeranyl, and presqualene. They regulate transcriptional and posttranscriptional events that in turn affect lipid synthesis, meiosis, apoptosis, developmental patterning, protein cleavage, and protein degradation.

Introduction

The mevalonate pathway (MP) also known as the isoprenoid pathway or 3-hydroxy-3-methylglutaryl-CoA reductase (HMGCR) pathway is an anabolic pathway providing metabolites for multiple cellular processes in eukaryotes, archaea, as well as some bacteria, thus underscoring its importance for nearly all living organisms including humans.

The mevalonate which is produced from acetoacetyl-CoA by HMGCR (Fig. 1) is further processed to sterol isoprenoids, such as cholesterol, which is an indispensable precursor of bile acids, lipoproteins, and steroid hormones, and to a number of hydrophobic molecules including nonsterol isoprenoids, such as dolichol, heme-A, isopentenyl tRNA, and ubiquinone. Intermediates of this network play important roles in the posttranslational modification of a multitude of proteins involved in inter- and intracellular signaling.

Besides its key role for cholesterol synthesis, the MP has become a challenging topic, when a large number of experimental and clinical studies suggested that inhibition of the MP might have valuable interest in human disease the management of multiple human diseases, besides cardiovascular diseases. Molecules arising from the MP are essential for cell growth and differentiation. They appear to be potential interesting therapeutic targets for many areas of ongoing research: oncology, autoimmune disorders, atherosclerosis, and Alzheimer disease. Also, considerable progress has been made in understanding the pathophysiology of two autoinflammatory disorders resulting from an inherited deficiency of mevalonate kinase (MK), the first committed enzyme of the MP.

Biochemistry of the MP

Upper MP

The mevalonate–isoprenoid pathway involves first the synthesis of 3-hydroxy-3-methylglutaryl-CoA (HMG)-CoA from acetyl-CoA through acetoacetylCoA. HMGCR, one of the best-regulated enzymes in nature, catalyzes the conversion of HMG-CoA to mevalonic acid. HMGCR is the rate-limiting enzyme of MP.

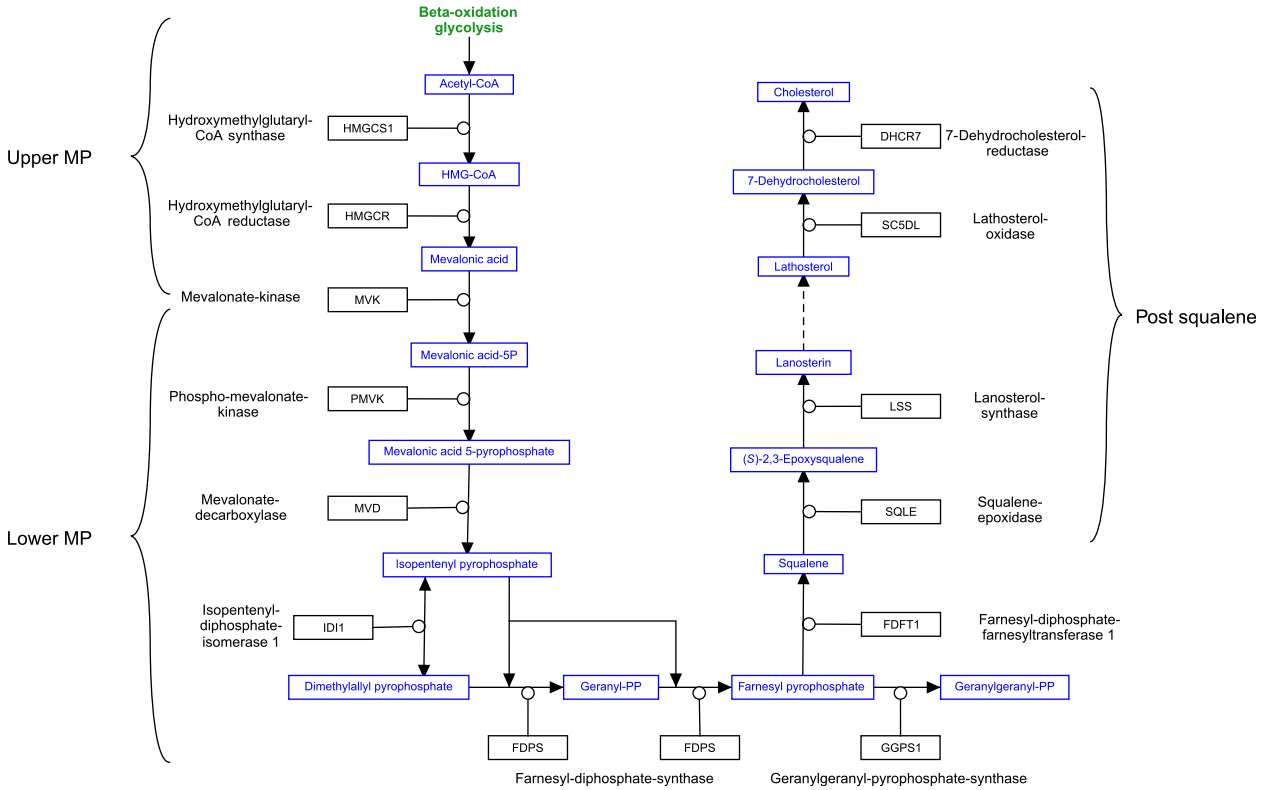

Fig. 1 Chemical reactions of the mevalonate pathway (MP). MP pathway enzymes condense three acetyl-CoA molecules in a two-step reaction to produce 3-hydroxy-3-methylglutaryl CoA (HMG-CoA). Both reactions are reversible and in equilibria, with the intracellular concentration of acetyl-CoA being the primary driver. HMG-CoA is then reduced by HMG-CoA reductase (HMGCR) to produce mevalonic acid (MA) via an irreversible reaction. MA is then converted into isopentenyl-diphosphate through a series of enzymatic steps, which serves as a monomeric unit for the consequent synthesis of all downstream metabolites. *Dashed arrows* indicate multiple steps.

In the absence of sterol isoprenoids in the cell, a family of transcription factors, named sterol regulatory element-binding proteins (SREBPs), directly activates HMGCR gene transcription. SREBPs regulate not only HMGCR gene transcription but also every step of cholesterol synthetic pathway by increasing gene expression of all the enzymes acting in the MP. In addition, other regulatory mechanisms can influence the activity of HMGR. The degradation rate of HMGR protein is influenced by cell's requirements for isoprenoids. Cell's requirements for isoprenoids will determine the rate of translation of HMGCR mRNA.

The investigation of yeast HMGCR accounted for mevalonate production following the reaction:

$$S-HMG-CoA+2NADPH+H^{+}\rightarrow R-mevalonate+2NADP+CoASH$$

The enzyme HMGCR is found in eukaryotes, archaea, and some eubacteria. The conversion of the thioesterified HMGCoA carboxyl to an alcohol represents a two-step reduction, accounting for the stoichiometry of NADPH in the reaction. The reaction thus proceeds through the successive reduction steps to first produce bound mevaldyl-CoA, collapse of the thiohemiacetal to release CoASH and form mevaldehyde; the second reduction step then forms product mevalonate.

The eukaryotic proteins (class I HMG-CoA reductases) are associated with the endoplasmic reticulum (ER) and interact through membrane spanning helices in the N-terminal domain. Consequently, the catalytic domain follows this membrane-anchoring sequence. These class I enzymes are potently inhibited by the class of statin drugs that effectively modulate sterol synthesis and, as a result, have been heavily investigated. There is no homologous sequence for membrane association at the N-terminus in the bacterial HMG-CoA reductases (class II), and a few of these (some in recombinant form) have been isolated as soluble proteins. The *Pseudomonas mevalonii* enzyme has a degradative function, allowing this microbe to grow on mevalonate as a carbon source. In contrast, the *Staphylococcus aureus* enzyme has a biosynthetic function and is encoded by a gene within a MP gene cluster.

Despite the low overall sequence homology (<20%) and overall protein structure architecture between class I (eukaryotic) and class II (bacterial) HMGCR enzymes, there is considerable similarity between these enzymes in the positioning of active site residues important to catalytic function. Residues from two different subunits contribute to an active site. The histidine proposed to function in protonation of product Coenzyme A is appropriately positioned for this role. The aspartate implicated by mutagenesis is located within the active site and involved in a hydrogen bond network with the lysine and the glutamate that have been identified by functional studies. While both lysine and glutamate are in close proximity to the HMG-CoA thioester carbonyl that is reduced to form

mevalonate, there are different proposals concerning their precise roles in substrate carbonyl polarization and/or the proton transfers that accompany substrate reduction by NADPH.

Lower MP

The lower MP converts mevalonate into the relatively unreactive isopentenyl pyrophosphate (IPP), which further is converted to the more reactive electrophile dimethylallyl pyrophosphate. There exist (at least) three variants of the lower MP: In eukaryotes, mevalonate (MV) is phosphorylated twice in the 5-OH position and then decarboxylated to yield IPP. In some archaea such as *Haloferax volcanii*, mevalonate is phosphorylated once in the 5-OH position, decarboxylated to yield isopentenyl phosphate (IP), and finally phosphorylated again to yield IPP (Archaeal Mevalonate Pathway I). A third MP variant found in the archaeon *Thermoplasma acidophilum* phosphorylates mevalonate at the 3-OH position followed by phosphorylation at the 5-OH position. The resulting metabolite, mevalonate-3,5-bisphosphate, is decarboxylated to IP and finally phosphorylated to yield IPP (Archaeal Mevalonate Pathway II).

In eukaryotes, the above-mentioned phosphorylation is done by MK. MK also known as MVK or ATP: mevalonate 5-phosphotransferase catalyzes the transfer of ATP's c-phosphoryl to the C5 hydroxyl oxygen of mevalonic acid, resulting in formation of mevalonate 5-phosphate and ADP. The reaction was characterized in yeast; the protein is found in eukaryotes, archaea, and certain eubacteria. The enzyme was highly purified from porcine liver and was demonstrated to catalyze a sequential reaction with mevalonate substrate binding first and MgADP product released.

MK is the second essential enzyme of the isoprenoid/cholesterol biosynthesis pathway, after HMGCR, catalyzing the phosphorylation of mevalonic acid into phosphomevalonate. Although MK not has the rate-limiting properties of HMGCR, it is demonstrated that MK activity is regulated via feedback inhibition by intermediates in the isoprenoid/cholesterol pathway geranyl pyrophosphate, farnesyl pyrophosphate (FPP), and geranylgeranyl pyrophosphate (GGPP).

High-affinity feedback inhibition has also been observed using a recombinant human protein and contrasted with lower-potency inhibition (10^{-5} M) of the *Staphylococcus aureus* enzyme.

Inherited human mevalonate kinase (MVK) mutations are correlated with two diseases, accounting for mevalonic aciduria (MVA) and Hyper-IgD syndrome.

Phosphomevalonate kinase (PMK) catalyzes the next step in isoprenoid/sterol biosynthesis, converting mevalonate 5-phosphate and ATP to mevalonate 5-diphosphate and ADP.

Activity of this enzyme was demonstrated in pig liver, and the pig liver enzyme has subsequently been isolated and more extensively characterized. PMK is found in eukaryotes and some eubacteria. The amino acid sequences for animal and low-homology invertebrate PMK proteins are not orthologous to those for PMK in plants, fungi, and bacteria. Thus, the proteins that catalyze the enzymatic reaction differ widely, depending on their source. Animal and invertebrate PMK proteins are known for a tertiary and quaternary structure, which is typical of the nucleoside monophosphate kinase family. The other PMK proteins are members of the galactokinase, homoserine kinase, MK, and phosphomevalonate kinase (GHMP) family. The tissue-isolated pig enzyme is reported to catalyze an ordered sequential reaction with mevalonate 5-phosphate assigned as the first substrate bound and ADP as the last product released. A recombinant form of *Streptococcus pneumoniae* has been characterized and reported to catalyze a random sequential bi-bi reaction. A recombinant form of *Enterococcus faecalis* PMK has also been isolated and characterized. The sequence of human PMK has been deduced.

Functional investigations of the recombinant human enzyme showed that the reaction catalyzed by PMK is a reversible reaction; kinetic constants of human PMK have been determined for both forward (formation of mevalonate 5-diphosphate) and reverse (formation of mevalonate 5-phosphate) reaction.

In the next step, mevalonate diphosphate decarboxylase; various abbreviations appear in the literature: MVD (in Fig. 1), also known as MDD, MPD, DPMDC, catalyzes the ATP-dependent decarboxylation of mevalonate 5-diphosphate to form isopentenyl 5-diphosphate (IPP), as indicated in the equation (Fig. 1).

This reaction is essential to the MP of polyisoprenoid and sterol synthesis. Activity has been measured in animals, plants, and yeast. Genetic complementation has implied activity in the *Staphylococcus aureus* and *Trypanosoma brucei* proteins. Highly purified active enzyme has been prepared from avian, porcine, and rat tissue and in recombinant form from bacteria expressing the yeast, human *Trypanosoma brucei*, and *Staphylococcus aureus* proteins. Characterization of the tissue-isolated protein implied the presence of an arginine that influences activity of the avian enzyme and documented the selectivity for divalent cation. The avian enzyme was also used to demonstrate that the transient phosphoryl transfer to the C3 oxygen proceeds with inversion of stereochemistry and, thus, no covalent E–P intermediate forms.

Farnesyl transferase (FTase) and geranylgeranyl transferases (GGTase) are two enzymes that carry out the process of prenylation in the cell. This process involves the covalent attachment of hydrophobic molecules (either the C-15 isoprene farnesyl or the C-20 isoprene geranylgeranyl groups) to the C-terminal end of some proteins including the γ-subunit of heterotrimeric G proteins, heme-A, nuclear lamins, and small GTP-binding proteins. Prenylation promotes the attachment of these proteins to internal cell membranes by means of a lipid anchors such as palmitate.

Such posttranslational modifications and activation GTP-binding proteins Rho, Rac, Rab, Rap, Ras play an important role in many important signaling cascades within the cell. Downstream from FPP the squalene synthase (FDFT1, also known as farnesyl-diphosphate farnesyl transferase 1) catalyzes the first committed step of the specific hepatic cholesterol biosynthesis at the final branch point of the cholesterol biosynthetic pathway, converting farnesyl-pyrophosphate into squalene. Squalene is then converted after a two-step cyclization into lanosterol, which is converted to cholesterol after a series of additional reactions.

Another downstream branch from FPP is catalyzed by the enzyme geranylgeranyl diphosphate synthase 1 (GGPS1) and leads to the synthesis of GGPP from farnesyl diphosphate and isopentenyl diphosphate. GGPP is an important molecule responsible for the C20-prenylation of proteins and for the regulation of a nuclear hormone receptor (**Fig. 1**).

Prenylation of Small GTPases and Brain Function

As mentioned earlier, FPP and GGPP are substrates for protein prenylation, and small GTP-binding proteins (sGTPases) represent the largest and most extensive characterized group of prenylated proteins. This superfamily is classified according to sequence and function similarity, into Ras, Rho, Rab, Sar1/Arf, and Ran families. The regulation of the activity of sGTPases is somewhat complex, and it has been extensively reviewed in greater detail, nonetheless, in general terms, sGTPases cycle between a guanosine diphosphate (GDP)- and GTP-bound conformation. The GDP-bound conformation is generally considered an inactive state, while the GTP-bound sGTPase activates downstream pathways by binding to specific effectors. sGTPases associate with the cytoplasmic leaflet of cellular membranes, where they perform their respective function. However, sGTPases are not transmembrane proteins, and in order to anchor to membranes they have to be covalently attached to lipid groups, with the exception of the so-called Ran (RAs-related nuclear protein) also known as GTP-binding nuclear proteins, for which no lipid modification has been reported. All the members of Ras, Rho, and Rab families undergo the lipid posttranslational modification of prenylation as the first committed step toward membrane association, while ARF family members undergo myristoylation. Both FPP and GGPP can be used as moieties for protein prenylation, catalyzed by the enzymes FTase and GGTase-I and -II, respectively.

Rho GTPases are essential players in neuronal development and function. Their activity is critical for neuronal cell migration, axon growth and guidance, dendritic arborization, dendritic spine formation and stabilization, growth cone motility and collapse, and synapse formation. Therefore, it is not surprising that studies in which statins or inhibitors of protein prenyltransferases were used, a decrease in neurite outgrowth and dendritic spines density was observed. In fact, inhibiting GGTase-I in vivo induces deficits in memory and learning in mice. However, there are also a number of studies showing that statins can actually increase neurite outgrowth, which might be explained by the different cell models, dosages, and statins that were used. Interestingly, neuronal survival has also been observed to diminish in the presence of statins, which was shown to be independent of a reduction on cholesterol levels, since the reversal of this phenotype was obtained by FPP/GGPP supplementation, but not by cholesterol addition.

Studies have shown that increased expression of CYP46A1 (= cholesterol 24-hydroxylase) in neurons enhanced prenylation and activation of sGTPases of the Rho and Rab family, and that this effect was dependent on the activation of the MP and GGTase-I activity, which is in accordance to previously mentioned studies. Moreover, it has been reported that this increase of sGTPases prenylation induced by CYP46A1 leads to an increase in neuronal dendritic outgrowth and dendritic protrusion density and elicits an increase of synaptic proteins in crude synaptosomal fractions, further highlighting the importance of how the activation of the MP and sustained production of isoprenoids are essential for neuronal development and function.

It is noteworthy that FPP and GGPP levels are much higher in the brain than in other tissues. Accordingly, in mouse brain cytosol, FPP and GGPP synthase activities are higher than those in the corresponding fractions from the liver, perhaps reflecting a higher demand for protein prenylation in the brain. Furthermore, it has been reported that in aged mouse brain, there is a reduction of GGTase-I activity, leading to a reduction of Rho GTPases membrane association, which is suggested to be one of the mechanisms underlying age-related cognitive dysfunction. There is a great lack of studies comparing the levels of nonsteroid products from the MP between neurons and astrocytes. It is noteworthy that CoQ10, which derives from the decaprenoide intermediary, has actually been measured and compared between both cell types (unpublished data reported in a PhD dissertation). Neurons were found to possess CoQ10 levels at around 68 pmol/mg protein, while in astrocytes the levels were significantly lower, about 38 pmol/mg protein. These results suggest that although neurons might have a lower cholesterol synthesis than astrocytes, an opposite profile might exist for isoprenoid synthesis, which supports our hypothesis that neurons undergo a shift from the postsqualene to the nonsterol branch of the MP. Based on those results and data presented in literature we hypothesize that the postsqualene branch and cholesterol synthesis might be downregulated in neurons to redirect the intrinsic MP toward the nonsterol branch, producing important isoprenoid intermediaries for neuronal function, while relying on external supply of cholesterol. Nevertheless, many questions remain unanswered: What are the underlying regulatory mechanisms involved the differential expression patterns of the MP enzymatic machinery in distinct neural cell types? Is the synthesis rate of isoprenoids different in different neural cell types? Is there a shuttle of isoprenoids from astrocytes to neurons? Is there a soluble factor released by astrocytes that signals for the shutdown of the postsqualene pathways in neurons? Are specific neuronal signaling pathways being modulated by isoprenoids levels, in a prenylation independent manner? Is there a specific deregulation of the nonsterol branch in neurons in pathological contexts? In order to answer these questions, the challenges ahead are also dependent on the development of new tools that facilitate imaging and quantification of the prenylome in neurons and astrocytes and to the identification their cognate protein prenyltransferases or unknown prenyl-binding proteins.

Evidence for a Redirection of the MP in Neurons

A compelling body of evidence suggests that, although neurons retain an active MP and can synthesize cholesterol, the efficiency of cholesterol synthesis is markedly lower when compared to astrocytes, possibly due to lower expression levels of enzymes belonging

to the postsqualene branch. There exists a hypothesis indicating that the postsqualene branch and cholesterol synthesis might be downregulated in neurons, and with this downregulation there is a redirection of the intrinsic MP toward the nonsterol branch, while neurons still rely on external supply of cholesterol. This hypothesis seems to be corroborated by data from other laboratories that published a RNA-Seq transcriptome of 7 days postnatal (P7) mice cortical neurons, astrocytes, oligodendrocytes, and vascular cells that corroborated a previous analysis of an array dataset using RNA isolated from forebrain cells of P7 and P16–17 (= 16–17 days old) mice. Based on data present in these two distinct datasets, the expression levels of genes involved in nonsterol, pre-, and postsqualene pathways in neurons and astrocytes and also between P7 and P16 neurons were compared. Both datasets suggest that the pre- and postsqualene branches in P7 neurons are substantially downregulated compared to astrocytes (blue and red, respectively). Nonetheless, the genes related to the nonsterol pathway have a similar or a higher-expression level in neurons when compared to astrocytes, with the exception of prenyl (solanesyl) diphosphate synthase, subunit 1 (Pdss1). Furthermore, the array data also enabled to compare the expression levels of genes involved in the MP in P16 neurons when compared to P17 astrocytes. Although there are two genes upregulated in the presqualene pathway (blue), the majority of genes have decreased mRNA levels in neurons when compared to astrocytes. Similar to P7 cells, while P16 neurons exhibit a clear downregulation of postsqualene pathway, they maintain or even increase the mRNA levels of genes belonging to the nonsterol branch, when compared to astrocytes. These expression patterns may indicate that while maintaining the efficiency of the nonsterol branch some what intact or even upregulated, there is a robust downregulation of the pre- and postsqualene pathway in neurons compared to astrocytes, which is a profile that seems to be conserved between these two cell types throughout CNS maturation. The fact that the nonsterol branch, in contrast to the pre- and postsqualene pathways, is not downregulated and might actually be somehow induced in neurons, is in line with the idea that the neuronal MP might be favoring the production of isoprenoids in detriment of cholesterol, which is ought to be supplied by astrocytes.

The decrease in mRNA levels from MP-associated genes in the presqualene pathway observed in neurons also favors the nonsterol pathway. Indeed, the affinity of GGPPS for FPP (*Km* value of 0.6 μM) is much higher than SQS (*Km* value of ~15 μM), thus under limited concentrations of FPP, isoprenoid synthesis will be favored. These kinetic findings together with the fact that during neuronal maturation the mRNA levels of Gggps increase while Fdft1 (the gene that codes for SQS) decrease argues that the nonsterol branch might be boosted in neurons in detriment of the postsqualene pathway. Accordingly, as previously mentioned, sGTPases activity is crucial during neuronal development and has been widely associated with neuronal dendritic development and synaptic regulation. Hence, as neurons mature, the demand for isoprenoids to prenylate sGTPases should increase, which is in agreement with the hypothesis of a redirection of the MP branch toward production of nonsterol intermediaries, while cholesterol needs are met by uptake from astrocytic-derived lipoproteins.

Role of the MP in Cancer

Cancer cells reprogram their metabolism to provide energy and the essential building blocks required to maintain their aberrant survival and growth. This reprogramming may occur through either mutations in metabolic enzymes (e.g., isocitrate dehydrogenases (IDHs)) or alterations in cell signaling owing to oncogenic events and/or the remodeled tumor microenvironment. These activated signaling cascades in turn deregulate the expression and/or the activity of enzymes in key metabolic pathways, including the MP.

The MP uses acetyl-CoA, NADPH, and ATP to produce sterols and isoprenoids that are essential for tumor growth (Fig. 1). The production of acetyl-CoA occurs following glucose, glutamine, or acetate consumption, which are often increased in cancer cells. NADPH is produced from a variety of sources, including the pentose phosphate pathway, malic enzyme, and IDHs. Therefore, the MP is highly integrated into the overall metabolic network of cancer cells. The transcription of genes encoding MP enzymes is primarily controlled by the SREBP family of basic helix–loop–helix leucine zipper transcription factors. When intracellular sterol levels are high, the SREBPs are maintained in an inactive state at the ER, where some MP enzymes are also localized. In response to sterol deprivation, a feedback response is initiated that leads to the SREBPs, along with their binding partner SREBP cleavage-activating protein (SCAP), dissociating from the insulin-induced genes (INSIGs) and translocating from the ER to the Golgi. At the Golgi, the SREBPs are sequentially cleaved by site-1 protease and site-2 protease, and they translocate to the nucleus where they bind to sterol regulatory elements (SREs) in the promoters of their target genes and activate the transcription of MP genes to restore sterol and isoprenoid levels. The importance of MP metabolites to the survival of cancer cells has been highlighted by recent studies that have identified a large number of MP enzymes as essential for the survival of several cancer cell lines. Additionally, numerous studies have shown that the statin family of drugs, which inhibit the initial flux-controlling enzyme of the MP, HMGCR, decrease growth and increase apoptosis in many cancer types in vitro and in vivo. These observations point to the MP as being a key dependency in tumors, and one that is readily targetable.

The MP has been suggested by some studies to be oncogenic. Early work in chronic lymphocytic leukemia showed that mevalonate can stimulate replication in primary leukemic cells. In another study, overexpression of the catalytic domain of HMGCR in primary mouse embryonic fibroblasts cooperated with HRASG12V to promote foci formation, suggesting that HMGCR is a metabolic oncogene. In addition, the direct infusion of MVA into mice harboring breast cancer cell xenografts caused an increase in tumor growth. Data from primary patient samples also suggest a role for the MP in promoting tumorigenesis, with a higher expression of MP genes correlating with poor prognosis in breast cancer. Collectively, this evidence indicates that the MP has a key role in cancer.

A series of evidences demonstrated that the MP is deregulated in cancer through aberrant cell signaling, which in turn establishes a tumor vulnerability that can be therapeutically targeted to improve outcomes for cancer patients.

MP-Derived Metabolites in Cancer

Initially, the regulation and function of the MP and its metabolites were studied in the context of normal and hypercholesterolemic tissues, which led to the Nobel prize-winning discoveries of Bloch and Lynen in 1964, and Brown and Goldstein in 1985. In recent years, the importance of MP-derived metabolites in cancer has become increasingly appreciated (discussed later).

Cholesterol

Cholesterol is an important component of most cellular membranes. Highly proliferative cancer cells need to produce membranes rapidly, and an increase in cholesterol synthesis contributes to this process. Cholesterol is also an integral component of lipid rafts, which are necessary to form signaling complexes. The cholesterol content of the ER has recently been linked to the antiviral type I interferon (IFN) response, with low ER cholesterol triggering an IFN response in macrophages that protects mice from viral challenge. Therefore, it is possible that high levels of cholesterol, produced by the MP, could have a role in protecting cancer cells from immune surveillance and various therapies. Cholesterol also serves as the precursor of downstream products, such as steroid hormones and oxysterols: steroid hormones drive the initiation and progression of various cancers, including breast and prostate carcinomas; increased oxysterol production can activate the liver X receptors, which have been proposed to be therapeutic targets in multiple cancer types. Therefore, cancer cells require cholesterol for growth and survival, and decreasing intracellular cholesterol biosynthesis is a promising anticancer strategy.

Isopentenyl-Diphosphate

In human cells, the MP is the sole intracellular source of isopentenyl-diphosphate (IPP) (**Fig. 1**). Aberrant activation of the MP in cancer results in increased intracellular levels of IPP, which has been shown to activate host γδ T cells that subsequently kill the IPP-overexpressing cells. These observations led to phase I clinical trials that evaluated the in vivo expansion of γδ T cells in response to zoledronate, a bisphosphonate (BP) that inhibits farnesyl diphosphate synthase (FDPS) and leads to the accumulation of IPP, in combination with interleukin-2 (IL-2) treatment in advanced-stage breast cancer and prostate cancer. In both studies, the therapy was well-tolerated and the number of sustained peripheral γδ T cells correlated with improved clinical outcome. Future phase II clinical trials will reveal whether combined zoledronate and IL-2 therapy is an effective anticancer strategy.

Farnesyl-Diphosphate and Geranylgeranyl-Diphosphate

Farnesyl-diphosphate (FPP) and geranylgeranyl-diphosphate (GGPP) are produced by sequential condensation reactions of dimethylallyl-diphosphate with two or three units of IPP, respectively. FPP and GGPP contain hydrophobic chains that are essential for the isoprenylation of proteins. This posttranslational modification tethers proteins to cell membranes, enabling proper protein localization and function. Most small GTPases—many of which are involved in tumorigenesis, such as RAS and RHO—are isoprenylated; inhibition of the MP can reduce the isoprenylation of these small GTPases and can induce the death of some cancer cells. This cell death can be reversed by the addition of GGPP, and sometimes FPP, suggesting that these MP metabolites are essential for tumor cell viability. Evidence suggests that it is unlikely that any one isoprenylated protein can be assigned functional responsibility for this cancer cell dependency on GGPP and FPP; instead, it seems that this is a "class effect," with the depletion of these isoprenoid pools potentially affecting the many proteins that are isoprenylated. Despite this dependency, directly inhibiting the isoprenylation of proteins using geranylgeranyl transferase inhibitors (GGTIs) or farnesyl transferase inhibitors (FTIs) has not been a successful anticancer strategy to date. The rationale behind these drug development programs was that key isoprenylated oncoproteins, such as RAS, could be targeted. However, the efficacy of FTIs was impeded by alternative isoprenylation using GGPP, and GGTIs have been disappointingly toxic. Further development of next-generation FTIs and GGTIs remains a fairly limited and focused area of research.

Dolichol

Dolichol is derived from 18 to 20 IPP molecules and is an essential component of the *N*-glycosylation of nascent polypeptides in the ER. Protein *N*-glycosylation is frequently altered in cancer and can contribute to tumor formation, proliferation, and metastasis. Not all *N*-glycans are associated with tumor progression; the complex branching of *N*-glycans leads to tumor-suppressive properties in some cancers. Glucose-derived *N*-acetylglucosamine has recently been shown to be necessary for the *N*-glycosylation of SCAP before ER-to-Golgi translocation. The SCAP–SREBP complex thus remains inactive in the ER when glucose is absent, even in the presence of low levels of sterols.

Coenzyme Q

Isoprenoids are also used to produce the quinone coenzyme Q (CoQ). The hydrophobic isoprenoid chain localizes CoQ to the inner membrane of the mitochondria, where the quinone group transfers electrons from complex I or II to complex III of the electron transport chain, thus enabling ATP production. Therefore, CoQ is crucial for ATP production in cancer cells that rely on oxidative phosphorylation to produce energy.

Oncogenic Regulation of the MP

Intracellular pools of MP metabolites are tightly regulated by modulating the expression and activity of the MP enzymes. MP gene expression is mainly controlled by the SREBP transcription factors (Fig. 2). There are three SREBP proteins, which are transcribed from two genes: SREBP2 is transcribed from the *SREBF2* gene and is the main transcription factor for MP-associated genes; SREBP1a and SREBP1c are transcribed from alternative start sites in the *SREBF1* gene, with SREBP1a regulating the expression of both MP and fatty acid metabolism genes, and SREBP1c predominantly regulating the expression of fatty acid metabolism genes.

Chromatin immunoprecipitation followed by sequencing (ChIP-seq) studies have indicated some overlap in the target genes of each SREBP, including MP genes, indicating some redundancy. Most studies have also shown an overlap in the regulation of the SREBPs; however, the majority of studies limit full characterization to SREBP1, and most do not distinguish between SREBP1a and SREBP1c as available antibodies cannot differentiate between the two. Given the importance of the MP in cancer, a complete characterization of SREBP2 in transformed cells is needed.

In recent years, oncogenic and tumor-suppressive pathways have been shown to converge on the MP and its regulatory feedback loop. Cancer cells, with their aberrant growth and metabolism, are thus primed to upregulate the MP to provide essential building blocks for continued proliferation. The integration of cellular signaling from growth factors and essential metabolites, with the regulation of the MP and its SREBP-regulated feedback response, highlights the importance of this pathway in cancer.

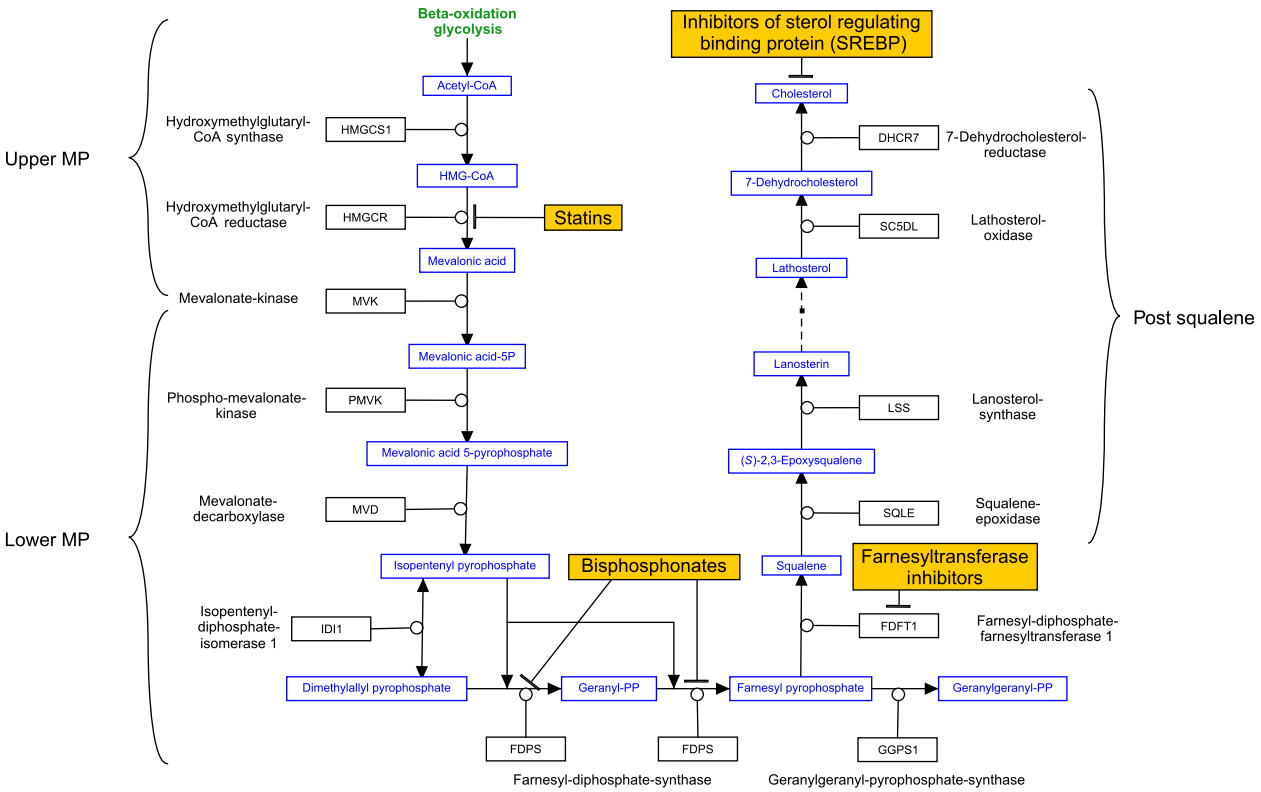

Fig. 2 Targets of inhibitors of the MP. *Statins* inhibit HMGCR, thereby reducing MP metabolites that are also essential for cancer cell growth and survival. This triggers sterol regulatory element-binding protein (SREBP) activation and the transcription of MP genes, thus restoring MP activity. Dipyridamole is one example of an agent that inhibits SREBP cleavage, preventing the restorative feedback response and increasing apoptosis in multiple cancer types. Combining SREBP cleavage inhibitors with statins may increase the therapeutic response compared with the use of statins alone. *Dashed boxes* represent metabolites or steps that are reduced by the indicated treatments. *Bisphosphonates* act downstream of statins and inhibit farnesyl pyrophosphate synthase, a key enzyme in the MP, with consecutive decrease of the formation of isoprenoid lipids such as farnesyl pyrophosphate and geranylgeranyl pyrophosphate. This part of the MP is also targeted by *farnesyl transferase inhibitors*.

PI3K–AKT

The PI3K–AKT signaling pathway is a major regulator of cell survival and proliferation in response to growth factors. It is the single most frequently altered pathway in cancer, and the second most frequently mutated gene is *PIK3CA*, which encodes PI3K catalytic subunit alpha. Inactivating mutations in the PI3K–AKT pathway negative regulator PTEN and/or the hyperactivity of growth factor receptor tyrosine kinases are also common in cancer. Alterations in the PI3K–AKT pathway generally act to augment signaling and consequently increase the proliferation of cancer cells. PI3K–AKT can activate the MP through various mechanisms. For example, the stimulation of PI3K–AKT signaling by growth factors, such as insulin, platelet-derived growth factor, and vascular endothelial growth factor, can increase the mRNA and protein expression of SREBP1 and SREBP. It should be noted that although PI3K–AKT signaling strongly and consistently increases the mRNA and protein levels of SREBP1a and SREBP1c, its effects on SREBP2 expression are context dependent. AKT has also been suggested to increase the stability of nuclear SREBP1a, SREBP1c, and SREBP2 by preventing their proteasomal degradation mediated by the F-box and WD repeat domain containing 7 (FBXW7) E3 ubiquitin ligase. The importance of this degradation pathway is highlighted by an increase in cholesterol and fatty acid synthesis in FBXW7-deficient cells. The residues that are recognized by FBXW7 are phosphorylated by glycogen synthase kinase-3β; AKT, which inhibits this phosphorylation, may prevent FBXW7-mediated degradation of the SREBPs. Insulin also causes the dissociation of INSIG from SCAP–SREBP1c in a sterol-independent manner, leading to the increased transcription of MP genes. These studies were further validated through genetic approaches, in which SREBP1 and SREBP2 expression and activity were increased with the expression of constitutively active PI3K or AKT, and abrogated by dominant-negative AKT. The increase in lipid and cholesterol production that is mediated by the PI3K–AKT–SREBP axis promotes the proliferation of cancer cells and tumorigenesis in vitro and in vivo. Increased MP activity is inconsequential without the availability of both acetyl-CoA and NADPH, and PI3K–AKT signaling meets this requirement by increasing glucose uptake and the rate of glycolysis in cancer cells. Conversely, inhibition of the MP decreases PI3K activity, possibly through decreased RAS isoprenylation, thus demonstrating a two-way regulatory relationship between PI3K–AKT signaling and the MP.

mTOR Complex 1

Downstream of PI3K–AKT signaling, mTOR complex 1 (mTORC1), acts as a sensor of growth signals (such as insulin) and nutrients (such as amino acids) to regulate cellular growth. mTORC1 is often deregulated in cancer, and this supports aberrant growth. mTORC1 increases mRNA translation by phosphorylating and activating ribosomal S6 kinase 1 (S6K1; also known as RPS6KB1) and repressing the activity of the inhibitor of cap-dependent translation, eukaryotic translation initiation factor 4E-binding protein 1 (4EBP1; also known as EIF4EBP1). SREBPs are major downstream effectors of mTORC1 signaling, as evidenced by increased lipogenesis in response to mTORC1 activation. The observation that SREs are the most common regulatory elements in mTORC1-induced genes further strengthens the link between mTORC1 and the SREBPs. This link is also evident in samples from patients with primary breast cancer, as patients with high levels of phosphorylated S6K1 had correspondingly high expression of SREBP target genes, such as fatty acid synthase (*FASN*), low-density lipoprotein receptor (*LDLR*), and mevalonate kinase (*MVK*). This study also compared proteins from tumor samples and adjacent normal breast samples and described an increase in FASN protein levels in the tumors that had higher levels of phosphorylated S6K1.

mTORC1 can regulate the SREBP transcription factors at multiple levels although there are some cell- and tissue-type differences. For example, S6K1 has been shown to activate SREBP2 processing and increase the expression of MP genes in a hepatocellular carcinoma (HCC) cell line although the mechanism involved remains unclear. Greater understanding of the role of mTORC1 in SREBP activity came with the development of torins, which are mTOR catalytic site inhibitors. The original allosteric mTOR inhibitor, rapamycin, prevents the phosphorylation of S6K1 but does not inhibit 4EBP1 phosphorylation equally in all systems. By contrast, torins inhibit the phosphorylation of multiple mTOR targets, including S6K1 and 4EBP1. Recent work comparing torin and rapamycin action implicated a role for lipin 1 (LPIN1) in mediating the effects of mTORC1 on the SREBPs. LPIN1 is a nuclear phosphatidic acid phosphatase that is inhibited through direct phosphorylation by mTORC1, independently of S6K1. Active, unphosphorylated LPIN1 indirectly prevents the transcription of SREBP target genes by preventing the SREBPs from binding to chromatin although the mechanism involved remains unclear. A further link between LPIN1 and the MP was uncovered by studies using skeletal muscle, in which statins and LPIN1 were shown to increase autophagy. Given the role of SREBP2 in transcribing numerous autophagy genes, further work is needed to fully understand the interplay between mTORC1, LPIN1, and the SREBPs.

The position of the SREBPs as key effectors of mTORC1 signaling presents a potential vulnerability in tumors that have deregulated mTORC1 activity. Previous studies have linked the loss of SREBPs in breast cancer to the induction of ER stress, which induced apoptosis through mTOR. A separate study showed that genetic knockdown of *SREBF1* and/or *SREBF2* reduced proliferation and increased cell death in mTORC1-activated breast cancer cell lines. The observation that double knockdown of *SREBF1* and *SREBF2* showed the greatest proapoptotic effect suggests that small-molecule inhibitors that target both SREBP1 and SREBP2 may have the greatest therapeutic benefit.

AMP-Activated Protein Kinase

With an opposing role to that of mTORC1, AMP-activated protein kinase (AMPK) acts to dampen anabolic pathways when intracellular ATP levels are low. This role of AMPK as an energy sensor and central regulator of metabolism is crucial in metabolic

disorders such as type 2 diabetes and cancer. AMPK was discovered through its ability to phosphorylate and reduce the activity of microsomal HMGCR in rat liver extracts. Further studies showed that AMPK phosphorylates Ser872 within the catalytic domain of HMGCR, inhibiting its enzymatic activity in a manner that is independent of its feedback regulation by MP metabolites. The SREBPs are also direct targets of AMPK phosphorylation. Activated AMPK specifically interacts with both the precursor and the nuclear forms of SREBP1c and SREBP2, and phosphorylation by AMPK inhibits SREBP proteolytic processing and transactivation activity. Activation of AMPK in HepG2 liver cancer cells by either polyphenols or metformin stimulates this phosphorylation, which suppresses the accumulation of SREBPs in the nucleus under hyperglycemic and hyperinsulinemic conditions. Moreover, activation of AMPK in the livers of insulin-resistant mice inhibited the transcription of enzymes that are involved in lipid and cholesterol biosynthesis, including the MP enzymes 3-hydroxy-3-methylglutaryl-CoA synthase 1 (HMGCS1) and HMGCR, which consequently resulted in a decrease in hepatic triglyceride and cholesterol levels. AMPK can thus inhibit MP activity both directly via the phosphorylation of HMGCR and indirectly through the phosphorylation and repression of SREBPs. However, the relevance of this regulation in the context of cancer is poorly understood.

The MP may also regulate AMPK activity, thereby forming a feedback loop. The tumor suppressor liver kinase B1 (LKB1; also known as STK11), which phosphorylates and activates AMPK, is farnesylated at a highly conserved carboxyterminal CAAX motif. Knock-in mice expressing a mutant form of LKB1, which could not be farnesylated, exhibited reduced membrane-bound LKB1 and impaired AMPK activity. This hints at a negative feedback loop, in which the activation of AMPK in response to decreased cellular energy results in the inhibition of the MP via the phosphorylation of HMGCR and the SREBPs. This in turn reduces the FPP pool within the cell, thereby hindering LKB1 farnesylation and inhibiting AMPK activation.

p53 and RB

TP53, which encodes the p53 tumor suppressor, is one of the most frequently altered genes in cancer, and mutations within the coding region of *TP53* can confer oncogenic properties to p53. Two gain-of-function mutations (*TP53*R273H and *TP53*R280K) enable p53 to functionally interact with nuclear SREBP2 and increase the transcription of MP genes. This MP gene activation was necessary and sufficient for mutant p53 to disrupt normal breast acinar morphology, and mutant TP53 expression in primary breast cancer tissues was correlated with the increased expression of sterol biosynthesis genes. Conversely, wild-type TP53 can reduce lipid synthesis under conditions of glucose starvation by inducing the expression of LPIN1, which, as described earlier, can prevent the association of SREBPs with chromatin. *TP53*R273H and *TP53*R280K mutations are also found in tumors from tissues other than the breast, for example, the ovaries, prostate, and lung.

The interplay between TP53 and the MP suggests that the MP may be a novel therapeutic target for tumors that harbor these specific p53 gain-of-function mutations.

The tumor suppressor protein RB has also been implicated as a regulator of the MP. In a mouse model of adenoma, loss of *Rb1* (which encodes RB) enhanced isoprenylation and activation of NRAS. Loss of RB relieved the suppression of the transcription factors E2F1 and E2F3, which were shown to bind and activate the promoters of numerous prenyltransferase genes, *FDPS* and *SREBF1*. Moreover, RB prevented the association of SREBP1 and SREBP2 with the *FDPS* promoter, suggesting that RB negatively regulates the MP at both the transcriptional and the posttranslational levels.

MYC

The MYC transcription factor is a potent oncogene that can drive transformation in multiple cancer types. It is deregulated in more than 50% of cancers and can reprogram cancer cell metabolism to enable the proliferation and survival of cancer cells. Like the SREBPs, MYC is a basic helix-loop-helix dimerizing protein and it has been shown to bind to SREBP1 to drive somatic cell reprogramming into induced pluripotent stem cells. Analysis of data from the Encyclopedia of DNA Elements (ENCODE) project also shows that MYC binds to promoters of MP genes in close proximity to SREBP1 and SREBP2 binding regions, suggesting that MYC can contribute to the expression of MP enzymes. As the MP is essential for cancer cells, and because MYC has a major role in metabolic regulation, deregulated MYC may ensure that MP metabolites are not limiting for tumorigenesis. The MP was also shown to be important in a MYC-driven transgenic model of HCC. In that study, atorvastatin reduced tumor initiation and growth, possibly through reduced isoprenylation of the RHO-family GTPase RAC1, leading to the activation of serine/threonine-protein phosphatase 2A, which is a negative regulator of MYC. More recently, *Myc*+/− mice (which are haploinsufficient) were shown to have an increased lifespan, which was associated with the decreased expression of MP genes, including *Hmgcr* and *Srebf2*. Given the importance of MYC in driving cancer, and the difficulty of targeting it therapeutically, further work is warranted to uncover the relationship between MYC and the MP.

Signaling From the MP

Altered metabolism in tumors not only fulfills the energetic and biosynthetic needs of a dividing cell but also produces metabolites that are important for downstream signaling. This is particularly true of the isoprenoid and sterol metabolites produced by the MP, which are also used by cancer cells to modulate multiple downstream signaling pathways that are important for tumor progression.

Yes-Associated Protein and TAZ

It was recently shown that the oncogenes Yes-associated protein (YAP) and transcriptional coactivator with PDZ-binding motif (TAZ; also known as WWTR1) require the MP to be fully functional. YAP and TAZ are transcriptional coactivators that facilitate the transcriptional activation of progrowth genes and the repression of proapoptotic genes. The nuclear localization of YAP and TAZ is negatively regulated, partly by the activation of the tumor-suppressive Hippo signaling pathway. Activation of the Hippo cascade results in the phosphorylation and activation of large tumor suppressor kinase 1 (LATS1) and LATS2, which phosphorylate YAP and TAZ and retain them in the cytoplasm. YAP and TAZ nuclear localization requires the MP, as concurrent knockdown of *SREBF1* and *SREBF2* reduces nuclear localization of YAP and TAZ. These effects were mimicked by GGTIs (geranylgeranyl transferase inhibitors) and were prevented by a RHOA mutant that does not require geranylgeranylation. This suggests that SREBP-mediated induction of the MP maintains intracellular GGPP pools, which is necessary for RHOA upregulation and for downregulation of RHOB (which is essential for initiating protein degradation and recycling through an endolysosomal pathway), as well as YAP and TAZ nuclear localization. Although some studies showed that MP-mediated YAP and TAZ signaling is independent of LATS1 and LATS2 via RNA interference-knockdown experiments, one study demonstrated that both atorvastatin treatment and GGTI treatment increase the phosphorylation of LATS1 and LATS2, suggesting that geranylgeranylation regulates Hippo signaling. A separate study reported constitutive SREBP activation in the livers of mice with a liver-specific *Lats2* deletion, which corresponded to an increase in free cholesterol in the liver and protection from p53-mediated apoptosis. Activation of the MP and activation of YAP and TAZ are correlated with mutant TP53 expression in primary tumors, suggesting a dysfunctional mutant p53–SREBP–YAP–TAZ axis in cancer. Overexpression of *TP53*R280K in a *TP53*-null cell line activated YAP and TAZ only when the MP was active, suggesting that the MP is a crucial intermediate in the oncogenic activation of YAP and TAZ by mutant TP53.

Hedgehog

Cholesterol has a multifaceted role in the regulation of cell signaling. For example, the Hedgehog (HH) signaling pathway, which has important roles in vertebrate development and tumorigenesis, is regulated by sterols at multiple levels. Cholesterol itself can serve as a substrate for the posttranslational modification of HH ligands, which is required for their proper trafficking. Cholesterol and cholesterol-derived oxysterols can also activate HH signal transduction in medulloblastoma, whereas inhibition of the MP or downstream sterol biosynthesis decreased HH signaling and reduced cell proliferation.

Steroid Hormone Signaling

Cholesterol also serves as the precursor of steroid hormones, which drive the initiation and progression of cancers such as hormone-dependent breast cancer and prostate cancer. In breast cancer, patients with estrogen receptor-α (ERα)-positive disease are commonly treated with aromatase inhibitors to deprive the tumors of estrogen. Recent work demonstrated that long-term estrogen deprivation of ERα-positive breast cancers leads to the stable epigenetic activation of the MP and cholesterol biosynthesis. This is coupled with an enrichment of SREBP1 and SREBP2 DNA-binding motifs, as determined by DNase I footprinting analyses, suggesting that there is increased SREBP occupancy on open chromatin. The resulting increased levels of 27-hydroxycholesterol were sufficient to activate ER1 (estrogen receptor alpha) signaling in the absence of exogenous estrogen, driving the activation of genes that promote an invasive cell phenotype. Similarly, in prostate cancer, the de novo synthesis of androgens from cholesterol drives androgen receptor activity in castration-resistant disease. This finding, coupled with the observations that SREBP expression is increased in advanced-stage prostate cancer, suggests a role for the MP in prostate cancer progression. These findings warrant further investigation into the utility of inhibitors of the MP and/or SREBPs in the treatment of hormone-driven cancers.

Inhibitors

Statins

Statins competitively inhibit HMGCR (3-hydroxy-3-methyl-glutaryl-coenzyme A reductase), the first committed enzyme of the MP, blocking the conversion of HMG-CoA to mevalonic acid (**Fig. 2**). The molecular mechanism of inhibition of HMGR by statins is a catalytic mechanism. The statins molecules occupy the catalytic portion of HMGCR, specifically the binding site of HMG-CoA, thus blocking access of this substrate to the active site. The structures of the catalytic domains of the enzyme in complex with statin molecules have been identified.

Efficacy of HMGCR inhibition by various compounds in the family of statin inhibitors is markedly dependent (e.g., nanomolar versus millimolar inhibitor affinity) on whether class I or class II enzyme is used. The inhibitors are characterized by hydroxymethylglutaryl (HMG)-like moieties linked to an extensive hydrophobic scaffold (e.g., a decalin ring in the case of mevastatin and simvastatin). Complexes of human enzyme catalytic domain with a variety of statins have been crystallized, and X-ray structures have been published. The structural results indicated binding of the HMG moiety in the active site pocket where the catalytic glutamate and lysine residues are located. In contrast, the NADPH substrate site is not occupied upon inhibitor binding. The structural results indicating that access to the substrate HMG-CoA is blocked by inhibitor binding are in accord with the observation of competitive inhibition with respect to HMG-CoA. A variety of additional polar interactions with the HMG moiety have also been documented.

The hydrophobic portion of the inhibitors is bound in a shallow hydrophobic groove of the human protein. A large number of van der Waals contacts between nonpolar amino acids in this groove and the diverse hydrophobic substituents that are a common feature of the various statins are proposed to represent the dominant contribution to high-affinity binding. A structure of lovastatin bound to the class II *P. mevalonii* enzyme has also been reported. As in the case of the class I enzyme, the structure indicates interactions with residues (e.g., lys, glu) identified in catalysis as well other polar residues in this pocket, with some hydrogen bonds mediated by water molecules. The hydrophobic decalin ring component of the inhibitor blocks a closure of the C-terminal flap domain of the protein, which includes the histidine residue that has been implicated in catalysis. Thus, inhibitor binding both blocks the active site and makes correct orientation of active site amino acids impossible. A large difference between class I and class II enzyme interactions with the statin inhibitor is suggested to involve a pocket formed, in part, by the alpha helix of the *P. mevalonii* enzyme. The structural results could expedite potential design of HMGCR inhibitors that can discriminate between class I and class II enzymes. Additionally, an approach proposed to increase inhibitor affinity involves derivatization of the parent inhibitory compound to incorporate chemical substituents effective in interaction with the NADPH site.

By interrupting cholesterol synthesis in the liver, statins activate the production of microsomal HMGCR and cell surface low-density lipoprotein (LDL) receptors. This results in a predictable increased clearance of LDL from the bloodstream and a decrease in blood LDL cholesterol levels that may range from 20% to 55%. Statins have shown strong evidence-based proved capacity of decreasing the cardiovascular morbidity and mortality in both primary and secondary prevention settings. Because of these properties, statins are among the most widely used pharmaceutical agents in the world, their role in the global battle against cardiovascular disease being compared with the crucial role of antibiotics in decreasing the mortality of infections. Subgroup analyses of several large clinical trials have suggested that changes in lipid levels alone may not explain all the beneficial effects of statins in human pathology. Evidence has emerged from both basic research and clinical trials that statins have many cholesterol-independent or so-called pleiotropic effects: improving endothelial function, atherosclerotic plaque-stabilizing effects, antiinflammatory and immunomodulatory effects, antithrombotic properties, effects on bone metabolism, on risk of dementia, induction of apoptosis, and antiproliferative effects.

Most of these pleiotropic effects result from inhibition of the synthesis of important isoprenoid intermediates of the MP, such of FPP and GGPP. Mevalonate-derived prenyl groups have been shown to have essential roles in many cellular functions including cell signaling, cell differentiation and proliferation, myelination, cytoskeleton dynamics, and endo−/exocytotic transport. In the last decade, substantial progress has been made in understanding the nonlipid-related pharmacological properties of statins and a growing interest in the potential therapeutical implications of these pleiotropic effects of statins has emerged. Recent experimental and clinical data indicate that statins may be of potential therapeutic use in a variety of nonvascular diseases, including autoimmune diseases, multiple sclerosis, rheumatoid arthritis, sepsis, dementia, and different types of cancer.

Many studies have shown that statins can directly and specifically inhibit the proliferation of tumor cells. For example, statins promote the apoptosis of cells derived from acute myeloid leukemia (AML), while normal myeloid progenitors do not undergo apoptosis and retain full proliferative potential. This tumor-normal therapeutic index may be due to the altered metabolic reprogramming of AML cells leading to an increased dependence on MP metabolites for growth and survival. The widespread use of statins for cholesterol management also demonstrates that these drugs cause minimal damage to normal cells. The side effects of these drugs are regularly treated by switching to a different statin or potentially by cotreating with CoQ although this cotreatment method is controversial owing to conflicting clinical evidence.

The data discussed earlier suggest that statins have a high therapeutic index to target tumors in vivo despite the ubiquitous expression of the MP. This rationale has led to multiple clinical trials investigating the efficacy of various statins as a therapeutic option in a variety of tumor types. Two recent breast cancer window-of-opportunity clinical trials, using atorvastatin and fluvastatin, showed reductions in the Ki67 index in a subset of patients who were administered with cholesterol-management doses of statins between cancer diagnosis and surgery. Statins have also been safely used in combination with other agents to increase efficacy. For example, pravastatin was combined with standard-of-care treatment in HCC and AML, resulting in significantly longer median survival in colorectal cancer and resulting in complete or partial response in 60% of patients with AML. In another study, combining lovastatin with thalidomide and dexamethasone in patients with relapsed or refractory multiple myeloma (MM) led to prolonged overall survival and progression-free survival.

Despite evidence of patient response to statins as anticancer agents, many patients remained nonresponsive to statin treatment in other cancer clinical trials. This is consistent with the current paradigm of interpatient tumor heterogeneity. This lack of response might also be expected considering the evidence that we discussed earlier showing that the MP is regulated by many key oncogenic signals. Similar to many anticancer agents, a personalized medicine approach is needed to implement statins, and/or other inhibitors of the MP, as a successful class of cancer therapeutics. To this end, a molecular signature of basal mRNA expression has been developed to predict statin response in breast cancer in vitro, and deregulated MYC expression has been a proposed indicator of statin response in specific tumor types; however, essential follow-up validation is required before these biomarkers can be used clinically. It is currently difficult to predict which cancers will be particularly sensitive to statin therapy. In addition to AML and MM, encouraging results from both clinical trials and epidemiological studies suggest that patients with hormone-dependent cancers, such as breast cancer and prostate cancer, may benefit from the addition of statins to their treatment regimen. This may be partly because the MP end-product cholesterol is the precursor of hormones such as estrogen and androgens, which have a major role in the development of these types of cancers. Colorectal cancer also seems to be particularly responsive to statins, perhaps because of the hepatotropic pharmacology of this family of drugs. Clinical trials are required in these and other cancers to further define the subset of cancers that are particularly statin-sensitive.

Targeting the SREBP in Combination With Statins

Crucial to the regulation of the MP is the tightly controlled, SREBP-mediated feedback mechanism, in which inhibition of the MP results in the activation of the SREBPs and an increase in the expression of MP genes, an effect that may be amplified in cancer cells. SREBP activation also increases the expression of the LDLR, which leads to the increased uptake of exogenous, lipoprotein-derived cholesterol: an effect that has been shown to be important in cancer cells. The SREBPs thus function to replenish MP metabolites, which can dampen the apoptotic response following statin treatment. This would be a classic resistance mechanism, similar to that seen with other anticancer therapeutics such as inhibitors of the BRAF protooncogene in BRAF-mutant melanoma. Cells treated with BRAF inhibitors, such as vemurafenib, can acquire an activating mutation in downstream kinases (e.g., the MEK1 mitogen-activated protein kinase kinase) or can have an increase in expression of receptor tyrosine kinases (e.g., epidermal growth factor receptor), bypassing the need for BRAF activity. These studies demonstrate that inhibiting both the cancer vulnerability and the resistance or feedback mechanism is crucial for maximum efficacy. Therefore, inhibiting the SREBP-regulated feedback response in conjunction with statin therapy could prevent resistance, thereby increasing the efficacy of statins as anticancer agents and the number of responsive patients.

Evidence that targeting the SREBPs in combination with statin therapy is a viable strategy has been provided by several studies. One study looking at breast and lung cancer cell lines used a short hairpin RNA screen to uncover genes that, when knocked down, potentiated the proapoptotic effects of statins. The MP genes *HMGCS1*, *GGPS1*, *SCAP*, and *SREBF2* all scored highly, adding credence to either inhibiting other enzymes in the MP or inhibiting the SREBP-mediated feedback response in combination with statin therapy. Another study showed that statin-induced SREBP processing can be blocked by another agent that has been approved for a noncancer indication, dipyridamole. Dipyridamole reduced the transcription of SREBP target genes such as *HMGCS1* and *HMGCR* and synergized with statins to increase apoptosis in AML and MM cell lines and patient samples. Other compounds, such as tocotrienols, have also been demonstrated to synergize with statins to induce cancer cell apoptosis, which is an effect that may be associated with their ability to degrade nuclear SREBP2 and inhibit its transcriptional activity. Although several other small molecules, including fatostatin, have been shown to inhibit SREBP processing, their lack of approval for use in patients limits their potential to immediately have an impact on cancer patient care.

Therefore, clinical investigation into the utility of combined statins and SREBP inhibitors for the treatment of cancer is currently warranted.

Bisphosphonates

BPs are potent inhibitors of osteoclast mediated bone resorption and are currently the most important and effective class of drugs used to treat metabolic bone disease. BPs bind avidly and achieve therapeutic concentration at sites of active bone metabolism in the mineralized bone matrix. By inhibiting bone resorption and inducing osteoclast apoptosis, BPs reduce bone turnover, increase bone mass, and improve bone mineralization. Recent experimental studies have shown that nitrogen-containing BPs may have interesting antitumor properties. As shown in **Fig. 2**, they inhibit FPP synthase, a key enzyme in the MP, with consecutive decrease of the formation of isoprenoid lipids such as FPP and GGPP. It has been demonstrated that the capacity of inhibiting FPP synthase is correlated to the synthesis from the accumulated isopentenyl diphosphonate of an ATP analogue, named Apppi. This, in turn, prevents the prenylation of a number of small GTPases, such as Rho, Ras, Rac, and Rab, which play a role in malignant transformation of cells by regulating intracellular signaling, cell growth, motility, and invasion. Interestingly, the ability of nitrogen-containing BPs to inhibit FPP synthase appears to be clearly related to the presence of a nitrogen atom at critical positions in the side chain. Consistent with their recently identified biochemical effects on protein prenylation, there is extensive evidence from preclinical research that BPs also exhibit antitumor activity in a variety of human cancers: myeloma, breast cancer, prostate cancer, pancreatic cancer, mesothelioma, mesenchymal tumors, and osteosarcoma. Summarizing, inhibition of the MP is the underlying molecular mechanism of many of these antitumor properties of nitrogen-containing BPs: inhibition of integrin-mediated tumor cells adhesion to bone. BPs act by inhibition of prenylation of small GTPases required for integrin activation–inhibition of cancer cells migration and invasion by inhibition of metalloproteinases and by inhibition of Rho activation by preventing geranylgeranylation. Inhibition of proliferation and induction of apoptosis of cancer cells were observed at high BP concentrations. Although inhibition of the MP was found to be the main molecular mechanism of promoting apoptosis, other mechanisms have also been described, that is, reduction of bcl-2 expression and activation of caspase. In addition, immunomodulatory effects mediated through accumulation of mevalonate metabolites in tumor cells, which stimulate T lymphocytes expressing the T cell receptor, were described.

Other Therapeutic Agents That Target MP

Extensive preclinical evidence suggested that manipulation of the MP through inhibition of FTase and GGTase, and, in consequence, inhibition of protein prenylation, can result in alteration of malignant cells' capacity of proliferation, growth, and migration. FTIs represent a new generation of signal transduction inhibitors, designed to target the critical posttranslational modification of Ras, a protooncogene that is believed to play a critical role in tumor growth or progression and may have prognostic significance.

Some studies suggest that FTIs inhibit not exclusively Ras proteins but also the farnesylation of additional cellular polypeptides that have not been identified, thereby exerting antitumor effects independent of the presence of activating Ras gene mutations. Lonafarnib SCH-66336 has been the first of these compounds to undergo clinical development. Several other FTIs have entered clinical trials for various cancer indications: examples are tipifarnib (R115777), BMS-214662, and L-778. Although phase I and II studies have shown that FTIs have a significant antitumor activity and an acceptable toxicity profile, the results of phase III trials have been disappointing, showing no overall significant amelioration of survival in solid cancers. The most promising activity to date has been demonstrated in patients with hematological malignancies, in particular AML and myelodysplastic syndrome. GGTIs are a novel class of drugs that are still in the experimental stage. It has been recently demonstrated that when FTase is blocked by FTIs, additional inhibition of geranylation by inhibitors of GGTase can augment antiproliferative properties of FTIs. Treatment of tumor cell lines in culture with varying doses of a GGTI in conjunction with a FTI can inhibit Ki-Ras prenylation and determine an apoptotic response that is greater than the apoptotic response elicited by either agent alone in vitro. However, the tolerability of this protocol in vivo was poor and suggested that the use of this approach in humans should be cautious because of a possible narrow therapeutic index. Recent preclinical research has identified a new inhibitor of protein prenylation, a selective, highly potent, and cell-active GGTase-I inhibitor, GGTI-DU40, and suggested that investigation of GGTIs, as potential new anticancer drugs should continue, in order to define their exact role and toxicity profile. In conclusion, in the last few years, there has been intense interest in understanding the clinical and therapeutical implications of MP, a metabolic pathway which plays a key role in regulation of cellular cholesterol synthesis and in controlling cell proliferation by generating prenyl intermediates. Since the discovery of MK deficiency as the direct biochemical and molecular cause of MVA and hyperimmunoglobulinemia D syndrome, considerable progress has been made in understanding the pathophysiology of these antiinflammatory disorders. However, it is still not known what is the causal relationship between the enzymatic defect and the inflammation and no effective treatment has been established so far. Also, MP is an important, attractive target for many areas of therapeutical research and application, through inhibition of the isoprenylation process of small intracellular proteins. Although extensively studied, many important issues remain unanswered, and this fascinating area of interference between biochemistry, clinical implications, and pharmacology remains a major focus for potential future investigation.

Outlook

Understanding tumor metabolism in the context of oncogenic signals has the potential to drive the development of targeted personalized therapies. The various signaling pathways that we describe in this book chapter are important drivers in many cancers, and they all have the ability to deregulate the MP, making these cancers potentially vulnerable to MP inhibition. Whether this occurs in every patient who presents with these lesions remains unclear. More work is needed to understand the extent to which driver mutations increase flux through the MP in patients. Rapidly developing technologies for the comprehensive flux-based analysis of MP metabolites will provide further advances in understanding how the MP receives and responds to oncogenic signals. In patients, it may be more feasible to determine pathway activity by mapping their oncogenic lesions to their sterol feedback response at the protein level (via SREBP localization) or mRNA expression level of MP genes, which may identify patients who will respond to MP inhibition. Designing clinical trials that will identify potential responders before treatment is required to prevent expensive failures of therapies that may still have benefits to a subset of patients. Improving reagents, particularly antibodies to HMGCR and SREBP2, will also aid trial design and interpretation.

The essentiality of the MP in many cancers, coupled with affordable and safe drugs that can target this pathway and its feedback response, provides a strong rationale for continuing to explore this key metabolic pathway in cancer and many other diseases.

Microbiota and Colon Cancer: Orchestrating Neoplasia Through DNA Damage and Immune Dysregulation

Alberto Martin and Thergiory Irrazábal, University of Toronto, Toronto, ON, Canada

Glossary

Adenoma Describes a wide range of neoplastic nodules with glandular appearance that arise in the epithelial tissue and show no cytological features of malignancy.

Bacteriome Term used to define a bacterial community that inhabit a particular environment and is usually shaped by a symbiotic interaction with its host and other microbes.

Dysbiosis Perturbation of the natural balance in the gut microbiota, that is usually associated with pathogenesis.

Genotoxin A molecule that cause DNA damage. It could cause DNA mutations (mutagen), trigger cancer (carcinogen), or lead to birth defects (teratogen).

Polyp Is a typically benign abnormal growth of diffuse mucosal tissue. Some polyps have a stalk and are called pedunculated, while other polyps are flat and are called sessile.

Virome Term used to define a viral community that inhabit a particular environment and is usually shaped by a symbiotic interaction with its host and other microbes.

Nomenclature

AOM Azoxymethane
APC Adenomatous polyposis coli

Healthy Human Enteric Microbiota

The gut microbiota is a dynamic structure that helps maintain host homeostasis by regulating metabolic and immune processes and establishing a network that keeps pathogenic microbes in line. Microbial composition is shaped by the host immune system, aging processes, dietary metabolites, oxygen levels, in situ microbial interactions, and other environmental factors. In the human colon, the microbiota is composed of archaea, eukarya, viruses, and bacteria. The *Methanobrevibacter* genus is the most prevalent archaea in healthy individuals and the phyla Ascomycota and Basidiomycota are the most prevalent fungi (Hoffmann et al., 2013). Intestinal bacteria are dominated by an inverse abundance ratio between Bacteroides and Firmicutes (Human Microbiome Project Consortium, 2012; Eckburg et al., 2005). However, the less abundant phylum Proteobacteria, which include pathogens such as *Escherichia coli* and *Helicobacter*, is the major source of gene variability between healthy hosts (Bradley and Pollard, 2017). Strict anaerobes such as *Bacteroides*, *Bifidobacterium*, *Eubacterium*, *Peptostreptococcus*, *Atopobium* and *Fusobacterium* constitute the major portion of the microbiota (Tlaskalova-Hogenova et al., 2004), whereas facultative anaerobes such as *Enterococci*, *Streptococci* and *Enterobacteriaceae* represent a minority. Both inflammation and antibiotic treatment can induce an increase in oxygen levels in the colon (Byndloss et al., 2017), which can favor dysbiosis by creating a niche for facultative anaerobes with potential pathogenic activity (Spees et al., 2013; Rivera-Chavez et al., 2016) (reviewed on Rivera-Chavez et al. (2017) and Litvak et al. (2017)).

Human Enteric Microbiota Associated With Carcinogenesis

Colorectal cancer (CRC) development is a multistep process that involves accumulation of mutations in colon epithelial cells (CECs), which lead to the formation of aberrant crypts (Irrazabal et al., 2014). Common genetic lesions that lead to colon carcinogenesis include loss of the *adenomatous polyposis coli* (*APC*) tumor suppressor gene, or mutations in the *β-catenin* gene, both of which lead to activation of β-catenin/TCF/LEF-1 signaling that in turn leads to uncontrolled CEC proliferation. In fact, 85% of sporadic CRC carry mutations in the *APC* gene (Medema and Vermeulen, 2011). These genetic changes are usually followed by mutations in *K-Ras*, *PIK3CA* and *TP53* genes (Raskov et al., 2014). In addition, mutations or epigenetic silencing that lead to mismatch repair (MMR) deficiency occur in approximately 20% of sporadic CRC (Poulogiannis et al., 2010) and are the most common mutation in patients with hereditary nonpolyposis colorectal cancer (HNPCC) or Lynch syndrome.

Recently, several studies have shown that besides these genetics changes, differences in the composition and diversity on the human microbiota are also strongly associated with CRC development. Although findings have shown that CRCs are colonized with specific bacteria (Maddocks et al., 2009; Gagniere et al., 2017; Viljoen et al., 2015; Kostic et al., 2013; Purcell et al., 2017; Biarc et al., 2004), it is not clear whether such bacteria are CRC initiators or passengers (Tjalsma et al., 2012). This distinction is necessary to differentiate causality from association. CRC initiators induce DNA damage either directly through the production of genotoxins, or indirectly, by promoting inflammation that in turn leads to the production of genotoxic agents or by transforming diet-derived metabolites into secondary genotoxic molecules (Belcheva et al., 2015). On the other hand, passenger bacteria exploit the unique microenvironment provided by the tumor to grow and out-compete other microbes. In this case, bacteria could simply be along for the ride, or might promote the growth of the tumor.

Current evidence supporting bacterial causality in human CRC has been challenging, which is mainly due to three factors: bacterial genetic plasticity, host genetic variability, and the prolonged period between the initiation of carcinogenesis and the detection of the cancerous lesion in the clinic. First, the microbiota is a dynamic structure, the composition of which is affected by many factors. Due to the high mutation rates in viruses (Minot et al., 2013), the constant horizontal gene transfer between unrelated bacteria (Lloyd-Price et al., 2016), and the very long times that the microbiota develop and adapt to each other in an adult individual, it is likely that each person will ultimately possess a unique virome, composed primarily of phages, and a unique bacteriome. Hence, trying to precisely implicate a single bacterium at a determinate point to CRC initiation can be likewise compared to trying to measure with absolute precision the position and momentum of a quantum particle, as outlined by Heisenberg's uncertainty principle.

Second, most of the potentially carcinogenic bacteria can colonize humans asymptomatically, and are able to induce or promote carcinogenesis only after chronic infection in genetically susceptible hosts. Hence, such bacteria might be carcinogenic only under

certain conditions, and defining these conditions might prove to be challenging. Furthermore, considering that not all inflammatory processes are equally detrimental to the mucosa, a detailed characterization of the host inflammatory state is critical, since gross histological scores minimize the potential relevance of unique inflammatory responses.

Third, although a single acute exposure of a specific genotoxic bacterium might initiate genetic defects that facilitate cancer initiation, the bacterial pathogen that initiated the oncogenic process might have disappeared by the time the patient presents with an adenoma or CRC at the clinic. In this regard, more research should focus on how a single challenge with pathogenic bacteria could potentially lead to chronic dysbiosis, and/or intestinal disease.

Despite these caveats, there is nevertheless strong evidence for the involvement of specific microbes in colon cancer, and these are described below.

Helicobacter pylori

Helicobacter pylori (*H. pylori*) is a Gram-negative human pathogen found in approximately 50% of the population (Moayyedi and Hunt, 2004). This pathogen promotes chronic inflammation in the upper gastrointestinal tract and is a known inducer of gastric cancer. In fact, *H. pylori* is the only bacteria classified as a Group I carcinogen by the International Agency for Research on Cancer (Anon, 1994). This link has led to extensive research of a possible role of *H. pylori* in other gastrointestinal cancers, such as CRC.

Although *H. pylori* has been detected in the human colon (Keenan et al., 2010) and in human colonic tumors (Papastergiou et al., 2016), there is no clear mechanism by which this pathogen can initiate CRC. Furthermore, the association between *H. pylori* infection and CRC is conflicting (Breuer-Katschinski et al., 1999; Fujimori et al., 2005; Moss et al., 1995; Shmuely et al., 2001). Recently, an epidemiologic study in the United States showed that the ethnic distribution of sessile serrated polyps is inversely associated with *H. pylori* prevalence (Sonnenberg et al., 2017). In contrast, a study focused on the Korean population showed that the rate of *H. pylori* infection was higher in patients with adenoma compared to polyp-free controls (Nam et al., 2017). In addition, while some studies have shown that the presence of anti-*H. pylori* IgG antibodies is positively associated with advanced colon cancer (Lee et al., 2016), other studies have not found such associations (Blase et al., 2016). Although, none of these studies have demonstrated that this pathogen could directly induce colonic carcinogenesis, given the known mechanism by which *H. pylori* induces gastric cancer, it is reasonable to hypothesize that *H. pylori* might directly promote CRC. In this section, we will discuss the mechanisms by which *H. pylori* induce gastric cancer and potentially CRC.

H. pylori Virulence Factors

H. pylori virulence is related to the presence of a *cag* pathogenicity island (*cag*PAI) locus, which encodes for a type IV secretion system (T4SS) and the CagA virulence factor. T4SS binds to β integrins and injects CagA into host epithelial cells (**Fig. 1**a). T4SS also delivers peptidoglycan into gastric epithelial cells, which is recognized by Nod1 receptors, leading to IL-8 induction (**Fig. 1**b) (Viala et al., 2004). After CagA is injected into the epithelial cells, this oncoprotein hijacks key signaling pathways in the gastric cell, such as NF-κβ, MAP kinase and Jak/STAT pathways. These pathways control fundamental processes in gastric cells, such as proliferation, inflammation, cell cycle, and apoptosis (reviewed on Tegtmeyer et al. (2017)) leading to deregulation in cell homeostasis.

Another virulent factor produced by *H. pylori* is the vacuolating cytotoxin VacA, which is the only known *H. pylori* protein that targets the mitochondria. VacA is internalized into gastric epithelial cells in endosomes, a process that alters intracellular trafficking and inhibits antigen presentation (Molinari et al., 1998). Internalized VacA localizes to the mitochondrial inner membrane where it forms anion-conductive channels that reduce the mitochondrial membrane potential, resulting in a lower production of ATP, cytochrome *c* release and apoptosis (**Fig. 1**c) (McClain et al., 2017). VacA channel-forming activity also leads to autophagy, which seems to be a host defense mechanism to reduce cellular damage (Terebiznik et al., 2009). On the other hand, VacA can trigger reactive oxygen species (ROS)-induced autophagy by decreasing intracellular levels of glutathione, one of the main antioxidants in the cell (Tsugawa et al., 2012). Additionally, VacA can inhibit the function and proliferation of several adaptive and innate immune cells (McClain et al., 2017). VacA activity differs between *H. pylori* strains due to gene variability (Blaser, 2002). Nevertheless, *H. pylori* strains that possess a functional T4SS, a *CagA* gene, and a cytotoxic *VacA* gene, are positively associated with induction of gastric tumor lesions (Blaser, 2002).

Once *H. pylori* reaches the stomach, it adheres to gastric epithelial cells by binding to some members of the CEACAM (carcinoembryonic antigen-related cell adhesion molecule) family expressed by epithelial cells (Koniger et al., 2016). Curiously, while CEACAM1 is a recognized tumor marker in the colon, this protein is downregulated during colon carcinogenesis (Neumaier et al., 1993), and its deficiency contributes to colon carcinogenesis in mice (Leung et al., 2006). These data suggest that the environment generated after tumor formation in the colon do not favor *H. pylori* colonization, but doesn't rule out such a role for *H. pylori* in tumor initiation.

Another protein that facilitate *H. pylori* adherence to gastric epithelial cells is the blood group binding adhesin (BabA), which binds to ABO/Le^b blood group antigens and fucosylated carbohydrates, such as the ones present in mucus. Interestingly, BabA binding to epithelial cells is reduced by low pH, and increased in neutral environments (Bugaytsova et al., 2017). Since the acidic gastric content is neutralized in the intestine, *H. pylori* could potentially bind mucus in the small and large intestine through BabA-mediated interactions. Furthermore, it is unknown whether an increase in mucus production, which is a phenotype of colitis and colitis-associated colon cancer (CAC), could affect *H. pylori* potential for intestinal colonization.

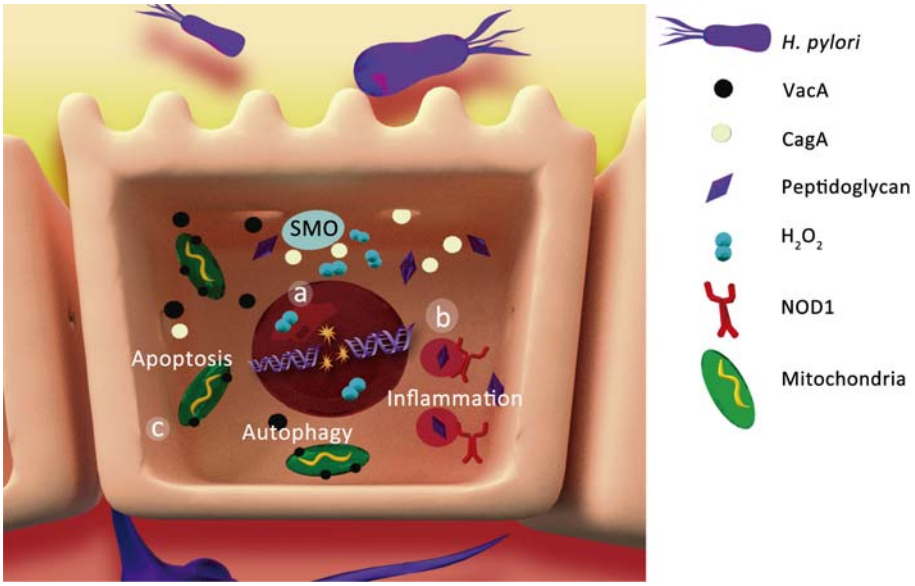

Fig. 1 (a) *H. pylori* injects the toxin CagA into the gastric epithelial cell using a type IV secretion system. CagA induces the expression of spermine oxidase (SMO), which produces H_2O_2 damaging the DNA. Notice that the enterotoxigenic *B. fragilis* toxin also induces SMO and DNA damage (b) *H. pylori* also delivers peptidoglycan into gastric epithelial cells, which is recognized by Nod1 receptors, leading to inflammation. (c) *H. pylori* produces VacA, which targets the mitochondria. VacA is internalized in endosomes, and localizes to the mitochondrial inner membrane where it forms pores that reduce the mitochondrial membrane potential, resulting in a lower production of ATP, and apoptosis. VacA also leads to autophagy as a response to antioxidant depletion.

Mechanisms by Which *H. pylori* Could Induce Colon Carcinogenesis

After *H. pylori* colonizes the gastric epithelial cells, it induces several physiological changes that have been associated with the induction of either gastritis or gastric cancer. These changes include: hypergastrinemia, inflammation, destruction of gastric cells, hypochlorhydria, and DNA damage, all of which could potentially promote colon carcinogenesis.

Hypergastrinemia

Chronic infection with *H. pylori* can increase the release of gastrin, which is a known inducer of hyperproliferation in human CECs (Renga et al., 1997); however, the mitogenic effects of gastrin are not related to the prevalence of adenomas in the colon of patients presenting hypergastrinemia (Sobhani et al., 1993). Since cell hyperproliferation is not sufficient for tumor formation, it is possible that *H. pylori* promotes neoplasia initiation under certain circumstances, such as in DNA repair-deficient hosts. Furthermore, given that mutations on DNA damage repair proteins appear early during colon carcinogenesis, it is possible that under these circumstances *H. pylori* accelerates cancer development.

Inflammation

Chronic inflammation induced by *H. pylori* leads to destruction of gastric glandular cells, a process that can facilitate microbial dysbiosis across the gastrointestinal tract (Kanno et al., 2009). Dysbiosis, in turn, could generate an environment suitable for overgrowth of other cancer-promoting pathogens and/or exacerbate inflammation. Chronic inflammation can also favor cell transformation by silencing some genes through epigenetic modifications, or by leading to the production of ROS which in turn induces DNA damage.

Hypochlorhydria

H. pylori also cause hypochlorhydria, which can cause a decrease in stomach protein hydrolysis and an increase in colonic protein fermentation (Cater 2nd, 1992). An increase in colonic protein availability could potentially provide an advantage to pathogenic bacteria that can ferment proteins and/or use nitrogen as a source of energy (Byndloss et al., 2017; Spees et al., 2013; Winter et al., 2013); under these circumstances *H. pylori* could act as a passenger that facilitate colonic tumor development.

DNA damage

H. pylori might promote DNA damage by at least three mechanisms: increasing ROS production (Chaturvedi et al., 2011), inducing mutations in mitochondrial and nuclear DNA, and reducing DNA repair (Machado et al., 2009). One of the main factors related to *H. pylori*-induced DNA damage is the toxin CagA. This virulence factor could potentially induce CRC by deregulating Wnt (Yong et al., 2016; Gnad et al., 2010) and p53 pathways (Buti et al., 2011; Wei et al., 2010), by inducing the expression of inflammatory mediators that are known CRC promoters, such as IL-8 (Ferreira et al., 2016; Chang et al., 2015) or by inducing DNA damage

(Chaturvedi et al., 2011; Xu et al., 2004). CagA *positive H. pylori* infection of gastric epithelial cells induces DNA double-strand breaks (DSBs) and telomere shortening. Specifically, *H. pylori* strains that express the oncogenic protein CagA induce upregulation of spermine oxidase (SMO) (Chaturvedi et al., 2011). SMO produces hydrogen peroxide (H_2O_2) as a by-product, leading to oxidative stress, DNA damage, and apoptosis of gastric epithelial cells (**Fig. 1**a) (Chaturvedi et al., 2011). Surprisingly, after *H. pylori* infection, a subset of gastric epithelial cells with high levels of DNA damage do not undergo apoptosis, a phenomenon that has been associated with the activation of the EGF receptor by *H. pylori* (Chaturvedi et al., 2014). Another mechanism that could increase survival of cells with high levels of DNA damage could take place in cells that harbor mutations in the DNA damage response (DDR). When the DDR is not active, cell cycle checkpoints are not activated, and cells with high levels of damaged DNA will proliferate. For example, ATM (ataxia-telangiectasia mutated)-deficient cells proliferate after irradiation due to its inability to activate the cell cycle checkpoints in response to double-stranded DNA breaks (Painter and Young, 1980; Falck et al., 2001).

Although CagA could induce CRC by several mechanisms, and some studies have shown that CagA seropositivity in patients infected with *H. pylori* is associated with a higher incidence of CRC (Shmuely et al., 2001), other reports have found no such correlations (Papastergiou et al., 2016; Chen et al., 2016). In the same way, it has also been shown that seropositivity against the toxin VacA is strongly associated with CRC risk (Epplein et al., 2013), but although both CagA (Chaturvedi et al., 2011) and VacA (Tsugawa et al., 2012) induce ROS and DNA damage in gastric cells, no reports have shown a direct effect of these toxins on CECs.

In conclusion, although it is possible that *H. pylori* could induce CRC, more research is required with specific focus on specific susceptible subjects. For example, *H. pylori* can directly induce DNA damage, and the potential role of *H. pylori* on DNA repair-deficient subjects have not been fully studied.

Helicobacter hepaticus

Other *Helicobacter* species, such as *Helicobacter hepaticus* (*H. hepaticus*), have also been associated with carcinogenesis. In 1992, *H. hepaticus* was shown to cause hepatocellular and hepatocholangiolar adenomas and carcinomas in genetically susceptible mice (Falsafi and Mahboubi, 2013). Subsequent work showed that *H. hepaticus* infection induced colitis and CRC in immunodeficient mice (Erdman et al., 2003, 2009; Ge et al., 2017; Nagamine et al., 2008a, 2008b; Wang et al., 2017).

Mechanisms by Which *H. hepaticus* Could Induce Colon Carcinogenesis

Although *H. hepaticus* has been found in patients with chronic liver disease (Nilsson et al., 2000; Yang et al., 2013; Hamada et al., 2009), there is no data that demonstrate that *H. hepaticus* colonize the human intestinal tract and therefore a direct causality on inflammatory bowel disease (IBD) or CRC in humans is nonexistent. Nevertheless, current research suggests that *H. hepaticus* can induce CRC in mice by at least two mechanisms: inflammation and DNA damage.

Inflammation

Lymphocyte homeostasis directly affects the progress of intestinal disease during *H. hepaticus* infection; SMAD3-deficient mice develop colitis after infection with *H. hepaticus*, a process that is dependent on the activation and dysregulation of effector lymphocytes in the gut (McCaskey et al., 2012). Although, one might expect that lymphocyte-deficient mice will not develop colitis after infection with *H. hepaticus*, recombinase-activating gene-2-deficient ($Rag2^{-/-}$) mice inoculated with *H. hepaticus* develop colitis and colonic polyps, which is attenuated by providing mice with T regulatory cells (Tregs) (Erdman et al., 2003, 2009). In the same line, mice deficient in the immunoregulatory molecule IL-10, also develop colitis after infection with *H. hepaticus*, and it has been suggested that monocyte recruitment into the lamina propria lead to CAC (Bain et al., 2018). While, the pathogenesis of *H. hepaticus* was thought to be due to its capacity to activate inducible nitric oxidase (iNOS) in macrophages, recent data suggest that *H. hepaticus* induce iNOS directly on the apical side of cecal epithelial cells (**Fig. 2**a). In $Rag2^{-/-}$ mice, *H. hepaticus*-mediated nitric oxide production leads to cecal epithelial cell hyperproliferation and DNA damage; phenotypes that are reverted after IL-22 depletion. *H. hepaticus*-mediated IL-22 induction was not only associated with nitric oxide production, but also with dysbiosis (Wang et al., 2017).

DNA damage

H. hepaticus also produces the cytolethal distending toxin (CDT), which is formed by three subunits encoded by the genes *cdtA*, *cdtB* and *cdtC. The* subunit CdtA allows the toxin to attach to the cell membrane, while CdtC promotes the translocation of the DNase CdtB into the nucleus (**Fig. 2**b) (Avenaud et al., 2004). Once this toxin is translocated into the nucleus, it catalyzes the formation of DSBs during S-phase of the cell cycle (Fedor et al., 2013), inducing DNA damage (Ge et al., 2017) and G2/M cell cycle arrest (Young et al., 2000). The mechanism by which CDT induces colitis and CRC has been extensively investigated in the context of other pathogens that can produce this toxin, such as enterotoxigenic *Escherichia coli* (see below), however the mechanisms by which *H. hepaticus* CDT induces disease in vivo has not been fully investigated. In vitro studies have shown that the DNA repair pathways activated by *H. hepaticus* CDT are very similar to those activated after irradiation (IR)-induced DNA damage. CDT activates both ATM-CHK2 and ATR-CHK1 pathways, and leads to the formation of persistent yH2AX foci in human fibroblasts (Fahrer et al., 2014) and colon epithelial cells from *Rag2*-deficient mice (Ge et al., 2017). When CDT-induced DNA damage is detected, cells undergo G2/M cell cycle arrest (Young et al., 2000), which is consistent with the protection against CDT-induced DSBs conferred

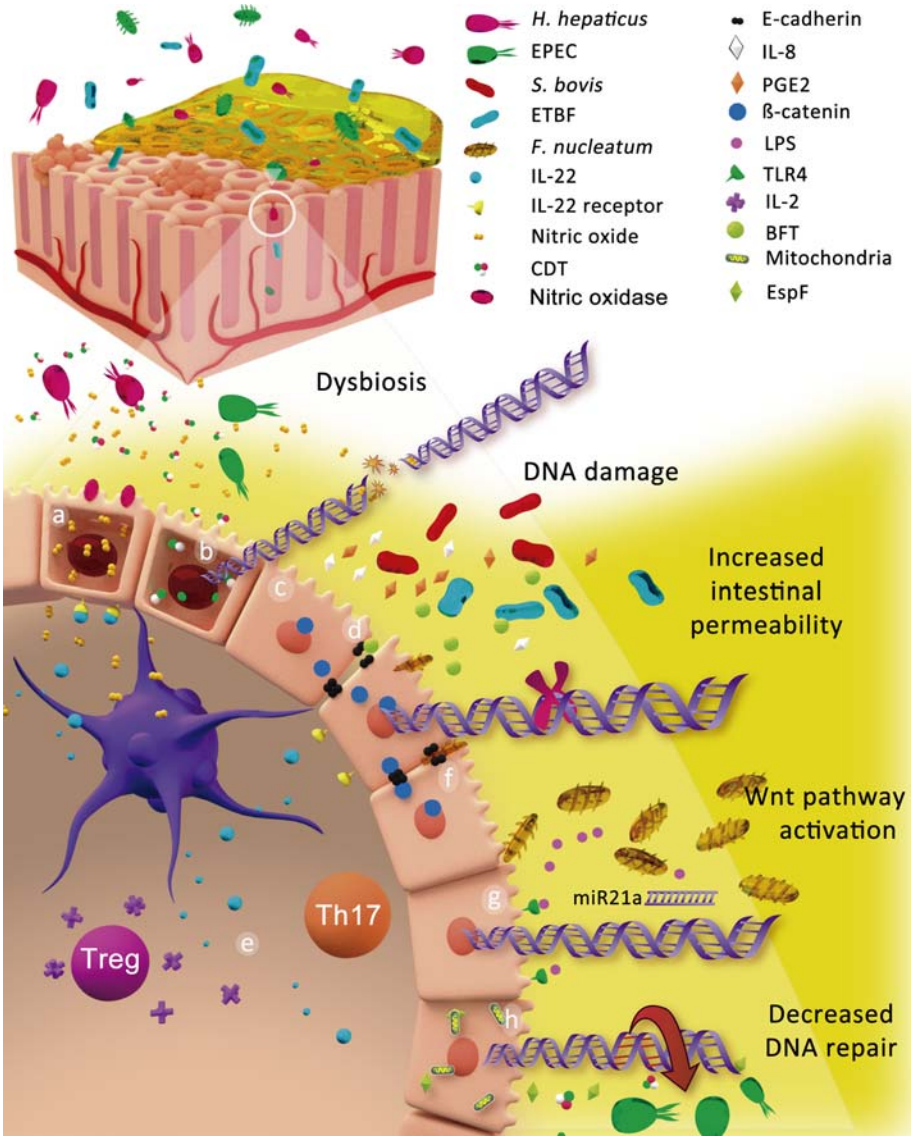

Fig. 2 (a) *H. hepaticus* induce IL-22 production by immune cells, which triggers iNOS expression on the apical side of the epithelial cells and nitric oxide production. Nitric oxide leads to cell hyperproliferation, DNA damage and dysbiosis. (b) *H. hepaticus* and EPEC produce the cytolethal distending toxin (CDT), which induces the formation of DSBs. (c) *S. bovis* can directly induce hyperproliferation of CECs and increase release of CXC chemokines, IL-8 and prostaglandins E2 (PGE2). PGE2 can activate the transcription of genes that regulate proliferation in the colon, such as the Wnt-pathway. (d) ETBF toxin (BFT) cleaves E-cadherin increasing intestinal permeability, and leading to the translocation of β-catenin into the nucleus, which induces proliferation. (e) After ETBF infection, Tregs are recruited into the lamina propria, creating a microenvironment that facilitates Th17 polarization, which promotes IL-17 mediated carcinogenesis. (f) *F. nucleatum's* FadA adhesin binds to E-cadherin, which increases free β-catenin, thereby activating the Wnt-pathway. (g) *F. nucleatum* also activates TLR4, which induces the expression of miR21a leading to the activation of the Wnt-pathway. (h) EPEC secretes EspF, which targets the mitochondria leading to the downregulation of the MMR activity.

by both homologous recombination (HR) and nonhomologous end-joining (NHEJ) in human fibroblasts (Fahrer et al., 2014; Bezine et al., 2016). Interestingly, since it is known that the MMR proteins MLH1 and MSH2 are necessary for DNA repair and the activation of the ATM-CHK2 pathway (Brown et al., 2003), it is possible that patients with MMR-deficiencies could be especially susceptible to CDT-induced DNA damage, although this would need to be investigated.

In conclusion, while *H. hepaticus* is clearly linked to CRC development in mice, the mechanism by which it does so in vivo is lacking. Other pathogens that produce CDT and have been associated with induction of CRC in humans, do not colonize mice efficiently, and therefore, although *H. hepaticus* might not colonize the human colon, it easily colonizes the mouse intestine without the need of antibiotic pretreatment, providing an excellent model to study the effects of CDT on colitis and CRC. Furthermore, different pathogens could lead to distinct immune responses resulting in divergent phenotypes. Therefore, one cannot assume that the effect of one toxin produced by a specific pathogen would be the same when the toxin is produced by another distant pathogen.

Streptococcus bovis Biotype I

Streptococcus bovis (*S. bovis*) is a gram-positive commensal bacterium that belongs to the Firmicutes phylum, and is found in 2.5%–15% of healthy humans (Hooper and Gordon, 2001). Surprisingly, when this opportunistic pathogen causes endocarditis, its infection is linked to CRC (McCoy and Mason 3rd, 1951; Hoppes and Lerner, 1974; Klein et al., 1977). Specifically, there is a striking association between endocarditis induced by *S. bovis* biotype I (*S. gallolyticus* subsp. *gallolyticus*, referred after as *S. bovis*) and CRC (Ruoff et al., 1989; Corredoira et al., 2005). In fact, both ulcerative carcinomas and precancerous polyps are associated with this microbe (Burns et al., 1985; Tjalsma et al., 2006). However, it is still under debate whether *S. bovis* infection can directly induce CRC.

S. bovis Adherence and Colonization of Epithelial Cells

Although *S. bovis* usually do not infect intestinal tissue, some reports suggest that ulceration in colorectal carcinomas facilitate the entry of *S. bovis* into the blood stream leading to bacteremia and endocarditis. *S. bovis* express several surface proteins that belong to the Microbial Surface Component Recognizing Adhesive Matrix Molecules (MSCRAMM) family (Sillanpaa et al., 2009). These proteins can bind to collagen-rich surfaces, which are found in both dysplastic colonic epithelium and damaged cardiac tissue. In vitro studies suggest that after *S. bovis has* attached to the epithelium, these bacteria can cross the epithelial layer via a paracellular mechanism, without inducing IL-1β or IL-8 responses that would otherwise clear the infection (Boleij et al., 2011). In contrast, in vivo studies have found that *S. bovis* infection lead to inflammation of the colonic mucosa (Ellmerich et al., 2000), which is associated with cancer development (Biarc et al., 2004).

Mechanisms by Which *S. bovis* Could Induce Colon Carcinogenesis

Animal models have shown that *S. bovis* can directly induce cellular transformation in vivo. Rats treated with the carcinogen azoxymethane (AOM) and either *S. bovis* or bacterial antigens extracted from its cell wall developed preneoplastic lesions characterized by hyperproliferation of CECs and increased release of CXC chemokines, IL-8 and prostaglandins E2 (PGE2) in the colonic epithelium (Biarc et al., 2004; Ellmerich et al., 2000). PGE2 can activate the transcription of genes that are usually under the control of the Wnt-pathway (**Fig. 2**c) (Shao et al., 2005), which when dysregulated can enhance tumor formation. Therefore, *S. bovis*-induced PGE2 could be a link between inflammation and carcinogenesis.

Potential Role of *S. bovis* in Human CRC

A causative association between *S. bovis* infection and CRC seems to be restricted to certain scenarios such as when the host is chronically infected and the colonic epithelium is inflamed, the latter of which could lead to an increased rate of genetic mutations and/or hyperproliferation. At least two studies have found that IBD patients have a trend toward an increase in the frequency of fecal *S. bovis*, results that were likely not significant due to the size of the sample (Klein et al., 1977; Dubrow et al., 1991; Moshkowitz et al., 1992). Nevertheless, further work is required to establish *S. bovis* in CRC in both humans and colitis-prone animal models.

In conclusion, it is not clear whether *S. bovis* is a CRC initiator or passenger, however given that this bacterium can induce inflammation and cell transformation in vivo, it is reasonable to hypothesize that *S. bovis* could generate an environment that can exacerbate colon carcinogenesis.

Enterotoxigenic *Bacteroides fragilis*

Bacteroides are one of the major phylum found in the colon, and compromise several symbionts, such as the human anaerobe *Bacteroides fragilis*, which constitute 1%–2% of cultured fecal bacteria. The presence of a 6 kb pathogenicity island that encodes the secretory metalloproteinase II (MPII) and one of the three homologous toxins named *B. fragilis* toxins (BFT), distinguishes two classes of *B. fragilis*. Strains that secrete BFT are called enterotoxigenic *Bacteroides fragilis* (ETBF) while strains that do not produce this toxin are called nontoxigenic *B. fragilis* (Sears et al., 2014). Although, ETBF can asymptomatically colonize the human colon (Sears, 2009), several reports linked ETBF infection to acute diarrhea in young children (Sack et al., 1992) and CRC (Viljoen et al., 2015; Purcell et al., 2017; Zhou et al., 2016; Wu et al., 2009; Goodwin et al., 2011; Housseau et al., 2016; Geis et al., 2015), which will be discussed in this section.

Mechanisms by Which *B. fragilis* Toxin Could Induce Colon Carcinogenesis

The mechanisms of action of BFT are not fully understood, however current research suggests that BFT can cleave E-cadherin, increase intestinal permeability, trigger inflammation and DNA damage, and induce morphological changes and cell proliferation in intestinal epithelial cells.

E-cadherin cleavage

The adhesion molecule E-cadherin, which usually enables cell-to-cell contacts in the epithelium, is a target for both MPII and BFT. While MPII binds to E-cadherin (Remacle et al., 2014), BFT cleaves it thereby weakening tight junctions, and increasing cell permeability, which lead to a series of morphological changes in human intestinal cells (Wu et al., 1998). E-cadherin is not only an adhesion molecule, its cytoplasmic domain associates with β-catenin. Binding of E-cadherin can lead to the translocation of β-catenin into the nucleus and transcriptional activation of several genes that control cell proliferation (**Fig. 2**d). Accordingly, when human CECs (HT29/C1) are treated with BFT, cleavage of membrane associated-E-cadherin leads to nuclear localization of β-catenin, and transcriptional upregulation of c-myc, triggering cell proliferation (Wu et al., 2003).

Some studies have suggested that BFT induces IL-8 secretion by cleaving E-cadherin in human intestinal cells. In fact, E-cadherin deficient cells do not express IL-8 after exposure to BFT. However, disruption of cell-to-cell interactions after EDTA-treatment is enough to induce IL-8 production by HT29/C1 cells. Furthermore β-catenin activation alone can induce IL-8 secretion, suggesting that E-cadherin cleavage is not required to induce IL-8 secretion (Hwang et al., 2013).

Inflammation

ETBF has also been shown to trigger either colitis or CAC depending on the host's T-cell polarization after infection. For example, $Apc^{min/+}$ (multiple intestinal neoplasia) mice infected with ETBF develop colonic neoplasia via activation of inflammatory Th17 cells (Wu et al., 2009). After ETBF infection, anti-inflammatory Tregs are recruited into the lamina propria, limiting IL-2 availability, and creating a microenvironment that facilitates pathogenic Th17 polarization, which promotes IL-17 mediated carcinogenesis (**Fig. 2**e) (Housseau et al., 2016; Geis et al., 2015). In agreement with this finding, ETBF-infected Treg deficient mice do not develop CAC, however in this scenario IL-2 is available for Th1 cell polarization, which produce interferon gamma (IFNγ) inducing colitis but not CRC. In this case, EBTF infection could result in two different inflammatory pathways, which depend on the immune status of the host. These findings highlight the importance of characterizing the nature of the inflammatory response after microbial infection (Irrazabal and Martin, 2015), information that is lacking with other CRC-associated bacteria.

DNA damage

BFT has also been shown to increase ROS production by inducing SMO, similar to that observed with the *H. pylori* toxin *CagA*, which in turn can lead to DNA damage (**Fig. 2**d). BFT upregulates the enzyme SMO in CEC cell lines (i.e., HT29/c1) and colonic tissue of C57BL/6 mice (Goodwin et al., 2011). SMO is a polyamine catabolic enzyme that leads to increased ROS production after inflammatory stimuli. BFT-mediated SMO-induction increases the levels of y-H2AX in colon cancer cell lines. On the other hand, chronic inflammation and CEC hyperproliferation in ETBF-infected mice is reduced when mice are treated with a SMO-inhibitor (Goodwin et al., 2011). In fact, colonic polyps can be reduced with administration of a SMO-inhibitor in BFT-infected $Apc^{min/+}$ mice.

Evidence Supporting a Role for ETBF in Human Colon Carcinogenesis

Given the evidence that ETBF could induce CRC in mice, research has now focused on studying the prevalence and association of ETBF with colon carcinogenic lesions in humans. Indeed, the presence and abundance of the BFT gene in mucosal tissue from patients undergoing colonoscopy is positively associated with early-stage tumoral lesions (Purcell et al., 2017). In addition, studies focused on different populations have found that ETBF is significantly increased in tumoral tissue compared to both adjacent normal tissue and healthy controls (Viljoen et al., 2015; Zhou et al., 2016).

In conclusion, extensive research supports a role of ETBF in CAC induction in genetically susceptible mouse models. ETBF is also increased in tumoral tissue in human subjects. However, there is not enough evidence to conclude that ETBF is linked to tumor initiation in healthy subjects. ETBF is found in normal tissue and control subjects, suggesting that ETBF might have pathological effects only under certain conditions.

Fusobacterium nucleatum

Fusobacterium nucleatum (*F. nucleatum*) is an invasive, adherent and proinflammatory gram-negative anaerobe that is normally found in the oral cavity, and rarely detected in the gut of healthy humans. However, *F. nucleatum* can be isolated from the intestines of individuals suffering with IBD (Strauss et al., 2011) which has stimulated further research into *F. nucleatum*, inflammatory intestinal disease, and CAC.

Mechanisms by Which *F. nucleatum* Could Induce Colon Carcinogenesis

F. nucleatum adheres to CECs, which has been reported to be mediated by binding of the fusobacterial protein Fap2 to Gal-GalNAc lectin that is expressed on CECs, and overexpressed in CRC cells (Abed et al., 2016). In fact, binding of Fap2-deficient *F. nucleatum* to CRC cells that express Gal-GalNAc is reduced (Abed et al., 2016), suggesting that colonic tumor microenvironment favors *F. nucleatum* attachment to epithelial cells. It has been proposed that *F. nucleatum* can induce CRC mainly by inducing CEC proliferation and inhibiting inflammatory cells.

Proliferation inducer

Cancer cell lines (Caco-2 and SW480) infected with an invasive *F. nucleatum* strain extracted from human CRC tissue have increased protein levels of activated β-catenin and its targets c-myc and cyclin D1 (Chen et al., 2017) suggesting that invasive *F. nucleatum* can directly induce hyperproliferation of CRC cells. There are a number of reports that suggest that the effects of *F. nucleatum* on proliferation could be mediated by the action of the adhesin FadA and through TLR4 activation. First, *F. nucleatum's* FadA adhesin binds to E-cadherin, which increases free β-catenin, thereby activating the Wnt-pathway and inducing cell proliferation (**Fig. 2f**) (Rubinstein et al., 2013). This adhesin could potentially be used as a diagnostic marker for CRC since the levels of the *fadA* gene in the colon of patients with adenomas are >10–100 times higher compared to controls. Second, inhibition of the Toll-like receptor 4 in CRC cells decreases *F. nucleatum*-induced activation of the β-catenin pathway (Chen et al., 2017). Interestingly, microRNA (miRNA) 21, which is expressed under the control of TLR4, can also affect CEC proliferation since inhibitors of miR21 reduce *F. nucleatum*-induced proliferation and invasion in cultured cells (**Fig. 2g**) (Yang et al., 2017). Indeed, *F. nucleatum*-infected miR21a-deficient mice have less tumors and increased survival compared to control mice. In addition, it has also been reported that elevated levels of *F. nucleatum* DNA in human tumors correlate with high MiR21 expression and worse clinical outcome (Yang et al., 2017).

Immunosuppresor

Besides being necessary for adherence, *F. nucleatum* Fap2 protein can inhibit specific immune responses. Fap2 interacts with the inhibitory receptor TIGIT, which is expressed in all human natural killer (NK) cells and on some T-cell populations, and therefore *F. nucleatum* can inhibit the activity of NK cells and tumor infiltrating lymphocytes (Gur et al., 2015). In fact, there is an inverse correlation between CRCs associated with *F. nucleatum* and $CD3^+$ T-cell density (Mima et al., 2015), suggesting that this bacterium could promote CRC by downregulating antitumoral T-cell cytotoxicity. In addition, *F. nucleatum*-induced CRCs in $Apc^{Min/+}$ mice have an elevated number of infiltrating myeloid-derived suppressor cells, which have immunosuppressive activity and allow tumor growth (Kostic et al., 2013). $APC^{min/+}$ mice gavaged with *F. nucleatum* develop more tumors in the colon (Kostic et al., 2013; Yang et al., 2017), and have higher mortality than vehicle treated controls (Yang et al., 2017). Tumors from *F. nucleatum*-treated $APC^{min/+}$ mice show a proinflammatory profile similar to human *Fusobacterium*-positive tumors, however *F. nucleatum* does not worsen colitis and CAC in mice (Kostic et al., 2013), suggesting that this bacterium can induce an antiinflammatory environment that facilitates tumor progression but not tumor initiation. Moreover, *F. nucleatum* produce butyrate, and butyrate can induce Treg differentiation (Furusawa et al., 2013), which could facilitate tumor growth by hampering antitumoral immune responses.

Evidence Supporting a Role of *F. nucleatum* in Human Colon Carcinogenesis

F. nucleatum is significantly increased in tumors compared to adjacent normal tissue and tissue from healthy controls (Viljoen et al., 2015; Zhou et al., 2016; Castellarin et al., 2012; Kostic et al., 2012). The presence of *F. nucleatum* is also significantly associated with microsatellite instability (MSI) high tumors (Nosho et al., 2016). In addition, *F. nucleatum* strains extracted from inflamed mucosa of IBD patients are more invasive than strains extracted from control patients (Strauss et al., 2011), and invasive *F. nucleatum* infection is positively associated with β-catenin activation in CRC tissues (Chen et al., 2017).

Overall there is substantial evidence supporting a positive association between *F. nucleatum* infection and CRC in humans. However, in contrast to other bacteria associated to CRC, *F. nucleatum* seems to have antiinflammatory capacities that facilitate tumor escape from immune surveillance, and therefore might promote tumor progression rather than initiate tumors.

Escherichia coli

Escherichia coli (*E. coli*) are commensal gram-negative bacteria found in normal gut microbiota and rarely cause disease. However, a subgroup of these bacteria, named enteropathogenic *E. coli* (EPEC), can attach to the intestinal mucosa and produce toxins that induce bowel disease in humans.

Mechanisms by Which EPEC Could Induce Colon Carcinogenesis

Some reports have found that EPEC incidence is significantly higher in CRC patients than in healthy controls (Magdy et al., 2015), prompting research in search for a possible link between EPEC and CRC. Current research indicates that inflammation might favor EPEC carcinogenesis, which could potentially be induced by two mechanisms: DNA damage, and MMR downregulation.

DNA damage

EPEC uses a type 3 secretion system (T3SS) to inject various effector proteins into the host cells, and it also express the genotoxins colibactin and CDT (**Fig. 2b**, see *H. hepaticus*). Colibactin is encoded within the *polyketide synthase* (*pks*) gene island, and crosslinks DNA (Vizcaino and Crawford, 2015), promoting genomic instability in vitro (Cuevas-Ramos et al., 2010), and DSBs in mouse enterocytes (Cuevas-Ramos et al., 2010; Arthur et al., 2012). In a colitis AOM/$IL\text{-}10^{-/-}$ model of CRC, infection with pks+ *E. coli* increased tumor counts (Arthur et al., 2012). This finding was recapitulated in an AOM/DSS treated mice models (Cuevas-Ramos et al., 2010; Cougnoux et al., 2014; Dalmasso et al., 2014). Additionally, inflammation seems to accelerate *pks*+ *E. coli*-induced carcinogenesis: AOM-treated $IL\text{-}10^{-/-}$ mice infected with *pks*+ *E. coli* exhibit significantly more tumors than

lymphocyte-deficient AOM-treated Rag2$^{-/-}$ IL-10$^{-/-}$ mice infected with *pks*+ *E. coli* (Arthur et al., 2014). The *E. coli* pks island is one of the top five operons upregulated in AOM-treated IL-10$^{-/-}$ mice compared to untreated mice (Arthur et al., 2014), suggesting that during carcinogenesis, the inflamed intestinal environment induce *pks* transcription hastening carcinogenesis in infected mice.

The EPEC genotoxin CDT also induces DSBs in cultured cells, which leads to ATM-mediated induction of G2/M cell cycle arrest (Fedor et al., 2013). Moreover, CDT accelerates growth in p53-deficient but not in KRAS-deficient human CECs (Graillot et al., 2016), suggesting that CDT genotoxicity could be exacerbated in DNA repair-defective cells.

MMR downregulation

EPEC has been found to downregulate the expression of the MMR proteins MSH2 and MLH1 in cultured CRC cell lines (**Fig. 2**h) (Maddocks et al., 2009). MMR activity downregulation is mediated by EPEC secretion of the protein EspF, which targets the mitochondria (Maddocks et al., 2013). Interestingly, *H. pylori* VacA also targets the mitochondria and reduce the MMR function, suggesting that these toxins may disrupt similar mitochondrial pathways.

Evidence Supporting a Role of EPEC on Human Colon Carcinogenesis

Sixty seven percentage of CRC patients harbor *pks*+ *E. coli* compared to 21% in normal controls (Arthur et al., 2012). Furthermore, although there is a significant increase in total *E. coli* colonization in human MSI tumors, colibactin-producing *E. coli* have been found to be enriched in microsatellite stable (MSS) tumors (Gagniere et al., 2017). In contrast, another report found that there is no significant difference in the concentration of *pks*-positive bacterial DNA between CRC, adenoma, and control patient groups (Shimpoh et al., 2017).

In summary, EPEC can induce CRC in inflammatory mouse models. In addition, EPEC encode two genotoxins that control the cell cycle and induce DNA damage. Moreover, current data indicate that there is a positive association between EPEC infection and CRC in humans (Magdy et al., 2015; Arthur et al., 2012), supporting a role for EPEC in CRC initiation in humans.

Conclusion

It is evident that most bacteria that have been linked to CRC seem to exploit similar mechanisms to induce carcinogenesis: DNA damage, immune dysregulation, and hyperproliferation (**Fig. 2**). All the bacteria previously described, with exception of *S. bovis* and *F. nucleatum*, have the capacity to induce DNA damage (Chaturvedi et al., 2011; Xu et al., 2004; Wang et al., 2017; Goodwin et al., 2011; Cuevas-Ramos et al., 2010). Remarkably, as with irradiation-induced DNA damage, most bacteria seem to trigger ROS production, which in turn leads to DSB formation. Oxidative stress induces DNA oxidation which is usually repaired by the MMR and BER (base excision repair) pathways (Russo et al., 2007). Therefore, DNA repair-deficient subjects might be more susceptible to the effects of ROS. Furthermore, it has been implied that *E. coli* can create the perfect storm for colon carcinogenesis by both inducing DNA damage and downregulating DNA damage repair proteins (Maddocks et al., 2013).

Immune dysregulation is another factor exploited by many microbes. *S. bovis* induce an inflammatory response that facilitate uncontrolled cell proliferation, while carcinogenesis induced by *H. pylori*, *H. hepaticus*, ETBF, and *pks*+ *E. coli* is facilitated by inflammation. Furthermore, ETBF infection in mice could lead to either colitis or CAC depending on the inflammatory response mounted by the host (Geis et al., 2015). In contrast, *F. nucleatum* seems to induce an immunosuppressive environment that facilitate tumor progression (Mima et al., 2015).

Many microbes implicated in CRC also induce CEC hyperproliferation. The most common CRC-associated mutations are in genes that control CEC proliferation (i.e., APC and β-catenin), and some microbes seem to exploit this pathway to induce proliferation of CECs. On the other hand, hyperproliferation induced by microbes could be a consequence of deficiencies in DDR in the host, since genetic mutations induced by microbes would not lead to the activation of cell cycle checkpoints, allowing damaged DNA to be propagated to daughter cells, facilitating carcinogenesis.

Finally, current research suggests that *H. pylori* is the only bacterium that can induce carcinogenesis in any host, irrespective of genetic background, while most of the aforementioned bacteria cannot induce CEC transformation in healthy subjects and need a "first hit," such as a specific genetic deficiency, that sensitizes the host to the oncogenic effects of the microbe. Indeed, this pathogen + susceptibility gene formula has been previously proposed for IBD (Cadwell et al., 2010), and seems applicable to many cases of microbial-induced CRC or CAC.

Mitogen-Activated Protein Kinases (MAPK) in Cancer

Ana Cuenda, Centro Nacional de Biotecnología/CSIC (CNB-CSIC), Madrid, Spain

Glossary

Apoptosis Programmed cell death.
Cell signaling Ability of the cell to perceive changes in the environment and to produce a correct response.
Differentiation Process by which a less specialized cell evolves to a more specialized cell type.
Kinase Enzyme that catalyzes the transfer of a phosphate group (phosphorylation) from a phosphate donating molecule to specific substrates.
Oncogene Gene that encodes a protein that promote tumor development.
Phosphatase Enzyme that catalyzes the removal of a phosphate group from its substrate.
Proliferation Process by which the cell number increases. It is the balance between cell division and cell loss.
Scaffold protein Protein that bring together two or more proteins in a relatively stable configuration.
Tumorigenesis The process of tumor development.
Tumor suppressor gene Gene that encodes a protein that suppresses the development of tumor.

Introduction

Mitogen-activated protein kinases (MAPKs) are a family of kinases, which are ubiquitous and highly conserved in all eukaryotes. They belong to the CMGC group of protein kinases that also includes glycogen synthase kinases (GSK), cyclin-dependent kinases (CDKs) and CDK-like kinases. The different members of the MAPK family share a number of common structural and regulatory features. MAPKs exhibit more than 40% amino acid identity across the kinase domain, but also have unique characteristics. All MAPKs are integrated in signaling modules called MAPK pathways. Several molecular intermediaries compose MAPK pathways: a MAPK, a MAPK activator (MAPK kinase, MKK, MAP2K or MEK), and a MKK activator (MKK kinase (MKKK, MAP3K or MEKK)) that become activated sequentially in response to vast amount of intra- and extracellular stimuli (Fig. 1). The different MAPK pathways are involved in the transduction of extracellular changes into coordinated and integrated adaptive intracellular responses. They, therefore, control many cellular functions including gene transcription, protein biosynthesis, proliferation, cellular differentiation, metabolism rate, apoptosis, migration or cellular interaction among others.

MAPKs are activated by dual phosphorylation of Thr and Tyr residues, in a conserved Thr-X-Tyr motif in the activation loop. This phosphorylation is catalyzed by the dual-specificity kinases MEKs. MAPK phosphatases reverse this phosphorylation and return the MAPK to their inactive state. Further MAPK regulation is achieved by scaffold proteins, which are usually specific for each of the MAPK pathways, and collect specific MEKK–MEK–MAPK core into organized signaling modules. Scaffold proteins are spatial regulators of MAPK signals, and depending on the subcellular localization from which the activating signals arise, defined scaffolds determine which substrates are phosphorylated (Fig. 2). After activation MAPKs phosphorylate specific Ser and Thr (followed by Pro) residues of target substrates, which include many transcription factors, and other kinases and proteins. MEKs are highly selective in phosphorylating specific MAPKs, and they are in turn activated upon phosphorylation of Ser/Thr residues in a conserved motif catalyzed by MEKKs. MEKKs are the first component activated in the MAPK signaling module (Fig. 1) and have distinct motifs in their sequences that confer selectivity to their activation in response to different stimuli; however, their regulation by a range of multiple upstream components is still poorly understood.

MAPKs have been extensively studied and, in mammals, subdivided mainly into four subfamilies, also known as "conventional MAPK" subfamilies: extracellular signal-regulated protein kinase 1/2 (ERK1/2), c-Jun N-terminal kinases 1–3 (JNK1, JNK2 and JNK3), p38 MAPKs (p38α, p38β, p38γ and p38δ) and ERK5 (also known as BMK) (Fig. 1). There are other MAPKs so called "atypical MAPK" that include ERK3/ERK4, Nemo-like kinase (NLK) and ERK7, which are not activated by MEKs and their biological function remains largely unknown.

ERK1/2 Pathway

ERK1 and ERK2 (ERK1/2) were the first MAPKs to be identified and are encoded by two genes *MAPK3* and *MAPK1*, respectively. Both are ubiquitously expressed, although their relative levels varies in different tissues. ERK1/2 are activated by a wide range of growth factors and mitogens, but also by cytokines, certain stresses, transforming agents and G protein couple-receptors among others. ERK1/2 activation is implicated in many cellular processes such as cell motility, proliferation, survival or differentiation. As all conventional MAPKs, ERK1/2 require dual phosphorylation on Thr185 and Tyr187 (for ERK2), in a Thr-Glu-Tyr motif in

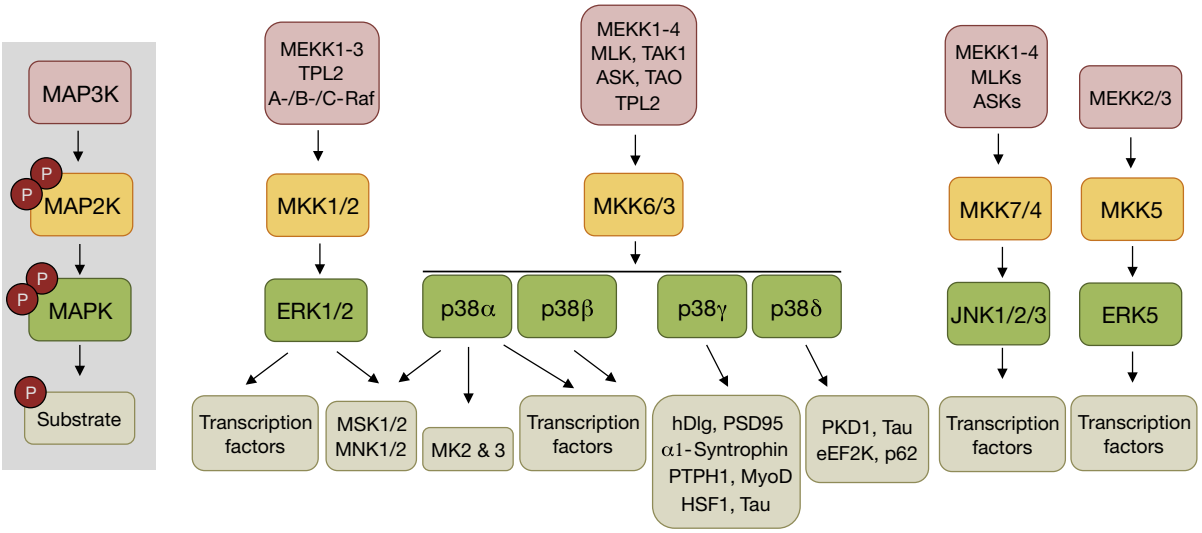

Fig. 1 Schematic representation of conventional MAPK pathways in mammals. *ASK*, apoptosis signal-regulating kinase; *MLK*, mixed lineage kinase; *TAK1*, transforming growth factor beta-activated kinase-1; *TAO*, thousand and one amino acid kinase. See text for more details.

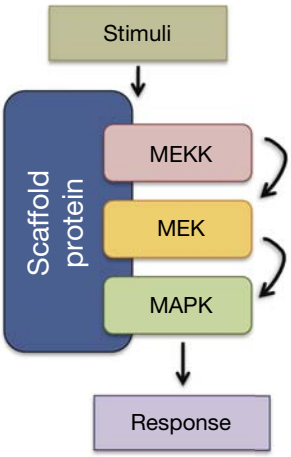

Signalling	Scaffold	Binding partners		
		MEKK	MEK	MAPK
ERK1/2	KRS1/2	Raf	MEK1/2	ERK1/2
	IQGAP1/2/3	Raf	MEK1/2	ERK1/2
	β-Arrestin	Raf	MEK1/2	ERK1/2
	Paxillin	Raf	MEK1/2	ERK1/2
JNK	JIP1	MLK3/DLK	MKK7	JNK1
	JIP2	MLK2/3	MKK7	JNKs
	JIP3	MLK2/3/DLK	MKK7	JNKs
	JIP4	MEKK3	MKK4	JNKs
	POSH1/2/3	MLK	MKK4/7	JNKs
p38 MAPK	JIP4	MEKK3	MKK3/6	p38MAPKs
	OSM	MEKK3	MKK3	p38MAPKs
ERK5	MEK5	MEKK2/3	-	ERK5

Fig. 2 MAPKs scaffold proteins. The figure shows some of the most studied scaffold proteins in the different MAPK pathways. Scaffold proteins bring together two or more proteins (from specific MAPK signaling pathways) in a relatively stable configuration and facilitate their activation in response to different stimuli to trigger the cellular response. *KSR*, kinase suppressor of Ras; *IQGAP*, IQ-motif-containing GTPase-activating protein; *JIP*, JNK interacting partner; *POSH*, plenty of SH3 domain; *OSM*, osmosensing scaffold for MEKK3.

the activation loop of subdomain VIII to be activated. More than 150 substrates for ERK1/2 have been described so far, and among them, ERK1/2 phosphorylate the transcription factors c-Myc, c-Fos, Elk1 and Ets, and also the protein kinases p90 ribosomal S6 kinase (RSK), mitogen- and stress-activated kinase 1 and 2 (MSK1/2) and the MAPK interacting kinase 1 and 2 (MNK1/2). ERK1/2 phosphorylation is catalyzed by two MEKs (MEK1 and MEK2), which are in turn activated mainly by the MAP3Ks Raf (Fig. 1), although in certain cell types and in response to specific stimuli MEK1/2 can also be phosphorylated by other MAP3K such as TPL2 (tumor progression locus 2; also known as cancer Osaka thyroid, COT). There are three Raf family members: ARaf, BRaf and CRaf, also called Raf-1, which is the most studied. Raf-1 is activated by a combination of cellular localization, phosphorylation and binding to Ras. Scaffold proteins also play a crucial role as ERK1/2 regulators, maintaining the pathway integrity and efficiency. At least 15 proteins have been identified as scaffolds for ERK1/2 pathway, which fine-tune signal amplitude and duration, and provide signal fidelity by isolating these complexes from external interferences. Scaffold proteins of the ERK1/2 pathway include kinase suppressor of Ras (KRS), MEK partner 1 (MP1), β-arrestins and IQGAP (Fig. 2).

ERK1/2 pathway regulates processes that are central for cellular transformation; for example, they are implicated in cell-cycle progression by controlling the expression of cyclin D1 and cyclin-dependent kinase (CDK) inhibitors p21 and p27. The intensity and the duration of ERK1/2 signaling determine whether cell undergoes differentiation, proliferation or cell-cycle arrest. In addition, ERK1/2 signaling controls cell survival and apoptosis by regulating both the expression and the activity of proapoptotic proteins.

ERK1/2 signaling is upregulated in cancer cells and in human tumors, which has led to the development of inhibitors of this pathway for cancer therapy. There is a broad spectrum of human tumors known to display aberrant ERK1/2 pathway activation caused by activating mutations in Ras (KRas, NRas and HRas) and Raf (BRaf). Among these tumors are: breast, colon, pancreatic, ovarian, prostate, non-small-cell lung and papillary thyroid cancer, as well as melanoma, glioma, acute myeloid leukemia or acute lymphocytic leukemia. Therefore, there is a need for exploring the potential of ERK1/2-pathway inhibitors as anticancer agents. Ras, Raf and MEK are better therapeutic targets than ERK1/2, since they are proteins that posses unique structural features. Very potent small-molecule inhibitors have been generated for Ras, Raf and MEK, and have been tested in several clinical trials, being so far Raf and MEK inhibitors more effective than Ras inhibitors. The treatment of cutaneous melanoma is one example in which MAPK pathway inhibitors have been used. The development of MEK inhibitors PD908059 and U0126 demonstrate the role of MEK-ERK1/2 pathway in human melanoma cell proliferation, survival and invasion. Approximately 50% and 28% of melanoma patients display mutations in BRaf (BRafV600E is the most predominant) and NRas, respectively. The Braf inhibitors vemurafenib (PLX4032) and dabrafenib (GSK2118436) have been used in the treatment of BRafV600E mutant melanoma patients, showing very good clinical responses in phase I to III trials (overall response of 80%). However, the response to the inhibitors is transient in most patients due to the development of drug-resistance caused by various mechanisms, most of them involving re-wiring of the MAPK pathway. In addition, approximately 30% of the patients treated with the BRaf inhibitors developed Ras-driven secondary cancers such as squamous cell carcinomas, colon cancer or leukemia, probably due to CRaf activation. This has prompted to the development of combination therapies using both BRaf and MEK inhibitors. The combination of Raf and MEK inhibitors in melanoma therapies reduces the development of secondary cancers and prolongs the response, but unfortunately patients still develop resistance. Nonetheless, therapies with BRaf and MEK inhibitors, such as trametinib/dabrafenib and cobimetinib/vemurafenib are currently accepted for the treatment of BRaf-mutant advanced melanomas. Additionally, alternative strategies are being tested nowadays, and drugs targeting ERK, RTK or BRaf and CRaf have been described.

JNK Pathway

There are three JNKs encoded by different genes JNK1 (*MAPK8*), JNK2 (*MAPK9*) and JNK3 (*MAPK10*). Additionally, the JNKs are alternatively spliced giving rise to at least 10 different JNK isoforms. JNK1 and JNK2 are expressed ubiquitously, whereas JNK3 is mainly expressed in the nervous system. JNKs are activated by dual phosphorylation of Thr183 and Tyr185 residues in the Thr-Pro-Tyr motif of the activation loop. This phosphorylation is catalyzed by the MAP2Ks, MKK4 and MKK7. The main targets of JNK are members of the activator protein 1 (AP1) group of transcription factors, such the transcription factors c-Jun, JunB, JunD and related proteins as Fos. JNK phosphorylates the N-terminal part of these molecules causing their activation and therefore promoting gene transcription. Other JNK targets are proteins involved in the control of the cell cycle, survival, cell death, migration, invasion and gene transcription. As ERK1/2, JNKs are also activated by mitogens, although they are preferentially and strongly activated by environmental stresses, toxins, translational inhibitor (cycloheximide and anisomycin), pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs), and by proinflammatory cytokines. As all MAP2Ks, MKK4 and MKK7 are regulated by Ser/Thr phosphorylation catalyzed by a variety of MEKK depending on the stimulus and on the cell type (Fig. 1). The specificity of JNK activation is achieved in part by scaffold protein such as the JNK interacting protein (JIP) family or the plenty of SH3 domains (POSH) family (Fig. 2).

It is well established that JNKs are involved in cell proliferation, survival, cell death and differentiation. However, their specific effect and degree of implication in those processes depends on the JNK family member, the cellular context, the stimuli, or on the strength and duration of the JNK activation. Therefore, to define the implication of the JNKs in cancer development is complex. It is well documented that JNK pathways are implicated in both pro- and antioncogenic processes. The oncogenic function of the JNKs is mainly based on their ability to activate AP1 by phosphorylating and stabilizing c-Jun, and their role as negative regulators of the tumor suppressor p53. On the other hand, tumor-suppressive functions are probably related to their proapoptotic activity. The role of JNK in cancer development is being investigated using mouse models. Studies using JNK1-null mice and JNK2-null mice have

further demonstrated that JNK can cause negative and positive effects in tumor development. For example, the deletion of JNK1 and JNK2 has opposite effects in the development of chemical-induced skin cancer. JNK2 deletion increases skin cancer, whereas the lack of JNK1 decreases the formation of skin tumors. Moreover, chemical-induced hepatocellular carcinoma (HCC) and Bcr-Abl-induced lymphoma are suppressed by JNK1 deletion, but not by the lack of JNK2. In contrast, studies of glioblastoma, prostate cancer and lung carcinoma cell lines have identified important roles for JNK2, but not for JNK1 in oncogenic processes. These data confirm that JNK pathways play a role in cancer development, and that the relative roles of each JNK isoform depend on type of cancer.

One clear example of the implication of the JNK pathway in cancer development is the HCC, which is the third most common cause of death from cancer in the world. Studies using knockout mice have demonstrated that JNK1 deletion, but not JNK2 deletion, decreases the development of chemical-induced HCC with the compound N-nitrosodiethylamine (DEN). In the liver, DEN causes hepatocyte death followed by compensatory regeneration, and maintained administration of DEN leads to the development of HCC. Compared to wild-type mice, JNK1-null mice exhibit decreased liver cell proliferation and tumor formation after DEN treatment, which is caused by a reduction in the expression of c-Myc and an increase in the levels of the cyclin-dependent kinase (CDK) inhibitor p21. These effects have also been found when JNK1 is depleted in human HCC cell lines. Thus JNK1 is central for HCC tumorigenesis. Pharmacological inhibition of JNK reduced HCC development in both DEN-induced liver cancer in mice and in xenografted human HCC cells, indicating that JNK1 is a promising therapeutic target for the HCC treatment.

The contribution of different JNKs to skin cancer development has also been described using the DMBA (7,12-dimethylbenz(*a*) anthracene)/TPA (12-*O*-tetradecanoylphorbol-13-acetate) model. In this model, JNK1 acts as a tumor suppressor as JNK1-null mice are more susceptible to skin tumor development than wild-type mice, whereas in JNK2-null mice the development of skin tumors is suppress, indicating an oncogenic role for JNK2 in this particular cancer model. The molecular mechanisms by which JNKs regulate skin cancer development are still under study. Nonetheless, it has been suggested that the altered AP1 transcription factor activity, together with the differential regulation of essential signaling pathways such as ERK1/2 or Akt, could account for the specific functions of JNK1 and JNK2 in skin cancer development. Akt pathway is a signal transduction pathway regulated by phosphoinositide 3-kinase and the mTOR (mammalian target of rapamycin) that promotes survival and growth in response to extracellular stimuli. JNKs have also been suggested to be targets for antimelanoma therapy as they regulate the survival of melanoma cells. Cutaneous melanoma is an extremely aggressive tumor with a high tendency to relapse and high metastasis rate, its represent only 5% of skin cancers, but it causes approximately the 75% of skin cancer deaths. In melanoma JNKs are frequently active; however their role is not clear as they can act as either oncogenes or tumor suppressors, depending on the upstream or the downstream JNK pathway components presents in a given cell. JNK inhibition causes cell-cycle arrest or apoptosis depending on the cell line. For example, in the human melanoma WM983B cells JNK inhibition causes apoptosis mediated by p53, Bad (Bcl-2-associated death promoter) and Bax (Bcl-2-associated X protein), whereas in 1205Lu cells causes the arrest of the cell cycle mediated by p21.

Additionally, somatic mutations in the JNK pathway (JNK1, JNK2, JNK3 and their upstream activators MKK4 and MKK7) have been identified in large-scale sequencing analyses of protein kinases in human tumors suggesting their involvement in cancer development. These mutations could cause either the loss of activity or the activation of the kinase; thus, the loss of JNK3 function promotes tumor formation, and mutations in the *MAPK10* gene were found in $\sim$53% of human brain tumor examined. Also, sustained activation of JNK1 is associated with altered histone H3 methylation in human HCC, and several members of the JNK pathway are upregulated in prostate cancer.

The role of JNKs in cell proliferation and apoptosis is being used for the development of therapeutic inhibitors. Several peptide inhibitors have been generated, such as JNKI1, which has been successfully used in mouse models for HCC; or BI-78D3, which inhibits JNK activity by interfering with the binding to JIP1 scaffold. The application of JNK inhibitors has been proven to work in human cells and in vivo in animal models; however, JNK pathway has not been translated into clinical use.

p38 MAPK Pathways

There are four p38MAPKs encoded by different genes: p38α (*MAPK14*), p38β (*MAPK11*), p38γ (*MAPK12*) and p38δ (*MAPK13*). Alternative spliced variants of p38α has been identified: CSBP1 (cytokine suppressive antiinflammatory drug-binding protein), Mxi2 (Max-interacting protein) or Exip (for exon skip), although their physiological functions have been poorly studied. Most of the literature on p38MAPK refers to p38α. This was the first p38MAPK identified, and therefore is the best characterized. Based on sequence homology, substrate specificities, and sensitivity to chemical inhibitors, the p38MAPKs can be further divided into two subgroup: p38α/p38β and p38γ/p38δ. p38γ and p38δ are also known as alternative p38MAPKs. Although p38MAPKs are widely expressed, their expression pattern varies in tissues. For instance, p38α is ubiquitously expressed in all cell types and tissues; p38β is highly expressed in the brain, thymus and spleen; p38γ is very abundant in skeletal muscle; and p38δ levels are high in pancreas, intestine, adrenal gland, kidney and heart.

The p38MAPKs are strongly activated by a wide variety of environmental and cellular stresses and by inflammatory cytokines, but they are poorly activated by growth factors. p38MAPKs and JNKs are activated by the same stimuli, and together are also called stress-activated protein kinase pathways. All p38MAPKs are activated by dual phosphorylation on Thr180 and Tyr182 of the The-Gly-Tyr activation motif mediated by the MAP2Ks MKK3 and MKK6, and in the case of p38α also by MKK4. p38α may also be activated by autophosphorylation in cardiomyocytes in ischemic heart, and in T lymphocytes stimulated through the T-cell antigen receptor (TCR). The activation of MKK3 and MKK6 is by phosphorylation of Ser/Thr residues mediated by different MEKKs, which are stimulus and cell type specific (**Fig. 1**).

The use of kinase inhibitors that specifically inhibit p38α and p38β, but do not block p38γ and p38δ activity, and the genetic deletion of specific p38MAPK isoforms has showed that they have some overlapping substrates and functional redundancy. However, there are particular proteins that are better substrates for p38α/p38β than for p38γ/p38δ. More than 100 proteins can be phosphorylated by p38α/p38β and a significant proportion of them is involved in the regulation of gene expression such as the transcription factors ATF2 (activating transcription factor 2), MEF2 (myocyte enhancer factor 2) or ELK1 (Ets like gene 1). Other p38α/p38β substrates are protein kinases such as MAPK-activated protein kinase 2 (MK2) or MK3; MSK1/2 or MNK1/2 (Fig. 1), which control numerous cellular processes. p38δ phosphorylates proteins such as the eukaryotic elongation factor 2 kinase (eEF2K), the protein kinase D1 (PKD1) or the signal adaptor p62; and p38γ the transcription factor MyoD. p38γ associates with PDZ-domain containing proteins, such as α1-syntrophin, SAP (synapse-associated protein) 90/PSD (postsynapse density) 95, hDlg (human disk large also known as SAP97) and the protein tyrosine phosphatase PTPH1 and under stress conditions it is able to phosphorylate them and modulate their activity. p38γ is unique among the MAPKs and contains a short sequence at its C-terminal that associates with PDZ-domains, whose function is facilitate protein–protein interaction (Fig. 3). Also, p38γ and p38δ are the principal p38 MAPKs phosphorylating the neuronal microtubule-associated protein Tau and the heat shock factor 1 (HSF-1).

p38 MAPK pathway are involved in processes that promote cell transformation and tumor development. They control the cell cycle, cell growth, apoptosis, angiogenesis, tissue invasion and metastasis. p38 MAPK pathway regulates the checkpoint controls and cell cycle at G0, G1/S and G2/M transitions. Depending on the cell type, p38α can either induce progression or inhibition at G1/S transition by differential regulation of specific cyclin levels (cyclin A or D1) as well as by phosphorylation of the retinoma protein (which is a hallmark of G1/S progression), and by phosphorylation of the p53 tumor suppressor and the upregulation of p16 tumor suppressor. On the other hand, activation of p38 MAPK in mammalian cells in response to various environmental stresses initiates G2/M checkpoint, which induces cell-cycle arrest and facilitate DNA repair. DNA damage checkpoints function as surveillance

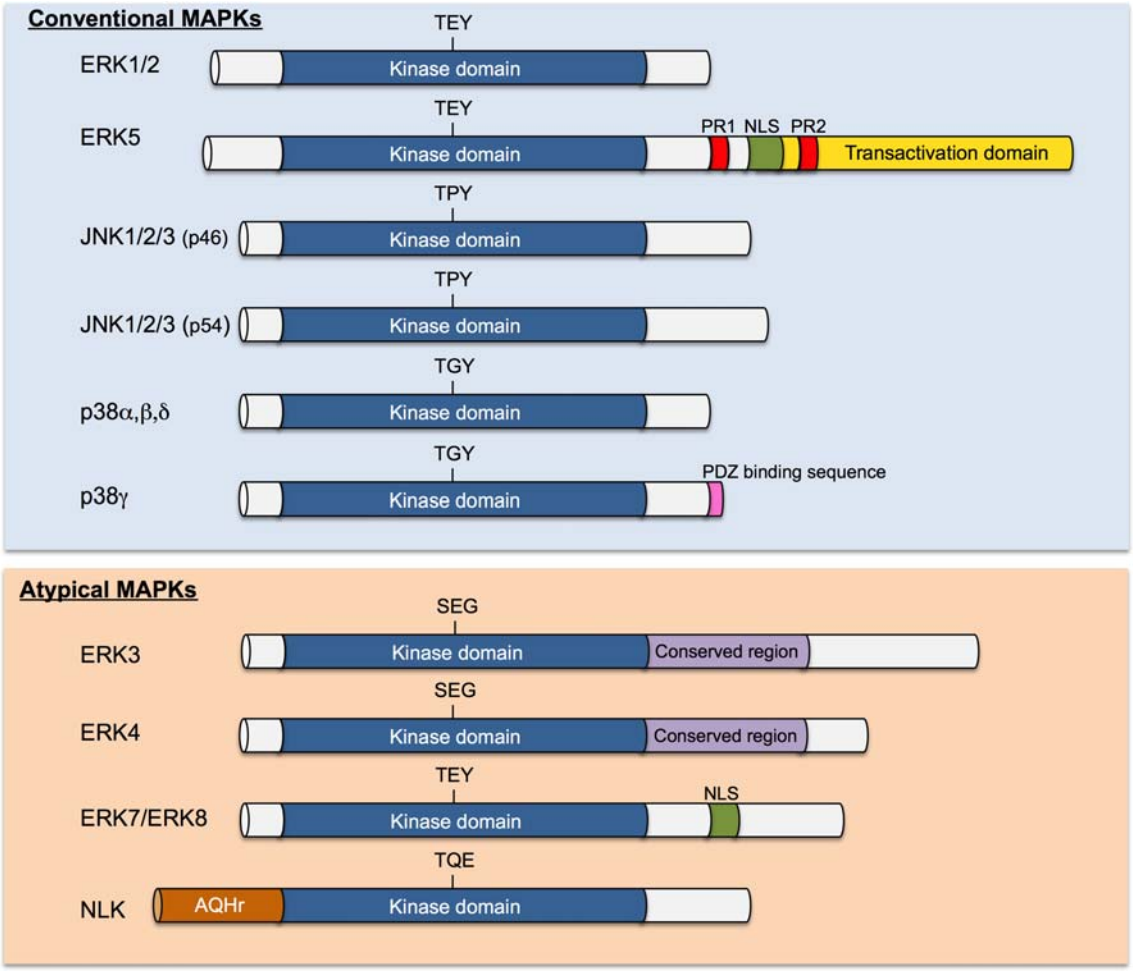

Fig. 3 Schematic representation of the structures of MAPKs. All MAPKs contain a kinase domain, and N- and C-terminal regions of different lengths. Additionally, some MAPK have specific domains/regions/sequences: NLS is a nuclear localization sequence; PR1 and PR2 are Pro rich regions; in p38γ there is a PDZ binding sequence; in ERK3 and ERK4 are C-terminal conserved region; AQHr is an Ala, Glu and His rich domain.

mechanisms during cell division to ensure that each step is completed properly, thus maintaining genetic integrity. Most of the work published on cell-cycle regulation by p38 MAPK pathway has been focused on studying the role of the isoforms p38α and p38β. In the case of p38γ, one report indicates its implication in G2 arrest after ionizing radiation. Although p38α is normally associated with negative regulation of proliferation, there are reports indicating that this kinase can also positively control cellular proliferation in several cancer cell lines. These opposite effects could be due to the strength of the p38 MAPK activation and on the crosstalk with different signaling pathways.

p38α is also implicated in the induction of apoptosis by modulating survival pathways and pro- and antiapoptotic proteins; whereas p38β seems to have antiapoptotic functions. Of particular interest is the key role of p38α in preventing tumorigenesis by promoting growth arrest and apoptosis in response to reactive oxygen species (ROS) in immortalized cells. In contrast, p38α can also facilitate the survival and proliferation of tumor cells supporting tumor growth and metastasis; it regulates angiogenesis and cell invasion by controlling the production, secretion and signaling of angiogenic factors such as VEGF (vascular endothelial growth factor) or MMPs (matrix metalloproteinases). Increased levels of phosphorylated p38α have been correlated with malignancy and poor prognosis in several types of cancers, such as breast carcinoma, glioma, head and neck squamous cell carcinoma, as well as in follicular, lung and thyroid carcinoma. In addition, p38α activation helps tumor cells to survive chemotherapeutic treatments, for example, the tamoxifen resistance in breast cancer patients.

The use of: p38α-deficient mice, p38α-inhibitors (such as SB203580, LY2228820 or PH797804), and the deletion of p38α-regulators (such as MKK6/MKK3 or the phosphatase Wip1), have provided evidence of the tumor suppressor role of p38α in mammary epithelial cells, lung, liver and colon. Studies using mice deficient in Wip1, which is a phosphatase that targets p38α, show reduced breast tumorigenesis upon expression of the oncogenes Erbb2 or HRas; this correlates with higher p38 MAPK phosphorylation. Contrary, pharmacological inhibition of p38α using the compounds LY2228820 and PH797804 impairs tumor growth in xenografts of human breast cancer cell lines and in mice with breast tumors induced by polyoma middle T (PyMT) expression. p38α-deficient mice are more sensitized to KrasG12V-induced lung tumorigenesis, and the specific deletion of p38α in hepatocytes facilitates the DEN-induced HCC by activating the JNK pathway and enhancing the accumulation of ROS.

Not only p38α but also other isoforms could mediate tumorigenesis. Studies in cancer patient samples, human cancer cell lines, cells from knockout mice, and in mouse cancer models indicate that p38γ and p38δ have both pro- and antioncogenic roles in tumor development. Thus, the tumor suppressor role of p38γ and p38δ has been shown in mouse embryonic fibroblasts, in which the deficiency in these kinases increases cell migration and MMP-2 secretion, and impairs cell contact inhibition. Additionally, the loss of p38γ in KRas-transformed fibroblasts leads to increased cell proliferation and tumorigenesis, both in vitro and in vivo. In contrast, it has been described that p38δ is overexpressed in cholangiocarcinoma, invasive human cutaneous squamous cell carcinoma (SCC), head and neck SCC, and in prostate cancer, whereas p38γ is overexpressed in triple-negative breast cancer cells, supporting the potential pro-oncogenic role of these kinases. This was confirmed in the two-step 7,12-dimethylbenz(*a*)anthracene (DMBA)/TPA chemical skin carcinogenesis model, in which p38γ and p38δ deletion blocks skin tumor development, probably by enabling formation of a proinflammatory microenvironment that fosters epidermal hyperproliferation and tumorigenesis. TPA-induced epidermal hyperproliferation and inflammation is reduced in p38γ/p38δ-deficient mice.

Inflammation has long been associated with cancer development. During tumorigenesis, innate and adaptive immune cells infiltrate the tumor microenvironment and regulate tumor cell fate either directly or via the production of inflammatory molecules. p38α, p38γ and p38δ control multiple functions of the immune cells and also the production of cytokines and chemokines, which may either promote or suppress tumor growth. Colitis-associated cancer (CAC) is a clear example of tumor development associated to inflammation. CAC is a colon cancer subtype associated with inflammatory bowel disease (IBD) such as ulcerative colitis or Crohn's disease. IBD confer an increased risk for colorectal cancer, one of the most common fatal malignancies worldwide. Patients with long-standing ulcerative colitis are particularly prone to CAC, the major cause of death in these patients. It has been shown that p38α controls colon homeostasis and that the loss of p38α in intestinal epithelial cells (IEC) increases proliferation, reduces the number of mucus-producing goblet cells and affects epithelial barrier function by altering tight junction assembly. The intestinal epithelia serve as a barrier that protects the intestinal tract against luminal invading pathogens and ingested toxin, which can promote inflammatory responses. p38α in IEC also controls the expression of chemokines that are essential for the recruitment of immune cells, which protect against mucosal infection and dextran sodium sulfate (DSS)-induced colitis. As a result, mice that do not express p38α in IEC are more susceptible to colitis-associated colon tumorigenesis in an azoxymethane (AOM)/DSS colitis-associated colon cancer model. In contrast, the downregulation of p38α in colon tumor cells reduces tumor number in mice. Pharmacological inhibition of p38α using the compounds PH797804 or SB202190 also reduces colon tumor growth either in AOM/DSS model, in xenografts of human colon cancer cell lines or in mice that express APC^{min}. These studies suggest a dual role for p38α in IEC, supporting colon tumor progression and suppressing the initiation of inflammation-associated colon tumor.

p38γ and p38δ also regulate inflammatory signaling that promote colon tumorigenesis in an AOM/DSS mouse model of CAC. Mice that do not express p38γ and p38δ are less susceptible to colitis-associated colon tumorigenesis compared to wild-type mice. These mice show a decreased number of colon tumors, which correlates with reduced inflammation, cytokine and chemokine production and inflammatory cell infiltration in the colon. Experiments using bone marrow transplants demonstrated that p38γ and p38δ in hematopoietic cells are essential for CAC development. Other study nonetheless shows that p38γ in IEC is also important for CAC development, as colon tumor formation is reduced in mice with IEC-specific p38γ deletion. These studies highlight the importance of p38γ and p38δ in cancer, although their specific functions in different cells are yet to be determined.

ERK5 Pathway

Extracellular signal-regulated kinase (ERK) 5, also known as Big MAPK (BMK), is twice the size of other MAPKs and is encoded by the *MAPK7* gene. Unlike the classical MAPKs, ERK5 has two distinct functional domains, a catalytic N-terminal domain, which is very similar to that of ERK1/2 and is responsible for conventional protein kinase activity; and a unique C-terminal half with no homology to any other protein, and responsible for ERK5 transcriptional transactivation activity. C-terminal domain contains a transcriptional transactivation domain, two proline-rich regions and a nuclear localization sequence (NLS) (**Fig. 3**). Interaction between the C- and N-terminal domains has an important role in regulating ERK5 localization and activity. ERK5 is activated selectively by dual phosphorylation on Thr218 and Tyr220 in the TEY motif by its only upstream kinase, MEK5 (**Fig. 1**). ERK5 is activated in cells by oxidative and osmotic stress, but also by several growth factors and cytokines. Some downstream targets of ERK5 have been identified, including the myocyte enhancer factor-2 (MEF2) transcription factor family members MEF2A, MEF2C and MEF2D, and other transcription factors such as SAP1 (switch-activating protein 1), c-Myc and cAMP response element-binding (CREB).

ERK5 plays a central role in cellular survival, differentiation and proliferation, and also in cell-cycle progression. Additionally, in the last decade the ERK5 signaling has been proposed to play a central role in the regulation of tumor angiogenesis, the development and aggressiveness of several types of cancer and in the function of a wide variety of oncogenes. Thus, the ERK5 pathway has been associated with advanced-stages of prostate adenocarcinomas in patients. Prostate cancer (PCa) is the second-leading diagnosed cancer in men in the world. ERK5 and MEK5 are over expressed in prostate cancer cells, which correlate with aggressiveness and more metastasis. For example, in the prostate cancer cell line PC-3 MEK5/ERK5 expression increases the proliferation of these cells by inducing DNA replication, whereas the silencing of ERK5 inhibits PC-3 proliferation and invasion. In addition, ERK5 has been suggested as a therapeutic target in patients with FOXF1-positive PCa. FOXF1 (Forkhead box F1) is a transcription factor that normal prostate tissue does not express, and it has been proposed that FOXF1 regulates ERK5 phosphorylation by increasing the expression of ERK5 upstream activators. Using murine orthotopic models of PCa, it has been shown that overexpression of FOXF1 in the Myc-CaP and TRAMP PCa cell lines induces tumor and metastasis progression, which is associated with increased ERK5 phosphorylation. Also, the silencing of ERK5 in Myc-CaP and TRAMP cells decreased proliferation and metastasis. On the other hand, the implication of ERK5 pathway in metastasis is also supported by its involvement in the regulation of key proteins and pathways, such as the MMP or the regulation of integrins/FAK signaling, that are implicated in invasion and metastasis. Deletion of ERK5 in PTEN-null mice increases T-cell infiltration in PCa tumors compared to single PTEN-deficient mice. The combined loss of PTEN and ERK5 reduce PCa tumor size and cell proliferation, and increased the expression of T-cell chemoattractants CCL5 and CXCL10, and the infiltration of CD4+ T cells in the tumors, which indicate that ERK5 can be a good target for PCa immunotherapy. PTEN (from phosphatase and tensin homolog) is a phosphatase that regulates intracellular levels of phosphatidylinositol-3,4,5-trisphosphate in cells.

Additional in vivo (using mouse models) and clinical data indicate that abnormal ERK5 signaling is also implicated in many others type of cancers such as colorectal cancer, esophageal cancer, osteosarcoma, pancreatic, neuroblastoma, bladder, lung, HCC, leukemia or in triple-negative breast cancer where ERK5 is considered a potential therapeutic target. ERK5 silencing and ERK5 kinase inhibitors, such as the compounds TG02 or XMD8-92, block cell proliferation of different cancer cell lines and tumor growth in xenografts models. For example, it has been shown that the treatment with XMD8-92 blocks the growth of skin tumor, lung carcinoma, pancreatic ductal adenocarcinoma, HCC or neuroblastoma in xenograft models; whereas in triple-negative breast cancer, the administration of XMD8-92 increase the sensitization of cancer cells to chemotherapy agents, such as doxorubicin, cisplatin, etoposide or bortezomib among others, potentiating their antitumor activity in vitro and in vivo.

Atypical MAPK

In addition to the "conventional MAPKs" (ERK1/2, JNK, p38MAPK and ERK5), there are "atypical MAPKs," which are not activated by MEKs. Atypical MAPKs include ERK3/ERK4, Nemo-like kinase (NLK) and ERK7 (also known as ERK8).

ERK3/ERK4

ERK3 and ERK4 are MAPKs encoded by the genes *MAPK6* and *MAPK4*, respectively. ERK3 is ubiquitously expressed, although its expression is higher in brain, skeletal muscle and the gastrointestinal tract; whereas ERK4 expression is more restricted to colon, heart, kidney, eye, lung, placenta, prostate, skin, ovary, pancreas and brain (where its expression is higher).

ERK3/ERK4 have very similar structure and their activation loops contain a single phospho-acceptor residue in the Ser-Glu-Gly motif that lacks the phospho-acceptor residue Tyr. Therefore, ERK3/ERK4 are very poor MEKs substrates. The identity of ERK3/ERK4 upstream activator kinase is unclear, although there are some reports identifying the group 1 of p21 activated kinases (PAKs) as ERK3/ERK4 activation-loop kinases. Ser189 residue in ERK3 and Ser186 in ERK4 are constitutively phosphorylated in vivo in growing cells, and so far no stimuli have been found to promote ERK3/ERK4 phosphorylation or activation in vivo. The only known ERK3/ERK4 substrate is the MAPK-activated protein kinase MK5.

ERK3 is a very unstable protein, with a half-life of 30–45 min depending on the cellular context, contrary to ERK4, which is highly stable. The biological role of ERK4 is largely unknown; however, several studies show that ERK3 participates in a number of biological processes. It has been suggested that ERK3 is a negative regulator cell proliferation and a positive regulator of cell differentiation. Is possible that ERK3 is implicated in oncogenic processes since its expression is induces in Raji lymphoma cells or in squamous cell carcinoma after stimuli that inhibit proliferation. Additionally, ERK3 phosphorylation and protein stability is regulated by CDK1 and the phosphatase Cdc14, indicating that ERK3 has a role in cell-cycle progression through mitosis. Also, ERK3 overexpression in various cell lines was found to inhibit the progression through S phase. Unfortunately, mice lacking ERK3 are not viable, and conditional knockout mouse models will be required to perform studies of the implication of this kinase (and of ERK4) in tumor development.

Nemo-Like Kinase (NLK)

The NLK kinase was originally identified as a vertebrate ortholog of Drosophila nemo, its catalytic domain shows a 45% amino acid identity with ERK2. NLK is ubiquitously expressed, but its expression is higher in brain and lymphoid organs. NLK lacks the phospho-acceptor residue Tyr in the Thr-Gln-Glu motif in the activation loop, and possesses unique N- and C-terminal extensions, that may contribute to the interaction with its substrates (**Fig. 3**). The exact MEKs that directly phosphorylate NLK are still unknown, but a potential kinase that could lead to NLK activation is the kinase homeodomain-interacting protein kinase 2 (HIPK2). Also, NLK could autophosphorylate itself in vitro. In cells, NLK can be activated by stimuli of the Wnt signaling pathway, and also by interleukin-6 (IL-6), granulocyte colony-stimulating factor (G-CSF) and transforming growth factor β (TGF-β). Transcription factors of the T-cell factor/lymphoid enhancer factor (TCF/LEF) family and STAT3 are NLK substrates.

Increasing evidences show that NLK can either act as an oncogene or as a tumor suppressor depending on the cell context. NLK has been described to be important for tumor cell proliferation, migration and apoptosis. Downregulation of NLK decreases the proliferation of gallbladder cancer cells and of HCC cells, by inducing G1 arrest. Contrary, NLK induction inhibits cell proliferation and increases apoptosis in human colon carcinoma cells, prostate and breast cancer cell, and in glioblastoma cells. In addition, altered expression of NLK has been found in different types of cancers. For example, the expression of NLK is increased in cervical squamous cell carcinoma, HCC or gallbladder; and decreased in prostate, ovarian, lung, breast cancer or glioma. Also, it has been suggested that NLK expression is associated with the risk of invasive epithelial ovarian cancer. Further studies are needed for the elucidation of molecular mechanisms mediated by NLK in tumor development.

ERK7

ERK7 (encoded by the gene *MAPK15*) was cloned from a rat brain cDNA library, and some years later the human kinase was identified and called ERK8. Surprisingly, ERK7 and ERK8 only show approximately 69% amino acid identity, which is lower than the typical identity found between other human and rodents MAPK orthologs. From now, I will refer to the human kinase as human ERK7, which is predominantly expressed in lung and kidney.

ERK7 activation loop contains the Thr-Glu-Tyr motif, being Thr and Tyr residues constitutively phosphorylated, which indicates that a MEK is involved in its activation. However, when inactive ERK7 mutant is expressed in cells, this is not phosphorylated in the Thr-Glu-Tyr motif suggesting that ERK7 phosphorylation is regulated by autophosphorylation. Human ERK7 can also be regulated by stimuli such as serum, amino acid starvation or hydrogen peroxide. So far no physiological substrates have been identified for ERK7.

Although the implication of ERK7 in cancer development has not been described, it is known that this kinase plays a role in cell proliferation, autophagy and in the response to glucocorticoids and estrogens.

Conclusions

Members of the MAPK family function in a cell context- and cell type-specific manner to integrate signal that affect numerous processes that are essential in tumorigenesis. The involvement of MAPK family members in cancer development has supported the potentially beneficial role of MAPK inhibitors with current cancer therapy. In addition, given the redundancy in MAPK signaling pathways and the adaptive capacity of cancer cells, drug combinations are increasingly being investigated for therapy. For instance, the incorporation of several Raf/MEK inhibitors in combination therapies are currently being tested in clinical trials. The toxic effect that MAPK inhibitors could have in normal proliferating cells is a concern, so the development of small-molecule inhibitors with sufficient potency and selectivity to inhibit MAPK signaling pathway specifically in cancer cells is a real challenge. Studies in mouse models have been essential to better understand how MAPKs control cancer development. The development of new MAPK mouse models, structural analysis and mutational analysis by next generation genomic sequencing are expected to provide new strategies for the design of improved therapeutic approaches.

Mod Squad: Altered Histone Modifications in Cancer

Matthew Murtha, Bellvitge Biomedical Biomedical Research Institute (IDIBELL), Barcelona, Catalonia, Spain
Manel Esteller, Bellvitge Biomedical Biomedical Research Institute (IDIBELL), Barcelona, Catalonia, Spain; University of Barcelona, Barcelona, Catalonia, Spain; and Catalan Institution for Research and Advanced Studies (ICREA), Barcelona, Catalonia, Spain

Introduction

It is now understood that "An epigenetic trait is a stably heritable phenotype resulting from changes in a chromosome without alterations in the DNA sequence" or in other words epigenetics is the heritable molecular determinants of a trait that are independent of DNA sequence. The principle mechanisms by which this is achieved are through DNA methylation, covalent histone tail modifications, and noncoding RNAs. These epigenetic modifications work in concert with the genetic sequence to determine cellular physiology and identity in human cells. It is now well understood that perturbations to these marks can lead to pathologies such as cancer. Each class of epigenetic mark, for example, DNA methylation, represents large fields of research. Here we will focus solely on the role of covalent modifications of histone tails to the appearance and progression of cancers. Excellent reviews for DNA methylation and noncoding RNAs can be found elsewhere.

The DNA molecules that comprise the genome are packaged within a cell by winding about octomers of histone proteins to form nucleosomes, the building block of chromatin. The histone proteins H2A, H2B, H3, and H4 are small positively charged proteins with exposed N-terminal tails that dimerize to form the core of the nucleosome particle. Approximately 147 bp of superhelicial DNA wraps around each octomer to form the core particle. The exposed N-terminal tails are the substrate for posttranslational modifications and are the basis for the "histone code," the molecular logic behind chromatin-based inheritance. The principle histone modifications are acetylation, methylation, phosphorylation, ubiquitination, and SUMOylation and lead to chromatin compaction and transcriptional expression or repression. Notable examples are listed in **Table 1**. Canonical nomenclature for the modification is to list the histone protein number, then the modified amino acid and its position in the protein, and finally the type of modification. For example, H3K27me3 represents trimethylation of a lysine at the 27th residue in histone H3.

Histone modifications are synthesized by an array of enzymes such as histone deacetylases and methyl transferases. These enzymes incorporate or remove the modifications or "marks" and are the target of a number of oncogenic mutations. While there are a large number of characterized chromatin marks, and advances in proteomics promises the discovery of more to come, a few classical marks such as H3K9me3 are well studied. While the functions of the best-studied marks are remarkably context dependent certain patterns have emerged, such as H3K9me3 being associated to chromatin compaction and transcriptional repression, and canonical marks are summarized in **Fig. 1**. Most tumors harbor both genetic and epigenetic defects with complex interactions between the two. Indeed, efforts to sequence the human cancer genome found some of the most frequent mutations were in genes encoding the subunits of protein complexes that read and write histone modifications like ATP-dependent remodeling complexes SWI/SNF and BAF and suggest that more than 20% of human cancers bear one of these remodeling mutations. In response there have been a number of international epigenome mapping projects such as the NIH's Roadmap Epigenomics Mapping Consortium, International Human Epigenome Consortium, The Cancer Genome Atlas Network, BLUEPRINT, and the International Cancer Genome Consortium. The result of these consortiums has been an ability to subclassify tumors based on their molecular etiology rather than clinical features. This ability allows for the advancement of precision medicine and patient specific treatments and will be discussed further at the end of the article.

Cancer is principally unrestrained cell division and is typically thought to be caused by dysregulation of gene expression. While transcription factors such as p53 or MYC are essential to tumor formation, they represent difficult drug targets as protein:protein and protein:DNA interactions are difficult to target with any specificity. Epigenetic proteins represent much better therapeutic targets given than many are enzymes. It should be noted that epigenome targeting drugs such as HDACis (histone deacetylase inhibitors) have been FDA approved and in use for years. Here we will describe how disruptions in histone modifications caused by HDACs, BETs, and methyltransferases lead to cancer.

Table 1 List of important histone modifications and their impact on transcription

Modification	*Position*	*Transcriptional effect*	*Associated enzymes*
Methylation	H3K4	Activation	MLL1-5, SETD1
	H3K9	Repression	SUV39H1, G9A, SETDB1
	H3K37	Repression	EZH1,2
	H3K36	Activation	SETD2, ASH1L
	H3K79	Activation	DOT1L
	H3R2, H3R17, H3R26	Activation	PRMT4
	H3R8	Repression	PRMT5
	H2AR3	Activation	PRMT1 PRMT5
	H4K20	Repression	SETD8, SUV4
Acetylation	H3K9, H3K14, H3K18, H3K23, H3K27	Activation	KAT2A, KAT2B, p300, CBP
	H4K5, H4K8, H4K12, H4K16	Activation	KAT5, KAT7, p300, CBP

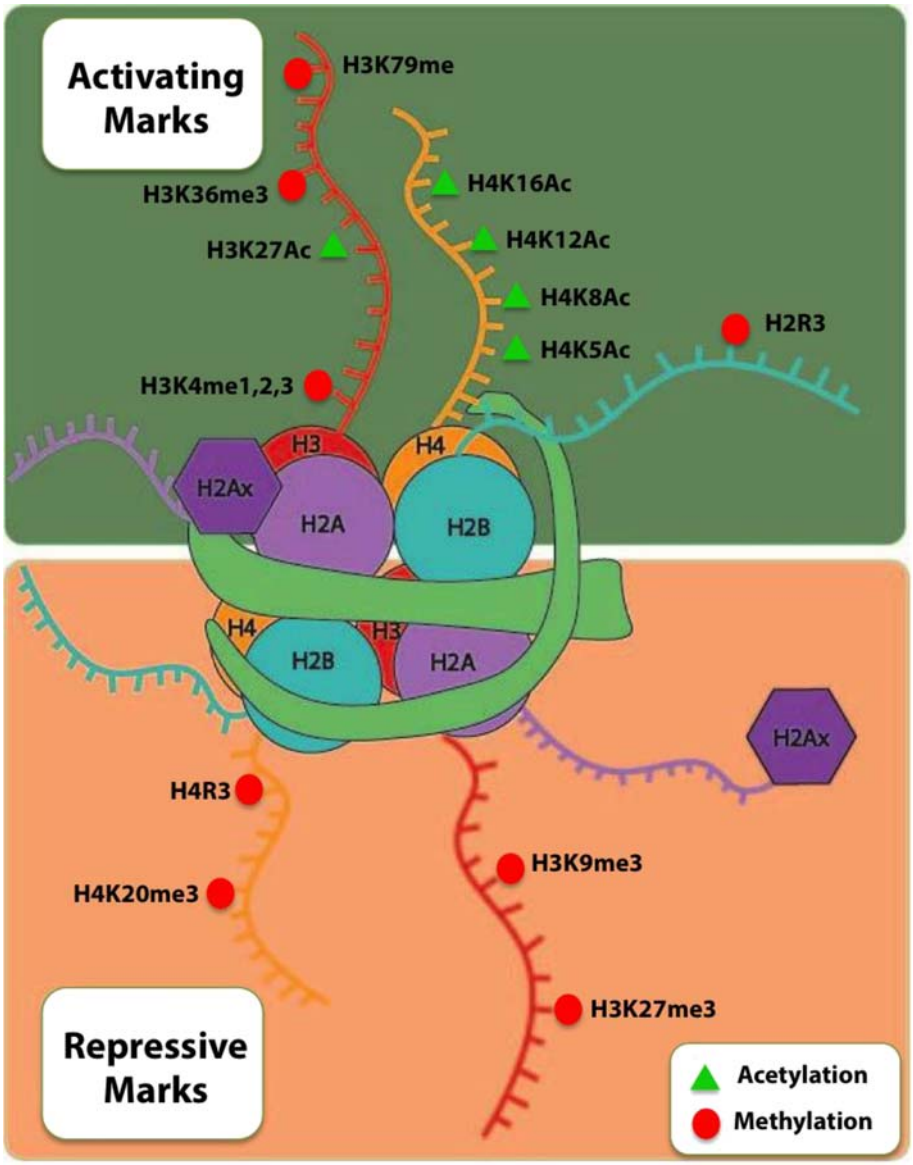

Fig. 1 Illustration of the nucleosome with selected important histone modifications. Schematic of the nucleosome with four pairs of histone proteins and important N-tail histone modifications. Methylation events are represented with a red circle, acetylation by a green triangle.

Altered Histones in Cancer

A hallmark study of altered histone modifications in cancer examined posttranslational modifications to histone H4 in a comprehensive panel of normal tissues, cancer cell lines and primary tumors. The study found a loss of monoacetylated and trimethylated forms of histone H4 characterized cancer cells. These changes appeared early and accumulated during the tumorigenic process, and were also observed in a mouse model of skin carcinogenesis. The losses occurred predominantly at H4K16Ac and H4K20me3 and were associated with the hypomethylation of DNA repetitive sequences, a well-known characteristic of cancer cells. This study was the first to suggest that the global loss of monoacetylation and trimethylation of histone H4 is a common hallmark of human tumor cells and alerted the field to the importance of altered histone modifications in cancer.

Chromatin Remodelers as Tumor Suppressors

Chromatin-remodeling complexes are large multisubunit complexes that mediate the compaction and expansion of chromatin in the nucleus while allowing for precise gene expression, DNA repair, and replication. The mammalian BAF (Brg/Brahma associated

factors) or SWI/SNF complex can be imagined as a single unit comprised of 15 subunits encoded by 29 genes. A mutation to one of these genes is found in at least 20% of cancers. The genes were first identified and characterized in yeast studies where they were discovered in screens attempting to identify signal transduction pathway members. Their role in chromatin compaction was confirmed by phenotypic rescue with secondary mutations in histone proteins, demonstrating that they remodeled chromatin rather than participated in signal transduction. In human cells they appear to primarily act to oppose the effects of the PRC2 complex, which is best known for its role in depositing the H3K27me3 mark.

There are many lines of evidence linking mutations to the BAF complex to cancer. Initial observations of malignant cell lines found that these lines often had deletions or mutations to critical subunits of the complex, suggesting a role as a tumor suppressor. Further study revealed subunits were able to bind RB protein and repress E2F function. Their role as tumor suppressor was confirmed through a study of malignant rhabdoid tumor (MRT), a rare cancer that occurs in children. Versteege et al. found that MRT tumors feature uniform loss of BAF47 (i.e., *INI1*, *hSNF5*, *SMARCB1*), typically from a germline loss of one allele followed by the loss of a second allele in the tumor tissue. This indicated that BAF47 mutations act as classic tumor suppressors, resembling the genetics of retinoblastoma. Further studies found cancer cell lines that featured inactivation of both Brg and Brm subunits, a finding that was replicated in several breast cancer cell lines and led to the common view that tumor suppression likely required at least one functional allele of either subunit.

The mechanisms by which mutations to chromatin remodelers caused cancer remained mysterious until the advent of genome-wide mapping of chromatin marks. The advent of genome sequencing allowed the sensitive detection of mutations, however this revealed that loss of both alleles of particular subunits were not necessary. For example, initial reports of ovarian cancers revealed that while 57% of ovarian clear cell carcinoma and 46% of endometriosis-associated ovarian carcinoma contained inactivating mutations to BAF250A (*ARID1A*), nearly all of the cases the mutations were in only a single allele. This suggested that at least in the case of ovarian cancers, BAF250A operated as a dominant tumor suppressor subunit, a finding that was confirmed by repeated studies. Further confounding mechanistic insight was the observation that BAF250 is not necessary for chromatin remodeling, at least not with respect to remodeling events that can be observed from in vitro nucleosomal template experiments. In addition, many subunits do not appear to be involved in tumor suppression as they are not observed to be mutated at particularly high rates in any known sequenced tumor.

So how can the BAF complex be both extremely sensitive to the loss of a given allele while at the same time having neither its function nor other subunits altered? Standford biologist Gerald Crabtree observed that this places three constraints on the mechanism for BAF tumor suppression. Firstly, it is dosage-sensitive, as evidenced by the observed genetic dominance. Secondly, the fundamental mechanism cannot be detected in an in vitro chromatin-remodeling assay. Lastly, the tumor-suppression function manifests itself in a highly tissue specific manner. A clear example of this is seen within small cell cancers: 90% of small cell ovarian cancers feature mutations to the ATPase BRG (*SMARCA4*) while less than 5% of small cell lung cancers carry mutations to the gene.

So how do mutations in BAF complex subunits mediate oncogenesis? BAF complexes target repressive Polycomb targets and work to oppose transcriptional repression. Mutations apparently cause mis-targeting and improper gene regulation. For example, mutation of BAF subunit ATPase Brg1 (*Smarca4*) in embryonic stem cells causes accumulation of H3K27me3 and the subsequent repression of genes underlying the mark. A similar mechanism, the inability for the BAF complex to properly regulate the placement and function of the PRC (Polycomb repressive complex) is at work in cancer. For example, tissue specific deletion of BAF47 in mice leads to rapid rise of T cell lymphoma. In these mutant cells, BAF deletion causes improper removal of Polycomb from the Ink4a (*Cdkn2a*) locus, which results in an aberrant accumulation of H3K27me3 and repression of Ink4a. Thus, altered modification of H3K27 causes the repression of a potent tumor suppressor and proliferation regulator. A similar mechanism is thought to be at play in MRTs albeit with different tissue specificity. That MRTs have the lowest mutational burden observed in any tumor suggests the tumors are induced into oncogenesis solely through changes to histone marks and epigenetic regulation.

Another beautiful illustration of altered histone modifications driving cancer progression is seen in human synovial sarcoma, a soft-tissue tumor featuring a precise translocation of the BAF SS18 (C90) subunit. This translocation fuses 78 amino acids of the C terminus of SSX to the C terminus of the SS18 subunit to create a well-studied oncogenic fusion protein termed SS18-SSX. This fusion protein outcompetes wild type SS18 in BAF complexes and results in the mistargeting of BAF47 and SS18-SSX complexes to loci containing oncogenic genes like SOX2 and PAX6. This retargeting results in the loss of PRC complexes at these loci and the subsequent loss of H3K27me3, thus allowing the expression of the oncogenes.

Not all BAF driven tumors operate through these mechanisms and even in the case of MRT and synovial tumors where BAF47 is mistargeted, the molecular mechanism is very distinct. These examples however clearly show the importance of correctly modified histones and the ability of epigenetic changes to induce cancer.

Interpreting Histone Acetylation

ε-N-acetylation of lysine residues in the N-terminal tails of histone proteins is one of the predominant and best-studied histone modifications. Acetylation is regulated by histone acetyltransferases (HATs) which act as "writers" adding acetyl groups to the histone tail, while histone deacetylases (HDACs) act as "erasers" and remove the mark. There are many examples of these enzymes suffering inactivating mutations that drive cancer. For example, mutations in CBP (KAT3A) and p300 (KAT3B) are found in B cell lymphomas, monoallelic loss of KAT5 in observed in human lymphomas, breast and head and neck cancers and homozygous

deletion of KAT6B in small cell lung cancer. Additionally, HDAC deregulation results in the silencing of tumor-suppressor genes or overexpression of oncogenes. For example, HDAC1, HDAC3 and HDAC6 are overexpressed in tumors. These studies have provided the basis for the development of HAT11 and HDAC inhibitors, some of which had already proved successful in clinical oncology and will be discussed further below.

Bromodomains (BRDs) are "readers" of acetyl marks in histone tails, targeting chromatin-modifying enzymes and other protein machinery to specific sites in the chromatin, thus regulating gene transcription. Bromodomains are a family of evolutionarily conserved motifs identified for in the *brahma* gene of *Drosophila melanogaster*. BRDs bind the acetylated lysines in histone tails allowing recruitment of other chromatin factors and transcriptional machinery. A total of 61 bromodomains were found in 46 different proteins of the human proteome. The bromodomain and extra-terminal (BET) family has been thoroughly investigated and holds great potential as a chemotherapeutic target in cancer therapy. The BET family is comprised of ubiquitously expressed BRD2, BRD3, BRD4, and BRDT, and BRDT, which is only expressed in testis. BET proteins are characterized by their two bromodomains in tandem (BD1 and BD2) in the N-terminal and a C-terminal extra-terminal (ET) domain.

It was elucidated some years ago that BRD4 and BRD2 play an important role in transcription elongation by recruiting the positive transcription elongation factor complex (P-TEFb) to acetylated chromatin. P-TEFb is composed of cyclin-dependent kinase-9 (CDK9) and its activator, cyclin T and mediates phosphorylation of the C-terminal repeat domain (CTD) of RNA polymerase II (RNAP II) to ensure efficient transcription. BRD4 recruits P-TEFb to acetylated chromatin through its BRD, allowing activation of the CDK9 kinase subunit, phosphorylation of RNAPII and efficient transcript elongation. BRD4 also controls the release of active P-TEFb from its inactive complex with HEXIM1 protein and 7S snRNA. Thus, correct histone acetylation is essential for the proper recruitment of P-TEFb by BRD4, which is then critical for proper transcriptional initiation and elongation of genes controlling cell proliferation.

BET proteins and their interactions with acetylated histone tails are now strongly implicated in cancer, not the least because BETs have been show to directly regulate the expression of oncogenes such as c-MYC. Indeed, inhibition of BET protein binding at the MYC locus with BET inhibitors leads to a reduction in cell proliferation.

The BET family can function as cell cycle regulators as well by controlling the expression of genes required for M to early G1 phase transition. BRD2 recruits the key transcriptional cell cycle-regulatory genes E2F1 and E2F2 and acts as a scaffold on which they assemble.

BRD4 regulates gene transcription globally, so its inhibition would be expected to cause downregulation of activity throughout the genome. Surprisingly, the impact of BRD4 inhibition is modest and somewhat specific as only a few hundred genes are downregulated. However, most of these genes are very important in tumorigenesis. The molecular basis for this surprising discrepancy is explained by the observation that BRD4 has a strong preference for binding enhancers and super-enhancers in key genes of hematological and solid tumors, such as MYC.

Brd4 acts as a general regulator that couples the acetylation state of chromatin with Pol II elongation. Midline carcinoma is generated when *BRD4* is mutated by chromosomal translocation to form in-frame fusions with the *NUT* gene. The resulting Brd4-NUT oncoprotein is an aberrant transcriptional regulator.

Targeting BET Bromodomains With Small-Molecules for Therapy

Mediating the interaction between histone modifications and transcription with enzymatic activity make BET a desirable target for small molecule therapies. Indeed, the field is proceeding rapidly as in 2010 two independent groups reported the antitumor efficacy of small-molecule inhibitors of BET bromodomains, called JQ1 and I-BET, which have a similar chemical structure and mode of target inhibition. JQ1 and I-BET are notable for their high affinity for bromodomains of the BET family (BD1 and BD2 of Brd2/Brd3/Brd4/Brdt) over other bromodomain subfamilies. BET inhibitors also have suitable pharmacokinetics for in vivo application, which has enabled a rapid evaluation of their potential therapeutic activity in various disease models.

BETs can become oncogenes upon translocational mutation. For example, *BRD4* can be mutated by chromosomal translocation to form in-frame fusions with the *NUT* gene to initiate an aggressive cancer called midline carcinoma. The resulting Brd4-NUT oncoprotein is an aberrant transcriptional regulator that relies on the bromodomains of Brd4 for its oncogenic function. As such, this malignancy provides a clear initial test case for the evaluation of therapeutic benefit of BET inhibitors. In midline carcinoma cell lines, JQ1 treatment led to the release of Brd4-NUT from chromatin and triggered terminal squamous cell differentiation and apoptosis. In patient-derived xenograft models of midline carcinoma, it was shown that daily exposure to JQ1 extended the survival of cancer-bearing mice at doses that had minimal toxicity to normal tissues. This pivotal study provided the first demonstration of efficacy for a BET inhibitor in a preclinical cancer model.

HDACi Demonstrate Utility of Altered Histone Modifications to Fight Cancer

HDAC inhibitors (HDACi) are a class of small molecules that interfere deacetylation and were first approved for the treatment of cutaneous T-cell lymphoma in 2006. HDACi's now have shown efficacy, either alone or in combination, in multiple myeloma, acute myelogenous leukemia and myelodysplastic syndrome. Treating solid tumors with HDACi has been challenging, although some efficacy was recently reported in non-small cell lung cancer when combined with a second epigenetic therapy.

Mapping the Histone Modifications of the Epigenome

The advent of whole genome and high-throughput sequencing technologies has enabled fast, accurate genome-wide maps of histone modifications at rapidly diminishing costs. This has led to international epigenome mapping projects such as the NIH's Roadmap Epigenomics Mapping Consortium, International Human Epigenome Consortium, The Cancer Genome Atlas Network, BLUEPRINT, and the International Cancer Genome Consortium. These projects aim to map the epigenomes of healthy and cancer cells and have led to a surplus of data and new insights.

Most strikingly, these epigenomic maps can be used to subclassify tumor samples allowing for precision and personalized medicine. There are myriad examples to choose from. H3K4 acetylation, H3K9 acetylation and H3K27 methylation can be used to identify breast tumor molecular subtypes. Indeed, most every major tumor type has now been profiled and study epigenetically, see for example malignant melanoma.

Targeting Altered Histone Modifications for Therapy

Drugs targeting the epigenome are now being extensively developed given their promise for halting tumor progression and preventing chemoresistance. They are considered broadly to act either in a broad pan-genome manner, termed genome medicine, or are developed to treat specific tumor subsets for precision or personalized medicine. HDACi were initially discovered based on drug screens for differentiation inducers in leukemias. There are now several prominent HDACi used in the clinic: for example, vorinostat (Zolinza; Merck & Co.), belinostat (Beleodaq; Spectrum Pharmaceuticals) and romidepsin (Istodax; Celgene) have all been approved for the treatment of cutaneous or peripheral T cell lymphomas, and panobinostat (Farydak; Novartis) was recently approved for the treatment of drug-resistant multiple myeloma when used in combination with the proteasome inhibitor bortezomib (Velcade; Millennium Pharmaceuticals). Notable examples of drugs targeting histone modification pathways are listed in Table 2. HDACi efficacy has been examined in other malignancies have shown limited single agent activity. iBETs, which reversibly bind to the bromodomains of BET proteins, are another prominent class of genome medicines that have shown promise. Most iBETs target BRD4, which is translocated in some cancers and is key in correct interpretation of histone acetylation (see above).

There are several notable examples of targeted therapies showing efficacy. Specific genetic defects in epigenetic pathways can be targeted using small molecules. One such example is apparent given mutation in the H3K27 histone *N*-methyltransferase EZH2 which is activated by mutations in lymphomas. Researchers found the application of a selective EZH2 inhibitor induced the specific death of cells harboring the EZH2 mutation in cell lines.

Synthetic lethality approaches can also be used to achieve subtype specificity for targeted therapy and precision medicine. For instance, inhibitors of H3K79 *N*-methyltransferase DOT1L have shown effective in vitro study of leukemias with activation of MLL (mixed-lineage leukemia; also known as histone-lysine *N*-methyltransferase 2A (KMT2A)), whereas a drug targeting lysine-specific histone demethylase 1 (LSD1; also known as KDM1A) is active in vitro only in malignancies with specific DNA methylation patterns. Preclinical studies have shown that these targeted therapies have particular efficacies in specific patient subsets, which is to be expected from targeted therapies and is different from broad genomic medicine approaches. Indeed, in the field of DNA methylation, epigenetics can aid in assigning the correct treatment regimen to Cancers of Unknown Origen suggesting that accurate epigenome profiling of histone modifications may also aid in developing precision medicine.

Table 2 Selection of drugs targeting regulators of histone modifications currently FDA approved or in advanced clinical trials

Inhibitor class	*Mechanism*	*Drug*	*Target*	*Cancer*
HDACi	Inhibition of histone deacetylation	Belinostat	Class I & II HDACs	Peripheral T-cell lymphoma
	Inhibition of histone deacetylation	Panobinostat	Class I, II, & IV	Multiple myeloma
	Inhibition of histone deacetylation	Romidepsin	Class I	Cutaneous T-cell lymphoma
	Inhibition of histone deacetylation	VOrinostat	Class I, II, & IV	Cutaneous T-cell lymphoma
	Inhibition of histone deacetylation	Entinostat	Class I	Breast cancer
	Inhibition of histone deacetylation	Givinostat	Class I & II	Hematological malignancies
	Inhibition of histone deacetylation	Mocetinostat	Class I	Hematological malignancies
	Inhibition of histone deacetylation	Resminostat	HDAC1,3,6	Hepatocellular carcinoma
	Inhibition of histone deacetylation	Ricolinostat	HDAC6	Solid tumors and hematological malignancies
iBET	Inhibition of BET binding to acetylated histones	OTX015	Pan-BET	Hematological malignancies
	Inhibition of BET binding to acetylated histones	INCB054329	Pan-BET	Leukemias and solid tumors
	Inhibition of BET binding to acetylated histones	BMS-986158	Pan-BET	Solid tumors
	Inhibition of BET binding to acetylated histones	GSK525762	Pan-BET	Solid tumors and hematological malignancies
EZH2 inhibitor	Inhibition of H3K27 methylation	CPI-1205	EZH2	Lymphoma
	Inhibition of H3K27 methylation	Tazemetostat	EZH2	Lymphomas & sarcomas

Concluding Remarks

As our understanding of the interactions between histone modifications and cell identity become clearer so too does our appreciation for the ways that altered histone modifications can lead to cancer. It stands to reason that deeper study of these covalent modifications will shed light on to the basic biology of how epigenetics can govern cellular functions in addition to the discovery of therapeutically relevant targets for chemotherapy development.

Molecular Epidemiology and Cancer Risk☆

Paulina Gomez-Rubio and Evangelina López de Maturana, Spanish National Cancer Research Center (CNIO), Madrid, Spain; and Biomedical Research Networking Centre in Oncology, Madrid, Spain

Glossary

Biomarker Any biological indicator that serves as an objective measure of physiological or pathogenic processes used to detect exposure to carcinogens and assess carcinogenic hazard.

Causal inference The process of deciding whether existing evidence is sufficient to conclude there is a causal relationship between a perturbation and an effect.

Exposome All environmental (nongenetic) exposures in a lifetime intended to explore the role of the environment in human health.

Molecular epidemiology A scientific field that seeks to study the contribution of risk factors, identified through biological indicators (i.e., biomarkers), to the etiology of pathological processes.

Omics The field that seeks to characterize and quantify large-scale data considered collectively from different biological fields such as genomics or proteomics.

Primary risk prevention Intervention applied before evidence of disease with the aim of preventing the onset of disease.

Reverse causation Observed when the outcome of interest precedes the exposure instead of the common presumption that exposure occurs before the outcome of interest.

Subphenotypes A subset of the phenotype with characteristics specific to a part of the population.

Introduction

Cancer continues to be a dire predicament worldwide. Established as the second leading cause of death after cardiovascular diseases in 2015; cancer represents a substantial personal and social burden with serious impact in both economy and quality of life (Fitzmaurice et al., 2017). Classic epidemiology has greatly contributed to the study of cancer risk. Illustrative of this is that most of what we initially learned from smoking and lung cancer resulted from traditional epidemiologic studies. During the early 1950's evidence based on questionnaire information started to surface linking smoking with lung cancer. The consistent evidence mounting over the years by different studies and the replicability of results across investigations made causal inference conceivable (Samet, 2016). More recently, molecular epidemiology approaches have enabled to further explore and understand carcinogenic mechanisms of tobacco compounds through the identification of biomarkers of smoking exposure and susceptibility.

The term molecular cancer epidemiology was first reported in 1982 by Perera and Weinstein who proposed combining the concepts of classic epidemiology with the use of advanced laboratory technology to identify specific environmental hazards and host factors that modify susceptibility, and to elucidate mechanisms of carcinogenesis. For this purpose, four categories of molecular markers (i.e., biomarkers) were described: internal dose, biologically effective dose, response, and susceptibility. The ultimate goal of implementing biomarkers in epidemiology is to improve the characterization of exposure providing an objective, quantifiable measure for a more precise evaluation of human cancer risk. This is particularly useful when evaluating complex exposures and weak effects which are difficult to assess through traditional epidemiology approaches (Perera and Weinstein, 1982; Perera, 1987, 2000).

Molecular epidemiology aims to gather evidence that specific compounds pose carcinogenic hazard to human health through the definition of exposure-cancer associations and the identification of populations at greater risk. Conversely, factors that protect against carcinogenesis could be defined. Therefore, based on the notion that up to some extent an important proportion of cancer could be prevented, modifiable risk factors represent a great opportunity for primary cancer prevention through avoidance or minimization of key exposures or through the promotion of protective factors. Moreover, molecular epidemiology represents a unique opportunity of increasing our understanding of the mechanisms underlying carcinogenesis hence shaping our knowledge towards the biological plausibility behind carcinogenic exposure.

The fast development of technology, particularly high-throughput technologies, has resulted in the rapid growth and evolution of molecular epidemiology in the past decades. More sophisticated molecular platforms have allowed to refine exposure assessment and to improve the definition of disease phenotype. Therefore, progress in the field has provided us with the valuable opportunity

☆ *Change History*: February 2018. Paulina Gomez-Rubio and Evangelina López de Maturana are involved in preparing the update. No change history of section/figures/tables is provided since, as previously discussed with the Editor, this article was written from stratch due to the tremendous evolution of the field in the past decade.

This article is an update of Frederica P. Perera, Molecular Epidemiology and Cancer Risk, in Encyclopedia of Cancer (Second Edition), edited by Joseph R. Bertino, Academic Press, 2002, Pages 213–220.

of increasing our knowledge and understanding of cancer risk. However, we have also encountered several difficulties that hamper their practical application in risk assessment. In the present article we discuss key contributions of molecular epidemiology in cancer risk assessment, prediction and prevention as well as some of its most relevant challenges in the current scientific landscape. In addition, while the role of genetic factors in disease is formally studied under the umbrella of genetic epidemiology, we will briefly comment on genetic susceptibility to cancer due to important interactions with other cancer risk factors, as well as their relevance in the *omics* and data integration fields.

Epidemiologic Study Designs for the Evaluation of Biomarkers

Molecular epidemiology builds upon classic epidemiology designs. Among these, the case-control studies are the most commonly used, entailing the retrospective recruitment of disease and disease-free subjects. While ascertainment of the diagnosis of cases before recruitment is one of the main advantages of case-control studies, these suffer from different drawbacks, one of them specifically pertaining to the difficulty of establishing reverse causation. For this purpose, prospective studies are ideal because information about exposure and biological samples are collected at baseline from a group of "healthy" subjects who are followed-up during a period of time in order to identify those who develop the disease of interest. Since exposure is assessed before disease development, prospective studies are less likely to introduce selection and information bias such as recall bias. Moreover, due to the prospective nature of this design reverse causation is precluded. Prospective studies also offer the possibility of collecting information and samples at different time points during the follow-up time. However, these studies are costly and time consuming particularly for uncommon diseases for which larger study populations and longer time periods are necessary to identify sufficient number of subjects with the disease of interest.

For different reasons, many large cohort studies are unable to measure the biomarker(s) of interest in the whole study population. Under this circumstance, nested case-control studies are an efficient sampling scheme. In this design, all cases identified up to a particular point in time are included in the study while controls are composed from a random sample of subjects free of the disease of interest by the time of the case diagnosis or by the end of the follow-up time. Similarly useful is the case-cohort design, in which disease-free subjects are sampled as controls at baseline from the pool of all subjects enrolled having the same disease risk as anyone at time zero of the study. This type of design requires specific statistical considerations since some controls could also be included as cases in the study (García-Closas et al., 2006, 2011).

Contributions of Molecular Epidemiology

Assessment of Exposure

The use of biomarkers in molecular epidemiology

The use of molecular markers to assess the precise contribution of individual factors, their interactions and those with the host result in a more objective measure of exposure, one that is exempt from the individual's perception or recall. Moreover, biological markers measured with laboratory methods more closely reflect the level of exposure that affects the target cells or organs (i.e., biological effective dose).

Risk assessment has particularly benefited from the advancement of refined laboratory techniques such as those used to measure metabolites of carcinogens and their interaction with DNA or proteins (adducts). DNA adducts are quantitative indicators of exposure used to evaluate carcinogenicity of specific compounds like those contained in tobacco. Tobacco was initially identified as a potent carcinogen in the mid-twentieth century and it is known to contain at least 70 human carcinogens including polycyclic aromatic hidrocarbons (PAHs). PAHs in tobacco smoke are metabolized and activated in the human body forming DNA adducts that have the potential to induce mutations and ultimately initiate a carcinogenic process (IARC, 2004). Consequently, DNA adducts are suitable biomarkers of carcinogenesis since they indicate a genetic damage that is relevant to such process not only reflecting exposure but also the host's ability to metabolize these compounds (Perera and Weinstein, 1982).

Levels of PAH DNA adducts have been reported to be higher in smokers than nonsmokers in different human tissues including those not directly exposed to tobacco smoke such as bladder, liver or pancreas (Phillips and Venitt, 2012). Accordingly, higher DNA adduct levels have been suggestive of increased risk of lung, bladder and breast cancer (Agudo et al., 2017; Jin et al., 2017; Munnia et al., 2017). Moreover, the role of PAHs in cancer is highlighted by reports that show that single nucleotide polymorphisms (SNPs) in key metabolism and conjugation genes are associated with PAH-DNA adducts levels (Etemadi et al., 2013).

As a result of the extensive research performed in the field during the past decades, different countries worldwide have applied smoking bans that along with smoking cessation strategies have had an impact in lowering the incidence of smoking related cancers (McAfee et al., 2015).

The emergence of omics data in molecular epidemiology

Cancer is a complex condition that entails many biological changes within the affected cells and the surrounding microenvironment. These include mutations and modifications of gene and protein expression through different mechanisms. Advances in high-throughput technology during the past two decades coupled with sound biostatistics and bioinformatics methodology

have allowed exploring the collective of different small biological molecules such as genes (genomics), gene expression (transcriptomics), epigenetic modifications (epigenomics), and metabolites (metabolomics), among others. These technologies represent an invaluable tool for a more comprehensive insight of human exposure, which is particularly useful in the inquiry of molecular mechanism of carcinogenesis.

During decades, researchers have been focusing in the study of single factors. Based on an a priori knowledge of the molecule's biological function, candidate studies were pioneer in the identification of association with disease (Zhu and Zhao, 2007). However, given that the available functional information is limited elaborating a priori hypothesis may be impaired. As a result, after its emergence, high-throughput technology has been widely used as an agnostic approach in an attempt to identify risk factors for diseases such as cancer. In genomics, through the analysis of thousands of genetic variants in a single run, genome-wide association studies (GWAS) have identified common low-penetrance alleles providing evidence of polygenic susceptibility. Among the different discoveries reached through GWAS, the region 8q24.21 is perhaps one of the most intriguing, harboring multiple independent risk loci for several tumor types including breast, bladder, colorectal, ovarian, pancreatic and prostate cancer (Al Olama et al., 2014; Michailidou et al., 2015; Sud et al., 2017).

DNA methylation, a form of epigenetic mechanism that does not alter DNA sequence but may affect gene expression, has also been identified as an important mechanism of carcinogenesis. As such, aberrant DNA methylation has been reported in different cancers. Methylation arrays allow the rapid assessment of global methylation patterns through the analysis of thousands of CpGs throughout the genome. Studies have reported that such epigenome-wide DNA methylation analysis could have a potential use in the identification of risk markers in cancers such as breast cancer (Severi et al., 2014).

Other *omics* platforms have been similarly applied in an attempt to better characterize cancer leading to advances in risk assessment through a greater understanding of this disease.

The exposome and its potential use in risk assessment

The exhaustive consideration of exposure in risk assessment was initially addressed by Wild in the early 2000s, who proposed the concept of exposome as a means to account for all exposures an individual encounters during their lifetime. The concept encompasses internal exposure, to which molecular and *omics* data contribute to; specific external exposure that includes pollutants, infectious agents, lifestyle factors or diet; and generalized external exposure such as social, economic and psychological exposures (Wild, 2005, 2012). Therefore, while molecular information can greatly contribute to a better definition of exposure it is unable to cover the totality of a subject's exposure. The integration of epigenomics, metabolomics and microbiome (microbial load and diversity data), with exposure information collected via epidemiological questionnaires and biological markers such as vitamin D or cholesterol, is likely to provide a more precise characterization of the exposome (López de Maturana et al., 2016).

The accurate assessment of the exposome would require prospective studies in which multiple repetitive measures are collected throughout the participants' lifetime. Therefore, to date, it is still debatable to what extent the assessment of the exposome and its common use in scientific research and risk assessment is pragmatic.

Definition of Phenotype

The multi-factorial etiology of cancer is highlighted by its great heterogeneity of both clinico-pathological and molecular features. Accordingly, there have been numerous reports on the wide diversity of the natural course of tumors and the way these respond to treatments. Consequently, the use of a single phenotype to describe a mixture of closely related subtypes of diseases (i.e. subphenotypes) is gradually becoming recognized as an unsuitable approach for the proper assessment of disease risk.

Improving the phenotyping accuracy has been an important focus of molecular epidemiology in recent years. Innovative technologies have given place to the definition of novel molecular tumor subtypes in different cancers. In this section, we focus in inter-patient tumor heterogeneity. For information about intra-tumor heterogeneity, the reader can refer to further reading.

Cancer subphenotyping was first explored in breast cancer, one of the most commonly diagnosed cancers in women worldwide and for which different treatment responses and clinical outcomes have been widely reported (Zardavas et al., 2015). Four main breast tumor subtypes were established through genome-wide expression: luminal A, luminal B, HER2 enriched and basal like, which reflect relevant biological entities regarding variation of growth rate, activation of specific signaling pathways and cellular compositions (Perou et al., 2000). Following its initial characterization, the evolution of technology allowed exploring these subtypes through a broad array of molecular platforms as mRNA expression microarrays, DNA methylation chips, SNP arrays or miRNA sequencing providing a deeper insight into each subtype like specific mutational processes or signaling pathways (TCGA, 2012). Accurate molecular subphenotyping of breast cancer has an important clinical impact, particularly in therapeutic decision making (Zardavas et al., 2015). Moreover, tumor subtypes might potentially reflect etiological differences with important implications in risk prediction. Up to date however, there has been a lack of consensus on the characterization of molecular breast cancer subtypes in epidemiological studies that, along with the limited statistical power in the less common subtypes, have hampered their use in etiological research (Ellingjord-Dale et al., 2017). Regarding risk, at present, the most consistent findings show a stronger protective effect of breastfeeding on the basal-like subtype; while, other factors such as parity have been consistently associated with decreased risk of luminal subtypes (Holm et al., 2017).

The effort of utilizing molecular information and its translation to specific tumor subtypes has expanded beyond breast cancer. With support of The Cancer Genome Atlas and The International Cancer Genome Consortiums different cancers have

been sub-phenotyped in the past years including colorectal, cervical and urothelial (Guinney et al., 2015; TCGA, 2017; Robertson et al., 2017). Along with the clinical impact of the subclassification of tumor types, the vision of a more precise definition of cancer etiologies and risk gradually becomes more tangible. However, there is still a long way ahead before establishing the practical use of this wealth of information in the public health arena.

High-Risk Populations and Primary Prevention Strategies

Measure of inter-individual variability

The concept of human variability, that is, diverse responses to similar exposures to carcinogens, is not new. Classic epidemiology has laid the groundwork for discerning between vulnerable groups. Illustrative is that initial work in the field was paramount to establish that intrauterine and preconceptional exposure to ionizing radiation was associated with the development of childhood cancer (Wakeford, 1995). Molecular epidemiology has also helped in the identification of interactions that explain a certain fraction of variability in risk. In addition to familial aggregation and high penetrance genetic variants, low penetrance variants can affect the way a person processes and reacts to an exposure thus affecting their vulnerability to a carcinogen. For example, arsenic, an environmentally ubiquitous element and whose metabolites are detected through mass spectrometry in urine, is classified as carcinogenic to humans by the International Agency for Research on Cancer (IARC). Since the discovery of the enzyme involved in arsenic metabolism (arsenic 3 methyl transferase, AS3MT), polymorphisms in the coding gene have been associated with arsenic methylation efficiency and consequently with cancer risk, helping in the identification of subsets of the population with different degrees of vulnerability to arsenic-associated carcinogenesis (Engström et al., 2015; Gomez-Rubio et al., 2010). Additionally, other nongenetic factors have been associated with susceptibility to arsenic toxicity such as sex and body mass index (Vahter et al., 2007; Gomez-Rubio et al., 2011).

The definition of key factors modifying cancer risk is essential for a better understanding of interindividual variability. Failure to account for this variation can result in overlooking important sensitive subgroups leading to inadequate health policies and measures.

Definition of high risk populations

One of the main goals of molecular epidemiology is disease prevention through the better understanding of exposure-susceptibility interactions. The appropriate definition of high-risk populations has been pivotal for risk assessment guiding the implementation of numerous health prevention measures. For instance, smoking cessation strategies have been implemented by different healthcare systems worldwide with the final aim of reducing smoking-related health effects such as lung and oropharyngeal cancers (McAfee et al., 2015). Moreover, molecular epidemiology studies associating occupational exposures with carcinogenicity have helped in the implementation of more healthy work policies and practices (Espina et al., 2013). For instance, in Sweden, incidence of mesothelioma linked to occupational exposure to asbestos, leveled off after being one of the first countries restricting asbestos use in the 70s (Hemminki and Shehnaz, 2008). Other characteristics defining cancer high-risk populations include genetic predisposition, age, sex or ethnicity. Appropriate screening and informed decisions of lifestyle modifications or even participation in chemoprevention programs could be expected as a result of proper risk stratification.

Though the definition of high-risk populations is not a substitute for general prevention efforts applicable to the whole populations (e.g., promotion of a healthy weight, or reduction of alcohol and tobacco consumption), certain interventions to high-risk individuals could be more effective, particularly when those interventions result in hazardous side effects (e.g., chemoprevention agents) and/or are too expensive to be applied in the whole population.

Improving the definition of risk

The underlying interplay of multiple etiological factors in human carcinogens is a reality scientists recognize and attempt to address. Up to date, the most common type of analysis performed has independently considered each biological process and their relationship with cancer status. While we have gained important insight with this approach, a great deal of disease complexity might be hidden behind networks of interactions between several disease processes. For example, higher risk of cancer has been reported when sets of morbidities are jointly analyzed in comparison with their individual analysis (Gomez-Rubio et al., 2017). Moreover, innovative statistical approaches have been implemented to integrate more than two types of *omics* data (e.g., genetic variants, DNA methylation and gene expression) with the aim of pinpointing potential carcinogenic mechanisms in different malignancies such as bladder and breast cancer (Sun et al., 2011; Pineda et al., 2015). Hence, the combination of multiple sources of data including molecular markers as well as lifestyle factors could provide with a more thorough and comprehensive definition of risk by accounting for the interplay among different risk factors. In breast cancer, the integration of genetic risk factors with the Gail's risk model based on demographic and clinical data conferred a modest improvement in classification of breast cancer risk compared to either the Gail's risk or the genetic score alone in a population of white non-Hispanic postmenopausal women (Mealiffe et al., 2010).

The clinical utility of risk models for disease prediction depends in their ability to accurately define population strata with different risk levels. Despite significant efforts devoted to developing integrative approaches for risk assessment, its transition into clinics is not currently regular practice. Therefore, risk prediction tools properly validated in prospective cohorts are urgently needed in order to adequately incorporate risk stratification in primary prevention strategies.

Challenges of Molecular Epidemiology in the New Era

In complex diseases, *omics* data can help to achieve a better and more accurate characterization of the exposure, genetic factors and phenotype providing a holistic view of the human health states by including both the combined exposure of all sources that reach the internal chemical environment and the response of our body to environmental influences, including metabolic processes (Rappaport and Smith, 2010; Miller and Jones, 2014). Technological progress in high-throughput biological data generation have provided with massive molecular *omics* data from different layers of the biological processes of the host (e.g., genomics, epigenomics, transcriptomics, proteomics or metabolomics, among others) and the nonhost, such as microbiome. Unfortunately, this substantial data production has not been accompanied with the development of next generation statistical methods to integrate in a computationally timely manner all the *omics* data needed to better characterize the phenotype, the exposome and the genome (Lopez de Maturana et al., 2014). The integration of this type of data is crucial and can be as costly as *omics* data generation (Mardis, 2010).

Although some progress has been achieved in the field, there is still a need of developing sophisticated analytical strategies that can handle the most common characteristic to *omics*-based studies: the vast number of variables versus a limited number of individuals, the so-called large p small n problem. Apart from volume, computational approaches should consider the complexity of each *omics* data type jointly with potential interactions among *omics* variants of the same or different type, correlated variants and possible (non)linear relationships (Green and Guyer, 2011; Tini et al., 2017). Moreover, these analytical strategies should also consider the integration of *omics* data with epidemiological data from questionnaires. Integration of both types of data represents a new challenge requiring of both sufficient understanding of the underlying biological concepts and of analytical algorithms to build hierarchical models and theories of disease causation.

Two main analytical strategies have been applied for data integration: the multistage and the meta-dimensional analyses (Ritchie et al., 2015). While meta-dimensional analysis combines multiple types of data for simultaneous analysis producing complex models, multistage (or multistep) approach first looks for the relationship between the data types and then, between the data types and the trait of interest. At present, multistage approach is adopted in most of the integrative studies; however, its main drawback is that due to its step-wise nature, this approach is not able to capture interactions. Therefore, despite the current efforts devoted to keeping up with the high biostatistics and bioinformatics demands of the existing data, there are still many issues that need to be addressed in order to take full advantage of this information.

Summary and Prospective Vision

Molecular epidemiology has experienced an important evolution during the past 15 years. Improved molecular technologies have given place to the opportunity to refine our accuracy of cancer risk estimation contributing in the implementation of proper prevention strategies. However, despite great efforts devoted to cancer risk assessment, and some important advances, the full potential of cancer prevention is yet to be attained. Practical application of cancer risk assessment is further hampered by the complexity of newly available high-dimensional data. As technology evolves and massive amounts of biological information are being generated, new methodology for data integration and analysis is demanded. Along with better methods, cancer consortia will prove to be fundamental for testing and validation of more complex risk assessment models.

Introduction

Multiple myeloma (MM) is a hematologic malignancy that originates from plasma cells in the bone marrow (BM). According to the National Cancer Institute, the prevalence of MM was estimated at 89,650 people in the United States in 2012, with an annual incidence of 6.3 new cases per 100,000 individuals. All MM are preceded by a monoclonal gammopathy of undetermined significance (MGUS) and smoldering myeloma (SMM). The diagnosis of MM is often suspected because of the presence of clinical symptoms such as bone pain with lytic lesions, an increased total serum protein concentration, the presence of a monoclonal protein in the urine or serum, anemia or hypercalcemia. MM is incurable, due to the lack of treatment able to target specific oncogenes involved in the pathogenesis of the disease. Genomic events such as chromosomal translocations, copy number variation and somatic mutations as well as epigenetic modifications are responsible of deregulation of specific oncogenes or tumor suppressor genes and their corresponding pathways, leading to MM proliferation.

Plasma Cell Differentiation and Myeloma Initiation

As MM is characterized by the production of a monoclonal immunoglobulin (Ig), its initiation is linked to B cell development. B-cells undergo rearrangement of their Ig genes into the bone marrow, generating a functional B cell receptor precursor, and migrate to lymph nodes where they encounter antigens. B cells are then activated and reach the germinal center where they undergo affinity maturation in response to antigen presented on antigen-presenting cells. This process is called somatic hypermutation (SHM) and induces mutations of the hypervariable regions of the immunoglobulin heavy chain locus (IGH), thus producing highly specific and avid antibodies. The functionality of these antibodies is increased by class switch recombination (CSR), which produces antibodies of different immunoglobulin isotypes. SHM and CSR require the expression of activation-induced deaminase (AID), which induces double strand DNA breaks (DSBs) in the Ig loci. AID-induced DSBs are mostly repaired locally, however they can be joined to DSBs occurring elsewhere in the genome, resulting in aberrant chromosomal translocations. These translocations occur preferentially into actively transcribed genes; however, the range of CSR-driven translocations in MM is limited. This may explain why only a subset of these translocations causes a proliferation advantage.

Once SHM and CSR completed, selected B-cells leave the germinal center and migrate to the bone marrow where they become mature plasma cells, secreting antibodies. This process requires cell cycle arrest, compaction of chromatin, silencing of cellular functions that are unnecessary for antibody production and activation of key programs that are required to generate and secrete antibodies. Deregulation of these pathways could potentially lead to malignant transformation. Normal plasma cell differentiation is regulated by different transcription factors. IRF4 downregulates BCL-6, resulting in the upregulation of BLIMP1, which in turn leads to downregulation of PAX5 and upregulation of XBP1. Expression of IRF4, BLIMP1 and XBP1 is necessary for survival of plasma cells. After exiting the germinal center, plasma cells migrate to the bone marrow where either they rapidly undergo apoptosis, or reside in specialized niches where they can survive for many years as memory plasma cells.

Inherited Variants

Although lifestyle or environmental exposures have not been consistently linked to the incidence of MM, there seems to be a two- to fourfold elevated risk of MM in relatives of individuals with the disease. This has been postulated to be a consequence of the co-inheritance of multiple low-risk variants. Investigating these families further and performing genome-wide association studies (GWAS) on large patient populations, three genetic loci were associated with a modest but increased risk of developing MM. These include 3p22.1 (rs1052501, in ULK4), 7p15.3 (rs4487645, surrounding by DNAH11 and CDCA7L) and 2p23.3 (rs6746082, surrounding by DNMT3A and DTNB). A follow-up study by the same group, including 4692 individuals with MM and 10,990 controls, revealed four new loci: 3q26.2 (rs10936599, surrounding by MYNN and TERC), 6p21.33 (rs2285803 in PSORS1C2), 17p11.2 (rs4273077 in TNFRSF13B) and 22q13.1 (rs877529 in CBX7). These seven identified loci provide further evidence for an inherited genetic susceptibility to MM and reportedly account for $\sim$13% of the familial risk of MM. The complete functional role of each of these candidate genes remains to be elucidated. The authors found no association between genotypes and the expression level of their genes. Interestingly, in another GWAS study, the same team identified a strong association between the variant rs603965, responsible for c807G>A polymorphism in *CCND1* and the translocation t(11;14)(q13;q32), in which CCND1 is placed under the control of the immunoglobulin heavy (IGH) chain enhancer. In this model, a constitutive genetic factor is associated with risk of a specific chromosomal translocation. Based on these initial studies, it is likely that more susceptibility loci will be identified in the future and possibly correlated with specific MM subtypes. For example, African-Americans have a higher risk of

developing MM than Caucasians; however, no potential genetic variants have been identified to date. Moreover, uncovering the functional role of these seven SNPs significantly associated with MM might help to advance our understanding of MM oncogenesis.

Chromosomal Translocations

In MM, most chromosomal translocations involve chromosome 14, and specifically the IGH locus on 14q32.33, placing a partner gene under the control of the IGH enhancer. These translocations are generated by abnormal class switch recombination (CSR) events and are usually present in all clonal cells. They are also detectable in monoclonal gammopathy of unknown significance (MGUS), consistent with their early development in MM oncogenesis. Five major chromosomal partners—t(4;14), t(6;14), t(11;14), t(14;16), and t(14;20)—seem to impart a selective advantage to the clone by up regulating expression of specific oncogenes—*MMSET* and *FGFR3*, *CCND3*, *CCND1*, *MAF* and *MAFB*, respectively. It is likely that all these translocations lead to deregulation in the cell cycle G1/S transition, which has been described as a key early molecular abnormality in MM. This can be direct through t(11;14) and t(6;14) deregulating CCND1 and CCND3 respectively. In t(14;16), this is modulated through MAF which up regulates CCND2 by directly binding to its promoter while in t(4;14), the exact mechanism is still uncertain but the translocation of FGFR3 and MMSET to the IGH enhancer is known to also up regulate CCND2. Recently mutations involving the *MYC* locus have been identified in MM.

Translocation (4;14) is observed in about 15% of MM cases and has been associated with adverse prognosis in a variety of clinical settings. The juxtaposition results in deregulation of the expression of FGFR3 and MMSET/WHSC1. The breakpoints all reside between FGFR3 and MMSET, resulting in overexpression of FGFR3 in 70% of cases and MMSET in all cases. MMSET is a methyl-transferase protein, whose up regulation leads to methylation of histone H3K36, which regulates expression of several genes. MMSET has been shown also to regulate histone H4K20 methylation and recruit 53BP1 at DNA damage sites. FGFR3 is a tyrosine kinase receptor oncogene activated by mutations in several solid tumor types. Notably, FGFR3 is up regulated in only 70% of patients with the translocation because of an unbalanced translocation with loss of the telomeric part of chromosome 4, bearing FGFR3. This suggests that MMSET is the main molecular target of the translocation. Interestingly, despite the poor prognosis associated with t(4;14), a survival advantage in these patients has been demonstrated through early treatment with the proteasome inhibitor Bortezomib.

Translocation (6;14) is a rare translocation present in only about 2% of MM patients and results in the direct up regulation of *CCND3* via juxtaposition to the *IGH* enhancers. The breakpoints are all located 5′ of the gene. The overall prognostic impact of this translocation is neutral.

Translocation (11;14) is the most frequent translocation cited as being present in about 15%–20% of patients with MM. Normally B cells express cyclin D2 and D3 but not D1. However, due to the translocation juxtaposing *CCND1* to the *IGH* enhancer, its expression is deregulated. The breakpoints seem to be located 5′ of *CCND1*. In terms of prognosis, this translocation is considered as neutral, however it has been shown recently that in 10% of t(11;14) a *CCND1* mutation co-occurs and the combination is associated with a poor prognosis when compared with non-mutated t(11;14) patients.

Translocation (14;16) is estimated to be present in about 5%–10% of patients with MM and results in overexpression of the *MAF* oncogene splice variant c-MAF, a transcription factor which up regulates a number of genes, including *CCND2*, by binding directly to its promoter. Breakpoints are located 3′ of *MAF* within the last exon of *WWOX*, a known tumor suppressor. Though t(14;16) was associated with poor prognosis in several studies. A more recent retrospective multivariable analysis on 1003 newly diagnosed MM patients showed that t(14;16) is not associated with poor prognosis.

Translocation (14;20) is present in about 1% of patients and is the rarest translocation of the major five. It results in upregulation of the *MAF* gene paralog *MAFB*. According to microarray studies, *MAFB* overexpression results in a similar gene expression profile (GEP) as that seen with *c-MAF*, implying common downstream targets including CCND2. The translocation is associated with poor prognosis when present in MM, but interestingly correlates to long-term stable disease when found in precursor conditions like MGUS and smoldering MM (SMM). This suggests that the translocation itself is not responsible for the poor prognosis, but additional genetic events are likely required to accumulate imparting this negative prognosis.

MYC translocations have been recently identified in a cohort of 463 whole exome sequencing including extra baits on the *MYC* locus. MYC translocations were found in 85 patients (18.4%). Partner genes include *IGH*, *IGL* and *IGK* loci, as well as *FAM46C*, *FOXO3*, *BMP6* and rarely *XBP1*, *TXNDC5*, *CCND1* and *CCND3*. These translocations lead to significant overexpression of *MYC*, probably resulting from juxtaposition of super-enhancers surrounding the partner gene to *MYC* locus. *MYC* translocations are associated with a poor outcome.

Hyperdiploidy

Hyperdiploidy (HRD) is defined as a chromosome number between 48 and 74. HRD MM are characterized by multiple chromosomal gains, preferentially trisomy of chromosomes 3, 5, 7, 9, 11, 15, 19, and 21. The mechanism underlying this is not known but one hypothesis suggests that the gain of multiple whole chromosomes occurs during a single catastrophic mitosis rather than through the serial gain of chromosomes over time. Nearly half of MGUS and MM tumors are hyperdiploid. Only a few HRD tumors have a co-existing primary IgH translocation—about 10% of the cases—whereas non-HRD tumors usually have an IgH

translocation. Interestingly, when HRD and IGH translocations coexist, HRD may precede IGH translocations in a proportion of patients, as revealed by single cell sequencing analysis. In terms of signaling pathways, HRD tumors display biological heterogeneity. Some harbor high expression of proliferation-associated genes while others are characterized by genes involved in tumor necrosis factor/nuclear factor-κB (TNF/NFκB) signaling pathway. HRD is associated with a more favorable outcome in general, however coexistent adverse cytogenetic lesions (del 17p, t(4;14) and gain of 1q) shorten survival in MM patients with HDR tumors.

Copy Number Variations

Copy number variations (CNVs) represent a common feature of MM and are thought to be secondary events, involved in tumor progression. CNVs result from gain and loss of DNA, which can be focal or involve an entire chromosome arm. Like single nucleotide mutations, CNVs are probably both driver and passenger events. Highly frequent and recurrent CNVs are likely to be driver, suggesting that the minimal amplified or deleted regions contain important genes involved in the development and progression of MM.

1q gain: Duplication of the long arm of chromosome 1 is present in 35%–40% of patients. This is known to have an adverse effect on overall survival. Gain of 1q21, detected with a specific probe for *CKS1B*, is an independent prognostic factor and remains when other adverse cytogenetic lesions that frequently coexist are removed. Though the relevant genes on 1q have not yet been fully explored, a minimally amplified region was identified between 1q21.1 and 1q23.3 containing 679 genes. Among these candidate oncogenes are *CKS1B*, *ANP32E*, *BCL9*, and *PDZK1*. Of these genes, *ANP32E*, a protein phosphatase 2A inhibitor involved in chromatin remodeling and transcriptional regulation, is particularly interesting and has been shown to be independently associated with shortened survival. These findings reinforce the role of gain of 1q in MM pathogenesis and suggest that patients with this type of CNV may benefit from specific inhibitors of these candidate genes and pathways that have been identified.

1p deletion: Deletions of 1p are observed in approximately 30% of MM patients and are associated with poor prognosis. Two regions of the 1p arm are of interest in MM pathogenesis when deleted: 1p12 and 1p32.3. 1p12 contains the candidate tumor suppressor gene *FAM46C*, of which expression has been correlated to that of ribosomal proteins and eukaryotic initiation/elongation factors involved in protein translation. This gene is frequently mutated in MM and this has been independently correlated with poor prognosis. Region 1p32.3 may be hemi- and homozygously deleted and contains the two target genes *CDKN2C* and *FAF1*. *CDKN2C* is a cyclin-dependent kinase 4 inhibitor involved in negative regulation of the cell cycle, whereas *FAF1* encodes a protein involved in initiation and enhancement of apoptosis through the Fas pathway. Deletion 1p is associated with adverse overall survival.

13q deletion: Monosomy of the long arm of chromosome 13 is present in about 45%–50% of patients and is commonly associated with non-hyperdiploid tumors. In approximately 85% of cases, deletion of chromosome 13 constitutes monosomy or loss of the q arm, whereas in the remaining 15% various interstitial deletions occur. Chromosome 13 has been extensively investigated as prognostic factor and as a location of tumor suppressor genes. The minimally deleted region lies between 13q14.11-13q14.3 and contains 68 genes including *RB1*, *EBPL*, *RNASEH2B*, *RCBTB2*, and the microRNA miR-16-1 and miR-15a. Molecular studies have shown that the tumor suppressor gene *RB1* is significantly under-expressed in these deletions, which may result in inferior negative cell cycle regulation. Establishing a prognostic significance of deletion 13 is challenging because it is frequently associated with other high risk cytogenetic lesions such as t(4;14). As such, the historic link between deletion 13 and poor prognosis is a surrogate of its association with high-risk lesions.

17p deletion: Most chromosome 17 deletions are hemizygous and involve the whole p arm, a genetic event observed in around 10% of newly diagnosed MM cases, with an increasing frequency in later stages of the disease. The minimally deleted region includes the tumor suppressor gene *TP53*. While cases without del(17p) have a rate of *TP53* mutation that is $<1\%$, cases with the deletion show a higher rate of mutation at 25%–37%—suggesting that mono-allelic 17p deletion contributes to the disruption of the remaining allele. The *TP53* gene, which has been mapped to 17p13, is known to function as a transcriptional regulator influencing cell cycle arrest, DNA repair, and apoptosis in response to DNA damage. Loss of 17p is associated with an adverse overall survival. The deletion is also linked to an aggressive disease phenotype, more extra-medullary disease, and shortened survival.

Somatic Mutations

The generalization of next generation sequencing a few years ago has enabled high throughput whole-exome sequencing in several cancers, including MM. The frequency of somatic mutations in MM is at the median across cancer types, with an average of 1.6 mutations per Mb, as compared to <0.5 per Mb in pediatric cancer, such as rhabdoid tumor or Ewing sarcoma, and about 10/Mb in melanoma and lung cancer. Studies by whole genome sequencing (WGS) and whole exome sequencing (WES) of patients with MM, comparing sequences from each tumor to its corresponding normal germline sample, allowed identification of tumor-specific mutations. Significantly mutated genes included three that were previously reported as being implicated in MM: *KRAS*, *NRAS*, and *TP53* as well as two newly described genes *FAM46C* and *DIS3*.

Several new oncogenic mechanisms were suggested by the pattern of somatic mutations across this data set. Nearly half the patients showed mutations of genes involved in protein translation. One of these is the *DIS3* gene, also known as *RRP44*, which encodes a highly conserved RNA exonuclease and serves as the catalytic component of the exosome complex involved in regulating

the processing and abundance of all RNA species. *DIS3* mutations, postulated to be loss of function, cluster in the catalytic pocket of the enzyme and deregulate protein translation as an oncogenic mechanism. Another significantly mutated gene, *FAM46C*, is less well characterized but thought to be functionally related to translation regulation.

The same team (Lohr et al., 2014) next reported massively parallel sequencing of a large cohort of patients with MM—including those previously studied. Beyond the five significantly mutated genes previously described, they identified another six significantly mutated genes (*BRAF*, *TRAF3*, *PRDM1*, *CYLD*, *RB1*, and *ACTG1*). Overall in this study, 65% of the patients had mutations in one or more of the 11 recurrently mutated genes.

Like *KRAS* and *NRAS*, *BRAF* is a known oncogene playing a role in regulating the MAP kinase pathway. Strikingly, mutations in *KRAS*, *NRAS*, and *BRAF* can be both clonal and sub-clonal. However, if mutations in these genes sometimes co-exist in the same tumor, they are almost never simultaneously clonal, indicating that they probably rarely occur in the same clone but rather in different sub-clones. In contrast, *KRAS* and *DIS3* mutations are reported to be often simultaneously clonal and therefore probably co-occurring in the same clone.

TRAF3 and *CYLD* are part of the NFkB pathway, which is also the case for nine other mutated genes of significance in this cohort (*BTRC*, *CARD11*, *IKBKB*, *MAP3K1*, *MAP3K14*, *RIPK4*, *TLR4*, and *TNFRSF1A*), which reaffirms the central role of the NFkB pathway in MM.

Another significantly mutated gene is *PRDM1* (also called *BLIMP1*), a transcription factor involved in plasma cell differentiation. Loss of function mutations of *BLIMP1* occur in diffuse large B cell lymphoma. The oncogene *IRF4*, a transcriptional regulator of *PRDM1* was also frequently mutated, in addition to mutations of *PRDM1*.

In parallel, a WES and copy number analysis of a series of MM samples led to the identification of two new recurrently mutated genes, *SP140* and *LTB*. *SP140* is a lymphoid restricted homologue of *SP100* that encodes a nuclear body protein implicated in antigen response of mature B cells, and is truncated in several cases. *LTB*, a type II membrane protein of the TNF family involved in lymphoid development, also harbor truncated mutations.

Finally, WES of a large number of patients enrolled in a phase III clinical trial (Walker et al., 2015) brought the list to 15 significantly mutated genes, comprising *KRAS*, *NRAS*, *TP53*, *FAM46C*, *DIS3*, *BRAF*, *HIST1H1E*, *RB1*, *EGR1*, *TRAF3*, *LTB*, *CYLD*, *IFR4*, *MAX*, and *FGFR3*. Interestingly, mutations in RAS (43% of the cases) and NFkB (17% of the cases) were prognostically neutral. In contrast, mutations in *CCND1* and the DNA repair pathway (*TP53*, *ATM*, *ATR*, and *ZFHX4*) were associated with a negative impact on survival in contrast to those in *IRF4* and *EGR1* that are associated with a favorable overall survival.

Identification of driver mutations in MM holds great promise for personalized medicine, whereby patients with particular mutations would be treated with the appropriate targeted therapy. However, if the mutation is present in only a fraction of the cells, one might doubt whether such targeted therapy would be clinically efficacious.

Clonal Heterogeneity and Clonal Evolution in Multiple Myeloma

In addition to the genetic complexity of MM, intra-clonal heterogeneity has emerged as a further level of complexity. Analysis of clonal heterogeneity by WES (Lohr et al., 2014) showed that most patients harbor at least three detectable sub-clones, some having as many as seven, which reaffirms that MM tumors are highly heterogeneous. The finding that tumors contain on average at least five sub-clones is even an underestimation of the clonal diversity in MM as the applied method only allows for the detection of sub-clones representing at least 10% of the entire tumor sample.

It has become clear that following disease initiation, the steps necessary for MM development do not occur through a linear fashion but rather via branching, non-linear pathways, as proposed by Darwin in explaining the evolution of species. This idea is based on the notion that mutations occur randomly and are selected and propagated based on the clonal survival advantage that they confer. A phenomenon of parallel evolution, whereby independent but not distantly related clones might acquire similar mutations conferring important growth or survival advantages, is revealed in single-cell level studies showing more than one alteration of same genetic pathway (RAS/MAPK) within the same tumor, but in separately evolving divergent clones. In a series of t(11;14) MM, evidence for the persistence of the earliest MM progenitor cell clone was found in two cases, characterized by the presence of a sub-clone carrying t(11;14) as the sole abnormality, validating that this translocation is an early event in myeloma pathogenesis. The clonal diversity is present at all stages of the disease. Although less genetically complex than MM, the pre-malignant stages MGUS and SMM harbor clonal heterogeneity. By studying sequential samples of SMM and overt MM, it was shown that the predominant clone of MM is already present at the SMM stage.

Treatment Implications

One of the main areas of development in genomics of MM is the critical need to comprehensively implement precision medicine. Perhaps more importantly, precision medicine aims to tailor the appropriate therapy to a patient in a personalized fashion, based on the disease genomic information. To this end, identification of driver mutations in MM holds great promise for precision medicine, whereby patients with particular mutations would be treated with the appropriate targeted therapy. A recent report describes a durable response to the mutation-specific BRAF inhibitor Vermurafenib in a patient harboring an activating mutation of *BRAF*. Several of the recurrently mutated genes in MM are potentially "actionable," meaning they can be targeted by therapies specifically

inhibiting the mutated or activated oncogene. However, this targeted therapy approach must be considered in light of the clonal heterogeneity and clonal competitions co-occurring in the cancer cell population. In fact, *BRAF* inhibitors are known to paradoxically activate the MAPK pathway in the event of co-existent *KRAS*-, *NRAS*-mutated or *BRAF*-WT sub-clones. This could be abrogated by the combination of *BRAF* and *MEK* inhibitors. Clonal heterogeneity poses a significant challenge; in fact, in most cases relapsed disease shows marked differences in genetic makeup compared with pre-treatment disease. This brings up the challenge of determining the most effective combinations of therapy. Thus, the comprehensive understanding of clonal heterogeneity is crucial to further develop targeted therapies in MM.

Conclusion

MM is a genetically complex and heterogeneous disease, combining primary events, secondary events and clonal diversity, leading to tumor development and progression from MGUS to late stages of MM. It is likely that many driver events need to co-occur for MM development and progression. This genomic complexity presents a challenge towards the cure of MM. In recent years, a tremendous amount of information has been obtained by next generation sequencing of MM tumors. Now that we have a good comprehension of the genomic landscape in MM at presentation, the near future should provide some insights regarding pre-malignant stages and resistance to treatment.

Mutational Signatures and the Etiology of Human Cancers

Ludmil B Alexandrov, University of California San Diego, San Diego, CA, United States
Maria Zhivagui, International Agency for Research on Cancer (WHO), Lyon, France

Glossary

Mutational process A mixture of DNA damaging and repair mechanisms that act collectively and have the ability to cause mutations in cells.
Mutational catalogue The conglomeration of all detected somatic mutations in the genome of a cell.
Mutational signature A characteristic pattern of somatic mutations imprinted by a mutational process on the genome of a cell.
Nonnegative matrix factorization A mathematical approach that allows unscrambling mixed signals and identifying meaningful components, such as, mutational signatures.
Somatic mutation Any change in the nucleotide sequence of DNA that is present in the genome of a somatic cell and has occurred after conception.

Nomenclature

AA Aristolochic acid
AFB1 Aflatoxin B1
APOBEC Apolipoprotein B mRNA editing enzyme, catalytic polypeptide-like
BaP Benzo[*a*]pyrene
BSS Blind source separation
DNA Deoxyribonucleotide acid
EBV Epstein Barr virus
HBV Hepatitis B virus
HCC Hepatocellular carcinoma
HMEC Human mammary epithelial cell
HPV Human papilloma virus
Hupki Human *TP53* knock-in
ICGC International Cancer Genome Consortium
Indels Small insertions and deletions
MEF Mouse embryonic fibroblast
MMR DNA mismatch repair
mRNA Messenger RNA
NGS Next-generation sequencing
NMF Nonnegative matrix factorization
PCR Polymerase chain reaction
ROS Reactive oxygen species
SBS Single-base substitutions
TSG Tumor suppressor gene
UTUC Upper tract urothelial carcinoma
UV Ultraviolet light

Introduction

The term "cancer" encompasses a broad group of over two hundred different diseases characterized by an abnormal cellular growth. The transformation from a normally functioning cell to a neoplastic cell is due to the accumulation of changes in the genetic material of the cell. These changes are known as somatic DNA mutations. Analogous to Darwinian evolution, some mutations can have no effect on the cell, some can be deleterious thus killing the cell in which they arouse, and others can provide a selective growth advantage. Mutations providing growth advantage ultimately allow cancer cells to survive, to proliferate, to invade, and to metastasize to other tissues in the body.

Somatic mutations can be caused by many different mutational processes. These mutational processes can be triggered by the internal molecular mechanisms of cells (e.g., mutations occurring due to normal cellular division), tissues-specific processes (e.g., inflammation), external environmental sources (e.g., exposure to radiation), and lifestyle choices (e.g., tobacco smoking). Each mutational process imprints a characteristic pattern of somatic mutations on the genome of cancer cells, termed, mutational signature. Mutational signatures can be deciphered from genomes of cancer cells by using next-generation sequencing data and advanced computational and mathematical approaches. This article reviews our current understanding of mutagenesis, mutational signatures in human cancer, and mathematical approaches for deciphering mutational signatures from next-generation sequencing data.

Somatic Mutations

By definition, a somatic mutation is a change in the DNA sequence of a somatic cell. This change can be a single base substitution, multi-base tandem substitutions, small insertion, small deletion, complex insertion and/or deletion, chromosomal rearrangement, copy number variation, or introduction of a foreign DNA (Fig. 1).

A single base substitution (SBS) modifies one DNA base pair to another. For example, a C:G base pair is substituted with an A:T base pair. Multi-base tandem substitutions simultaneously change multiple adjacent DNA base pairs. For example, a CC:GG sequence is substituted with a TT:AA sequence. Small insertions and/or deletions, commonly termed indels, result from the loss or the gain of a small number of adjacent nucleotide base pairs (Fig. 1). Most indels in a cancer genome have a length of less than 10 base pairs but some can be as long as a few hundred base pairs. Depending on the base changes and positions, single base substitutions and indels can have distinct effects on cellular functionality. For example, silent or synonymous mutations do not alter the translated protein sequence of the transcripted RNA. However, they may affect the translation fidelity of the transcripted RNA in the ribosomal subunits. Conversely, non-synonymous mutations change the protein sequence by introducing amino-acid changes, frameshifts, or stop codons. Further, many indels and SBSs occur in the non-coding region of the genome where they can disrupt gene expression by, for example, affecting the binding affinity of transcription factors.

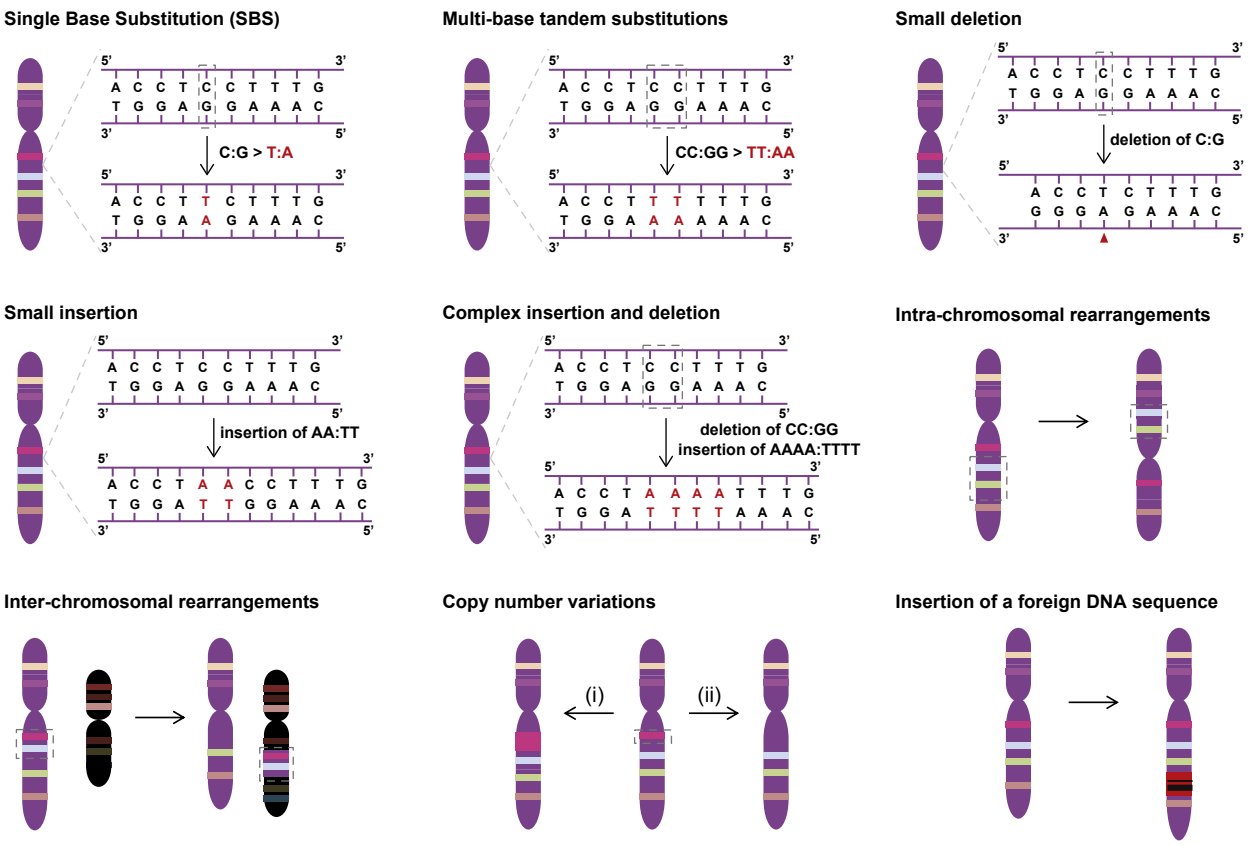

Fig. 1 Illustrative examples of the different types of genomic alterations present in cancer genomes. Small changes of the genome consist of single base substitutions, multi-base tandem substitutions, small insertions, small deletions, and complex insertions and deletions. Chromosomal rearrangements comprise intra-chromosomal translocations and inter-chromosomal translocations. Copy number variation of a specific DNA sequence leading to an increased (i) or a depleted (ii) copy of genome region. Insertion of new DNA sequence (e.g., viral DNA). Each alteration is represented relative to its position on chromosomes.

In addition to indels and SBSs, chromosomal rearrangements and copy number variations are commonly found in many types of human cancer. Chromosomal rearrangements occur when DNA segments break off and re-attach at different genomic locations. These locations can be on the same chromosome or on a different chromosome, resulting in intra- or inter-chromosomal rearrangements, respectively (Fig. 1). Chromosomal rearrangements have many functional implications and can lead, for example, to gene disruption, to fusion of two distinct genes, or to abnormal gene expression.

Copy number changes of a DNA sequence can increase its two copies in a normal diploid genome to several hundred copies in a cancer genome. This increase is referred to as genomic amplification, which is a common mechanism for the activation of many proto-oncogenes. Copy number changes can also reduce the copies of a DNA sequence due to large chromosomal deletions. These deletions may induce the complete absence of a DNA segment resulting in the loss of an associated gene; a commonly observed mutational mechanism for tumor suppressor genes.

Insertion of a foreign DNA sequence, originating from an exogenous source, is another important mechanism unambiguously implicated in the development of different types of cancer. Notable examples include incorporation of the sequence of the human papilloma virus (HPV), Epstein Barr virus (EBV), or hepatitis B virus (HBV).

Driver and Passenger Somatic Mutations

Mutations accumulate progressively during the lifespan of an individual in every single cell of the body. In general, it is accepted that mutations occur somewhat randomly across the genome and that they can be broadly separated into two categories—(i) mutations that provide selective advantage for clonal expansion and (ii) mutations that do not result in any growth advantage. The latter have been termed passenger mutations, while the former are referred to as driver mutations. It is widely believed that the number of driver mutations in a cancer genome is limited to a handful, usually between two and ten mutations. In contrast, the genome of a cancer can harbor more than a million somatic mutations most of which are considered passengers. Passenger mutations are not per se involved in cancer development but are rather the residual molecular fingerprints of the operative mutational processes.

Mutational Catalogues of Cancer Genomes

Even before the official start of the Human Genome Project, it was hypothesized that systematically analyzing the genetic information of cancer cells at a single base resolution will provide significant insights into the mechanisms of cancer development. While previous approaches allowed identification of large genomic events (e.g., copy number changes, chromosomal translocations, etc.) examining cancer genes by interrogating their sequence at a single-base resolution held the promise for observing previously unseen mutational events. At first, such sequencing examinations were performed using polymerase chain reaction (PCR)-based capillary sequencing for a targeted set of genes; however, the development of next-generation sequencing methods allowed rapidly sequencing of the complete set of exons in a cancer genome (i.e., an approach known as whole-exome sequencing) and, currently, even whole-genome sequences of cancer samples can be generate at a low cost.

Regardless of the experimental approach, the idea behind sequencing cancer genomes (or parts of these genomes) is simple. Genomic DNA is extracted from both the cancer and the normal tissue (which is usually but not always blood) and then these genomic DNAs are sequenced separately. The identified normal and cancer nucleotide sequences are aligned to the reference human genome, they are compared to it, and then they are compared to each other. The nucleotides that differ from the reference genome and that are found in both the normal and the cancer tissues are attributed to germline polymorphisms. Conversely, DNA sequence changes identified only in the cancer tissue, but not in the normal tissue, are attributed to somatic mutations specific for the cancer. All DNA changes identified only in the cancer tissue constitute the mutational catalogue of the cancer genome. An illustrative example identifying a somatic base substitution and a single nucleotide polymorphism from next generation sequencing (NGS) reads is provided in Fig. 2.

The majority of somatic mutations identified in the mutational catalogues of cancer genomes are passenger mutations. The ability to examine hundreds and even thousands of mutational catalogues of cancer genomes has resulted in the development of advanced statistical methods that allow pinpointing a handful of driver mutations from an ocean of passenger mutations. In simple terms, these algorithms evaluate which genes are mutated more often than purely expected by chance while correcting for a multitude of different factors.

Using a targeted capillary sequencing approach, an early cancer genomics study demonstrated that mutations in the BRAF gene are found in ~70% of melanomas. This was followed by subsequent studies identifying PIK3CA and EGFR as genes commonly mutated in human cancer. These early successes and their clinical significance made the identification of cancer genes through the systematic sequencing of cancer genomes, one of the main topics in cancer research. The emergence of NGS technologies allowed rapid and cheap examination of the genetic material of cancer cells. This led to the formation of the International Cancer Genome Consortium (ICGC). The goal of the ICGC is the identification of novel cancer genes through the molecular characterization of 50 types of human cancer (and their matched-normal tissues) from more than 25,000 patients. Nowadays, large-scale initiatives, such as the ICGC, continue to identify genes causally implicated in tumorigenesis and the census of genes driving human cancer gets updated on nearly a monthly basis.

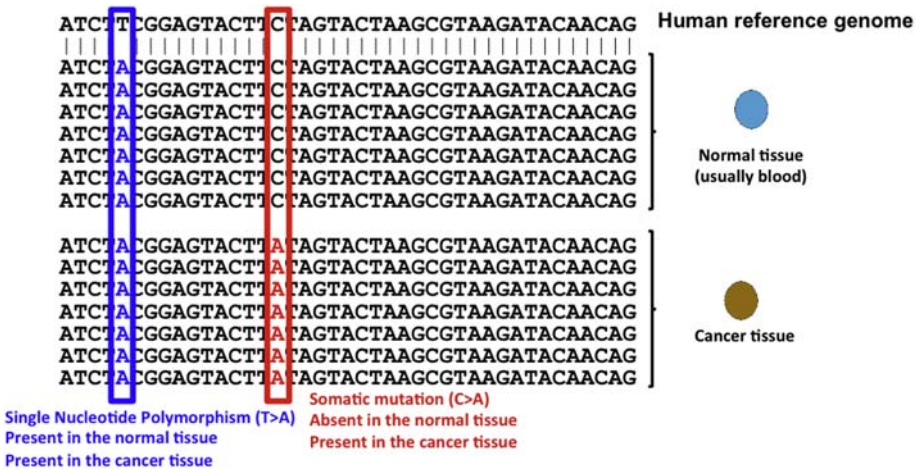

Fig. 2 Somatic mutations in cancer and nucleotide polymorphisms in the germline. Illustrated example demonstrating the identification of germline polymorphisms and somatic mutations from sequencing data.

Endogenous and Exogenous Mutational Processes

The genome of a cancer cell can be examined as a historical record that bears the imprints of the different mutagens to which the lineage of this cell has been exposed. Mutations can be caused by a plethora of endogenous factors, such as defects in the DNA repair machinery, or a variety of exogenous factors, such as dietary compounds, smoking, viruses, as well as some occupational and environmental carcinogens.

Differences in incidence rates across cancer types have stimulated a discussion on whether stochastic DNA changes (i.e., somatic mutations due to the variations in stem cell divisions in different organs) could explain these variations. Correlative analyses of the lifetime risk for developing a certain cancer with the number of stem cells divisions within the same organ implied that replication-related mutations are associated with neoplastic development. Mathematical analyses leveraging DNA sequencing and epidemiological data from 69 countries, representing 4.8 billion people, estimated that at least 29% of mutated driver genes are linked to environmental factors, whereas 66% can be attributed to replicative errors. However, it is impossible to completely separate replication-related mutations from exogenous factors. For example, consumption of very hot beverages, which has been linked to oesophageal carcinogenesis, induces severe damage to the cellular lining of the esophagus, which in turn will trigger stem cells located in the deep layers to divide in order to replace the damaged cells. Therefore, divisions of stem cells, caused by an exogenous factor can introduce replication-related mutations. Moreover, the endogenous production of reactive oxygen species (ROS), which can trigger replicative mutations, has been associated with several environmental compounds that act indirectly on DNA. Examples of such compounds are pesticides, mycotoxins, and heavy metals.

Numerous epidemiological studies emphasize the contribution of the environment to the cancer burden observed in particular populations. For instance, hepatocellular carcinoma (HCC) shows a high incidence rate in regions with a high risk of exposure to aflatoxin B1 (AFB1) compared to other regions where AFB1 exposure is minimal. In addition, comparing cancer incidence of Japanese subjects residing in Hawaii versus those living in Japan, especially ones living in Okinawa, revealed a dramatic decrease in cancers of the mouth, pharynx, and esophagus in all Japanese migrants. This result suggests that Japanese migrants have escaped exposure to mysterious environmental cancer risk factor(s) particular to the Okinawa region. Multiple epidemiological studies employing different approaches have estimated that extrinsic factors contribute 70%–90% of the risk for cancer development, with the rest being due to intrinsic factors. Thus, current epidemiological estimates indicate that the majority of global cancer risk is preventable. Taking the ongoing discussion regarding the contribution of replication errors into account, a smaller proportion of cancers would be amenable to a reduction of environmental exposures, while the majority would require cancer prevention measures based on early detection and early intervention. Regardless of the cancer prevention approach, uncovering the causes that lead to cancer will allow developing measures that seek to reduce or completely eradicate the exposure factors.

Cancer Etiology and Approaches to Identify the Sources of Somatic Mutations

All cancer genomes harbor mutational patterns that reflect tumor heterogeneity and that stem from exposures to multiple mutagenic carcinogens. Some mutagenic carcinogens leave a specific SBS imprint on DNA, exemplified by tobacco smoke carcinogens in lung (viz., C:G > A:T), ultraviolet light in most cancers of the skin (viz., C:G > T:A), and AFB1 in liver cancers from certain regions around the world (viz., C:G > A:T). A further refined classification of these SBS mutations can be applied by taking into consideration the immediate 5′ and 3′ nucleotide bases flanking the somatic mutation. This elaborated classification makes it possible to discriminate between the mutational patterns of C:G > A:T transversions observed in lung and liver cancers. Currently, the analysis of human cancer mutational spectra offers the possibility to study cancer etiology with much greater resolution. In the next few

sections, we discuss leveraging somatic mutations in single genes as well as somatic mutations across larger parts of the genome for elucidating cancer etiology.

Single gene approaches

Previously, mutagenicity and genotoxicity evaluation of compounds relied on simple assays employing prokaryotic systems, such as the Ames test, as well as assays that are laborious, such as the comet and micronucleus assays. However, these assays do not provide insights regarding the specific base changes and their sequence context. Leveraging single-gene sequencing in experimental models and primary human tumors provides an alternative to study the mutagenic processes associated with specific carcinogenic exposures. The experimental systems used for this purpose depend either on a phenotypic selection method (e.g., bacterial reporter genes) or on genes that are frequently mutated in human cancers.

Commonly utilized in vitro reporter genes rely on endogenous genes (e.g., *HPRT*, *DHFR*, or *TK*) to convert certain media supplements to toxic metabolites implying the occurrence of genetic changes in the encoded genes. In contrast, animal in vivo model systems include the genomic integration of a transgene consisting of a reporter gene (e.g., *lacI*, *lacZ*, *gpt*, *gpa*, *hprt*, *aprt*, *supF*, or *cII*) and a viral shuttle vector. After exposure, the transgene is packaged into phage particles ensuring the efficient delivery of the target gene into a bacterial host. Mutation detection is examined using chromogenic or viability selection. Reporter gene assay allowed the assessment of the mutagenicity of a number of carcinogens, for instance, the heterocyclic amine 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine, a common dietary carcinogen in cooked meat, which was associated with an increased rate of C:G > A:T transversions. Other examples include the dietary carcinogen acrylamide (viz., T:A > A:T and C:G > G:C), AFB1 (viz., C:G > A:T), and the chemotherapeutic agent 8-methoxypsoralen (viz., T:A > A:T).

Sequencing of cancer genes facilitates the identification of driver mutations in a cancer type. This approach also provided the first evidence of the molecular mechanisms by which environmental carcinogens leave characteristic imprints on DNA. Examples of the most frequently mutated genes in human tumors include TP53, KRAS, and BRAF genes. Single cancer gene sequencing in skin and lung tumors identified mutational patterns characteristic of exposures to ultraviolet light (UV-light) and benzo[*a*]pyrene (BaP), respectively. UV-light induces C:G > T:A transitions at dipyrimidines in skin cancers, and tobacco smoke prompts C:G > A:T transversions in lung tumors (**Fig. 3**). These tumor-associated mutational patterns are in agreement with results from in vitro controlled experimental exposure studies of UV-light and BaP. Indeed, sequencing of the TP53 gene in cancer patients with different exposures history (i.e., exposed vs. non-exposed) strengthens the link between environmental factors and cancer development. Lung tumors from smokers display a predominant C:G > A:T mutational pattern which is not evident in lung tumors from non-smokers, and the amount of the C:G > A:T imprint correlates with the level of tobacco consumption.

Human exposure to the plant carcinogen aristolochic acid (AA) has been linked to the endemic Balkan nephropathy as well as upper tract urothelial carcinoma (UTUC) and cancers of the liver, bladder, and kidneys. Indeed, TP53 mutation screening of these

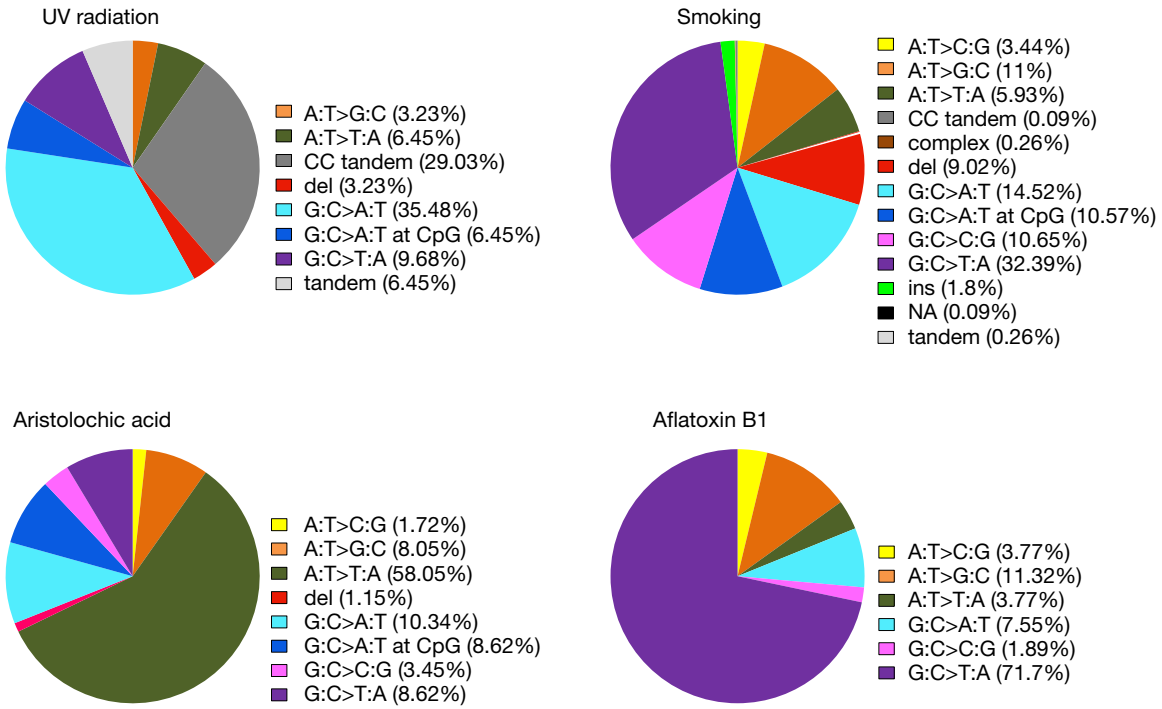

Fig. 3 Data extracted from the International Agency for Research on Cancer's TP53 database. Pie chart representations of the proportion of TP53 single base substitutions observed in human cancers of the skin, lung, kidney, and liver. Each of the pie charts corresponds to a specific exposure linked with one or more of these cancer types. The database can be found at: http://p53.iarc.fr/TP53SomaticMutations.aspx.

cancers identified a pronounced T:A>A:T mutational fingerprint associated with the unique mutation pattern of AA observed in laboratory experiments. Finally, the TP53 gene exhibits a unique mutational profile characterized by predominant C:G>A:T transversions in HCC cases from regions where AFB1 exposure is prevalent. Liver cancers from other populations, where AFB1 exposure is minimal and other risk factors prevail, exhibit other distinct TP53 mutational fingerprints.

Different in vivo and in vitro experimental systems contributed to the identification of TP53 mutational patterns, representing "rudimentary signatures" of mutagens, and their putative associations to specific cancer types. These models include a genetically engineered mouse system, harboring the human TP53 gene, from which embryonic fibroblasts were derived. These Hupki (Human TP53 knock-in) mice were exposed to UV-light inducing characteristic TP53 gene mutations similar to those predominantly observed in human skin cancer (viz., C:G>T:A). Moreover, Hupki mouse embryonic fibroblasts (Hupki MEFs) were exposed to a number of carcinogens revealing an analogy between the Sanger sequenced TP53 genes from the in vitro assays and human tumors associated with the same exposures.

Yeast systems were also exploited for TP53 mutagenesis using a strain transfected with an expression vector harboring human TP53 cDNA that had been in vitro irradiated with UV-light. The results revealed CC:GG>TT:AA mutations which is consistent with the observations from data derived from sequencing UV-light associated skin cancers. Normal human fibroblasts were also treated with other known carcinogens, such as BaP, AFB1, and acetaldehyde. The observed mutational patterns of TP53 were evaluated and they were consistent to the mutational patterns observed in some human cancers. Overall, the experimental identification of carcinogen-specific mutational patterns has demonstrated a convergence between mutational data and epidemiological studies. These mutational data can be effectively utilized for establishing of causal associations between environmental exposures and human cancers.

Despite their significant contribution to understanding the sources of somatic mutations in cancer, single gene sequencing studies harbor major limitations. First, many samples from a specific cancer type are needed to accumulate enough alterations to extract a specific mutational profile. This profile is specific for a cancer type and, due to the small numbers of mutations in a gene, one cannot examine individual samples. Second, the patterns of mutations in single genes are usually affected by selection as, in many cases, these genes provide a selective growth advantage. The selection imprint can severely bias the observed mutational spectrum. Third, single genes have specific nucleotide sequences that are not representative of the human genome. The nucleotide structure of genes affects the opportunity for observing a somatic mutation and it further biases the observed mutational spectrum. Advances in NGS and bioinformatics analyses have addressed these challenges and allowed efficient testing of hypotheses regarding putative cancer-risk factors.

Genome-wide mutational patterns and deciphering mutational signatures from human cancers

Massively parallel sequencing has revolutionized many aspects of biology, including mutation research, due to high speed sequencing capacities and the reduction in the overall sequencing cost. NGS enables examining the complete genomes of cancer cells at a single-base level, providing an unprecedented resolution of the mutational processes that have molded these genomes through the lineage of the cancer cells. The generation of large mutational datasets required the development of novel mathematical models and computational frameworks that allow meaningful interpretation of these data. Below, we provide a description of a mathematical model that was previously used to identify the signatures of the mutational processes operative in human cancer by examining thousands of cancer genomes.

A mutational catalogue of a cancer genome can encompass a diverse set of mutation classes including single base substitutions, insertions/deletions, structural rearrangements, copy number changes, and others (Fig. 1). Each class of mutation can then be further sub-classified. For example, SBSs can be sub-classified according to the six unique types of single base substitutions. For simplicity, the pyrimidine of the Watson–Crick base pair is usually used as a reference for a SBS mutation, thus, a C:G>A:T mutation will be written as a C>A mutations. Using this abbreviate nomenclature the six unique SBS types are: C>A, C>T, C>G, T>A, T>C, and T>G. This classification can be further elaborated to include a variety of mutational features such as the sequence context of the mutated base and the transcriptional strand on which the substitution has arisen.

For the purpose of mathematical modeling, a limited number of features of a mutational catalogue need to be selected. The choice of features may be influenced by prior biological knowledge. The choice is also often constrained by statistical considerations and the available data. Mathematically, a set of mutational features can be expressed as a finite alphabet Ξ with K letters, where each letter corresponds to a mutational feature. The simplest alphabet for SBSs, Ξ_6 contains $K = 6$ letters. Ξ_6 is based on the six types of single base substitutions and it has six letters: C>A, C>T, C>G, T>A, T>C, and T>G. It should be noted that this alphabet of mutation types could be easily extended by, for example, including other mutation types such as doublet base substitutions. Here, we focus on mathematical alphabets representing SBSs as these alphabets have been the ones most commonly used to examine mutational signatures.

The Ξ_6 alphabet is perhaps the simplest possible alphabet as it considers only the six types of somatic substitutions. This alphabet is generally not used in any analysis but, rather, its simplicity is leveraged to provide examples and visual representations that clarify mathematical concepts.

The Ξ_{96} alphabet provides a greater resolution for examining the six types of single nucleotide variants (i.e., the Ξ_6 alphabet) by including the immediate sequence context of each mutated base. In this alphabet, a mutation type contains a somatic substitution and both the 5′ and 3′ base immediately next to the somatic mutation. For example, a C>T mutation can be characterized as …Tp<u>C</u>pG… > …Tp<u>T</u>pG… (mutated base underlined and presented as the pyrimidine partner of the mutated base pair in the

trinucleotide sequence) generating 96 possible mutation types—(six types of substitutions) * (four possible types of 5′ base pairs) * (four possible types of 3′ base pairs).

The Ξ_{1536} further extends Ξ_{96} by including two base pairs 5′ and 3′ to the mutated base resulting in 1536 possible mutated pentanucleotides—(six types of substitutions) * (16 possible types of the two immediate 5′ base pairs) * (16 possible types of the two immediate 3′ base pairs). For example, using the Ξ_{1536} alphabet, one of the 256 subclasses of a C>T mutation is …ApTpCpGpC… > …ApTpTpGpC… (mutated base underlined and presented as the pyrimidine partner of the mutated base pair in the pentanucleotide sequence).

Lastly, Ξ_{192} elaborates Ξ_{96} by considering the transcriptional strand on which a substitution resides. In contrast to all previously discussed alphabets, Ξ_{192} is defined only in the regions of the genome where transcription occurs, which in most analyses has been limited to the genomic footprints of protein coding genes. Thus, the previously defined 96 substitution types are extended to 192 mutation types. For example, C>T mutations at TpCpA are split into two distinct categories: C>T mutations at TpCpA occurring on the untranscribed strand of genes and C>T mutations at TpCpA occurring on the transcribed strand of genes. In general, one would expect that these two numbers are approximately the same unless the mutational processes are influenced by the activity of the transcriptional machinery. This could happen, for example, due to recruitment of the transcription-coupled component of nucleotide excision repair. For example, if a mutational process has a higher number of C>T substitutions on the transcribed strand compared to C>T substitutions on the untranscribed strand (note that a C>T mutation on the untranscribed strand is the same as a G>A mutation on the transcribed strand), this could indicate that the mutations caused by this process are being repaired by transcription-coupled nucleotide excision repair, although other explanations are also possible. A known example of such strand-bias due to an interplay between a DNA damaging process and a repair mechanism is the formation of photodimers due to ultraviolet light exposure that are repaired by transcription-coupled nucleotide excision repair, resulting in a higher number of C>T mutations on the untranscribed strand of UV-light associated cancers.

Quantitatively, a mutational catalogue of a cancer genome is a vector, m, containing the number of somatic mutations of a genome, g, defined over a finite alphabet of mutational types Ξ. Mathematically, a mutational catalogue is a morphism between the pre-defined finite alphabet, Ξ, and a set of K nonnegative integers, ${\mathbb{N}_0}^K$, that is, $m : \Xi \rightarrow {\mathbb{N}_0}^K$. Thus, for a given genome, its mutational catalogue can be expressed as a K-tuple of natural numbers, $m = [m^1, m^2, \ldots, m^K]^T$. Comparing the mutational catalogues of two cancer genomes, $m_1 = [{m_1}^1, {m_1}^2, \ldots, {m_1}^K]^T$ and $m_2 = [{m_2}^1, {m_2}^2, \ldots, {m_2}^K]^T$, requires that both mutational catalogues are defined over the same mutational alphabet Ξ. A comparison can be performed either by using a cosine distance to compare the difference between the mutational patterns in two catalogues or by using a Euclidean distance to compare the absolute mutational difference between two catalogues.

Different cancer genomes can be exposed to a particular mutational process at different intensities. For example, a mutational process may cause 350 mutations in one cancer genome while causing 350,000 in another. We refer to this number of mutations as a *mutational exposure* (or simply *exposure*) of a signature of a mutational process in a cancer genome. Hence, one may say that a mutational process with a signature P has an exposure e,corresponding to the number of mutations caused by this process in a mutational catalogue m of a cancer genome.

Multiple mutational processes can be operative in a single cancer genome and each of these processes can have a distinct mutational exposure. Thus, the mutational catalogue of a cancer genome $m = [m^1, m^2, \ldots, m^K]^T$,defined over the mutation alphabet Ξ with K letters, is a superposition of the signatures of the N operative mutational processes $P_i = [{p_i}^1, {p_i}^2, \ldots, {p_i}^K]^T$, $i = 1 \ldots N$,each defined over the mutation alphabet Ξ, with their respective exposures e^i, $i = 1 \ldots N$. This superposition is never perfect as DNA sequencing, bioinformatics analyses, and other pre- and post-processing of the data causes non-systematic noise, n. Taking into account this noise, the number of the j-the mutational type in an m mutational catalogue can be examined as:

$$m^j = \sum_{i=1}^{N} P_i^j e^i + n^j \tag{1}$$

Note that in this definition, m, e, and n are vectors, while P is expressed as a matrix. Indeed, the signature P_1 of a mutational process, defined over an alphabet Ξ with K letters, can also be expressed as a nonnegative K-tuple, $P_1 = [{p_1}^1, {p_1}^2, \ldots, {p_1}^K]^T$, where $\sum_{i=1}^{K} p_1^i = 1$ and ${p_1}^i$ is the probability of the mutational processes P_1 to cause the mutation type corresponding to the i-th letter of the alphabet Ξ. As previously described, a set of N mutational signatures can be expressed as a nonnegative mutational signature matrix $P = \begin{bmatrix} p_1^1 & p_2^1 & \cdots & p_{N-1}^1 & p_N^1 \\ \vdots & \vdots & \cdots & \vdots & \vdots \\ p_1^K & p_2^K & \cdots & p_{N-1}^K & p_N^K \end{bmatrix}$ with size $K \times N$,where K is the number of mutation types and N is the number of signatures. The subscript index indicates the signature, while the superscript index corresponds to the mutation type.

The mutational catalogue of a cancer genome, defined over the alphabet of mutation types Ξ, is represented by a morphism m, where $m : \Xi \rightarrow {\mathbb{N}_0}^K$. For a given genome,$i$, its mutational catalogue can be expressed as a nonnegative K-tuple, $m_i = [{m_i}^1, {m_i}^2, \ldots, {m_i}^K]^T$. Hence, the mutational catalogues of G cancer genomes can be expressed as a nonnegative matrix of mutational catalogues $M = \begin{bmatrix} m_1^1 & m_2^1 & \cdots & m_{G-1}^1 & m_G^1 \\ \vdots & \vdots & \cdots & \vdots & \vdots \\ m_1^K & m_2^K & \cdots & m_{G-1}^K & m_G^K \end{bmatrix}$ of size $K \times G$. In this case, the mutational catalogues are the columns of the matrix, where K is the

number of mutation types and G is the number of genomes. The subscript index indicates the mutational catalogue while the superscript index corresponds to the mutation type.

The exposure to a mutational process with a signature $P_1 = [p_1{}^1, p_1{}^2, \ldots, p_1{}^K]^T$ is a scalar describing the number of mutations, $e^1 \in \mathbb{N}_0$, attributed to that signature in a given mutational catalogue. In this notation, the product $p_1{}^2 \times e_g{}^1$ is the number of mutations of type corresponding to the second letter of alphabet Ξ caused by the mutational process P_1 in a cancer genome with number g. Hence, one can define a set of exposures of G genomes to a set of N processes as a nonnegative matrix $E = \begin{bmatrix} e_1^1 & e_2^1 & \cdots & e_{G-1}^1 & e_G^1 \\ \vdots & \vdots & \cdots & \vdots & \vdots \\ e_1^N & e_2^N & \cdots & e_{G-1}^N & e_G^N \end{bmatrix}$ with size $N \times G$. Here, the subscript index indicates the genome while the superscript index corresponds to the signature. In addition to the signatures of the operative mutational processes, the mutational catalogue of a cancer genome also reflects the effect of random error processes, which may occur due to the used experimental approach (e.g., DNA sequencing) and/or bioinformatics methods (e.g., algorithms for identifying somatic mutations from next-generation sequencing data). This noise term n reflects an additive white Gaussian noise that occurs due to non-systematic errors. The noise term is specific to each mutational catalogue and it is defined over the alphabet Ξ of the mutational catalogue, where $n : \Xi \rightarrow \mathbb{R}^K$. Hence, for a set of mutational catalogues of G cancer genomes, the noise term can be expressed as a matrix $N = \begin{bmatrix} n_1^1 & n_2^1 & \cdots & n_{G-1}^1 & n_G^1 \\ \vdots & \vdots & \cdots & \vdots & \vdots \\ n_1^K & n_2^K & \cdots & n_{G-1}^K & n_G^K \end{bmatrix}$ of real numbers with size $K \times G$. The subscript index indicates the noise term for the mutational catalogue while the superscript index corresponds to the mutation type.

The signatures of N different mutational processes and their respective exposures need to be extracted from the mutational catalogues of M cancer genomes. Using the introduced notations, this could be expressed as:

$$\begin{bmatrix} m_1^1 & m_2^1 & \cdots & m_{G-1}^1 & m_G^1 \\ \vdots & \vdots & \cdots & \vdots & \vdots \\ m_1^K & m_2^K & \cdots & m_{G-1}^K & m_G^K \end{bmatrix} = \begin{bmatrix} p_1^1 & p_2^1 & \cdots & p_{N-1}^1 & p_N^1 \\ \vdots & \vdots & \cdots & \vdots & \vdots \\ p_1^K & p_2^K & \cdots & p_{N-1}^K & p_N^K \end{bmatrix} \times \begin{bmatrix} e_1^1 & e_2^1 & \cdots & e_{G-1}^1 & e_G^1 \\ \vdots & \vdots & \cdots & \vdots & \vdots \\ e_1^N & e_2^N & \cdots & e_{G-1}^N & e_G^N \end{bmatrix} + \begin{bmatrix} n_1^1 & n_2^1 & \cdots & n_{G-1}^1 & n_G^1 \\ \vdots & \vdots & \cdots & \vdots & \vdots \\ n_1^K & n_2^K & \cdots & n_{G-1}^K & n_G^K \end{bmatrix} \quad (2)$$

or one can simplify Eq. (2) using matrix notations as:

$$M = P \times E + N \quad (3)$$

In practice, one knows only the mutational catalogues in the matrix M as M corresponds to the mutations identified by NGS. To identify the signatures of the operative mutational processes one needs to decompose M and identify P and E such that these matrices best describe the original matrix without over-fitting the data.

Finding an optimal solution for Eq. (3) can be achieved by leveraging a blind source separation (BSS) technique. BSS problems involve unscrambling latent (i.e., not observed) signals from a set of mixtures of these signals, without knowing or assuming anything about the mixing process. In the cases of mutational signatures, each cancer genome can be examined as a mixture of distinct mutational processes that have imprinted their mutational signatures on this genome. In principle, BSS algorithms are capable of revealing hidden features and dependencies in large sets of observed data. Then, these features can be used to build a representation of the data that can contribute to understanding of the underlying mechanisms behind these data. The unmixing and reconstruction of the original signals is usually based on some constrained and/or regularized optimization procedure minimizing an objective (i.e., cost) function together with a few imposed constraints, such as: maximum variability, statistical independence, nonnegativity, smoothness, sparsity, simplicity, etc. The choice of the optimization constraints is usually based on a priori knowledge about the examined data, and, hence, constraints are usually specifically tailored for a particular problem and/or a specific mathematical model.

Unscrambling mutational signatures from the genomes of cancer cells can be effectively done by leveraging nonnegative matrix factorization (NMF). NMF is a BSS approach that assumes simple nonnegativity of the different signals. In turn, the nonnegativity makes each of the identified latent variable (i.e., mutational signature) a component of the original data, thus, resulting in easily identifiable and interpretable latent variables. Moreover, NMF contains a natural sparsity constraint that allows separating distinct latent variables only when there are sufficient data for such separation.

In 2013, a computational framework, based on NMF, was first developed and later used by Alexandrov and colleagues to identify signatures of mutational processes from 7042 cancer patients with 30 different types of human cancer. More than 20 distinct mutational signatures were identified, many of which were attributed to either exogenous or endogenous mutational processes. In the past few years, the map of mutational signatures in human cancer has been further refined and more than 30 distinct mutational signatures have been discovered. The newest set of mutational signatures in human cancer can be found on the COSMIC website: http://cancer.sanger.ac.uk/cosmic/signatures.

Signatures of Mutational Processes With Proposed Etiology

The analysis of thousands of cancer genomes has revealed more than 30 signatures of mutational processes in human cancer. From some of these signatures, previous analyses have been able to identify or, at least, to propose a putative etiology. Tobacco-associated

lung cancers are overwhelmed by signature 4 (Fig. 4), which displays a predominant C>A pattern with transcription strand bias indicative of damage to guanine. This signature matches well the in vitro pattern of mutations induced by tobacco smoke carcinogens and, most specifically, the pattern induced by in vitro exposure to BaP. Bladder, kidney, and liver cancers from certain regions around the world exhibit a unique mutational signature known as signature 22 (Fig. 4). Signature 22 is characterized by T>A mutations and it has been ascribed to exposures to AA. Skin-cancers associated with ultraviolet-light harbor large-numbers of mutations that are attributed to signature 7 (Fig. 4). Signature 7 is predominantly characterized by C>T mutations at dipyrimidine nucleotides with a transcriptional strand bias that is consistent with the formation of photodimers. Importantly, the hitherto described mutational signatures (and others) confirmed prior observations derived from single-gene sequencing of TP53 and provided a strong mutational link between a specific cancer type and its main aetiological factor.

The mutational catalogue of a cancer is a composite of superimposed mutational signatures left by various mutagenic insults. In HCC, many individual cancer samples exhibit more than five distinct mutational signatures, reflecting the variety of carcinogens that can cause mutations in hepatocytes. Some of the known risk factors attributed to liver cancer are HBV infection, HCV infection, alcohol consumption, and exposure to AFB1. Amongst the identified signatures, signature 16, characterized by T>C transitions at ApTpN sites, is observed exclusively in the majority of liver tumors. Nevertheless, its etiology is still unknown. Signature 24 was uncovered in AFB1-exposed liver cancers and it is characterized by a transcription asymmetry of C>A transversions (Fig. 4). Integrated experimental analysis across human cell lines, animal models, and primary HCC tumors further confirmed the association between signature 24 and exposure to AFB1.

Interestingly, endogenous mutational processes constitute almost half of the identified mutational signatures. Signature 1, attributed to the spontaneous deamination of 5′-methylcytosine, is seen in almost all tumors and it contributes up to 80% of mutations in some cancer types, for example, in myeloid leukemia. Together, signatures 1 and 5 has been termed clock-like mutational signatures as the number of mutations attributed to each of these signatures in cancer (and normal somatic) cells are proportionate to the chronological age of the person from which the cancer (or normal cells) were taken. A number of mutational signatures have been attributed to the disruption of processes regulating DNA homeostasis. Signature 9 reflects infidelity of the DNA polymerase eta, while signature 10 is due to a malfunction of the DNA polymerase epsilon. Defects in DNA mismatch repair (MMR) were found to generate at least five distinct mutational signatures depending on the nature of MMR failure: signatures 6, 15, 20, 21, and 26. Failure of DNA double strand repair by homologous recombination also causes a specific mutational signature, termed, signature 3. Signature 30 was attributed to failure of base-excision repair due to defects in the cancer predisposition gene NTHL1. Notably, in more than half of the cancer types analyzed to date, mutational signatures attributed to the APOBEC (apolipoprotein B mRNA editing enzyme, catalytic polypeptide-like) family of deaminase, known as signatures 2 and 13, have been identified. The patterns of the APOBEC signatures have been further supported by extensive experimental work utilizing various model systems. The APOBEC deaminases have been implicated in virus restriction and suppression of retrotransposition. Signatures 2 and 13 have been overwhelmingly found in cervical cancer as well as in cancers of the head and neck, both of which are related to HPV infection. Moreover, signatures 2 and 13 are highly elevated in samples with prior evidence for HPV infection, implying the recurrent activation of APOBEC upon viral infection. In addition to mutational signatures with known etiology, the mechanisms underlying many of the identified mutational signatures still remain mysterious. A comprehensive information of the current set of mutational signatures in human cancer can be found on the COSMIC website.

Orphan Mutational Signatures and Approaches for Understanding Them

Genome-wide mutational analysis of thousands of human cancers highlighted a number of mutational signatures attributed to endogenous and exogenous mutagens. In order to reveal the causal factors underlying a mutational signature, the convergence of multiple lines of evidence from different areas of research is required including experimental studies, epidemiology data, and individual patient history including exposomics data.

Amongst the 30 distinct mutational signatures thus far identified, 40% remain with unknown etiology reflecting the need for controlled experimental studies. In vivo exposure bioassays as well as in vitro exposure assays are two roads that can lead to a controlled assessment of the genotoxicity, mutagenicity, and carcinogenicity of a compound. Ideally, such exposure studies would use model systems that enable the testing of a large number of compounds within a reasonable timeframe.

Normal primary cells, both human and rodent, have a limited lifespan when transferred from their in vivo environment to culture. These cells undergo stress-associated senescence, with a permanent exit from the cell cycle and eventual death of the cell population. Occasionally, one cell may bypass this fate due to genetic changes and resume the cell cycle producing a clone of immortalized cells that replicates indefinitely in vitro. Clonal expansion is a prerequisite property of the system allowing the investigation of the acquired somatic mutations in more or less homogeneous cell populations by deep sequencing analysis.

Cellular models suitable for mutational signatures analyses should include a bottleneck step followed by a clonal expansion, thus, mimicking key steps of carcinogenesis: (i) initiation via exposures, (ii) promotion, (iii) and progression. There are two approaches that should be considered for an in vitro system: (i) bypassing a biological barrier, such as crisis or senescence, and emergence of an immortalized clonal population; or (ii) single cell subcloning after exposure for cells for which a selective biological bypass step is not applicable; also known as clonal expansion. Moreover, these experimental models should recapitulate key aspects of human biology (e.g., metabolic activity as well as activity of DNA repair pathways).

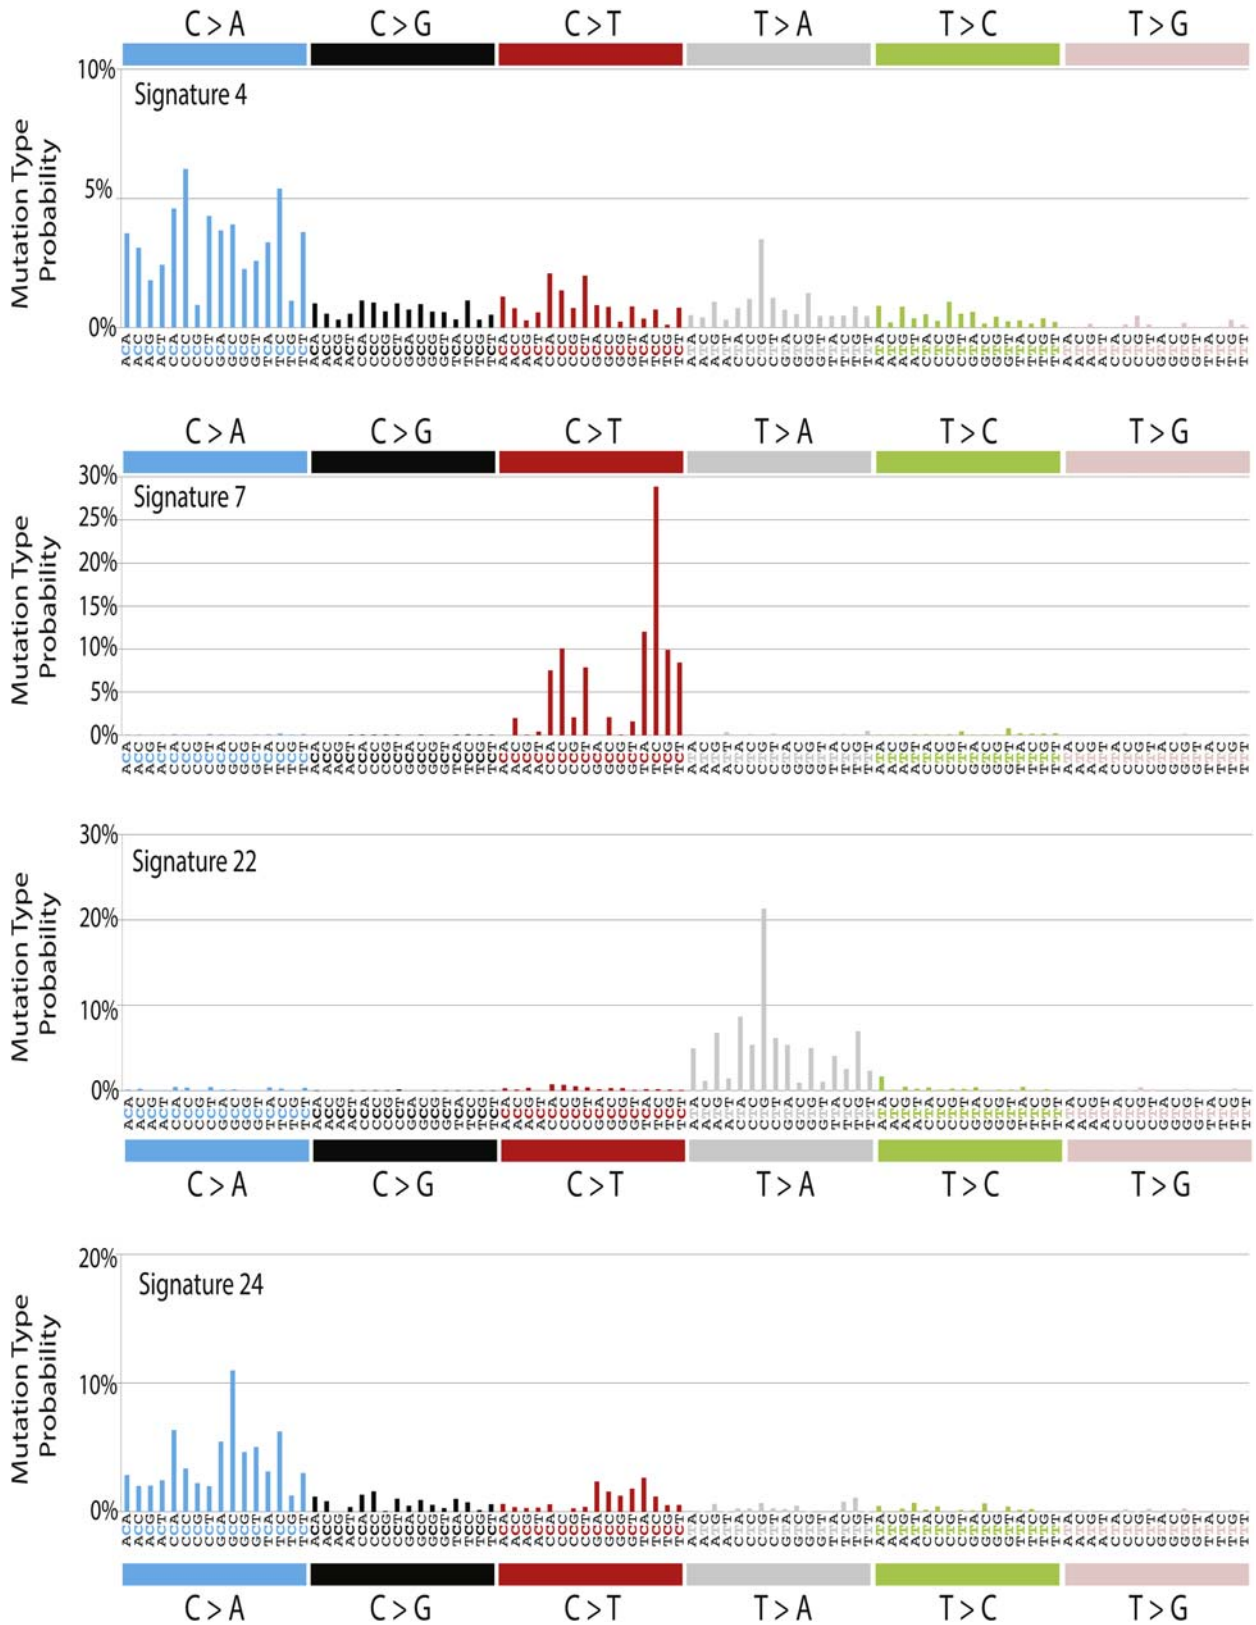

Fig. 4 Examples of mutational signatures identified from examining next-generation sequencing data from human cancers. Signature 4 has been overwhelmingly found in lung cancer from smokers and it has been attributed to smoking tobacco cigarettes. Signature 7 generates the majority of mutations in cancers of the skin and it has been attributed to exposure to ultraviolet light. Signature 22 and 24 has been found in cancers of the liver from specific regions around the world and they have been attributed to exposure to aristolochic acid and aflatoxin B1, respectively.

Through extensive laboratory work, multiple mouse-derived and human-derived cells have been employed to experimentally investigate the genome-wide mutagenic effects of candidate cancer-risk factors. First, Hupki MEFs have proven suitable for cell immortalization due to their sufficiently long telomeres. Interestingly, the scope of overlap between the genome-wide mutational patterns observed in human datasets and immortalized MEF cell lines, exposed to a number of strong carcinogens, includes: (i) the SBS mutational pattern based on the six possible types of SBS mutations, (ii) the transcription strand bias of specific SBSs, and (iii) the immediate sequence context of the dominant mutation type. Second, a number of human cell line models have been explored for the analysis of mutational patterns, namely a proximal tubule human kidney cell line, viz., HK-2, as well as HepaRG and HepG2 cells derived from HCC, and the human mammary epithelial cells (HMEC). As for most human model systems, their use requires long-term exposure and the number of compounds that can be tested is a limiting factor. Nevertheless, the use of human cancer target cell models is an elegant strategy to identify the mutational pattern of a carcinogen triggering cancer development in a specific site. Other emerging models such as induced pluripotent stem cells and organoids are versatile systems capable of clonal expansion that can be generated from different cell and tissue types. However, these models lack the biological barrier step of HMEC and Hupki MEFs and it is not clear whether this will influence the imprinted mutational signatures. Further, taking into consideration in vivo carcinogen-animal models may provide new avenues for a better understanding of the molecular alterations observed in human diseases, and thus improve our knowledge on cancer initiation, progression, diagnosis, and treatment.

In addition to experimental examination, future epidemiological studies can be used to identify novel mutational signatures as well as to reveal the identity of known mutational signatures with mysterious etiology. Coupling of epidemiology and cancer genomics approaches can provide synergistic results by allowing association of epidemiological features with mutational signatures or other molecular cancer data. Further, cancer risk assessment through the establishment of new epidemiological studies with thorough follow-up of human subjects can enable the exploration of carcinogenic risk associated to specific carcinogens and eventually the categorization of mutational signatures to cancer risk factors.

Prospective Vision

Characterization of novel mutational signatures specific to cancer-risk agents may ultimately contribute to the overall interdisciplinary mission of cancer research and provide novel avenues for cancer prevention.

Multiple national and international initiatives have started with the goal for better understanding mutational signatures in human cancer. Notably, the *Mutographs of Cancer* project is investigating whether different mutational signatures can explain geographical differences in cancer incidence across the world. This international project will collect cancer samples and information about cancer-causing exposures from 5000 patients with colorectal, oesophageal, pancreatic, and kidney cancer living in regions of high or low cancer incidence across five continents. The complete DNA of these cancers (and their matched normal tissues) will be sequenced and the mutational signatures will be comparted and linked to cancer risk factors. Further, *Mutographs* will also identify specific causes of mutational signatures by sequencing the DNA of rodent cancers and cultured human cells experimentally exposed to more than 150 cancer-causing agents, thus assembling a compendium of mutational signatures associated with known causes of cancer. The overall outcome of the *Mutographs* project will provide a comprehensive understanding of mutational signatures in cancer and may lead to new approaches to prevent cancer as well as provide opportunities for more effective application of existing cancer therapies.

Interestingly, in recent years, evidence has emerged linking epigenetics modifications to environmental factors and human malignancies. Cancer genomes frequently undergo epigenetic changes that follow the Darwinian natural selection process and favor the growth of cells with characteristically altered chromatin structure and deregulated gene expression. These changes are brought through epigenetic modifier genes that are frequently mutated in human cancer. Some examples include DNA methyltransferases, DNA demethylases, histone modifiers, ATP-dependent chromatin remodelers, and other. The results of epigenetic deregulation can range from dysregulated expression of individual oncogenes or tumor suppressor genes to large-scale chromatin structure alterations and genomic instability.

Well-established cancer-risk agents and lifestyle factors have been studied in terms of epigenome deregulation, improving the understanding of their long-lasting effects on cancer outcome. Tobacco smoking, diet, infections, inflammation and age are known to affect epigenetic states and can play a role in the early onset of cancers through different mechanisms. Smoking, which is the strongest exposure factor causing lung cancer, harbors an epigenetic signature characterized by consistent methylation changes in the Aryl-hydrocarbon receptor repressor gene. Age is the strongest demographic risk factor for cancer and, interestingly, DNA methylation profiles of chronological age established an "epigenetic clock" that can be affected by different external and endogenous factors.

Progress in epigenetic research can open the door to a new era where epigenetic signatures can serve as surrogate for diagnostics and risk stratification of cancer in tissues and can provide evidence on the interactive role of epigenetic deregulation in the roadmap between environmental exposures and cancer.

Mutations in Chromatin Remodeling Factors

Katherine A Giles, UNSW Sydney, Sydney, NSW, Australia
Phillippa C Taberlay, University of Tasmania, Hobart, TAS, Australia

Glossary

ATPase A motor enzyme that performs a reaction by ATP hydrolysis.

Chromatin The multilayered protein-DNA structure that packages DNA inside a nucleus.

Chromatin remodeling An ATP-dependent process that mobilizes nucleosomes either by sliding them through DNA or the removal of histone proteins from chromatin. Facilitated by chromatin remodeler complexes.

DNA accessibility Refers to how open or relaxed the chromatin structure is. More "open" chromatin has longer linker DNA between nucleosomes or has a higher nucleosome turnover and is permissible for DNA regulatory factors to bind.

DNA repair The process by which an error in DNA is corrected. There are several pathways for DNA repair that is dependent on the type of damage.

Histone modification The addition of chemical moieties to histone proteins, such as methylation or acetylation.

Nucleosome The basic repeating unit of chromatin that consists of an octamer of histone proteins that accommodates 147 bp of DNA in approximately two helical turns.

Transcription RNA polymerase transcribes or "copies" the coding strand of the DNA into an RNA molecule.

Introduction

DNA does not exist as a linear molecule within a cell; instead it is wrapped around proteins into a dynamic multilayer structure called chromatin. The basic repeating unit of chromatin is the nucleosome, the core of which is comprised of an octamer of histone proteins (two of each histone H2A, H2B, H3 and H4) that accommodates 147 base pairs (bp) of DNA in approximately two helical turns. The H1 linker histone sits outside of the core and influences the orientation of DNA at the entry and exit points of the nucleosome, locking them into position. The length of the linker (inter-nucleosomal) DNA between two nucleosomes varies from ~20–90 bp depending on the degree of chromatin compaction and physiological conditions. A single piece of linker DNA coupled with the nucleosome forms the chromatasome and an array of these structures forms the characteristic "beads on a string" chromatin fiber in the presence of low salt. Chromatin protects DNA from damage and naturally represses gene transcription, unless this state is actively circumvented. Therefore, nucleosomes must be mobilized so that the DNA strand becomes physically accessible to transcription factors, the transcriptional machinery and other chromatin binding factors in order for gene expression to be activated. To do so, two major subclasses of protein complexes are actively recruited to specific genomic regions to control transcription. These are: "chromatin posttranslational modifiers" and "ATP-dependent chromatin remodelers."

The first broad group of chromatin modifiers refers to those that alter histone protein posttranslational modifications (PTMs). These complexes are the epigenomic "writers" and "erasers" that add or remove chemical groups for other complexes to "read" and interpret. PTMs include, but are not limited to: acetylation, methylation, phosphorylation, ubiquitination, sumoylation and poly-ADP-ribosylation. Most of the currently known modifications occur on the histone tails that project out from the nucleosome core, although the globular domains can also be modified, and contribute to the epigenetic landscape of a genomic locus. These epigenetic histone modifications play a critical role in many DNA-based processes and in chromatin stability. There are four broad classes of proteins that are able to "read" histone modifications including; chromatin architectural proteins, ATP-dependent chromatin remodeling enzymes, chromatin modifiers (as many of the enzymes that "write" and "erase" these modifications also contain domains to "read" them) and adapter proteins that recruit molecular machinery for processes such as transcription. For example, the ATP-dependent chromatin remodeler, CHD1, utilizes its tandem chromodomains to recognize and remodel nucleosomes carrying histone 3 lysine 4 is tri- methylation (H3K4me3), a modification found at active gene promoters. When recruited, CHD1 localizes with transcription elongation factors to positively promote transcription at highly transcribed genes. While histone posttranslational modifications are important in chromatin biology, this chapter will instead focus on the role of ATP-dependent chromatin remodelers.

ATP-dependent chromatin remodelers mobilize nucleosomes and alter their physical positions. First, by loosening the DNA around the nucleosome, then by either translocating the nucleosome through the DNA or completely removing the nucleosome from the DNA strand (Fig. 1). Conversely, these complexes can re-position nucleosomes during the process of gene repression and chromatin compaction (Fig. 1). Nucleosome movement is not only essential for transcriptional control, but also for normal cellular processes including cell cycle progression, DNA replication and DNA repair. For example, progression through the cell cycle requires nucleosome compaction for DNA condensation and sister chromatid segregation. During DNA replication, histone cores are loaded onto newly synthesized DNA while the DNA repair process is impaired by the presence of

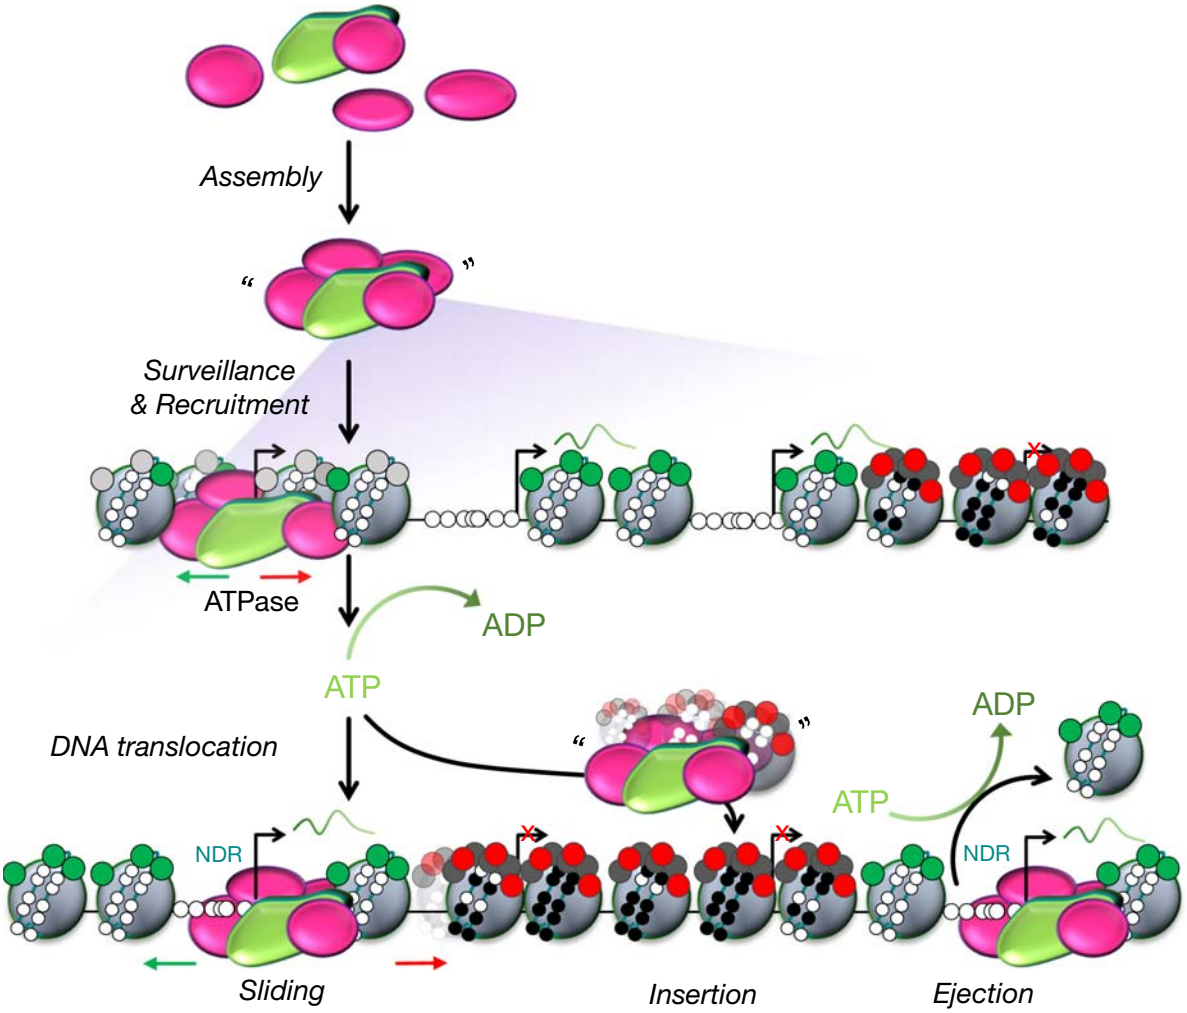

Fig. 1 *Mechanisms of ATP-dependent chromatin remodeling for the alteration of DNA accessibility.* Utilizing ATP hydrolysis, chromatin remodeler protein complexes act on chromatin to modulate the physical positioning of nucleosomes to allow or inhibit the binding of regulatory factors to DNA. Chromatin remodelers do not recognize a particular consensus sequence and continually "survey" chromatin for suitable substrates. On recruitment, chromatin remodelers may slide, insert of eject nucleosomes from chromatin. Mobilization by *sliding* nucleosomes alters the position of the nucleosome and simultaneously changes the length of the internucleosomal DNA fragment. This may involve lengthening (depicted by the *green arrow*), when a nucleosome depleted region (NDR) is formed, or shortening (depicted by the *red arrow*), causing loss of the detectable NDR. Alternatively, nucleosome positions may be altered by *deposition* or *eviction*. In some cases, such as with the INO80-like family, remodelers are able to exchange canonical histones for histone variants, such as dimer exchange of H2A-H2B for H2A.*Z*-H2B. A generic chromatin remodeling complex (pink) with an ATPase subunit (*green*) is depicted. The complex may be recruited to active chromatin (unmethylated at CpG dinucleotides (*small white circles*) and enriched with active histone posttranslational modifications (*green circles*)), poised chromatin (unmethylated and enriched with permissive histone posttranslational modifications (*gray circles*)) or silenced chromatin (methylated and enriched with repressive histone posttranslational modifications (*red circles*) to coordinate sliding, insertion or ejection of nucleosomes (*large gray circles*). Transcriptional start sites are indicated by arrows, and may be active (*green line*) or inactive (*red cross*).

nucleosomes, which must be removed to make DNA accessible to the repair machinery. Chromatin remodelers are also responsible for exchange of canonical histones for variant histones. These histone variants, such as H3.3 and H2A.Z, provide additional resolution at which chromatin structure is controlled by altering the affinity between DNA and the nucleosome core on a finer scale. Hence, chromatin remodelers may be described as the "gate-keepers" of chromatin structure that facilitate or impede access to DNA.

There are four structural families of chromatin remodelers: Switch/Sucrose Non-Fermenting (SWI/SNF), Imitation Switch (ISWI), Inositol 80 (INO80) and chromodomain-helicase-DNA binding (CHD) (Fig. 2). Common features of these complexes include: that they have a high affinity for the nucleosome, have an essential catalytic subunit that utilizes ATP hydrolysis to mobilize nucleosomes, a high degree of similarity between their helicase ATPase domain structures (DExx and HELICc), and that they interact with other regulatory factors (both protein and RNA) to facilitate chromatin control. Despite their common properties, each remodeling family has evolved their own unique mechanistic properties and functions (Fig. 3). SWI/SNF ATPases have a bromo-domain

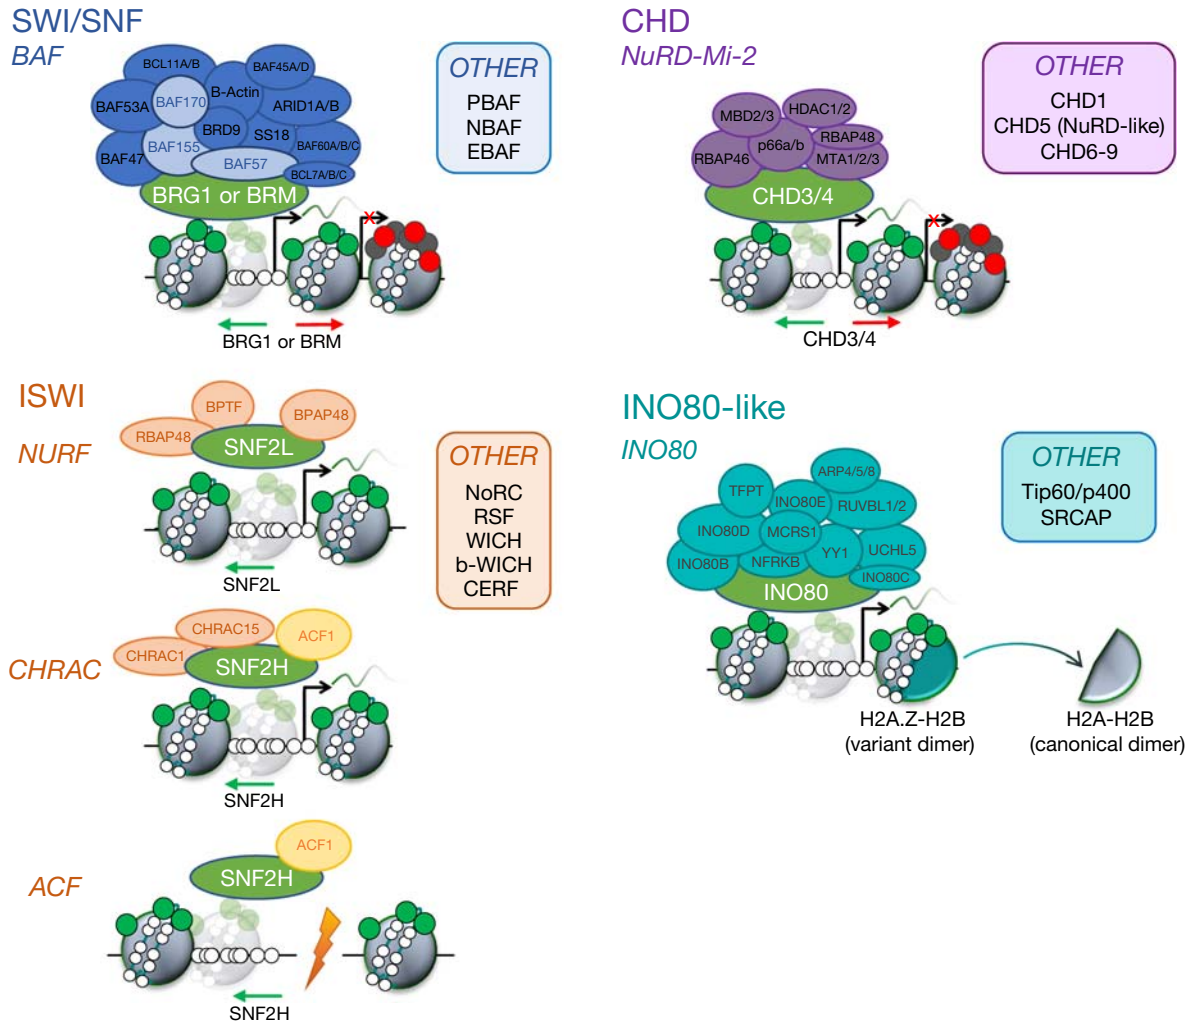

Fig. 2 *The classical organization of ATP-dependent chromatin remodeling families based on the SNF2 ATPase catalytic subunit structure.* Typical subunit composition is shown for common SWI/SNF, ISWI, CHD and INO80-like complexes. *BAF* is a SWI/SNF complex containing either BRG1 or BRM as the ATPase, and is present in most cell types. Other SWI/SNF complexes are present only in certain cell types, such as embryonic BAF (EBAF) in embryonic stem cells. Most SWI/SNF complexes can remodel chromatin ready for transcription activation or repression. *NURF* and *CHRAC* are both ISWI complexes with known roles in transcriptional activation. *NURF* contains the SNF2L ATPase and aberrantly activates oncogenes in cancer cells while *CHRAC* contains the SNF2H ATPase and is known to activate transcription in both normal and cancer cells. *ACF* contains the SNF2H ATPase and remodels nucleosomes after DNA damage (orange lightning bolt). The *NuRD/Mi-2* complex containing the CHD3/4 ATPase is representative of the CHD family that has roles in remodeling chromatin for transcriptional activation or repression. *INO80* from the INO80-like complexes contains INO80 as the ATPase and is activates transcription by nucleosome mobilization and facilitating exchange of the canonical H2A-H2B dimer for the variant H2A.Z-H2B. Nucleosomes, *large gray circles*; CpG sites, *small white circles*; active histone posttranslational modifications, *green circles*; repressive posttranslational histone modifications, *red circles*; transcriptional start site, *arrow*.

recognizing acetylated histones; ISWI ATPases have a HAND/SLANT/SLIDE domain that recognizes nucleosomes and inter-nucleosomal DNA; INO80 complexes have a longer peptide chain between their DExx and HELICc domains that has been proposed to accommodate replication forks and Holliday junction DNA structures, and CHD ATPases have tandem chromo-domains recognizing methylated histones (Fig. 3). The inclusion of divergent additional domains within the ATPase subunit, as well as the variety of accessory subunits recruited, suggests that each remodeler complex can uniquely decode chromatin, accounting for their differing roles within the cell.

Chromatin remodelers are known to utilize two primary mechanisms to identify a target nucleosome. Firstly, they can continually scan chromatin for an appropriate nucleosome substrate, relying on their recognition of histone PTMs and inter-nucleosomal DNA. Alternatively, a remodeler can be recruited to and interact with a sequence-specific protein or noncoding RNA (ncRNA) species at a particular genomic locus when required. Since ATP-dependent chromatin remodelers act generically in the absence of consensus sequences, these cofactors provide an additional layer of chromatin regulation that ensures remodeler complexes are recruited to the right place at the right time.

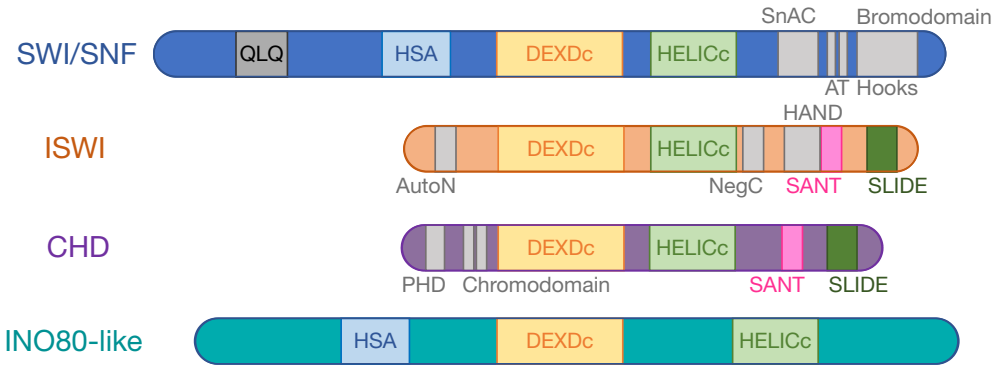

Fig. 3 *Domain structures of the ATPase catalytic subunit of the remodeller families containing their signature motifs.* Each chromatin remodeler contains a core SNF2 ATPase domain consisting of an N-terminal DEXDc and C-terminal HELICc domains (*yellow/green*). The SWI/SNF remodelers also contain a N-terminal helicase-SANT (HSA) domain (*blue*) for actin binding and a C-terminal bromodomain (*gray*) for the recognition of acetylated histones. The ISWI family also contain a C-terminal HAND/SANT/SLIDE domain (*gray/pink/green*) for the recognition of nucleosomes and regulatory domains N-terminal AutoN (*gray*) and NegC (*gray*) C-terminal to the ATPase domain. The CHD family each contain tandem chromodomains (*gray*) and a PHD domain (*gray*, Class II only) for recognizing methylated histones at the N-terminal, and various other domains depending on whether they fall into subclass I, II and III (not all shown). The ISWI remodelers have a split ATPase with a spacer between the DEXDc and HELICc domains, and a N-terminal HSA domain (*blue*), similar to the SWI/SNF family.

The outcomes of recent genomic sequencing studies have revealed that chromatin remodelers are frequently mutated in multiple cancer types. Indeed, the frequency of mutation of the SWI/SNF complex alone rivals that of *TP53*, which is otherwise known as the "guardian of the genome." There are conflicting reports of chromatin remodelers functioning as both tumor suppressors and oncogenes, highlighting the diverse roles that they are likely to play in tumor biology. Modulating chromatin is critical for cell proliferation and it is unsurprising that the factors involved play an important role in cancer initiation and disease progression. Sequencing of cancer genomes has demonstrated that chromatin organization is directly associated with genome-wide mutation rates, where open chromatin as a result of remodeling is more likely to contain indels and substitutions than closed chromatin. As informative links between chromatin remodelers and their role in tumor development have been established, a desire for further insight into both the normal function of these complexes and the mechanisms by which cancer develops as a consequence of their mutation is rising.

SWI/SNF

Of all the remodeling complexes, SWI/SNF has been the most comprehensively studied. It is a large multisubunit complex initially identified in *Saccharomyces cerevisiae* and highly conserved from yeast to humans. Core subunits of this complex include a catalytic ATPase, either the mutually exclusive Brahma (BRM, encoded by *SMARCA2*) or Brahma-related gene 1 (BRG1, encoded by *SMARCA4*), SNF5 (also known as BAF47 and INI1, encoded by *SMARCB1*), BAF170 (encoded by *SMARCC2*) and BAF155 (encoded by *SMARCC1*). Accessory subunits such as the mutually exclusive ARID1A and ARID1B that bind to AT-rich, nonsequence specific DNA are responsible for the targeting, assembly and regulation of SWI/SNF. SWI/SNF mutant cancers demonstrate a role for the complex in DNA repair, proliferation, motility, invasion and metastasis, and genes involved in these processes are generally up-regulated in SWI/SNF deficient tumors. Therefore, it is not unexpected that the expression of SWI/SNF subunits and activity of the complex is altered in several cancer types.

The SWI/SNF complex has a well-characterized role in the normal DNA repair process; defective DNA repair directly results in genome instability and cancer development. There are several reports demonstrating that loss of functional SWI/SNF leads to an increased susceptibility to DNA damage, most likely mediated through interactions between SWI/SNF and the histone variant, γH2A.X. BRG1 normally promotes double stranded break (DSB) repair by binding to acetylated H3 histones at the site of damage in the presence of γH2A.X; thus, loss of BRG1 slows the repair process leading to inefficient repair. Contrary, loss of other subunits within the SWI/SNF complex does not necessarily affect DSB repair pathways. SNF5 and ARID1A deficient tumors exhibit little genome instability, remain diploid and are characteristically normal on single nucleotide polymorphism (SNP) arrays, again highlighting the multifaceted functions that each subunit can have within this complex.

SWI/SNF interacts with and regulates several known cancer associated genes, including genes involved in cell cycle progression (*RB, E2Fs, CCND1, MYC, GLI1*), nuclear receptor signaling (glucocorticoid (*GR*), estrogen (*ER*), androgen (*AR*), vitamin D (*VDR*) and retinoic acid (*RARA*)), and cell-to-cell interaction/adhesion proteins (integrin's and *CD44*). Interestingly, SWI/SNF can both up- and down- regulate the same gene; the outcome being dependent on cellular context. For example, in response to estrogen, SWI/SNF is bound by ER and recruits p300 to activate ER-responsive genes, while estrogen antagonists, such as the tumor suppressor protein Prohibitin, recruit SWI/SNF and HDAC1 to repress these same genes. Similarly, SWI/SNF has a complex role in regulating *MYC* oncogene expression. *MYC* over-expression in a variety of cancers disrupts the expression of genes involved in cell cycle progression, apoptosis and differentiation. SWI/SNF can normally directly repress *MYC*, but in certain cancers such as leukemia, over expression

of the SWI/SNF complex causes chromatin de-condensation at cell-specific enhancer regulatory elements to increase *MYC* expression. The following section outlines the roles played by significant subunits of the SWI/SNF complex in cancer.

SNF5

Some of the strongest evidence linking chromatin remodeling and cancer comes from studies of rhabdoid tumors (RT). RTs are an aggressive, soft-tissue childhood cancer with a poor response to therapy and bi-allelic loss of SNF5 is a defining feature—occurring in 95% of these cancers (**Table 1**). RTs can derive from both somatic and familial mutations in *SMARCB1* (encoding SNF5), which causes gene inactivation by deletion, nonsense, missense and frameshift mutations. Schwannomatosis and occasionally other sarcomas also report a bi-allelic loss of SNF5, and other cancers demonstrating high mutation frequency in SNF5 include colorectal, gastric and bladder (**Table 1**). The use of knockout mouse models further confirm the functional role of SNF5 in RT initiation; SNF5 knockout mice develop RT with a rapid onset, indicating that SNF5 is likely a driver mutation in these cancers.

Loss of SNF5 in RT occurs concomitant with an increase in expression of the Polycomb group (PcG) protein, EZH2. EZH2 is the catalytic subunit of Polycomb repressive complex 2 (PRC2), which contributes to the repression of genes through the tri-methylation of histone 3 lysine 27 (H3K27me3). Depletion of EZH2 in SNF5 deficient tumors is associated with a decrease in cellular proliferation, suggesting that EZH2 is required for the growth of these tumors. This is in part due to the role that SNF5 and the PcG proteins play in the regulation of key tumor suppressor genes. For example, SNF5 is required for activation of the *INK4b-ARF-INK4a* locus and in the absence of SNF5, epigenetic repression of this region is initiated by EZH2 and the PcG proteins. This study also demonstrated that with re-expression of SNF5 into a SNF5-deficient RT human cell line, PcG proteins were evicted from the *INK4b-ARF-INK4a* locus and that the activity of the SWI/SNF complex was restored. Moreover, the authors noted that the mixed lineage leukemia 1 (MLL1) histone posttranslational modifier is recruited following PcG eviction, in order to restore an active epigenetic signature on histone 3 lysine 4 (H3K4).

Precisely how atypical SNF5 expression disrupts the function of SWI/SNF is unclear. It is possible that aberrant SNF5 expression alters the composition of the SWI/SNF complex, driving atypical interactions with other proteins in a context dependent manner to promote tumorigenesis. In SNF5-deficient cell lines, continued growth is reliant on increased expression of BRG1, which could explain why loss of SNF5 in cancers activates gene expression pathways to promote growth whilst in primary cells it triggers cell cycle arrest. Indeed, several cell cycle dependent proteins are consequently disrupted following loss of SNF5. One example is of p16INK4A, a cyclin-dependent kinase (CDK) inhibiting cyclinD1-CDK4 phosphorylation, which the downregulated concomitant with SNF5 inactivation. Conversely, expression of cyclinD1 itself, MYC and E2F target genes are elevated.

SNF5 loss has been linked to the disruption of cancer promoting signaling pathways. Hedgehog signaling is essential for the growth of RTs and is up-regulated in SNF5-deficient tumors. *RHOA* stimulates cell migration, actin stress fiber formation and contractility. When SNF5 is lost, *RHOA* expression increases which is correlated with poor prognosis in cancer. These data suggest that SNF5 has broad roles in establishing the cancer phenotype, potentially by driving aberrations in histone posttranslational modification marking at gene regulatory regions.

BRG1 and BRM

A SWI/SNF complex always contains either BRG1 or BRM as two possible alternative ATPases. While they share approximately 75% sequence homology, BRG1 has a unique N-terminal domain not existent in BRM, through which it can bind to zinc-finger proteins. BRG1 and BRM have partially overlapping functions and therefore may offer some compensation when one of them is lost or disrupted in cancer. However, the ATPases also have clearly defined roles since BRG1, but not BRM, is embryonic lethal. Both BRG1 and BRM suppress cancer development through control of the cell cycle and cell-to-cell adhesion. In cancer cell lines deficient of both functional BRG1 and BRM, re-expression of either ATPase can induce Rb-mediated cell cycle arrest. Similarly, loss of BRG1 and/or BRM in lung cancer drives cancer development and alters cell-to-cell contacts through an increased *VIM* expression and down-regulation of *CDH1*, *CD44* and *CSF-1*. Furthermore, BRG1 has a synthetic lethal relationship with BRM and research has shown that cancers depend on BRM for growth and survival. Loss of BRM in these cancers results in cell cycle arrest, senescence and increased tri-methylation of H3K9 (H3K9me3). The cancer-specific differences in SWI/SNF activity may be partially explained by the variance in expression of BRG1 and BRM in tumors, which likely alters feedback loops that balance tumor suppressive and oncogenic activity of SWI/SNF.

SMARCA4 (encoding BRG1) is down-regulated in bladder, colon, nontriple negative breast cancers, head and neck, esophageal, melanoma, pancreatic and ovarian cancers; where mutation rates have been reported between 4% and 13% in these cancers (**Table 1**). Conversely, *SMARCA4* is over-expressed in cancers of the prostate, triple negative breast cancers and some leukemias (**Table 1**). Interestingly, no *SMARCA4* mutations have been reported in cancers over-expressing BRG1, suggesting that atypical *SMARCA4* expression may have an epigenetic basis, although this has not been experimentally confirmed. The context-dependent function of BRG1 makes it difficult to fully define its role in cancer; however, there is sufficient evidence that the balance between tumor suppressive and oncogenic activity of BRG1 is important.

Functional studies have assessed the outcomes of both depletion and restoration of the BRG1 protein. Aberrant BRG1 expression disrupts proliferation, cell motility and epithelial to mesechymal transition (EMT). For example, in combination with lung-specific carcinogens, haploinsufficiency of *SMARCA4* increases the likelihood of lung cancer development while conversely, re-expression of BRG1 protein in lung cancer cells reduces proliferation, metastasis and EMT via up-regulation of miR-148b. Mechanistic studies in cell lines demonstrate changes in cell motility occur concomitant with BRG1 depletion and similarly, the loss of BRG1 in a pancreatic cancer cell line stimulates actin stress fibers and motility. Conversely, in a cervical cancer cell line deficient in BRG1, restoration

Table 1 Summary of SWI/SNF subunits with an identified role in cancer as either a tumor suppressor and/or an oncogene

Gene	*Protein*	*Function*	*Tumor suppressor*	*Oncogene*
SMARCB1	SNF5/INI1/BAF47	Binds to lateral surface of the nucleosome, scaffold	Bladder, colorectal, gastric, rhabdoid tumors, sarcoma, Schwannomatosis	
SMARCA4	BRG1	ATPase, mutually exclusive with BRM, interacts with acetylated histones	Bladder, breast (except triple negative), cholangiocarcinoma, colorectal, esophagus, gastric, head and neck, lung, medulloblastoma, melanoma, ovarian, pancreatic, uterine	Colorectal, leukemia, prostate, triple negative breast cancer
SMARCA2	BRM	ATPase, mutually exclusive with BRG1, interacts with acetylated histones	Adenoid, bladder, colorectal, gastric, lung, prostate, uterine	
ARID1A	ARID1A/BAF250a	Nonsequence specific DNA binding, mutually exclusive with ARID1B	Bladder, breast, Burkett's lymphoma, cervical, cholangiocarcinomas, colorectal, endometrial, esophagus, gastric, heptoblastoma, liver, lung, medulloblastoma, melanoma, neuroblastoma, ovarian clear cell, pancreatic, prostate, renal, sarcoma	
ARID1B	ARID1B/BAF250b	Nonsequence specific DNA binding, mutually exclusive with ARID1A	Bladder, breast, cervical, colorectal, esophagus, gastric, melanoma, lung, sarcoma	
SMARCE1	BAF57	Interacts with nuclear receptors and DNA, HMG domain		Breast, endometrial, ovarian, prostate
BRD7	BRD7	Interacts with acetylated histones	Breast, colorectal, gastric, lung, ovarian, prostate	
ARID2	ARID2	Role in NER damage response pathway	Bladder, colorectal, esophagus, gastric, hepatocellular, lung, melanoma, NSCLC, uterine	
PBRM1	BAF180	Interacts with acetylated histones	Bladder, breast, cholangiocarcinoma, clear cell renal cell carcinoma, gastric, head and neck	
SMARCC2	BAF170	Role in neural differentiation	Bladder, gastric	
SMARCC1	BAF155	Interacts with SNF5 through SWIRM domain	Colorectal, gastric, lung	
SMARCD1/2/3	BAF60A/B/C	Role in cellular senescence, lipid, nutrient and energy, metabolism	Colorectal	
ATRX	ATRX	ATRX/DAXX complex, ATPase, DNA damage response, heterochromatin formation, deposits H3.3 into chromatin	Brain, osteosarcomas	

of BRG1 resulted in reduced actin stress fibers and increased expression of *ROCK1*, a major driver of cell motility. By contrast, over-expression of BRG1 promotes proliferation and cancer development. Several studies have reported that *SMARCA4* over-expression in prostate cancer is a feature correlated with disease progression and invasiveness. In leukemia, BRG1 plays a role in regulating the actin cytoskeleton and proliferation, where loss of BRG1 down-regulates hedgehog signaling, decreases proliferation via down-regulation of *MYC*.

Unlike the divergent BRG1 expression profiles observed between cancers and cancer subtypes, the BRM ATPase is typically depleted. This is consistent with the observations that BRG1 has both tumor suppressive and oncogenic roles, while all studies of BRM in tumors suggest that it acts solely as a tumor suppressor. This is supported by the observation that BRM loss correlates with advanced disease in prostate and lung cancers (**Table 1**). Indeed, there is an anticorrelation between the proliferative markers, ki-67 and E2F1, and BRM in these cancers. In prostate cancer, BRM loss occurs concomitant with an increased rate of EMT and perturbed cell cycle progression. Moreover, decreased BRM expression leads to increased androgen-dependent growth, and homozygous deletion of BRM in prostate epithelial cells causes acquisition of lobe-specific, castration-resistant proliferation. BRM is silenced in 15% of nonsmall cell lung cancer (NSCLC), and lung tumors with loss of BRM have a lepidic growth pattern pathology and *EGFR* mutations. Two studies conducted in cancer cell lines found no evidence of deleterious BRM mutations, and in both of these studies, BRM expression was restored following treatment with histone deacetylase (HDAC) inhibitors. These data suggest that BRM is epigenetically silenced and is supported further by work showing that certain mutations, BRM-741 (rs34480940) and BRM-1321 (rs3832613), in the BRM promoter facilitate the binding of HDACs. Interestingly, tumors with these genetic variants are associated with worse overall survival.

BRG1 and BRM expression changes can at least be partially attributed to epigenetic mechanisms, indicating that epigenetic therapies could be effective for cancers deficient in either BRG1 or BRM. Epigenetic therapies to alter BRG1 expression are of particular interest in cancers traditionally treated with the chemotherapeutic agent, cisplatin; cancers with reduced BRG1 are more sensitive to this line of treatment. Work in head and neck cancer cell lines with knockdown of either BRG1 or BRM found the enhanced sensitivity of cancer cells to cisplatin was through the reduced repair of intrastrand adducts and interstrand crosslink formation and cisplatin-induced DSB repair was impaired from ineffective recruitment of ERCC1 for later stage repair. Furthermore, this study demonstrated that altered cell cycle checkpoint activation and enhanced apoptosis in these cancers. In BRM depleted cancers, there is potential use for HDAC inhibitors. Treatment of lung cancer cells with HDAC inhibitors restored BRM expression, but inhibited BRM function. Removal of HDAC inhibitors kept BRM expression elevated for a few days and the complex was functional before BRM levels again were depleted. Future targeting of this pathway must refine the HDAC inhibitors to reduce the impact on BRM function.

ARID1A and ARID1B

The AT-rich interactive domain (ARID) subunits, ARID1A and ARID1B, are mutually exclusive within the SWI/SNF complex. They facilitate interaction with DNA that is not sequence specific. While these subunits share approximately 60% sequence homology, they are nonredundant. SWI/SNF complexes containing ARID1A repress *MYC*, but complexes with ARID1B increase *MYC* expression. Additionally, as cells progress through the cell cycle the expression of ARID1A decreases and ARID1B increases.

ARID1A is one of the most frequently mutated genes in a variety of primary tumor types. Its down-regulation positively correlates with tumor progression, indicating that its main role is that of a tumor suppressor. Loss of function mutations in *ARID1A* have been identified in bladder, colorectal, breast, Burkitts Lymphoma, cervical, endometrial, gastric, melanoma, medulloblastoma, uterine corpus endometrioid carcinomas, neuroblastoma, cholangiocarcinomas, carcinosarcomas, ovarian clear cell, lung, pancreatic, prostate, renal and heptoblastoma cancers (**Table 1**). Many of these cancers have heterozygous mutations in ARID1A and express a lower level of the protein. Indeed, it has been observed that loss of ARID1A, BRG1 or SNF5 can occur without complete loss of function in some leukemias. Conversely, in ovarian clear cell carcinomas, one of the most lethal subtypes of ovarian cancer, approximately 50% of cases present with a mutation in *ARID1A* and the majority of these express a truncated form of the ARID1A protein. Interestingly, *ARID1A* mutations are more frequent in solid tumors, particularly in the gastrointestinal tract, than hematopoietic cancers.

ARID1B mutations have been identified in bladder, breast, colorectal, carcinosarcomas, lung, melanoma, cervical and gastric cancer (**Table 1**). Loss of ARID1B is detrimental to cells and mutations are known to cause a host of other diseases and syndromes relating to intellectual disability and developmental delays. A recent study has found that ARID1B expression is required in order for ARID1A-deficent tumors to survive. Cancers with a homozygous deletion of *ARID1A* can tolerate a heterozygous mutation in *ARID1B*, where only one functional copy is sufficient for tumor survival. The loss of both *ARID1A* and *ARID1B* destabilizes SWI/SNF and reduces proliferation of affected cells. This suggests that ARID1B could be a therapeutic target in ARID1A deficient cancers, providing another therapeutic angle through which to target SWI/SNF mutant cancers, and development is underway for small molecule inhibitors of ARID1A and ARID1B.

Other SWI/SNF subunit mutations

BAF57 is an accessory subunit of SWI/SNF that is only present in higher eukaryotes. BAF57 plays a direct role in determining how the SWI/SNF complex interacts with chromatin, as it contains both a high mobility group domain and DNA binding properties. There is no evidence supporting a direct role for BAF57 in the initiation of cancer but rather, in cancer progression where increased BAF57 expression correlates with tumor grade, invasion and metastasis. In breast, ovarian, prostate and endometrial carcinoma BAF57 tends to have elevated expression (**Table 1**); indeed, 38% of endometrial carcinomas are reported to exhibit increased

BAF57 expression. Mutations have only been reported in breast cancer cell lines. As part of its normal and cancer related functions, BAF57 interacts and promotes the activities of GR, AR and ER nuclear hormone receptors. In prostate cancer, BAF57 interacts with AR to increase the expression of α2-integrin, giving those cells a metastatic advantage. In breast cancer, BAF57 expression correlates with expression of PTK2, a key player in migration, motility and adhesion to promote metastasis. Loss of BAF57 decreases the rate of breast cancer metastasis to the lung and furthermore, BAF57 depletion causes a subsequent down-regulation of ER target genes. In ovarian cancer, BAF57 expression strongly correlates with sensitivities to cisplatin, doxorubicin and 5-fluorouracil, and depletion of BAF57 in ovarian cells increases the number of cells arresting in the G1 phase of the cell cycle.

BRD7 is a tumor suppressor that is down-regulated in breast, lung, gastric, colorectal, ovarian and prostate cancer (**Table 1**). While low levels of BRD7 have determined it to function as a tumor suppressor, no significant mutations have been identified. BRD7 has a bromodomain, indicating that it contributes to the localisation of SWI/SNF at loci enriched with acetylated histones. In breast cancer, BRD7 binds to the *ESR1* promoter (an ER protein) and while BRD7 depletion does not affect the recruitment of SWI/SNF and RNA polymerase II (RNA PolII) to *ESR1*, it does reduce ER expression. BRD7 is also a binding partner of BRCA1 and p53, coregulating many of the same genes. In lung cancer, when BRD7 is over-expressed it inhibits proliferation through the down-regulation of *CCND1* and *MYC*. It can also down regulate AKT to promote apoptosis.

ARID2 is only found in the PBAF form of the SWI/SNF complex, and is mutated in bladder, colorectal, esophageal, gastric, hepatocellular, lung, melanoma, NSCLC and uterine at a rate of approximately 5%–10% (**Table 1**). It is one of the most frequently homozygous deleted genes in NSCLC and has been identified as a driver mutation in melanoma. Additionally, the four major subtypes of hepatocellular carcinoma all harbor increased ARID2 mutation rates. Little is known about the mechanistic effects of ARID2 mutations or atypical expression of ARID2 in cancer, but it is proposed that ARID2 alterations disrupt the nucleotide excision repair (NER) pathway by inhibiting the recruitment of xeroderma pigmentosum complementation group G (XPG).

BAF180 has essential functions with the cell, is important for normal development and is embryonic lethal in mice. It has been suggested that BAF180 provides functional specificity via its six bromodomains that each have different targeting affinities, as well as a high-mobility group domain recognizing nucleosomes. Loss of function mutations in the BAF180 subunit have been identified in clear cell renal cell carcinoma (ccRCC) and breast cancer. It is the second most commonly mutated gene in ccRCC after *PTEN*, where it is inactivated in 40% of these cancers (**Table 1**). Loss of BAF180 promotes proliferation while re-expression of BAF180 causes G1 arrest, likely through its ability to inhibit p21 expression. BAF180 also plays a role in regulating p53 activity, suggesting that aberrations in this gene would have a general and widespread role in cancer development.

ISWI

ISWI is a large and diverse family of remodeler complexes. Each has specialized functions including DNA repair, replication and transcription. At the core of each ISWI complex is an ATPase: either SNF2H or SNF2L. The SNF2 ATPase forms the ISWI complexes; WSTF-ISWI chromatin remodeling complex (WICH) with WSTF, B-WICH complex containing WSTF and nuclear myosin I, Nucleolar remodeling complex (NoRC) with TIP5, Remodeling and spacing factor (RSF) with RSF, ATP-utilizing chromatin remodeling and assembly factor (ACF) with ACF1 and chromatin assembly complex with ACF1, CHRAC15 and CHARC17. SNF2L forms the ISWI complex Nucleosome Remodeling factor (NURF) with BPTF, RBAP46, and RBAP48 and both SNF2L and SNF2H can form CERC2-containing remodeling factor (CERF) with CECR2. Homologues of ISWI are found in a range of species, and have a highly conserved role in chromatin biology. ISWI proteins are generally tumor suppressors and display loss of function mutations in cancer. However, there are cases of ISWI-associated subunits acting as oncoproteins. ISWI has a well-studied role in DNA repair, forming part of the homologous repair (HR), nonhomologous end joining (NHEJ) and NER pathways.

SNF2H and SNF2L

SNF2H mutations have been identified in approximately 5% of colorectal and uterine cancers (**Table 2**). Alternatively, down-regulation of SNF2H in cancer can be mediated by miR-99a and miR-100 species. Loss of functional SNF2H affects the fidelity of DNA repair in cancer. Ordinarily, the ACF and WICH SNF2H complexes are both recruited to the site of DNA damage by transcription factors and histone modifications for the repair process. During DSB repair SIRT6 deacetylates histone 3 lysine 56 (H3K56), and both SIRT6 and SNF2H coordinate to incorporate γH2A.X into chromatin, then the ACF SNF2H remodeling complex relaxes chromatin at the break site. In response to UV damage, ACF and WICH SNF2H complexes respond and require a functional SLIDE domain of SNF2H to proceed with repair. After deposition at the damage site, SNF2H uses its HAND domain to reposition itself away from the center of the damage ready for the next stage of repair. SNF2H also has an important role in chromatin architecture. SNF2H, but not SNF2L is involved in the positioning and phasing of nucleosomes around CTCF binding sites. Defects and delays in DNA repair, along with loss of well-positioned nucleosomes at CTCF sites can lead to genomic instability and cancer progression in cases where SNF2H function is lost.

SNF2L is mutated at a higher rate than SNF2H, at around 4%–12% in cholangiocarcinomas, uterine, colorectal and gastric cancers (**Table 2**). However, there have been conflicting reports regarding differences in expression and function of SNF2L. In melanoma, it was found that SNF2L protein levels were undetectable in malignant cells compared to normal melanocytes. In the HeLa cervical cancer cell line, a functional study has indicated that atypical SNF2L expression causes an increase in cell proliferation and migration, through the activation of Wnt signaling pathways. Conversely, the results of another study that compared multiple cell lines indicated that SNF2L expression was highly similar between normal and cancer cells, but that cancer cells are sensitive to SNF2L knockdown. This same study found that SNF2L loss inhibits growth, down regulates p53 and p21, up regulates cell cycle

Table 2 Summary of ISWI subunits with an identified role in cancer as either a tumor suppressor and/or an oncogene

Gene	*Protein*	*Function*	*Tumor suppressor*	*Oncogene*
SMARCA5	SNF2H	ATPase, nucleosome phasing at CTCF sites, DSB damage response	Colorectal, uterine	
SMARCA1	SNF2L	ATPase, regulates transcription, DNA damage response	Cholangiocarcinomas, colorectal, gastric, uterine	
BAZ1A	ACF1	ACF ISWI complex, found at replicating pericentromeric heterochromatin, relaxes chromatin at DSB	Colorectal, esophageal, gastric, melanoma, renal cell carcinomas, squamous cell carcinoma, uterine	
BAZ1B	WSTF	WICH ISWI complex, regulates genes in EMT and proliferation pathways, involved in UV DNA damage response		Colorectal, lung
BAZ2A	TIP5	NoRC ISWI complex, shifts nucleosomes to induce DNA methylation, H4 hypoacetylation and H3K9 methylation for heterochromatin formation	Colorectal, lung, melanoma, uterine	Prostate
CECR2	CECR2	CECR2 ISWI complex, inhibits γH2A.X stability, recognizes acetylated histones, histone chaperone	Melanoma, Oligodendroglioma	Adrenal gland, breast, colorectal, esophagus, liver, lung, ovarian, uterine
BPTF	BPTF	NURF ISWI complex, recognizes residues 1–15 of H3K4, regulates HOX gene expression, up regulates EMT and pro survival pathways	Bladder, cholangiocarcinoma, colorectal, gastric, lacrimal gland adenoid cystic carcinomas, lung, melanoma, prostate	Heptacellular, lung, NSCLC, melanoma
RSF1	RSF1	RSF ISWI complex, histone chaperone, DSB repair	Colorectal, gastric, melanoma	Breast, lung

checkpoint genes, increases the phosphorylation of DNA damage response proteins as well as the level of DNA damage, and increases apoptosis. As SNF2H and SNF2L are generally not part of the same ISWI complex, the sensitivity of cancer cells to SNF2L loss could be attributed to lack of compensation from other chromatin remodeling complexes.

ACF1

ACF1 (ATP-utilizing chromatin assembly and remodeling factor 1, encoded by *BAZ1A*) is mutated in approximately 5% of all cancers (Table 2). Renal cell carcinomas have diverse copy number variants, many involving ACF1. Additionally, chromosome 14 q12-q13, where ACF1 is located is frequently amplified and over-expressed in esophageal squamous cell carcinoma. Enrichment of ACF1 is found at replicating pericentromeric heterochromatin, which is a barrier to DNA repair and correlates with somatic mutation rates in cancer. ACF1-containing ISWI complexes have a role in DNA repair, by relaxing chromatin at the DSB site. Indeed, the accumulation of DNA damage as a result of ACF1 repression further delays progression through S-phase of the cell cycle.

WSTF

WSTF (Williams syndrome transcription factor, encoded by *BAZ1B*) is partnered with SNF2H, in the WICH ISWI complex and is mutated in 5% of cancers (Table 2). A study examining any protein containing a kinase domain across colorectal cancer development, reported WSTF was significantly increased in these cancers. Moreover, over expression of WSTF in lung cancer promotes several cellular processes essential for cancer development including proliferation, colony formation, migration, invasion and EMT. Specifically, the EMT gene *fibronectin* and EMT-inducing genes *FOS*, *CEACAM6* and *N-cadherin* are up-regulated concomitant with increased WSTF. There is also up regulation of the PI3K/AKT pathway. In T-cells, it has been noted that WSTF senses L-arginine levels to promote cellular survival. Elevated L-arginine levels induce a metabolic change, which directly impacts T-cell metabolic fitness and is crucial for their antitumor response.

As is observed for many chromatin remodelers, WSTF also has a role in DNA repair. It forms a complex with RUNX2, INTS3 and γH2A.X in response to UV damage and interacts with phosphorylated γH2A.X (pTyr142) to maintain γH2A.X at sites of DNA damage. Following depletion of the oncoprotein, RUNX2, the interaction between WSTF and γH2A.X is lost, while WTSF deletion causes abnormal γH2A.X signals in early pachytene of meiosis.

TIP5

TIP5 (encoded by *BAZ2A*) is part of the ISWI NoRC complex. This complex shifts nucleosomes to induce DNA methylation, H3K9 methylation, and hypoacetylation of H4. TIP5 has a TAM (TIP5/ARBP/MBD) domain that contains a unique C-terminal extension for binding to RNA. The TAM domain binds to ncRNA, which targets the NoRC complex to the genome by recognition of histone 4 lysine 16 acetylation (H4K16ac). Binding to this mark by NoRC mediates heterochromatin formation at rRNA genes, centromeres and telomere repetitive elements to preserve the structural integrity of chromatin. Loss of a functional NoRC complex causes

centromeric and telomeric heterochromatin relaxation, abnormalities in mitotic spindle assembly, impaired chromosome segregation during mitosis and increased genome instability. Conversely, when critical sites of the TAM domain are mutated, ncRNAs can no longer bind and expression of rRNA genes increase. Silencing of rRNA genes drives cells into senescence, therefore an increase in TIP5 expression may induce senescence in cancer cells where TIP5 has been lost. TIP5 is over-expressed in prostate cancer and a potential marker for disease reoccurrence and metastasis (Table 2). TIP5 directly interacts with the PRC2 protein EZH2 and together they regulate genes involved in metastasis progression. In addition, over-expression is associated with the CpG Island methylator phenotype (CIMP) in prostate cancer.

CECR2

Cat eye syndrome chromosome region candidate 2 (CECR2) forms ISWI complexes with both SNF2H and SNF2L. In the testis, CECR2 predominately associates with SNF2H and in the neuronal cells of an embryo, with SNF2L. It contains a bromodomain, recognizing acetylated histones. CRCR2 has diverse roles in cancer and is mutated in approximately 5% of cases including in oligodendroglioma and melanomas (Table 2). It is up-regulated in cancers of the adrenal gland, breast, colorectal, liver, lung, ovarian, esophagus and the urinary tract. In leukiemas, it is a fusion partner of ASXL proteins. CECR2 is a novel DNA damage repair protein and has strong inhibitory activity on γH2A.X stability, though little else is known about the function of CECR2 in remodeling and cancer development.

BPTF

The bromodomain and PHD domain transcription factor (BPTF) is the largest subunit in the NURF ISWI complex. It recognizes residues 1–15 of H3K4, specifically binding when it is tri-methylated at active gene promoters. BPTF has a key role in development, regulating HOX gene expression and development of the mesoderm, endoderm and ectoderm. It is also essential for proper differentiation of mammary stem cells, T-cells and melanocytes.

As with CECR2, BPTF has diverse affects in different cancers. BPTF is mutated in almost 30% of lacrimal gland adenoid cystic carcinomas, involved in translocations of both prostate and lung cancer and frame shift mutations in gastric and colorectal cancer (Table 2). BPTF is over-expressed in melanoma, NSCLC, lung adenocarcinomas and HCC, where it is associated with poor prognosis and metastasis. The tumor promoting activity of BPTF has been linked to the up-regulation of EMT and pro-survival pathways, through partnership with c-MYC. It has been demonstrated that depletion of BPTF from T-cells improves antigen processing and tumor antigenicity, while in mammary cells, it results in loss of open chromatin, particularly at enhancers.

INO80-Like

The INO80-like family includes the ATPases INO80, SRCAP and p400. These complexes are involved in transcription, but have a more prominent role in DNA repair, DNA replication and exchange of histone variants. This includes the insertion of H3.3 and exchange of the canonical H2A−H2B dimer for H2A.Z-H2B at active promoters, active enhancers and at sites of DNA damage. Interestingly, while all INO80-like complexes can exchange histone variants, only INO80 and not SRCAP and p400, can translocate nucleosomes and only the p400 complex has the ability to acetylate H2A.Z through its subunit Tip60.

INO80 complexes

A significant rate of mutations in the INO80 ATPase has not been found in cancer. However, over-expression of INO80 has been reported in melanoma, NSCLC, cervical tumors and cervical cancer cell lines. In melanoma (Table 3), INO80 is required for expression of known oncogenes and tumor growth. In these cancers, INO80 occupies and increases chromatin accessibility at enhancers of tumor development genes. It is also known that recruitment of INO80 to Sox9 and MITF target genes activates genes for melanoma progression and when INO80 is silenced in melanoma cell lines there is an impairment of BRAF- and NRAS-directed tumorigenesis, as well as tumor maintenance. INO80 has a similar role in NSCLC, where it is required to facilitate chromatin de-compaction at enhancers of lung cancer associated genes and therefore, INO80 expression negatively correlates with lung cancer prognosis. In cervical cancer cells, inhibition of INO80 hinders cancer growth by initiating G1/G0 arrest, but does not affect migration and metastasis.

INO80 complexes can also contribute to cancer progression through their involvement in DNA repair, telomere stability, replication and transcription. INO80 interacts with YY1 for HR directed repair and is important for the recruitment of 53BP1, but not Rad51. This suggests that INO80 complexes have a role in the early stages of the DNA repair pathway. Deletion of either the INO80 ATPase or accessory subunit, ARP5, hampers the repair of UV-induced DNA lesions, which occurs due to the inability of DNA repair factors to assemble at the site of damage. Loss of the INO80 complex inhibits proliferation in a p21 dependent manner and creates defects in telomere structure.

INO80 has a known role in normal cells promoting progression of the replication fork through the chromatin template after stalling. This is mediated by an interaction between INO80 with CDC48, and together they evict RNA pol II from transcribed genes after a collision with the replication fork and mediate its degradation. Aberrant INO80 function preventing replication fork progression has the potential to jeopardize the completion of genomic DNA replication, and a subsequent loss of genome integrity that is likely to contribute to cancer progression.

Table 3 Summary of INO80 like complex subunits with an identified role in cancer as either a tumor suppressor and/or an oncogene

Gene	*Protein*	*Function*	*Tumor suppressor*	*Oncogene*
INO80	INO80	ATPase, loads H2A.Z-H2B dimers onto chromatin, translocates nucleosomes		Cervical, melanoma, NSCLC
SRCAP	SRCAP	ATPase, loads H2A.Z-H2B dimers onto chromatin	Bladder, colorectal, gastric, head and neck, lung, melanoma, nasopharyngeal, prostate, uterine	
EP400	p400	ATPase, loads H2A.Z-H2B dimers onto chromatin	Breast, colorectal, gastric, head and neck, lymphoma, prostate	
ERCC2	ERCC2/XPD	Role in transcription and UV damage and NER	Gastric, melanoma, uterine	
ACTR5	ARP5	Stimulates ATP hydrolysis and nucleosome sliding	Colorectal, gastric, melanoma	
KAT5	TIP60	p400 complex, acetyltransferase of H2A, H2A.Z, H2A.X, H4	Breast, head and neck squamous cell carcinoma, lymphoma, prostate	
TRRAP	TRRAP	p400 complex, required for MYC transformation, reduces proliferation gene, recruits p400 to sites of damage	Brain, melanoma	Brain
RUVBL1/2	RUVBL1/2	AAA+ ATPase, All INO80 like complexes, regulates TERT and proliferation genes		Colorectal, gastric, pancreatic

SRCAP complexes

Like INO80, Snf-2-related CREB-binding protein activator protein (SRCAP) complexes have a role in histone variant exchange. SRCAP is a known coactivator of transcription factors that interact with CBP and knockdown of SRCAP reduces the level of H2A.Z deposition within chromosomes. However, as H2A.Z is generally associated with active regions of the genome and de-condensed chromatin, it is interesting that SRCAP can be found at both active and inactive promoters. This suggests the SRCAP complex is poised at its target genes for activation upon the correct cellular signaling cascade.

Mutations in *SRCAP* have been identified in bladder, colorectal, gastric, head and neck, lung, melanoma, nasopharyngeal, prostate and uterine cancers ranging from 5% to 10% (**Table 3**) and colorectal cancers with mutated SRCAP demonstrate a high level of chromosome instability. In prostate cancer, SRCAP is a known coactivator of AR and directly targets PSA (*KLK3*). When SRCAP is lost in prostate cancer cells there is a subsequent decrease in the amount of H2A.Z enrichment at the *KLK3* promoter, a decrease in PSA gene expression and inhibited cell growth.

As with INO80 complexes, SRCAP can also contribute to cancer through the DNA damage pathway. SRCAP facilitates repair by exchanging H2A.Z-H2B dimers and is also important for the recruitment of RPA and Rad51 to break sites for DSB repair. In colorectal cancer, mutated SRCAP confers resistance to DNA damage and increases genomic instability.

p400 Complexes

p400 is a large complex with tumor suppressor activity in both primary human tumors and mouse cancer models. Mutations have been reported in head and neck, breast, prostate, colon and gastric cancers as well as lymphoma. Expression of the p400 complex is significantly down-regulated in breast cancer and in 61% of gastric cancers (**Table 3**), displaying a high correlation with invasion and metastasis in these cancers.

p400 has essential roles in transcription and DNA damage. It plays an important role in ER signaling in breast cancer, where p400 loads histone variant H2A.Z at ER responsive promoters. Inhibition of p400 and H2A.Z slows growth of breast cancer cells, and conversely over-expression of p400 increases proliferation. p400 is required for efficient DNA repair where its recruitment to sites of DNA damage is independent of ATM signaling. At DSBs p400 is required for RNF8-directed ubiquinitation of chromatin and the recruitment of repair factors BRCA1, 53BP1 and Rad51.

TIP60 is a lysine acetyl transferase (KAT), also known as KAT5, of the MYST family of acetyltransferases. TIP60 is only present in the p400 complex and not in other INO80-like complexes; its role is to acetylate H2A.Z, H2A.X, H2A and H4. TIP60 is frequently mutated in breast cancer, head and neck squamous cell carcinoma, lymphoma and prostate cancer (**Table 3**). Free H2A.Z is known to stably associate with TIP60 in the nucleus; H2A.ZK5ac strengthens this interaction and assists p400-driven deposition of H2A.Z-H2B dimers into chromatin. TIP60 is an essential part of the DNA damage response and is required to acetylate histone proteins at the site of damage, which facilitates the chromatin opening. Depletion of TIP60 reduces the rate and efficiency of DNA repair causing an accumulation of DSBs and widespread genome instability. After damage is repaired, TIP60 is required to acetylate H2A.X, which signals for H2A.X's removal from chromatin. TIP60 also has roles in transcription activation. It is a coactivator of AR and prostate cancer biopsies show TIP60 accumulates in the nucleus compared to normal prostate cells. In both xenografts and LNCaP (Lymph Node Cancer of the Prostate) cells withdrawal of androgens increases the levels of TIP60.

Accessory subunit of p400, Transformation/Transcription domain associated protein (TRRAP), has been reported as both a tumor suppressor and oncogene in brain cancer (**Table 3**). Loss of TRRAP reduces proliferation and increases sensitivity to apoptotic stimuli in brain tumors; however, TRRAP also interacts with MYC and E2F oncoproteins and is essential for MYC induced transformation. TRRAP helps recruit the p400 complex to sites of DNA damage, where TIP60 then normally acetylates histones, and

allows p400 to remodel chromatin into an open configuration allowing entry of repair machinery. TRRAP is also mutated in 4% of melanomas (Table 3).

RUVBL1 and RUVBL2

RUVBL1 and RUVBL2, also known as TIP48 and TIP49, are present in each of the INO80-like complexes. RUVBL1/2 are AAA+ ATPases with a hexamer ring structure and together they form a heterodimer. Depleting both these proteins in human cells and also in mouse models has shown they are essential for cellular proliferation. Studies have shown that cells in which RUVBL2 is knocked down are moderately more sensitive to anticancer therapies including cisplatin and 5-Aza-2′-deoxycytidine, and there is reduced cell growth after treatment.

Driver mutation events have to date not been identified in RUVBL1/2, but they are overexpressed in colorectal, gastric and pancreatic cancers contributing to cancer growth through a number of mechanisms (Table 3). Pancreatic ductal adenocarcinoma (PDAC) is known as an extremely invasive cancer that will metastasise early. Loss of RUVBL1 in PDAC reduces actin polymerization and the concentration of globular actin in the cell protrusions of migrating cells; reducing their invasiveness and motility. In NSCLC cells loss of RUVLB1/2 reduces growth and causes G2/M arrest, but there is no increase in apoptosis. There is also a role for RUVB1/2 in chromosome stability, where loss of either protein results in chromosome alignment and segregation defects, and disruption to the mitotic spindle assembly. In colon cancer, RUVBL2 regulates human telomerase reverse transcriptase (hTERT) and the increased expression of both of these is associated with advanced nodel disease. The RUVBL1/2 proteins also associate with several oncogenic factors such as c-Myc and E2F1, and several proteins in the DNA damage repair pathway to drive cancer progression.

CHD

The ATPases of this remodeling family are highly diverse, with three subfamilies found in humans. Class I contains CHD1 and CHD2, Class II is CHD3 and CHD4, which form part of the NuRD complex and CHD5, and Class III comprises of CHD6-CHD9. All CHD ATPase remodelers contain a SNF2-like ATPase domain and tandem chromodomains, but vary in their other protein domains. CHD1 and CHD2 have a DNA binding domain located towards the c-terminal; CHD3, CHD4 and CHD5 have PHD Zinc-finger-like domains, and CHD5 also contains a DEAH-box domain; CHD6 has a Pdxk domain with pyridoxal kinase function and CHD7-CHD9 have BRK domains with unknown function. As more is known about the precise role of the NuRD complex in cancer, this section will first discuss the NuRD complex and key subunits within it, followed by the remaining CHD ATPases.

NuRD complex

The Nucleosome Remodeling Deacetylase (NuRD, also known as Mi-2) complex is highly conserved from plants to animals and was first described for its role in gene repression. It is now known that it's roles in chromatin biology extend to transcriptional activation, DNA repair, replication and genome stability—all processes that must be tightly regulated to ensure proper cell function and to inhibit cancer progression. NuRD has more specific roles in development including hematopoietic stem cell maintenance and differentiation, controlling key genes in B- and T-cell development. The NuRD complex contains two catalytic subunits; an ATPase that is either one of the mutually exclusive CHD3 or CHD4, as well as either one of histone deacetylase 1 (HDAC1) or 2 (HDAC2). Other key subunits include the methyl-CpG-binding domain 2 (MBD2) and 3 (MBD3), metastasis-associated gene 1 (MTA1), 2 (MTA2) and 3 (MTA3) and retinoblastoma-binding protein 4 (RBBP4) and 7 (RBBP7).

Like SWI/SNF, the NuRD complex both promotes and represses tumor development, which is dependent on subunit composition and cell type. In addition to mutations, many subunits of this complex can contain PTMs and perturbed remodeling function may arise from disruption of this. Several lines of evidence have demonstrated that the NuRD complex associates with oncogenic transcription factors to promote the repression of tumor suppressors, as well as interacting with known fusion genes. Promyelocytic leukemia (PML)—retinoic acid receptor-α (RARα) is a fusion oncoprotein transcription factor that recruits the NuRD complex to its target loci through protein-protein interactions in order to repress tumor suppressors such as retinoic acid receptor β2. As stated above, in other cases the NuRD complex itself directly functions as a tumor suppressor.

The NuRD complex has an essential role in proliferation and is implicated in the regulation of both the G1/S and G2/M checkpoints. Knockdown of either CHD4 or MTA1 blocks G1/S transition and G2/M progression is inhibited by unrepaired DNA damage following CHD4 loss. NuRD can also prevent deacetylation of p53, which results in increased p21 levels and cell cycle arrest. In lymphocytes, NuRD foci have been observed at the pericentromeric heterochromatin of chromosomes 1, 9 and 16 during S-phase. The NuRD foci correlate with proteins associated with active replication forks such as PCNA and CAF1, suggesting a role for NuRD in assembly, stability and chromatin condensation at these regions. Interestingly, PcG complexes are usually observed at these pericentromeric heterochromatin regions, but are absent in lymphocytes with NuRD foci, suggesting a unique cell specific role for the NuRD complex.

CHD3 and CHD4

CHD3 and CHD4 are highly similar in structure and are the alternative ATPase subunits of the NuRD complex. They are both known to interact with transcription factors and cofactors in order to direct the NuRD complex to its target sites. The PHD domains of CHD3/4 recognize the tails of H3, enabling transcriptional regulation; interestingly, while H3K9me3 enhances the binding of these

remodelers to chromatin, H3K4me3 abolishes this binding. CHD4 complexes that contain HDAC1 are shown to mediate transcriptional repression via colocalisation with DNA methyltransferase 1 (DNMT1) at tumor suppressor gene promoters.

CHD3 and CHD4 are known to interact with several regulatory factors to coordinate transcriptional control in cancer. ZIP, a transcriptional corepressor for cell proliferation, survival and migration pathways, preferentially interacts with CHD3/4 from the NuRD complex in breast cancer and when ZIP is lost there is aggressive tumor growth in mouse xenografts. A similar role has been reported for CHD3/4 binding to ZGPAT in breast cancer, which also represses genes for cellular proliferation, survival and migration and when interacting with NGFI-A Binding Protein 2 (NAB2), CHD3/4 repress early growth response 1 (EGR1) activities. Although they share highly similar functions for transcriptional control, CHD3 and CHD4 have differing roles in DNA damage. At sites of DSBs, KAP1 phosphorylation disrupts the interaction with and releases CHD3 from chromatin, while CHD4 is rapidly recruitment to site of damage.

There are limited studies on the effects of CHD3 mutations in cancer. However, there are reports of mutations in colorectal, gastric and prostate cancers (**Table 4**). In ovarian cancer, CHD3 is silenced due to DNA hypermethylation of its promoter, which is correlated with tumor resistance to platinum-based therapies, more invasive tumors and an EMT phenotype. It has been proposed that CHD3 would be a useful prognostic marker for ovarian cancers, but it remains unclear whether this is likely to extend to other types of cancer.

Table 4 Summary of CHD and NuRD complex subunits with an identified role in cancer as either a tumor suppressor and/or an oncogene

Gene	*Protein*	*Function*	*Tumor suppressor*	*Oncogene*
CHD1	CHD1	ATPase, promotes HR over NHEJ	Colorectal, gastric, prostate	
CHD2	CHD2	ATPase, deposits H3.3 onto chromatin	Bladder, chronic lymphoblastic leukemia's, colorectal, gastric, monoclonal B lymphocytosis, uterine	
CHD3	CHD3	NuRD complex, ATPase, H3 tail recognition	Bladder, colorectal, gastric, lung, melanoma, ovarian, prostate, uterine	
CHD4	CHD4	NuRD complex, ATPase, H3 tail recognition, DNA damage response	Bladder, colorectal, endometrial, gastric, lung, uterine	
CHD5	CHD5	ATPase, binds unmodified H3 tails, forms NuRD like complex	Breast, colorectal, gallbladder, gastric, glioblastoma, head and neck, heptacellular, laryngeal squamous cell carcinoma, leukemia, lung, melanoma, neuroblastoma, ovarian, pancreatic, renal cell carcinoma	
CHD6	CHD6	ATPase, transcription activation	Colorectal, gastric, lung, melanoma, prostate, transitional cell bladder, prostate, uterine	
CHD7	CHD7	ATPase, transcription activation	Colorectal, gastric, lung, medulloblastoma, melanoma	Breast, pancreatic
CHD8	CHD8	ATPase, establishes heterochromatin to euchromatin boundaries	Breast, colorectal, esophagus, gastric, lung, prostate, uterine	Endometrial, ovarian, prostate
CHD9	CHD9	ATPase	Colorectal, gastric, lung, melanoma, neuroblastoma, uterine	
MBD2	MBD2	NuRD complex, binds methylated DNA, mutually exclusive with MBD3	Gastric, colorectal, prostate	Brain, breast, colorectal
MBD3	MBD3	NuRD complex, binds unmethylated DNA, mutually exclusive with MBD2	Colorectal, endometrial, gastric, pancreatic	Brain
MTA1	MTA1	NuRD complex, mutually exclusive with MTA2 and MTA3, binds transcription factors		Breast, endometrial, esophageal, hepatocellular, lung, lymphoma, ovarian, pancreatic, prostate
MTA2	MTA2	NuRD complex, mutually exclusive with MTA1 and MTA3, binds transcription factors		Breast
MTA3	MTA3	NuRD complex, mutually exclusive with MTA1 and MTA2, binds transcription factors	B-cell lymphomas, breast, ovarian, prostate	
HDAC1/2	HDAC1/2	NuRD complex, Histone deacetylase		Breast, cervical, colorectal, endometrial, gastric, hepatocellular, lung, pancreatic, prostate, thyroid
RBBP4	RBBP4	NuRD complex, provides structural support	Lung, prostate	
RBBP4	RBBP4	NuRD complex, provides structural support	Cholangiocarcinomas	

CHD4 mutations have been found in a variety of cancers. It is mutated in 17% of endometrial cancer and 23.7% uterine carcinomas with these mutations predicted to impair function (Table 4). Loss of CHD4 also occurs in gastric and colorectal cancers that have microsatellite instability. The contribution of CHD4 to cancer progression is intriguingly diverse. Following DSB breaks, CHD4 is rapidly recruited to sites of damage, and its activity is dependent on binding to the PARP complex. Phosphorylation of CHD4 is then catalyzed by ATM enabling CHD4 to interact with RNF8 to mediated chromatin unfolding. Mutations in CHD4 at S1349—the site of phosphorylation—reduces its association with chromatin at break sites. Similarly, depletion of CHD4 results in hypersensitivity to DNA damage and accumulation of unrepaired breaks. CHD4 is also important for the cell cycle, where its loss results in cell cycle delay through the G2/M checkpoint.

MBD2 and MBD3

MBD proteins recognize methylated or unmethylated DNA and provide a mechanism for crosstalk to occur between the DNA sequence and chromatin. DNA methylation primarily follows a CpG context and can occur either in response to chromatin compaction or provide the signal that chromatin compaction is required. CpG sites are not distributed evenly throughout the genome; instead, they tend to be clustered into regions of high CpG density, called CpG Islands. CpG Islands are generally found at the promoters of ubiquitously expressed genes and are unmethylated in normal somatic cells. DNA methylation is frequently and ubiquitously disrupted in cancers and is characterized by genome-wide DNA hypomethylation, and site-specific DNA hypermethylation. Promoter DNA hypermethylation, particularly at CpG Islands, is associated with tumor suppressor transcriptional silencing.

MBD2 and MBD3 are mutually exclusive subunits of the NuRD complex. They share 71% sequence homology; however, MBD2 is capable of binding to methylated DNA, while MBD3 is not. This difference is due to two amino acid changes in the methyl-binding domain; K30 to H30, and Y34 to F34. Interestingly, MBD2 knockout causes only mild defects in cells, while MBD3 loss is embryonically lethal. Mutations in these proteins have been found in neurological disorders and tend to be truncating missense mutations.

MBD2 has a prominent role in suppressing transcription and over-expression induces gene silencing across the genome. Overlapping with the methyl-binding domain (MBD) is a transcriptional repressor domain (TRD)—that is absent from MBD3—suggesting that the methyl- binding and repressive functions of MBD2 are tightly connected. MBD2 is up-regulated in colorectal cancer cell lines, breast cancer and in brain cancer, but down-regulated in prostate and gastrointestinal cancers (Table 4). MBD2 contributes to tumor development by silencing the tumor suppressor genes: *GSTP1* in prostate cancer, *CDKN2A* in colorectal cancer, and *hTERT* in the HeLa cell line by promoter DNA hypermethylation. It has been demonstrated in cell lines that the knockdown of MBD2 allows for the re-expression of tumor suppressors p16INK4A and p14ARF. Furthermore, MBD2 depletion within the NuRD complex increases chromatin accessibility.

MBD3 is normally enriched at unmethylated promoters and enhancers, containing the active marks H3K4me3 and histone 3 lysine 27 acetylation (H3K27ac) respectively. It is also reported to bind to 5-hydroxymethylated regions in brain tissue and in ES cells. MBD3 has inactivating mutations in cancer and is down-regulated in gastrointestinal, endometrial and pancreatic cancer. However, there are reports that it is up-regulated in brain tumors. MBD3 can function as a tumor suppressor, demonstrated by it binding to the un-phosphorylated JUN oncoprotein to repress JUN's transcriptional activity. When MBD3 is inactivated in mice, the expression of JUN target genes increases, leading to hyper-proliferation and susceptibility to tumor development. Functional studies to understand the oncogenic roles of MBD3 found it recruits HDACs to silence tumor suppressor promoters including *CDKN1A*, and interactions with the proto-oncogene, *FBI-1* in transformed cell lines.

MTA1, MTA2 and MTA3

The functions of the MTA subunits are very well studied in cancer development. Each subunit is associated with transcription factor binding but mutually exclusive within the NuRD complex. Within the MTA family there are three alternate subunits: MTA1, MTA2 and MTA3. MTA1 and MTA2 promote cancer development, while MTA3 is a tumor suppressor (Table 4).

Increased MTA1 levels have been detected in cancers of breast, esophageal, endometrial, pancreatic, ovarian, lunge, prostate, liver and in lymphoma and is positively correlated with higher tumor grade, invasion and poor prognosis. This is in part due to activation of MTA1 by the MYC oncoprotein, which requires MTA1 for transformation of cells. In breast cancer, up-regulation of the HER2 pathway increases MTA1 expression, which then interacts with ER to suppress transcription, including the BRCA1 gene. MTA1 has also been linked to breast cancer through tumor hypoxia, since hypoxia induces MTA1 expression to turn on hypoxia-inducible factor 1α (HIF1α) promoting angiogenesis. MTA1 can also inactivate p53 inhibiting growth arrest and apoptosis.

Like MTA1, MTA2 is known to promote breast cancer development (Table 4). In these cancers, MTA2-containing NuRD complexes associate with TWIST, a key player in EMT and metastasis, and it is this association that causes subsequent repression of *CDH1*, promoting EMT. MTA2 also interacts with the ER receptor and MYC to promote breast cancer development.

MTA3 has opposing roles to both MTA1 and MTA2, acting as a tumor suppressor. Mutations have been reported in breast, ovarian and prostate cancers. MTA3 inhibits EMT through the suppression of SNAIL, a factor known to decrease cell adhesion and increase motility. MTA3 is also required for BCL-6 repression of genes involved in plasma cell differentiation in B-cell lymphomas.

HDAC1 and HDAC2

HDAC1 and HDAC2 are the only two histone deacetylases to form a part of the NuRD complex and share 80% sequence homology. As they can also form part of the CoREST and SIN3 complexes that are both associated with transcriptional repression, it can make

their role within the NuRD complex difficult to determine. It is unknown whether NuRD complexes containing HDAC1 or HDAC2 work synergistically or on different regions of the genome. However, it is clear that they have differing roles in development where HDAC1 is essential for stem cell survival and is embryonically lethal, while HDAC2 is not.

HDAC1/2 have a low frequency of mutations, but have a tendency to be over-expressed in cancers of the colon, breast, prostate, thyroid, cervical, gastric, hepatocellular carcinoma, pancreatic, endometrial and lung cancers (Table 4). A negative correlation with overall survival has been reported in colorectal cancer, hepatocellular carcinoma, pancreatic, endometrial, lung cancer. Additionally, an association with advanced disease, metastasis and aggressive disease has been found in hepatocellular carcinoma, colorectal cancer, prostate, NSCLC, breast cancer. Furthermore, HDAC2 truncating mutations have been reported in cancers with microsatellite instability, with these cells more resistant to the antiproliferative and pro-apoptotic effects of HDAC inhibitors.

As with most chromatin remodeling complexes, HDAC1/2 has roles in transcription and promotion of cancer development pathways. HDAC1/2 over-expression results in increased cell proliferation, migration, angiogenesis and invasion, and decreased apoptosis. HDAC1 is known to promote proliferation of breast cancers by repressing ER transcription. Loss of HDAC1/2 causes arrest in G1 or in G2/M and reduces proliferation in breast cancer.

RBBP4 and RBBP7

The RBBP proteins directly associate with histone tails. Like HDACs, they can also be subunits within other complexes making their role complicated to understand. It is assumed that these subunits provide structural support and promote protein-protein interactions within the NuRD complex. RBBP4 is mutated in approximately 5% of lung and prostate cancers, and RBBP7 is mutated in 12.5% of cholangiocarcinomas (Table 4). Functional studies in LNCaP prostate cancer cells have shown that over-expression of either RBBP4 or RBBP7 results in reduced proliferation.

CHD5

More recently, CHD5—also a Class II CHD ATPase—has been demonstrated to form NuRD-like complexes containing each of the main subunits detailed above. CHD5 preferentially binds to unmodified H3K4 tails via it's dual PHD domains, but can also bind H3K27me3 through its tandem chromodomains. CHD5 is predominately expressed in neurons and the testis; however, low expression has been associated with poorer survival and advanced tumors in a variety of cancer tissue types. Mutations in key residues of CHD5 prevent it binding to H3, and in turn, prevent it from inhibiting tumor growth. Several tumors including breast, lung, colorectal cancer, ovarian, gastric, laryngeal squamous cell carcinoma, gall bladder, hepatocellular carcinoma, pancreatic, leukemia and renal cell carcinoma (Table 4), have demonstrated significant hypermethylation at the CHD5 promoter, concomitant with a decrease in expression. Several of these studies demonstrate that CHD5 expression can be restored with 5-Aza-2′-deoxycytidine treatment, which reduced cellular proliferation. Deletion of the 1p36 chromosome locus containing CHD5 has also been found in glioblastoma, neuroblastoma, renal cell carcinoma and ovarian cancer.

CHD5 suppresses genes involved in motility, proliferation, apoptosis, EMT markers and epigenetic regulators. CHD5 also has a role in the DNA damage response with an increase in γH2A.X associated with CHD5 down-regulation in pancreatic cancer. CHD5 controls proliferation through activation of *CDKN2A* to mediate Rb and p53 pathways.

Class I and class III CHD ATPases

CHD1 is a tumor suppressor and plays a significant role in the development of prostate cancer. CHD1 is located at 5q21, and deletions within this region are one of the most frequent to occur in prostate cancer, second only to PTEN. Approximately 17% of prostate cancers contain a CHD1 mutation or deletion (Table 4). CHD1 has a synthetic-lethal relationship with PTEN, where in PTEN-deficient prostate cancer, CHD1 is stabilized. Loss of CHD1 in these cancers reduces proliferation and survival of cells supporting the hypothesis that CHD1 is important in the early stages of prostate cancer development. Deletion of CHD1 in mouse prostate epithelial cells results in morphological changes and increased invasiveness, but not transformation. CHD1 loss has also been linked to PSA failure and ERG-fusion absence and is required for androgen receptor (AR) transcription and regulates tumor suppressor genes including NKX3–1, FOXO1 and PPARγ. Prostate cancer patients with CHD1 depletion are more sensitive to PARP inhibitors that target tumors with HR DSB defects. It has been suggested that CHD1 is a prognostic marker for stratification of prostate cancer patients for PARP inhibitor therapeutics. CHD1 is also mutated in 5%–10% of cancers of the digestive tract. (Table 4).

CHD1 deletion affects HR DSB repair but not NHEJ. CHD1 is required to open chromatin around the break site, in order to facilitate HR repair protein entry. When CHD1 is depleted in cancer, the tumors switch from utilizing HR to NHEJ mechanisms, leading to increased error prone repair. CHD1 depleted cancers tend to have increased genome instability, concomitant with increased chromosome deletions, particularly on chromosomes 2q, 5q and 6q.

Like CHD1, CHD2 is also a tumor suppressor, but less information about its role in cancer exists. Mutations in CHD2 have been reported in cancers of the digestive tract ranging from 5% to 10%, 5.3% in chronic lymphoblastic leukemia's (CLL) and 7% of monoclonal B lymphocytosis that can evolve to CLL (Table 4). The majority of known mutations are truncating, or occurring in a functional domain. Functional studies following CHD2 depletion in mice have shown heterozygous mutations increase their susceptibility to lymphoma due to the abnormal differentiation of stem cells. Loss of CHD2 also decreases the level of H3.3 deposition in chromatin at promoters and at sites of DNA damage. Cells containing CHD2 mutations also have a higher level of γH2A.X remaining after damage and an aberrant DNA damage response after x-ray radiation. Furthermore, loss of functional CHD2 results in growth and viability defects.

CHD6 was discovered in 2002 and studies of the role of CHD6 in cancer are also limited. Mutations have been reported in 19.5% of colorectal cancers and 7% in transitional cell bladder cancer (Table 4). CHD6 has a high affinity for short linker DNA, down to 20 bp and disrupts nucleosomes in a nonsliding mechanism. CHD6 colocalizes with hypo- and hyper- phosphorylated forms of RNA PolII and is present at the sites of RNA synthesis, suggesting that it positively regulates transcription.

CHD7 has been reported as both a tumor suppressor and an oncogene. CHD7 is enriched at sites marked by H3K4me1/2, located near the TSS and near DNase hypersensitive sites, suggesting a pro-transcriptional role. Mutations have been reported in 11.1% of gastric cancers and 42% of colorectal cancer cases (Table 4). CHD7 mutations have been linked with lung cancer in heavy smokers and a number of lung cancer cell lines display PVT1-CHD7 fusion genes. CHD7 has been described as an oncogene and associated with more aggressive subtypes in breast cancer. Deletion of CHD7 in breast cancer cell lines inhibits proliferation and is associated with down-regulation of known oncogenes, such as NRAS. In pancreatic cancer, patients with low CHD7 expression are more sensitized to gemcitabine, the primary treatment for these cancers, and have increased overall survival. CHD7 could therefore be used to stratify patients predicted to have a positive response to gemcitabine in pancreatic cancer.

CHD8 plays a role in both transcription and at the boundaries between heterochromatin and euchromatin. CHD8 binds to active promoters in the G1/S transition and is required for the loading of E2F1 and E2F3 onto genes expressed exclusively during S-phase; MLL recruitment to these genes is impaired in the absence of CHD8. CHD8 is a marker of aggressive gastric cancer, with 15.9% of cases containing mutations and 35.75% exhibiting with a loss of expression. In these cancers, CHD8 regulates b-catenin/Wnt pathways and low expression of CHD6 is considered to be a prognostic marker for poor outcome. CHD8 has a bimodal role in prostate cancer; the CHD8 promoter is hypermethylated in 45% of cases, but high CHD8 expression results in poor clinical outcomes and metastasis. Conversely, CHD8 is a coregulator of androgen dependent transcription and loss of CHD8 is sufficient to stimulate proliferation of prostate cancer. CHD8 mutations are associated with increased risk of cancer development in those carrying familial BRCA1 mutations. In ovarian cancer, amplification of the NSD3-CHD8-BRD4 pathway is associated with worse survival rates. This amplification also occurs in 9% of serous endometrial cancer and again, is associated with worse overall survival. In AML, these proteins colocalize across the genome and are released from chromatin by BET inhibitor treatment.

Little is known about the role of CHD9 in cancer, though a study of neuroblastoma found mutations in approximately 4% of patients. Down-regulation of CHD9 in these cancers was correlated with increased bone metastasis and decreased patient survival (Table 4). The mutation sites identified were close to a phosphorylation site for CHD9, potentially inhibiting the ability of this remodeler to be phosphorylated and therefore, for CHD9 to be activated. CHD9 is also mutated in cancers of the digestive tract, including 11.1% of gastric cancers. To date, growing evidence suggests that CHD9 is a tumor suppressor.

ATRX

ATRX an ATP-dependent chromatin remodeler with high homology to SWI/SNF and with roles in genome stability, DNA damage and heterochromatin formation. ATRX forms a complex with DAXX, a chaperone of histone H3.3. Somatic mutations in ATRX have been identified in brain tumors and osteosarcomas, and are positively correlated with increased rates of single nucleotide variation in cancer. ATRX binds to the 3′ exons of zinc finger genes to maintain genomic stability and also has a major role in the formation of heterochromatin. ATRX deposits the histone variant H3.3 at pericentric heterochromatin and at telomeres to maintain H3K9me3 enrichment. Reduced ATRX is associated with loss of H3K9me3 and telomere lengthening—a feature of many cancers. ATRX also maintains the silencing of imprinted genes and retrotransposons through the same mechanism.

Concluding Remarks

Chromatin modifying proteins have an integral role within a cell to maintain proper chromatin integrity and genome stability (Fig. 4). Chromatin remodelers and modifiers control access to the genes needed for development and progression of cancer. In normal cells, there is tight regulation around these genes and disruption to chromatin remodelers in cancer either by way of mutation and/or changes in expression driven by epigenetic mechanisms can lead to the altered chromatin structure. DNA is therefore extremely vulnerable to further mutations from damaging agents, either intra- (e.g., DNA methylation) or extra- cellular (e.g., UV damage). Particularly, the unrestricted access to genes due to global chromatin instability and "loosening" is all that cancer cells need to gain a simple proliferative and survival advantage. Aberrant function of chromatin remodelers is known to directly result in tumor development, and many cancer types contain mutations in at least one chromatin remodeler.

Prospective Vision

Moving forward, it will be particularly important to characterize the role of epigenetic mechanisms in driving atypical changes in chromatin remodeler expression. Moreover, it will be essential to determine whether epigenetic reprogramming of the cancer genomes causes additional mutations affecting chromatin remodeler activity. Future study into the role of ncRNA targeting chromatin remodellers to the genome is an exciting area of development. ncRNA is ideal for this purpose due to the sequence specificity and the dynamic secondary structure. DNA methylation and activity of the APOBEC family of cytidine deaminases involved in C to U mRNA repair may be of particular interest as the field seeks to characterize the evolution of chromatin remodeller mutations over

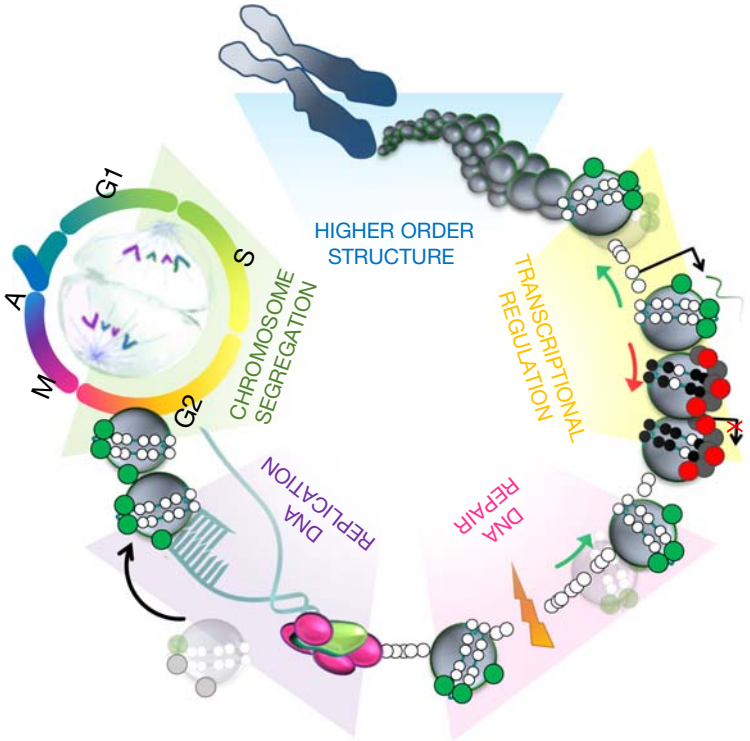

Fig. 4 *The mutation or disruption of chromatin remodellers has the potential to reduce genome integrity in cancer.* Atypical expression or activity of chromatin remodelers by mutation or epigenetic reprogramming has the potential to alter higher order chromatin structures, including enhancer-promoter interactions by DNA looping; transcriptional regulation (abnormal gene expression patterns); DNA repair (misrepair or incomplete repair), DNA replication (unfaithful) and chromosome segregation (impaired) from the mitotic spindle during the cell cycle. the course of cancer progression. The interplay between chromatin remodellers and the epigenome is likely to be complex, and bi-directional. The influence of somatic chromatin remodeller mutations on the epigenome are likely to hold key clues to cancer etiology and identification of the most promising epigenetic therapies.

Glossary

CpG islands Genomic regions with a high frequency of CpG sites. In mammalian genomes, CpG islands are typically 200–3000 base pairs in length, less methylated than other CpG sites cross the genome, and many of them are associated with gene promoters and play a role in gene transcriptional regulation.

Epigenetics Stable heritable traits that cannot be explained by changes in DNA sequence. The epigenetic inheritance is maintained through cell divisions and passed from one cell generation to the next even though they do not involve changes in the DNA sequence of the organism. The known mechanisms of epigenetic inheritance involve regulation of gene activity and expression by covalent modifications of chromatin (DNA and histones), nucleosome positioning, RNA transcripts, and prions, etc.

Hematopoiesis The process of generating all types of blood cellular components from hematopoietic stem cells (HSCs). This process involves the maintenance of the HSCs by a self-renewal mechanism and step-wise differentiation from HSCs into different lineages of mature blood cells. The cell fate determination during hematopoiesis is controlled by cellular autonomous mechanisms, which include epigenetic regulation, transcription factors and signaling pathways, as well as extracellular signals induced by cytokines and cell–cell interactions.

Leukemia A group of hematopoietic cancers that usually begin in the bone marrow and result in high numbers of abnormal white blood cells which are not fully differentiated. The major types of leukemia include acute myeloid leukemia (AML), acute lymphoblastic leukemia (ALL), chronic myeloid leukemia (CML) and chronic lymphocytic leukemia (CLL).

Myelodysplastic syndromes (MDS) A heterogeneous group of hematopoietic malignancies characterized by impaired peripheral blood cell production and most commonly a hypercellular, dysplastic-appearing bone marrow.

Tricarboxylic acid (TCA) cycle A looped metabolic pathway that consists of series of enzyme-catalyzed chemical reactions occurred in living cells to release energy through oxidation of acetate, in the form of acetyl-CoA, into carbon dioxide and water. It is a key metabolic pathway that connects carbohydrate, fat, and protein metabolism, as it provides precursors of certain amino acids, as well as the reducing agent NADH that are used in numerous other biochemical reactions. It is also known as citric acid cycle (CAC) and the Krebs cycle.

Introduction

Recent cancer genomic studies have led to the discovery of many previously unrecognized cancer-causing genes. Functional classification of these genes facilitates us to pinpoint essential cellular regulatory processes that contribute to tumorigenesis. DNA methylation is one of such processes, since several newly identified mutated genes in cancers encode enzymes responsible for "writing" and "erasing" an important epigenetic mark of the genome—5-methylcytosine (5mC; i.e., methylation of the DNA base cytosine at the 5th atom in the pyrimidine ring). DNA methylation plays important roles in many biological processes in mammalians, including transcriptional repression, genomic imprinting and X chromosome inactivation, as well as cell fate decision. As illustrated in Fig. 1, multiple members of three families of enzymes that control the key steps of DNA methylation and demethylation have been found being recurrently mutated in cancer: (1) DNMT3A belongs to a family of DNA methyltransferases (DNMTs) that transfer the methyl group from *S*-adenosyl methionine (SAM) to cytosine. (2) TET2 (ten-eleven translocation 2) belongs to a family of TET dioxygenases that convert the 5mC to 5-hydroxymethylcytosine (5hmC) through a hydroxylation reaction, followed by further processing to complete the demethylation. (3) IDH1 and IDH2 belong to a family of isocitrate dehydrogenases (IDHs) that convert isocitrate to α-ketoglutarate, which is an essential co-factor for the TETs. Thus, DNMTs and TETs act as "writers" and "erasers" of DNA methylation, respectively, whereas IDHs are important co-regulators; mutations in these enzymes cause aberrant DNA methylation patterns in cancer. Accumulating studies seek to explore the mechanism of how the mutations in these enzymes contribute to tumorigenesis and to identify potential new therapeutics to treat cancer. In this article, we will introduce the basic concepts and newly acquired knowledge regarding the functions of the DNA methyltransferases and demethylases in development and cancer. An adequate understanding of the underlying mechanisms should lead to identification of new therapeutic strategies for cancer treatment.

Location and Biological Functions of DNA Methylation

Location of DNA Methylation in Human Genome

In mammals, the majority of 5mCs occurs on the cytosine nucleotide followed by a guanine nucleotide (CpG site), although few non-CpG 5mCs have also been observed in specific cell types such as embryonic stem cells, some neural cells, and hematopoietic

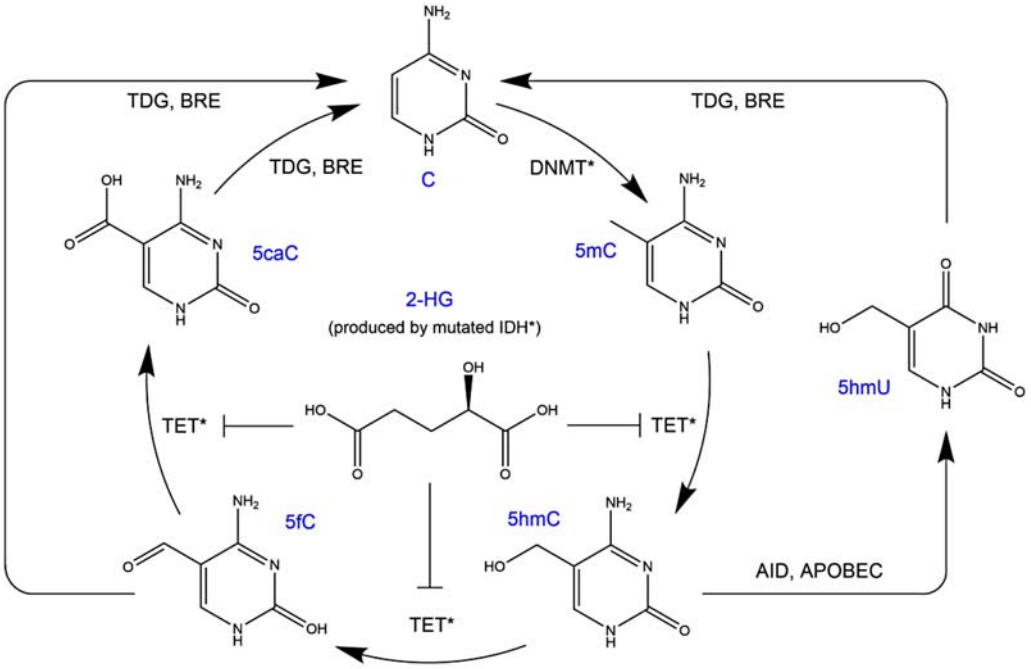

Fig. 1 Mutated enzymes in the pathway of DNA methylation and demethylation. Asterisks denote the enzymes known to be affected by somatic mutations in cancer. The DNA methyltransferases (DNMTs) catalyze DNA methylation by transferring a methyl group to cytosine (C) to form 5-methylcytosine (5mC). The TET methylcytosine dioxygenases oxidize 5mC to 5-hydroxymethylcytosine (5hmC), and further oxidation reactions results in the successive conversion of 5hmC to 5-formylcytosine (5fC) and 5-carboxylcytosine (5caC). The 5hmC can also be deaminated to 5-hydroxymethyluracil (5hmU) by AID/APOBEC (activation-induced cytidine deaminase/apolipoprotein B mRNA-editing enzyme complex). These oxidation products can be removed by the TDG (thymine DNA glycosylase) and BRE (repaired by the base excision repair) enzymes, returning to an unmodified cytosine. Activities of the TETs are dependent on α-ketoglutarate (α-KG), the natural product of isocitrate dehydrogenases (IDHs), but are inhibited by 2-hydroxyglutarate (2-HG), the product of cancer-associated IDH mutants.

progenitors. Mammalian genomes are depleted of CpG sites, probably because 5mC can be spontaneously deaminated to thymine and therefore is vulnerable to mutagenic potentials. Indeed, the total number of CpG sites in humans is approximately 28 million, which is much lower than what is expected according to the average GC content of human genome. The CpG sites in the genome are overall heavily methylated, except for some specific genomic regions such as CpG islands. In different genomic regions, the localization pattern, regulatory mechanism and biological function of the methylated CpG sites could be different (Fig. 2).

In the specific genomic regions named CpG islands, which have a higher CpG density than the rest of the genome, the CpG sites are much less methylated. As many mammalian genes have CpG islands associated with their promoters, the 5mCs in CpG islands play an important role in gene transcriptional regulation. It has been shown that the presence of multiple methylated CpG sites in the CpG islands results in silencing of gene expression. Given the relative stability of 5mC, the gene silencing mediated by methylation of CpG islands is usually stable. This mechanism is particularly important for genomic imprinting, an epigenetic phenomenon in which certain genes are expressed from only one of the two parental chromosomes and their expression is determined in a parent-of-origin specific manner. Besides the imprinted genes, 5mCs also regulate gene expression in development and tumorigenesis. Notably, however, the CpG islands associated with gene promoters rarely show tissue-specific methylation pattern. Instead, the differences of CpG methylation between tissues, or between normal and cancer samples, are observed in the regions called CpG island shores, located a short distance from the CpG islands.

The CpG methylation also locates in the gene body, and its enrichment in these regions is positively correlated with gene expression levels. In mouse embryonic stem cells, this distribution pattern has been shown to be established and maintained through a direct recognition of histone lysine 36 trimethylation (H3K36me3) by the Pro-Trp-Trp-Pro (PWWP) domain of the DNMT3B. Given the high similarity between DNMT3A and DNMT3B, DNMT3A should be able to recognize H3K36me3 as well, though probably in different cell types and/or genome sites. The intragenic DNA methylation has been suggested to play a role in repression of cryptic transcriptional initiation and regulation of splicing, although the detailed mechanisms remain to be further clarified.

DNA methylation plays an important role in permanent silencing of transposable and viral elements, which comprise approximately 45% of the human genome. If expressed, these elements are potentially harmful to the cell. However, it is interesting to note that these elements may also provide a resource for stimulating immune responses. Indeed, recent studies have shown that some

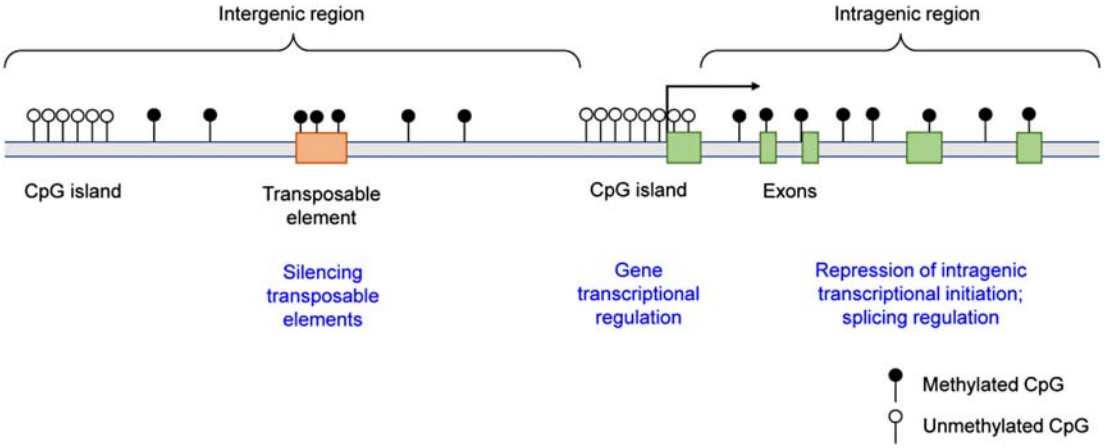

Fig. 2 Localization and basic functions of DNA methylation in human genome. The majority of DNA methylation (5mC) occurs on the CpG sites, and most CpG sites tend to be methylated, except for the CpG islands, which are less methylated. The CpG islands associated with gene promoters play an important role in transcriptional regulation, whereas those located in the gene body may regulate cryptic intragenic transcriptional initiation and splicing. The methylated CpG sites located in the intergenic regions are important for silencing the transposable elements. Modified from Wikipedia (https://en.wikipedia.org/wiki/File:DNAme_landscape.png).

demethylating agents can induce a cell autonomous immune activation response by stimulating expression of the endogenous retroviruses. This response probably explains some of the anti-tumor activities of these drugs.

DNA Methylation Dynamics in Development and Cancer

Despite its stability, the patterns of DNA methylation can be substantially altered in development and cancer. In mammals, there are two waves of genome-wide DNA demethylation and re-methylation during the development. The first wave occurs in early embryogenesis. DNA methylations on both paternal and maternal genomes are largely erased shortly after fertilization, and a de novo methylation then takes place during the implantation stage of the embryo. The second wave of genome-wide DNA demethylation occurs during the specification of primordial germ cells (PGCs), the first germline cells established during embryogenesis and the precursors for both the oocytes and sperms. At the beginning of their specification and migration, PGCs are shown to have the same DNA methylation patterns as the epiblast cells from which the PGCs are generated. However, by the time they arrive at the genital ridge, their DNA methylations are almost completely erased. This DNA methylation reprogramming is possibly required for totipotency of the germ cells in the newly formed embryos.

Even before the discovery of the mutations of the DNA methyltransferase and demethylases in cancer, altered DNA methylation patterns have been heavily implicated in various cancers. As a stable gene silencing mechanism, DNA hypermethylation has been commonly observed in cancers to silence tumor-suppressor genes. Particularly, in some familial cancers, when one allele of the key tumor-suppressor gene has mutated in germ line, there is a fair chance that the second allele is silenced by DNA methylation. Besides the individual cancer-related genes that are directly targeted by DNA methylation, alterations of DNA methylation patterns in broad genomic regions, such as repetitive elements, low-density CpG regions, and lamin-associated domains, have also been observed in cancer cells, although their functional roles in cancer remain to be defined.

It has been widely accepted that a genome-wide profile of DNA methylation (methylome) of cancer is a useful method not only for understanding the molecular mechanism of epigenetic regulation of cancer, but also for precise diagnosis and treatment of cancer. Differentially methylated regions (DMRs) are commonly used to describe potentially functionally relevant genomic regions that are differentially methylated between different cells/tissues. In another way, the concept of CpG island methylator phenotypes (CIMPs) has been invented to identify concordant CpG methylations of a group of genes in a certain type of cancer and thereby to classify a subtype of cancer from others based on their specific methylation patterns.

Mutations in *DNMT3A*

DNMT3A is one of the most frequently mutated genes in adult hematopoietic malignancies. It belongs to an evolutionarily conserved family of methyltransferases. Except for *DNMT3A*, none of other members of the family have been found being recurrently mutated in cancer, though *DNMT3B*, the closest homologue of *DNMT3A*, is mutated in patients with a rare autosomal recessive immune disorder termed immunodeficiency, centromeric instability, and facial anomalies (ICF) syndrome. It is also unanswered why *DNMT3A* mutation is only heavily implicated in hematopoietic malignancies, but not other types of cancer. Understanding the basic function of *DNMT3A* in DNA methylation regulation and normal hematopoiesis would be helpful to clarify the functions and mechanisms of *DNMT3A* in leukemogenesis.

The DNMT Family

The DNMT family in humans contains five members: DNMT1, DNMT2 (also known as TRDMT1), DNMT3A, DNMT3B and DNMT3L (Fig. 3). They are evolutionarily conserved as each of them has homologue(s) found in vertebrates and they likely share a common ancestor in invertebrates such as fruit fly (Fig. 3A). They share a homologous catalytic domain in their C-terminuses, and some of them have acquired additional domains that may mediate substrate recognition, protein interaction and other regulatory activities (Fig. 3B). Indeed, the biological functions of the DNMT family members are highly specified. Although DNMT2 is the most conserved member in the family, it has been shown not being able to methylate DNA, instead it can methylate the transfer RNA (tRNA) Asp-GTC on cytosine 38 in the anticodon loop. The other DNMTs possess DNA methylation activity but they are functionally classified as two types: de novo and maintenance methyltransferases. DNMT3A, DNMT3B and DNMT3L are de novo DNMTs, as they create hemimethylated CpG sites in double-strand DNA, and are responsible for setting up the pattern of methylation. The high similarity between DNMT3A and DNMT3B implies that they may exert redundant functions, but they may also play different roles in gene- and cell type-specific manners. While DNMT3L is catalytically inactive, it can facilitate the activities of DNMT3A and DNMT3B. DNMT1 is the maintenance DNMT that adds methyl group to the cytosine when one strand has already been methylated, and is responsible for maintaining the methylation pattern that had been established by the de novo DNMTs.

Structure and Function of DNMT3A

DNMT3A contains three conserved domains (Fig. 3B). The PWWP domain can bind both DNA and histone marks such as H3K36me3, through which DNMT3A is recruited to the H3K36me3 enriched genomic regions, including gene body region and

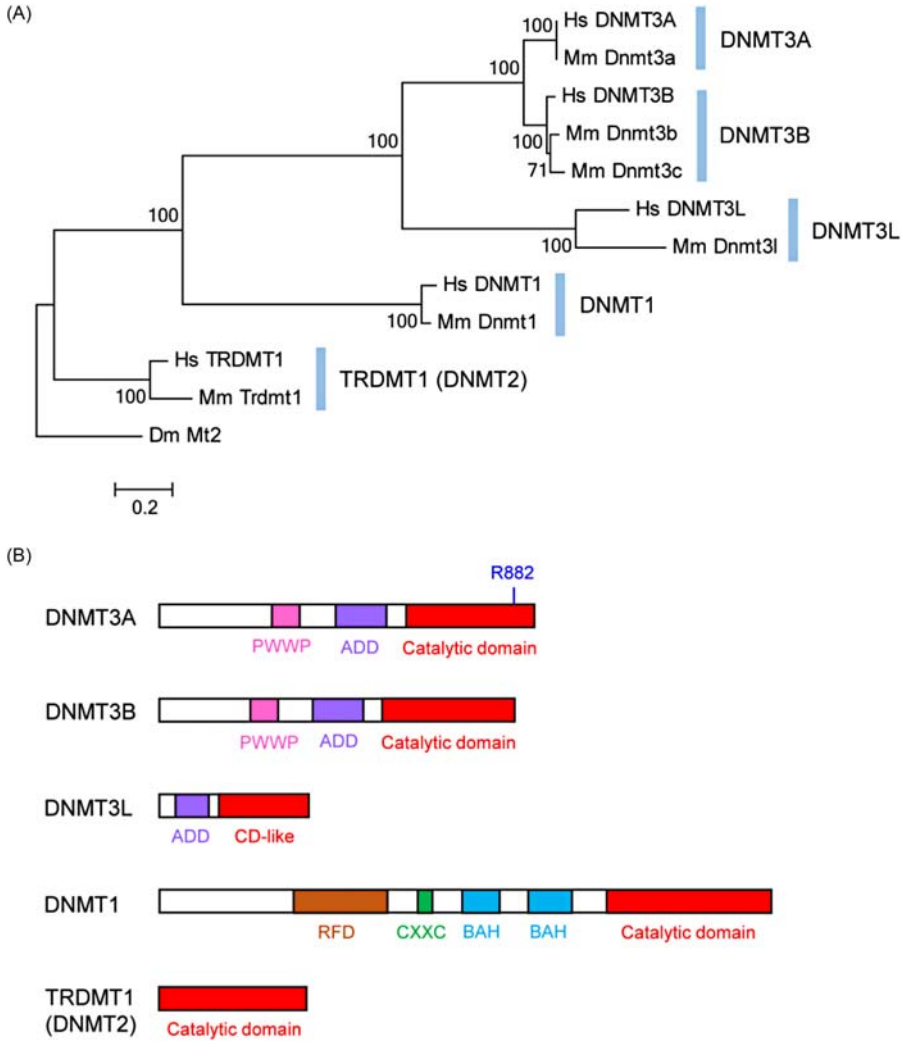

Fig. 3 The DNMT family. (A) Phylogenic tree of human (*Homo sapiens*, *HS*) and mouse (*Mus musculus*, *Mm*) DNMT family members. Construction of the tree is based on an alignment of the amino acid sequences of the catalytic domains. The methyltransferase 2 (Mt2) of fruit fly (*Drosophila melanogaster*, *Dm*) represents the common ancestor of the mammalian DNMTs. (B) Domain architectures of the human DNMT family members. The DNMT3A mutational hotspot R882 is localized within the catalytic domain.

pericentromic heterochromatic foci. The ATRX-DNMT3-DNMT3L (ADD) domain binds H3 tail peptides with or without lysine 4 (H3K4) methylation, and, in the presence of H3K4me3, acts as an autoinhibitor for the enzymatic activity of DNMT3A. The C-terminal catalytic domain is a C5-type *S*-adenosyl methionine (SAM)-dependent methyltransferase domain. It has been shown that the catalytic domain preferentially binds unmethylated DNA. DNMT3A can form oligomers, including dimer and tetramer, through two distinct binding interfaces in the catalytic domain. The oligomeric states of DNMT3A, as well as its hetero-oligomerization with DNMT3B and DNMT3L, are important for their catalytic activities. Regulation of the oligomerization thus greatly contribute to the function of DNMT3A in both hematopoiesis and tumorigenesis.

DNMT3A in Hematopoiesis

Deletion of *Dnmt3a* in mouse models leads to enhanced self-renewal of hematopoietic stem cells (HSCs). Although the *Dnmt3a*-null HSCs are phenotypically indistinguishable from wild-type HSCs, with identical cell surface markers, intact abilities to differentiate to all hematopoietic lineages, and similar levels of proliferation and apoptosis, serial bone marrow transplantation assays indicate a gradual expansion of the *Dnmt3a*-null long-term hematopoietic stem cells (LT-HSCs). Transplantation of the *Dnmt3a*-null HSCs lead to development of myeloid and lymphoid malignancies, which recapitulate many clinical features of human malignancies caused by *DNMT3A* mutations.

Dnmt3a-null HSCs display significant genome-wide hypomethylation with focal areas of hypermethylation. The DMRs identified in *Dnmt3a*-null HSCs are significantly enriched at the edges of large hypomethylated regions known as methylation canyons. Many methylation canyon-associated genes involved in HSC self-renewal are up-regulated in *Dnmt3a*-null HSCs and remain inappropriately activated in differentiated cells, suggesting that the *Dnmt3a* deficiency results in an inability of the cells to turn off the genes that regulate differentiation.

DNMT3A Mutations in Hematopoietic Malignancy

DNMT3A mutations are presented in approximately 20% of patients with de novo and secondary acute myeloid leukemia (AML), especially in the French–American–British (FAB) classified M4 and M5 subtypes. *DNMT3A* mutated AMLs frequently harbor *NPM1* (*nucleophosmin 1*) and *FLT3* (*fms related tyrosine kinase 3*) mutations. Although *DNMT3A* mutations have been defined as an earliest driver event in tumorigenesis, the impact of *DNMT3A* mutations in AML prognosis is under debate. Besides AML, *DNMT3A* mutations have also been reported in other myeloid malignancies, including myelodysplastic syndrome (MDS), myeloproliferative neoplasm (MPN) and myelodysplastic/myeloproliferative overlapping disease (MDS/MPN), although their prevalence is much lower than in AML. Furthermore, *DNMT3A* mutations have also been recurrently detected in lymphoid malignancies. Notably, in T-cell acute lymphoblastic leukemia (T-ALL), the prevalence of *DNMT3A* biallelic mutation is higher than in myeloid malignancies, implying potentially different mechanism for *DNMT3A*-driven lymphoid and myeloid neoplastic transformation.

The majority of *DNMT3A* mutations detected in hematopoietic malignancies occur within the C-terminal catalytic domain, with a significant enrichment for mutations at amino acid arginine 882 (R882), although non-R882 missense and truncating mutations are found with much lower frequency in other domains. In myeloid malignancies, R882 mutations are usually heterozygous, whereas in T-ALL, there is a high frequency of non-R882 biallelic mutations. The DNMT3A R882H mutant has been shown to exert a dominant-negative effect against the wild-type protein. Mechanistically, the R882H mutant can dimerize with wild-type DNMT3A, but prevent the formation of a tetramer, which represents a stronger enzymatic activity. Thus, the existence of the R882H mutant can reduce the DNA methyltransferase activity in the cells, explaining the genome-wide hypomethylation observed in patients with *DNMT3A* R882 mutations. In addition, DNMT3A R882 mutants may also exert its function through affecting other proteins/pathways. For example, DNMT3A R882 mutants can interact with the polycomb repressive complex 1 (PRC1) to down-regulate specific target genes involved in hematopoietic differentiation. It can also activate the mechanistic target of rapamycin (mTOR) pathway and increase the protein level of cyclin-dependent kinase 1 (CDK1), which are associated with a dysregulation of cell cycle of HSCs. Indeed, the mTOR inhibitor rapamycin elicited a significant therapeutic response in the knock-in and bone marrow transplantation mouse models of the *DNMT3A* R882H mutation.

Mutations in *TET2*

TET2 mutations have been found to be associated with multiple hematopoietic malignancies, as well as melanoma and few cases of glioma. *TET2* somatic mutations and loss of heterozygosity (LOH) occur in patients with MDS, MPN and AML. *TET2* mutations have also been reported in T-cell lymphomas. Unlike *DNMT3A*, *IDH1* and *IDH2* (see below), *TET2* does not display a dominant hotspot mutation site, instead nonsense and missense mutations, as well as deletions, are found across multiple exons.

The TET Family

The founding member of the TET protein family was first identified as a fusion partner of *MLL* (*mixed-lineage leukemia*; also known as *lysine methyltransferase 2A*, *KMT2A*) in patients with t(10;11)(q22;q23) AML, and therefore this gene was named as *ten-eleven translocation 1* (*TET1*). The TET family contains three members, TET1, TET2 and TET3 (**Fig. 4**A), all of which have been identified as

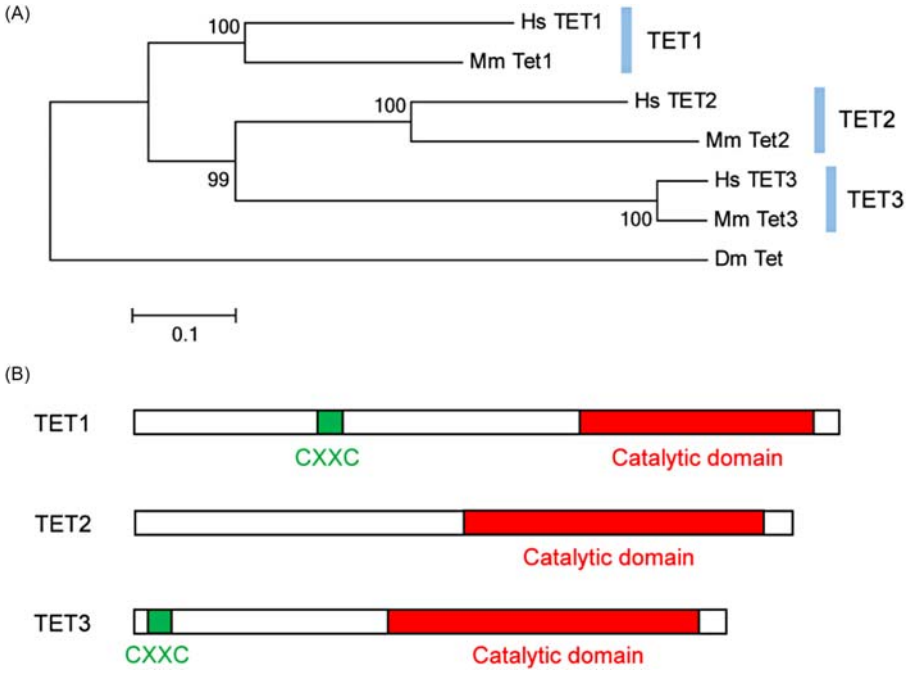

Fig. 4 The TET family. (A) Phylogenic tree of human (*HS*) and mouse (*Mm*) TET family members. Construction of the tree is based on an alignment of the amino acid sequences of the catalytic domains. The fruit fly (*Dm*) Tet protein represents the common ancestor of the mammalian TETs. (B) Domain architectures of the human TET family members.

methylcytosine dioxygenases that catalyze the conversion of 5mC to 5hmC. The three TET family members share a catalytic domain in their C-terminuses; TET1 and TET2 also contain a N-terminal CXXC domain, whereas TET2 does not (Fig. 4B).

Structure and Function of TET2

The dioxygenase activity of the TET family members is mediated by the double-stranded beta helix (DSBH) fold domain termed base J-binding protein (JBP) domain. This JBP domain virtually defines a much larger superfamily of 2-oxoglutarate (2-OG)- and ferrous iron (Fe(II))-dependent dioxygenases (2OGFeDO), which are found in various eukaryotes, bacteria and bacteriophages. Notably, the co-factor of TETs, 2-OG (also known as α-ketoglutarate (α-KG)), is an important metabolite in the tricarboxylic acid (TCA) cycle (also known as citric acid cycle or Krebs cycle), and it is converted from isocitrate by the IDHs. Thus, the discovery of TETs as key enzymes for DNA demethylation makes a direct connection between epigenetic regulation and cellular metabolism. Alterations of both aspects had already been considered as hallmarks of cancer but the mechanistic link between them has otherwise been lacking.

Besides the catalytic JBP domain, TET1 and TET3, but not TET2, contain a conserved CXXC domain that is shown to bind unmethylated CpG sites. Interestingly, although TET2 does not contain the CXXC domain, a CXXC domain-containing gene, *IDAX* (also known as *CXXC4*), locates upstream of the *TET2* genomic locus, suggesting that an ancient CXXC-containing *TET2* gene was split into two separate genes through evolution. Nevertheless, biochemical studies revealed that the IDAX protein is still able to interact with TET2, and that this interaction is associated with caspase-mediated TET2 degradation, providing a flexible regulatory mechanism for TET2 stabilization.

TET2 in Hematopoiesis

Deletion of *TET2* in hematopoietic cells in mice leads to an expansion of hematopoietic stem/progenitor cells (HSPCs) in vivo. These cells show increased re-plating potential and colony formation ability in vitro. In competitive bone marrow transplantation assays, *TET2*-null HSPCs are capable of outcompeting wild-type cells. These observations suggest that *TET2* deficiency results in increased self-renewal of HSCs, which may lead to neoplastic transformation. Indeed, aged *TET2* knockout mice have been reported to develop myeloid malignancies, which are mostly characterized as a chronic myelomonocytic leukemia (CMML)-like disease. In addition, other hematopoietic malignant phenotypes, such as a MDS-like disease and increased immature thymic T cells and mature splenic B cells, were observed in other *Tet2* knockout mouse models. These diverse phenotypes of the *Tet2*-deleted mice may attribute to different approaches to target *Tet2* and/or different genetic background. It is also conceivable that, because there was always a considerable latency before the mice developed full-blown hematopoietic malignancies, secondary genetic events acquired through time could contribute to tumorigenesis and specify disease phenotypes.

TET2 Mutations in Hematopoietic Malignancy

Somatic deletions and mutations in *TET2* were first found in patients with MDS, MPN and AML based on mapping of loss-of-heterozygosity and microdeletions within a minimal region of chromosome 4q24. It turned out that *TET2* mutations are among the most common genetic abnormalities observed in patients with MDS (6%–26%) and CMML (20%–58%). *TET2* mutations are also frequently observed in primary and secondary AMLs (12%–32%). In addition, *TET2* mutations are detected in B-cell and T-cell lymphomas. This broad spectrum of hematopoietic malignancies associated with *TET2* mutations in humans is consistent with the above described diverse phenotypes of *Tet2*-knockout mice. *TET2* mutations can be observed at both early and late stages of the development of hematopoietic malignancies, and they may exert different function at different stages. *TET2* mutations are mostly heterozygous, in which the wild-type allele of *TET2* in the patients remains expressing, whereas biallelic *TET2* inactivation occurs in less than 10% of patients with leukemia. Furthermore, there is not a prominent hotspot mutation site in *TET2*. These observations suggest that *TET2* can function as a haploinsufficient tumor suppressor in most patients.

By a curious paradox, mutations of the two enzymes, *DNMT3A* and *TET2*, which apparently take opposite biochemical actions on DNA methylation (i.e., writing versus erasing), result in hematopoietic malignancies similarly. Furthermore, *DNMT3A* and *TET2* have been found to be co-mutated in some patients with hematopoietic malignancies, and, as described above, loss of *Dnmt3a* or *Tet2* in mice similarly results in expansion of HSCs. These observations suggest that *DNMT3A* and *TET2* may work in parallel and/or cooperatively in hematopoiesis and malignancies. Consistent with this notion, it has been shown that Dnmt3a and Tet2 can cooperatively repress the erythroid transcription factor *Klf1* (*Kruppel like factor 1*), and that the double knockout of *Dnmt3a* and *Tet2* synergistically up-regulate *Klf1* and related pathway, which may contribute to malignant transformation.

Mutations in *IDH1* and *IDH2*

Interference with cellular energy metabolism has recently been defined as one of the emerging hallmarks of cancer. *IDH1* and *IDH2* are key enzymes involved in the TCA cycle; frequent mutations of both enzymes in cancer provide a prominent example to support this notion. *IDH1* mutations were first identified in glioblastoma through whole-exome sequencing, and *IDH2* mutations were identified in AML through a candidate gene approach. Mutations of *IDH1* and *IDH2* have now been detected in a broad spectrum of cancer types including astrocytoma, glioblastoma and AML.

The IDH Family

The IDHs catalyze the oxidative decarboxylation of isocitrate to α-ketoglutarate, which is an essential step in the TCA cycle. There are five IDHs in human genome and they belong to two distinct subclasses: IDH1 and IDH2 utilize NADP(+) as the electron acceptor, whereas IDH3 α, β and γ use NAD(+). They also show different subcellular localization: while IDH2, IDH3 α, β and γ localize to mitochondria, IDH1 predominantly functions in the cytoplasm. The IDH family is extremely conserved through evolution, as both of the NADP(+)- and NAD(+)-dependent IDHs have homologues in all eukaryotes ranging from yeasts to humans. Unlike the DNMT and TET families in which the different members in mammals share a common ancestor in invertebrates, the homologues of both IDH1 and IDH2 are found in invertebrates such as the nematode *Caenorhabditis elegans* (**Fig. 5**A), suggesting that their different roles were specified much earlier through evolution than that of the DNMT and TET family members.

Gain-of-Function Mutations in *IDH1* and *IDH2*

Mutations of *IDH1* and *IHD2* identified in cancer are heterogenous, and, as same as *DNMT3A*, they clearly show mutational hotspots—most of the mutations occur at one of three highly conserved arginine residues: R132 of IDH1 and R140 and R172 of IDH2 (**Fig. 5**B). Based on the evolution analysis and sequence alignment, the R132 in IDH1 is exactly the homologous residue of R172 in IDH2 (**Fig. 5**C). As there has not been evidence for haploinsufficiency of *IHD1* and *IDH2* in cancer, their mutational pattern suggests a possibility that these mutants might be gain-of-function. Supportive of this possibility, the mutant IDH1 and IDH2 have been found to acquire a neomorphic enzymatic activity that converts α-KG to 2-hydroxyglutarate (2-HG). It has also been shown that patients with AML harboring *IDH1* or *IDH2* mutations have significant higher level of 2-HG in their serum, suggesting that 2-HG could be considered as a biomarker of *IDH*-mutated AMLs. Furthermore, 2-HG has been shown to be sufficient to promote malignant transformation of hematopoietic cells, and this effect is reversible upon removal of 2-HG. Thus, 2-HG represent an "oncometabolite," which is produced specifically in cancer cells and exert a cancer-inducing activity.

Mutual Exclusivity Between *IDH1/2* and *TET2* Mutations

The structural similarity between α-KG and 2-HG suggests that the 2-HG could act as an inhibitor of the enzymes that naturally require α-KG as a co-factor. Indeed, members of several subfamilies of α-KG-dependent dioxygenases have been shown to be inhibited by 2-HG. These dioxygenases include the TETs, which, as described above, are responsible for erasing the DNA methylation and are also frequently mutated in hematopoietic malignancies. Interestingly, genomic and epigenomic studies of a large cohort of patients with AML have demonstrated that *IDH* mutations and *TET2* mutations are mutually exclusive, and that patients

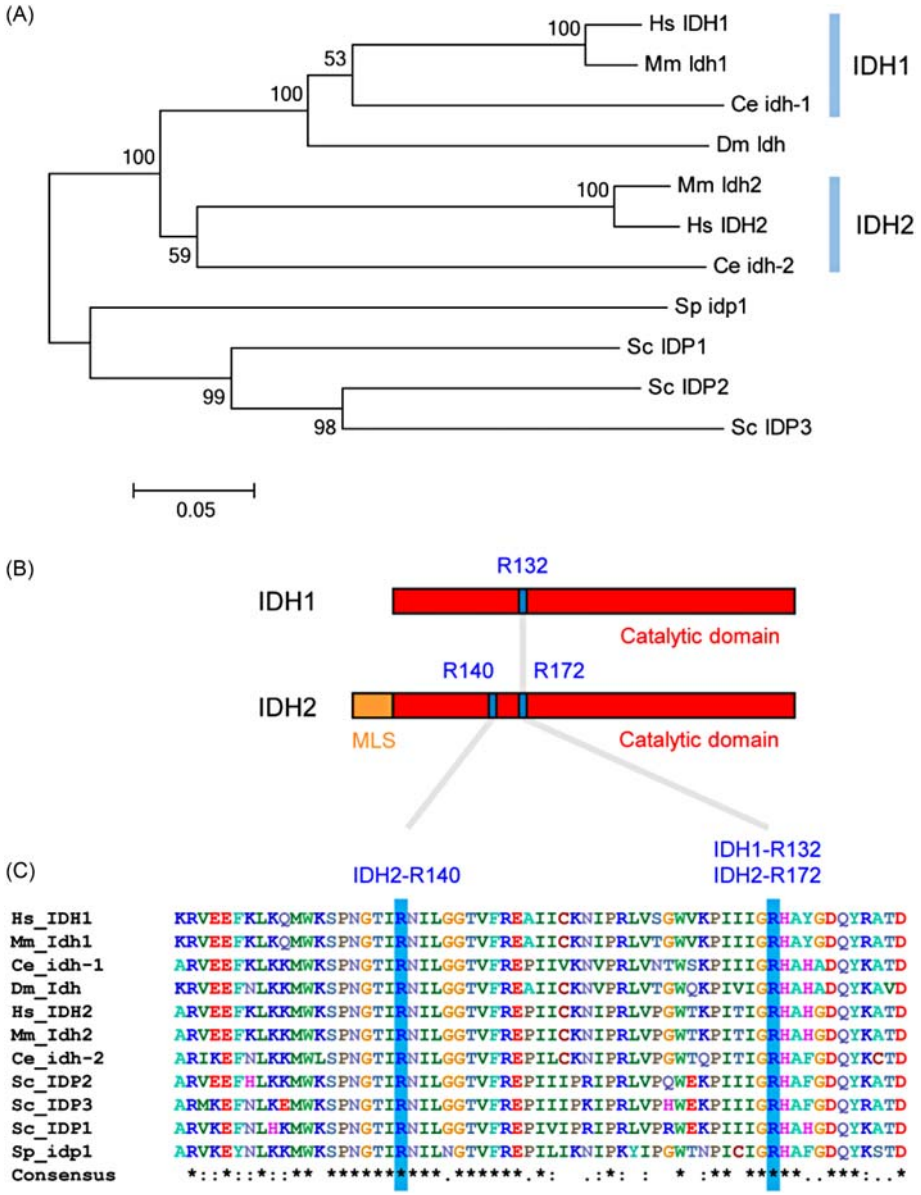

Fig. 5 The IDH1/2 family and the mutational hotspots. (A) Phylogenic tree of the IDH1/2 family members in human (*HS*), mouse (*Mm*), fruit fly (*Dm*), nematode (*Caenorhabditis elegans*, *Ce*), fission yeast (*Schizosaccharomyces pombe*, *Sp*) and baking yeast (*Saccharomyces cerevisiae*, *Sc*). Note that the *Caenorhabditis elegans* contains two IDHs (idh-1 and idh-2) related to the mammalian IDH1 and IDH2, respectively. (B) Domain architectures of human IDH1 and IDH2. A mitochondrial localization signal (MLS) is on the N-terminus of IDH2. The three mutational hotspots are localized in the catalytic domains of IDH1 and IDH2; the R132 of IDH1 is corresponding to the R172 of IDH2. (C) Alignment of the amino acid sequence context of the mutational hotspots in the IDH1/2 family members, showing the high conservation of these two R residues as well as their sequence context.

harboring mutations in *TET2* or *IDH1/2* share similar genome-wide methylation profiles, thus suggesting that the *TET2* and *IDH1/2* mutations affect the same pathway.

2-HG Is Involved in Many Cellular Processes Through Various α-KG-Dependent Dioxygenases

Besides the TETs, many other α-KG-dependent dioxygenases can also be inhibited by 2-HG. Given that these enzymes play important roles in different signaling pathways, the cancer-associated *IDH1* and *IDH2* mutations and their product 2-HG are involved in many cellular processes and thereby can regulate different aspects of development and cancer.

First, the Jumonji C domain-containing histone lysine demethylases are α-KG dependent dioxygenases sensitive to 2-HG. Ectopic expression of *IDH1/2* mutants leads to dramatic accumulation of lysine-methylated histones. Compared to the wild-type cells, IDH1 mutated oligodendroglioma shows elevated H3K9me3 and H3K27me3.

Second, a pair of α-KG-dependent dioxygenases, the fat mass and obesity-associated protein (FTO) and the alkB homologue 5 (ALKBH5) RNA demethylases, are responsible for removing the RNA N^6-adenosine methylation (m6A); the m6A modulates several aspects of RNA functions including splicing, nuclear export, stability and translation. There has been evidence suggesting that the IDH mutants affects mRNA m6A levels in leukemia cells likely through 2-HG inhibition of FTO activity.

Third, in the hypoxia signaling pathway, the stability of the hypoxia-inducible factors (HIFs) is mainly regulated through HIF hydroxylation mediate by two families of enzymes, namely the three prolyl hydroxylase domain proteins (PHD1, PHD2 and PHD3) and an asparaginyl hydroxylase factor inhibiting HIF (FIH). These hydroxylases require α-KG as a co-factor and potentially can be inhibited by 2-HG. The correlations between IDH mutation, DNA methylation and hypoxia signaling turn out to be cellular context dependent; the detailed underlying mechanisms require further clarification.

Lastly, the type IV collagen can be hydroxylated at their proline and lysine residues by the α-KG-dependent prolyl 4-hydroxylases 1, 2 and 3 (P4HA1, 2 and 3) and procollagen-lysine 2-oxoglutarate 5-dioxygenases 1, 2 and 3 (PLOD1, 2 and 3), respectively. Through 2-HG inhibition of type IV collagen hydroxylation, the *IDH* mutations may trigger collagen maturation defects which possibly contribute to tumor behaviors such as angiogenesis.

Targeted Therapy

The discovery of frequent mutations in epigenetic modifiers provide an enormous potential for targeted therapy of cancer. In contrast to the transcription factors, which also play an important role in gene regulation and heavily implicated in cancer but difficult to be targeted, inhibition of the enzymes responsible for DNA methylation and other epigenetic modifications is a much easier strategy. As many of the mutations in DNA methyltransferases and demethylases have been shown to be driver mutations occurred in cancer stem cells, inhibition of these mutated enzymes provides an opportunity to eliminate the cancer stem cells which otherwise are barely targeted by chemotherapy. Furthermore, the cross-talks between DNA methylation and cellular metabolism, as well as other signaling pathways, suggest a potential for combination therapy with DNA methylation agents and other available therapeutics, such as receptor tyrosine kinase inhibitors, DNA damaging agents, mTOR inhibitors, and immune therapy.

Two DNA methyltransferase inhibitors, 5-azacytidine (azacytidine, AZA) and decitabine (5-aza-2′-deoxycytidine, DAC) have already obtained approval for treatment of MDS and leukemia by the US Food and Drug Administration. Both drugs are cytidine analogues that can incorporate into DNA, block the catalytic activities of DNMTs and trigger their degradation, leading to a global DNA demethylation in the cells. Many studies have suggested that the promoter demethylation and derepression of the aberrantly silenced tumor suppressor genes underlies the anti-tumor effects of these DNMT inhibitors. However, recent studies have provided another mechanism that the DNMT inhibitors can induce the expression of double strand RNAs derived at least in part from endogenous retroviral elements, leading to an activation of interferon signaling pathway and an immune response. These studies open a new perspective on application of DNMT inhibitors in cancer immunomodulation.

Many pharmacological inhibitors of mutated IDH1 and IDH2, which are expected to diminish 2-HG production in IDH1 and IDH2 mutated cells, have been developed and are currently under clinical investigation. Among these inhibitors, for example, AGI-6780 is capable of binding in an allosteric manner at the dimer interface of the mutated IDH2 (IDH2-R140Q) but is less potent against wild-type IDH2. Interestingly, treatment with AGI-6780 induced differentiation of human acute myelogenous leukemia cells, providing a great potential for a differentiation therapy of cancer.

In summary, since the initial identification of recurrent *IDH* mutations in glioblastoma and *TET2* and *DNMT3A* mutations in myeloid malignancies, encouraging and rapid progress has been made to frame new concepts, clarify underlying mechanisms and develop targeted therapeutic strategies. While the detailed molecular mechanisms of epigenetic regulation of development and cancer need to be more thoroughly investigated, the development of drugs by mechanism-based design and functional screening approaches, as well as the translational and clinical studies, are of great importance for grasping the favorable opportunity to target these enzymes and metabolites, thereby completing the bench-to-bedside transition efficiently.

Mutations in Histone Lysine Methyltransferases and Demethylases

Sara Weirich and Albert Jeltsch, Stuttgart University, Stuttgart, Germany

Glossary

Compound heterozygous mutations Compound heterozygous mutations consist of two different mutations in the paternal and maternal alleles of a gene.

Dominant negative A dominant negative variant acts to reduce the activity of the wild-type gene.

Gain-of-function mutation A mutation that confers a new molecular function on the mutated gene.

Genetic dominance One allele in a heterozygous genotype masks the effect of the other.

Haploinsufficiency A single functional copy of a gene cannot provide sufficient gene product to preserve the wild-type phenotype leading to an altered or diseased state.

Heterozygous mutation A mutation of only one allele of a gene.

Homozygous mutation An identical mutation of both, the paternal and maternal alleles, of a gene.

Loss-of-function mutation A mutation that results in the gene product having less or no function (being partially or completely inactivated).

Epigenetic modification Covalent modification of the DNA or chromatin that encodes epigenetic information.

Epigenetics Stable heritable traits (or "phenotypes") that are not caused by changes in DNA sequence but often are not fully stable.

SET domain A 130 to 140 amino acid protein domain initially characterized in the Drosophila proteins Su(var)3–9, Enhancer-of-zeste and Trithorax that contains the active center of one family of PKMTs.

JmjC domain A protein domain that adopts the cupin fold and contains the active center of one family of KDMs.

PKMT Enzymes that methylate lysine residues in proteins.

KDM Enzymes that demethylate methyllysine residues in proteins.

Introduction

Setting and Removing of Histone Lysine Methylation

All human cells contain the same genetic information, yet they follow different developmental pathways and differentiate into the numerous different cells types found in the human body. The cellular fate and phenotype are determined by epigenetic regulatory mechanisms, which modulate the chromatin structure and control gene expression. The basic functional unit of chromatin is the nucleosome, which contains 147 base pairs of DNA wrapped around a core histone octamer comprising of two subunits of each of the histones H2A, H2B, H3, and H4. Epigenetic signals include DNA methylation, noncoding RNAs, and modifications of the histone proteins mainly within the N-terminal tails of H3 and H4, which are subject to a large variety of posttranslational modifications like acetylation, methylation, phosphorylation, or ubiquitylation. Methylation of histone tails can occur on Lys and Arg residues.

Lysine methylation is a dynamic process and methylation levels change during biological processes such as cellular differentiation or carcinogenesis. Histone lysine methylation is introduced by protein lysine methyltransferases (PKMTs, also abbreviated as KMTs) which use S-adenosyl-L-methionine (AdoMet) as methyl group donor and belong to two distinct families of proteins (see **Table 1** for a compilation of all human PKMTs and KDMs). Most histone methylating PKMTs contain a SET domain of approximately 130–140 amino acids, while currently known examples of seven-ß-strand PKMTs with histone substrates are limited to DOT1L. For the removal of lysine methylation, two families of lysine demethylase enzymes (KDMs) are responsible, the LSD family and enzymes containing Jumonji C (JmjC) domains. LSD1 and LSD2 are members of the monoamine oxidase superfamily, which are using flavin adenine dinucleotide and molecular oxygen as cofactors for the oxidation of C–N single bonds to an unstable imine intermediate generating hydrogen peroxide as byproduct. Subsequently, the imine is hydrolyzed and the methyl group is released as formaldehyde. This catalytic mechanism permits demethylation of secondary and tertiary but not of quaternary amines, limiting the substrate to mono- and dimethylated lysines. The second and much larger family of JmjC domain containing KDMs comprises about 20 human enzymes subgrouped into five subfamilies. These enzymes utilize oxygen, α-ketoglutarate, and Fe(II) ions as cofactors in the hydroxylation of lysine-bound methyl groups which is followed by the elimination of the hydroxymethyl group as formaldehyde. Enzymes of this family catalyze the removal of methyl groups from mono-, di-, and trimethylated lysine residues at various sites of the histone tails. PKMTs and KDMs are involved in several diseases including cancer.

Table 1 List of human PKMTs and KDMs with their different abbreviations, main histone substrates, and the corresponding UniProtKB entry

Enzyme name	*Full name*	*Abbreviation and abbreviation of selected synonyms*	*Main histone substrate(s)*	*KB#*
DOT1L	DOT1-like protein	DOT1L, KMT4	H3K79	Q8TEK3
EZH1	Enhancer of zeste homolog 1	ENX-2	H3K27	Q92800
EZH2	Enhancer of zeste homolog 2	EZH2, KMT6	H3K27	Q15910
G9a	Euchromatic histone-lysine *N*-methyltransferase 2	BAT8, C6orf30, G9A, KMT1C, NG36	H3K9	Q96KQ7
GLP (EuHMT1)	G9a-like protein 1	EUHMTASE1, GLP, KIAA1876, KMT1D	H3K9	Q9H9B1
MLL1 (KMT2A)	Myeloid/lymphoid or mixed-lineage leukemia protein 1	MLL1, KMT2A	H3K4	Q03164
MLL2 (KMT2B)	Myeloid/lymphoid or mixed-lineage leukemia protein 4	HRX2, KIAA0304, MLL2, MLL4, TRX2, WBP7	H3K4	Q9UMN6
MLL3 (KMT2C)	Myeloid/lymphoid or mixed-lineage leukemia protein 3	MLL3, KMT2C	H3K4	Q8NEZ4
MLL4 (KMT2D)	Myeloid/lymphoid or mixed-lineage leukemia protein 2	ALR, MLL2, MLL4	H3K4	O14686
SETD1A	SET domain-containing protein 1A	KMT2F, SET1, SET1A	H3K4	O15047
SETD1B	SET domain-containing protein 1B	KIAA1076, KMT2G, SET1B	H3K4	Q9UPS6
NSD1	Nuclear receptor-binding SET domain-containing protein 1	NSD1, KMT3B	H3K36	Q96L73
NSD2	Histone-lysine *N*-methyltransferase NSD2	NSD2, MMSET, WHSC1	H3K36	O96028
NSD3	Nuclear SET domain-containing protein 3	WHSC1L1		Q9BZ95
SET7/9 (SETD7)	SET domain containing protein 7	KIAA1717, KMT7, SET7, SET9	H3K4	Q8WTS6
SETD2	SET domain-containing protein 2	SETD2, KMT3A	H3K36	Q9BYW2
SETD8 (PR-SET7)	Histone-lysine *N*-methyltransferase KMT5A	PRSET7, SET07, SET8, SETD8	H4K20	Q9NQR1
SETDB1	SET domain bifurcated 1	KIAA0067, KMT1E	H3K9	Q15047
SETDB2	Histone H3-K9 methyltransferase	C13orf4, CLLD8, KMT1F	H3K9	Q96T68
SMYD1	SET and MYND domain-containing protein 1	/	H3K4	Q8NB12
SMYD2	SET and MYND domain-containing protein 2	KMT3C	H3K4 and H3K36	Q9NRG4
SMYD3	SET and MYND domain-containing protein 3	ZMYND1, ZNFN3A1	H3K4 and H3K5	Q9H7B4
SMYD4	SET and MYND domain-containing protein 4	KIAA1936		Q8IYR2
SMYD5	SET and MYND domain-containing protein 5	RAI15		Q6GMV2
SUV39H1	Suppressor of variegation 3–9 homolog 1	KMT1A, SUV39H	H3K9	O43463
SUV39H2	Suppressor of variegation 3–9 homolog 2	KMT1B	H3K9	Q9H5I1
SUV420H1	Suppressor of variegation 4–20 homolog 1	KMT5B	H4K20	Q4FZB7
SUV420H2	Suppressor of variegation 4–20 homolog 2	KMT5C	H4K20	Q86Y97
KDM1A	Lysine-specific histone demethylase 1A	AOF2, KDM1, KIAA0601, LSD1	Methylated H3K4 and H3K9	O60341
KDM1B	Lysine-specific histone demethylase 1B	AOF1, C6orf193, LSD2	H3K4	Q8NB78
KDM2A	Lysine-specific demethylase 2A	CXXC8, FBL7, FBXL11, JHDM1A, KIAA1004	Methylated H3K36	Q9Y2K7
KDM2B	Lysine-specific demethylase 2B	CXXC2, FBL10, FBXL10, JHDM1B, PCCX2	Methylated H3K4 and H3K36	Q8NHM5
KDM3A	Lysine-specific demethylase 3A	JHDM2A, JMJD1, JMJD1A, KIAA0742, TSGA	Methylated H3K9	Q9Y4C1
KDM3B	Lysine-specific demethylase 3B	C5orf7, JHDM2B, JMJD1B, KIAA1082	Methylated H3K9	Q7LBC6
KDM4A	Lysine-specific demethylase 4A	JHDM3A, JMJD2, JMJD2A, KIAA0677	Methylated H3K9 and H3K36	O75164
KDM4B	Lysine-specific demethylase 4B	JHDM3B, JMJD2B, KIAA0876	Methylated H3K9	O94953
KDM4C	Lysine-specific demethylase 4C	GASC1, JHDM3C, JMJD2C, KIAA0780	Methylated H3K9 and H3K36	Q9H3R0
KDM4D	Lysine-specific demethylase 4D	JHDM3D, JMJD2D	Methylated H3K9	Q6B0I6
KDM4E	Lysine-specific demethylase 4E	KDM4DL	Methylated H3K9	B2RXH2
KDM5A	Lysine-specific demethylase 5A	JARID1A, RBBP2, RBP2	Methylated H3K4	P29375
KDM5B	Lysine-specific demethylase 5B	JARID1B, PLU1, RBBP2H1	Methylated H3K4	Q9UGL1
KDM5C	Lysine-specific demethylase 5C	DXS1272E, JARID1C1, SMCX1, XE169	Methylated H3K4	P41229
KDM5D	Lysine-specific demethylase 5D	HY, HYA, JARID1D, KIAA0234, SMCY	Methylated H3K4	Q9BY66
KDM6A	Lysine-specific demethylase 6A	UTX (Ubiquitously transcribed X-chromosome tetratricopeptide repeat protein)	Methylated H3K27	O15550
KDM6B	Lysine-specific demethylase 6B	JMJD3, KIAA0346	Methylated H3K27	O15054

Critical Enzymatic Properties of PKMTs and KDMs

PKMTs were initially identified as histone lysine methyltransferases and shown to have very important roles in the regulation of gene expression and chromatin biology. Later, they were also shown to methylate several nonhistone substrates. Similarly, KDMs show activity on histone and nonhistone proteins, which both have roles in cancer. Locus-specific histone lysine methylation can signal either gene activation or repression, depending on the site of modification. For example, H3K4me3 has an activating function, while H3K9me3 and H3K27me3 are repressive marks. For the biological outcome of the lysine methylation it is also important to consider that a lysine side chain can be mono-, di-, or trimethylated and different methylated forms in general cause different effects. For example, H3K4me1 is associated with enhancers, while H3K4me3 is associated with promoters of active genes. The biological effects of lysine methylation are mediated by reading domains, which specifically interact with methylated lysine residues and trigger downstream signaling. Lysine methylation of nonhistone proteins can influence their stability and interaction with other proteins. However, the biological effects of nonhistone lysine methylation are not well understood in most cases.

The substrate spectrum of PKMTs and KDMs is determined by the recognition of the target peptide in the active site, which includes readout of the peptide sequence. Moreover, the access of PKMTs and KDMs to target lysine residues is controlled by the interaction of the enzyme with substrate proteins. In the case of histone methylation and demethylation, the locus-specific targeting of the PKMTs and KDMs by either endogenous binding domains or (more often) other proteins and RNAs is essential for the biological activity. In the cell, PKMTs and KDMs form large complexes with a number of additional proteins, which have roles in their regulation and targeting. These complexes often contain other epigenetic writers or erasers and they regularly contain several DNA binding and epigenetic reading domains for locus-specific targeting. For example, while isolated EZH2 is weakly active, the PRC2 complex consisting of EZH2 and six protein partners, which has a molecular weight of approximately 500 kDa, is a highly active H3K27 trimethyltransferase. Regulation of PKMTs and KDMs often includes conformational changes between active and auto-inhibited states that prevent the aberrant activity at nontarget sites. Moreover, the ability of PKMTs and KDMs to generate different methylation states is an important property of these enzymes. More to that, PKMTs and KDMs differ in their ability to use differentially methylated lysine residues as substrates. For example, the SUV420H1 enzyme introduces H4K20 trimethylation. However, it is only weakly active on unmethylated H4, but needs monomethylated H4K20 as substrate, which is generated by the SET8 PKMT. Hence SUV420H1 is dependent on lysine methylation introduced before by SET8, which restricts its biological effects. Similarly, LSD family KDMs are not able to remove methylation from trimethylated lysine residues, which limits their potential effects.

In summary, the critical enzymatic properties of PKMTs and KDMs are their amino acid sequence recognition, the preference for particular methylation states of the target lysine, their ability to generate mono-, di-, or trimethyllysine, protein–protein interaction, and their regulation and targeting. All these properties can be potentially altered by mutations in cancer cells, which in turn can cause massive changes in the signaling potential of the mutated enzymes.

Somatic Cancer Mutations in Epigenetic Enzymes

Carcinogenesis is driven by the acquisition of a series of mutations and epigenetic changes, many of which ultimately confer a growth advantage upon the cells in which they have occurred. Epigenetic enzymes that modify histone proteins and DNA are involved in several diseases including cancer. Various genome-wide exome sequencing studies revealed several genes that are recurrently mutated in tumor tissues. Among them are mutations in genes that are involved in epigenetic functions either directly or indirectly, including many PKMTs and some KDMs, which will be described in this article in detail.

The prevalence of somatic mutations in chromatin-modifying genes highlights the central role of transcriptional dysregulation in tumorigenesis. Somatic mutations in these enzymes might lead to either loss- or gain-of-function similar to mutations in other genes. Loss-of-function refers to mutations that reduce or disrupt the enzymatic activity, while gain-of-function refers to mutations, which confer novel activities on the mutated enzymes. Loss-of-function mutations include not only nonsense mutations, frameshift mutations, and deletion, which all directly disrupt protein synthesis, but also some missense mutations, which affect amino acid residues essential for catalysis or protein folding, for example. Somatic mutations can occur on one allele only (heterozygous) or on both alleles. If both alleles are affected, usually they carry different mutations (compound heterozygous). Gain-of-function effects are caused by missense mutations leading to amino acid exchanges, which alter critical enzymatic properties. They are almost always dominant yielding biological effects in heterozygous state. Loss-of-function mutations have biological effects if they occur as compound heterozygous mutation such that both alleles are affected. Heterozygous loss-of-function mutations (still combined with one wild-type allele) can have biological effects if the mutations act in a dominant negative or haploinsufficient manner meaning that the mutated gene reduces the activity of the remaining wild-type gene or the reduced amount of the wild-type gene product is not sufficient to fulfill its biological task.

The physiological effects of loss-of-function mutations are often predictable because they directly relate to the function of the corresponding gene product. In contrast, understanding the pathogenic mechanism of gain-of-function mutations is complex and it requires an in-depth experimental investigation of each specific mutation of the corresponding protein. On the other hand, understanding the mechanisms of gain-of-function mutations provides unique information about carcinogenic pathways and it may aid in the development of individualized cancer therapies.

Somatic Cancer Mutations in PKMTs and KDMs

This review will focus on the description of somatic cancer mutations in PKMTs and KDMs (Fig. 1). The strongest enrichment of somatic cancer mutations among PKMTs is observed in EZH2, but MLL3, MLL4, SETD2, SYMD1, SMYD3, and SUV420H1 also show relatively high frequencies of somatic cancer mutations when compared to the size of the proteins. Among KDMs, the highest frequency of mutations is observed in KDM6A followed by KDM4D. Of note, this distribution may be influenced by sample bias, because the initial observation of mutations in one enzyme will always stimulate targeted follow-up work that may lead to the discovery of additional mutations. In addition, the mutational spectrum depends on the tumor type, but currently databases are dominated by blood cancers (due to the relative ease of preparing pure tumor cells for analysis). Therefore, the picture may change in future when more data for various other cancers will become available.

As described above, somatic cancer mutations in PKMTs and KDMs could have loss-of-function or gain-of-function effects. While frame-shifts and deletion mutations will mainly have loss-of-function effect, the situation is less clear for missense mutations, which cause an amino acid exchange in the protein. Such point mutations could inactivate the enzyme, if they disrupt cofactor binding, folding, or the binding of the substrate peptide. However, point mutations can also have gain-of-function effects, like the alteration of the peptide interaction potentially leading to the methylation or demethylation of novel substrates, the change of the product methylation state or preferred substrate methylation state, or an alteration of the interaction with other proteins leading to changes in the regulation or targeting of the PKMT (Fig. 2). Depending on the original role of the mutated PKMT or KDM in the regulation of cancer-related genes by histone methylation, somatic mutations in PKMTs or KDMs can lead to the overexpression of oncogenes or loss of expression of tumor suppressor genes via different pathways. If effects are based on the altered methylation of nonhistone proteins, oncogenic proteins can be stabilized or activated or proteins with tumor suppressor activity can be destabilized or inactivated.

To allow an initial prediction of the main effect of somatic cancer mutations in enzymes, one can calculate the ratio of the missense mutations divided by the sum of frame-shift and nonsense mutations (Sense Score) (Fig. 3). This number corresponds to the probability of a widespread gain-of-function mechanism, because a missense mutation has the potential to cause gain-of-function effects, while frame-shift or nonsense mutations will lead to loss-of-function. Thus, a high Sense Score as seen in DOT1L, GLP, SETD1A, SMYD1, SMYD4, SMYD5, SUV39H1, KDM1B, KDM4A, and KDM4B proposes a gain-of-function effect of many mutations in these enzymes. These effects are often dominant and the mutated enzymes act as oncogenes. In contrast, low Sense Scores as in MLL4, SETD2, or KDM6A predict loss-of-function effects as main mechanism suggesting that the corresponding wild-type proteins have a tumor suppressor activity. However, the Sense Score can only provide a rough approximation, since each mutation obviously has its own effects on the enzyme that may differ from the "average" effects of all other mutations. Moreover, epigenetic enzymes can have different roles in different tumors acting as oncogenes in some cases and tumor suppressors in others. In the following sections, we will introduce several important families of PKMTs and KDMs, briefly summarize their role in cancer, and describe the effects of somatic cancer mutations in the respective enzymes.

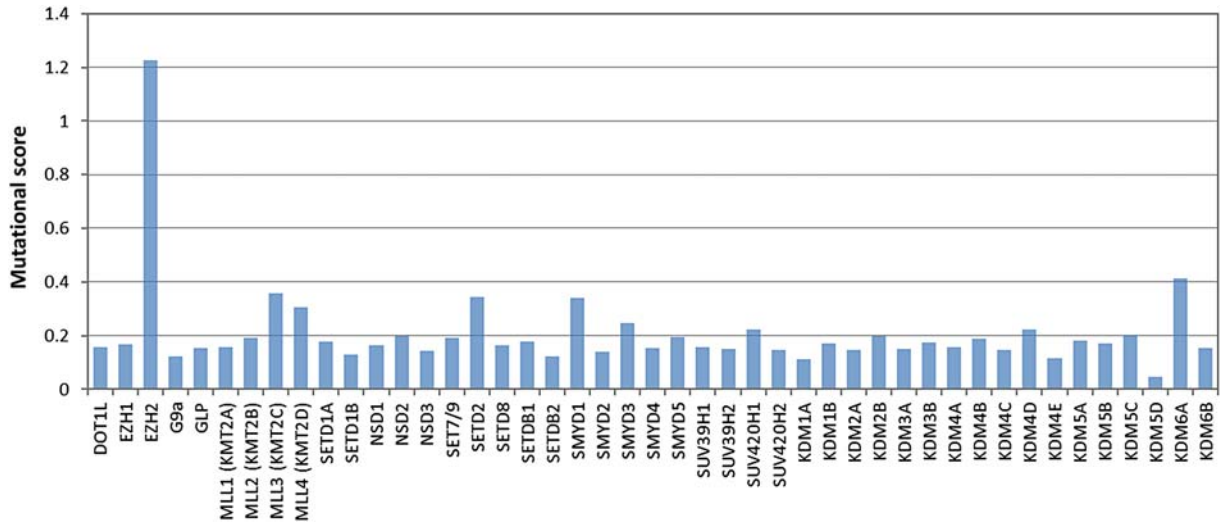

Fig. 1 Graphical representation of the Mutational Scores of PKMTs and KDMs. Data were retrieved in September 2017 from the Cosmic database. The Mutational Score is defined by the ratio of the total number of somatic tumor mutations in the corresponding enzyme divided by the length of the protein in amino acids.

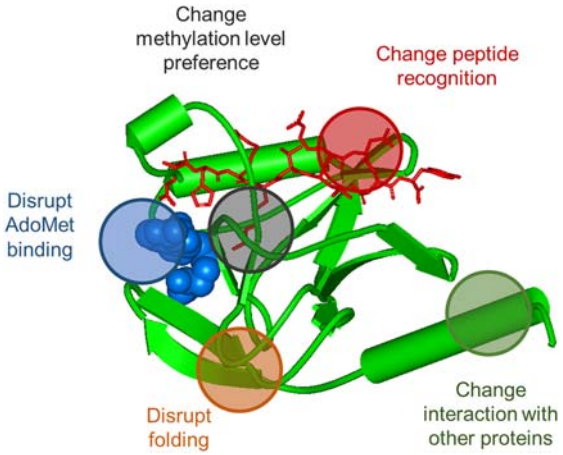

Fig. 2 Potential effects of somatic cancer mutations in PKMTs and KDMs. Mutations may interfere with AdoMet binding or protein folding, which will lead to loss of activity. Mutations may alter the methylation level preference of the PKMTs and KDMs with respect to either the product or the substrates representing a gain-of-function effect. In addition, mutations may change the interaction with other proteins and alter the regulation or targeting of the PKMT. Finally, mutations may change the recognition of the target peptide or binding of the substrate protein leading to either loss of activity on the original substrate or eventual activity on novel substrates. From Kudithipudi, S. and Jeltsch, A. (2014). Biochimica et biophysica acta (BBA)—review on cancer 1846, 366–379 with permission.

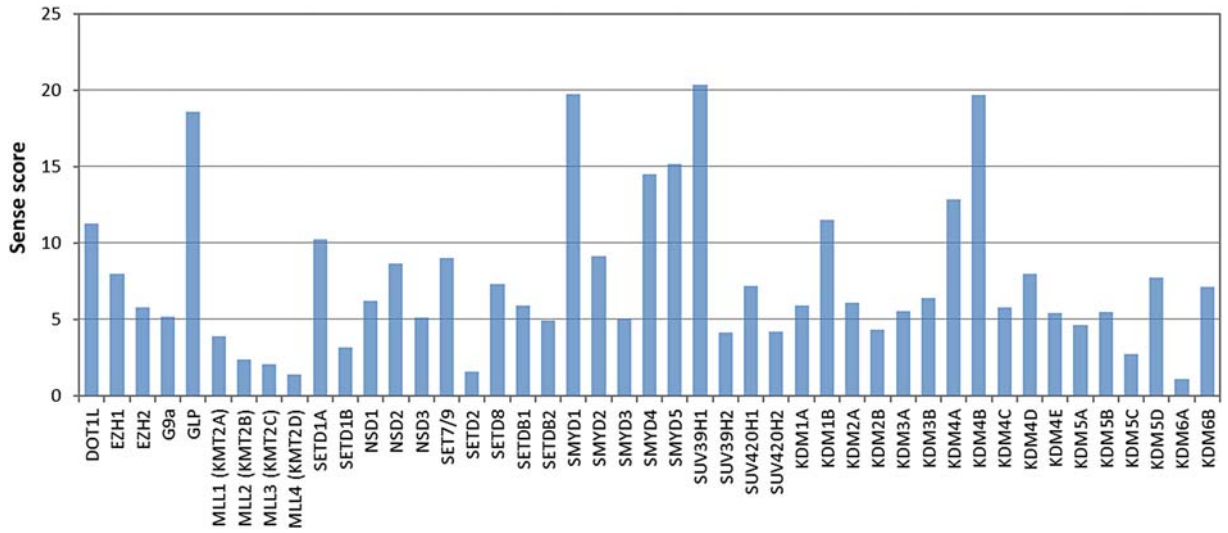

Fig. 3 Graphical representation of the Sense Scores of somatic cancer mutations in PKMTs and KDMs. Data were retrieved in September 2017 from the Cosmic database. The Sense Score is defined by the ratio of the missense mutations (which depending on the exchange can cause loss-of-function or gain-of-function effects) divided by the number of frame-shift and nonsense mutations (which will usually cause loss-of-function effects).

Specific Roles of PKMTs and Their Known Somatic Mutations in Cancer

The EZH2 H3K27 PKMT

The Polycomb repressive complex 2 (PRC2) introduces H3K27me3, which is an important repressive chromatin mark. In mammals, the PRC2 core complex consists of EED, SUZ12, NURF55, Rbap46/48, and the catalytic subunits EZH1 or EZH2. It also has some variable additional subunits including PHF1, JARID2, and AEBP2, which further regulate the PRC2 activity. The SET domain containing EZH1 and EZH2 subunits represent the catalytically active components that introduce up to three methyl groups on H3K27. The interaction between EZH1/2 and the embryonic ectoderm development (EED) protein in the PRC2 complex is particularly essential for activity because EED stimulates the catalytic activity of EZH2 as a scaffolding protein. Moreover, EED contains a seven-bladed β-propeller WD-40 domain forming an aromatic cage that binds trimethylated H3K27 and mediates the association of PRC2 with H3K27me3 containing chromatin thereby supporting the propagation of H3K27me3. Genes repressed by PRC2 include HOXC8, HOXA9, MYT1, CDKN2A, and retinoic acid target genes, which all have important roles in development

and differentiation. In addition, Polycomb proteins play an important role in epigenetic gene silencing in X-chromosome inactivation and imprinting. Furthermore, Polycomb target genes include transcription factors (TFs), signaling genes that play a main role in cell fate determination, and tumor suppressor genes, which function to prevent uncontrolled cell proliferation. The PRC2 complex may also serve as a recruiting platform for DNA methyltransferases, thereby linking these two epigenetic repression systems.

The Role of EZH2 and Its Somatic Mutations in Cancer

Mutations in Polycomb proteins cause developmental defects due to the deregulation of gene expression of key TFs, such as the Homeobox proteins. Polycomb-mediated silencing of those genes prevents the cell from undergoing senescence, which might ultimately lead to the occurrence of cancer. EZH2 overexpression is observed in many tumors and it correlates with a poor prognosis in several tumor types. EZH2 overexpression can lead to the hyper-silencing of differentiating genes or tumor suppressor genes, which can be reverted pharmacologically with EZH2 inhibitors. However, other studies reported that EZH2 has both oncogenic and tumor suppressive roles. The oncogenic histone H3K27M missense mutation identified in pediatric glioblastoma inhibits the PRC2 complex by binding to the catalytic active site of EZH2 and blocking its activity. Moreover, EZH2 methylates nonhistone proteins including the TF GATA4 and retinoic acid receptor alpha, which also could have an effect in carcinogenesis.

Next-generation sequencing of follicular lymphoma and diffuse-large B-cell lymphoma has revealed recurrent somatic mutations within the catalytic SET domain of EZH2 very frequently at Y641 (mainly to F, N, S, and H) and less frequently at A677 (mainly to G). Heterozygosity and the presence of equal quantities of both mutant and normal mRNA as well as expressed protein suggest a dominant gain-of-function mode of action. The Y641 residue is part of the so-called aromatic cage in the active center of EZH2 that surrounds the target lysine ε-amino group. For several PKMTs it was reported that mutations of aromatic cage residues affect the substrate preference and product pattern. The structure of the wild-type and mutant SET domain of EZH2 showed that the hydroxyl group of Y641 (supported by the carbonyl of A677) forms a hydrogen bond to one proton of the lysine ε-amino group, which prevents trimethylation of the target lysine. As a consequence, wild-type EZH2 introduces mono- and dimethylation of H3K27 preferentially using the unmethylated peptide as substrate, while the Y641 mutants prefer mono- and dimethylated peptide substrates to introduce trimethylation. Therefore, these mutations change the methylation level of the product of the EZH2 reaction. EZH2 overexpression or activating mutations likely have a common carcinogenic mechanism based on the hyper-silencing of differentiating genes or tumor suppressor genes. The dominant mode of action of these hyperactive variants suggests EZH2 inhibitors as therapeutic strategy for cancers containing this mutation or overexpressed EZH2. Indeed, several efficient EZH2 inhibitors were developed showing promising effects in animal models and first clinical studies. This development illustrates that understanding of the mechanism of cancer mutations in PKMTs is an important step for targeted and individualized cancer treatment.

The MLL1 and MLL3 H3K4 PKMTs

The mixed lineage leukemia (MLL) family of PKMTs are composed of six members: MLL1–4, SET1A, and SET1B. Each enzyme has H3K4 methyltransferase activity, but they are not redundant and have specific cellular functions. H3K4 can be mono-, di-, and trimethylated and specific MLL proteins introduce defined methylation states of H3K4 at distinct genomic regions. MLL1/2 (KMT2A/B) are trimethyltransferases at promotor regions of genes involved in early development and hematopoiesis, MLL3/4 (KMT2C/D) introduce monomethylated H3K4 at enhancer elements, and the SET1A and SET1B proteins contribute to the bulk of H3K4 trimethylation in mammals. To achieve full methyltransferase activity, MLL proteins require the formation of a core complex containing tryptophan-aspartate repeat protein-5 (WDR5), retinoblastoma-binding protein-5 (RBBP5), and absent small homeotic-2-like (ASH2L) (WRA complex). Interaction with complex partners reorients the SET-I helix in the SET domain switching the enzyme from an inactive autoinhibited state into an active conformation. This effect is mainly caused by the interaction with the RBBP5/ASH2L heterodimer, leading to efficient activation of MLL3 in the presence of these two factors. The interaction of MLL1 with the RBBP5/ASH2L heterodimer is weaker compared to the other MLL enzymes. Therefore, MLL1 requires WDR5 for efficient binding of the RBBP5/ASH2L heterodimer such that MLL1 only exhibits full methyltransferase activity in the presence of all three complex partners. The isolated SET domains of MLL1 and MLL2 also show activity and monomethylate H3K4. In complex with WDR5, ASH2L, and RBBP5 they trimethylate the substrate lysine residue. Although the MLL1 protein contributes to only about 5% of the global H3K4 trimethylation, it is majorly responsible for the regulation of HOX genes and loss of WDR5 expression in cells reduced the H3K4 methylation of HOX gene promoters and decreased Hox gene expression. In addition to the core complex partners, different MLL complexes contain variable additional subunits involved in more specific targeting and regulation.

The Role of MLL1 and Its Somatic Mutations in Cancer

MLL1 undergoes numerous chromosomal translocations with more than 70 different partner genes that are found in several human acute leukemia. AF4, AF9, AF10, and ENL are reported to form fusion partners in more than 75% of MLL associated leukemia; these fusion genes are sufficient to transform normal cells to leukemic cells. In these chromosome translocations, the N-terminus of MLL1 is fused in frame with the partner proteins such that the fusion proteins retain the DNA binding and targeting domains of MLL1, but they lose the C-terminal catalytic SET domain. This leads to dysregulation of developmental genes, like HoxA9 and Meis1.

Aggressive leukemia in children and adults with MLL1 gene translocations show high expression of HOX genes. MLL1 knockdown affects cell cycle-regulating genes especially cyclin A, cyclin B, and p57, which results in a cell cycle arrest in the G2/M phase and apoptosis in cultured cells. Malignant cells are more sensitive to MLL1 knockdown than the normal cells, which might be due to the essential requirement of the MLL1 gene for the high proliferation of malignant cells. Consequently, knockdown of MLL1 in a xenograft mouse tumor model was shown to suppress tumor growth. In summary, MLL1 is an oncogenic protein; it is overexpressed in tumors or it forms fusion partners with other genes finally enhancing the expression of HOX genes. Similarly, MLL2, the closest paralog of MLL1, functions as oncogene and its deletion led to a reduction in the survival of MLL–AF9 leukemia cells. In addition, the combined loss of MLL1 and MLL2 further reduced AML growth. These discoveries indicate that addressing MLL1 and/or MLL2 could be valuable therapeutic strategies.

Several somatic cancer mutations were found in MLL1 leading to nonsense, missense, and frame-shift mutations (Fig. 1), but only few of them have been studied mechanistically. The catalytic activity of four MLL1 cancer mutants found in different tumors was determined in absence and presence of the complex partners WDR5, RBBP5, and ASH2L. Two mutants, R3903H and S3865F, showed partial or complete loss of activity. This result was in agreement with the relatively low Sense Score of MLL1 mutants. However, two mutants, R3841W and R3864C, were more active than wild-type MLL1 and both were not stimulated by the WRA complex. Because of their hyperactivity and the lost control of activity by the WRA complex, these mutants are likely to cause gain-of-function effects. Mechanistically, all these effects were triggered by conformational changes of the enzyme into more stable active or inactive states. These data show that different somatic cancer mutations of MLL1 found in different tumors can lead to inhibition or stimulation of MLL1 combined with a loss of the regulation of its methyltransferase activity by complex partner proteins. This finding highlights the multifaceted roles of MLL1 in cell fate determination and gene regulation. Furthermore, the inhibition of the cancer mutants by the MM-102 inhibitor was tested, which disrupts the interaction between MLL1 and WDR5 leading to growth inhibition of MLL-AF9 leukemia cells. In line with the enzymatic results described above, the activity of R3841W and R3864C, which did not depend on WDR5 binding for activity, was not reduced by MM-102, indicating that this compound would not be a therapeutic option for patients with these mutations in MLL1. This observation highlights the importance of genetic analysis of tumor samples combined with specific functional investigation of the effect of somatic tumor mutations in the design of individualized therapies.

The Role of MLL3 and Its Somatic Mutations in Cancer

MLL3 is often deleted in myeloid leukemia and inactivation of MLL3 in mice leads to epithelial tumor formation, which suggests that the methyltransferase activity of MLL3 suppresses tumorigenesis. MLL3 expression was also decreased by at least twofold in almost half of the breast cancer patients when compared to the matched normal tissue, but the expression changes did not correlate with the tumor progression and the pathological effects of changes in the MLL3 expression in breast cancer are still ambiguous. In addition, in colorectal cancer cell lines the MLL3 promoter is hypermethylated, which results in the repression of MLL3 protein expression. Taken together, these findings indicate that MLL3 has a tumor suppressor role in several cancers.

MLL3 and MLL4 are frequently mutated in cancers (Fig. 1) but their pathological effects are not known in most cases. MLL3 shows a high frequency of loss-of-function mutations (Fig. 3), which are spread over the entire protein including the PHD fingers and SET domain. Three mutations located in the catalytic SET domain of MLL3 (S4757C, N4848S, and Y4884C) were investigated regarding their effects on critical enzymatic properties. One mutation, N4848S, led to a loss of catalytic activity, which is in agreement with the location of N4848 in the AdoMet binding site of MLL3. This result is in line with the evidence for a tumor suppressive function of MLL3 described above. However, another mutation, Y4884C, located in the aromatic pocket of the SET domain, showed a striking gain-of-function effect. Kinetic data demonstrate that MLL3 wild-type preferentially transfers one single methyl group to unmethylated H3K4 generating H3K4me1. In contrast, in vitro methylation studies showed that the Y4884C mutation converts MLL3 into a trimethyltransferase with H3K4me1 as preferred substrate. This result was further confirmed by global histone H3K4me3 methylation analysis from human cell lines. Hence, the mutagenic phenotype and pathogenic mechanism of Y4884C mirrors that of Y641 mutations in EZH2. By generation of abnormal H3K4me3 instead of H3K4me1, enhancer regions could be reprogrammed to function as promoters leading to abnormal gene expression. Interestingly, like in MLL1, these results suggest that each MLL3 mutant has individual roles during tumorigenesis, which may be related to the corresponding tumor types and tumorigenic pathways in different cell types. MLL3 inhibitors might be beneficial in patients carrying the Y4884C mutation, while they are unlikely to be effective in cases with inactive MLL3.

MLL4 is a H3K4 monomethyltransferase belonging to the same subfamily as MLL3. It is often found mutated in cancers and a large fraction of the MLL4 cancer mutations are nonsense or frame-shift mutations which inactivate the enzyme (Fig. 3), indicating a tumor suppressor role of MLL4 at least in some cell types. Somatic loss-of-function mutations of MLL4 were observed on a single copy of the gene suggesting that MLL4 acts as a haploinsufficient tumor suppressor.

The DOT1L H3K79 PKMT

DOT1L was initially identified in a genetic screen aiming to identify proteins involved in telomeric silencing in yeast. The yeast and human homolog was later demonstrated to methylate K79 of histone H3, which is located in the core structure of histone H3. DOT1L is a unique histone lysine methyltransferase because it does not contain a SET domain. Instead, its active site is located in a seven-ß-strand Rossmann-fold domain, also found in other class I methyltransferases, like protein arginine and DNA

methyltransferases and other PKMTs, which methylate nonhistone substrates. H3K79 methylation is associated with active gene transcription and it is also involved in cell cycle regulation. H3K79me3 and me2 are majorly localized in the coding regions of active genes, whereas H3K79me1 is broadly distributed across the coding region. DOT1L-mediated H3K79 methylation is important for embryonic development and a germline knockout of the mouse DOT1L homolog causes embryonic lethality. DOT1L is the sole enzyme that methylates H3K79 indicating that it represents the main target protein in diseases related to the aberrant H3K79 methylation.

The Role of DOT1L and Its Somatic Mutations in Cancer

During the last years, several reports have demonstrated that DOT1L is linked to MLL-mediated leukemia. As described above, 70% of the infant leukemia patients were found to have MLL translocations, in which the N-terminal part of MLL containing its DNA recognition motifs is expressed as a fusion protein with several partner proteins like AF10, AF9, AF4, or ENL. These fusion proteins retain the MLL DNA binding and chromatin targeting domains, which results in an altered MLL target gene regulation depending on the fusion partner. Interestingly, it was found that all of these fusion proteins physically interact with DOT1L either directly or indirectly. This leads to a recruitment of DOT1L to MLL target loci. The resulting increased H3K79 methylation is a positive transcription mark that, bypassing the normal transcription regulation, causes the expression of proleukemogenic genes (like HOXA9 and MEIS1) and by this stimulates the development of leukemia. H3K79 trimethylation plays a crucial role in the regulation of HOX genes such as Hoxa9, Hoxa7, and Meis1, which are overexpressed after aberrant H3K79 methylation in leukemic cells. Thus, DOT1L is an example in which the mistargeting of a PKMT causes methylation at aberrant genomic loci.

By rational drug design and genetic approaches, it was shown that either inhibition of the activity of DOT1L or loss of the DOT1L protein has dramatic effects on the expression of HOX genes. A DOT1L-specific competitive inhibitor of AdoMet binding selectively inhibited H3K79 methylation and blocked the expression of leukemogenic genes. This compound was efficient in killing leukemic cells with MLL translocations with relatively small effect on non-MLL leukemic cells. This result shows that the methyltransferase activity of DOT1L plays a central role in the MLL fusion-mediated cellular transformation and maintenance of the transformed state and it is a very important drug target. In addition to its pathological function in MLL-mediated leukemia, H3K79 hypermethylation was observed in lung cancer cell lines and tissues. Downregulation of DOT1L in lung cancer cell lines blocked the proliferation of cells, which further supports the oncogenic role of DOT1L. Several somatic cancer mutations in DOT1L have been identified (**Fig. 1**), but their mechanism has not yet been described. Based on the known role of DOT1L in cancer, gain-of-function or hyperactivation effects of the mutations are likely, which is also in agreement with the high Sense Score of DOT1L somatic tumor mutations (**Fig. 3**).

The SETD2 H3K36 PKMT

SETD2 was first described as Huntingtin-interacting protein B (HYPB). Later, studies have uncovered that it can trimethylate H3K36 via its SET domain, leading to its renaming to SETD2. The SETD2 protein interacts with the Ser2/Ser5 hyperphosphorylated RNA polymerase 2 during transcriptional elongation via its SRI (Set2 Rpb1 interacting) domain, which explains why H3K36 trimethylation is enriched in the body of actively transcribed genes. In humans, H3K36 mono- and dimethylation is introduced by several PKMTs (including the NSD enzymes), while H3K36me3 is only generated by SETD2.

The Role of SETD2 and Its Somatic Mutations in Cancer

The SETD2 protein interacts with p53 via its C-terminal SET and WW domains and stimulates p53 activity. Knockdown of SETD2 lowered the expression of different p53 target genes such as Puma, Noxa, Huntingtin, and p21. In addition, SETD2 also increases the stability of the p53 protein by lowering the expression of the HDMT2 Ring finger-type E3 ubiquitin ligase, which triggers degradation of p53 by ubiquitination. SETD2 mRNA expression was lost in human breast malignant tissue and the SETD2 expression levels were negatively correlated with the tumor stage. These data suggest that SETD2 can be used as a biomarker for the breast cancer and SETD2 acts as a tumor suppressor gene.

SETD2 is among the PKMTs with the highest frequency of somatic cancer mutations (**Fig. 1**). Somatic mutations of SETD2 are often observed in high grade gliomas, clear cell renal cell carcinoma, and leukemias and the majority of them are nonsense and frame-shift mutations, which lead to loss-of-function (**Fig. 3**). Gliomas with disruption of SETD2 showed a considerable decrease in H3K36 trimethylation, indicating that the SETD2 mutants negatively affect the activity of the enzyme. SETD2 truncating mutations are majorly found in the C-terminus, which either leads to the loss of the SET or SRI domains; the former leads to loss of PKMT activity and the latter disrupts the interaction with the phosphorylated RNA polymerase II. The SETD2 D1616N mutation that is located in the SET domain of the protein has been identified in the cRCC cell lines, which show a considerable loss of H3K36 trimethylation, similarly as other cRCC tumor cell lines containing mutations in the SETD2 protein. Finally, K36M mutations in histone H3, found in chondroblastomas at frequencies of up to 96%, inhibit SETD2 and lead to genome wide loss of K36me3 accompanied by gains in K27me3 and changes in the expression of cancer-associated genes. All these results document that the loss of SETD2 function plays a pivotal role in the initiation and progression of cancer, and somatic cancer mutations of SETD2 are examples of loss-of-function.

The NSD Family of H3K36 PKMTs

The nuclear receptor-binding SET domain containing protein (NSD) family consists of three members: NSD1, NSD2, and NSD3. They differ in protein size and domain organization and have specific biological functions in normal development and pathophysiology. All NSD enzymes contain a catalytic SET domain, in addition to several PHD domains and two PWWP domains. The SET domain introduces H3K36 mono- and dimethylation using unmethylated H3K36 as substrate in vivo and in vitro. The other domains mediate the interaction with chromatin and other proteins. NSD1 and NSD2 were reported to methylate several other substrates including H1.5 K168, which is efficiently methylated by NSD1, and H4K44, which is methylated by NSD1 and NSD2. Defects in the NSD family proteins are implicated in several diseases. Mutations and deletions in NSD1 lead to SOTOS syndrome, a developmental disease associated with fetal overgrowth. Loss of NSD2 activity causes Wolf-Hirschhorn syndrome (WHS) which is characterized by several developmental defects, growth retardation, and brain anomalies leading to mental retardation.

The Role of NSD Enzymes and Their Somatic Mutations in Cancer

An increasing number of reports document defects in NSD family members in several cancers: NSD1 is associated with acute myeloid leukemia and multiple leukemia, NSD2 is linked to prostate cancer and myeloid leukemia, and NSD3 is associated with breast cancer and lung cancer. Protein expression studies with 3000 different tumor samples revealed higher NSD2 expression when compared to normal tissue. Moreover, NSD2 expression positively correlated with the progression and advanced tumor stage. The cells with high levels of NSD2 contained enriched H3K36me2 and lower levels of H3K27 trimethylation and they showed a change in the distribution of H3K36me2, which is enriched in gene bodies in normal cells, but dispersed in the NSD2 overexpressing cells. Depletion of NSD2 in a xenograft mouse tumor model showed a decrease of H3K36me2 and also a reduction in tumor growth. Moreover, NSD proteins are involved in chromosomal translocations forming different fusion proteins in several cancers including fusions to the nucleoporin gene (NUP98) in NUP98-NSD1 or NUP98-NSD3, which are found in acute myeloid leukemia. The fusions enhance HOXA5-A10 gene expression via increasing H3K36 dimethylation. In summary, the deregulation of NSD proteins plays a causative role in cancers and the histone methyltransferase activity of these proteins is critical for promoting malignant growth.

Recent genomic sequence data of cancer cell lines revealed somatic mutations in NSD enzymes (Fig. 1), which especially in the case of NSD2 suggest a gain-of-function mechanism (Fig. 3). The E1099K mutation was found at very high frequency in NSD2 mostly in pediatric lymphoid malignancies, such as hypodiploid acute lymphoid leukemia (ALL), chronic lymphocytic leukemia (CLL), multiple myeloma, and lung or stomach adenocarcinoma. E1099 is located in the SET domain in a loop next to the histone binding groove and in vitro methylation assays have shown higher activity of NSD2 E1099K on nucleosomes. In addition, increased H3K36 dimethylation and decreased H3K27me3 were observed in cell lines harboring the E1099K mutant, also suggesting an increased H3K36 methyltransferase activity. However, different from the EZH2 mutations described above, the E1099K mutation enhances the methyltransferase activity of NSD2 without apparent changes of the product specificity. In addition, ALL tumors frequently contain a D1125N mutation in NSD2; this variant is also associated with higher H3K36me2 methyltransferase activity. Hence, the somatic cancer mutations in NSD2 are examples of a gain-of-function similarly as the overexpression of NSD2. These observations indicate that NSD2 has a vital role as oncoprotein and is a very promising drug target in particular for tumors with overexpressed or hyperactive NSD2.

The SMYD PKMT Family

The SMYD PKMT protein family consists of five members named SMYD1–5. SMYD proteins are not well characterized; among them SMYD2 and SMYD3 are best studied. They were grouped based on their similar domain architecture containing a split SET domain, which carries an inserted MYND (Myeloid, Nervy, and DEAF-1) domain. The MYND domain is responsible for protein–protein interactions and the split SET domain contains the catalytic elements as in other SET domain enzymes. SMYD2 has been reported to monomethylate several lysine residues on histone and nonhistone proteins. It was initially shown to methylate H3K36 but later it was reported that the interaction with HSP90α changes its specificity toward H3K4. Additional studies showed that SMYD2 also methylates K266 of estrogen receptor alpha, K370 of p53, and K810 and K860 of the retinoblastoma (RB) protein. SMYD3 was initially identified as H3K4 di- and trimethyltransferase. Later reports showed that SMYD3 can also methylate H4K20 with a preference for the dimethylated lysine as a substrate, and that it trimethylates histone H4 at K5. Apart from that, SMYD3 also methylates nonhistone proteins, like vascular endothelial growth factor receptor 1 (VEGFRI) at K831, which enhances its kinase activity. Overall, the methylation site(s) of SMYD3 are still ambiguous and the full spectrum of substrate proteins is not well known.

The Role of SMYD Family Enzymes and Their Somatic Mutations in Cancer

Methylation of nonhistone targets by SMYD2 has clear connections to cancer and overexpression of SMYD2 has a tumor-promoting effect. For example, SMYD2 methylation of p53 at K370 impairs the tumor suppressor activity of p53. Moreover, methylation of the Rb protein at K810 enhances its phosphorylation at S807 and S811 leading to the dissociation of Rb from E2F, which enhances its transcriptional activity and promotes cell cycle progression. SMYD2 is significantly overexpressed in several cancers. For example,

the SMYD2 mRNA levels were reported to be almost 8-fold increased in leukemic cells, when compared with normal bone marrow controls and patients with high SMYD2 expression showed lower survival rate. Similarly, SMYD2 protein overexpression was identified in esophageal squamous cell carcinoma (ESCC), bladder, and gastric cancer. Knockdown of SMYD2 in ESCC cell lines with overexpression of SMYD2 led to the suppression of proliferation due to a G_0–G_1 arrest, suggesting that SMYD2 inhibitors might be good cancer drugs in these cases. In summary overexpression of SMYD2 is frequently observed in several cancers and it is correlated with lower survival rate indicating that SMYD2 acts as an oncoprotein.

Similarly as SMYD2, SMYD3 acts as an oncogenic protein. Elevated levels of SMYD3 expression were observed in colorectal carcinoma (CRC), hepatocellular carcinoma (HRC), breast, pancreatic, gastric, and lung cancer cells, whereas weak or no expression was observed in noncancerous cells of other tissues. In agreement with this, suppression of SMYD3 significantly reduced the growth of CRC and HRC cells. In breast cancer cell lines, a truncated SMYD3 protein lacking the first 34 amino acids was observed as well, which was shown to have a higher activity than the full-length SMYD3. Moreover, it has been shown that SMYD3 upregulates the expression of the oncogene matrix metalloproteinase MMP-9, which is involved in tumor progression and metastasis by stimulating cell migration, tumor invasion, and angiogenesis. Suppression of SMYD3 reduces MMP9 gene expression supporting its oncogenic property. Furthermore, SMYD3 methylation of additional nonhistone substrates is a key event in Ras-driven carcinomas. SMYD3 methylates the MAP3K2 kinase at K260, which increases MAP kinase signaling and leads to the formation of Ras-driven carcinomas. In addition, MAP3K2-K260 methylation inhibits binding of PPP2 phosphatase complex, which is a cellular phosphatase and a key negative regulator of MAP kinase signaling pathway.

Low SMYD4 gene expression has been reported in breast cancer cells where it was correlated to higher expression of the platelet-derived growth factor receptor α (Pdgfr-α). In several mammalian cancers, Pdgfr-α is an oncogene, which is involved in the proliferation and survival of tumors. Re-expression of SMYD4 in breast cancer cell lines repressed the Pdgfr-α gene, suggesting that SMYD4 acts as potential tumor suppressor at least in this cellular model system. Altogether these data suggest that the SMYD proteins play vital roles in regulating the expression of oncogenes in several cancers with SMYD4 acting as tumor suppressor while SMYD3 and SMYD2 function as oncogenes.

Recent genomic sequencing in cancer patients revealed several somatic mutations in SMYD proteins with SMYD1 and SMYD3 showing the highest proportion of mutations (**Fig. 1**). The somatic mutations in SMYD PKMTs include missense and nonsense mutations as well as insertions and deletions. Interestingly, the mutational patterns are indicative of a gain-of-function effect in particular for SMYD1, but also SMYD4 and SMYD5 (**Fig. 3**). This finding is not in agreement with the observation that SMYD4 acts as tumor suppressor in breast cancer cells as described above, suggesting that the role of SMYD4 is complex and tumor type specific. Since SMYD proteins methylate several histone and nonhistone substrates they may play roles in gene expression regulation and tumor formation. It will be important to determine the full substrate spectrum of all SMYD proteins and understand the pathogenic mechanism of the somatic missense mutations on the methylation of different substrate proteins. Hyperactive somatic mutations could have the same effect as the overexpression of SMYD2 or SMYD3 in cancer cells and they may, for example, aberrantly increase the lysine methylation of tumor suppressor p53 and decrease its tumor suppressor function. Additionally, it will be interesting to see whether SMYD protein mutations may change the product specificity of the PKMT, although such an effect still awaits experimental validation.

Roles of KDMs and Their Known Somatic Mutations in Cancer

The UTX H3K27 KDM Family

The Ubiquitously Transcribed Tetratricopeptide repeat on Chromosome X (UTX) demethylase, also known as KDM6A, is a member of the Jumonji-containing lysine demethylase family. UTX catalyzes the demethylation of H3K27me2/3 in an Fe(II)-dependent dioxygenase reaction using α-ketoglutarate and oxygen as cosubstrates with the production of formaldehyde and succinate. UTX was found as a specific complex partner of the MLL3/4, which catalyze the H3K4 monomethylation at enhancers of active genes. H3K4 and H3K27 have antagonistic roles, as H3K27me2/3 leads to the repression of the same target genes, which are activated by H3K4 methylation. By demethylation of H3K27, UTX supports the maintenance of the H3K4 activation mark set by MLL3/4. UTX knockdown studies have documented its essential role in embryonic development, tissue-specific differentiation, and its requirement for correct reprogramming.

The Role of UTX and Its Somatic Mutations in Cancer

Deletion of UTX and point mutations in UTX cause the Kabuki Syndrome (KS) characterized by distinctive facial features, developmental delay, mild to moderate intellectual disability, postnatal growth retardation, and additional features such as skeletal anomalies. Previously, mutations in MLL4 were found in about half of all KS patients indicating that the switching from H3K27 methylated silenced to H3K4 methylated active chromatin states is disturbed in this disease. Moreover, UTX was the first demethylase that was found somatically mutated and associated with human cancer. Cancer mutations in the UTX gene include homozygous (in females) or hemizygous (in males) large deletions, nonsense mutations, small frame-shifting insertion/deletions, and consensus splice site mutations that lead to aberrant splicing and premature termination codons. Inactivating UTX mutations and deletion were found in several cancer types, including multiple myeloma, leukemia, esophageal, and renal cancer (**Figs. 1 and 3**). These data document that UTX acts as a tumor suppressor. Still, it was found that GSKJ4, an inhibitor of UTX and

JMJD3, is a promising suppressor of breast cancer stem cells (BCSCs) due to its efficient repression of the expansion and self-renewal capacity of BCSCs. In addition, xenograft models confirmed a significant inhibition of tumor progression in vivo. This study suggested that targeting UTX is a therapeutic option for cancer treatment, despite of its tumor suppressive role in some cancers, indicating that PKMTs and KDMs (and their somatic mutations) have tumor-specific effects.

The KDM1 Family

The human KDM1 family of histone demethylases, LSD1 (KDM1A) and LSD2 (KDM1B), catalyze the demethylation of mono- and dimethyl marks of H3K4 and H3K9. The enzymes contain a SWIRM and Amine oxidase domain, LSD2 also an N-terminal Zinc finger domain. In LSD1 the Amine oxidase domain is split by an inserted Tower domain. The substrate specificity of LSD1 is influenced by its association with different partners. LSD1 generally demethylates H3K4me1/2, but when LSD1 interacts with the androgen receptor (AR) its enzymatic specificity switches to H3K9me1/2. This dual activity enables LSD1 to regulate both the repression and activation of genes. LSD1 is a component of large transcription regulatory complexes including the nucleosome remodeling and deacetylating (NuRD) complex, RCOR1 complex, and the CtBP corepressor complex. The interaction with RCOR1 is especially relevant, since it stabilizes the protein and strongly promotes its H3K4me1/2 demethylation activity. In embryonic stem cells, KDM1A has been identified at enhancers, in association with the NuRD complex. When associated with these complexes, LSD1 promotes gene silencing by removing activating methyl marks from H3K4. KDM1A-containing complexes are recruited to their respective target genes in the genome by a series of TFs that act in specific cell types during normal development or, potentially aberrantly, in human disease. In contrast, when LSD1 interacts with the androgen or estrogen receptor, it promotes transcriptional activation by demethylating the repressive H3K9me2 (dimethylation of histone H3 at K9) histone modification. In addition, the enzyme can work on nonhistone substrates including p53, DNMT1, E2F1, MYPT1, STAT3, HIV Tat, HSP90, and MTA1. LSD2 has been described to demethylate H3K4me1/2 but the biological roles of LSD2 (KDM1B) are less known.

The Role of KDM1 Enzymes and Their Somatic Mutations in Cancer

LSD1 and its downstream targets are involved in a wide range of normal physiological processes, including embryonic development, stem cell maintenance, and differentiation, but it is also a key player in oncogenic processes, including tumor-cell growth and metastasis, compromised differentiation, enhanced cell motility, and metabolic reprogramming. LSD1 has been reported to be overexpressed in a variety of tumors and inactivating LSD1 or downregulating its expression inhibits cancer-cell development. The function of somatic tumor mutations in LSD1 and LSD2 has not yet been described, but the mutational spectrum of LSD2 (**Fig. 3**) suggests the occurrence of gain-of-function mutations.

The Role of KDM4 Enzymes and Their Somatic Mutations in Cancer

The KDM4 family comprises five members (KDM4A-E). The KDM4A, B, and C proteins are very similar to each other and contain a JmjN and JmjC domain, two PHD-, and two Tudor domains. KDM4D and KDM4E lack the C-terminal region including the PHD and Tudor domains. All KDM4 enzyme demethylate H3K9, KDM4A-C also H3K36, and some of them also H3K27. KDM4 enzymes have roles in steroid receptor regulation and they can activate the expression of oncogenes. KDM4 genes were found amplified and overexpressed in various tumor types. The effects of somatic cancer mutations have not yet been described, but a very high Sense Score of KDM4B and KDM4A mutations (**Fig. 3**) is in agreement with an oncogenic role of these enzymes.

Somatic Mutations in Related Proteins

Examples of other frequently mutated epigenetic enzymes not described in detail in this article include the DNA methyltransferase 3A (DNMT3A), the Ten-eleven-translocation 2 methylcytosine hydroxymethyltransferase (TET2), and SWI/SNF chromatin remodeling complexes. DNMT3A is an essential DNA methyltransferase frequently containing an R882H mutation in blood cancer, which has been reported to reduce its activity and changes its oligomerization in a dominant negative way and by this it may alter the DNA methylation pattern. Somatic TET2 mutations are frequently observed in various cancers. These include nonsense, deletion, and missense mutations at very crucial residues for the enzymatic activity thus predicted to inactivate the enzyme. Finally, mutations that inactivate SWI/SNF chromatin remodeling complexes subunits are found in nearly 20% of human cancers. These complexes catalyze the opening or condensation of chromatin and by this help to execute the epigenetic program.

In addition, recurrent somatic mutations were found in genes indirectly related to PKMTs and KDMs. Different isocitrate dehydrogenase (IDH) isoforms catalyze the oxidative decarboxylation of isocitrate to α-ketoglutarate (α-KG) in the TCA cycle, while reducing NAD^+ or $NADP^+$ depending on the isoform catalyzing the reaction. Unexpectedly, frequent mutations were found in IDH enzymes and shown to be involved in the progression of tumors. All discovered IDH mutations are missense mutations in the active site of the enzymes, often affecting R132 in IDH1, and either the analogous arginine residue (R172) or R140 in IDH2. The mutations occur heterozygously, suggesting that the alterations lead to a dominant gain-of-function effect. Unexpectedly, the mutant IDH enzymes were found to catalyze the NADPH-dependent reduction of α-KG to 2-hydroxyglutarate (2-HG). This oncometabolite has a similar structure as α-KG and acts as competitive inhibitor for enzymes that employ α-KG as cofactor, like

the TET enzymes and the Jumonji family of histone lysine demethylases. In agreement with this observation, hypermethylation of many histone methylation marks was observed following introduction of IDH1 mutations into cells and DNA hypermethylation by IDH mutations has been observed as well. Another example of somatic cancer mutations with indirect epigenetic effects are mutations in the histone proteins themselves. As already mentioned, different cancers frequently contain missense mutations in genes encoding histone H3.3 (H3F3A) and H3.1 (HIST3H1B), which alter methylated lysine residues to methionine, like K27M or K36M. When incorporated into chromatin, the histone mutants were shown to inhibit the corresponding PKMTs leading to massive disturbances of chromatin modification patterns.

Prospective Vision

Proteomic and genomic approaches have allowed addressing several mechanisms of carcinogenesis, but cancer is continuously confronting us with new challenges. It is well established that cancers arise as a result of gene mutations and clonal proliferation of cells containing growth-promoting alterations. The specific mutations identified in defined cancer subtypes have important diagnostic significance. For instance, Janus kinase 2 mutation (JAK V2617F) is present in many myoproliferative neoplasma and polycythemia vera and now this mutation is used as diagnostic marker for this condition. In addition, epigenetic alterations were recognized to play important roles in tumor formation. The recent discovery and characterization of somatic tumor mutations in epigenetic enzymes connect these two processes, because in these cases the genetic changes drive the appearance of epigenetic alterations. Two large classes of epigenetic enzymes are PKMTs and KDMs and the investigation of the role of somatic mutations in these enzymes in carcinogenesis is an emerging approach to the mechanistic understanding of tumor formation and progression.

While the mechanism of loss-of-function mutations in PKMTs and KDMs can be deduced from the function of the corresponding gene, this is not necessarily true for gain-of-function mutations, which might have diverse pathogenic effects: they might enhance the enzymatic activity, increase the stability of the protein, or alter the cellular targeting. Somatic mutations in PKMTs and KDMs might also alter their association with interacting partners leading to changes in the substrate profile, or recruit the enzymes to specific chromatin loci resulting in the altered expression of particular oncogenes or tumor suppressor genes. The higher activity of a mutated PKMT or KDM might lead to abnormal methylation of histones at particular loci, which either enhance or inhibit the transcription of oncogenes or tumor suppressor genes. Mutations in the catalytic SET domain of PKMTs and JmjC domain of KDMs might change their peptide sequence specificity leading to the methylation or demethylation of novel targets. Mutations may also change the product specificity leading to a change in the final methylation state of the target lysine residues. In most cases, the mechanistic consequences of somatic mutations in PKMTs and KDMs are not yet known and careful biochemical studies will be needed for their elucidation. The study of the pathomechanism of somatic cancer mutations in PKMTs and KDMs holds great promises for several reasons:

(1) Different studies have demonstrated that depending on the tumor type, inhibition of a PKMT or KDM or its hyperactivity and loss of regulation can promote tumor formation illustrating the complex and multifaceted role of these epigenetic enzymes in cell fate determination and gene regulation. Therefore, dedicated biochemical investigations are needed for each somatic tumor mutation of important PKMTs and KDMs in order to decipher its pathological role.
(2) It will be important in future to investigate the effects of somatic mutations in order to develop individualized cancer treatments. For example, inhibitors developed against specific PKMTs or KDMs might assist treatment of cancers with hyperactive enzyme mutants, but these inhibitors cannot be used to treat the cancers caused by the loss of enzyme activity. This makes the investigation of the pathomechanism of somatic cancer mutations very relevant for the development of novel more causative and individualized tumor therapies.
(3) The investigation of somatic cancer mutations in PKMTs and KDMs is also imperative for the general understanding of the role of these enzymes in carcinogenesis. Different processes such as expression changes, abnormal posttranslational modifications (PTM), or somatic mutation can alter the activity of PKMTs or KDMs in cells. However, expression levels and PTM patterns of proteins are very difficult to measure in tumor tissues and these changes may occur only transiently during a critical phase of cellular transformation. In contrast, somatic cancer mutations are stable, and they can be studied in tumor samples, cell lines, or in vitro much more easily. Therefore, studying and understanding of the mechanism of somatic cancer mutations is a powerful tool to unravel the role of the corresponding PKMT and KDM even in cases not involving mutations.
(4) The screening for somatic cancer mutations holds great promises in clinical practice, since the detection of mutations occurs at DNA level, which can be done from small samples of cancer tissue. In contrast, the detection of expression changes or aberrant PTMs needs RNA and proteomic methods, which are much more demanding with respect to sample size and sample treatment. Furthermore, simple patient blood samples can be used as normal controls in mutational screenings, while the acquisition of matching "normal" tissue for comparison is sometimes very difficult in expression studies and proteomic studies.

In summary, the investigation of the pathomechanism of somatic cancer mutations in PKMTs and KDMs is an important and urgent challenge in biomedical research. For this, relevant assay systems need to be established to investigate the properties of the wild-type enzymes and their cancer mutants in vitro and in cellular settings. These studies will also pave the way toward the generation of novel and more potent and specific PKMT and KDM inhibitors and guide their rational application in clinical studies.

Mutations: Driver Versus Passenger

Scott W Piraino, Valentina Thomas, Peter O'Donovan, and Simon J Furney, Royal College of Surgeons in Ireland, Dublin, Ireland

Glossary

Driver mutation A driver mutation is causally implicated in tumor development. It has been positively selected for and has contributed to the survival and proliferation of a tumor.

Genomic mutation rate This refers to the number of mutations in a genome. In cancer genomic mutations rates are heterogeneous can vary considerably both between individuals and within tumor genomes.

Mutational signature A mutational signature is a distinctive profile that has been inferred from mutations in tumor genomes. These signatures are the consequence of exposure to multiple mutational processes.

Passenger mutation A passenger mutation is a mutation that has not contributed to tumor development.

Proto-oncogene Proto-oncogenes normally require a gain-of-function mutation or chromosomal gain to drive tumorigenesis, and when mutated in cancer they promote proliferation.

Tumor heterogeneity This refers to genomic or epigenomic differences between different patients, different tumors from the same patient, or different regions in an individual tumor.

Tumor suppressor gene Tumor suppressor genes are generally antiproliferative and in general require inactivation of both alleles to contribute to tumor development.

Introduction

In the 1950s Armitage and Doll provided evidence, based on cancer incidence, that tumorigenesis is the end-result of several successive events (e.g., mutations) in a cell. Since then molecular studies have described the transformation of a normal cell into a cancer cell as a multistep process, with each intermediate stage conferring a selective advantage on the cell. For example, in colorectal cancer, the canonical pathway of tumorigenesis involving the gradual accumulation of mutations in *APC*, *KRAS*, and then genes such as *PIK3CA*, *SMAD4*, and *TP53* has been well described.

These alterations to specific genes or regions of the genome are a result of aberrations in the DNA sequence or structure (e.g., translocations, mutations, and copy-number alterations). One of the consequences of the inherent genomic instability underlying the tumorigenic process is the collateral accumulation of passenger mutations in cancer genomes that are unlikely to contribute to tumor formation. Only a subset of the mutations present in a tumor cell actually contribute to the survival and proliferation of that tumor—in fact, a significant majority of the mutations observed in a tumor cell are "passenger mutations," which have a neutral or even negative effect on the cell's survival. In contrast, a small number of mutations in cancer cells are "driver mutations" which actively benefit the survival of the tumor. A driver mutation is not necessarily required for the survival of the tumor at every stage in its life, but by definition must have been actively selected for at some point in a tumor's evolutionary history. Genes with the potential to carry driver mutations are called cancer genes. The identification of cancer genes and the specific mutations in these genes that act as drivers is a key focus of cancer research.

Driver genes may be classified according to the cellular pathway that a gene affects—genes that operate in the same pathway tend to be mutated in a mutually exclusive manner in an individual tumor, as a mutation that has the same effect as an already existing mutation will not be selected for. Some cancer genes are mutated more frequently than others—for most cancers, the genomic "landscape" of mutations features a small number of "mountains" (genes that are very frequently mutated in that cancer) and a far greater number of "hills" (genes that are only rarely mutated in that cancer). The process of tumorigenesis is driven by alterations to specific genes.

At a rudimentary level, these cancer-driving genes can be classified as either proto-oncogenes (e.g., *BRAF*, *KRAS*, and *MYC*) or tumor suppressor genes, for example *TP53*, *PTEN*, and *CDKN2A*. Proto-oncogenes normally require a gain-of-function mutation or chromosomal gain to drive oncogenesis, and when mutated or dysregulated in cancer, they promote proliferation. On the other hand, tumor suppressor genes are generally antiproliferative and in general require inactivation of both alleles to contribute to tumor development. This can occur in many ways, such as loss of function mutations, deletions, or epigenetic silencing. In addition to proto-oncogenes and tumor suppressor genes, genes directly involved in DNA damage response pathways (e.g., base excision repair and mismatch repair genes), which repair various types of damage to DNA, have been proposed as an additional type of cancer gene. More recently, genes with novel roles in tumorigenesis, such as splicing and chromatin remodeling genes, have been implicated in cancer.

Driver mutations may activate oncogenes or inactivate tumor suppressor genes. Because there are far more ways to inactivate a protein than to activate it, oncogene driver mutations tend to be focal amplifications or missense mutations at specific codons, whereas tumor suppressor mutations tend to be deletions, frameshifts, splice-site mutations, and nonsense mutations found in

a wider range of sites across the gene. This has led to a "20/20" rule of thumb for predicting whether a known cancer gene is more likely to be an oncogene or a tumor suppressor—if over 20% of the mutations in a cancer gene are missense and in consistent locations, that gene is likely to be an oncogene, whereas if over 20% of the mutations in a cancer gene are nonsense or otherwise inactivate the protein then the gene is likely to be a tumor suppressor. It is important to note the distinction between a driver gene and a driver mutation. A driver cancer gene is a gene for which there is very strong evidence of a role in tumorigenesis, and which may be affected by driver mutations. A list of cancer driver genes is curated and updated in the Sanger Institute Cancer Gene Census (http://cancer.sanger.ac.uk/census). However a driver gene may also contain passenger mutations, which do not confer a gain or loss of function at the protein level.

Since driver mutations are far rarer than passenger mutations, it would not be practical to functionally test all mutations identified in cancer genomes. Instead, researchers examining cancer genome data predict which mutations are most likely to be drivers. The main methods for doing this are examining the frequency of the mutation across different tumors and predicting the likely functional impact of the observed mutation. Frequency based approaches are based on the fact that driver mutations are by definition actively selected for. This means that a driver mutation should appear more frequently across many samples of a given cancer type than would be expected given the background mutation rate. Function based approaches examine the likely biological impact of a mutation and try to identify putative drivers by looking more closely at mutations likely to inactivate a tumor suppressor or activate an oncogene. Analyzing the likely impact of a mutation may involve predicting the impact of that mutation on the structure of the protein, the evolutionary conservation of the region mutated, the biochemical similarity of the original amino acid and its replacement, the protein domain affected or the protein family of the identified cancer gene.

The recent advances in sequencing technologies have revolutionized cancer genome analysis and have created an unprecedented amount of genomic data from tumors. Interpretation of these data has required the development of new analytical and statistical approaches for the identification of cancer driver genes. Furthermore the progress in the field in the last decade has unearthed previously unknown mechanisms of tumor development and has implicated a host of novel driver genes. Strides have been made in understanding factors affecting genomic mutation rates, the mutational processes impacting tumor genomes, and intratumor heterogeneity. Whole genome sequencing data have facilitated the search for noncoding driver mutations in cancer. In the following sections we discuss coding and noncoding cancer driver identification and highlight the progress that has been made, the issues and considerations in driver and passenger mutation identification, discuss how passenger mutations can provide clinically relevant information, and summarize the main cancer genome analysis initiatives worldwide.

Cancer Gene Identification

Chromosomal Alterations

Aneuploidy is observed frequently in tumor cells. Cytogenetic techniques such as spectral karyotyping (SKY), fluorescence in situ hybridization (FISH), comparative genomic hybridization (CGH), and SNP arrays have been employed in the past to identify small and large-scale chromosomal alterations (e.g., amplifications, gains, losses, and deletions) in cancer. In addition, chromosomal translocations and gene fusion events have been shown to play an important role in tumor development in some cancer types, particularly in leukemias and lymphomas. Perhaps the most well-known chromosomal translocation in cancer is the Philadelphia chromosome, which results in the chimeric, constitutively active tyrosine kinase *BCR–ABL* fusion protein in chronic myeloid leukemia (CML). This driver translocation event has been the focus of much attention due to the effectiveness of the tyrosine kinase inhibitor Gleevec (imatinib) in treating CML. Numerous other chromosomal translocations in cancer have been described and are catalogued in the Mitelman Database of Chromosome Aberrations in Cancer (https://cgap.nci.nih.gov/Chromosomes/Mitelman). This database is manually curated from published literature and relates the aberrations to tumor characteristics.

Coding Sequence Mutations and Mutational Screens

Somatic mutations in the coding sequence of a gene, for example single nucleotide variants (SNVs) and small insertions or deletions (indels) can have varying consequences (**Fig. 1**). SNVs can be classified as (1) synonymous (no amino acid change), missense (amino acid change), or nonsense (change of the amino acid to a stop codon); and (2) loss of function or gain of function. Indels can result in frameshift mutations (change of the reading frame) or in-frame mutations (no change to the reading frame). Different types of mutations affect genes altered in cancers. For example, oncogenes usually sustain gain-of-function mutations, such as the *BRAF* V600E mutation in melanoma and other cancers. This mutation leads to the constitutive activation of the protein even in the absence of an activating signal resulting in sustained signaling of the *MEK/ERK* pathway. Conversely, tumor suppressor genes can be inactivated by loss-of-function mutations. For example, a host of loss of function missense and nonsense mutations has been found in the cell cycle gene *CDKN2A* in multiple cancer types.

To identify novel cancer genes mutational screens in the early 21st century used capillary sequencing to focus on previously implicated signaling pathways and gene families such as the tyrosine kinases, lipid kinases, tyrosine phosphatases, and tyrosine kinase receptors. These studies highlighted the significance of members of these gene families in cancer by identifying recurrent mutations in genes such as *BRAF*, *PI3KCA*, and *EGFR* in multiple cancer types. In 2006, the first genomic mutational screen of the somatic landscape of cancers was conducted in human breast and colorectal tumors. In an initial screen, the authors sequenced the coding sequences of $>13{,}000$ genes in 11 breast and 11 colorectal tumors, removing any silent changes, and known germline

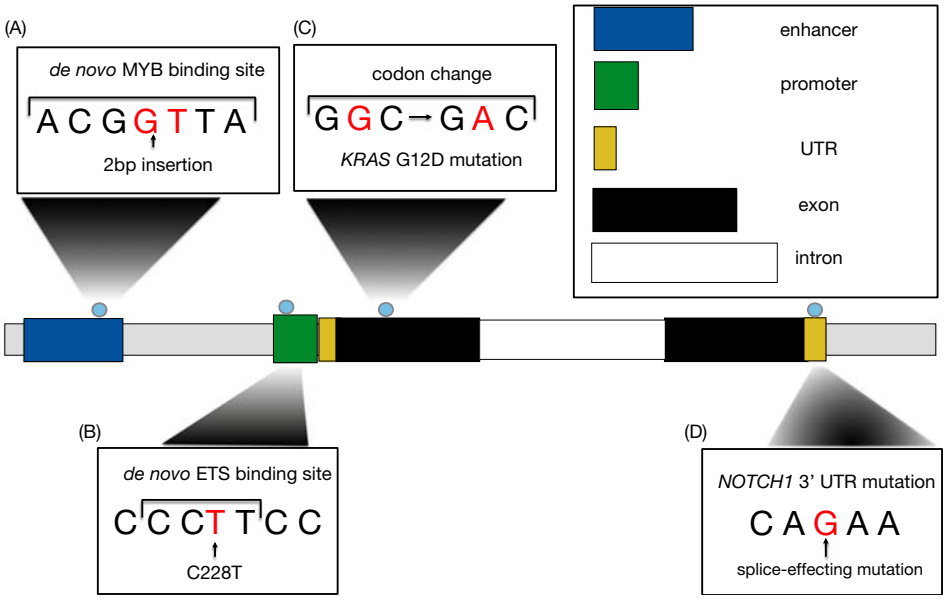

Fig. 1 Driver mutations can operate by a variety of functional mechanisms. Mutations in enhancers (A) or promoters (B) can alter the regulation of driver genes, effecting their expression or response to transcriptional signals. Coding mutations (C) change the amino acid sequence of a gene and can alter the function of the encoded protein. UTR mutations (D) can have a variety of effects, including altering the splicing of the encoded driver gene. From Piraino, S. W., Furney, S. J. (2016). Beyond the exome: The role of non-coding somatic mutations in cancer. *Annals of Oncology* **27**(2), 240–248.

events or SNPs. Candidate mutations were then sequenced in 24 additional breast and colorectal tumors. They developed a statistical score (cancer mutation prevalence score—CaMP) to discriminate driver mutations from passenger events. The CaMP score adjusts for the background mutation rate and takes into account the type of the base mutated, the resulting base change, the 5′ and 3′ neighbors, and the codon usage. Using this approach the study identified 122 and 69 candidate genes for the breast and colorectal tumors, respectively. Among the lessons learnt from this landmark study, and an expanded follow-up in 2007, were that the majority of the genes identified had not been previously implicated in cancer, and that genes showed different biases in the type of nucleotide changes. Furthermore, it highlighted that different genes were mutated in the two cancer types and that samples of the same cancer type showed heterogeneous mutational landscapes. This first large-scale sequencing effort identified important principles and issues in the identification of candidate driver genes and mutations and laid the foundation for subsequent cancer genome profiling initiatives, such as The Cancer Genome Atlas (TCGA), which were to take advantage of the development of new sequencing technologies.

Advances in Sequencing Technologies

Rapid technological advances in sequencing technologies over the last decade have paved the way for massively parallel sequencing (MPS) or next-generation sequencing (NGS) enabled cancer genomics. The first cancer genome sequence was reported by the Genome Center at Washington University in 2008. Using MPS, the study sequenced DNA from tumor and normal skin cells from a patient with acute myeloid leukemia (AML) at a coverage of 33 times for the tumor genome and 14 times for the normal genome, finding only eight heterozygous, nonsynonymous somatic single nucleotide variants in the tumor genome. In 2010, the Cancer Genome Project at the Sanger Institute published the whole genome sequences of a malignant melanoma cell line and a small-cell lung cancer cell line. They compared each cell line to the respective normal genomes to identify somatic variants, alterations and distinctive mutational signatures corresponding to DNA damage due to ultraviolet light in the melanoma genome and tobacco smoke in the lung cancer genome. Building on these foundations, the enormous NGS-driven activity in the field of cancer genomics in the last decade has unearthed previously unknown mechanisms of tumor development and has implicated a host of novel driver genes. One of the most prominent examples is the discovery of recurrent somatic mutations in genes that encode spliceosome components in multiple cancer types, including chronic lymphocytic leukemia, uveal melanoma, and breast cancer. The majority of spliceosome-related mutations are found in splicing factor 3B subunit 1 (*SF3B1*), serine/arginine-rich splicing factor 2 (*SRSF2*), U2 small nuclear RNA auxiliary factor 1 (*U2AF1*), and zinc finger RNA-binding motif and serine/arginine-rich 2 (*ZRSR2*). In addition, mutations in genes implicated in epigenetic regulation and chromatin remodeling processes have been identified in a large number of studies. The mutated genes are involved in a range of processes, including DNA methylation (e.g., *DNMT3A*, *DNMT1*), DNA demethylation (e.g., *TET1*, *TET2*), histone methylation (e.g., the lysine methyltransferases *EZH2*, *SETD2*, and *MLL* family genes), histone acetylation (e.g., the histone acetyl transferases *CREBBP* and *EP300*, and histone deacetylase (HDAC) family genes), the SWI/SNF complex chromatin remodeling complex (e.g., *ARID1A*, *ARID1B*, *ARID2*, SWI/SNF-related

matrix-associated actin-dependent regulator of chromatin (SMARC) genes, and *PBRM1*), and alternative lengthening of telomeres (e.g., *ATRX* and *DAXX*).

Cancer Gene Census

In 2004, the Cancer Genome Project published a census of cancer genes, curated from the literature. This database (http://cancer.sanger.ac.uk/census), which is updated regularly, is a list of genes in which mutations have been causally implicated in cancer and contains relevant information including the tumor types in which mutations are found and the type of mutation/alteration affecting each gene. Currently, there are >560 cancer genes in this database, of which ~100 are mutated in the germline setting and >500 are mutated somatically in cancer. Translocations are the commonest mechanism of altering a gene (55%), followed by missense mutations (43%), nonsense mutations (27%), frameshift mutations (27%), splicing mutations (13%), large deletions (7%), and amplifications (4%).

In addition to the discovery of new driver mutations and genes, whole genome sequencing and pan-cancer genome analyses have identified a variety of factors and mutational processes that affect mutation rates in cancer genomes, and confound the differentiation of driver and passenger mutations. For instance, there is considerable variation in mutation rates both within and between cancer types (**Fig. 2**). In the next two sections, we explore the factors that affect mutation rates and discuss the mutational processes that have been identified in cancer genomes. In this light, it is important to acknowledge the importance of analyzing both driver and passenger mutations to elucidate the mechanisms and variables influencing the acquisition of somatic mutations in cancer genomes. Accounting for these factors can then assist in the refinement of approaches for driver mutation identification.

Factors Impacting Genomic Mutation Rates

Somatic mutation rates vary considerably across regions of the genome. Understanding the factors that contribute to this variation is essential for methods for the detection of driver genes, and is also independently of interest in terms of understanding cancer biology (**Fig. 3**). One of the first genomic features to be associated with genomic mutation rate is gene expression level. Highly transcribed genes generally show lower mutation rates compared to weakly expressed genes. It has also been noted that the transcribed strand of genes shows lower mutations rates compared to the nontranscribed strand, which has been interpreted as suggesting that the impact of gene expression on mutation rate may be due to transcription-coupled nucleotide excision repair.

DNA repair has emerged as a central factor in mutation rate variation in cancer genomes. Early efforts to characterize the variability of mutation rate across the genome identified chromatin markers associated with chromatin state as being particularly associated with cancer genome mutation rate. Markers of closed chromatin have generally been associated with higher mutation rate, while open chromatin states have been associated with lower mutation rate. This observed association was given a mechanistic interpretation when chromatin state was linked to access of DNA repair machinery to the underlying DNA in the context of mutation rates. It has been observed that while mismatch repair proficient tumors demonstrate substantial mutation rate variability across the genome, this variability is considerably reduced in mismatch repair deficient tumors. Combined with the observed association of mutation rate with chromatin state, these results suggest a model in which open chromatin state makes DNA more available for repair, resulting in lower mutation rates in these regions when DNA repair is proficient.

Other studies have suggested a plausible role for the interaction of DNA repair and chromatin state in more specific chromatin interactions. Reduced mutation rates have been observed in DNase I hypersensitive sites, while this hypomutation is absent in tumors with deficient nucleotide excision repair, again suggesting easier access of repair machinery in open chromatin as a factor influencing mutation rates. While DNase I hypersensitivity sites show reduced mutation rates, increased mutation rates have been

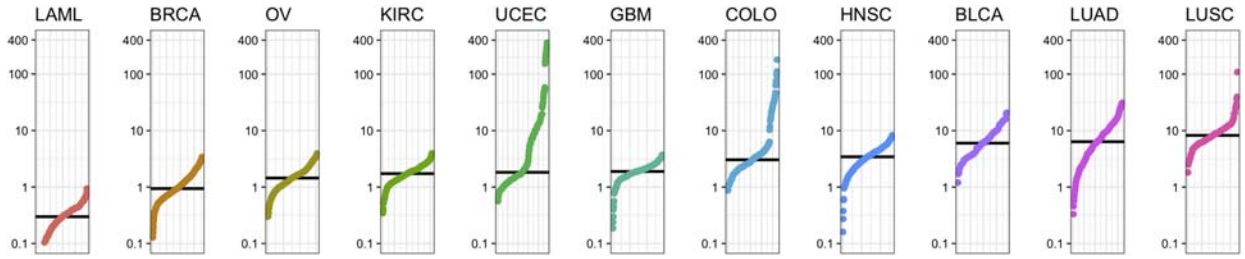

Fig. 2 Mutation rates per Mb across different cancer types. The *black bar* is the median mutation rate of each cancer type. There is considerable variation in mutation rates both within and between cancer types. Some of the top cancer in terms of median mutation rate (LUSC and LUAD) have a known environmental exposure that can causes large numbers of mutation (tobacco smoke). UCEC and COLO have moderate median mutation rates and long tail of samples with very high mutation rates, possibly as a result of hypermutator tumors within these cancer types. *BRCA*, breast adenocarcinoma; *LUAD*, lung adenocarcinoma; *LUSC*, lung squamous cell carcinoma; *UCEC*, uterine corpus endometrial carcinoma; *GBM*, glioblastoma multiforme; *HNSC*, head and neck squamous cell carcinoma; *COLO*, colon and rectal carcinoma; *BLCA*, bladder urothelial carcinoma; *KIRC*, kidney renal clear cell carcinoma; *OV*, ovarian serous carcinoma; *LAML*, acute myeloid leukemia. Data was obtained from the supplemental materials of https://www.nature.com/nature/journal/v502/n7471/full/nature12634.html.

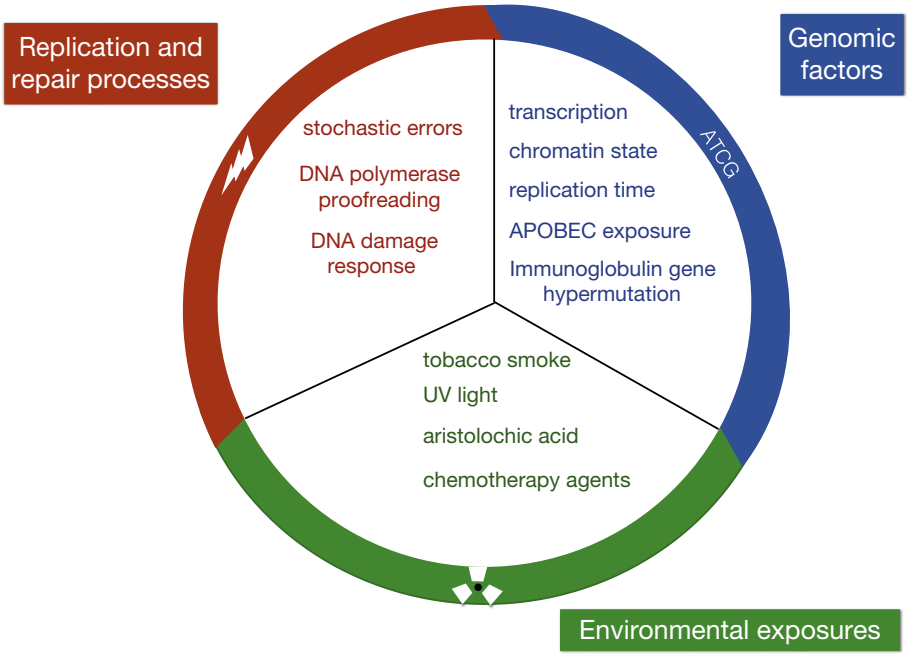

Fig. 3 Many factors influence mutations rates both within individual cancer genomes and across individuals. Here we give several examples of factors that influence mutation rates from three categories: environmental exposures, factors that impact DNA replication and repair, and features that vary across the genome. From Piraino, S. W., Furney, S. J. (2016). Beyond the exome: The role of non-coding somatic mutations in cancer. *Annals of Oncology* **27**(2), 240–248.

noted at the actual site of protein binding. Transcription factor binding sites coincide with decreased excision repair activity as measured by excision repair sequencing, and the excess mutation rate at these sites relative to flanking regions is disrupted in XPC-deficient skin cancers, suggesting that this mutation rate variability is again caused by access to DNA repair factors. In colorectal cancer, CTCF binding sites have an excess of mutations, while colorectal tumors harboring mutations that disrupt the proofreading activity of POLE actually have fewer mutations at these sites compared to background mutations, again implicating an interaction between protein binding and DNA repair.

Understanding mutation rate variability both within and between cancer genomes has important implications for the detection of driver genes. The number of mutations available for driver gene discover influences the power to detect driver genes. Mutation rate variability can also lead to "false positives" in analyses, genes that have high mutation rates but are not driver genes. Accounting for factors that influence mutation rate can help improve the performance of statistical methods and decrease the likelihood of false positives. Recently, ratiometric methods which use the ratio of different types of mutations as opposed to raw rates have been suggest as a method that can improve performance in the presence of un-modeled variation in mutation rates.

In addition to varying across the genome, mutation rates also vary substantially across individuals. Environmental exposures such as tobacco smoke, UV light, and aristolochic acid can result in increased mutation rates in cancer genomes. Mutation rates across individuals are also impacted by variability in the activity of certain cellular processes. In the next section we discuss some of the environmental and endogenous-driven mutational processes that contribute to the heterogeneity of mutation rates.

Mutational Signatures

DNA is exposed to constant attacks from a variety of exogenous and endogenous sources. These exposures often trigger mutational processes and result in DNA damage, which results in the accumulation of somatic mutations. Each mutational process affects specific nucleotides and generates patterns of base substitutions, indels or structural variations, thus leaving recognizable imprints on the cancer genome, known as mutational signatures. The recent deluge of data produced by global sequencing initiatives, in tandem with mathematical modeling approaches, has allowed the identification of a growing number of mutational signatures in human cancer and the completion of mutational catalogues. At least 30 distinct mutational signatures have been identified so far, and classified into signatures associated with endogenous mutational processes, signatures associated with exogenous mutational processes and signatures of mutational processes with unknown origins. Mutational signatures offer evidence of the biological history of a cancer, and pan-cancer analyses of next generation sequencing data have revealed that tumor types are characterized by discrete genome-wide mutation profiles, which are a consequence of different exposure to mutational processes. Such mutational records therefore provide the opportunity to identify and examine new mechanisms of mutagenesis.

Current efforts have identified distinct mutational signatures from the analysis of mutations from thousands of cancer genomes (http://cancer.sanger.ac.uk/cosmic/signatures). About half of these have been attributed to known exogenous carcinogenic exposure or endogenous mutational processes (Fig. 4). Experimental exposure to exogenous mutagens such as tobacco smoke and ultraviolet (UV) radiation has been shown to produce specific classes of mutations (mainly G • C → T • A transversions in the former, and C • G → T • A transitions in the latter) that matched those emerging from analyses of mutated genes in lung cancers and melanomas, respectively. Other mutations, however, occur as a result of disruptions in endogenous processes, such as mismatch repair (MMR) deficiency and DNA replication errors that result in discrete mutational signatures. For example, Signature 1 is the result of an endogenous mutational process characterized by spontaneous deamination of 5-methylcytosine and is correlated with age of cancer diagnosis. The etiologies of several of the mutational signatures remain unelucidated.

Mutational Signatures Linked to Specific Driver Genes

A number of the mutational signatures have been linked to defects in or the actions of specific genes. The *APOBEC* gene family of deaminases has a major role in viral restriction and suppression of retrotransposition, and aberrant activity of *APOBEC* in human cancer is reported to produce mutational signature 2 and 13. Genes involved in DNA damage response pathways are known to contribute to tumorigenesis in many cancer types. Defects in gene involved in homologous recombination, in particular *BRCA1* and *BRCA2*, result in a range of mutations, which correspond to particular mutational signatures. Defects in genes involved in mismatch repair, which results in microsatellite instability and an increased mutation rate, are associated with four specific mutational signatures. Altered activity of the *POLE* gene, which encodes the catalytic subunit of an enzyme involved in DNA proofreading, is proposed as the mutational process underlying another mutational signature and has been associated especially with colorectal cancers. Therefore the combination of driver and passenger mutations can provide a powerful insight into the processes underlying tumor development. In addition, recent studies have highlighted how signatures and mutational burdens can be relevant clinically. For example, whole genome sequencing of pancreatic cancers revealed that the *BRCA*-associated mutation signature

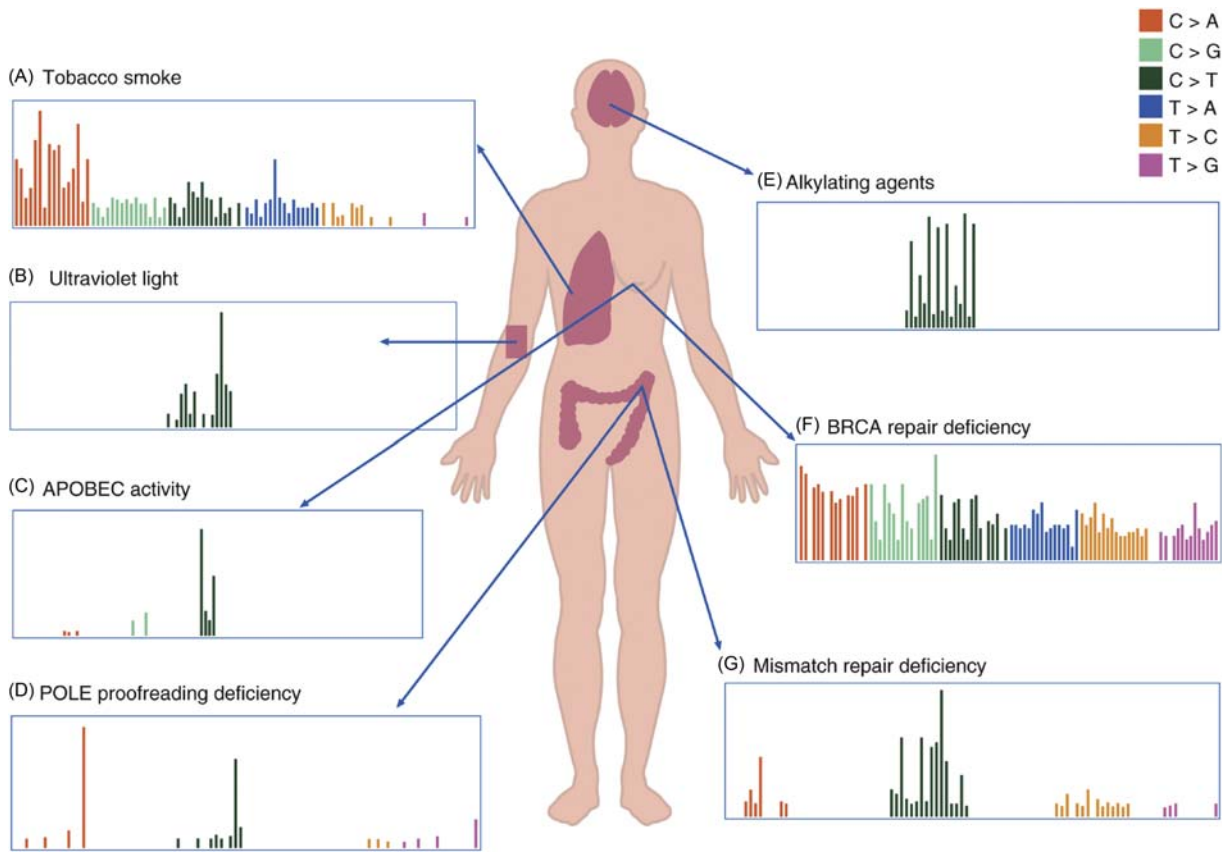

Fig. 4 Some of the mutational signatures identified to date have significant clinical or epidemiological implications. Signatures such as those associated with tobacco smoke (A), ultraviolet light (B) and alkylating agents (E), can reveal previous mutagenic exposure. Signatures associated with altered DNA damage response including deficiency in *POLE* (D), *BRCA* (F) and mismatch repair genes (G) may serve as markers for prognosis and response to certain types of therapy. Further signatures have been attributed to the activity of the AID/APOBEC family of cytidine deaminases (C). From Piraino, S. W., Furney, S. J. (2016). Beyond the exome: The role of non-coding somatic mutations in cancer. *Annals of Oncology* **27**(2), 240–248.

was correlated with genomic instability as well as sensitivity to platinum-based therapies, suggesting that some of the mutational signatures may be potential biomarkers for therapeutic response. Furthermore, a number of studies have suggested that sensitivity to immune checkpoint inhibition is associated with the mutational landscape of tumors, with factors such as mutation burden, neo-antigen burden, and DNA repair deficiency playing a role in response to therapy.

Methods of Driver Identification

Driver mutations confer a selective advantage to the cancer cells in which they occur, and as a result are under positive selection within the tumor. In cancer sequencing data, this positive selection is expected to result in properties that distinguish driver mutations from passenger mutations. Several classes of methods have been developed which exploit these properties in order to use sequencing data to identify putative driver mutations (Fig. 5). The previous two sections have outlined some of the mutational processes and factors that can confound the systematic identification of driver genes. In this section, we discuss the properties that driver mutations display and methods that have been developed to detect driver mutations based on these properties. It is fundamental to note that the foundation of all the approaches we discuss is the identification of *somatic* variants in cancer genomes, a task in itself that is not trivial. A number of prominent somatic mutation calling algorithms have been developed including

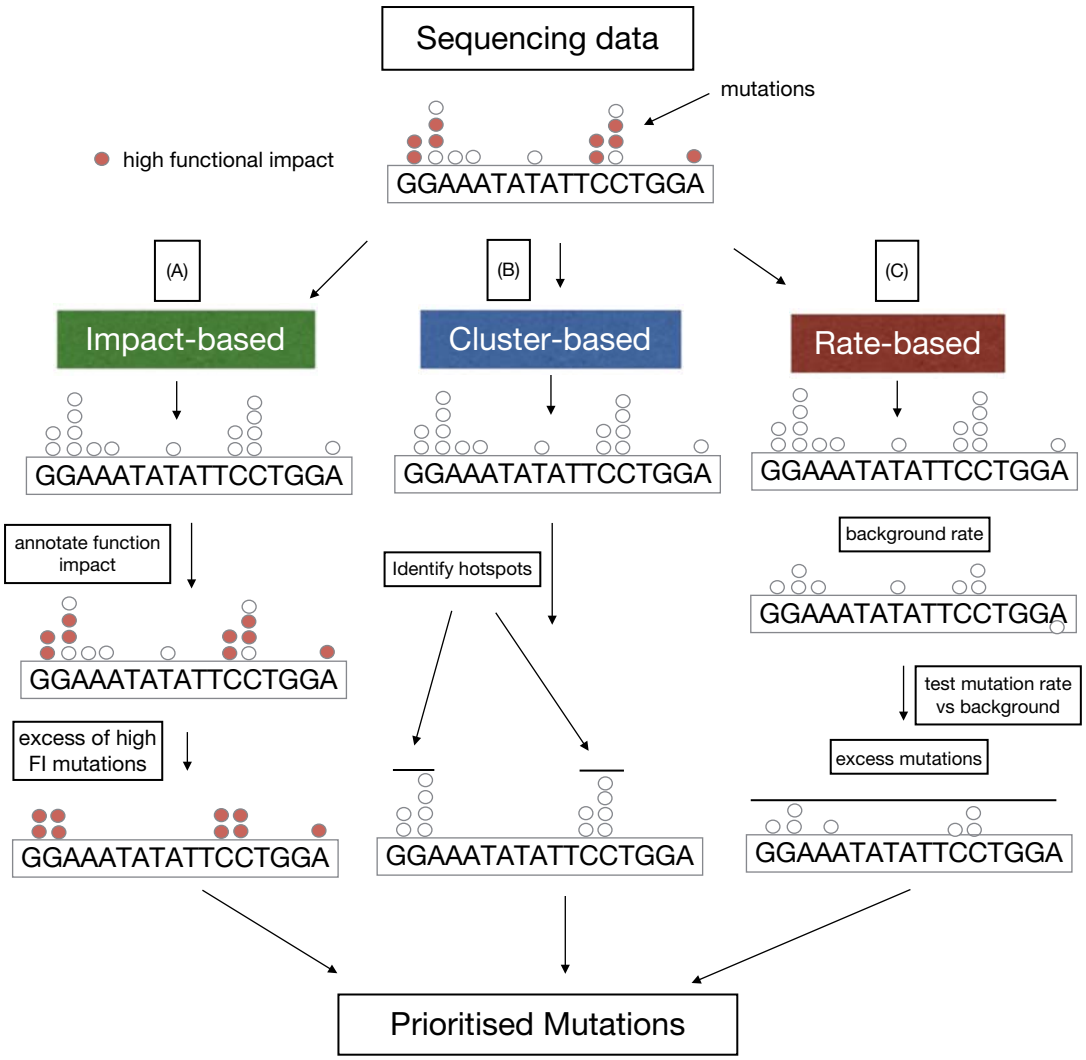

Fig. 5 Examples of DNA sequences that might be identified by different driver detection methods. In (A), *color* indicates the functional impact of a mutation, and the sequence shows a large number of highly functionally impactful mutations, and therefore could be identified by functional impact-based methods. In (B) the sequence has highly localized hotspot regions, and could be identified by clustering-based methods. In (C) the sequence shows a large, evenly distributed mutation rate, and could be identified by rate-based methods. From Piraino, S. W., Furney, S. J. (2016). Beyond the exome: The role of non-coding somatic mutations in cancer. *Annals of Oncology* **27**(2), 240–248.

Varscan (http://dkoboldt.github.io/varscan/), SomaticSniper (http://gmt.genome.wustl.edu/packages/somatic-sniper/), Mutect (https://software.broadinstitute.org/gatk/documentation/tooldocs/current/org_broadinstitute_gatk_tools_walkers_cancer_m2_MuTect2.php), CaVEMan (https://github.com/cancerit/CaVEMan), and Strelka (https://github.com/Illumina/strelka). Each of these approaches for somatic single nucleotide variant identification has its own approach, biases, and limitations. As such, users must remain cognizant that any list of somatic variants output by an algorithm is a combination of true and false positives, and may omit false negative mutations (those that are present in the tumor but were not identified by the algorithm). Furthermore, the computational identification of short insertions and deletions has proved to be a far more difficult task than point mutations to date.

Although driver mutations mechanistically impact cancer cells at the level of the individual mutation, mutations within the same functional elements may have similar biological effects. As a result, mutations are often considered in terms of their impact on functional elements. In particular, much cancer genomic research has focused on the identification of driver genes, protein-coding genes that contain driver mutations. We focus on the identification of driver genes, although the concepts discussed here are applicable to other functional elements as well.

One of the most prominent properties expected of driver mutations in their increased occurrence in tumor genomes. Driver mutations are not simply generated by mutational processes in cancer genomes and remain unselected for like passenger mutations, but are instead causally related to the development of the tumor. As a result, driver mutations are expected to appear more frequently across multiple independent tumors in cancer sequencing data relative to the base rate that these mutations would occur at due to mutational processes alone. This concept has given rise to a class of methods that seek to identify regions of the genome that display an excess of mutations relative to an expected base rate that is due to mutational processes. Under this model, an excess of mutations is a signature of positive selection, and genes that are mutated more frequently than expected are possible driver genes.

The baseline or background model of mutation rates is a critical component of these methods. Seminal work by multiple groups has demonstrated that the mutation rate within cancer cells is not constant across the genome, but instead varies along with genomic features such as gene expression, chromatic state, epigenetic markers, and base composition. As a result, rate-based methods for the identification of driver genes typically use a model for the neutral mutation rate of a gene and statistically compare the observed mutation counts to their expectation under the background model. Examples of rate-based methods include MutSigCV (http://software.broadinstitute.org/cancer/software/genepattern/modules/docs/MutSigCV), and Genome MuSiC (http://gmt.genome.wustl.edu/packages/genome-music/).

In additional to methods based on mutation rate, another class of methods focuses on the functional impact of mutations that occur within a gene. Genes under positive selection are expected to display a "functional impact bias," an excess of mutations that have functional effects compared to mutations that are not as impactful in terms of biological function. Functional impact based methods start with a method of identifying the degree of functional impact that individual mutations have. For example, a simple method could be based on the idea that nonsynonymous mutations are more likely to have large functional consequences compared to synonymous mutations. The functional bias method then looks for genes that tend to have large numbers of high functional impact mutations compared to lower impact mutations. Driver mutations have functional effects that contribute to tumorigenesis, and as a result, functional impact methods identify driver genes as genes that display an excess of functionally impactful mutations. These methods can be extended in novels ways by incorporating different measures of functional impact and by including a model of the expected functional impact score for a gene or genomic element that accounts for potential confounding factors, such as mutational processes. Examples of functional impact based methods include OncodriveFM and its extension OncodriveFML. Appropriately chosen measures of functional impact may also assist in the identification of interesting categories of driver genes. For example, looking for genes with an excess of truncating or other deleterious mutations can help in the identification of tumor suppressor genes, while identification of genes with an excess of mutations targeting phosphorylation sites can be used to identify genes involved in aberrant phosphorylation signaling.

A critical component of functional impact methods is variant annotation. Many software tools, databases, and other resources aim to facilitate this task, and some resources are available that bring together multiple existing resources to address this challenge. Within the wider field of genomics and analysis of genetic variants, a host of tools exist to annotate genetic variations, including the Variant Effect Predictor (VEP, http://www.ensembl.org/info/docs/tools/vep/index.html), and ANNOVAR (http://annovar.openbioinformatics.org/en/latest/), which provide general annotation of genetic variants. These general annotations also give access to more specific functional annotations, including tools such as SIFT (http://sift.jcvi.org), PolyPhen (http://genetics.bwh.harvard.edu/pph2/), MutationAssessor (http://mutationassessor.org/r3/), and many others aimed at predicting the functional impact of mutations. Cancer-specific mutation annotation such as CHASM (http://wiki.chasmsoftware.org/index.php/Main_Page), and Oncotator (https://portals.broadinstitute.org/oncotator/) also exist.

A third method for the identification of driver genes is based on the observation that driver mutations which target a specific functional element within a protein (e.g., a phosphorylation site) will often be clustered near to each other in the linear sequence of the gene. Genes can contain domains and elements that make up a single functional protein component or serve a common function. If a functional element can be impacted by multiple different mutations along its length, then driver mutations targeting that element may cluster within the region of the gene containing the functional element. As a result, genes that display significant spatial clustering of mutations as opposed to mutations evenly distributed throughout the gene can be classified as putative driver genes.

Noncoding Driver Mutations

In addition to coding driver mutations, recent efforts directed at the noncoding regions of the genome have revealed the presence of noncoding driver mutations. Major efforts to characterize the functional properties of noncoding DNA, particularly regulatory regions, have created the opportunity to discover important insights about the role of noncoding variation in disease, including cancer. We review important examples of noncoding driver mutations and the role they play in cancer biology.

Among the most important and well-known noncoding driver mutations are *TERT* promoter mutations (Fig. 1). *TERT* mutations occur in a mutually exclusive manner and result in the creation of an *ETS* transcription factor binding site, resulting in increased expression of the *TERT* transcript. *TERT* promoter mutations are extremely frequent across multiple cancer types and have been associated with clinical features in multiple cancer types.

TERT promoter mutations are an example of noncoding driver variants caused by point mutations. Another noncoding driver mutation that has been identified is generated by a small indel in T-cell acute lymphoblastic leukemia. It has been observed that insertions create a *MYB* binding site upstream of the *TAL1* oncogene, resulting in increased *TAL1* expression.

There have also been several attempts to systemically identify putative noncoding driver mutations in cancer. These efforts have employed a variety of methods for the identification of putative noncoding driver regions, including rate and clustering-based methods similar to those used to examine coding driver genes, methods based on annotations of noncoding mutations such as the impact of the mutation on regulatory motifs, and methods based on correlating the presence of mutations with gene expression across tumors. In addition to identifying prominent noncoding drivers such as *TERT*, these efforts have also revealed other putative noncoding driver regions such as regions upstream of *PLEKHS1*, *WDR74*, *SDHD*, and *MED16*.

In addition to pan-cancer studies of potential noncoding driver mutations, several large genomic studies in individual cancer types have identified recurrent noncoding mutations. Analysis of breast tumors identified recurrent promoter mutations upstream of one protein-coding gene (*FOXA1*), and two noncoding RNA genes (*RMRP* and *NEAT1*). An analysis in chronic lymphocytic leukemia revealed mutations in the 3′-untranslated region of the gene *NOTCH*1, resulting in aberrant splicing of the *NOTCH1* transcript, as well as mutations in an enhancer putatively targeting the gene *PAX5*.

Notwithstanding the discoveries made by these studies to date, the interrogation of the somatic noncoding genome is complex and encumbered by our lack of knowledge about the function of noncoding DNA relative to coding sequences. The generation of a greater number of whole genome sequences of tumors, through initiatives such as the pan-cancer analysis of whole genomes, in tandem with efforts to understand functional elements in the genome, for example the Encyclopedia of DNA Elements (ENCODE) Project, should elucidate the importance of non-coding elements in tumor development further.

Tumor Heterogeneity

Tumor heterogeneity is thought to play a significant role in treatment resistance and failure. Tumor heterogeneity can be classified as:

(i) Intertumor heterogeneity, which is differences between tumors in different patients (Fig. 2). This is the focus of many cancer studies, contributes to differential patient responses to therapy and is the basis for precision medicine approaches.
(ii) Intersite heterogeneity, which describes differences between distinct tumors within an individual patient (e.g., between primary and metastatic tumors, or between multiple metastatic sites).
(iii) Intratumor heterogeneity, which refers to differences between cellular populations in a distinct tumor, the extent of which has been demonstrated through recent multiregion next generation sequencing analyses.

In this section, we discuss intersite and intratumor genetic heterogeneity, which are based on the view of cancer as an evolutionary process that can give rise to genetically divergent subclonal populations within tumors. Morphological differences in tumors have been described in numerous pathology studies and cytogenetic studies have revealed intratumor heterogeneity in copy number alterations. Intratumor heterogeneity refers to the fact that cells within a tumor do not share identical genomes—different cells acquire different mutations as the tumor grows. In addition to the clonal mutations that are shared by all cells in the tumor and that were presumably present in the tumor's ancestral cell, tumor cells may also harbor subclonal mutations, which are unique to a cell or subset of cells in the tumor. These genomic differences can take the form of point mutations, copy number variations or differences in chromosomal structure or number. With the use of next generation sequencing, the extent of intratumor heterogeneity is beginning to be understood more clearly, as is the fact that some tumor types show a greater degree of heterogeneity than others. Furthermore, some driver mutations are more likely to be subclonal than others—for example, across several cancer types it has been suggested that mutations in genes involved in the *PIK3-AKT-mTOR* pathway are more likely than genes involved in the *RAS-MAPK* pathway to be subclonal. The likelihood of a mutation being clonal or subclonal can depend on the cancer type—for example, mutations in *TP53* are almost always clonal in ovarian cancer and nonsmall cell lung cancer, but are often subclonal in chronic lymphocytic leukemia and clear cell renal cell carcinoma.

Since intratumor heterogeneity is only detectable in sequenced samples, detecting subclonal mutations and working out whether apparently clonal mutations are truly clonal is dependent on how many tumor regions are sequenced. Sampling bias in methods used to select regions to sequence may lead to subclonal mutations appearing to be clonal, or to subclonal clinically

relevant driver mutations being missed in sequencing. For example, the TRACERx lung cancer study has shown that significantly more driver events are identified with the use of multiregion sequencing than by analysis of a single sample. In fact, >75% of the tumors in this study harbored a subclonal driver alteration, with genes such as *TP53*, *PIK3CA*, *KRAS*, and *NF1* being affected.

As well as directly impacting the biology and clinical course of a cancer, intratumor heterogeneity allows researchers to analyze the evolutionary history of a tumor by extrapolating the temporal sequence in which the driver mutations occurred. Understanding of intratumor heterogeneity of driver mutations and tumor evolution may facilitate more refined management of cancer therapy by using known evolutionary constraints to contain the cancer to slow its progress. However, the existence of intratumor heterogeneity poses a major challenge for targeted therapies of driver mutations—a given therapy may successfully disrupt the major clonal driver mutation, but if cells in the targeted tumor harbor subclonal driver mutations that the therapy does not eradicate, the cancer may recur.

The majority of sequencing studies have focused on the cancer genomic landscape of primary tumors. However, several studies have identified intersite heterogeneity between matched primary and metastatic tumors. This is of particular importance if different driver mutations are required for tumor development and for metastatic spread. Furthermore, a metastatic site may be seeded by a cell from the original tumor that harbors subclonal driver mutations. Initial large-scale studies of metastatic tumors, such as the MSK-IMPACT and the Michigan Oncology Sequencing (MI-ONCOSEQ) Program, have begun assess the metastatic genomic landscape. The MSK-IMPACT results were similar when compared to the primary tumors from the TCGA. However, important differences between the two patient cohorts were identified. For example, *TP53* was significantly enriched for mutations in several tumor types. However, these studies did not profile matched primary and metastatic tumors from individual patients. Sequencing of matched samples will elucidate further intersite heterogeneity of driver mutations and tumor evolution.

Number of Driver Mutations

Cancer is driven by the acquisition of driver mutations that disrupt normal biological processes and allow somatic cells to form detectable lesions. This raises the question, how many driver mutations are typically required for cancer to develop? Early work on this problem used the relationship between cancer incidence and age to attempt to estimate the number of "rate limiting" events that are required before the formation of various cancers, estimating this number in the range of six to seven events. More recent work has attempted to estimate the number of driver mutations required in lung and colorectal cancer by comparing the increased incidence in cancer due to certain risk factors (smoking in lung and genetic predisposition in colorectal) with the increased mutational burden caused by those risk factors. This method estimates that approximately three driver mutations may be required in these cancers.

It remains unclear exactly how many driver mutations are required in different cancer types, though cancers of the blood require fewer drivers than solid tumors. Despite this uncertainty, it appears likely that most if not all cancers require more than one driver mutation to proliferate. Additional drivers may be required for metastasis and for relapse after therapy, although subclonal mutations could also be selected for in response to treatment. In addition to their number, there is considerable interest in when mutations occur during the evolution of a tumor. Driver mutations may occur throughout the development of the tumor. The time during tumorigenesis at which certain drivers tend to emerge can give clues about the role the driver plays in tumor development (e.g., the stepwise accumulation of mutations in *APC*, *KRAS*, and subsequently genes including *PIK3CA*, *SMAD4*, and *TP53* in certain colorectal tumors). In this way some drivers may only be selected once other driver mutations have already occurred or during a particular phase of tumor development. The presence and frequency of driver mutations may also change throughout tumor development as certain subclones are selected and increase in frequency within the tumor. The analysis of whole genome sequences from projects such as the pan-cancer analysis of whole genomes and the application of phylogenetic methods to sequencing data from multiple regions of tumors is beginning to elucidate some of the early and late driver mutations that occur during tumor evolution. Indeed, initial analysis of the pan-cancer analysis of whole genomes dataset has suggested that each tumor carries on average 4.6 driver events.

Oncogenomic Resources

Interest in cancer genomics in recent years has driven the creation of many publically available resources aimed at facilitating better understanding of the cancer genome.

International Cancer Genome Consortium

The International Cancer Genome Consortium (ICGC, http://icgc.org) is a large collaborative project which has produced substantial amounts of genomic data from many countries and cancer types. ICGC provides access to genomic data such as somatic mutations, RNA expression, methylation, and clinical data from large numbers of cancer patients. ICGC provides several ways of accessing data easily and conveniently, including an interactive data portal.

The Cancer Genome Atlas

The Cancer Genome Atlas (TCGA, https://cancergenome.nih.gov) is a large collaboration initiated by the National Institutes of Health similar to ICGC which hosts a large set of -omics data. Like ICGC, TCGA also allows access to a vast array of data through the TCGA data portal.

Catalogue of Somatic Mutations in Cancer

The Catalogue of Somatic Mutations in Cancer (COSMIC, http://cancer.sanger.ac.uk/cosmic) is a database of cancer genomic information organized by the Wellcome Trust's Sanger Institute. It includes databases of cancer somatic mutations, as well as several other components, such as curated lists of cancer genes and cancer mutations (e.g., the Cancer Gene Census) and the cancer cell lines project, which provides data on cancer cell lines. COSMIC also provides resources on mutational signatures in cancer (http://cancer.sanger.ac.uk/cosmic/signatures).

Pan-Cancer Analysis of Whole Genomes

The pan-cancer analysis of whole genomes (PCAWG, http://docs.icgc.org/pcawg/) is a large collaborative effort to assemble a set of uniformly processed cancer whole genomes from multiple cancer types available in an easily accessible manner. The data from PCAWG are available through the ICGC as well as several other data portals and analysis utilities. PCAWG provides the research community with access to an international sample of over 2800 donors and vast numbers of somatic mutations from a wide array of cancer types.

cBioPortal for Cancer Genomics

The cBioPortal for Cancer Genomics (http://www.cbioportal.org/) provides a visualization and analysis platform for cancer genomics data sets, including the TCGA and many smaller studies that have used a variety of sequencing strategies to profile tumors. Results from DNA and/or RNA sequencing of $>45{,}000$ samples can be queried through a user-friendly web interface.

Cancer Genomics Software

Analysis of cancer genomic data often makes use of specialized software. Publically available software exists for many important tasks in cancer genomics, including identification of driver genes, mutation annotation, and analysis of intratumor heterogeneity. Several research groups and institutions provide central locations for multiple different cancer genomic software applications, including the McDonnell Genome Institute at Washington University in St. Louis (http://gmt.genome.wustl.edu/index.html), The Broad Institute (https://www.broadinstitute.org/data-software-and-tools), and the Sanger Institute (http://www.sanger.ac.uk/science/tools). Many other publically available software tools also exist outside these institutional repositories.

Variant Interpretation

Several resources also seek to link cancer variants to information that may give insights into the clinical or therapeutic relevance of mutations, such as the Cancer Genome Interpreter (https://www.cancergenomeinterpreter.org/home), OncoKB (http://oncokb.org), and CIViC (https://civic.genome.wustl.edu/about). OncoKB is a precision oncology database, curated by a team of clinicians and investigators at Memorial Sloan Kettering Cancer Center, containing information about the effects of and treatment options for driver mutations or alterations. The database provides information about alterations in >400 cancer genes and classifies treatment options according to clinical actionability. Clinical Interpretation of Variants in Cancer (CIViC) is an open access, open source database providing information on the prognostic, diagnostic and predisposition of inherited and somatic variants. CIViC has been designed to enable precision medicine and address many of the issues inherent in the clinical interpretation of cancer genome alterations. CIViC currently contains several thousand curated interpretations of clinical relevance for >1700 variants in 330 cancer genes.

Prospective Vision

We have witnessed a genomics revolution as advances in next generation sequencing technologies have resulted in dramatic decreases in sequencing costs. As a consequence, NGS has moved from research and development spheres into the clinical arena to enhance precision medicine for patients. Indeed, over the last decade oncology has been at the forefront of the application of clinical genomics to diagnosis and treatment. Genomic profiling has increasingly become common in many cancer types and clinical trials have been instigated to match patients to targeted therapies based on shared genomic features. With the significant decrease in sequencing costs it has been predicted that millions of cancer patients will have their tumors sequenced over the next decade. One of most the significant and immediate challenges in the field of cancer genomics is the clinical interpretation

of mutational data. The refinement of methods to identify driver mutations and genes, to interpret the clinical significance of specific mutations, and to match patients to therapies based on these mutations and on their genomic profiles, is imperative over the coming years. Finally, the identification of driver mutations promoting recurrence and resistance to therapy will be of significant interest for the foreseeable future.

Myelodysplastic Syndromes: Mechanisms, Diagnosis, and Treatment

Eric Solary, Gustave Roussy, Villejuif, France; and Paris-Sud University, Le Kremlin-Bicêtre, France
William Vainchenker, Gustave Roussy, Villejuif, France

Glossary

Myelodysplastic syndrome (MDS) Clonal hematopoietic stem-cell disorders that associate cell dysplasia and ineffective hematopoiesis.
Myelodysplastic syndrome/myeloproliferative neoplasm (MDS/MPN) Independent category of diseases that associate MDS feature with overproduction of at least one category of myeloid cells.
Spliceosome Intracellular multiprotein complex involved in the maturation of messenger RNAs.

Nomenclature

ARCH Age-related clonal hematopoiesis
ASCT Allogeneic stem cell transplantation
CHIP Clonal hematopoiesis of indeterminate potential
CMML Chronic myelomonocytic leukemia
EPO Erythropoietin
ESA Erythropoiesis supporting agents
HMA Hypomethylating agents
IPSS International Prognostic Scoring System
MDS Myelodysplastic syndrome
MDS/MPN Myelodysplastic syndrome/myeloproliferative neoplasm
MDS-RS Myelodysplastic syndrome with ring sideroblasts
sAML Secondary acute myeloid leukemia

Introduction

Myelodysplastic syndromes (MDS) are a heterogeneous group of clonal hematopoietic stem-cell disorders characterized by cell dysplasia and ineffective hematopoiesis. These acquired bone marrow failures lead to blood cytopenias with a variable propensity to evolve into acute myeloid leukemia (AML). They most commonly develop in older adults (median age at diagnosis is 65–70 years and less than 10% MDS patients are younger than 50) with a slight male predominance, except for MDS with isolated 5q deletion in which women predominate. The age-adjusted annual incidence rate of these malignancies is estimated to be 4 per 100,000 individuals (reaching at least 75 cases per 100,000 and possibly more after 65 years of age). Risk factors include rare but increasingly recognized inherited genetic predisposition, to be explored in pediatric and young adult cases as well as families with other cases of MDS. Environmental factors include exposure to chemotherapy, radiation, and other toxic insults such as benzene and derivatives and tobacco smoking, but 85% of patients do not have any well-identifiable cause. The pathophysiology of MDS combines sequentially acquired chromosome aberrations and somatic mutations with microenvironmental factors. Disease diagnosis remains mostly based on blood and bone marrow cytological examination. The number and extent of cytopenias, percentage of blast cells in the marrow, and nature of genetic alterations provide prognostic information. Treatment varies from careful monitoring to allogeneic stem cell transplantation. Two therapies, hypomethylating agents and lenalidomide, were approved for these patients. Median overall survival ranges from a few months to almost a decade, depending on age, degree and number of cytopenias, blast percentage, and cytogenetic and genetic aberrations.

MDS Diagnosis

An MDS diagnosis is suspected when peripheral blood cytopenias are identified on a routine analysis or a blood exam performed because of nonspecific clinical symptoms: fatigue and destabilization of a preexisting cardiovascular disease because of anemia, repeated infections because of neutropenia and neutrophil dysplasia, bleeding because of thrombocytopenia and platelet dysfunction. Cytopenias can be detected also while exploring an immune disorder including vasculitis, polychondritis,

and polyarthritis, which are commonly associated with MDS and often diagnosed simultaneously. Anemia, which is the most frequent cytopenia (90% of MDS), is usually nonregenerative and typically macrocytic. Neutropenia and thrombocytopenia are less frequent (30%), and usually combined with anemia. The presence of circulating blast cells over 1% is used for disease classification while the presence of immature granulocytes is rare. A monocyte count higher than $1000/mm^3$ and 10% of white blood cell count reclassifies the disease as chronic myelomonocytic leukemia (CMML), which belongs to a distinct category of myeloid malignancies according to the World Health Organization (WHO) and associates myelodysplastic and myeloproliferative features (MDS/MPN). Of note, a fraction of patients diagnosed with an MDS secondarily develop a monocytosis, joining the MDS/MPN category.

MDS diagnosis requires morphologic inspection of bone marrow aspiration and sometimes biopsy. The aspirate allows for detailed evaluation of dysplastic features, including ring sideroblasts (erythroblasts with abnormal accumulation of iron in perinuclear mitochondria), and for precise evaluation of the percentage of marrow blasts (to be assessed on 500 nucleated cells). The bone marrow trephine biopsy, whose utility is more controversial, allows for a more accurate determination of bone marrow cellularity and detection of marrow fibrosis. Because morphological assessment of dysplasia can be subjective, especially in the absence of blast excess, interobserved diagnostic discrepancies were observed in up to 20% of patients, especially those with a low grade MDS. Therefore, additional techniques are used to support MDS diagnosis.

The most important additional test remains the analysis of bone marrow cell karyotype, as a cytogenetic abnormality is found in 40%–50% of MDS, with partial or complete loss or gain of chromosomes (5q-, 7q-, −7, +8, 20q-, 17p-) being the most frequent findings. These heterogeneous abnormalities, whose identification supports the diagnosis when morphologically uncertain, have a strong prognostic significance. For example, complex karyotype is usually associated with an excess of blast cells and a poor outcome. Cytogenetics can also guide the therapeutic choice, for example, lenalidomide is used preferentially to treat MDS with isolated 5q-. The routine 20 metaphase cytogenetic analysis can be completed by fluorescence in situ hybridization (FISH) with probes targeting the most-frequently altered chromosomes when fewer than 20 mitoses have been obtained by routine cytogenetics. The occurrence of additional chromosomal aberrations with evolution can precede transformation to AML.

Flow cytometry with increasingly standardized combinations of markers helps recognizing minimal dysplasia by identifying abnormal phenotypic patterns, thus could enter the standard workup in the next future. Specifically, identification of an accumulation of classical monocyte subset in the peripheral blood is a strong argument to predict evolution of an MDS into a CMML.

Finally, DNA sequencing has established that MDS arises through the sequential acquisition of somatic mutations in a set of recurrently involved genes. New generation sequencing (NGS) analyses are increasingly included in the routine work-up of patients with MDS as they inform on diagnosis, prognostic, and potential therapeutic targets.

In patients with minimal or no diagnostic evidence of dysplasia and no blast excess, additional tests exclude other causes of cytopenia that include aplastic anemia, paroxysmal nocturnal haemoglobinuria clone, toxic exposure, vitamin or iron deficiency, hypersplenism, auto-immune cytopenias, viral infection, hereditary context, and others. When another cause of cytopenia has been excluded, patients with a cytopenia but no dysplasia are considered in the subset of idiopathic cytopenia of unknown significance (ICUS). A fraction of them may have clonal somatic mutations and cytogenetic abnormalities, and their natural history is still poorly known.

The 2016 WHO classification of myeloid malignancies still defines MDS subtypes on the basis of the number of dysplastic and cytopenic lineages, the prevalence of blasts, the percentage of ring sideroblasts (RS), and the presence of specific cytogenetic abnormalities.

A limited role is given to genetics as the mere presence of recurrent somatic mutations cannot be considered as definitive evidence of MDS diagnosis, for example, can be detected in patients with ICUS. In certain context however, genetic data provide diagnostic utility in MDS, for example, mutations in the spliceosome gene *SF3B1* define a subgroup of patients with ring sideroblasts and favorable outcome. Detection of an *SF3B1* mutation therefore establishes a diagnosis of MDS-RS in the presence of cytopenias and dysplasia, even when RSs make up as few as 5% of all nucleated erythroid cells (the traditional cutoff is 15%).

MDS Pathophysiology

Haploinsufficiency Through Chromosomal Deletion

A characteristic event is the occurrence, in a hematopoietic stem cell, of an interstitial deletion in the long arm of chromosome 5, known as del(5)(q31q33), leading to gene haploinsufficiency. The size of the deletion varies but, in MDS patients with an isolated 5q-, a common deleted region that encompasses about 40 genes has been identified, defining the 5q- syndrome. This deletion induces haploinsufficiency for the ribosomal subunit *RPS14*, which triggers a p53-dependent block in erythroid proliferation and differentiation, and haploinsufficiency of *CSNK1A1* (*CSK1*) and two micro-RNAs, mir-145 and mir-146a, which may account for dysmegakaryopoiesis and thrombocytosis. MDS with complex karyotypes have larger 5q deletions with haploinsufficiency of tumor suppressor genes such as *CTTNA1* or *EGR1*. The selective clonal suppression of del(5q) cells by lenalidomide preserves del(5q) hematopoietic stem cells. A similar haploinsufficiency model might apply also for MDS with del(7q), del(20q), and other recurrent interstitial deletions.

Recurrently Mutated Genes

A comprehensive picture of the mutational landscape in MDS has emerged over the past 10 years. With an approach focusing on a set of ~50 genes recurrently mutated in myeloid malignancies, a somatic mutation in at least one gene is identified in 90% of patients. These genes encode RNA splicing factors, epigenetic regulators, cohesin components, transcription factors, DNA damage response and signal transduction molecules. These mutations are sequentially acquired, suggesting a disease initiation step with founder mutations driving asymptomatic clonal expansion within the hematopoietic compartment (the so-called age-related clonal hematopoiesis—ARC—or clonal hematopoiesis of indeterminate potential—CHIP), followed by acquisition of mutations that both synergize with the founder mutation on hematopoietic stem cells/progenitors and impair later stages of hematopoiesis and alter blood counts to generate an overt MDS, leading, in 30%–40% of patients, to eventual secondary AML (sAML).

The spliceosome is a multiprotein complex that mediates intron excision and exon ligation in the generation of mature messenger RNA. Genes encoding components of the spliceosome, most commonly *SF3B1*, *SRSF2*, *U2AF1*, and *ZRSR2*, are the most frequently mutated genes detected in MDS (60% of patients). Mutant splicing factors result in altered patterns of premessenger RNA splicing. The splicing factor mutations are generally heterozygous and mutually exclusive, suggesting that either cells cannot tolerate two mutations or these changes have a redundant role in disease pathogenesis. *SF3B1* mutation, the most frequent one, is strongly associated with ringed sideroblasts.

A second common class of mutations are those affecting genes involved in DNA methylation and histone modification. Recurrent mutations in *DNMT3a*, a DNA methyltransferase, *TET2*, an enzyme that hydroxylates methylated cytosines to initiate the process of DNA demethylation, and isocitrate dehydrogenase gene 1 (IDH1) and IDH2 alter the DNA methylation pattern. *IDH* gene mutations result in the generation of 2-hydroxyglutarate, an oncometabolite that inhibits the activity of numerous targets, including TET2. Components of histone modification complexes are also recurrently mutated in MDS, most commonly *ASXL1* and *EZH2*, which are affected by loss-of-function mutations in approximately 20% and 5% of cases, respectively.

Another commonly altered multiprotein complex is cohesin, which is composed of STAG1, STAG2, SMC1A, SMC3, and RAD21. Mutually exclusive loss of function mutations in these components are found in ~10% and ~20% of low- and high-risk MDS, respectively. These mutations may disrupt DNA loops involved in enhancer-promoter interactions, thus driving aberrant transcriptional programs and complementing loss-of-function mutations in core transcription factors.

Mutations in transcription factors such as GATA2 and RUNX1 usually occur somatically. However, they can also be inherited in the germline and cause familial bone marrow failure syndromes with a propensity to evolve into myeloid malignancies.

Missense mutations in the tumor suppressor *TP53* are highly prevalent among patients with MDS who have undergone chemotherapy. They are frequently associated with the loss of the second *TP53* allele via deletion of the short arm of chromosome 17 and their presence correlates with a poor outcome, even with most aggressive treatment regimens.

Pre-MDS Clonal Mutations

Recurrent somatic mutations in myeloid malignancy-associated genes, such as *DNMT3a*, *TET2*, and *ASXL1* can be identified in the peripheral blood of healthy individuals with normal blood counts. These CHIP or ARCH increase the risk of malignant transformation (0.5%–1% per year) through the acquisition of additional mutations (even though the principal cause of morbidity is vascular diseases). Accordingly, mutations in the above-mentioned epigenetic regulators are founder events in MDS pathogenesis. Germline polymorphisms and cell extrinsic factors may promote the rare progression of CHIP into overt MDS or AML. For example, treatment with chemotherapy could enable the preferential expansion of clones carrying mutations in *TP53*.

Post-MDS Clonal Mutations

Evolution to sAML can be considered the final stage of disease progression through the acquisition of characteristic genetic changes, such as activating mutations in signaling molecules such as *FLT3* and *N-RAS*, as well as inactivating mutations in *CEBPA*. At the time of leukemic transformation, the antecedent MDS clone is outcompeted by aggressive subclones. Of note, mutations in *SRSF2*, *SF3B1*, *U2AF1*, *ZRSR2*, *ASXL1*, *EZH2*, *BCOR*, and *STAG2* identify a subset of patients with AML who have no history of preceding MDS and who share the aggressive clinical behavior of sAML.

Epigenetic Changes

Genetic alterations are frequently associated with epigenetic changes arising in hemopoietic stem cells and including aberrant DNA methylation, which was most studied in the promoter region of the tumor suppressor gene P15 *INK4B*. These alterations are only partly related to gene mutations in epigenetic regulators. Hypomethylating drugs appear to modulate the methylation of DNA without eradicating the mutated cells, which can be sufficient to get a more balanced hematopoiesis.

Ineffective Hematopoiesis

The occurrence of cytopenias despite a generally hypercellular marrow indicates ineffective hematopoiesis, which was shown to result from an increased susceptibility of clonal myeloid progenitors to apoptosis. This excessive apoptosis can result from intrinsic

stresses due to the above-described genetic and epigenetic alterations. For example, iron retention in SF3B1 mutated erythroblasts induce mitochondrial depolarization and ribosomal defects in 5q- syndrome lead to reticulum endoplasmic stress. One of the hallmarks of MDS is activation of the NLRP3 inflammasome, which drives clonal expansion and pyroptotic cell death, independently of genotype, Pyroptosis is triggered by the alarmin S100A9 that is found in excess in MDS HSPCs and bone marrow plasma excessive apoptosis can also result from external insults triggered by the microenvironment such as death receptor ligands, including Fas-L and tumor necrosis factor, and myelosuppressive cytokines, such as transforming growth factor β. Importantly, a shift of from apoptosis to proliferation that emerges in a subclonal progenitor, for example, as a consequence of NFkB pathway activation, leads to disease progression to acute myeloid leukemia.

Microenvironment and Immune Cells

The hematopoietic stem-cell niche contributes to the pathogenesis of MDS. In the recent years, several mouse models have shown that genetic alterations in specific cells of this microenvironment could promote the emergence of a myelodysplastic clone. Clonal T-cell expansion is commonly detected, especially in patients with a hypoplastic syndrome, inflammatory Th17 cells and myeloid-derived suppressive cell may contribute to ineffective hematopoiesis whereas regulatory T cells contribute to evasion from antitumoral immunity in higher-risk disease. Several of the drugs commonly used in MDS may have an effect on this pathological environment and immune reaction, beyond their specific effect on the malignant cells. It remains unknown if these abnormalities are secondary events that modify the environment of the leukemic clone and facilitate its dominance on polyclonal hematopoiesis or they are primary events that favor the emergence of mutated clones able to escape this altered environment. Analysis of the genetic predisposition to MDS and other myeloid malignancies may help to distinguish the egg and the chicken: if the environment defect is the first to appear, it is expected that some hereditary cases will be the consequence of mutations altering the environment.

Among myeloid malignancies, MDS are at the crossroad of several disorders: (1) CHIP and ICUS that we have previously described (2) aplastic anemia, including those of auto immune origin and (3) *BCR-ABL*-negative MPNs in which primary myelofibrosis could be considered as an MDS. One interesting hypothesis is that somatic mutations identified in these diseases have been selected as they provide HSCs an advantage on aging or immunologically altered HSCs. These mutations provide some advantage to early stages of hematopoiesis but some of them are deleterious for terminal hematopoiesis, leading to cell dysplasia. These mutations can induce a genetic instability that favors secondary mutations and clonal evolution, or behave as rescue mutations such as JAK2V617F mutation whose acquisition in the context of SF3B1-driven refractory anemia with ring sideroblasts, induce some correction of anemia and a thrombocytosis, improving the disease outcome.

Risk Stratification

Because the prognosis of patients with MDS is highly heterogeneous, accurate prognostic systems are used to guide the therapeutic choices and timing. A number of scoring systems have been developed, the most widely used being the International Prognostic Scoring System (IPSS) and the Revised IPSS (IPSS-R).

The original IPSS, established in 1997, assigned to each patient a risk score that is based on bone marrow blast percentage, cytogenetics, and number of cytopenias (**Table 1**). Patients with low or intermediate-1 risks are considered to have low-risk disease, those with intermediate-2 or high scores to have high-risk MDS. Median OS ranges from approximately 5 months in untreated

Table 1 International prognostic scoring system for myelodysplastic syndromes (IPSS-R)

Define first the cytogenetic risk as follows					
Good	Normal, -Y, del(5q), del(20q)				
Intermediate	All other situations				
Poor	Complex (3 or more abnormalities) or chromosome 7 abnormalities				
Then, include the cytogenetic risk in the scoring system					
Points	0	0.5	1	1.5	2
Cytogenetic	Good	Intermediate	Poor		
BM blast	<5%	5%–10%		11%–20%	20%–29%
Cytopenias[a]	0–1	2 or 3			
Finally, calculate the prognostic risk score					
0					Low risk
0.5–1					Intermediate risk 1
1.5–2.0					Intermediate risk 2
2.5–3.5					High risk

[a]Cytopenias defined as either hemoglobin <100 g/L or absolute neutrophil count <1800/μL or platelet count <100,000/μL.

Table 2 Revised international prognostic scoring system for myelodysplastic syndromes (IPSS-R)

Define first the cytogenetic risk as follows							
Very good	-Y, del(11q)						
Good	Normal, del(5q), del(12p), del(20q), double including del(5q)						
Intermediate	del(7q), +8, +19, i(17q), any other single or double independent clones						
Poor	Complex (>3 abnormalities)						
Then, include the cytogenetic risk in the scoring system							
Points	0	0.5	1	1.5	2	3	4
Cytogenetic	Very good		Good		Intermediate	Poor	Very poor
BM blast	Up to 2%		2%–5%		5%–10%	>10%	
Hemoglobin	>10		8–10	<8			
Platelets	>100	50–100	<50				
ANC	>0.8	<0.8					
Finally, calculate the prognostic risk score							
Lower or equal to 1.5 points							Very low risk
>1.5–3							Low risk
>3–4.5							Intermediate risk
>4.5–6							High risk
>6							Very high risk

patients with high risk to almost 6 years in patients with low-risk disease. This very simple and easy to use system has limitations, especially in patients with low risk disease.

The IPSS-R, which was developed from a data set of over 7000 patients, uses different cut-off points of cytopenias, places a higher weight on cytogenetics, and refines the bone marrow blast categories (Table 2). Again, this score separates MDS patients with lower risk (very low or low risk scores) from those with higher risk (high or very high risk scores). The main limitation of IPSS-R is that no drug therapy has been approved yet using this scoring system.

A new molecular IPSS system is now expected as somatic mutations may impact the therapeutic choice. It is now clear that patient outcomes progressively worsen as the number of oncogenic mutations increases. In addition, specific somatic mutations reproducibly predict patient outcomes in univariate analysis, including the better clinical outcome of MDS with SF3B1 mutations and the worse outcome of those with *TP53*, *EZH2*, *ETV6*, *RUNX1*, *ASXL1*, and *SRSF2* mutations. However, genetics only modestly improves scoring systems such as R-IPSS and their precise role in clinical practice has still to be better delineated. Specific mutations can help in specific settings, for example, *TP53* and *DNMT3A* mutations are associated with a poor outcome after allogeneic stem cell transplantation, patients with *TET2* mutations better respond to azacitidine and those with *IDH1* or *IDH2* mutations may deserve targeted drugs.

Nevertheless, morphologic and clinical criteria still play a central role in evaluating MDS prognosis and these systems could be further refined by introducing comorbidities that affect the natural history of MDS patients while specific scoring systems could improve the prognostication in hypocellular and therapy related MDS.

Treatment of MDS

Therapeutic decision-making is guided by individual risk assessment performed using the IPSS, R-IPSS or similar tools. MDS patients with an indolent disease course and a relatively long life expectancy do not necessarily warrant therapy, for example, those without significant cytopenias can be monitored closely without treatment. Therapy is introduced to reduce transfusion needs and improve quality of life. A common practice is to start with growth factor support and consider lenalidomide or an azanucleoside secondarily. Patients that fail are candidates for clinical trials or allogeneic stem cell transplantation (ASCT). Ideally, treatment may delay transformation to AML and improve survival. Earlier therapeutic intervention is proposed to lower risk patients with a less favorable prognosis, with several innovative therapeutics currently tested, including transforming growth factor β superfamily ligand traps to treat anemia, oral azanucleosides, proteasome inhibitors, and antagonists of toll-like receptor signaling. Because higher-risk MDS patients have a higher rate of progression to AML and shorter survival, the goal of treatment is to alter the natural history of these diseases, prevent progression to AML and improve overall survival. Current available therapies include hypomethylating agents, intensive chemotherapy, and ASCT. Additional supportive care measures include the use of prophylactic antibiotics and iron chelation. There are no approved interventions for patients with progressive or refractory disease after these treatments. The management of patients with an intermediate score must be individualized, taking into consideration age, presence of bone marrow fibrosis and other relevant prognostic data such as gene mutations.

Supportive Care

Prophylactic antibiotics are usually used in the context of cytotoxic or immunosuppressive therapy and not in untreated patients as there is not major increase in the risk of infection in those with isolated neutropenia. Iron accumulation, as a consequence of red cell

transfusions, could increase the risk of infection as well as that of AML transformation, and induce liver cirrhosis or cardiomyopathy in lower risk, long living patients, but the use of chelation therapy is currently limited to patients with very high ferritin levels, above 2500 ng/mL.

Growth Factor Support

The vast majority of MDS patients develop some degree of anemia during the course of the disease, approximately 40% become transfusion-dependent, and severe anemia decreases health-related quality-of-life and increases cardiovascular risk. There is no consensus on the optimal hemoglobin level threshold for transfusions. Erythroid stimulating agents (ESA) are commonly used in these patients to prevent or correct anemia. A 3-month treatment is needed before evaluating the response. Recommended doses are higher than those used for patients with anemia due to chronic renal insufficiency. Treatment is generally well tolerated, and the incidence of cardiac and thrombotic events is low. Response rates range from 30% to 50% with a median response duration of 18–24 months. Algorithms have been developed, for example, by the Nordic MDS group, to predict response to ESAs, which is much higher in patients with a low endogenous serum erythropoietin (EPO) level EPO levels of <500 U/L and with low transfusion requirement (<2 units of packed red blood cells each month). Substantial improvements in well-being correlate with erythroid response. ESA are discontinued when the transfusion effect is lost.

The addition of granulocyte-colony-stimulating-factor (G-CSF) has been proposed in patients failing to respond to ESAs alone. ESAs may improve the natural history of the disease but questions on their potential tumorigenic effect have resulted in increased scrutiny of their use. Pooled analyses and large retrospective studies suggest a small OS benefit with these agents in the MDS population responding to treatment. In patients with thrombocytopenia, the use of eltrombopag remains cautious as there is a fear that, like romiplostim, the use of the MPL agonists expose to disease transformation and marrow fibrosis.

Immunomodulatory Drugs (IMiDs)

Thalidomide initially demonstrated some activity in reducing red blood cell transfusion needs in patients with MDS that had previously failed ESAs. Then, lenalidomide was developed as an orally bioavailable analog of thalidomide with immunomodulatory, antiangiogenic, and antiproliferative properties. In patients with anemia and del(5q), lenalidomide (10 mg for 21 days every 4 weeks) has become the standard of care. del(5q) is the most common cytogenetic abnormality in MDS (10%–15%). The so-called "5q-syndrome" includes refractory anemia, isolated del(5q), female predominance, normal to increased monolobulated megakaryocytes, $<5\%$ bone marrow myeloblasts and relatively indolent course. In patients with a 5q-syndrome and a good platelet count, lenalidomide results in lower transfusion requirements and, in 50% of them, cytogenetic complete remission. Response is fast (median time 5 weeks). The median rise of hemoglobin is 5 g/dL. The most common adverse events are early neutropenia and thrombocytopenia, which generally occur within the first two cycles. Their occurrence is associated with a higher probability of response as they correspond to suppression of the del(5q) clone. While deep venous thrombosis is a well-known adverse event associated with the use of lenalidomide in multiple myeloma, it was reported in only 3% of MDS patients. This treatment does no increase the incidence of AML transformation and increases survival for responding patients, indicating that the drug can change the natural history of this specific MDS.

A mechanism of action of lenalidomide has been deciphered. This drug binds to an E3 ubiquitin ligase, alters its substrate affinity and induces the selective degradation of a kinase named casein kinase 1A1. This kinase is encoded by a gene in the commonly deleted region of chromosome 5. Complete loss of this kinase triggers p53-mediated apoptosis. This explains why mutations in *TP53* are associated with poor response to lenalidomide and *TP53*-mutant subclones expand in patients treated with this drug.

Lenalidomide has been used also in transfusion-dependent MDS patients without chromosome 5 alterations: 25% achieved transfusion independence after a median of 5 weeks of therapy, with median response duration of 41 weeks. The median hemoglobin increase was less robust than that observed in patients with isolated del(5q), cytogenetic responses were infrequent, and the median duration of transfusion independence was shorter than in patients with 5q-syndrome. The drug may not be used in patients with thrombocytopenia.

DNA Methyltransferase Inhibitors

Aberrant DNA methylation may be an important component of MDS pathogenesis. DNA methyltransferases (mainly DNMT3A/B) are the main enzymes that catalyze the addition of methyl groups to the 5′ position of cytosine nucleotides into DNA. Two drugs that inhibit DNMTs are the standard of care for most patients with high risk MDS, namely 5-azacitidine and 5-aza-2′-deoxycitidine (decitabine). These azanucleosides are also known as hypomethylating agents (HMAs).

Azacitidine is a ribonucleoside that is phosphorylated by uridine cytidine kinase to be incorporated into RNA. Decitabine is a deoxyribonucleoside that is directly incorporated into DNA. About 10% of azacitidine is also incorporated into DNA through enzymatic conversation by ribonucleotide reductase. Decitabine requires phosphorylation by a deoxycytidine kinase to become biologically active. Both drugs incorporate into nucleic acids during the S-phase and irreversibly bind to and deplete DNMTs. Demethylation of DNA was associated with clinical response in chronic myelomonocytic leukemia.

Although response rates to these two drugs are similar, only 5-azacitidine (75 mg/m^2 subcutaneously daily for 7 days every 4 weeks) has been demonstrated to improve survival in higher risk MDS patients, thus is the standard front line treatment in these patients. Patients respond slowly, in 90% of cases by six cycles, suggesting that therapy should not be abandoned prior to six cycles unless there is documented disease progression. Fifty to sixty percentage of these patients experience hematologic improvement after six cycles, which improves their quality of life compared to best supportive care only. The median duration of response is 15 months. Therapy should be given indefinitely in the absence of severe toxicity or disease progression. The most common toxicities are hematologic, grade 3 or 4 neutropenia is most common and may be more prominent with the initial cycles whereas nonhematologic toxicity is dominated by injection-site reactions to subcutaneous injections. Loss of response after discontinuation can be rapid and retreatment results in inferior quality and duration of responses compared to initial treatment.

Achievement of CR is not a prerequisite for improved survival. Power of mutational data to predict HMA response is modest. Nevertheless, early clonal mutations in *TET2* gene, encoding a protein involved in the demethylation of 5-methylcytosine, have been associated with an increased response rate. A set of differentially methylated regions, mostly localized in nonpromoter regions, also predicts response to HMAs.

Low dose HMAs can be considered in patients with lower risk disease that are transfusion dependent and have failed or are not candidates for growth factor support or lenalidomide. An oral formulation of 5-azacitidine is being studied for patients with lower risk MDS.

AML-Like Induction Chemotherapy

The classical anthracycline- and cytarabine-based chemotherapy used to treat AML is less efficient in treating high-risk MDS. In addition to being hard to use because of the advanced age of MDS patient, this treatment results in lower CR rates (40%–60%), higher treatment-related mortality and morbidity, shorter CR duration ($\sim$12 months) and longer periods of aplasia. In particular, patients with a complex karyotype or an alteration of chromosome 7 have a low CR rate and a short duration of response. Therefore, AML-like therapy is now restricted to younger patients with favorable karyotype, usually as a bridge to allogeneic stem cell transplantation. A large retrospective study comparing azacitidine to induction chemotherapy or both prior to allogeneic stem-cell transplant found that OS, event-free survival, relapse rate and nonrelapse mortality are similar between azacitidine and induction chemotherapy.

Immune Therapy

Immune-modulatory agents can be used in hypocellular MDS patients, which are a difficult group of patients. A deregulation of both cellular (abnormal CD8$^+$ cytotoxic T-lymphocytes) and innate immunity is identified in a subset of MDS patients, autoimmunity is commonly associated to these diseases, and there is overlap between MDS and immune-mediated bone marrow failure syndromes such as aplastic anemia. Equine antithymocyte globulin (ATG, 15 mg/kg intravenously for 5 days) combined with oral cyclosporine for 6 months, but also growth factors and steroids, which are all used in aplastic anemia, are considered in younger MDS patients with severe hypocellular bone marrow and short transfusion dependency when allogeneic stem cell transplantation is not feasible. Responses are slow as they may take up to 6 months to manifest. Response rates are around 30%. The impact of ATG based therapy on transformation-free and overall survival is still questioned. Among the new agents, the activity of alemtuzumab, an antibody against CD52, and eltrombopag, which was tested as salvage therapy, is currently investigated.

Allogeneic Stem Cell Transplantation

Allogeneic stem cell transplantation is the only curative therapeutic strategy for MDS. Timing of the procedure, optimal conditioning regimen and maintenance therapies are still debated issues.

Because of its high morbidity and mortality, allogeneic stem cell transplantation is usually not recommended in patients with lower risk MDS at initial presentation, even if they are young. Because of the time required for donor identification, it is important, nevertheless, to search rapidly for an appropriate donor while evaluating the risk of this therapeutic approach.

Young patients with higher risk disease or hypoplastic MDS at diagnosis and MDS patients who have been exposed to multiple therapies should be considered for transplantation. Early transplantation is associated with a prolonged survival obtained in 30%–50% of the patients.

It is important to identify which patients will benefit the most from transplant through accurate pretransplant risk evaluation. Risk factors include cytogenetics (monosomy 7 predicts a poor outcome), elevated serum ferritin levels and some genetic alterations as mutations in *TP53*, *DNMT3A*, *RUNX1*, and *ASXL1* mutations are potential markers of poor outcome.

Different transplant modalities and donor sources are currently evaluated, which may allow considering older patients for transplantation in the future. Retrospective studies suggest that MDS patients between ages 60 and 70 with a suitable donor can benefit from transplant following a reduced intensity conditioning as long as they are medically fit.

Questions include whether or not disease debulking with chemotherapy or hypomethylating agents is recommended prior to transplant when marrow blasts $>10\%$ in order to decrease the very high relapse risk posttransplant. Most of these patients receive azanucleosides as a donor search is initiated and pretransplant testing is completed. Posttransplant hypomethylating use could also

improve outcome, especially in patients who showed decreased donor chimerism (< 80%) while still in morphologic and hematologic complete response.

Investigational New Therapeutic Options

All the currently available agents for the treatment of MDS have considerable shortcomings and every patient with a relapsed or refractory disease should be considered for an investigational clinical trial if allogeneic stem cell transplantation is not feasible.

Novel therapeutic targets have emerged from recent advances in our understanding of the molecular pathophysiology of these diseases. Targeted molecules include small-molecule inhibitors of either mutant isocitrate dehydrogenase enzymes, or spliceosome, which are currently evaluated in early phase clinical trials. Kinases inhibitors, including those targeting Flt3 and the Ras pathway could also take place in the precision medicine approach.

Another approach, whose development has been limited by toxicity, is the combination of azanucleoside with other drugs such as lenalidomide, anthracyclines or histone deacetylase inhibitors. An oral formulation of azacitidine and second-generation azanucleosides such as SGI-110, a dinucleotide form of decitabine and deoxyguanosine that protects it from deamination, are also tested.

Since thrombocytopenia can be difficult to manage in MDS patients, thrombopoietin receptor agonists, including romiplostim and eltrombopag, have been tested. Concerns regarding an increase in the rate of progression to AML have led to stop the development of romiplostim. Preliminary results indicated that eltrombopag increases platelet count in lower risk MDS patients.

Agents targeting a variety of pathways are currently under clinical investigation for the treatment of anemia, including inhibitors of p38 MAPK and Tie2 (ARRY-614), PI3K and PLK1 (rigosertib), and the TGF-β superfamily (LY2157299, sotatercept). Rigosertib, clofarabine and immune checkpoint inhibitors are also tested in MDS. Finally, high doses of vitamin C could partially revert the phenotypic effects of *TET2* mutations but the potential interest of these observations deserve to be tested in clinical trials.

Prospective Vision

A number of genetic alterations that drive MDS have been identified but how these somatic aberrations occur and the conditions in which they generate the disease phenotype remain open questions: the role of germline factors, microenvironment alterations and host factors such as immune response and microbiota composition in disease emergence and progression may be clarified in the coming years. Lenalidomide and hypomethylating agents have a major place in the current armamentarium against MDS, as targeted therapies have demonstrated limited efficacy so far, but coming years may define the potential interest of IDH and spliceosome inhibitors and, hopefully, alternative strategies will emerge from ongoing pathophysiological studies.

Definition and Classification

Nasopharyngeal carcinoma (NPC) is a carcinoma which arises in the nasopharyngeal mucosa and shows light microscopic or ultrastructural evidence of squamous differentiation. The term encompasses three distinct entities: nonkeratinizing, keratinizing, and basaloid squamous cell carcinoma.

Nonkeratinizing squamous cell carcinoma (ICD-O code: 8072/3) is composed of large atypical cells, without morphological evidence of keratin production, whereas keratinizing squamous cell carcinoma (8071/3; also called large cell squamous cell carcinoma, keratinizing squamous cell carcinoma, and keratinizing epidermoid carcinoma) is a squamous cell carcinoma with prominent production of keratin. Basaloid squamous cell carcinoma (8083/3) is histologically characterized by the presence of cells with hyperchromatic nuclei, scant amount of cytoplasm, and peripheral nuclear palisading.

Presentation and Diagnosis

NPCs most commonly originate in the pharyngeal recess (fossa of Rosenmüller), or—less frequently—in the superior posterior wall of the nasopharynx. The tumor can present as a smooth bulge in the mucosa, a discrete raised nodule (in some cases with surface ulcerations), or an infiltrative fungating mass. In some cases, the lesions are not grossly visible. NPC is highly malignant, with extensive locoregional infiltration and lymphatic spread occurring early in the course of the disease.

Most patients present with locoregionally advanced disease, commonly with cervical lymph node metastases. The presenting symptoms are related to the presence of a mass in the nasopharynx (e.g., epistaxis, obstruction, and blood-stained postnasal drip), Eustachian tube dysfunction (such as hearing impairment, tinnitus, and serous otitis media), and skull base involvement with impairment of the cranial nerves, most frequently the fifth and the sixth (e.g., headache, diplopia, facial pain, numbness, and paresthesia). Painless neck mass appears due to lymph node metastases. About 10% of patients are asymptomatic.

Fiberoptic endoscopic examination of the nasopharynx following complete physical examination including palpation of the head and neck for adenopathy is routinely used to elicit the tumor. The jugulodigastric node is the most commonly palpable

node at presentation. Computed tomography (CT), positron emission tomography (PET)-CT scan, or magnetic resonance imaging (MRI) is used to evaluate the extent of primary tumor and adenopathy as well as the skull base invasion. MRI is often more helpful than CT as it provides a better resolution for assessing parapharyngeal spaces, marrow infiltration of the skull base, intracranial disease, and deep cervical nodes. Neuro-ophthalmological and audiological evaluations allow to evaluate the degree of impairment of the cranial nerve function.

Diagnosis is made based on the pathological evaluation of the nasopharyngeal mass from the primary tumor site. Determining the Epstein-Barr virus (EBV) infection status helps to confirm nonkeratinizing NPC diagnosis. Detecting Epstein-Barr virus (EBV) by hybridization in situ for the Epstein-Barr encoding region (EBER) is particularly helpful in the evaluation of the cervical lymph nodes harboring undifferentiated or poorly differentiated squamous cell carcinoma, with the positive result being strongly suggestive of the NPC diagnosis (see "**Biomarkers**" section). A cytological evaluation of fine-needle aspirates (FNA) of the neck followed by immunohistochemistry is useful for diagnosing metastatic keratinizing and nonkeratinizing NPC.

Epidemiology and Risk Factors

Burden

Even though NPC is the most common neoplasm of the nasopharynx, it is relatively uncommon compared to other cancer types. However, it has a very unique geographical distribution overall, with remarkable variations in incidence. About 70% of cases are diagnosed in east and south-east Asia, and those occurring in south-central Asia, and east and north Africa roughly account for the remaining 30%, while the annual incidence in North America is only 0.3–0.7 cases per 100,000 population. In 2012, almost 86,700 new NPC cases were reported worldwide (about 0.6% of all cancers), of which over 21,200 occurred in the WHO South-East Asia region. The highest incidence rates were reported for Malaysia, followed by Singapore before Indonesia and Vietnam (**Fig. 1**). The peak incidence is between 40 and 60 years of age.

The age-standardized incidence of NPC has declined over the past decades, particularly among Hong Kong Chinese, and the NPC-related mortality rates are also going down. Still, 120,000 new NPC cases and over 20,000 NPC-related deaths are predicted for the year 2030.

Etiology and Risk Factors

Men are two to three times more likely to develop NPC than women. In contrast to Caucasians in whom NPC is rare, NPC is quite common in some specific ethic groups, including the Inuits in the North Pole, the Bidayuh in Borneo, and the Nagas in northern India, suggesting that they may have a genetic predisposition to develop the disease.

The etiology of NPC seems to be multifactorial, with viral infections playing an important but not exclusive role in the tumorigenesis. Epstein-Barr virus (EBV), a very common herpesvirus, is strongly associated with the development of nonkeratinizing NPC, in particular in endemic NPC regions, but not with that of the keratinizing type. Conversely, infection with high-risk types of the human papilloma virus (HPV) has been shown to be associated with NPC from nonendemic regions and in particular with the keratinizing type, even though the evidence is not yet so strong as for EBV.

Consumption of salted and fermented food has been implicated in the etiology of nonkeratinizing NPC in populations where this type is endemic. In particular, consumption of traditional salted fish in China has been shown to be a risk factor. These foods have a high content of N-nitrosamine. The carcinogenicity of N-nitrosamine compounds has been clearly shown for several other cancer sites and it is also hypothesized to be the carcinogen associated with the NPC risk.

Tobacco smoking and heavy alcohol consumption have also been proposed as putative risk factors, however the evidence for the latter remains controversial. Among other environmental factors, occupational exposure to wood dust, heat, smoke, formaldehyde, and chemical fumes have been identified as potentially contributing to the risk of NPC, and two of these exposures have been classified as carcinogenic for the nasopharynx by the IARC monographs (**Table 1**).

The risk of developing NPC is also associated with genes coding for certain tissue antigens (human leukocyte antigen (HLA) complex). For example, high-resolution genotyping studies have consistently shown an association between NPC and the *HLA-A*0207* allele which is common in the Chinese population. Genetic polymorphisms in genes coding for metabolic and DNA repair enzymes have also been associated with an increased risk of NPC. Familial clustering of NPC is well documented. However, the clinical characteristics of familial and sporadic NPCs do not differ.

Pathology and Genetics

Deletions on chromosomes 3p and 9p (spanning the *CDKN2A* gene on chromosome 9p21) have been identified to be early events in NPC carcinogenesis. Most frequent chromosome gains are on chromosome 12. Gene fusions have been reported in about 10% of cases. Somatic mutations in the *TP53* gene are common (15%–20%).

The most remarkable characteristic of the NPC genome is the presence of multiple alterations targeting chromatin remodeling pathway, with three genes having been identified as significantly mutated by whole-exome sequencing: *BAP1*, *MLL2*, and *TSHZ3*. The most frequently altered gene in this category is *ARID1A*. Alterations in the chromatin remodeling pathway have been shown to

be associated with both EBV burden and poor overall survival in univariate but not in multivariate analysis. Interestingly, suppressing endogenous *ARID1A* in vitro results in an increased anchorage-independent colony formation, cell migration and xenograft growth. Another altered pathway includes receptor tyrosine kinases (*ERBB2*, *ERBB3*) and their downstream effectors (*PI3KCA*, *KRAS*). Patients with alterations in this pathway seem to have shorter survival and more advanced stage disease. Finally, a number of alterations are observed in genes regulating autophagy (Table 2).

Biomarkers

Epstein-Barr Virus (EBV)

EBV is prevalent in NPC, with almost all cases of nonkeratinizing NPC being associated with EBV infection. EBV testing has been shown to be useful for early detection and differential diagnosis of NPC as well as for prognostication and monitoring response to treatment (Table 3).

The most reliable method to detect EBV in tumor tissue is in situ hybridization for EBV-encoded RNA (EBER) or immunohistochemical staining for latent membrane protein (LMP), even though the reliability and specificity of this method is questioned by some sources. EBV DNA load in blood serum or plasma may be quantified by real-time polymerase chain reaction (RT-PCR)

Table 1 Risk factors for nasopharyngeal carcinoma (NPC)

Carcinogenic agents classified by IARC Monographs on the Evaluation of Carcinogenic Risks to Humans (volumes 1–120)
Agents of sufficient evidence for nasopharynx carcinogenicity in humans
Epstein-Barr virus (EBV; association shown for NK-NPC)
Formaldehyde
Chinese-style salted fish consumption (NK-NPC)
Tobacco smoking (K-NPC)
Wood dust
Other carcinogenic agents and lifestyle risk factors
High-risk human papillomaviruses (HPV; K-NPC)
Heavy alcohol consumption (putative risk factor)
Occupational exposure to heat, smoke, or chemical fumes (putative)
Phenotypic and genetic risk factors
Male sex
Ethnicity
Family history of NPC

K-NPC, keratinizing NPC; *NK-NPC*, nonkeratinizing NPC.

targeting such genomic EBV sequences as *BamHI-W*, *EBNA*, or *LMP*. However, the sensitivity and specificity of PCR-based assays varies and given the plethora of commercially available assays used in clinical settings (e.g., from Viracor Eurofins and Roche Molecular Diagnostics), there is an urgent need to harmonize and validate reliable EBV detection and quantification protocols.

In patients who present solely with cervical adenopathy, finding EBV in tissue is strongly suggestive of a primary NPC and indicates a necessity of a more in-depth diagnostics to this effect. Testing for EBV also helps to make a differential diagnosis in case of nonkeratinizing or undifferentiated histology, the latter of which for example being sometimes difficult to distinguish from lymphoma at a histological level. Several studies have also shown a diagnostic value of EBV detection in transoral brushing specimens and in nasopharyngeal swabs for detecting both primary and recurrent NPC.

A number of studies have shown elevated titers of IgA antibodies against EBV antigens (virus capsid antigen (VCA) and EBV early antigen (EA)) in NPC patients compared to healthy individuals, supporting the use of EBV serology as a screening method. High titers persisting after therapy have also been associated with a worse prognosis. Other studies suggested that EBV DNA load in blood serum or plasma is a more reliable diagnostic, monitoring, and prognostic marker. In particular, it has been validated as an

Table 2 Gene loci that are most frequently altered in nasopharyngeal carcinoma

Pathway	*Gene (locus)*	*Alteration type*
–	Deletions on chromosomes 3p and 9p (spanning *CDKN2A* on 9p21)	
Chromatin remodeling	*ARID1A* (1p36.11)	Deletions and point mutations; likely associated with EBV and poor survival
	BAP1 (3p21.1)	Point mutations
ERBB/P13K signaling (cell metabolism)	*PIK3CA* (3q26.32)	Activation by hot-spot mutations and amplifications
	ERBB2 (17q12) and *ERBB3* (12q13.2)	Point mutations
	KRAS (12p12.1)	Amplifications and point mutation
	AKT2 (19q13.2)	Amplifications
	PTEN (10q23.31)	Deletions
Autophagy regulation	*ATG2A* (11q13.1), *ATG7* (3p25.3), and *ATG13* (11p11.2)	Deletions and point mutations
G1/S transition (cell-cycle) control	*CDKN2A* (9p21.3)	Deletions and point mutations
	TP53 (17p13.1)	Deletions and point mutations

Table 3 Biomarkers for the detection and management of nasopharyngeal carcinoma (NPC)

Biomarker	*Characteristics and clinical utility*
Diagnostic and monitoring biomarkers	
EBV in tissue	Detected in tumor tissue, strongly suggestive of primary nonkeratinizing NPC; useful for differential diagnosis in case of nonkeratinizing or undifferentiated histology, and for early detection in patients with cervical adenopathy; detected in brushing biopsies/swabs, strongly specific for detecting primary or recurrent NPC
EBV serology	Elevated anti-EBV IgA titers in NPC patients compared to healthy individuals
EBV DNA load in blood serum/plasma	Elevated EBV DNA levels in NPC patients compared to healthy individuals; also a potential monitoring biomarker allowing early detection of local and distant treatment failures; variable detection sensitivity issues remain to be solved
Prognostic biomarkers	
Tumor stage at presentation	Inversely correlated with prognosis
Tumor size/increasing tumor volume	Increasing tumor volume associated with an increased risk of local treatment failure
EBV serology	High titers persisting after treatment associated with poor prognosis
EBV DNA load in blood serum/plasma	EBV DNA levels inversely correlated with overall survival in early-stage NPC patients; persistent EBV detection after definitive radiotherapy associated with an increased risk of tumor recurrence and with adverse prognosis; detection methods require standardization and validation (cut-offs, timing, sensitivity)
Predictive biomarkers	
EBV DNA load in blood serum/plasma	Persistent high posttreatment levels may be a criterion to select patients most likely to benefit from adjuvant chemotherapy after chemoradiation (currently being tested)

EBV, Epstein-Barr virus.

independent prognostic marker which inversely correlates with overall survival in early-stage NPC patients. Several studies have confirmed that persistent EBV detection after definitive radiotherapy, with or without chemotherapy, is associated with an increased risk of tumor recurrence and with adverse prognosis. It has also been associated with distant metastases. Monitoring EBV DNA levels can therefore complement traditional imaging techniques in surveillance for local and distant treatment failures. However, the detection sensitivity of EBV DNA in plasma remains an issue and standardized cut-off values for prognostication have to be defined and validated. Moreover, the detection periods or time-points are not clearly defined (e.g., what is the period of posttreatment recurrence predicted by elevated EBV DNA levels, or else at what time points and for how long these levels should be monitored).

The use of EBV DNA load as a biomarker to select patients that are most likely to benefit from adjuvant therapy following chemoradiation has also been suggested. The effectiveness of posttreatment patient stratification based on EBV DNA load into low-risk (undetectable posttreatment plasma EBV DNA) and high-risk as a strategy to select patients for adjuvant therapy is currently being tested in phase II and III clinical trials. The goal of this approach is to create a treatment decision tree allowing to eliminate unnecessary adjuvant chemotherapy for low-risk patients and maximize progression-free survival for those of the high-risk patients who are most likely to benefit from such a regimen. Conversely, monitoring EBV DNA levels during the initial chemoradiation (mid-treatment monitoring) has been suggested as a potential tool to identify cases with a good response to treatment and a favorable prognosis. It has been hypothesized that it may also allow to personalize treatment regimens, with decreasing EBV DNA levels indicating a possibility to de-intensify the treatment. However, this approach has not been validated and remains controversial.

Other Prognostic and Predictive Biomarkers

The most powerful prognostic biomarker for NPC is tumor stage at presentation, with the overall survival decreasing with increasing tumor stage (Table 3). Tumor size, and in particular increasing tumor size, is a negative prognostic factor associated with an adverse patient outcome, with an estimated 1% increase in the risk of local treatment failure per 1 cm^3 increase in tumor volume. Also the involvement of neck lymph nodes adversely affects the outcome.

Other factors that have been linked to diminished survival by some (but not all) studies include patient age, male sex, cranial nerve palsy and ear symptoms at presentation, and a long interval between biopsy and the beginning of radiotherapy. The relationship between NPC histological type (keratinizing versus nonkeratinizing) and prognosis remains unclear, with conflicting reports.

The significance of high-risk HPV types is not yet elucidated. EBV and HPV infections are usually mutually exclusive. Several studies have suggested that HPV-related tumors are associated with worse prognosis than those related to EBV but may have a better outcome than tumors in patients negative for both EBV and HPV.

Many putative molecular and immunohistochemical prognostic markers have been studied but so far only serum/plasma EBV DNA load tests have been applied in routine clinical practice.

Developing reliable screening biomarkers for early detection of NPC in high-risk patients, predictive biomarkers which would allow to predict response to treatment and apply personalized treatment regimens, as well as monitoring biomarkers for early detection of recurrence would be invaluable in the management of NPC.

Management and Therapy

NPC is usually not curable by surgical resection due to the tumor localization as tumor-free margins cannot be obtained at the base of the skull. Therefore, radiotherapy (RT) with high-energy x-rays, often combined with chemotherapy is the treatment of choice, with different modalities depending on the tumor clinicopathological features.

Small (T1) early-stage tumors with no lymph node involvement and no distant metastases are highly curable by RT alone (definitive RT), while a combination of RT and chemotherapy is used for more advanced tumors. Induction chemotherapy prior to RT has been shown to give high response rates but the overall survival benefit is not clear, even though some studies have suggested that using a combination of cisplatin, 5-fluorouracil (5-FU), and a taxane (usually docetaxel) for the induction therapy may significantly improve survival. So far, RT with concurrent cisplatin-based chemotherapy is the standard treatment in Western countries. It may be followed by adjuvant chemotherapy (either cisplatin with 5-FU, or carboplatin with 5-FU). However, studies on the associated clinical benefits give conflicting results. In particular, it is worth to bear in mind that adjuvant therapy after RT is often poorly tolerated. Validating biomarkers which would allow to select patients most likely to benefit from adjuvant therapy would add much value to the current treatment schemes. EBV DNA levels in blood plasma offer some hope to this effect (see "**Biomarkers**" section).

The RT with concurrent chemotherapy regimen appears to increase the 5-year survival rates up to two-fold. However, many patients do not complete the planned therapy because of its toxicity. Given the NPC localization and high total radiation doses, RT alone may result in severe sequelae including local ulceration, occasionally with necrosis, retinopathy, fibrosis of soft tissues in the neck, and middle ear changes. Chemoradiotherapy is associated with an even higher rate of hematological and nonhematological acute toxic effects. Late adverse effects from RT may be limited by using modern radiation technology, for example intensity-modulated radiotherapy (IMRT) which is the recommended option for NPC RT wherever available. It allows to minimize irradiation of normal tissue adjacent to the tumor, thus substantially limiting the radiation-induced adverse effects.

A comprehensive assessment of the primary tumor response to treatment includes clinical examination, endoscopic examination of the nasopharynx (with or without biopsy) to assess superficial lesions, radiological imaging for the assessment of deeper lesions within the skull base, and EBV DNA titer measurement. Of note, differentiating between postradiation changes and residual disease on radiological imaging may be challenging. To this effect, PET with 2-deoxy-2-[fluorine-18]fluoro-D-glucose PET integrated with CT (^{18}F-FDG PET/CT) has emerged as the most sensitive and specific method. However, some characteristics captured by MRI are also useful to assess early treatment response.

In case of primary treatment failure (local recurrence), re-treatment is the most frequent choice and it has higher success rates than re-treatment of other head and neck cancers. Still, high total dose irradiation of the primary site is needed. This may be done by IMRT or brachytherapy. Limited post-RT failures in the neck may be controlled by surgery (neck dissection).

Patients with metastatic NPC have heterogeneous outcomes and long-term survivorship is possible. Cisplatin-containing doublet regimens remain the standard for the first-line systemic treatment of metastatic disease, with the most "classic" choice being cisplatin with 5-FU (response rates of 70%–80%). Other cisplatin-containing combinations for doublet and even triplet regimens, for example with gemcitabine, capecitabine, paclitaxel, and docetaxel, have also been tested. However, the reports on their efficacy (measured by tumor response rates, progression-free survival, and/or overall survival) compared to the conventional treatment remain contradictory. In case of platinum-resistant disease, a monotherapy with gemcitabine, capecitabine, or docetaxel is used, with reported response rates of approximately 30%–40%. Several doublet combinations have been tested to this effect but none of them has been shown to yield better response rates.

In the era of personalized medicine, targeted molecular therapies also hold promise for treatment of recurrent and metastatic NPC. In particular, inhibitors of epidermal growth factor receptor (EGFR), such as cetuximab, and of vascular endothelial growth factor (VEGF) have shown clinical efficacy in patients with platinum-refractory disease. Of note, VEGF-targeting drugs increase the

risk of bleeding and are therefore not suitable for patients who have a recurrent tumor within a previously irradiated field or a tumor invading major vascular structure.

The high prevalence of EBV in NPC patients and its relation to patient outcome opens the door to EBV-specific T-cell-based immunotherapies. Several vaccines targeting EBV in recurrent and metastatic NPC patients are currently under clinical trials, with promising results. Moreover, EBV-associated tumors express programmed death ligand 1 (PD-L1). A phase II trial testing nivolumab, a PD-L1 inhibitor, in recurrent and metastatic NPC is currently ongoing. Positive results would support the strategy to combine non-antigen-specific immune checkpoint inhibitors with immunogenic vaccination against tumor-specific antigens, which could become standard for the treatment of metastatic NPC in the future.

Prospective Vision

Many cancer genomic studies have focused on prognostic biomarkers. However, while identifying patients at higher risk of recurrence and unfavorable prognosis is important to define optimal treatment regimens, identifying new targets for treatment of metastatic NPC remains the major urgent unmet need. Indeed, metastases are frequent in NPC patients and systemic therapy is key for a successful treatment, with personalized approach being the choice of the future. Among others, mutations in the genes of the chromatin remodeling pathway, linked to EBV burden, seem to be potentially interesting surrogate targets as tumors with these mutations may be sensitive to histone deacetylase inhibitors (HDACi). Several clinical trials testing the safety, tolerability and efficacy of different HDACi in combination with other drugs are currently underway. Moreover, given its apparently frequent involvement in NPC, targeting the autophagy pathway may represent another, yet untested, opportunity.

Paolo Boffetta, MD, MPH, graduated in Medicine from the University of Turin and obtained a Master in Public Health from Columbia University. He worked at the American Cancer Society, the International Agency for Research on Cancer, a specialized agency of the World Health Organization located in Lyon, France, and at the German Cancer Research Center in Heidelberg, Germany. In 2010 he moved to Icahn School of Medicine at Mount Sinai, New York, where he is Professor of Medicine, Global Health, Oncological Sciences, and Preventive Medicine, and Associate Director for Global Oncology of the Tisch Cancer Institute, a NCI-designated Cancer Center.

Dr. Boffetta also holds a full professorship at the University of Bologna and adjunct appointments at Harvard School of Public Health, Vanderbilt University, Catholic University of Rome, and University of South Carolina. Since 2017 he is Senior Advisor for Research at Vinmec Health System. His main fields of research are cancer epidemiology and cancer prevention, with emphasis on modifiable risk factors (environmental exposure and personal behaviors), gene–environment interactions, molecular epidemiology, and evidence integration. He is the initiator and coordinator of several large-scale international consortia of molecular cancer epidemiology studies, including ILCCO (lung cancer), INHANCE (head and neck cancer), PANC4 (pancreatic cancer), StoP (stomach cancer), and ILCEC (liver cancer).

Dr. Boffetta is the editor or associate editor of 5 scientific journals and member of the editorial board of 10 additional journals; he is a member of review panels of NIH and several medical research agencies in Europe. He has edited 13 books and is Editor in Chief of the new edition of Elsevier's *Encyclopedia of Cancer*. He has published over 1250 peer-reviewed publications; his publications have been quoted more than 90000 times; his h-index is 148.

Pierre Hainaut is Professor of Exceptional Class in Cancer Biology at University Grenoble-Alpes, France and Director of the Institute of Advanced Biosciences (IAB), a joint research center of Institut National de la Santé et de la Recherche Médicale (Inserm), Centre National de la Recherche Scientifique (CNRS), and University Grenoble-Alpes. He also heads the IAB research team on Molecular Biology and Biomarkers.

Pierre Hainaut holds a PhD in Biology (Zoology) from University of Liège, Belgium (1987). After postdocs in Nice (France, 1988–90), Cambridge, and York (United Kingdom, 1990–94), he joined the International Agency for Research on Cancer (IARC, World Health Organization) in 1995, where he held the post of Head of Molecular Carcinogenesis from 1999 to 2011. In 2012, he joined the International Prevention Research Institute (Lyon, France) and became Professor at the Strathclyde Institute of Pharmacy and Biomedical Science (Glasgow, United Kingdom). In 2014, he was awarded a Chair of Excellence in Translational Research from University Grenoble-Alpes (Grenoble, France).

His research focuses on *TP53* mutations and p53 protein regulation in cancer and chronic diseases. From 1994 to 2011, he has led the development of the international IARC TP53 database, a source of information on the causes and consequences of mutations affecting the *TP53* suppressor gene in cancer. His work addresses the mechanisms of *TP53* mutagenesis as well as the prognostic and predictive significance of *TP53* mutations in lung, liver, and oesophageal cancers. His studies on p53 regulation have focused on the role of environmental mutagens in *TP53* mutagenesis, on the biochemical mechanisms of p53 control by oxidation-reduction and by metabolism, and on the identification of p53 isoforms as factors acting as dominant inhibitors of p53 functions in cancers without *TP53* mutations. His current activities focus on germline *TP53* mutation and on the diversity of genetic and nongenetic factors that modulate the penetrance of the Li–Fraumeni Syndrome, as well as on the mechanisms that maintain optimal p53 protein balance in cells and tissues over lifetime. He is the author of over 450 publications and 50 book chapters. He is Editor of the Cancer Biology section of *Current Opinion in Oncology*. He has co-edited books on p53 (*25 Years of p53 Research*, 2005, 2007, *p53 in the Clinics*, Springer), a textbook on molecular epidemiology (*Molecular Epidemiology: Principle and Practice*, IARC Press, 2011) and two-volume textbook on human biobanking (*Human Biobanking, Principle and Practice*, 2017, 2018).

SECTION EDITORS

Fred T. Bosman MD PhD, studied Medicine at the University of Leiden (MD 1971), where he also earned his PhD degree (in cytogenetics, 1976), and trained as a pathologist. He was staff pathologist at the University of Leiden, Professor and Chair of Pathology at the Faculty of Medicine of the University of Maastricht, Faculty of Medicine of the Erasmus University in Rotterdam, Director of the University Institute of Pathology, and Professor of Pathology at the University Medical Center (CHUV) of Lausanne in Switzerland, now emeritus. He is Honorary Fellow of the Royal College of Pathologists (United Kingdom) and foreign correspondent of the Royal Netherlands Academy of Sciences.

Fred Bosman's research activities (combining diagnostic and experimental pathology) focused on the biology of digestive tract cancer, notably Barrett's esophagus and colorectal cancer, with a strong emphasis on the development of molecular diagnostics. He has written over 350 original publications and over 50 book chapters. Fred Bosman was Series co-editor of the 4th edition of the WHO Series *Classification of Human Tumours*, the international standard for tumor classification, and co-editor of the Volume on *Tumours of the Digestive Tract*.

Graham A. Colditz, MD, DrPH, FAFPHM, is an internationally recognized leader in cancer prevention. As an epidemiologist and public health expert, he has a longstanding interest in the preventable causes of chronic disease, particularly among women. He focuses his research on early life and adolescent lifestyle, growth, and breast cancer risk. He is also interested in approaches to speed translation of research findings into prevention strategies that work. Dr. Colditz developed the award-winning Your Disease Risk website (www.yourdiseaserisk.wustl.edu) which communicates tailored prevention messages to the public. He has published over 1100 peer-reviewed publications, six books and six reports for the Institute of Medicine, National Academy of Sciences. His h-index is over 220.

In October 2006, on the basis of professional achievement and commitment to public health, Dr. Colditz was elected to membership of the National Academy of Medicine, an independent body that advises the US government on issues affecting public health. In 2011, he was awarded the American Cancer Society Medal of Honor for cancer control research. In 2012 he received the AACR-American Cancer Society Award for Research Excellence in Cancer Epidemiology and Prevention. He also received awards in 2014 for cancer prevention research from ASCO and from AACR. During 2016 he served on the Implementation Science Work Group of the Blue-Ribbon Panel to advise the National Cancer Moonshot. He received the 2018 Daniel P. Schuster Award for Distinguished Work in Clinical and Translational Science, Washington University School of Medicine. He was also elected as a Fellow, American Association for the Advancement of Science

Carlo La Vecchia received his MD from the University of Milan and a Master of Science degree in Medicine (epidemiology) from Oxford University. Presently, he is Professor of Medical Statistics and Epidemiology at the Faculty of Medicine at the University of Milan. Dr. La Vecchia serves as an editor for numerous clinical and epidemiologic journals. He is among the most renowned and productive epidemiologists in the field with over 2040 peer-reviewed papers in the literature and is among the most highly cited medical researchers in the world, according to ISI HighlyCited.com, the developer and publisher of the Science Citation Index (2003, 2017, H index 153, H10 index 1543, second Italian in Clinical Medicine). Dr. La Vecchia is Adjunct Professor of Medicine at Vanderbilt Medical Center and the Vanderbilt-Ingram Cancer Center (2002-18).

Gerd. P. Pfeifer received a PhD degree in biochemistry from Goethe University in Frankfurt, Germany. After postdoctoral training, he became a faculty member at the Beckman Research Institute of the City of Hope in Duarte, California, where he spent much of his career working on cancer research. In 2014, Dr. Pfeifer joined the new Center for Epigenetics at the Van Andel Research Institute in Grand Rapids, MI, United States, as a Professor of Epigenetics. Dr. Pfeifer has authored more than 300 publications, has held an NIH MERIT award, and was elected Fellow of the American Association for the Advancement of Science in 2015. Research in Dr. Pfeifer's laboratory has been concerned with genetic and epigenetic mechanisms of human carcinogenesis, with emphasis on DNA methylation and genetic toxicology.

Marco Alessandro Pierotti graduated in 1973 in Biological Sciences at the University of Milan, Italy, and started working at the Fondazione IRCCS Istituto Nazionale dei Tumori (INT) in Milan. From 1978 to 1980 he was Visiting Investigator at the Laboratory of Chemical Cancerogenesis of the NCI-NIH Bethesda (MD, United States) and Postdoctoral Research Fellow at the Laboratory of Viral Oncology of the Memorial Sloan-Kettering Institute in New York. In 2006, Dr. Pierotti was appointed Scientific Director of the Fondazione IRCCS Istituto Nazionale dei Tumori in Milan, where, since 1970, he had already held various positions, including Director of the Department of Experimental Oncology.

Since 1988, he has been Professor of Molecular Genetics of Cancer at the Postgraduate School of Oncology, University of Milan Medical School and co-director of the Laboratory of Molecular Diagnosis at the INT. In September 2014 he resigned from his position at INT to take the position of President and CEO of Nerviano Medical Sciences (NMS) srl, one of the biggest oncological pharma companies in Europe. In April 2015 he left the company and took the position of Scientific Coordinator of the Institute of Pediatric Researches (IRP) in Padua, Italy, devoted to study molecular aspects of the main pediatric diseases with particular focus on pediatric onco-hematology. The Institute was created by a private Charity, The City of Hope Foundation of Monte Malo (Vi).

Since 2000 he is Senior Group leader of the Molecular Genetics of Cancer group at the Institute FIRC of Molecular Oncology (IFOM, Milan). Past President (2006–08) of the Italian Cancer Society, Dr. Pierotti is a member of the American Association for Cancer Research and of its Advisory Board and the Laboratory Research Awards Selection Committee. He has also been President (2006–08) of the European Association for Cancer Research (EACR) and in this role was among the founders of the European CanCer Organisation (ECCO) where he was appointed as member of the Policy Committee.

In recent years, he was the Italian Representative at the Scientific Committee of the International Agency for Research on Cancer (IARC), Lyon. From 2006 to 2014 he was Scientific Secretary of Alleanza Contro il Cancro (ACC), promoted by the Italian Ministry of Health. In 2008 he was Member of the Evaluation of the Research Program Functional and Structural Genomics for DKFZ. He was an expert for the Oncology Research Projects of the European Community and was a consultant in oncology research for the Ministries of Research of different Countries. From 2006 to 2014 he was Chair of the regional Project, The Region Lombardy Oncological Network (ROL), selected in 2014 by the EC as one of the best examples of oncological network. His appointments in the Organisation of European Cancer Institutes (OECI) started in 2007 when he took the position of Vice-President. From 2008 he was the President-elect and then the President of the Organization. Finally, in 2014 he was appointed OECI Executive Secretary.

Over the years, Dr. Pierotti has been Principal Investigator or Head of several national and international research grants, funded by both private and public bodies. His authorship includes over 470 publications that deal with various aspect of experimental oncology including studies on immunology, biochemistry, and molecular biology using both experimental and human tumors.
In addition, since its fifth edition he is the first author of the chapter on "Oncogenes" in the most reputed textbook *Cancer Medicine* (Holland-Frei). The metrics of his scientific activity is summarized by an H index of 96 and total citations of 37.256 (Google scholar June 2018).

Professor **Thomas Tursz**, born in Kraków, Poland, in 1946, died in Paris, France, on April 27 2018. He was Professor of Oncology at the Faculty of Medicine Paris-Sud since 1986 and General Director of the Institut Gustave Roussy (1994–2010). He was the leader of the French Doctoral School of Oncology which he founded in 1999, and President of the French Federation of Comprehensive Anticancer Centres (FNCLCC) from 2004 to 2010. He was highly involved in the European Organization for the Research and Treatment of Cancer (EORTC) as both Chairman of the Scientific Advisory Committee (2003–06) and Vice President of the Board (2006–09). His experience as President of the FNCLCC was crucial for the Organization of European Cancer Institutes (OECI) when he acted as President from 2002 to 2005.

His scientific interests included the biology of virus-induced tumors, as well as immunological responses including the role of thioredoxin in lymphocytes infected by Epstein–Barr virus. In the clinical research area, he conducted a number of important clinical trials in breast cancer, lung cancer, and soft-tissue sarcoma. He had a particular interest in cytokines and gene therapy, and his clinical research activities were further disseminated to the European level when he was the Chairman of the Sarcoma Group of the EORTC (1993–96).

Prof. Tursz received several prestigious awards, such as the Prix de Cancérologie from the French National League Against Cancer (1979), the Bernard Halpern Immunology Award (1983), the Rosen Oncology Award (1989), the Grand Prix in Oncology from the Academy of Medicine (1992), the Hamilton Fairley Award for clinical research (1998), and the Prix de Rayonnement Français (2001). He was the author of 350 international scientific publications. He was also an esteemed member of the Editorial Board of *Molecular Oncology* ever since its creation in 2007.

Modified from Ulrik Ringborg and Julio E. Celis. Thomas Tursz (1946–2018) in: *Molecular Oncology* (2018). Published by FEBS Press and John Wiley & Sons Ltd. https://doi.org/10.1002/1878-0261.12361

HOW TO USE THE ENCYCLOPEDIA

Structure of the Encyclopedia

All articles in the encyclopedia are arranged alphabetically as a series of entries.

There are four features to help you easily find the topic you are interested in: an alphabetical contents list, cross references, a full subject index, and contributors.

1. Alphabetical contents list: The alphabetical contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia. So that they can be easily located, entry titles generally begin with the key word or phrase indicating the topic, with any generic terms following. For example, "Multiple Myeloma: Pathology and Genetics" is the entry title rather than "Pathology and Genetics of Multiple Myeloma".
2. Cross references: Virtually all the entries in the encyclopedia have been extensively cross-referenced. The cross references which appear at the end of an entry, serve three different functions:
   i. To draw the reader's attention to related material on other entries
   ii. To indicate material that broadens and extends the scope of the article
   iii. To indicate material that covers a topic in more depth

Example
The following list of cross-references appears at the end of the entry "Carcinogen—DNA Adducts".

> ***See also:*** Cancer Risk Reduction Through Lifestyle Changes. Cell Responses to DNA Damage. Genetic Instability. Hereditary Risk of Breast and Ovarian Cancer: BRCA1 and BRCA2. Molecular Epidemiology and Cancer Risk. Role of DNA Repair in Carcinogenesis and Cancer Therapeutics.

3. Index: The index appears at the end of volume 3 and includes page numbers for quick reference to the information you are looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.
4. Contributors: At the start of each volume there is a list of the authors who contributed to all volumes.

This page intentionally left blank

SUBJECT CLASSIFICATION

Causes of Cancer

Aflatoxins
Aging and Cancer
Cancers as Ecosystems: From Cells to Population
Diabetes and Cancer
Dietary Factors and Cancer
Helicobacter Pylori-Mediated Carcinogenesis
HIV (Human Immunodeficiency Virus)
Obesity and Cancer: Epidemiological Evidence
Opisthorchis Viverrini, *Clonorchis Sinensis*, and Cholangiocarcinoma
Papillomaviruses
Physical Inactivity and Cancer
Radiation Therapy-Induced Metastasis and Secondary Malignancy
Sleep Disturbances and Misalignment in Cancer

Diagnosis and Therapy

Acute Lymphocytic Leukemia: Diagnosis and Treatment
Acute Myelogeneous Leukemia: Diagnosis and Treatment
Bladder Cancer: Pathology, Genetics, Diagnosis, and Treatment
Bone and Soft Tissue Sarcoma: From Molecular Features to Clinical Applications
Cancer Vaccines: Dendritic Cell-Based Vaccines and Related Approaches
Cholangiocarcinoma: Diagnosis and Treatment
Chromatin Dynamics and Cancer: Epigenetic Parameters and Cellular Fate
Chronic Myelogenous Leukemia: Pathology, Genetics, Diagnosis, and Treatment
Colorectal Cancer: Diagnosis and Treatment
End of Life Support
Esophageal Cancer: Diagnosis and Treatment
Glioblastoma: Biology, Diagnosis, and Treatment
Interferons: Cellular and Molecular Biology of Their Actions
Kidney Cancer: Diagnosis and Treatment
Laryngeal Cancer: Diagnosis and Treatment
Malignant Tumors of the Eye, Conjunctiva, and Orbit: Diagnosis and Therapy
Myelodysplastic Syndromes: Mechanisms, Diagnosis, and Treatment
Nasopharyngeal Carcinoma: Diagnosis and Treatment
Neuroblastoma: Diagnosis and Treatment
New Rationales and Designs for Clinical Trials in the Era of Precision Medicine
Non-Hodgkin Lymphoma: Diagnosis and Treatment
Oncology Imaging
Oral Cavity Cancer: Diagnosis and Treatment
Ovarian Cancer: Diagnosis and Treatment
Pancreatic Cancer: Diagnosis and Treatment
P-Glycoprotein-Mediated Multidrug Resistance
Pituitary Tumors: Diagnosis and Treatment

Prostate Cancer: Diagnosis and Treatment
Radiation Oncology
Squamous Cell and Basal Cell Carcinoma of the Skin: Diagnosis and Treatment
Symptom Control
Thyroid Cancer: Pathology, Genetics, Diagnosis, and Treatment
Uterine Cervix Cancer: Diagnosis and Treatment

Hallmarks of Cancer

Anoikis
Autophagy and Cancer
Cancer-Related Inflammation in Tumor Progression
Cell Adhesion During Tumorigenesis and Metastasis
Cell Responses to DNA Damage
DNA Mismatch Repair: Mechanisms and Cancer Genetics
Epithelium to Mesenchyme Transition
Genetic Instability
Glutamine Metabolism and Cancer
Induced Pluripotent Stem Cells and Yamanaka factors
Inhibitors of Lactate Transport: A Promising Approach in Cancer Drug Discovery
Lipid Metabolism
Metastatic Signatures—The Tell-Tale Signs of Metastasis
Mevalonate Pathway
Mitogen-Activated Protein Kinases (MAPK) in Cancer
Pyruvate Kinase
Role of DNA Repair in Carcinogenesis and Cancer Therapeutics
Senescence and Cellular Immortality
Telomeres, Telomerase, and Cancer
TGF-β in Cancer Progression: From Tumor Suppressor to Tumor Promotor
TP53
Tumor-Associated Macrophages
Tumors and Blood Vessel Interactions: A Changing Hallmark of Cancer
Tunneling Nanotubes (TNTs): Intratumoral Cell-to-Cell Communication

Mechanisms

Animal Models of Cancer: What We Can Learn From Mice
Ataxia Telangiectasia Syndrome
Carcinogen—DNA Adducts
Carcinogenesis: Role of Reactive Oxygen and Nitrogen Species
Chromosome Rearrangements and Translocations
Copy Number Variations in Tumors
Defective 5-Methylcytosine Oxidation in Tumorigenesis
DNA Methylation Changes in Cancer: Cataloguing
DNA Methylation Changes in Cancer: Mechanisms
Enhancers in Cancer: Genetic and Epigenetic Deregulation
Environmental Exposures and Epigenetic Perturbations
Epigenetic Therapy
Genome Wide Association Studies (GWAS)
Hereditary Risk of Breast and Ovarian Cancer: BRCA1 and BRCA2
Hormones and Cancer
Li–Fraumeni Syndrome
Lynch Syndrome
Microbiota and Colon Cancer: Orchestrating Neoplasia Through DNA Damage and Immune Dysregulation
Mod Squad: Altered Histone Modifications in Cancer
Mutational Signatures and the Etiology of Human Cancers
Mutations in Chromatin Remodeling Factors

Mutations in DNA Methyltransferases and Demethylases
Mutations in Histone Lysine Methyltransferases and Demethylases
Mutations: Driver Versus Passenger
Polyomaviruses in Human Cancer
Systems Biology Approach to Study Cancer Metabolism
TCA Cycle Aberrations and Cancer
Unprogrammed Gene Activation: A Critical Evaluation of Cancer Testis Genes
Wnt Signaling in Intestinal Stem Cells and Cancer
Xeroderma Pigmentosum: When the Sun Is the Enemy

Pathology and Genetics of Specific Cancers

Adrenal Glands Tumors: Pathology and Genetics
Anal Cancer: Pathology and Genetics
Bladder Cancer: Pathology, Genetics, Diagnosis, and Treatment
Bones and Joints Cancer: Pathology and Genetics
Breast Cancer: Pathology and Genetics
Chronic Lymphocytic Leukemia: Pathology and Genetics
Chronic Myelogenous Leukemia: Pathology, Genetics, Diagnosis, and Treatment
Colorectal Cancer: Pathology and Genetics
Endometrial Cancer: Pathology and Genetics
Esophageal Cancer: Pathology and Genetics
Eye and Orbit Cancer: Pathology and Genetics
Gastric Cancer: Pathology and Genetics
Germ Cell Tumors: Pathology and Genetics
Glioblastoma: Pathology and Genetics
Hepatocellular Carcinoma: Pathology and Genetics
Hodgkin Lymphoma: Pathology and Genetics
Integrative Molecular Tumor Classification: A Pathologist's View
Jaws Cancer: Pathology and Genetics
Larynx Cancer: Pathology and Genetics
Malignant Skin Adnexal Tumors: Pathology and Genetics
Melanoma: Pathology and Genetics
Multiple Myeloma: Pathology and Genetics
Neuroblastoma: Pathology and Genetics
Non-Hodgkin Lymphoma: Pathology and Genetics
Nonsmall-Cell Cancers of the Lung: Pathology and Genetics
Oral and Oropharyngeal Cancer: Pathology and Genetics
Ovarian Cancer: Pathology and Genetics
Pancreatic Cancer: Pathology and Genetics
Parathyroid Cancer: Pathology and Genetics
Pituitary Tumors: Pathology and Genetics
Prostate Cancer: Pathology and Genetics
Renal Cell Cancer: Pathology and Genetics
Small-Cell Cancer of the Lung: Pathology and Genetics
Thyroid Cancer: Pathology, Genetics, Diagnosis, and Treatment
Uterine Cervix Cancer: Pathology and Genetics
Wilms Tumor: Pathology and Genetics

Prevention and Control

Aspirin and Cancer
Cancer Disparities
Cancer in Populations in Transition
Cancer in Sub-Saharan Africa
Cancer in the Middle East
Cancer Risk Reduction Through Lifestyle Changes

Cancer Survival and Survivorship
Cervical Cancer: Screening, Vaccination, and Preventive Strategies
Chemoprevention of Cancer: An Overview of Promising Agents and Current Research
Chemoprevention Trials
Diet and Cancer
Environmental and Occupational Exposures
Financial Burden of Cancer Care
Hereditary Cancer Syndromes: Identification and Management
Metformin
Molecular Epidemiology and Cancer Risk
Prevention and Control: Nutrition, Obesity, and Metabolism

PREFACE

Cancer holds a special status in biology, medicine, and society. It offers formidable challenges to basic, clinical, and population science; it ranks at the top of medical research priorities and healthcare costs in most countries. The general public is continuously exposed to news of discoveries promising to defeat the disease in the near future. Indeed, ground-breaking advances are being made, from preventive vaccines to genome-guided personalized medicine, sophisticated imaging and surgical technologies, and systemic therapies aimed at awakening natural immune responses against cancer. These novel therapeutic approaches make cure a real possibility for a growing number of patients. They also launch cancer care into a new era of maintaining the disease under control for an indefinite period of time, turning it into a form of chronic disease. At the same time, evidence-based prevention and early detection strategies have opened a new window on the natural history of the disease, enabling effective intervention well ahead of diagnosis. As a result, the first two decades of this millennium have witnessed a marked decrease in the mortality and, in some instances, the incidence of cancers that have dominated the death toll in more developed countries during the second half of the 20th century.

A turning point in our understanding of cancer is the deciphering of the human genome and its spin-off endeavors aimed at exploring the genomic landscape and architecture of human cancers. These discoveries are causing a major overhaul of our vision of cancer as a dynamic, rapidly evolving, and heterogeneous disease at the individual level. Harnessing this complexity requires mastering increasingly complex sources of data at molecular, cellular, systemic, personal, environmental, and societal level, heralding the emergence of big-data science in cancer diagnosis and treatment. However, this exceptional acceleration in knowledge and solutions cannot hide the fact that cancer remains a global scourge that exerts a massive burden on humankind and societies worldwide, in particular in societies in transition and in low-resource contexts.

Today, cancer crystallizes many of the major societal challenges pertaining to lifestyles, sustainable development and environmental policies, demography and population aging, access to education and healthcare, sharing of resources and knowledge, and protection of persons and personal information. The information on cancer available at a fingertip is overwhelming in volume, complexity, veracity, and velocity. We worked on the Third Edition of Elsevier's *Encyclopedia of Cancer* with this rapidly changing background. Rather than aiming at developing a comprehensive framework encompassing all aspects, we attempted to address the literal meaning of the greek terms ἐγκύκλιος παιδεία, which means "general education". While we retained some articles from the previous edition, which, at the time of the publication, represented an exceptional achievement of Dr. J. Bertino, we largely modified the structure and the list of chapters, and the possibility of continuous update of the articles has been a great incentive for us and for the authors of the chapters. This new edition of the Encyclopedia consists of six major parts: (i) mechanisms of cancer, (ii) hallmarks of cancer, (iii) causes of cancer, (iv) cancer prevention and control, (v) diagnosis and treatment of specific cancers, and (vi) pathology and genetics of specific cancers. This repartition is necessarily artificial and is complemented by the extensive cross-references between articles. The repartition, however, reflects our effort to identify discrete topics that would best address the needs of a wide community of readers.

The primary target readership of the Encyclopedia comprises medical and other health science students, as well as non-specialized physicians and other health practitioners. Cancer researchers, oncologists, and other cancer professionals may find the articles pertaining to their specific field to be too short, over-simplistic, and perhaps obsolete; they too, however, may benefit from articles on topics other than their own. The Encyclopedia also offers an easy way to navigate across concepts and topics that should be appealing to readers from other communities, including social sciences or stakeholders in public decision-making.

We were fortunate to work with a formidable team of section editors, including Fred Bosman, Graham Colditz, Carlo La Vecchia, Gerd Pfeifer, and Marco Pierotti. An additional section editor was Professor Thomas Tursz, who passed away prematurely during the preparation of the Encyclopedia. Thomas was a great colleague and mentor, and a major figure in oncology in France and internationally. We had the privilege to involve him in the last project of his long career, and we want to dedicate this work to him. We wish to thank the many article authors, who agreed to contribute to the success of this international endeavor, and in particular Dr. Katarzyna Szymańska, who drafted several cancer-specific articles. Finally, we want to thank the staff at Elsevier, whose patience and perseverance helped us bringing the project to the final stage. All these individuals are responsible for the many strengths of the new edition of the *Encyclopedia of Cancer*, while weaknesses are mainly ours.

Paolo Boffetta
Pierre Hainaut

CONTENTS OF ALL VOLUMES

VOLUME 1

Acute Lymphocytic Leukemia: Diagnosis and Treatment 1
Katarzyna Szymańska and Sophie Park

Acute Myelogeneous Leukemia: Diagnosis and Treatment 9
Katarzyna Szymańska and Sophie Park

Adrenal Glands Tumors: Pathology and Genetics 18
Thomas G Papathomas, Thomas J Giordano, Eamonn R Maher, and Arthur S Tischler

Aflatoxins 30
Joshua W Smith and John D Groopman

Aging and Cancer 44
Mingyang Song

Anal Cancer: Pathology and Genetics 53
Fred T Bosman

Animal Models of Cancer: What We Can Learn From Mice 60
Giustina Ferone, Paul Krimpenfort, and Anton Berns

Anoikis 75
Sharan Malagobadan and Noor Hasima Nagoor

Aspirin and Cancer 85
Mangesh A Thorat

Ataxia Telangiectasia Syndrome 101
Palak R Parekh and France Carrier

Autophagy and Cancer 112
Christina G Towers and Andrew Thorburn

Bladder Cancer: Pathology, Genetics, Diagnosis, and Treatment 122
Katarzyna Szymańska, Fred T Bosman, and Pierre Hainaut

Bone and Soft Tissue Sarcoma: From Molecular Features to Clinical Applications 134
Sarah Watson and Olivier Delattre

Bones and Joints Cancer: Pathology and Genetics 153
Pancras C W Hogendoorn and Carlos E de Andrea

Breast Cancer: Pathology and Genetics 170
Amy E McCart Reed, Emarene Kalaw, Andrew Reid, and Sunil R Lakhani

Cancer Disparities 184
Ivana Kulhánová and Salvatore Vaccarella

Cancer in Populations in Transition 191
Aleyamma Mathew and Preethi S George

Cancer in Sub-Saharan Africa 212
Mariana Brandão, Ivo Julião, Carla Carrilho, Filipa Fontes, and Nuno Lunet

Cancer in the Middle East 225
Iman El Sayed

Cancer Risk Reduction Through Lifestyle Changes 243
Christina Bamia

Cancer Survival and Survivorship 250
Dana Hashim and Elisabete Weiderpass

Cancer Vaccines: Dendritic Cell-Based Vaccines and Related Approaches 260
Laurence Chaperot, Olivier Manches, and Caroline Aspord

Cancer-Related Inflammation in Tumor Progression 275
Alberto Mantovani

Cancers as Ecosystems: From Cells to Population 278
Graham A Colditz

Carcinogen—DNA Adducts 282
Annette M Krais, Rajinder Singh, and Volker M Arlt

Carcinogenesis: Role of Reactive Oxygen and Nitrogen Species 296
Jean Cadet and J Richard Wagner

Cell Adhesion During Tumorigenesis and Metastasis 307
Lubor Borsig and Heinz Läubli

Cell Responses to DNA Damage 315
Jean Y J Wang

Cervical Cancer: Screening, Vaccination, and Preventive Strategies 326
Paolo Giorgi Rossi and Francesca Carozzi

Chemoprevention of Cancer: An Overview of Promising Agents and Current Research 345
Elizabeth G Ratcliffe, Andrew D Higham, and Janusz A Jankowski

Chemoprevention Trials 352
Kunal C Kadakia, Ashley G Matusz-Fisher, and Edward S Kim

Cholangiocarcinoma: Diagnosis and Treatment 367
Katarzyna Szymańska

Chromatin Dynamics in Cancer: Epigenetic Parameters and Cellular Fate 372
Daniel Jeffery, Katrina Podsypanina, Tejas Yadav, and Geneviève Almouzni

Chromosome Rearrangements and Translocations 389
Stefan K Bohlander, Purvi M Kakadiya, and Alix Coysh

Chronic Lymphocytic Leukemia: Pathology and Genetics 405
Julio Delgado, Neus Villamor, Ferran Nadeu, and Elías Campo

Chronic Myelogenous Leukemia: Pathology, Genetics, Diagnosis, and Treatment 418
Katarzyna Szymańska and Sophie Park

Colorectal Cancer: Diagnosis and Treatment 425
Katarzyna Szymańska

Colorectal Cancer: Pathology and Genetics 428
Fred T Bosman

Copy Number Variations in Tumors 444
Tao Huang

Defective 5-Methylcytosine Oxidation in Tumorigenesis 452
Gerd P Pfeifer and Seung-Gi Jin

Diabetes and Cancer 459
Rachel Dankner

Diet and Cancer 471
Livia S A Augustin, Concetta Montagnese, Ilaria Calabrese, Giuseppe Porciello, Elvira Palumbo, Sara Vitale, and Stephanie Nishi

Dietary Factors and Cancer 501
Isabelle Romieu

DNA Methylation Changes in Cancer: Cataloguing 512
Tibor A Rauch and Gerd P Pfeifer

DNA Methylation Changes in Cancer: Mechanisms 520
Hideyuki Takeshima and Toshikazu Ushijima

DNA Mismatch Repair: Mechanisms and Cancer Genetics 530
William J Graham V, Christopher D Putnam, and Richard D Kolodner

End of Life Support 539
Kavitha J Ramchandran and Jamie Von Roenn

Endometrial Cancer: Pathology and Genetics 549
Ben Davidson

Enhancers in Cancer: Genetic and Epigenetic Deregulation 559
Kaixiang Cao and Ali Shilatifard

Environmental and Occupational Exposures 569
Harvey Checkoway

Environmental Exposures and Epigenetic Perturbations 574
Igor P Pogribny

VOLUME 2

Epigenetic Therapy 1
Richard L Bennett, Aditya Bele, Sayantan Maji, and Jonathan D Licht

Epithelium to Mesenchyme Transition 14
Laia Caja and E-Jean Tan

Esophageal Cancer: Diagnosis and Treatment 24
Katarzyna Szymańska

Esophageal Cancer: Pathology and Genetics 32
Jean-François Fléjou

Eye and Orbit Cancer: Pathology and Genetics 47
Sarah E Coupland, Santosh U Kafle, and Jakub Khzouz

Financial Burden of Cancer Care 61
Bernardo H L Goulart and Veena Shankaran

Gastric Cancer: Pathology and Genetics 77
Irene Gullo and Fátima Carneiro

Genetic Instability 99
Meiyun Guo, Lin Mei, and Christopher A Maxwell

Genome Wide Association Studies (GWAS) 110
Giuliana Restante, Elena Arrigoni, Marzia Del Re, Antonello Di Paolo, and Romano Danesi

Germ Cell Tumors: Pathology and Genetics 121
J W Oosterhuis and Leendert H J Looijenga

Glioblastoma: Biology, Diagnosis, and Treatment 154
Akanksha Sharma, Maciej M Mrugala, and Jan Buckner

Glioblastoma: Pathology and Genetics 165
Christian Hartmann and Pieter Wesseling

Glutamine Metabolism and Cancer 179
Nianli Sang, Dan He, and Shuo Qie

Helicobacter Pylori-Mediated Carcinogenesis 187
Matthew G Varga and Meira Epplein

Hepatocellular Carcinoma: Pathology and Genetics 198
Luigi M Terracciano, Salvatore Piscuoglio, and Charlotte K Y Ng

Hereditary Cancer Syndromes: Identification and Management 211
Roberta Pastorino, Alessia Tognetto, and Stefania Boccia

Hereditary Risk of Breast and Ovarian Cancer: BRCA1 and BRCA2 214
Claus Storgaard Sørensen

HIV (Human Immunodeficiency Virus) 218
Jay A Levy and JoAnn C Castelli

Hodgkin Lymphoma: Pathology and Genetics 227
Stefano A Pileri, Stefano Fiori, Vincenzo De Iuliis, and Valentina Tabanelli

Hormones and Cancer 237
Kristen D Brantley, Susan E Hankinson, and A Heather Eliassen

Induced Pluripotent Stem Cells and Yamanaka factors 254
Stina Simonsson, Rocío C Viñuelas, Leonie Hartl, Itedale N Redwan, and Joydeep Bhadury

Inhibitors of Lactate Transport: A Promising Approach in Cancer Drug Discovery 266
Thomas D Bannister

Integrative Molecular Tumor Classification: A Pathologist's View 279
Fred T Bosman

Interferons: Cellular and Molecular Biology of Their Actions 286
Dhananjaya V Kalvakolanu, Shreeram C Nallar, and Sudhakar Kalakonda

Jaws Cancer: Pathology and Genetics 313
Pieter J Slootweg and Daniel Baumhoer

Kidney Cancer: Diagnosis and Treatment 325
Katarzyna Szymańska

Laryngeal Cancer: Diagnosis and Treatment 332
Fernando López Álvarez and Juan Pablo Rodrigo

Larynx Cancer: Pathology and Genetics 346
Nina Zidar and Nina Gale

Li–Fraumeni Syndrome 356
Orli Michaeli and David Malkin

Lipid Metabolism 369
Fatima Ameer, Rimsha Munir, and Nousheen Zaidi

Lynch Syndrome 374
Päivi Peltomäki

Malignant Skin Adnexal Tumors: Pathology and Genetics 389
Katharina Wiedemeyer and Thomas Brenn

Malignant Tumors of the Eye, Conjunctiva, and Orbit: Diagnosis and Therapy 402
Laurence Desjardins, Nathalie Cassoux, and Alexandre Matet

Melanoma: Pathology and Genetics 414
Lorenzo Salvati, Giuseppe Palmieri, Vincenzo De Giorgi, Antonio Cossu, Mario Mandalà, and Daniela Massi

Metastatic Signatures—The Tell-Tale Signs of Metastasis 426
Christina Ross and Kent Hunter

Metformin 435
Matteo Lazzeroni and Sara Gandini

Mevalonate Pathway 445
Heidrun Karlic and Franz Varga

Microbiota and Colon Cancer: Orchestrating Neoplasia Through DNA Damage and Immune Dysregulation 458
Alberto Martin and Thergiory Irrazábal

Mitogen-Activated Protein Kinases (MAPK) in Cancer 472
Ana Cuenda

Mod Squad: Altered Histone Modifications in Cancer 481
Matthew Murtha and Manel Esteller

Molecular Epidemiology and Cancer Risk 487
Paulina Gomez-Rubio and Evangelina López de Maturana

Multiple Myeloma: Pathology and Genetics 494
Marie Yammine and Salomon Manier

Mutational Signatures and the Etiology of Human Cancers 499
Ludmil B Alexandrov and Maria Zhivagui

Mutations in Chromatin Remodeling Factors 511
Katherine A Giles and Phillippa C Taberlay

Mutations in DNA Methyltransferases and Demethylases 528
Xiao-Jian Sun, Zhu Chen, and Sai-Juan Chen

Mutations in Histone Lysine Methyltransferases and Demethylases 538
Sara Weirich and Albert Jeltsch

Mutations: Driver Versus Passenger 551
Scott W Piraino, Valentina Thomas, Peter O'Donovan, and Simon J Furney

Myelodysplastic Syndromes: Mechanisms, Diagnosis, and Treatment 563
Eric Solary and William Vainchenker

Nasopharyngeal Carcinoma: Diagnosis and Treatment 571
Katarzyna Szymańska

VOLUME 3

Neuroblastoma: Diagnosis and Treatment 1
Gudrun Schleiermacher and Thierry Philip

Neuroblastoma: Pathology and Genetics 15
Nai-Kong V Cheung and Estibaliz Lopez-Rodrigo

New Rationales and Designs for Clinical Trials in the Era of Precision Medicine 30
Mina Nikanjam and Razelle Kurzrock

Non-Hodgkin Lymphoma: Diagnosis and Treatment 44
Katarzyna Szymańska and Sophie Park

Non-Hodgkin Lymphomas: Pathology and Genetics 48
Laurence de Leval

Nonsmall-Cell Cancers of the Lung: Pathology and Genetics 76
Erik Thunnissen and Egbert F Smit

Obesity and Cancer: Epidemiological Evidence 88
Yikyung Park

Oncology Imaging 98
Stefan Delorme and Michael Baumann

Opisthorchis viverrini, *Clonorchis sinensis*, and Cholangiocarcinoma 119
Catherine de Martel and Martyn Plummer

Oral and Oropharyngeal Cancer: Pathology and Genetics 124
Pieter J Slootweg and Justin A Bishop

Oral Cavity Cancer: Diagnosis and Treatment 131
Corbin D Jacobs, Michael J Moravan, Jennifer Choe, Russel Kahmke, Yvonne Mowery, and Joseph K Salama

Ovarian Cancer: Diagnosis and Treatment 169
Katarzyna Szymańska

Neuroblastoma: Diagnosis and Treatment

Gudrun Schleiermacher and Thierry Philip, Curie Institute, Paris, France

Glossary

Image-defined risk factors in neuroblastoma (IDRF) Guidelines for imaging and staging of neuroblastic tumors as defined per consensus in the International Neuroblastoma Risk Group Project.

International neuroblastoma pathology classification (INPC) Guidelines for the pathological characterization and staging of peripheral neuroblastic tumors.

International neuroblastoma risk group—staging system (INRG) The International Neuroblastoma Risk Group (INRG) classification system was developed to establish a consensus approach for pretreatment risk stratification for patients with peripheral neuroblastic tumors, taking into account clinical, radiological, pathological, and biological features. By defining homogenous pretreatment patient cohorts, the INRG classification system will greatly facilitate the comparison of risk-based clinical trials conducted in different regions of the world and the development of international collaborative studies.

International neuroblastoma staging system (INSS) International consensus for the diagnosis and staging of neuroblastoma.

Iodine-123-metaiodobenzylguanidine scintigraphy (MIBG scintigraphy) A scintigraphy method using a radiolabeled molecule, Iodine-123-metaiodobenzylguanidine, which is similar to norepinephrine; based on its uptake by neuroblastic cells through the norepinephrine transporter this scintigraphy method is useful for the diagnosis and metastatic work up of peripheral neuroblastic tumors.

Introduction

Neuroblastoma is the most common extracranial solid tumor of early childhood. It is an embryonic tumor derived from the developing sympathetic nervous system corresponding to the cells of the neural crest that form the adrenal medulla and the sympathetic ganglia. The large clinical heterogeneity, with a spectrum ranging from the possibility of spontaneous regression to threatening progression despite all treatment, as well as the important biological heterogeneity, has led to intense research on clinical and biological prognostic factors with an aim of improving the definition of risk defined patient subgroups and of developing new therapeutic approaches.

Epidemiology of Neuroblastoma

Neuroblastoma represents 8%–10% of all pediatric cancers, with a mean annual incidence of 7–12 cases per million children in Western countries, and a prevalence of 1 case per 8000–10,000 births. Neuroblastoma is a disease of early childhood, with a median age at diagnosis of 18 months, and 90% of patients diagnosed before the age of 5 years. Age at diagnosis is an important prognostic factor, as patients under 18 months usually have a better prognosis, whereas in adolescents and adults is very rare it generally shows a more indolent clinical course with de novo resistance to chemotherapy treatments. Neuroblastoma is slightly more frequent in males than in females (M/F ratio 1.1–1.2). As neuroblastoma can be detected following an increase of urinary catecholamine metabolites (see below), screening programs were put in place in several countries including Japan, Germany, France, and Canada. An increase in the prevalence of neuroblastoma in infants was observed in these countries; however, there was no decrease neither in the prevalence or nor in the mortality of neuroblastoma in patients older than 1 year. This suggests that spontaneous regression of symptomless neuroblastoma is at least as frequent as neuroblastoma leading to clinical symptoms.

Etiology of Neuroblastoma

Developmental Origin

During embryonal development, the neural crest arises from the neural tube after its closure. Neural crest development involves epithelial to mesenchymal transition, and cells will migrate from the neural tube for the further development of numerous anatomic structures, giving rise to various cell types, including neural, pigmented, craniofacial, and conotruncal cardiac cells, during embryogenesis. This complex process is regulated by various epigenetic programs based on histone modification and DNA methylation, and transcriptional programs involving multiple transcription factors which further activate downstream transcriptional regulators of proliferation and differentiation. The neural crest of the trunk contributes to the development of the peripheral nervous system, including sympathetic ganglia and the adrenal gland. It is thought that neuroblastoma arises from these embryonal sympathoadrenal progenitors.

To date, the precise etiology of neuroblastoma is unknown, and unlike many adult malignancies, environmental factors are not thought to play a major role, although predisposing effects of prenatal exposures to potentially toxic substances warrant further investigation. However, genetic factors, at both a constitutional and a somatic level, are thought to play a major role in neuroblastoma development.

Hereditary Genetic Factors

Several observations support the hypothesis of a major role of underlying hereditary genetic factors in the etiology of neuroblastoma.

First, rare familial cases have been described, accounting for $< 1\%$ of all neuroblastoma cases. Gain-of-function mutations in the tyrosine kinase domain of the anaplastic lymphoma kinase gene *ALK* have been detected in the majority of familial cases associated with an autosomal dominant pattern of inheritance with incomplete penetrance.

Second, neuroblastoma can arise in a context of syndromic associations. Neural crest-derived developmental disorders associated with an increased risk to develop neuroblastoma have been linked to inactivating mutations of the *PHOX2B* gene, a master regulator of neural crest development, which was identified as the first predisposition mutation in neuroblastoma. Whereas expansions of the second polyalanine stretch of PHOX2B are mainly observed in patients presenting with Ondine's curse (also called CCHS, for Congenital Central Hypoventilation Syndrome) associated with a low risk of peripheral neuroblastic tumors, nonpolyalanine repeat expansion mutations occur preferentially in patients with Hirschsprung's disease which is associated with a higher risk to develop neuroblastoma. Further associations between neuroblastic tumors and cancer predisposition syndromes include neurofibromatosis type 1 (*NF1*), characterized by constitutive activation of the RAS–MAPK pathway, as well as Noonan syndrome with involvement of the *PTPN11* gene.

Third, recent powerful genome-wide association studies have demonstrated that neuroblastoma is a disease of complex underlying genetic factors as at least a dozen common polymorphic alleles, occurring at various loci throughout the genome, have been shown to influence neuroblastoma oncogenesis. Of low individual impact on disease initiation (relative risks of 1.5–2.0), these polymorphic alleles can cooperate in an individual patient to promote malignant transformation during neurodevelopment, and some genes targeted by these polymorphic alleles play potential roles in the pathogenesis of neuroblastoma, including BARD1, LMO1, DUSP12, DDX4, HACE1, and LIN28B. The described polymorphic alleles show a correlation with either high-risk or low-risk disease, indicating that favorable and unfavorable forms of neuroblastoma may represent distinct entities in terms of the genetic events that initiate tumorigenesis.

Furthermore, rare cases with various abnormal constitutional karyotypes have been described in neuroblastoma patients, including constitutional copy number anomalies, balanced and unbalanced translocations, as well as specific chromosome deletions. Altogether, there are probably as yet undiscovered additional genes that predispose to neuroblastoma when altered in the germline. However, to date there are no clinically validated guidelines for who should be screened for germline mutations, nor how to perform surveillance of patients or families with known predisposition alleles.

Somatic Genetic Alterations

With only 1%–2% of neuroblastoma occurring in a familial or predisposition context, over 98% of all cases occur sporadically. A large number of recurrent somatic genetic alterations have been described in neuroblastoma, the most frequent of which concern quantitative genomic alterations with gains or losses of genetic material. These genetic abnormalities are closely linked to the distinct biological and clinical subgroups of the disease.

Amplification of the *MYCN* oncogene, mapping to 2p24.1, occurs in approximately 25% of all neuroblastomas and 40% of high-risk tumors. It remains one of the most important genetic alterations associated with advanced stages of disease, an aggressive phenotype, and poor outcome, and is the first genetic marker to be used in clinical practice for risk stratification and adaptation of treatment intensity. Closely associated with poor survival in localized disease and in infants, its prognostic impact in metastatic disease of older children with an overall poor outcome is less pronounced. At a cytogenetic level, amplification of the MYCN oncogene occurs either as double-minute chromosomes or homogeneously staining regions, which contain between 10 to over 100 ectopic copies of the *MYCN* oncogene. The oncogenic role of MYCN has been clearly demonstrated as its ectopic expression in the neural crest is sufficient to drive neuroblastoma tumorigenesis in zebrafish and mice models. Its oncogenic role is based on an enhancement of the expression of genes involved in cell proliferation, and on the repression of genes involved in differentiation and apoptosis.

Other recurrent amplifications concern the *ALK* gene on chromosome 2p23, as well as amplicons of chromosome 12q13–14 encompassing, among others, the MDM2 and CDK4 genes. Preliminary data indicate that NB with focal amplifications other than MYCN might present with atypical clinical features and a poorer outcome.

Other recurrent structural alterations recurrently observed in neuroblastoma concern segmental chromosome alterations (SCA), including deletions of chromosome arms 1p, 3p, 4p, and 11q, and gains of 1q, 2p, or 17q. Deletion of 1p36 is observed in 20%–35% of cases, predicts survival in multivariate analyses, and is significantly associated with aggressive disease markers. Deletions of 11q in a consensus region at 11q23 occur in approximately 40% of cases and are inversely correlated with *MYCN* amplification, identifying a molecularly distinct high-risk patient subset, characterized by advanced stage, older age, and a higher genomic instability with a higher number of chromosome breakpoints. Gains of chromosome 17q21-qter represent the most frequent genetic

alteration in neuroblastoma, occurring in 70% of tumors. Numerous studies have reported that 17q gain is significantly associated with advanced stage of disease, increased patient age, *MYCN* amplification, and other unfavorable genetic parameters.

The overall genomic profile has been shown to be of prognostic impact in neuroblastoma. Whereas numerical chromosome alterations, consisting of gains or losses of whole chromosomes, are associated with a favorable outcome, segmental chromosome alterations of any chromosome region, without or with numerical chromosome alterations, are associated with a higher risk of relapse. Although intense decade-long research has focused on the identification of hypothetical tumor suppressor genes or oncogenes in recurrently altered regions of chromosome loss or gain, the smallest regions of overlap remain quite extensive, and to date do not point to single gene candidates as tumor suppressors or oncogenes. This suggests that an overall imbalance of copy number regions is of importance in neuroblastoma oncogenesis.

Recent next generation sequencing approaches have indicated that most neuroblastoma harbor only few mutations, with an average of 10–20 predicted nonsynonymous variations in coding regions per genome, indicating an exonic mutation frequency of 0.2–0.4 per Mb. The frequency of somatic events strongly correlates with tumor stage, lower-stage tumors harboring a lower number of mutations.

The most frequent recurrent somatic mutation in neuroblastoma concerns the gene *ALK* (anaplastic lymphoma kinase), with mutations activating the tyrosine kinase domain in approximately 10% of all cases at diagnosis. The somatic ALK-1174 mutation appears to contribute to a more aggressive phenotype, but unlike ALK-1275 mutations, these specific mutations are not found in familial neuroblastoma and are not tolerated in the germline. The oncogenic role of activating ALk mutations in neuroblastoma has been demonstrated in vitro and in vivo in both zebrafish and mouse models, with co-expression of ALK-F1174L and MYCN producing a synergistic effect for neuroblastoma tumorigenesis in mice. Small molecule inhibitors targeting the activated kinase domain of ALK are now available, making this a promising target for molecular therapy but still requiring more specific development.

Other recurrent mutations in neuroblastoma target distinct cellular pathways and include PTPN11 mutations (in 3% of cases), as well as genes involved in cytoskeleton maintenance, neuritogenesis, and other regulators of the RAC/Rho pathway.

Interestingly, genes involved in chromatin remodeling have been found to be targeted in a significant number of cases, either by mutations or by structural variations, including mutations in the ARID1A/ARID1B genes. Somatic alterations of ATRX are associated with an increase in telomere length, and with an absence of the ATRX protein in the nucleus. ATRX alterations appear to be more frequent in older children and occur in mutually exclusive fashion with *MYCN* amplifications. ATRX mutations are associated with activation of a telomere maintenance mechanism termed alternate lengthening of telomeres (ALT), which may be associated with primary chemotherapy resistance. Recurrent genomic rearrangements of the promotor region of the *telomerase reverse transcriptase* (*TERT*) gene on chromosome 5p15.33 have been described in $>10\%$ of neuroblastoma cases, defining a further subgroup of high-risk disease and occurring in mutually exclusive fashion with *MYCN* amplification and *ATRX* mutations.

Thus, a large number of high-risk neuroblastomas are affected by genetic alterations of either *MYCN*, *TERT*, or *ATRX*, all of which converge to an activation of telomere lengthening mechanisms either by direct activation or by ALT, leading to a capacity of near-infinite cell proliferation. Advances in the development of inhibitors of these pathways and their evaluation in clinical trials will lead to new treatment opportunities.

Studies in relapsed neuroblastoma have suggested that genetic alterations can evolve over time and that clonal evolution is common, resulting in the acquisition of somatic alterations in known oncogenic pathways, some of which are targetable. Early evidence suggests that activation of the MAPK pathway and other signaling pathways of epithelial-mesenchymal transition processes might emerge at relapse and might represent promising targets for molecular targeted treatment approaches. Altogether, both spatial and temporal genetic heterogeneity plays an important role in neuroblastoma (**Fig. 1**).

In addition to genetic changes, neuroblastoma can also be characterized by specific expression profiles. A large number of studies have focused on the analysis of differential expression patterns, seeking to identify expression patterns that might enable to distinguish patients with different clinical courses and thus define different prognostic subgroups in high-risk disease, and potentially to identify new therapeutic targets. However, these approaches have not yet found a routine application in a clinical setting.

The paucity of recurrent genetic mutations as compared to adult tumors in adults indicates that additional mechanisms such as epigenetic alterations may play an important role in the molecular pathogenesis of these developmental tumors. Alterations in DNA methylation represent one of the most common molecular events in neoplasia, and CpG-island hypermethylation of gene promoters is a frequent mechanism for functional inactivation of relevant tumor-associated genes in neuroblastoma.

Cellular Identity

In neuroblastoma, two distinct cellular identities corresponding to either a sympathetic noradrenergic identity, or to a neural crest cell-like, mesenchymal identity can be evidenced. These cellular identities are governed by distinct core regulatory circuits corresponding to different super-enhancer profiles, including the transcription factors PHOX2B, HAND2, and GATA3 for the sympathetic noradrenergic and the AP-1 transcription factors for the neural crest cell-like identity. The committed adrenergic cells and undifferentiated mesenchymal cells can coexist in a tumor and, importantly, can interconvert. This represents an additional important aspect of tumor heterogeneity with an important role with regards to differential sensitivity to chemotherapies.

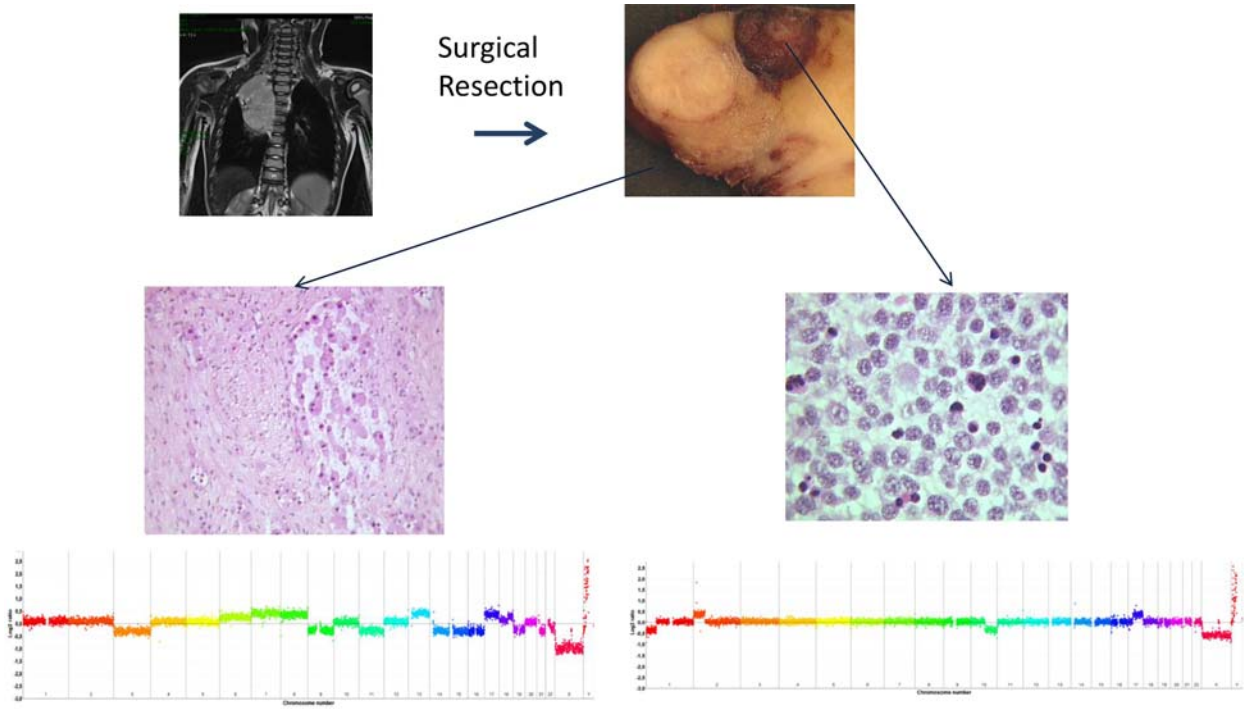

Fig. 1 Macroscopical and microscopical heterogeneity of neuroblastoma. This tumor was histologically composed of a stroma-rich component, and of several stroma-poor nodules corresponding to neuroblastoma, stroma-poor, poorly differentiated. Different copy number profiles can be observed: numerical chromosome alterations (NCA) only, versus segmental chromosome alterations (SCA) with (in this case) chromosome 1p and 11q deletion, and chromosome 2p and 17q gain.

Biological Pathways

A number of biological pathways corresponding to important hallmarks of cancer appear to be affected in neuroblastoma. These include abnormal patterns of gene or protein expression involved in tumor differentiation, apoptosis, drug resistance, angiogenesis, invasion, and metastasis.

Neurotrophin signaling plays a central role in normal neuronal development and may be involved in both differentiation and regression of neuroblastoma. Differential expression of tropomyosin receptor kinase (Trk) receptors has been shown to influence both the biological characteristics and clinical behavior of neuroblastoma, with TrkA expression (with the ligand NGF) observed in favorable neuroblastoma, and TrkB expression (with the ligand BDNF) observed in unfavorable neuroblastoma.

Delayed activation or disruption of normal apoptotic pathways may also be an important phenomenon involved in spontaneous regression, as well as therapy resistance of neuroblastoma. Major elements of the apoptotic signaling cascade with abnormal expression or activation patterns include the BCL2 family, survivin, and caspase-8. Acquired resistance to chemotherapeutic agents may also be conferred by enhanced drug efflux via overexpression of classical multidrug resistance proteins, including the multidrug resistance gene 1 (*MDR1*) and the gene for the multidrug resistance-related protein (*MRP*).

Increased tumor angiogenesis and expression of pro-angiogenic factors, such as vascular endothelial growth factor, are both correlated with an aggressive phenotype in neuroblastoma. Angiogenesis inhibitors represent a potential treatment option that is currently being evaluated in clinical trials.

Immunological Aspects

Immune factors and the tumor microenvironment contribute to the variable natural history of neuroblastoma. As age at diagnosis is of strong prognostic impact in patients with neuroblastoma, it is likely that age-related differences in the host immune reaction to a developing tumor might influence outcome.

Further evidence of the possible role of disease control by the immune system derives from observations of the neuroblastoma-associated paraneoplastic syndrome OMS, in which lymphoid infiltrates are frequently observed in the tumor; these patients typically have an excellent oncological prognosis.

In metastatic neuroblastoma, higher levels of CD163+ M2 macrophages have been demonstrated, a finding associated with adverse outcomes in several other cancers. Age-dependent differential expression of inflammatory genes associated with tumor associated macrophages has also been observed in neuroblastoma. Cancer-associated fibroblasts in the neuroblastoma microenvironment have been shown to play a role in the immunosuppression which might favor tumor development in neuroblastoma.

Altogether, in high-risk neuroblastoma infiltration with suppressive myeloid cells can decrease antitumor immune responses and favor tumor growth. Both active and passive immunotherapies, including antibody-based therapies, are now being explored in neuroblastoma.

Further advances in the understanding of the biology of neuroblastoma are currently based on the use of deep-sequencing approaches for comprehensive molecular characterization of the tumor cells and the host, also at a single cell level to account for tumor heterogeneity, with the goal not only to define precise patient risk groups, but also to identify key therapeutic targets.

Diagnosis

Clinical Presentation

Clinical signs and symptoms of neuroblastoma depend on the localization of the primary tumor and its metastatic sites. Localized disease often presents as an incidental finding, whereas metastatic disease is linked to systemic symptoms.

Primary tumors can arise anywhere along the sympathetic nervous system, but the distribution varies across the sites with age. Cervical neuroblastomas, observed in 4%–5% of cases, may involve the cervical ganglion (ganglion stellatum), causing Horner's syndrome (ptosis, miosis, enophthalmus, and anhidrosis). Thoracic neuroblastomas, localized in the upper, middle, or lower mediastinum and representing 15% of all cases, may be asymptomatic or more rarely cause respiratory distress. Over half of all primary tumors have their origin in the medulla of the adrenal gland, a localization associated with poorer survival. Bilateral primary adrenal tumors occur in $<1\%$ of all cases, possibly occurring in a context of genetic predisposition. Altogether abdominal localization is observed in 80% of cases, and large abdominal tumors can cause hypertension, abdominal distention, and pain. Pelvic tumors are uncommon and either present as an asymptomatic mass, or cause constipation or urinary symptoms. Tumors arising in any paraspinal sympathetic ganglia can grow along the nerve roots, penetrate into the intervertebral foramina, and lead to spinal cord compression, resulting in neurological symptoms. In very rare cases, no primary tumor can be identified.

Metastatic disease is present in 50% of patients at diagnosis, with regional or distant lymph nodes, bone marrow, and bone involved most frequently, whereas liver and skin metastasis can be observed especially in young infants with favorable outcome. Metastasis to other sites such lung or CNS occurs more rarely. Metastatic involvement can cause systemic symptoms such as fever, weight loss, bone pain, or signs of bone marrow involvement such as anemia and thrombocytopenia. Specific metastatic sites can lead to localized bone pain and limping, while periorbital metastasis can cause periorbital ecchymoses (Hutchinson's syndrome). Other clinical symptoms such as respiratory distress linked to compression by a large mass, coagulation disorders due to liver involvement, or lower body edema due to vena cava compression occur more rarely.

Associated paraneoplastic syndromes can be observed in approximately 5% of all patients with neuroblastoma. A hypersecretion of the vaso-intestinal peptide (VIP) can lead to abundant intractable watery diarrhea, requiring treatment with somatostatine or octreotide in rare cases if the symptoms persist after resection of the tumor.

Opsoclonus-myoclonus syndrome (OMS, also called Kinsbourne Syndrome or Dancing Eye Syndrome) is a rare neurological syndrome characterized by the association of opsoclonus (rapid, multidirectional eye movements), myoclonus, and cerebellar ataxia, most likely as a result of autoimmune process. This syndrome is observed in 2%–3% of children with neuroblastoma, while a neuroblastoma can be detected in 50%–80% of all children with OMS. These symptoms may precede the detection of a neuroblastoma, and may improve following surgical resection, but in many cases patients require specific immunosuppressive treatment for the neurological symptoms. Symptoms may reappear during infectious episodes, and although the oncological outcome of these patients is favorable, the majority of these children have long-term neurological sequelae.

Laboratory Parameters and Tumor Markers

Elevation of serum markers such as LDH, NSE, or ferritine are associated with unfavorable prognosis, but these markers are not specific to neuroblastoma.

An increase in urinary secretion of catecholamines or their metabolites, including dopamine, homovanillic acid (HVA), and/or vanillylmandelic acid (VMA), can be detected in 90% of patients. The profile of urinary catecholamines reflects the degree of cellular maturation with a high dopamine level or HVA/VMA ratio associated with an unfavorable prognosis. An elevation of norepinephrine or epinephrine occurs more rarely and can lead to arterial hypertension. With catecholamine metabolites routinely measured in urine samples at diagnosis and during treatment and follow-up, plasma levels of normetanephrine, metanephrine, and methoxytyramine might represent a convenient alternative to urine markers.

Radiological Local and Metastatic Assessment

Disease evaluation at diagnosis requires radiologic assessment of the primary tumor as well as an assessment of possible osteomedullary, soft tissue, or other metastatic sites.

Although ultrasound is often the first imaging exam because of its high availability and non-invasive nature, local assessment should include an exploration either by CT or MRI, with a high preference now given to MRI due to a higher contrast resolution and an absence of exposure to ionizing radiation, despite the longer acquisition times and sedation requirements in young children (Fig. 2). Neuroblastic tumors are often heterogeneous, and might present calcifications and involvement of regional lymph nodes.

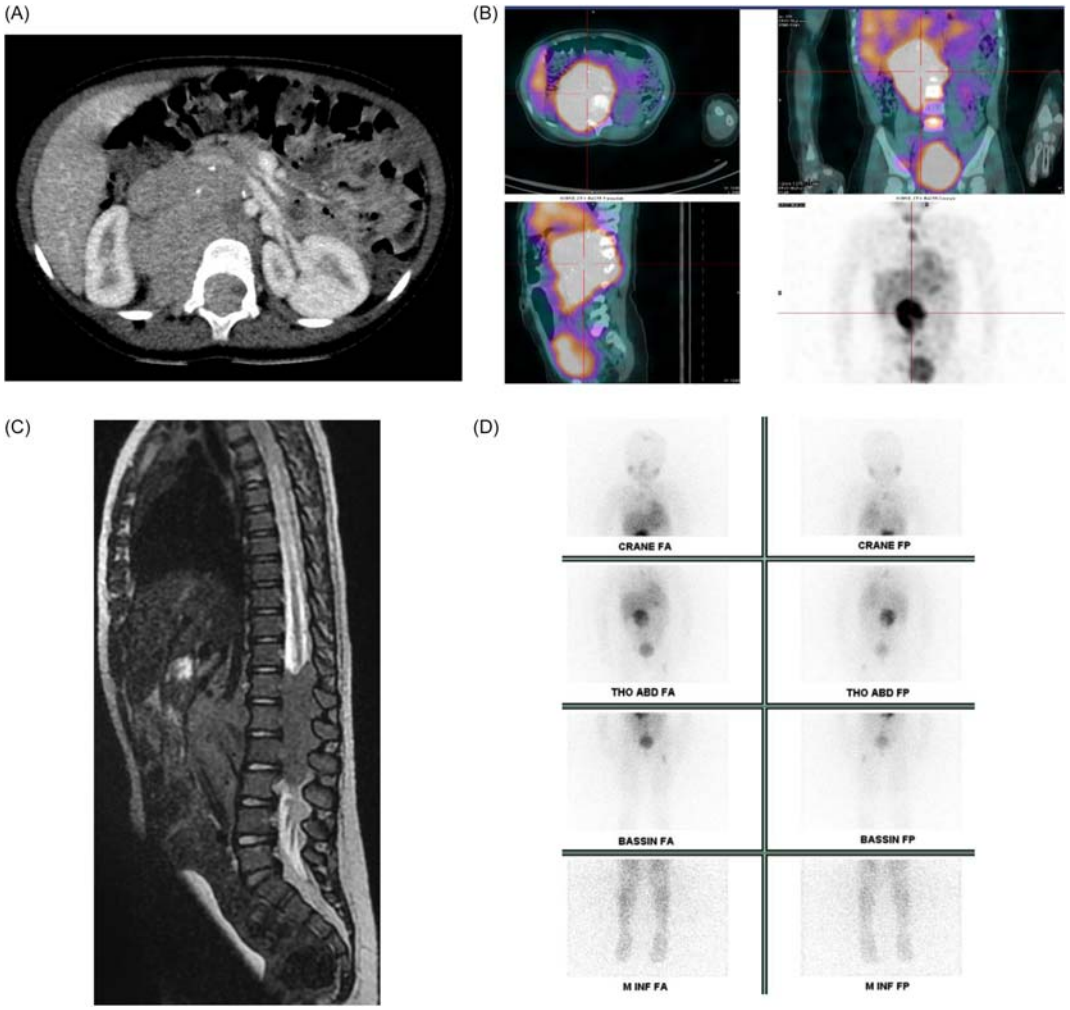

Fig. 2 Imaging of a neuroblastoma at diagnosis in a 2-year-old girl. An extensive retroperitoneal latero-aortic mass with microcalcifications shows intraforaminal invasion between D12 and L2 with spinal cord compression. The mass encases the aorta. MRI imaging reveals mediastinal lymph nodes confirmed my MYBG SPECT, which furthermore shows multiple osteomedullary lesions.

The precise analysis of local extension and involvement of adjacent organs includes the identification of image defined risk factors (IDRFs) in relation to possible surgical excision, taking into account perivascular disease, infiltration of tissues and adjacent organs, intraforaminal infiltration, and the epidural space of the spinal canal.

The extent of local disease is classified according to the absence or presence of IDRFs. The classification currently proposed by the INRG staging system categorizes tumors as L1 (limited tumor to a body compartment and the absence of any IDRF) or L2 (presence of IDRFs).

In addition to an evaluation of local disease extent, metastatic soft tissue, and bone marrow disease are evaluated by a meta-dibenzylguanidine scintigraphy (mIBG), preferably using iodine 123 (^{123}I), rather than ^{131}I due to lower exposure to ionizing radiation, improved quality of images, and lower thyroid toxicity. mIBG uptake depends on expression of the norepinephrine transporter, and about 90% of neuroblastomas express this transporter and thus are mIBG-avid. mIBG imaging has an estimated sensitivity and specificity of 90% and 99%, respectively. New imaging modalities using multimodal camera systems and integration of single photon emission computed tomography (SPECT) with CT combine the contrast provided by tumor-avid radioactive drugs with the anatomic precision of CT. Different scores (SIOPEN score, Curie score) have been developed to quantify metastatic involvement based on mIBG imaging, also enabling comparisons across different clinical trials in different cooperative groups. For mIBG non-avid neuroblastoma, disease extent should be evaluated by an additional technique, either with a technetium-99 bone scan, or ^{18}F-fluorodeoxyglucose positron emission tomography–computerized tomography (PET-CT). Recent PET techniques using ^{18}F-DOPA or ^{68}Ga-DOTATATE are now also being evaluated.

Comprehensive metastatic assessment also requires an assessment of bone marrow involvement. This investigation requires bilateral bone marrow aspirates and trephine bone marrow biopsies, obtained from bilateral iliac crest sites, with histological examination and immunohistochemistry for a quantitative approach to detect metastatic disease. Approaches measuring neuroblastoma

specific gene transcripts such as *PHOX2B* or tyrosine hydroxylase (*TH*) with qRTPCR can provide additional prognostic information, but are not yet incorporated into routine clinical evaluation. New approaches for detection and monitoring of disease might also rely on study of liquid biopsies such as analysis of cell-free circulating tumor DNA (Table 1).

Pathology of Neuroblastic Tumors

A pathological analysis of a tumor sample obtained either by surgical resection at diagnosis, or by surgical or percutaneous needle biopsy, allows confirmation of the histological diagnosis and a more precise classification according to the criteria of the International Neuroblastoma Pathology Committee (INPC).

Peripheral neuroblastic tumors show different degrees of differentiation, enabling one to distinguish ganglioneuroma tumor cells show maturation with terminal differentiation, ganglioneuroblastoma (some tumor cells show neuronal differentiation, others correspond to ganglion cells), and neuroblastoma (mostly immature small round tumor cells) with differentiating, poorly differentiated or undifferentiated features. A new histopathological classification of neuroblastoma combined biological characteristics including patient's age and a cellular index of mitosis and karyorrexis (MKI). The International Neuroblastoma Pathology Committee (INPC) defined a modification of the initial classification, taking into account the component of stromal Schwannian cells to classify neuroblastic tumors into four categories: neuroblastoma (Schwannian stroma-poor = SP); ganglioneuroblastoma, intermixed (Schwannian stroma-rich = SR); ganglioneuroblastoma, nodular (composite SR/SD and SP); and ganglioneuroma (Schwannian stroma-dominant = SD). The INPC defines a histoprognostic classification taking into account these categories, the index of mitosis and karyorrexis (MKI), and the age at diagnosis.

Staging and Prognostic Classification

In neuroblastoma, disease staging based on the extent of the disease is crucial in order to define prognosis and to inform treatment intensity. The previously used INSS definitions are based on the local and distant tumor extension and the resectability of the tumor (Table 2). However, this staging system is based on peroperative findings, and cannot easily be used in a context of unresectable disease.

The International Neuroblastoma Risk Group (INRG) classification system was then designed to identify homogeneous risk groups prior to any treatment to permit uniform therapeutic stratification and a comparison of patients groups in clinical trials conducted by different cooperative groups.

Table 1 Analyses for diagnostic confirmation and risk stratification of neuroblastoma

Tumor biopsy: pathology and biology	Pathological, immunohistochemical analysis and INPC classification
	FISH for *MYCN*, *aCGH*, SNPa or other techniques for genomic copy number profile
	DNA index (Ploidy)
	Optional: *ALK* mutations, NGS sequencing panel, expression profile
	Storage of tumor tissue for further translational studies recommended
Bilateral bone marrow aspirate and biopsy	Cytology, pathology, IHC
Imaging	Ultrasound, CT and/or MRI of primary site (neck, chest, abdomen, pelvis)
	Cranial CT or MRI (if clinically involved)
	^{123}I-mIBG scan; if tumor is not mIBG avid, ^{18}FDG-PET scan
Laboratory	Full blood count, blood coagulation studies
	Blood electrolytes, creatinine, uric acid, liver function tests
	Ferritin, LDH
	Urine VMA, HVA, dopamine

Table 2 INSS staging system

Stage	*Description*
1	Localized tumor with complete gross excision, with or without microscopic residual disease. Representative ipsilateral lymph node microscopically negative for tumor
2A	Localized tumor with incomplete gross excision. Representative ipsilateral non-adherent lymph nodes microscopically negative for tumor
2B	Localized tumor with or without complete gross excision, with ipsilateral non-adherent lymph nodes positive for tumor. Enlarged contralateral lymph nodes must be microscopically negative for tumor
3	Unresectable unilateral tumor, infiltrating across the midline, with or without regional lymph node involvement; or localized unilateral tumor with contralateral lymph node involvement; or midline tumor with bilateral extension by infiltration or lymph node involvement
4	Any primary tumor with dissemination to distant lymph nodes, bone, bone marrow, liver and/or other organs (except as defined for Stage 4S)
4S	Localized primary tumor (as defined for Stage 1, 2A, or 2B), with dissemination limited to liver, skin, and/or bone marrow ($<$10%). Limited to infants $<$12 months of age

Table 3 International neuroblastoma risk group staging system (INRGSS)

Stage	*Description*
L1	Localized tumor confined to one body compartment, no involvement of vital structures; image defined risk factors (IDRFs) absent
L2	Locoregional tumor with presence of one or more image-defined risk factors (IDRFs)
M	Involvement of distant metastatic sites (unless stage MS)
MS	Metastatic disease in children <18 months with metastases confined to the skin, liver, and/or bone marrow (bone marrow involvement should be limited to $<10\%$)

In this system, the extent of the disease is determined by the presence or absence of IDRFs and/or the presence of metastases at diagnosis, prior to any treatment (**Table 3**). This staging system based on preoperative, diagnostic images will be more robust than one based on operative findings and enable classification of tumors that are not resected upfront. Since the surgical risk factors are based on radiological findings, the term *image-defined risk factors* (IDRFs) was chosen and a consensus was reached for the definition of IDRFs.

The INRG Task force developed the INRG Consensus Pretreatment Classification Schema to establish a consensus approach for current pretreatment risk stratification (**Table 4** and **Fig. 3**). This is important in order to facilitate the comparison of risk-based patient populations in different clinical trials conducted by cooperative groups, by defining homogeneous pretreatment patient cohorts. In addition to the INRG stage, other prognostic factors are included in this classification, including age at diagnosis (age >18 months being associated with unfavorable outcome), pathology and genetic characteristics, including MYCN amplification status (MYCN amplification is associated with unfavorable prognosis), and the overall genomic copy number

Table 4 Modified International Neuroblastoma Risk Groups (INRG), taking into account the genomic profile

INRG stage	*IDRFs of primary tumor*	*Distant metastases*	*Age at diagnosis (months)*	*Histological category*	*Grade of differentiation*	*MYCN status*	*Genomic profile*	*Ploidy*	*Risk group for treatment strategy*

Notes: Definition of risk groups according to data from iINRG; http://inrgdb.org/neuroblastoma-information/staging-system.

L1, localized disease without image-defined risk factors; *L2*, localized disease with image-defined risk factors; *M*, metastatic disease, *Ms*, metastatic disease in infants (<18 months) restricted to liver, skin, and bone marrow; *GN*, ganglioneuroma; *GNB*, ganglioneuroblastoma; *NB*, neuroblastoma; *NA*, non-amplified; *A*, amplified. Favorable genomic profile corresponds to absence and unfavorable to presence of segmental chromosome alterations (SCA).

Cohn, S.L., Pearson, A.D., London, W.B., Monclair, T., INRG Task Force, et al. (2009). The International Neuroblastoma Risk Group (INRG) classification system: An INRG Task Force report. *Journal of Clinical Oncology* **27**, 289–297.

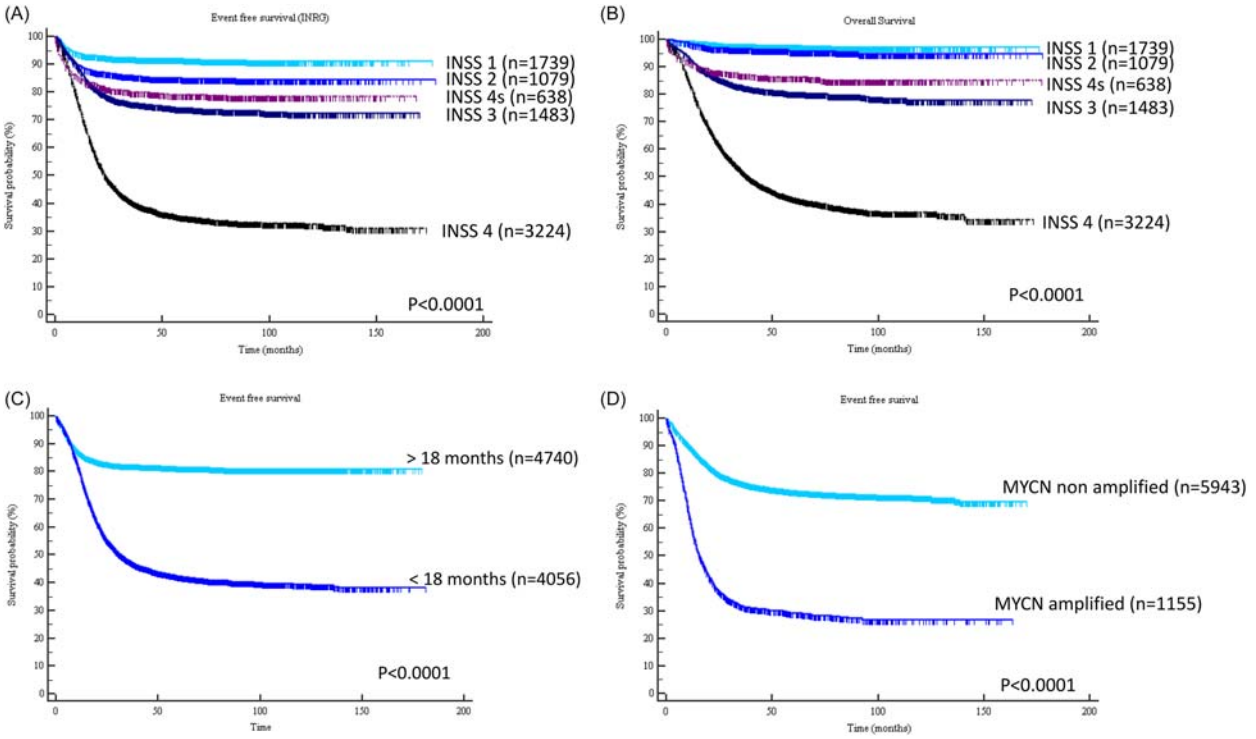

Fig. 3 Event-free survival (EFS) and overall survival (OS) of neuroblastoma patients (8800 patients with data recorded in the iINRG). EFS and OS were calculated according to the Kaplan Meier method, and compared using the log rank test. Clinical, pathological, and biological features of 8800 patients included in the iINRG database were analyzed to determine EFS and OS according to tumor stage (INSS), MYCN amplification status, and age at diagnosis. (A and B) EFS and OS according to INSS. Patients with INSS stage 4 have a poorer outcome. (C) EFS according to age at diagnosis, using a cut-off of 18 months at diagnosis. Patients aged >18 months at diagnosis have a poorer outcome. (D) EFS according to MYCN amplification. Patients whose tumors present MYCN amplification have a poorer outcome. Data from iINRG; http://inrgdb.org/neuroblastoma-information/staging-system; Cohn, S.L., Pearson, A.D., London, W.B., Monclair, T., INRG Task Force, et al. (2009). The International Neuroblastoma Risk Group (INRG) classification system: An INRG Task Force report. *Journal of Clinical Oncology* **27**, 289–297.

profile (the presence of segmental chromosomal alterations being of unfavorable prognosis). With the evolution of molecular biology techniques allowing even more detailed tumor biological characterization, it is likely that the risk groups will be further refined.

Early Detection and Screening

With the possibility of screening methods based on the detection of urinary catecholamines, several cooperative groups in France, Japan, the United States, Canada, and Germany have investigated the feasibility and impact of large-scale population-based screening programs. However, initial programs based on screening at an early age did not change the incidence of advanced disease after 1 year of age, and mass screening-negative children who presented later with neuroblastoma showed unfavorable genomic indicators like *MYCN* amplification. In an attempt to be more effective in preventing advanced disease, screening was then postponed to older infants (>6 months). However, although screening of 7–12-month-old infants resulted in more than one-third of neuroblastoma patients being identified by screening with unfavorable tumor genetic markers, it did not significantly reduce mortality. In a large German study based on urine screening for neuroblastoma at approximately 1 year of age, a similar incidence of stage 4 neuroblastoma was detected in the screened and the control group, and in a follow-up study, similar mortality rates between the two groups were observed. Thus, these results did not support a general screening for neuroblastoma at 1 year of age, and the screening program was abandoned.

Treatment of Neuroblastoma

The therapeutic management of patients with neuroblastoma depends on the risk groups and reflects the heterogeneity of this pathology, with a very broad spectrum of possible management, from simple observation to intensive multimodal treatment. Upfront, first-line treatment modalities currently include chemotherapy, surgery, radiotherapy, and immunotherapy.

Chemotherapy

As the majority of patients present with localized unresectable disease or metastasis at diagnosis and thus require systemic treatment, chemotherapy plays a pivotal role in the treatment of neuroblastoma. Major chemotherapeutic agents which have been used over the past decades include alkylating agents (cyclophosphamide, busulfan, melphalan), vinca alkaloids (vincristine), platinum derivatives (cisplatin and carboplatin), epipodophyllotoxins (etoposide), and anthracyclines (doxorubicin) with well-established activities against neuroblastoma, and are considered standard options.

Only few new drugs have been introduced into first-line therapy in recent years. Topotecan, irinotecan, and temozolomide are expected to improve the response rate slightly in high-risk neuroblastoma patients. High-dose chemotherapy with various combinations of busulfan, melphalan, carboplatin, and etoposide, followed by autologous stem cell transplantation (ASCT) rescue, is currently used as consolidation treatment in high-risk patients.

Surgery

Surgery plays a key role in both diagnosis and treatment. A tumor sample, either from the primary or in some situations from a metastatic site, is required at the time of diagnosis to confirm the pathological diagnosis and to establish biological features for risk classification. This can be obtained by surgical resection, surgical biopsy, or in many instances by percutaneous needle biopsies. With the rising importance of both pathological and biological investigations of tumor tissue, it is important to ascertain a sufficient sample size to enable all required analyses at the time of diagnosis.

For patients with localized disease, surgery is the treatment of choice in the absence of IDRFs and if surgical resection is deemed feasible. For these patients, in the absence of unfavorable biology such as MYCN amplification, surgery is the only treatment necessary to cure the majority of patients with localized disease, even if macroscopic remnants of the tumor are left behind. If surgical risk factors are detected in patients with localized disease, pre-surgical chemotherapy is necessary to induce tumor decrease prior to resection. However, IDRFs frequently persist after neoadjuvant chemotherapy and decisions of surgical resection should be taken following careful multidisciplinary discussions.

In contrast to its role in localized disease, in patients with metastatic disease, the place of aggressive surgery is still controversial. Meta-analyses in large patient cohorts are hampered by fragmented and inconsistent documentation of surgical approaches and a lack of immediate post-operative imaging results to distinguish complete from partial macroscopic resection. Due to the character of neuroblastoma, microscopically complete resection is not attainable in a majority of cases, and not of relevance. As local relapse can occur also in initially metastatic disease, the current recommendation in most high-risk treatment protocols is to perform resection of the primary tumor after inducing remission of metastases. In delayed primary or second-look surgery, the surgeon evaluates the response to therapy, and removes the residual tumor to a maximum extent whenever possible.

With the development of precision medicine programs based on detailed molecular characterization and search for targetable genetic alterations to orient toward early phase clinical trials, the role of a new tumor biopsy in case of relapse is now also widely acknowledged.

Radiotherapy

Neuroblastoma is a radiosensitive tumor, and doses ranging from 15 to 36 Gy have been used for local irradiation depending on tumor site, volume, and age of the patient. The definition of the role and modalities of irradiation, either as external beam radiotherapy or more recent treatment modalities, is under continuous refinement. Local irradiation is also successfully used within palliative care on painful metastatic sites.

Targeted radio-pharmaceutical treatment is based on ^{131}I carried by mIBG (^{131}I-MIBG), which is incorporated into neuroblastoma cells by the norepinephrine transporter. The importance of dosimetry and radioprotection issues limits the use of this therapeutic approach to selected treatment centers.

Some groups have used radio-pharmaceutical treatments within first line strategies. More promising approaches have included general radio-metabolic therapy using ^{131}I-MIBG in a conditioning phase prior to ASCT, and current use as salvage treatment in relapsed disease is also under investigation.

Treatment of Patients With Low-Risk and Intermediate-Risk Neuroblastoma

Low-risk neuroblastoma refers to patients with neuroblastoma of stages INRG L1, L2 $<$18 months, and Ms $<$12 or 18 months, without MCN amplification, according to the definitions in **Table 3**, and account for nearly half of all newly diagnosed neuroblastoma patients. For these patients, therapeutic decisions aim to provide minimum treatment in order to minimize any medium- or long-term treatment-related sequelae, while maintaining excellent survival. Infants ($<$1 year) with a localized adrenal mass may probably be observed safely, even without histological documentation. For patients with localized disease that appears to be resectable due to the absence of IDRFs (INRG L1 stage) or on the basis of surgical evaluation, the tumor may be removed surgically. In the absence of MYCN amplification, a residual tumor is not considered a risk factor for relapse, with a 5-year event-free survival (EFS) of $>$90% and an overall survival (OS) of 99%–100% for these patients. For patients with low-risk neuroblastoma, INRG L2, or Ms, the overall therapeutic strategy depends on clinical symptoms and more precise prognostic factors, including the genomic profile. For

these patients, in the absence of clinical symptoms and in the case of a favorable genomic profile, careful observation can be proposed in the Ms stage, and the feasibility of such an approach is being studied in the context of international studies within the SIOPEN and COG cooperative groups (SIOPEN LINES Study—NCT01728155; COG ANBL1232—NCT02176967). In the presence of clinical symptoms, or as a result of unfavorable prognostic factors, in particular of an unfavorable genomic profile, chemotherapy treatment is indicated, minimizing the number of cycles. There is no indication for radiotherapy in these patients, and the indication of surgical resection of the primary tumor in the case of persistent IDRFs should be evaluated carefully.

Intermediate risk neuroblastoma is defined as INRG L2 stage >18 months or M <12 or 18 months, without MYCN amplification. For these patients, two to eight cycles of chemotherapy are proposed, with combination chemotherapy combining etoposide and carboplatin, and vincristine, cyclophosphamide, and doxorubicin. Surgical resection of the primary tumor is performed whenever possible. Chemotherapy alone for children with INRG L2 unresectable neuroblastoma >18 months with unfavorable histology without *MYCN* amplification might not be sufficient; their lower survival indicates that a more intensive treatment regimen including radiotherapy and perhaps high-dose chemotherapy is warranted. Based on these treatment approaches, the estimated overall 5-year survival of intermediate risk neuroblastoma is $>90\%$ for infants with stage M disease but only 70% of children >18 months with L2 disease. In the future, it is expected that treatment intensity of patients with intermediate-risk neuroblastoma will be adjusted according to treatment response and other tumor biology parameters.

Treatment of Patients With High-Risk Neuroblastoma

A high-risk neuroblastoma is defined by INRG stage M disease in children $>12/18$ months, or patients whose tumor harbor MYCN amplification. Although the 5-year survival rate has risen from $<15\%$ prior to the 1980s to the present 40%, further therapeutic advances are imperative. The current approach incorporates induction chemotherapy to reduce the primary tumor and metastases, local treatment by surgery and radiotherapy, consolidation with high-dose chemotherapy, and re-injection of ASCT, as well as maintenance therapy in residual disease with anti-GD2 monoclonal antibody and therapy of differentiation by isotretinoin (retinoic acid).

Induction chemotherapy aims to achieve complete metastatic remission. Patients achieving a complete or near-complete remission at the end of induction have a significantly greater event-free survival compared to partial or less than partial response, and this has led to increasing dose intensity in induction, with current regiments incorporating multiple pairs or triplets of active drugs in a sequential fashion. Current regimens include combinations of etoposide, carboplatin, cisplatin, cyclophosphamide, and vincristine, with or without doxorubicin, allowing a complete and partial response rate of 70%–80% at the end of induction in the protocols used in different cooperative groups (SIOPEN, GPOH, COG, and JNBST). A current study compares two induction regimens, one of which proposes cures every 10 days (rapid COJEC) and the other one every 3 weeks (modified N7 arm) (Study SIOPEN HR NBL-01, NCT01704716). For the 10%–15% of high-risk patients who are refractory to standard induction therapy, depending on the prior treatment, a combination of irinotecan and temozolomide, or topotecan, vincristine, and doxorubicin, has been proposed with an aim to achieve a secondary metastatic response. Another approach might be the use of therapeutic ^{131}I-MIBG, with an estimated 30% response rate in refractory disease.

Surgical resection of the primary tumor is proposed once metastatic remission has been achieved but is often difficult in high-risk neuroblastoma, even after chemotherapy, due to frequent encasement of renal or abdominal blood vessels, or invasion of neural foramina. Radiation therapy is frequently administered to the tumor bed at doses of 21–36 Gy to reduce the risk of local recurrence.

Myeloablative high dose chemotherapy followed by ASCT has resulted in improved EFS for patients with high-risk neuroblastoma. The collection of hematopoietic stem cells is carried out by peripheral blood cytapheresis, frequently once metastatic bone marrow remission has been achieved. Initially myeloablative regimens included total body irradiation (TBI) to treat metastatic foci, but this has now been abandoned due to the significant late effects of TBI such as infertility, growth delay, and secondary malignancies. Myeloablative treatment is now based on high-dose chemotherapy. The current SIOPEN trial compared a regimen of busulfan and melphalan (BuMel) to carboplatin, etoposide, and melphalan (CEM), with an advantage in terms of EFS in favor of the BuMel arm. This treatment also shows a more favorable short-term toxicity profile. A recent COG randomized trial consisting of tandem transplant using thiotepa/cyclophosphamide followed by CEM compared to CEM alone showed a significant improvement in EFS for the tandem regimen, providing further evidence for the importance of myeloablative therapy. Pilot studies are also testing targeted radiopharmaceutical treatment with ^{131}I-mIBG to try to eliminate residual metastatic disease prior to transplant.

A possible complication of high-dose chemotherapy is veino-occlusive disease, an obstructive micro-angiopathy most often occurring in the liver, but sometimes also in the lungs. Treatment with defibrotide may be proposed for VOD, in addition to symptomatic treatment.

Despite the improvement in EFS with myelosuppressive chemotherapy followed by ASCT, 50% of children will have a relapse. The addition of a molecule causing the differentiation of neuroblastic cells, isotretinoin or retinoic acid, given orally, has been shown to improve EFS. The development of anti-GD2 monoclonal antibodies, targeting the disialoganglioside GD2 expressed on tumor cells, has also led to an improvement in EFS. A large randomized trial using the chimeric anti-GD2 antibody ch14.18 showed a significant improvement in EFS following high dose chemotherapy and ASCT for the combination of ch14.18, interleukin 2, GM-CSF, and isotretinoin, compared to isotretinoin alone. Studies are currently ongoing to improve the treatment modalities (long-term infusion to reduce side effects such as pain) and its combination (with the immunomodulator IL2) for maintenance therapy. Overall, the administration of anti-GD2 treatment is now widely recognized as a standard component of maintenance treatment in high-risk neuroblastoma. Importantly, recent studies have compellingly suggested that anti-GD2-based treatment

might demonstrate increased efficacy when combined with chemotherapy, justifying its further evaluation not only in relapse but also in upfront induction chemotherapy schedules.

Management of Specific Complications

Spinal cord compression occurs in approximately 5%–10% of all patients with neuroblastoma, and is an absolute medical emergency. Immediate treatment aims to increase chances of neurological recovery. In addition to symptomatic treatment using high-dose corticosteroids, treatment options include chemotherapy or neurosurgical intervention, either by laminectomy or by laminotomy. Although many investigators prefer a chemotherapy approach based on the possibility of rapid tumor volume decrease and spinal cord decompression, detailed multidisciplinary discussions are necessary to allow decisions to reduce paraplegia or other sequelae.

OMS is associated with medium- and long-term neurological (in particular neurocognitive) sequelae, despite a favorable oncological prognosis. Due to the underlying autoimmune mechanism, high-dose corticosteroid therapy (bolus of dexamethasone) is proposed. In cases of insufficient response, this treatment may be combined with other immunosuppressive treatment approaches such as further chemotherapy, rituximab, or (if necessary) polyvalent immunoglobulins, immunomodulatory agents, or (in severe cases) plasmapheresis.

Relapse Management

In cases of relapse after treatment of a low-risk or intermediate risk neuroblastoma, high-risk-based treatment strategies can often be proposed. In cases of high-risk relapse, OS unfortunately remains very poor. Nevertheless, in these cases, new combinations of chemotherapy have succeeded in permitting partial or complete remission in some cases. Current treatments are based on chemotherapy combinations (combining topotecan with cyclophosphamide, irinotecan with temozolomide, or topotecan with temozolomide). Other salvage treatments use 131I-mIBG therapy. Overall relapse treatment strategies should now be incorporated into global "basket" treatment approaches.

Early clinical trials proposed within the cooperative groups COG in collaboration with NANT, or SIOPEN in close collaboration with ITCC are focusing more on biomarker-based biology-driven treatment strategies. An important aspect for this is the molecular characterization to search for targetable genetic alterations, often proposed within general precision medicine programs. The inclusion of robust predictive biomarkers in phase I/II clinical trials will enhance the success in drug development and reduce exposures and toxicity for populations unlikely to benefit from a particular therapy. These approaches will also enable to determine the indication of inclusion of novel therapeutic strategies in first-line treatment in particular of high-risk neuroblastoma patients.

Among these targeted therapies, ALK inhibitors can be offered to 10%–15% of patients with detected ALK mutation at relapse. Combinations strategies of ALK inhibitors, including newer inhibitors with higher efficacy on the activating ALK mutations, together with chemotherapy, are currently being evaluated. Further strategies seek to target MYCN. Aurora Kinase inhibitors have shown promising response rates in phase I studies and have also been combined with chemotherapy for neuroblastoma, as they have been shown to destabilize MYCN as well as inhibiting cell cycle with G2/M arrest. Bromodomain inhibitors, based on their inhibition of MYCN transcription by binding to the promotor site, and CDK1, CDK2, and CHEK1, which present synthetic lethality with MYCN, are currently under early phase development. Aberrant PI3K/mTOR activity in neuroblastoma correlates with poor outcome, drives oncogenic stabilization of MYCN, and can be targeted using clinical PI3K/mTOR inhibitors. Other promising targets are HDAC inhibitors, and targeted disruption of the TP53–MDM2 interaction.

Treatments with preclinical promise also include immunotherapy currently in phase I or II studies with checkpoint inhibitors, anti-GD2 antibody with NK cells, or anti-GD2 vaccines and T cells engineered to express chimeric antigen receptors targeting GD2. Finally, a simple strategy with oral etoposide is often proposed in the palliative care setting.

Long-Term Survival

Studies of high-risk survivors treated with modern multimodel therapy, which is based on intensive chemotherapy, surgery, radiation, and immunotherapy, suggest a high prevalence of significant late effects, including endocrinological disorders, renal dysfunction, hearing loss, and, importantly, second malignancy. Hypothyroidism in neuroblastoma survivors may be due to the repeated exposure to ^{131}I-MIBG, as well as external beam radiation. Female survivors of high-risk neuroblastoma demonstrate a high rate of pubertal dysfunction and primary ovarian failure, and males might have azoospermia or oligospermia based on exposure to alkylating agents. Avoidance of late toxicity can be enhanced by a refined definition of patient subgroups. The strategy of using clinical and biological features at diagnosis to determine which patients might need less therapy will result in an overall decrease in late toxicity burden.

Outlook

The evolution of therapeutic strategies for patients with neuroblastoma will depend on an improved understanding of oncogenesis, by precise characterization of genetically and epigenetically controlled mechanisms, taking into account the tumor

microenvironment as well as the host itself. By integrating new biological insights, the discovery of new therapeutic targets and the understanding of resistance mechanisms, we shall improve the therapeutic management by increasing the survival rate of patients with high-risk neuroblastoma and by reducing the risk of sequelae.

From a biological point of view, the development of better animal models including GEMM (genetically engineered mouse models), zebrafish models as well as patient-derived xenografts (PDX) will contribute to elucidate further the pathogenesis of this disease. These approaches will enable us to study how single or multiple gene alterations, noncoding genetic elements, and epigenetic changes might contribute to the oncogenesis of neuroblastoma. The recent development of CRISPR/Cas9 technologies and other advances in genetic engineering will greatly accelerate research on the developmental origin and oncogenesis of this disease.

More intense collaborations and worldwide efforts in the molecular characterization of neuroblastoma will contribute further to the identification of molecular pathways which play a role in neuroblastoma progression and treatment resistance. The complex intratumoral, spatial, and temporal genetic heterogeneity of neuroblastoma has to be unraveled further in order to take into account its role in the process of clonal evolution of neuroblastoma. Furthermore, the recent discovery of different cellular identities with the possibility of switch from one cellular identity to another adds an additional level of complexity to the understanding of neuroblastoma oncogenesis.

The importance of data integration enabling large transversal data analyses is now widely acknowledged, and significant efforts have been placed in the construction of large-scale clinical and clinicobiological and biological databases (iINRG: http://inrgdb.org/neuroblastoma-information/staging-system; R2: http://r2.amc.nl). A crucial step in the understanding of neuroblastoma treatment resistance will be the integration of pharmacogenetics and pharmacogenomics data. This will enable contributions both to the understanding of early and late toxicity as well as to response rates based on differential drug exposure.

Importantly, the development of new tools for diagnosis and disease follow-up will contribute significantly to a more precise staging and response assessment. Such new tools will take into account molecular and cell-based techniques. One important question is that of minimal residual disease, which might be assessed by high-resolution cytological techniques, as well as molecular techniques based on the detection of neuroblastoma-specific mRNAs or circulating tumor DNA. Circulating tumor DNA will also enable study of the evolution of genomic biomarkers over time and during treatment. Indeed, ctDNA markers have the potential to evolve toward both biomarkers for response and biomarkers for detection of decision-making genetic alterations in the field of precision medicine.

From an immunological point of view, further studies will allow better comprehension of the role of the immune system of the host in the defense against neuroblastoma cells. Newer immunotherapeutic approaches to be developed include CAR-T cell approaches, approaches based on expanded and activated NK cells, allogeneic transplant strategies including KIR mismatch, and new humanized antibody conjugates and vaccines.

Importantly, the integration of molecular constitutional and somatic genetic knowledge, and immunological information, into clinical study and trial designs will require new adaptive trial designs. The widespread scientific collaborations fostered through associations such as ANR (Advances in Neuroblastoma Research Association; https://www.anrmeeting.org/index.php) will prove crucial to these collaborative efforts in the future.

Introduction

Neuroblastoma (NB) is the most common extracranial solid tumor in children, accounting for 8%–10% of all pediatric malignancies, and 12% of childhood cancer mortality (Whittle et al., 2017; Ahmed et al., 2017; Tolbert et al., 2017). There are approximately 20–50 cases per million, 650 new cases per year in the US (Ahmed et al., 2017; Matthay et al., 2016). The median age at diagnosis is 19 months, with 90% of patients being younger than 5 years (Whittle et al., 2017; Ahmed et al., 2017). Individuals of African ancestry show more aggressive forms compared to those of European descent (Whittle et al., 2017; Ahmed et al., 2017; Matthay et al., 2016). It is more common in boys than in girls although the underlying reasons for this gender preference remain unclear (Matthay et al., 2016).

NB is an embryonal tumor of neural crest origin that derives from sympathetic nervous system (SNS) precursors during development (Matthay et al., 2016; van Noesel, 2012; Cheung and Dyer, 2013; Ratner et al., 2016). It is a highly heterogeneous tumor in

regards to its presentation: age at diagnosis, stage, histological, molecular and genetic features lead to very different clinical behavior and outcome (Cheung and Dyer, 2013). Increasing knowledge on each of those areas has allowed for a more precise risk stratification of these patients that dictates management and prognosis, ranging from observation alone, with near 100% cure rates, to aggressive multimodal therapy with poor outcomes (Whittle et al., 2017; Ahmed et al., 2017; Cheung and Dyer, 2013; Kushner, 2017).

A better understanding of the relationship between normal development and tumor biology has also led to major therapeutic advances: expression of tissue related oncofetal differentiation proteins like GD2 or B7-H3 (used as antibody based immunotherapy targets); tissue differentiation inducers (like retinoids); and metabolic pathways (catecholamine metabolism) have led to diagnostic and therapeutic strategies that are improving outcomes of high risk patients (Cheung and Dyer, 2013; van Groningen et al., 2017; Ahmed et al., 2015). Whole genome sequencing (WGS) and genome wide association studies (GWAS) data are shedding some light into other potential genetic lesions relevant in NB (Tolbert et al., 2017; Matthay et al., 2016; Cheung and Dyer, 2013; Cao et al., 2017; Esposito et al., 2017). The low mutanome found in these tumors has hampered targeted therapies and immune based therapies (Esposito et al., 2017; Lee et al., 2017). Lack of mutations found in the majority of tumors at diagnosis, and recurrent patterns of whole chromosome or large segmental DNA copy number alterations, suggest that NB may be driven by gene copy number changes (Matthay et al., 2016). The goal of this article is to give an overview of the body of knowledge on NB biology that has influenced diagnosis, prognosis and therapeutic approaches to date.

Clinical Presentation Spectrum and Paraneoplastic Syndromes

NB is a tumor of neural crest origin that derives from SNS precursors, which give rise to the adrenal medulla and the sympathetic paravertebral ganglion chain (**Fig. 1**) (Cheung and Dyer, 2013). Primary tumor location follows this distribution pattern with up to 65% arising from the adrenal medulla and 35% from paravertebral ganglia (Cheung and Dyer, 2013).

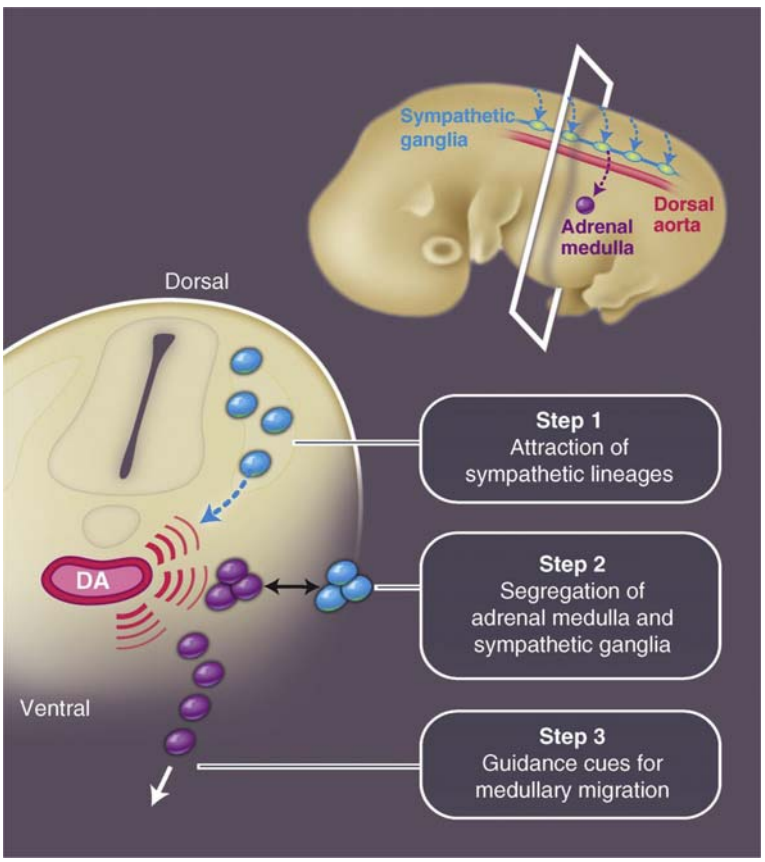

Fig. 1 *Early development of the sympathetic nervous system.* The dorsal aorta acts as a morphogenetic center for sympathetic lineages. Cells from the neural crest migrate ventrally and at the region where common precursors of sympatho-adrenal lineages migrate, receive signals from the dorsal aorta. Aortic signals determine the segregation of adrenal medullary cells from sympathetic ganglia. Finally, the dorsal aorta supports guidance molecule(s) for medullary cells to migrate ventrally. Reproduced with permission from AAAS, from Takahashi, Y., Sipp, D. and Enomoto, H. (2013). Tissue interactions in neural crest cell development and disease. *Science* **341**, 860–863, https://doi.org/10.1126/science.1230717.

Location influences clinical presentation: retroperitoneal masses may be asymptomatic or cause pain, abdominal distension and hypertension secondary to renal vasculature compression (Ahmed et al., 2017; Graeme Eisenhofer and Cheung, 2017). Paraspinal tumors may affect nerve structures causing Horner's syndrome (ptosis, miosis, enophthalmos, hemifacial anhidrosis) if located in the cervical/thoracic region or paresias or paraplegias from spinal cord compression, present in up to 15% of cases at presentation (Ahmed et al., 2017; Matthay et al., 2016). Half of the patients present with localized or regional disease, 35% having regional lymph node involvement at diagnosis (Ahmed et al., 2017). Bilateral disease is rare and should point at familial NB syndromes (Ahmed et al., 2017; Cheung and Dyer, 2013). The other 50% present with distant metastasis with bone marrow, bone and liver being the most common sites affected (Matthay et al., 2016; Graeme Eisenhofer and Cheung, 2017). Patients with distant metastasis limited to lymph nodes (4N), associated with younger age and favorable clinical features, have better outcome than those with generalized metastasis (Ahmed et al., 2017). NB has a predilection for metaphyseal, skull and orbital sites, the latter leading to periorbital ecchymosis at presentation ("racoon eyes") (Ahmed et al., 2017). In metastatic cases patients can develop constitutional syndrome with fever, weight loss and malaise (Ahmed et al., 2017; Matthay et al., 2016). Metastasis to other sites like lung or in the central nervous system (CNS) at initial diagnosis are rare (Matthay et al., 2016). However, relapse in CNS is increasingly common (Kramer et al., 2001; Cheung et al., 2012).

A particular pattern of dissemination seen in infants, classified as stage 4S (S for special), presents with skin, diffuse liver involvement, below 10% bone marrow involvement and small primary tumors (van Noesel, 2012). This particular distribution resembles that of early neural crest stem cells, which migrate to the skin and temporarily to the aorta-gonad-mesonephros (AGM), an embryologic structure from which fetal liver hematopoiesis and a small part of definitive bone marrow hematopoiesis derives (van Noesel, 2012). These neural crest stem cells that, from the AGM, migrate along fetal hematopoietic precursors, may be origin of 4S disease (van Noesel, 2012). These infants have a course of initial tumor growth followed by gradual simultaneous spontaneous regression over months, requiring therapy only if hepatomegaly causes life-threatening complications.

Paraneoplastic syndromes are rare and usually associated with more differentiated tumors. Secretory diarrhea resulting from tumor cell secretion of vasoactive intestinal peptide (VIP) resolves upon tumor removal (Graeme Eisenhofer and Cheung, 2017). Alternatively, a neuro-autoimmune process that cross-reacts with neurons, primarily of the cerebellum, called opsoclonus-myoclonus-ataxia syndrome (OMAS), is seen in up to 2%–3% of cases, and often leads to long term impairments despite tumor eradication (Whittle et al., 2017; Matthay et al., 2016; Ratner et al., 2016; Graeme Eisenhofer and Cheung, 2017). It is estimated that between 50% and 80% of patients with OMAS have underlying NB (Matthay et al., 2016). Interestingly, primary tumors from these patients have a dense inflammatory cell infiltrate (CD20+ B cells, CD4+ and CD8+ T cells), which is far less common in advanced stage NB (Ratner et al., 2016).

Development of the Sympathetic Nervous System

The neural crest is an embryonal structure that gives rise to different cell types, including peripheral neurons and glia of the sympathetic, parasympathetic and enteric nervous systems, the adrenal medulla, melanocytes, Schwann cells, craniofacial cartilage and bone cells (Graeme Eisenhofer and Cheung, 2017). The adrenal medulla hosts postganglionic neurons that respond to preganglionic neurons in the spinal cord releasing catecholamines (Graeme Eisenhofer and Cheung, 2017). The remainder sympathetic ganglions are distributed along the paravertebral chain from the neck down to sacral regions (Graeme Eisenhofer and Cheung, 2017) (**Fig. 1**). Migration and differentiation is controlled by the expression of specific markers that respond to different environmental signals (Graeme Eisenhofer and Cheung, 2017; Takahashi et al., 2013). Multipotency is maintained until destination is reached (Graeme Eisenhofer and Cheung, 2017). In the adrenal medulla and also at extraadrenal sites, these cells give rise to different populations: chromaffin cells (catecholamine producers), small intensely fluorescent (SIF) cells, neurons and glial cells (Graeme Eisenhofer and Cheung, 2017). For this specification process, bone morphogenic proteins (BMPs), synthesized in the dorsal aorta, are crucial in determining a chromaffin cell vs. sympathoneuronal fate, although the precise pathways involved are not completely clear (Graeme Eisenhofer and Cheung, 2017; Takahashi et al., 2013). NBs do not display the full chromaffin morphology, but instead resemble progenitors destined towards a neuronal path of differentiation (neuroblast) (Graeme Eisenhofer and Cheung, 2017). *N-myc proto-oncogene* (*MYCN*) blocks the transition of neural crest cells to a chromaffin cell fate, being a key gene in the development of these tumors (Graeme Eisenhofer and Cheung, 2017). Hypoxia pathways are also very relevant in the development of the sympathoadrenal system (Takahashi et al., 2013). Hypoxia is a stimulus for catecholamine secretion, and intact signaling pathways (HIF1α and HIF2α) are needed to ensure appropriate development of cathecholamine systems, which in turn facilitates fetal survival under hypoxic conditions (Graeme Eisenhofer and Cheung, 2017). HIF2α seems crucial for the survival of sympathetic neurons (Graeme Eisenhofer and Cheung, 2017). Expression of HIF2α in NB cells maintains them in an undifferentiated state, rendering more aggressive features (Graeme Eisenhofer and Cheung, 2017).

The observation that neuronal differentiation was driven by retinoids in vitro led to the use of isotretinoin (13-*cis*-retinoic acid) as a differentiating agent to treat high risk patients (Cheung and Dyer, 2013; Ratner et al., 2016). Despite being standard of care for a long time in the treatment of high risk patients, a recent meta-analysis showed no benefit when used after autologous stem cell transplantation (Peinemann et al., 2015). Resistance to isotretinoin therapy has been ascribed to RAF-MEK pathway activation; hence adding MEK inhibition may improve the activity of isotretinoin therapy (Ratner et al., 2016; Holzel et al., 2010).

Another relevant feature of neuroblastic cells is the expression of specific markers such as GD2, B7-H3, GPC2 also present in tumor cells, which are the target of antibody based therapies, rapidly becoming standard of care in high risk patients (Cheung and Dyer, 2013; Ahmed et al., 2015).

Histological Features and Classification

Peripheral neuroblastic tumors show different grades of morphological differentiation: NB is one of the small round blue cell tumors and its differential diagnoses requires consideration of clinical, radiological and histological features. The clinical pathology of NB typically shows nests of neuroblasts in various stages of differentiation, separated by fine fibrovascular septa and variable amount of Schwannian stroma (Ahmed et al., 2017; Wang et al., 2013). X-inactivation studies showed that neuroblastic and Schwannian-like stromal cells developed from the same progenitor, that led to the different cell fates (Mlakar et al., 2017). In these studies, chromosomal imbalances were seen only in the neuroblastic lineage, pointing at the fact that these chromosomal changes happen after cells have commited to a neuroblastic fate (Mlakar et al., 2017). Rosettes can be seen in up to one third of NB (Ahmed et al., 2017). The presence of neuropil and immunohistochemical findings (synaptophysin, chromogranin, tyrosine hydroxylase, nuclear Phox2B) can facilitate diagnosis (Graeme Eisenhofer and Cheung, 2017). In some instances, ganglion cells suggestive of neuroblast differentiation can be seen, leading to the diagnosis of ganglioneuroblastoma (where there are coexisting neuroblasts with terminally differentiated tumor derived ganglion cells) (Matthay et al., 2016; Wang et al., 2013). Ganglioneuroma (where tumor cells are terminally differentiated to ganglion cells) with no neuroblastic elements, possibly derived from a more differentiated lineage of the sympathetic system, requires only conservative management (Ahmed et al., 2017; Wang et al., 2013). Schwannian NB cells may derive from the malignant clone, whereas Schwann cells in mature ganglioneuromas may be normal infiltrating Schwann cells (Ratner et al., 2016) (**Fig. 2**).

Schwannian stroma poor tumors are the most undifferentiated appearing and aggressive (Ahmed et al., 2017). The Shimada histology-grading system is based on age plus histological features, which include the presence or absence of differentiation, Schwannian stromal content, and mitotis-karyorrhexis index (MKI) (Ahmed et al., 2017; Matthay et al., 2016; Cheung and Dyer, 2013). A more recent classification proposed by the International Neuroblastoma Pathology Committee (INPC), distinguishes favorable histology as any differentiation in NB, with low/intermediate MKI in patients younger than 18 months, and differentiating NB with low MKI in patients between 18 months and 5 years of age (Ahmed et al., 2017). Unfavorable histology includes undifferentiated or high MKI in any age, poorly differentiated and/or intermediate MKI in patients between 18 months and 5 years and any grade, any MKI in patients 5 years or older (Ahmed et al., 2017).

Catecholamine Synthesis and Metabolism: Diagnostic and Therapeutic Relevance

NBs are primitive catecholamine producing tumors (Graeme Eisenhofer and Cheung, 2017). In NB cells, catecholamines are usually synthesized and metabolized though not commonly secreted (Graeme Eisenhofer and Cheung, 2017). They are stored in dense core

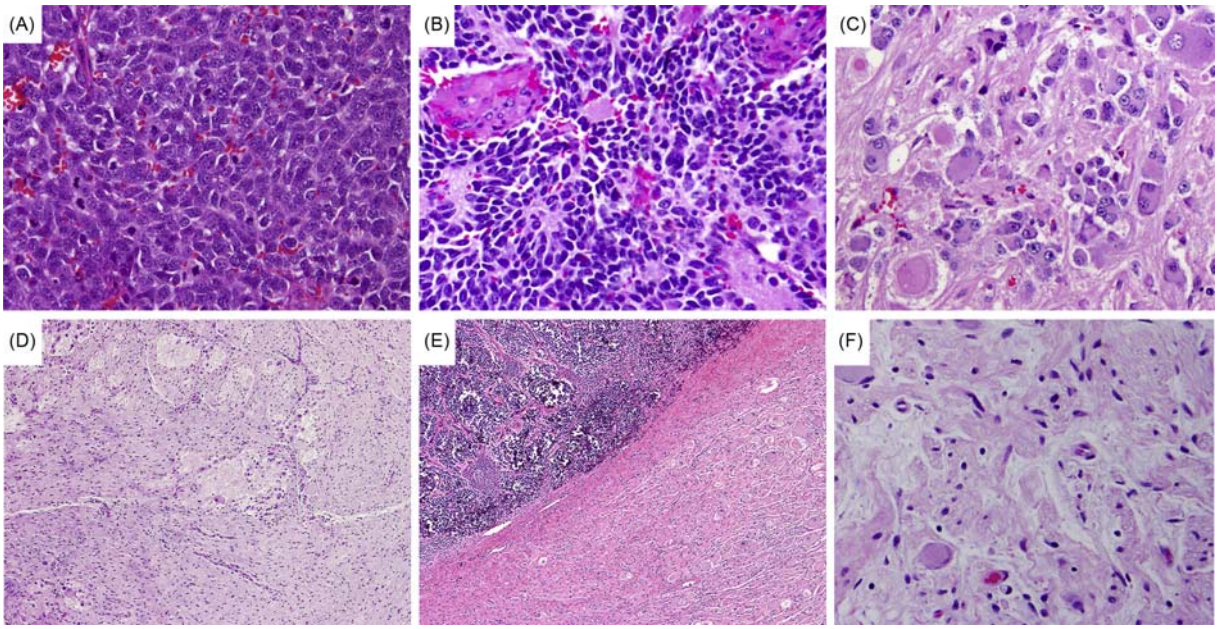

Fig. 2 *Hematoxylin and eosin staining of neuroblastic tumors.* Neuroblastoma: undifferentiated (A); poorly differentiated (B); differentiating NB (C). Low power GNB: intermixed (D); nodular (E). Ganglioneuroma (F). Pictures courtesy of Dr. Satish K. Tickoo, Department of Pathology, MSKCC.

vesicles (DCVs) which can be seen in NB cells (Cheung and Dyer, 2013). Most catecholamine metabolism results from leakage from the DCVs (Cheung and Dyer, 2013). Meta-iodobenzylguanidine (MIBG), an analogue of norepinephrine, is taken up by NB cells and a fraction stored in DCVs (Cheung and Dyer, 2013). Approximately 90% of NBs are MIBG avid (Ahmed et al., 2017; Matthay et al., 2016). Radioiodinated MIBG is used for diagnostic (^{123}I–MIBG) and therapeutic (^{131}I-MIBG) purposes (Cheung and Dyer, 2013) (**Fig. 3**).

In humans, homovanilic acid (HVA) and vanillylmandelic acid (VMA) are the main metabolic end products of dopamine metabolism, eliminated mainly through the urine (Graeme Eisenhofer and Cheung, 2017). Elevated urinary HVA and VMA is detected in most NB cases at diagnosis, and if coupled with bone marrow tumor infiltration determined through bone marrow aspirate or biopsy, will meet the diagnostic criteria of NB in the absence of a primary tumor sample (Ahmed et al., 2017). HVA and VMA can be determined in a random urine sample normalized to urine creatinine, as there is low diurnal variation and good correlation with 24 h urine collection levels (Graeme Eisenhofer and Cheung, 2017). Measurement in serum samples has less sensitivity, although in cases where urine sampling is not possible, determination of serum normetadrenalin, metadrenalin and methoxytyramine can be of use (Matthay et al., 2016; Graeme Eisenhofer and Cheung, 2017). A high ratio of HVA to VMA, of dopamine to VMA, or of dopamine to norepinephrine, indicates a relative deficiency in dopamine-B-hydroxylase, resulting in a decreased tumor cell conversion of dopamine to norepinephrine (Graeme Eisenhofer and Cheung, 2017). This immature metabolic pattern has been associated with more aggressive tumors and *MYCN* amplification (Ahmed et al., 2017; Graeme Eisenhofer and Cheung, 2017).

Molecular Genetics and Biology

NB can be classified into three groups based on its biological behavior. Type 1 includes those that differentiate into ganglioneuroblastomas (Graeme Eisenhofer and Cheung, 2017). Type 2 includes those regressing spontaneously overtime, which happens mostly in infancy, and is exemplified by stage 4S and some locoregional tumors despite residual microscopic disease (Graeme Eisenhofer and Cheung, 2017). The incidence of type 2 NB may be underestimated as it is thought that up to half may go undiagnosed (Matthay et al., 2016). Type 3 (>50%) includes those that progress and metastasize to distant organs (Graeme Eisenhofer and Cheung, 2017). Recent discoveries have helped understand the genetic basis of NB and Omics data should one day be integrated into the diagnosis and prognostication for accurate risk stratification and therapy selection for these patients. It is now estimated that approximately 10% of NB patients carry germline mutations in genes that might confer increased susceptibility to NB development (Tolbert et al., 2017). Many of the more highly penetrant mutations in NB predisposition, inherited or de novo, may affect the risk for other malignancies in survivors (Matthay et al., 2016). Here we will summarize the more relevant findings, and how they may relate to the biology and therapy of NB.

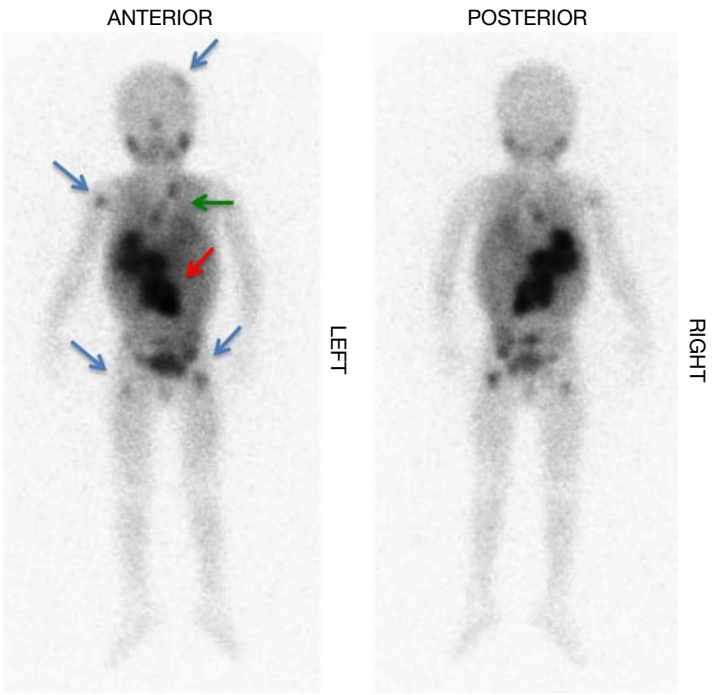

Fig. 3 *I123MIBG SCAN 24h.* Retroperitoneal mass and lymphadenopathies (*red arrow*), lymph node involvement (*green arrow*), multiple sites of bone involvement: skull, scapula, humerus, bilateral iliac and femurs (*blue arrows*).

Familial NB

Familial NB cases are rare, accounting for < 2% of all diagnosis (Tolbert et al., 2017; Cheung and Dyer, 2013). These patients do not seem to present at younger age, but may have multifocal primary disease (Ahmed et al., 2017; Tolbert et al., 2017; Matthay et al., 2016; Cheung and Dyer, 2013; Kamihara et al., 2017). Two genes have been identified within familial neuroblastoma cases: the *paired-like homeobox 2b* (*PHOX2B*) and the *anaplastic lymphoma kinase* (*ALK*) gene (Tolbert et al., 2017; Matthay et al., 2016; Cheung and Dyer, 2013; Cao et al., 2017). The disease is inherited in an autosomal dominant fashion, though pedigrees show considerable heterogeneity in the biology of tumors that arise in these families: benign ganglioneuromas and malignant NBs have been reported in the same family, and some pedigrees show incomplete penetrance (Tolbert et al., 2017; Kamihara et al., 2017).

A small proportion of patients have a clinically recognizable genetic syndrome: (a) most cases are related to abnormalities in neural crest development, like in congenital central hypoventilation syndrome (CCHS), aganglionosis of the colon (Hirschsprung disease), ROHHAD syndrome (rapid-onset obesity, hypothalamic dysfunction, hypoventilation, and autonomic dysfunction); (b) in the context of RASopathies such as Costello syndrome, Noonan syndrome, neurofibromatosis type 1; (c) epigenetic syndromes such as Beckwith–Wiedemann syndrome (BWS, including hemihypertrophy, or 11p overgrowth) (Kamihara et al., 2017). Germline mutations in *TP53* (in particular R337H), *SDHB*, *PTPN11* and *APC* have been reported to occur rarely in NB patients (Ahmed et al., 2017; Kamihara et al., 2017; Varan et al., 2016).

Inactivating mutations in *PHOX2B* were the first found in the study of syndromic NB cases, along with Hirschprung disease and/or CCHS (Matthay et al., 2016; Cheung and Dyer, 2013). Mutations in this gene account for a minority of familial NB cases (Tolbert et al., 2017; Matthay et al., 2016; Cheung and Dyer, 2013; Cao et al., 2017). It is a transcription factor that promotes cell cycle exit and neuronal differentiation of neural crest derived autonomic precursors (Cheung and Dyer, 2013). *PHOX2B* has two polyalanine repeat sequences (PARMS), and mutations in these are associated with a 1%–2% risk of developing tumors (Cheung and Dyer, 2013; Kamihara et al., 2017). On the other hand, nonpolyalanine repeat expansion mutations relate to the more severe phenotype including the NB-Hirschprung disease-CCHS association (Cheung and Dyer, 2013), and an increased risk (45%) of developing a neural crest tumor.

Activating mutations in *ALK* are accountable for up to 80% of familial NB cases (Tolbert et al., 2017; Matthay et al., 2016; Cheung and Dyer, 2013). It encodes for a receptor tyrosine kinase member of the insulin receptor superfamily (Ahmed et al., 2017). It is expressed in developing sympathoadrenal lineage of neural crest cells regulating multiple pathways, including the mitogen activated protein kinase (MAPK) ans Ras related protein 1 (Rap1) pathways (Cheung and Dyer, 2013). PHOX2B can directly regulate *ALK* expression, connecting both pathways found to be affected in familial NB cases (Cheung and Dyer, 2013). The overall penetrance of germline *ALK* mutations is estimated around 50% (Kamihara et al., 2017). There is a correlation between mutation type and penetrance: the R1275Q, the most common mutation seen in up to 45% of familial NB (Cao et al., 2017), leads to near complete penetrance, whereas G1128A renders a weaker activation and is correlated with a 25% risk of developing NB (Tolbert et al., 2017). Mutations in *ALK* can also be found in up to 6%–10% of sporadic NB tumors, while another 3%–4% carry amplifications, and overexpression is found in up to 33% of cases (Ahmed et al., 2017; Cheung and Dyer, 2013). The two most highly activated somatic hot-spot mutations (F1174 and F1245) were each observed in the germline once, associated with severe neurocognitive defects and brain stem abnormalities together with NB (Tolbert et al., 2017). ALK is a pharmacologic target: crizotinib, an ALK small molecule inhibitor, and newer agents for crizotinib resistant cases are being developed (Esposito et al., 2017). A specific *ALK* mutation (F1174L) has been used to develop a NB murine model (Cheung and Dyer, 2013; Graeme Eisenhofer and Cheung, 2017). *ALK* gain of function mutations in sympathetic precursor cells (using *dopamine-β-hydroxylase (Dβh)* promoter) require overexpression of *MYCN* (using *tyrosine-hydroxylase* (*Th*) promoter) to develop NB both in zebrafish and in a murine *Th* driven model (Matthay et al., 2016). The reason why *ALK* alone is enough to develop NB in F1174L transgenic animal model and not in others is unclear.

The search for additional familial NB genes continues: *GALNT14* was detected in three individuals from two families. Aberrant function of galactosaminyltransferases has been associated with tumor aggressiveness in various cancers, suggesting that *GALNT14* may be involved in NB predisposition or pathogenesis, yet further studies are required (Kamihara et al., 2017).

Genetic testing for mutations in genes known to be associated with NB predisposition should be considered in any individual diagnosed with NB who has a family history of NB, features suggesting predisposition such as bilateral or multifocal primary tumors, or clinical features associated with these other predisposition genes. Recently published guidelines recommend to start screening for tumor development once the mutation is identified, especially during the first decade of life (Kamihara et al., 2017).

Sporadic NB

In sporadic NB, *MYCN* amplification, defined as 10 or more copies per genome or fourfold larger signal relative to chromosome 2, is found in up to 20%–30% of cases, conferring poor prognosis (Ahmed et al., 2017; Cheung and Dyer, 2013) (**Fig. 4**). In normal development, several signaling pathways regulate its expression, which leads to proliferation, growth, differentiation and survival of neurons in developing central and peripheral nervous system (Cheung and Dyer, 2013). Intratumor heterogeneity of *MYCN* amplification has been described with coexisting amplified and nonamplified cells within tumors (Mlakar et al., 2017). Concomittant *ALK* mutation/amplification in addition to *MYCN* amplification is associated with highly lethal disease. The *MYCN* locus also encodes an antisense transcript: *MYCNOS* (encoding N-CYM), which is always coamplified and coexpressed with *MYCN*, and its

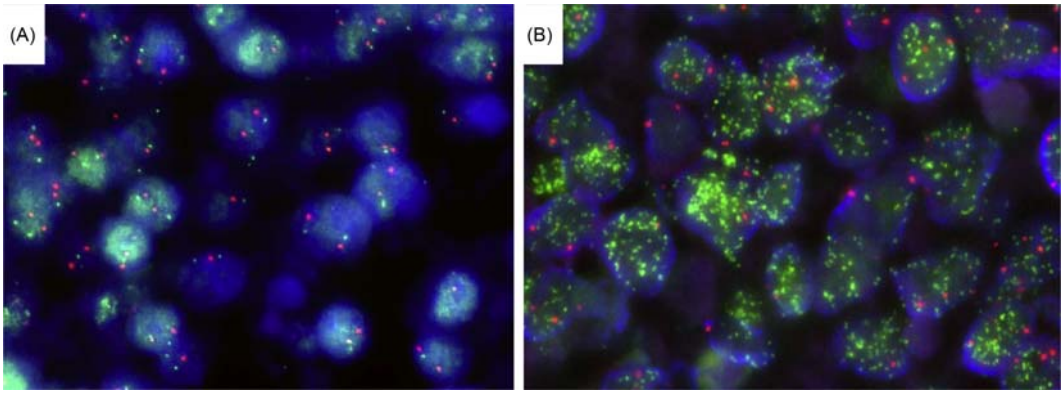

Fig. 4 Fluorescent in situ hybridization (FISH) image to detect *MYCN* amplification. The *green dots* represent MYCN and the *red signals* are for the centromere region of chromosome 2 and *blue* is DAPI counterstain labeling cell nuclei. (A) Shows a non *MYCN* amplified NB specimen with two copies for MYCN (*green dots*) and two centromeric regions in chromosome 2 (*red dots*), one per allele. Pictures courtesy of Dr. Yanming Zhang, Director of Cytogenetics Laboratory, Department of Pathology, MSKCC.

expression is associated with poor clinical outcome (Matthay et al., 2016). N-CYM stabilizes N-MYC by inhibiting its degradation, and mice transgenic for both *MYCN* and *MYCNOS* show frequent metastasis (Matthay et al., 2016). However, transgenic mice for *MYCNOS* alone do not develop NB (Matthay et al., 2016). MYC is a master transcription factor of cell proliferation and is considered a compelling target, though the knowledge of mechanisms affecting its expression, function and downstream targets has opened the possibility of an indirect therapeutic approach (Cheung and Dyer, 2013; Esposito et al., 2017) (**Table 1**).

The *alpha thalassemia/mental retardation syndrome X-linked* (*ATRX*) gene loss-of-function mutations are the most commonly found in older children and young adults, and its presence is mutually exclusive with *MYCN* amplification (Matthay et al., 2016; Cheung and Dyer, 2013). No *ATRX* mutations have been identified in patients <18 months, in contrast to 17% of children between 18 months and 12 years and 44% over 12 years with stage 4 disease at diagnosis, who have a poor prognosis (Cheung and Dyer, 2013). *ATRX* encodes for a SWI/SNF chromatin remodeling ATP dependant helicase (Cheung and Dyer, 2013). The role of *ATRX* in sympathoadrenal development or NB differentiation remains unknown (Cheung and Dyer, 2013). Mutations have also been associated with X-linked mental retardation and alpha-thalassemia, though in these patients no increased incidence of NB is seen (Cheung and Dyer, 2013). Most of *ATRX* mutated NBs have evidence of alternative lengthening of telomeres possibly related to a defect in histone H3.3 deposition at telomeres (Cheung and Dyer, 2013; Graeme Eisenhofer and Cheung, 2017). This highlits the importance of telomere content and length in NB, where in up to 30% of cases high telomerase activity is found, associated with adverse outcome (Cheung and Dyer, 2013). *ATRX* mutations have not been modeled although indirect targeted therapies are being evaluated.

Telomerase reverse transcriptase (*TERT*) rearrangements, have recently been detected in around 20%–30% of NB (Ahmed et al., 2017; Matthay et al., 2016; Graeme Eisenhofer and Cheung, 2017). These rearrangements are mutually exclusive from *ATRX* mutations and *MYCN* amplifications (Matthay et al., 2016). As *TERT* is also an N-MYC target, this may mean that all NB require a way to activate TERT or lengthening of telomeres, through *MYCN* amplification (*TERT* expression is elevated in *MYCN* amplified tumors), enhancer hijacking, or through *ATRX* mutations (Matthay et al., 2016).

By WGS, recurrent lesions have also been reported for genes involved in the Rac/Rho pathway and chromatin remodeling genes (*AT-rich interactive domain 1A* and *1B*: *ARID1A* and *ARID1B*) (Matthay et al., 2016; Cheung and Dyer, 2013). The role of these genes in NB initiation, progression and prognosis is yet to be determined (Cheung and Dyer, 2013).

The PI3K/AKT/mTOR pathway is involved in the development and progression of NB, though the activating molecular mechanisms of this pathway remain to be elucidated (Esposito et al., 2017). RAS pathway mutations are rare at diagnosis: *NF1* and *PTPN11* have been found mutated in 6 and 3% of patients (Holzel et al., 2010). Increased incidence of activating mutations in the MAPK pathway is seen in relapsed specimens; mutations in *ALK* as well as *NRAS*, *KRAS*, *HRAS*, *PTPN11* and *FGFR* have been described (Matthay et al., 2016).

In NB, P53 pathway (p53/MDM2/p16) is rarely mutated at diagnosis, but is frequently aberrant at relapse contributing to chemoresistance (Esposito et al., 2017). Targeting P53-MDM2 interactions, to prevent MDM2 mediated P53 inhibition, could be a therapeutic approach (Esposito et al., 2017). In NB this has shown to depend on *MYCN* status, as overexpression of *MYCN* sensitizes NB cells to MDM2 inhibition (Esposito et al., 2017).

Genetic Susceptibility for Sporadic NB

GWAS have helped pinpoint additional mutations/single nucleotide polimorphisms (SNPs) in genes that, when combined in the germline, may influence the probability of NB occurrence (Cheung and Dyer, 2013). DNA alleles that have been significantly

Table 1 Indirect MYCN—NMYC targeting strategies

Interaction	*Pathway*	*Function*	*Preclinical evidence*	*Trials*
MYCN expression inhibition	Retinoic acid PI3K/AKT/mTOR	*MYCN* promoter binding		Variable efficiency
N-MYC function/ degradation	Histone DeACelytales (HDAC)	Interaction with Sirt proteins (Marshall et al., 2011)	Favor N-MYC degradation	Vorinostat
	Aurora kinases (AURK)	Highly conserved serine/threonine kinases important in mitosis and its overexpression is associated with genetic instability and aneuploidy. Overexpressed in different human tumors. Its inhibition leads to cell cycle exit and apoptosis (Bavetsias and Linardopoulos, 2015)	AURKA inhibition leads to N-MYC degradation, as AURKA has been found to sequester N-MYC away from ubiquitin mediated proteolytic degradation. AURKB is a direct transcriptional target of N-MYC, and its increased expression is associated with poor outcomes (Esposito et al., 2017). In NB cell lines and murine models with *MYCN* amplification/ overexpression, the use of a pan-Aurora inhibitor decreased N-MYC expression and tumor growth (Bavetsias and Linardopoulos, 2015)	In clinical trials, AURKA inhibition in NB showed low efficacy, particularly in *MYCN* amplified patients. Newer drugs targeting protein-protein interaction are being developed (Esposito et al., 2017)
	N-MYC/MAX interaction	N-MYC requires the formation of an heterodimer with the MAX protein for the activation of transcription (Esposito et al., 2017)	Blockers of N-MYC/MAX interaction have been tested in vitro leading to apoptosis and neuronal differentiation. Yet to test in vivo efficacy (Esposito et al., 2017)	
	Bromodomain and extraterminal (BET)	BET proteins recognize and bind acetylated lysine residues on histone tails and are therefore considered "readers" (Varan et al., 2016)	One of the BET family members, BRD4, acts as a transcriptional coactivator of many genes including *MYC*. BRD4 inhibitors have been shown to reduce *MYC* expression by releasing BET proteins from *MYC* locus, indicating that BET proteins directly regulate *MYC* gene expression. In preclinical studies in NB cell lines, BET inhibition induced cell cycle arrest and apoptosis as well as downregulation of *MYC* expression. In murine NB models they decreased growth and significantly increased survival regardless of *MYC* amplification status. In addition to antitumor activity, neuronal differentiation was seen both in vitro and in vivo in *MYCN* amplified tumors (Varan et al., 2016)	Current open clinical trials exclude children younger than 16 years of age. Concerning potential side effects include defective spermatogenesis, viral reactivation and altered bone formation, which could impact growth (Varan et al., 2016)

Ornitine decarboxylase 1 (ODC1)	Rate limiting enzyme in polyamine synthesis, and its level is increased in highly metabolic active cells	Known target of N-MYC. Difluoromethylornithine (DFMO) is an anti-protozoal drug that causes irreversible inhibition of ODC1, and is being investigated as maintenance therapy in NB patients.	In a phase II study on high risk patients in remission after standard chemotherapy, the addition of DFMO maintenance was well tolerated (Esposito et al., 2017)
Tropomyosin Receptor Kinase (TRK) family of neurotrophin receptors	TrkA and its ligand, nerve growth factor (NGF), are required for neuronal differentiation	TrkA (coded by *NTRK1*) expression is increased in NB with favorable biology and spontaneous regression. NTRK1 polymorphisms have been have been associated with reduced survival. In high risk patients, TrkA expression is low or absent. TrkB (coded by *NTRK2*) and its ligand, Brain-derived neurotrophic factor (BDNF), are highly expressed in biologically unfavorable NB and associated with *MYCN* amplification, drug resistance and increased proangiogenic factors. No mutations or rearrangements have been found in *NTRK2*. Entrectinib, a novel ALK inhibitor, has shown to be effective for TrkB dependent NB in preclinical models. Preferential TrkB inhibitors are currently being developed with good in vitro activities (Esposito et al., 2017)	
ALK	ALK activation of the phosphoinositide-3-kinase (PI3K) signaling, stabilizes N-MYC. ALK also signals through RAS, with downstream activation of the MAPK pathway.	*ALK* and *MYCN* can be co-amplified, given its close localization in chromosome 2, associated with advanced stage at presentation and poor prognosis (Ahmed et al., 2017; Matthay et al., 2016). The synergy may be related to downstream activation of the MAPK pathway, which is frequently activated in relapsed NB	Targeted therapeutic interventions using ALK and MAPK pathway inhibition in NB, currently underway

associated with the development of high and low risk NB predisposition include *CASC15*, *BARD1*, *LMO1*, *LIN28B*, *HACE1*, *DUSP12*, *DDX4*, *IL31RA*, *HSD17B12*, *NEFL*, *TP53* and *NBPF23* (Cheung and Dyer, 2013).

A few germline mutations affecting DNA repair genes including *CHEK2*, *PINK1*, *BARD1* and *PALB2* have been found in NB patients (Cao et al., 2017). A GWAS study of high risk NB identified up to six SNPs in *BRCA1-associated RING domain 1* (*BARD1*), all affecting three different N-terminal introns (Tolbert et al., 2017). In depth studies into BARD1 have found an isoform, *BARD1b*, which lacked the RING domain for BRCA1 binding, as preferentially expressed in NB cell lines homozygous for the risk alleles (Tolbert et al., 2017). Knockdown of this isoform inhibits cell growth, whereas overexpression increases proliferation. Additionally, BARD1b was found to stabilize the Aurora family of kinases in NB cell lines, suggesting a possible mechanism of action and therapeutic strategy (Tolbert et al., 2017). Four SNPs on *LMO1* gene, were also shown to be associated with high risk disease and decreased survival (Tolbert et al., 2017). This gene encodes for a cysteine-rich transcriptional cofactor preferentially expressed in the nervous system. Both *BARD1* and *LMO1* risk alleles seem to be more prevalent in the African–American population, which may underlie the more aggressive disease observed in these patients (Cheung and Dyer, 2013).

LIN28B encodes an RNA binding protein developmentally regulated that blocks the expression of *let-7* family of micro-RNAs (Matthay et al., 2016). *LIN28B* and *let-7* are involved in stem cell differentiation with opposing effects, inhibiting and promoting differentiation, respectively. *LIN28B* was expressed at significantly higher levels in NB lines homozygous for the risk allele, which correlated with low levels of *let-7*, and its inhibition decreased cell growth (Matthay et al., 2016). In a murine model, forced expression of *LIN28B* under the *Dbh* promoter drives development of NB with high levels of N-MYC (Matthay et al., 2016). Mechanistic studies have shown that besides depleting *let-7* family of micro-RNAs, LIN28B modulates the activity of the GTP-binding nuclear protein RAN and the stability of Aurora Kinase A (AURKA), pointing at potential therapeutic benefits on using AURKA inhibitors in these patients (Matthay et al., 2016).

Chromosomal Instability

Ploidy is one of the strongest prognostic determinants in NB (Cheung and Dyer, 2013). In general, low/intermediate and 4S NB have whole chromosomal gains (hyperdiploidy) and high risk have intrachromosomal segmental rearrangements (Cheung and Dyer, 2013). It is thought that together with oncogene amplifications, large scale genomic alterations may deregulate messenger RNAs, micro RNAs and other non coding RNAs, that interfere with apoptosis, differentiation and immune surveillance (Cheung and Dyer, 2013). The incidence of segmental chromosomal aberrations increases with age at diagnosis (from infants to children) and is a predictor of outcome (Cheung and Dyer, 2013). Markers of poor prognosis include losses of 1p, 11q and gain of 17q, present in up to 35%, 40% and 50% respectively (Ahmed et al., 2017).

Loss of 11q is associated with older age (30%–60% in adolescents and young adults), no *MYCN* amplification and more chromosomal breaks (commonly associated with 17q gain and 3p loss) (Mlakar et al., 2017). It is reported in 20%–45% of all high risk NB, depending on detection method used (Matthay et al., 2016). Loss of heterozygosity has been detected in 34%–44% of cases, also associated with high risk features (Mlakar et al., 2017). 11q23 is the region most commonly deleted (Mlakar et al., 2017). Chromosomal instability is one of the main features of 11q deleted tumors (Mlakar et al., 2017). Mapping studies are trying to determine the candidate coding genes (*CCND1*,*CHK1*), and miRNAs within that region; none alone has to date mimicked 11q loss (Mlakar et al., 2017).

Chromothripsis, that occurs in 2%–3% of human tumors, has been described in up to 18% of stage 4 tumors though there is variability within different series (Cheung and Dyer, 2013).

Some recurrent segmental alterations also occur at relapse, including 1p and 6q deletions (Matthay et al., 2016). Presence of candidate tumor suppressor genes in deleted regions of 1p have been identified: *CHD5*, *CAMTA1*, *KIF1B*, *CASZ1* and *mir-34A* (*Matthay et al., 2016*).

NB Methylome

The NB genome is epigenetically distinct, being largely hypomethylated (Decock et al., 2016). Differences at an epigenomic level cluster in groups that correlate with clinicobiological features (Decock et al., 2016). NB methylation changes affect all chromosomes, with hypomethylated regions being enriched in chromosome 6, and hypermethylated regions being more abundant in chromosomes 1 and 5 (Decock et al., 2016).

DNA methylation of cytosines in the context of CpG dinucleotides is a major regulatory mechanism implicated in cellular processes critical for mammalian development (Gomez et al., 2015). At a CpG level, high risk NB tumors show higher levels of hypermethylation compared to low risk tumors, targeting mainly enhancers and polycomb repressed regions, affecting genes involved in differentiation, neuron development and biosynthetic processes. Low risk tumors show limited number of de novo CpG hypermethilated sites, mostly in promoter and enhancer related regions of genes, including *LIN28B*. Hypomethylation in low risk tumors is seen in genes related to development (*FOXP1*, *SOX13*, *RARRES3*) and in high risk tumors, in genes related to regulation of gene expression and RNA processing.

The methylome of human embryonic stem cells as well as adult human and mouse brain cortex is enriched for methylation in non-CpG sites (Gomez et al., 2015). Similar to CpG methylation, non-CpG methylation goes through a process of reconfiguration during development (Gomez et al., 2015). Significant non-CpG methylation changes have been found to correlate with NB clinicobiologic features: higher non-CpG methylation was found to be associated with favorable biology, wheras in

unfavorable tumors, non-CpG methylation was very low or absent (Gomez et al., 2015). *ALK* is one of the genes found to be regulated by non-CpG methylation in clinically favorable tumors rendering low *ALK* expression levels, in contrast to unfavorable tumors (Gomez et al., 2015). In pre- and post chemotherapy coupled samples where treatment related histological signs of differentiation were seen, higher levels of non-CpG site methylation were also found, showing that non-CpG methylation is modulated during treatment induced NB differentiation, and may be associated with changes in *ALK* gene expression(Gomez et al., 2015).

Tumor Regression

Several mechanisms have been proposed to explain the phenomenon of spontaneous regression of NB, including neurotrophin deprivation, humoral or cellular immune response, loss of telomerase activity or alterations in epigenetic regulation (Matthay et al., 2016; Ratner et al., 2016).

High TrkA, a neurotrophin receptor, is associated with favorable clinical and biological features. These tumors in vitro undergo neuronal differentiation when exposed to nerve growth factor (NGF, TrkA ligand), and these same cells die within a week when deprived from NGF. These culture conditions recapitulate the behavior of high TrkA tumors which either undergo differentiation or regression depending on the presence of NGF in the microenvironment. Migrating neural crest precursors (and favorable NB with high TrkA) can survive despite a lack of NGF in the microenvironment upon the expression of TrkAIII, a constitutively active alternatively spliced isoform. Thus, the conversion from TrkA, NGF independent to an NGF dependent tumor, could be a consequence of a developmentally programmed switch from TrkAIII to TrkA. NGF depletion in developing sympathetic neurons induces pro-apoptotic gene expression: *TP53*, *TP63*, *E2F1*, *UNC5D*, *KIF1B* and *PRUNE2*, which are also expressed at high levels in favorable NB tumors, including 4S (Matthay et al., 2016).

High risk disease evades the attack from the immune system by downregulating the expression of HLA class I molecules (Cheung and Dyer, 2013). On the contrary, patients with 4S NB express normal levels of class I HLA, which may augment immune surveillance and response (Ratner et al., 2016).

Telomeres are important for chromosome replication and stability, and its length is partly controlled by telomerases (Ratner et al., 2016). Telomerase activity is low in 4S NB, consistent with absence of *TERT* expression, suggesting that telomere crisis may also have a role in tumor regression (Ratner et al., 2016).

Finally, epigenetic developmental changes affecting DNA methylation, histone modifications and chromatin remodeling, may impact the survival of these cells and lead to spontaneous regression (Ratner et al., 2016).

Risk Stratification

Age and stage at diagnosis together with the presence of *MYCN* amplification, are the three strongest determinants of outcome (Cheung and Dyer, 2013). Those features, combined with loss of 11q, histological properties and ploidy, are the foundations of the current risk stratified classification of NB. There are two different staging systems currently in use, with the main difference being presurgical (International Neuroblastoma Risk Group, INRG) vs post-surgical (Intenational Neuroblastoma Staging System, INSS) tumor extent evaluation (**Table 2**). The benefit of the INRG classification is that it makes pretreatment patient cohorts comparable among different groups, with no surgical bias. Extent of disease is stablished upon the absence (L1) or presence (L2) of image defined risk factors (IDRFs) for locoregional tumors (Cohn et al., 2009). IDRFs refer to involvement of anatomical structures that increase surgical risk (Monclair et al., 2009). Stage M refers to widespread metastatic disease. Stage MS (S for special) refers to distant disease in children 0–18 months, limited to skin, liver and $<10\%$ bone marrow with no cortical bone involvement (Cohn et al., 2009). Besides staging evaluation, the INRG classification expands the infant group up to 18 months of age (Cohn et al., 2009), a major shift in risk classification that spares the 12–18 month age group of high dose chemotherapy and radiation. The INRG is a more granular definition of pretreatment risk group classification among the very low, low, intermediate and high risk categories (Cohn et al., 2009).

Table 2 International neuroblastoma staging system

Stage 1	Localized NB not crossing midline. Complete gross surgical excision. No metastasis to ipsilateral lymph nodes that were not attached to the tumor
Stage 2A	Localized NB not crossing midline but incomplete surgical resection
Stage 2B	Localized NB not crossing midline but presence of ipsilateral lymph node involvement
Stage 3	NB crossing midline and unresectable, with or without regional lymph node involvement Localized NB not crossing midline with bilateral lymph node involvement Localized NB with epidural extension
Stage 4	Any or no primary, with metastasis to distant sites (except 4S distribution)
Stage 4S	Localized primary (stage 1-2B), <1 yo, metastases limited to skin, liver or bone marrow ($<10\%$ involvement)

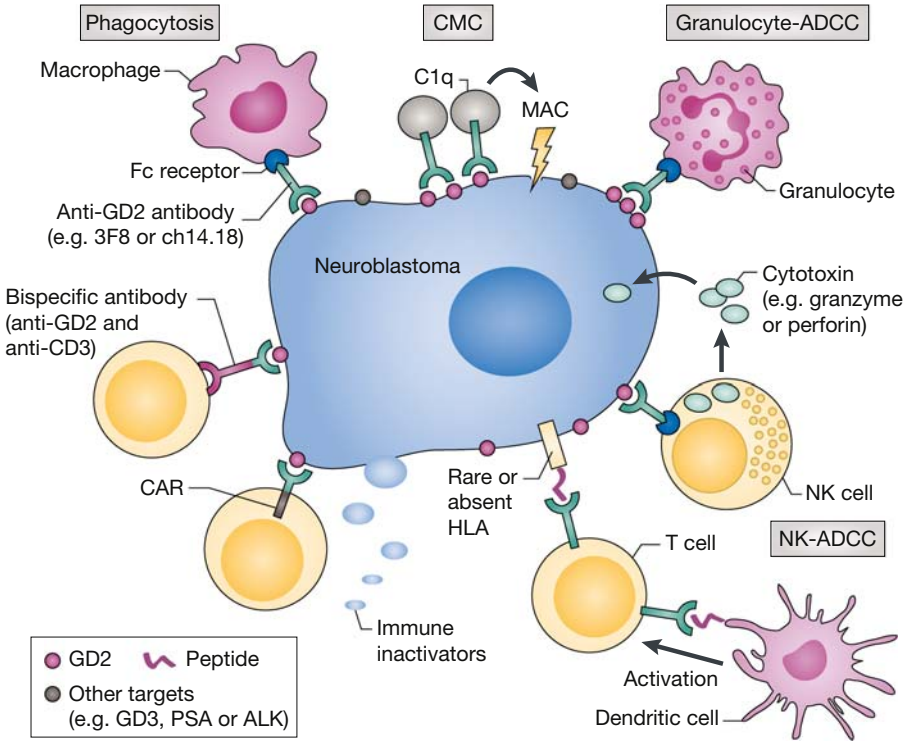

Fig. 5 *Immunotherapy against NB*: NB evades T-cells by downregulating or losing HLA expression, thereby interfering with the afferent arm (priming through dendritic cells), homing of T-cells to NB, and the CTL effector phase of adaptive immunity. Soluble inhibitors of immune response (e.g., FasL, gangliosides) are constantly released into the tumor stroma to impair cellular immunity. In addition, NB recruits pro-tumor macrophages and silences NK cells. Myeloid suppressor cells and T-reg can also suppress immunity. The paucity of mutations in NB compared to adult cancers like melanoma, the immaturity of the immune system in young patients, their massive disease and the intensive chemotherapy all combine to make NB poorly immunogenic for T-cells. Carbohydrate differentiation antigens (e.g., GD2, GD3 and polysialic acid (PSA)), all of which being classically T-independent antigens, offered alternative targets for antibody-based therapies. In the presence of monoclonal antibodies (e.g., 3F8 or ch14.18) specific for GD2, NB loses their defense and becomes highly susceptible to (1) NK (natural killer) cell mediated antibody-dependent cell mediated cytotoxicity (ADCC), (2) granulocyte mediated ADCC (3), complement mediated cytotoxicity by binding to C1q thereby activating the complement cascade, delivering membrane attack complex (MAC) to tumor cell membrane, and (4) monocyte-macrophage mediated cytotoxicity. Even polyclonal T-cells can be retargeted to kill NB through MAbs in the form of chimeric antigen receptors (CAR) or bispecific antibodies (anti-GD2 x anti-CD3). CARs are anti-tumor single chain Fv fragments (scFv) genetically fused through a transmembrane domain to T-cell activating motifs (CD3 ξ and CD28/41BB) and transfected into killer lymphocytes. Reprinted from Cheung, N. K, Dyer, M. A. (2013). Neuroblastoma: Developmental biology, cancer genomics and immunotherapy *Nature Reviews Cancer* **13**, 397–411, https://doi.org/10.1038/nrc3526.

Immune Microenvironment and Immunotherapy

Beyond the paucity of somatic mutations that confers NB low immunogenicity, these tumors have developed an immunosuppressive microenvironment to protect themselves from the development and function of effective immune response (Cheung and Dyer, 2013) (**Fig. 5**).

Immune Evasion

NB escapes T cells and natural killer (NK) cell surveillance by downregulation of HLA and adhesion molecules (Cheung and Dyer, 2013). NB cells can express or release proteins that inhibit or eliminate T cells and NK cells, and recruit tissue macrophages to help disable these lymphocytes (Cheung and Dyer, 2013). Patients older than 18 months with *MYCN* nonamplified tumors, have shown to have higher expression of inflammatory genes in tumor associated macrophages (TAMs), such as *CD33*, *FCGR3* (also known as *CD16*), *IL6R*, *IL10* and *CD14*, associated with adverse prognosis. Increased levels of prostaglandin E_2 have been seen in 11q deleted tumors (Matthay et al., 2016). How macrophages or other myelolid cells affect tumor growth is yet to be discerned: IL6R, expressed in NB cells, binds IL6, produced by TAMs, and activates signal transducer and activator of transcription 3 (STAT3) transcriptional program, which affects proliferation, drug resistance and immune evasion(Matthay et al., 2016).

NB cells also express on their surface ganglioside and sialic acid containing sugars and proteins important for migration, adhesion and metastasis (Cheung and Dyer, 2013). These epitopes are poorly immunogenic and in preclinical models immunosuppressive (Cheung and Dyer, 2013). Development of natural host antibodies against NB is rare; hence, NB survives in circulation despite the lack of complement decay accelerating factor (CD55). It can also express protectin (CD59) to resist complement mediated lysis

(Cheung and Dyer, 2013). While NB downregulates HLA to evade T cells, it can also re-express HLA to resist NK cell antibody dependent cell mediated cytotoxicity (NK-ADCC) when treated with monoclonal antibodies (MAbs) (Cheung and Dyer, 2013). NB may also escape to or hide in immune sanctuaries like the CNS (Cheung and Dyer, 2013). In fact, the increasing frequency of CNS, soft tissues and bone relapses, is creating a new challenge in the era of MAb therapy (Cheung and Dyer, 2013; Kramer et al., 2010).

Monoclonal Antibody (MAb) Therapies

GD2 is an oncofetal differentiation antigen expressed during fetal development in maturing neurons, pain fibers and skin cells (Cheung and Dyer, 2013). It belongs to a unique class of T cell independent carbohydrate antigens with high density, membrane proximity, homogeneity within and across NBs and rare occurrence of antigen loss (Cheung and Dyer, 2013). Research over the past 20 years has demonstrated that high risk patients can be maintained in remission with anti-GD2-specific MAb therapy, and therefore it is currently standard of care for these patients (Cheung and Dyer, 2013; Kushner, 2017; Cheung et al., 2012) (**Fig. 6**). Granulocyte and NK cell mediated ADCC are important effector mechanisms (Cheung and Dyer, 2013). By activating effector cells, anti-GD2 MAb therapy can be more effective, and for that purpose, regimens include concomitant administration of IL-2 and/or granulocyte-macrophage colony stimulating factor (GM-CSF) (Cheung and Dyer, 2013; Yu et al., 2010). IL-2 activates NK cells and has a modest effect against NB as a single agent, though has significant toxicity with the development of capillary leak syndrome (Cheung and Dyer, 2013). IL-15 has been shown to activate NK, NK-T and CD8 T cells without causing capillary leak syndrome, activation-induced cell death or increased T_{reg} activation in primates (Cheung and Dyer, 2013). It could be an alternative to IL-2.

Five different intravenous antibodies have been tested clinically: 14G.2a, chimeric 14.18 (ch14.18, dinutuximab, Unituxin™), hu14.18-K322A, murine m3F8 and humanized hu3F8. Intravenous ch14.18 administered with (GM-CSF), IL-2 and oral isotretinoin was shown to improve OS, but not EFS in a randomized trial. 3F8 with subcutaneous GM-CSF m3F8 + GM-CSF cleared BM of chemoresistant histologically-evident NB in 87% of patients with primary refractory disease (Cheung et al., 2014) and improving 10-year long-term survival of these patients (45%), as well as those treated in ≥second remission (44%) (Kushner et al., 2015) and in first remission (67%) (Cheung et al., 2012; Kushner et al., 2015), among high risk stage 4 patients. Dose is limited by pain, believed to be secondary to complement activation (Cheung and Dyer, 2013). Mutations in the Fc region and complement blocking antibodies have been tested to decrease complement activation, ameliorating though not eradicating pain (Cheung and Dyer, 2013). The presence of minimal residual disease (MRD) after two cycles of immunotherapy is predictive of treatment failure (Cheung and Dyer, 2013).

One critical observation in patients receiving anti-GD2 MAb therapy is the induction of a host anti-tumor or antiidiotype response, which may be important for long term tumor control (Cheung and Dyer, 2013). Human antimouse Ab (HAMA), an indirect measure of the host antiidiotype network, correlated with long term survival in patients that received murine 3F8 (Cheung and Dyer, 2013). This observation led to the development of antiidiotypic vaccines, though their efficacy may be limited by their narrow target coverage (Cheung and Dyer, 2013). The oligosaccharide GD2 antigen has also been conjugated to keyhole limpet hemocyanin (KLH) to overcome poor immunogenicity producing long term remission (Cheung and Dyer, 2013; Kushner et al., 2014).

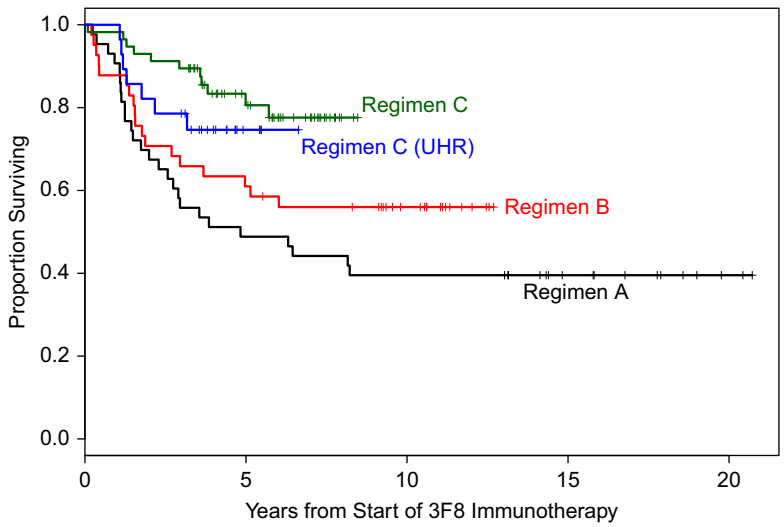

Fig. 6 *Kaplan Meier Survival curves of High Risk NB patients from initiation of anti-GD2 immunotherapy.* Overall survival (OS) among 169 patients with stage 4 neuroblastoma in first remission after consecutive immunotherapy regimens: 3F8 alone (regimen A–high risk [HR]; $n = 43$), 3F8 + intravenous granulocyte-macrophage colony-stimulating factor (GM-CSF) + 13-*cis*-retinoic acid (CRA; regimen B-HR; $n = 41$), and 3F8 + subcutaneous GM-CSF + CRA (regimen C-HR; $n = 57$ and regimen C–ultra HR [UHR]; $n = 28$); $P = 0.003$ (derived from log-rank test to compare OS among these four groups). Murine anti-GD2 monoclonal antibody 3F8 combined with granulocyte-macrophage colony-stimulating factor and 13-cis-retinoic acid in high-risk patients with stage 4 neuroblastoma in first remission. *Journal of Clinical Oncology*, **30**, 3264–3270.

GD2 has also been used as a target using antibodies for selective delivery of radioisotopes, nanoparticles and liposomes (Cheung and Dyer, 2013).

In the study of other potential surface targets, candidates such as GD3, GPC2, ALK, polisyalic acid, L1CAM and B7-H3 are being evaluated (Cheung and Dyer, 2013; Ahmed et al., 2015; Bosse et al., 2017). B7-H3 specific MAb 8H9 has been used successfully in compartimental radioimmunotherapy of CNS NB metastasis, a complication previously incurable (Kramer et al., 2010). More recently, a drug conjugated antibody against GPC2 has shown promising in vitro data (Bosse et al., 2017).

T Cell Mediated Immunity

Recovery of T cell function after high dose chemotherapy is required for effectiveness of T cell mediated strategies. NB antigens that can be recognized by cytotoxic T cells (CTLs) exist, such as cancer testes antigens, N-MYC and survivin; however, the absence or down regulation of HLA expression can severely limit CTL efficiacy (Cheung and Dyer, 2013). Despite preclinical efficacies in animal models, there has been limited success in clinical trials with the use of vaccines for classic T cell mediated adaptive immunity (Cheung and Dyer, 2013). Dendritic cell vaccines are also being developed without much clinical success (Cheung and Dyer, 2013).

The use of immune checkpoint inhibitors is being studied in many pediatric tumors including NB (Wagner and Adams, 2017). The Cytotoxic T-Lymphocyte Associated Protein 4 (CTLA4) was the first target for immune checkpoint inhibitiors (ICI), which binds to B7.1 and B7.2. CTLA4 expression occurs upon T cell activation, and once present curtails T cell activity (O'Donnell et al., 2017). Programmed Death 1 (PD-1) is another important checkpoint, when binding to its ligand (PD-L1), halts T cell activation and induces T cell exhaustion (O'Donnell et al., 2017). PD-L1 is expressed in a variety of different tumors, dendritic cells, macrophages and T cells (Wagner and Adams, 2017; O'Donnell et al., 2017). There is increasing evidence of increased PD-L1 expression with mutational burden or microsatellite instability in some pediatric sarcomas, NB and high-grade gliomas. Despite the expression of PD-L1 in up to 70%–100% NB tumors studied and the association of lower survival with higher PD-L1 expression, clinical results with ICIs have been disappointing (Wagner and Adams, 2017). The presence of inflammation (through interferon gamma) and hypoxia within a tumor have been shown to upregulate PD-L1 expression (Wagner and Adams, 2017). Interestingly, anti-GD2 therapy can induce cytokines within tumors, including interferon gamma, *ergo* enhancing PD-L1 tumor expression, suggesting a potential benefit of combined anti-GD2 and anti PD-L1 therapy to invigorate NK-ADCC (Wagner and Adams, 2017).

Given that autologous tumor reactive T-cells rarely develop in these patients, genetically redirected T cells, using chimeric antigen receptors (CARs) (Cheung and Dyer, 2013) and bispecific antibodies (BsAb) (Wu and Cheung, 2017) hold promise. Anti-GD2 and anti-L1CAM CAR-T cells have been tested, though the persistence of these cells was short-lived (Cheung and Dyer, 2013). To enhance survival, Epstein Barr virus (EBV) specific CTLs, which are life long from continuous antigenic challenge, have also been used(Cheung and Dyer, 2013). These dual specific T cells, anti-EBV through its T-cell receptor and anti-GD2 through the CAR, seem to persist and control the tumor for years (Cheung and Dyer, 2013). Similar strategies for NK and NKT cells are being explored. More recent studies highlight the exhaustion of CAR-T cells when they come into contact with tumor or antigen. BsAb (CD3xGD2) are showing great promise whereby polyclonal T cells can be activated without exhaustion to infiltrate neuroblastomas turning them from "cold" into "inflamed," overcoming PD-L1 resistance, leading to tumor ablation (O'Donnell et al., 2017). Here ICIs have shown benefit in preclinical models and clinical results should soon become available.

Conclusions and Prospective Vision

Neuroblastoma is a very heterogeneous disease which exemplifies how both tumor and host developmental biology intertwine at presentation, marked by a molecular and immunologic signature that determine tumor behavior and prognosis. While some tumors regress spontaneously with >95% cure rates, others are lethal despite multimodal therapy. Aside from *ALK* and *ATRX*, the low mutanome has limited the general application of gene-specific targeted therapies, though increased use of WGS and epigenomics may identify subgroups of high risk patients which might benefit from pathway-specific targeted therapies. On the other hand, NB has been one of the most successful stories for immunotherapy with the use of MAb, where prolonged survival is sustained over decades. Therapeutic strategies to engage T cells, vaccinate host immune system while decreasing treatment side effects, should further improve the prognosis for a metastatic solid tumor whose cure was unthinkable just two decades ago.

New Rationales and Designs for Clinical Trials in the Era of Precision Medicine

Mina Nikanjam and Razelle Kurzrock, UC San Diego Moores Cancer Center, San Diego, CA, United States

Glossary

Basket study A study that treats various cancers based on genomic characteristics and pools patients independent of histologic diagnosis.

Master protocol A study that combines the features of basket, umbrella, and platform studies testing multiple histologies with multiple platforms.

Matched therapy Providing a therapeutic regimen which incorporates at least one targeted agent which is specific to an identified tumor genetic alteration.

Molecular profiling The identification and documentation of the structure of a specific DNA, RNA, or protein molecules, in particular the alterations for standard present in tumors.

Octopus study A study that tests multiple drugs.

Platform study A study based on a technologic biomarker platform.

Precision medicine The customization of medical decisions, practices, or products which are tailored to the individual patient.

Umbrella study These studies enroll patients who share a tumor type, test molecular markers for a wide variety of potential molecular targets, and then assign patients to an arm of the study.

Introduction

The vast and rapidly expanding body of knowledge about cancer genomics has enabled the development of therapies targeted to specific molecular alterations or other biomarkers. While standard late-stage oncology clinical trials are histology specific, this model is suboptimal for assessing the efficacy of genomically targeted agents. It may also be suboptimal for evaluation of immunotherapy, as recent studies indicate that response to immunotherapy (checkpoint blockade with anti-PD-1/PD-L1 agents) can be predicted based on genomic markers such as microsatellite instability high (MSI-H) or high tumor mutational burden (TMB). The goal of precision medicine-based trials is to generate insight into relationships between biomarkers in tumors and responses. The most successful biomarkers to date have been genomic, but other biomarkers based on protein assays, transcriptomics, and more are emerging. One of the most important observations emerging from next generation sequencing (NGS) of solid tumors is that molecular alterations do not segregate by tumor organ of origin. Further, metastatic solid tumors harbor complex and unique genomic landscapes—no two are alike. The term "malignant snowflakes" has been coined to reflect this heterogeneity and distinctness.

These observations present a conundrum for the practice of precision medicine. In order to target tumors "precisely," it appears that therapy must be "personalized." Hence, the reality unveiled by genomic science, that is, the need for N-of-one treatments, does not fit well with canonical trial design that attempts to find commonalities between patients and treat them alike. Novel clinical trial designs are necessary. Most likely, these innovative designs will eventually focus on a unified strategy for assigning patients to treatment, but will permit different drugs for each patient based on the aberrations in their cancer. Herein, we review the evolution/revolution that is taking place in clinical research in the era of precision medicine.

Basket, Umbrella, Platform, Octopus, and Master Protocols

The cornerstone of traditional clinical trials in oncology has been finding commonalities between patients so that they can be fit onto a specific drug regimen (drug-centered trial). Historically, the commonality was organ of origin of the tumor (e.g., breast cancer trial or lung cancer trial). Newer designs base eligibility on biomarker commonalities. For instance, basket trials will treat a single gene alteration across multiple histologies (e.g., *BRAF*-altered basket trial). Other new types of trials include the following: umbrella trials, which examine multiple genomic alterations within a single histology; platform trials, which include multiple histologies and genomic or other biomarkers, but are based on a single technological platform (e.g., NGS) to interrogate the tumor; octopus trials (previously coined complete phase I trials when performed in the phase I setting) that have multiple arms testing different drug combinations; and master protocols, which can be comprised of multiple histologic arms (previously known as "broad phase II trials") or multiple basket or umbrella subtrials, trials, and/or multiple platforms. The ultimate evolution of the master protocol is to the patient-centered, N-of-one trial that permits individualized treatment based on the best available biomarkers.

Basket Trials

Basket trials treat various cancers based on genomic characteristics and pool patients independent of histologic diagnosis. These trials assume that response to targeted therapy can be evaluated independently from tissue of origin and independent of other molecular aberrations in the tumor; thus enrollment can be increased by combining patients with different tumors in the same studies. Some trials can be modified over time as new targets and treatments are identified. This design can result in certain arms opening and closing quickly. This methodology allows the testing of many potentially active drugs simultaneously.

Umbrella Trials

Umbrella studies enroll patients who share a tumor type, test molecular markers for a wide variety of potential molecular targets, and then assign patients to an arm of the study. Each arm represents a potentially effective treatment for the molecular marker. As with basket trials, some trials can be changed over time as new targets and therapies are discovered. This design can result in certain arms opening and closing rapidly, permitting the testing of many agents simultaneously.

Octopus Study

An octopus study design denotes multiple arms testing different drugs or drug combinations in a single trial. These were considered "complete phase I trials" (a terminology coined by Dan Von Hoff) when performed in the phase I setting.

Platform Study

Traditional

Traditional platform trials include multiple histologies and genomic or other biomarkers and are based on a single technological platform (e.g., next generation sequencing (NGS)) to interrogate the tumor. The standard platform trial design consists of a fixed number of treatments. There are several treatments and a control with equal randomization and a fixed number of patients in each arm. No additional treatment can be added beyond those included at the start of the trial. Each treatment is compared to the control. A modification of this strategy uses interim monitoring for success and futility at equally spaced intervals. If a treatment is dropped due to futility, the accrual on the remaining active arms is greater. The open platform employs an adaptive design where treatments can be dropped or added during the course of the trial. New treatments can be added to replace ineffective treatments during the trial. These trials have the potential to find effective treatment faster and with fewer resources than investigating one treatment per trial. They also do not require a new trial infrastructure for each treatment studied.

Innovative platform trials

Newer platform trials include multiple histologies and genomic or other biomarkers and are based on a single technological platform (e.g., NGS) to probe the tumor, but are not randomized.

Master Protocol

A master protocol uses either a single multiplex diagnostic assay to assign subjects to different candidate drugs or arms of the trial within the same trial or network of trials or it may use multiple discrete biomarker assays alone or in combination. Master protocols offer more options for patients and can also make screening and recruitment more efficient. A master protocol is an overarching protocol designed to answer multiple questions. Master protocols can include one or more interventions in multiple diseases or a single disease, with multiple interventions. Master protocols may include umbrella, basket, or platform trials.

Precision Medicine Clinical Trials and Studies With Results

Multiple studies have assessed the benefit of matching therapies to specific alterations. **Table 1** presents 19 studies with results. Of these studies, 4 were for a specific disease while 15 were for advanced cancers; 14 studies were prospective, 1 was retrospective, and 4 were registry-style studies. For these studies, the median number of patients screened was 698 with an interquartile range (IQR 25%–75%) 250–1360. The median percentage of patients matched was 17% with an IQR 12%–26%. Of the 11 studies that compared matched therapies to unmatched options, 10 of these studies (91%) showed a statistically significant benefit with the matched therapy. While these studies utilized different designs and had different objectives, collectively they show a net benefit in matching therapies to specific molecular alterations and provide motivation for evaluating new therapies with novel precision medicine-based trial designs.

Table 1 Precision medicine clinical trials with reported results (includes only studies where biomarkers were used to match patients)

Year	*First author/chairs*	*Trial name*	*Institute*	*Type of trial*	*Type of cancer*	*N (total screened)*	*% of patients matched*	*Type of biomarker*	*Outcome*	*Comment*	*References*
2010	Von Hoff	Bisgrove	US (9 sites)	Prospective navigation	Metastatic refractory cancer	106	62	IHC, FISH, microarray	27% of matched patients had a PFS ratio of $\geq$1.3 ($P = .007$)		Von Hoff et al. (2010)
2012	Tsimberdou Kurzrock	MD Anderson Personalized Cancer Therapy Initiative	MD Anderson	Registry style Navigational	Advanced cancer	1283	16	PCR-based	Response rate = 27% in matched vs. 5% unmatched ($P < .05$); Longer TTF (<0.001), OS (<0.001), and PFS ($P = .017$) in matched group		Tsimberidou et al. 2014	Johnson	N/A	Vanderbilt	Retrospective	Advanced cancers	103	17	NGS	N/A	No outcomes provided	Johnson et al. (2014)
2014	Kris	Lung cancer mutation consortium	14 sites	Prospective	Lung adeno-carcinoma	1537	18	Multiplex genotyping	Improved survival with matched therapy ($P = .006$)		Kris et al. (2014)
2014	Jameson	N/A	US sites	Prospective	Breast cancer	28	89	RRPA, cDNA MA, IHC, FISH	Time to progression with multiomic based treatment improved in 44%		Jameson et al. (2014)
2014	Tsimberdou Kurzrock	MD Anderson Initiative validation	MD Anderson	Registry style Navigational	Advanced cancers	1542	9	PCR-based	Longer response rate ($P < .0001$), PFS ($P = .001$), OS ($P = .04$) in matched group		Tsimberidou et al. (2014)
2015	Andre	SAFIR01/UNICANCER	Goustave Roussey (18 French sites)	Prospective	Metastatic breast cancer	423	13	aCGH/Sanger sequencing	9% response, 21% SD $>$16 weeks (matched group)		Andre et al. (2014)
2015	Le Tourneau	Shiva	Institut Curie (8 French sites)	Prospective Randomized	Refractory cancer	741	13	NGS	PFS not improved with matched therapy ($P = .41$)	$\sim$80% of patients received single agent hormone modulators or everolimus	Le Tourneau et al. (2015)
2016	Schwaederle Kurzrock	PREDICT	UC San Diego	Registry-type	Advanced cancers	347	25	NGS	Higher rates of SD $\geq$ 6 months/PR/CR, PFS, OS in matched group ($P = .039$)		Schwaederle et al. (2016)

2016 Wheler Kurzrock	MD Anderson personalized cancer therapy initiative	MD Anderson	Prospective Navigational	Advanced cancers	500	24	CGP/NGS	Higher rates of SD $\geq$ 6 months/PR/CR ($P = .024$), TTF ($P = .0003$), OS ($P = .05$) with better matching score		Wheler et al. (2016)
2016 Stockley	IMPACT/COMPACT	Princess Margaret (Canadian centers)	Prospective	Advanced cancers	1893	4.7	NGS	Higher overall response rate with matched therapy ($P < .026$)		Stockley et al. (2016)
2016 Aisner	Lung cancer mutation consortium II	16 sites	Prospective	Lung adeno-carcinoma	980	13	NGS	Improved survival with matched therapy ($P = .039$)		Aisner et al. (2016)
2016 Sohal	Cleveland clinic study	Cleveland clinic	Prospective	Advanced cancers	250	10	NGS	N/A	Outcomes not provided	Sohal et al. (2015)
2017 Sicklick Kurzrock	I-PREDICT	UC San Diego Avera	Prospective navigational	Advanced cancers	47	36	CGP	Longer PFS with matched therapy ($P = .0019$)	Preliminary results	Sicklick et al. (2017)
2017 Massard	MOSCATO	Goustave Roussey	Prospective	Advanced cancers	1110	18	aCGH, NGS, RNAseq	33% on matched therapy had improved outcome vs. prior baseline ($P = .004$)		Massard et al. (2017)
2017 Tsimberidou Kurzrock	IMPACT	MD Anderson	Registry-style Navigational	Advanced cancers	1436	27	PCR-based	Matched therapy with higher response ($P = .0099$), longer failure-free survival ($P = .001$), longer overall survival ($P < .001$)		Tsimberidou et al. (2017)
2017 Tredan	PROFILER	Centre Leon Berard (3 French sites)	Prospective	Advanced cancers	2676	5	NGS/aCGH	5 year OS 34.8% with matched vs. 28.1% for unmatched	Study is ongoing	Tredan et al. (2017)
2017 Hainsworth Kurzrock	MyPathway	Genentech (US sites)	Prospective	Advanced cancers	251	92	Genomic testing	23% response rate;38% HER2 group, 43% BRAF group	Study is ongoing; no comparison between matched therapy and prior therapy provided	Hainsworth et al. (2017)
2017 Kim	NEXT	Samsung Medical Center, Korea	Prospective	Advanced cancers	654	9	IHC/DNA sequencing	Improved clinical trial enrollment	Outcomes of matched therapy not provided	Kim et al. (2017)

Abbreviations: aCGH = Array comparative genomic hybridization, ASCO = American Society of Clinical Oncology, cDNA MA = cDNA microarray, CGP = comprehensive genomic profiling, FISH = fluorescence in situ hybridization, IHC = immunohistochemistry, N/A = not available, NGS = next generation sequencing, OS = overall survival, PCR = polymerase chain reaction, PFS = progression free survival, RRPA = reverse phase protein array, TTF = time to treatment failure.

Bisgrove Study

Von Hoff et al. (2010) performed a prospective navigational pilot study at nine United States sites attempting to match treatment regimens based on molecular profiling for patients with refractory metastatic cancer. A total of 106 patients were consented. Molecular profiling (IHC, FISH, and microarray analysis) was attempted in 81% ($N = 86$ patients) with molecular targets detected in 98% ($N = 84$): 68 of the screened patients (64%) were treated; 66 of the screened patients (62%) were treated according to molecular profiling and two patients (2%) were not. The use of matched therapy resulted in significantly longer progression-free survival as compared to each patient's own most recent prior progression-free survival from prior therapy (9.7 vs. 5 months, $P = .026$). Overall, 27% of matched patients had a progression-free survival ratio of greater than 1.3 as compared to their prior therapy ($P = .007$). The study concluded that molecular matching of therapy has a positive influence on the clinical course for an individual.

MD Anderson Personalized Cancer Therapy Initiatives

Four studies that described outcomes have been published. Matching rates ranged from 9%–27% of consented patients. All showed improvement in outcome parameters associated with matching. An exploratory Matching Score (number of matches divided by number of genomic alterations) for patients receiving combination therapies demonstrated significant correlation between higher Matching Scores and better outcomes (Wheler et al., 2016).

MD Anderson personalized initiative #1

Tsimberidou et al. (2012) reported an analysis of patients referred to the MD Anderson phase 1 clinical trials center with advanced cancer treated in the Clinical Center for Targeted Therapy aimed to determine if matching targeted therapies to detected molecular alterations would result in improved outcomes. Overall, 1283 patients were screened; 1144 patients (89%) had sufficient tissue for molecular analysis (polymerase chain reaction (PCR)-based genomic testing), and 36% ($N = 460$) were found to have at least one alteration. In total, 352 patients with molecular alterations were treated (27%). Matched therapy was administered to 211 (16%) patients and 144 (11%) did not receive matched therapy. The patients on matched therapy had improved response rates (27% vs. 5%, $P < .001$) and longer median progression-free (13.4 vs. 9.0 months, $P = .017$) and overall survival (5.2 vs. 3.1 months, $P < .001$).

MD Anderson personalized initiative validation

A follow-up validation registration-style navigational study with additional patients referred to the phase 1 clinical trial program at MD Anderson Cancer Center also explored differences between patients with advanced cancers who received targeted therapies and those who did not have a targeted option available (Tsimberidou et al., 2014). A total of 1542 patients were screened. Overall, 1276 patients (83%) had adequate tumor tissue for genomic analysis, 48% ($N = 739$) had at least one genomic alteration (PCR-based genomic testing). In total, 379 patients (25%) were treated: 143 patients (9%) received therapy matched to at least one alteration as compared to 236 (15%) who did not receive a matched therapy. The patients with matched therapy had greater median overall survival (11.4 vs. 8.6 months, $P = .04$), objective responses (12% vs. 5%, $P < .001$), and progression-free survival (3.9 vs. 2.2 months, $P = .001$). This was consistent with prior observations.

MD Anderson IMPACT

The Initiative for Molecular Profiling and Advanced Cancer Therapy (IMPACT) was a registry-style navigational study conducted at MD Anderson (Tsimberidou et al., 2017). Patients from the phase 1 clinical trials program with advanced cancer who underwent molecular analysis were assigned to clinical trials with a matched targeted agent when available. Of 1436 patients with molecular profiling by PCR-based genomic testing, 914 (77.5%) had a targetable mutation, 637 (44%) were treated: 390 with matched therapy (27%) and 2247 with nonmatched therapy (17%). Patients with matched targeted therapies had higher rates of response (11% vs. 5%; $P = .0099$), longer failure-free survival (3.4 vs. 2.9 months; $P = .0015$), and longer overall survival (8.4 vs. 7.3 months, $P = .041$).

MD Anderson/Foundation Medicine comprehensive genomic profiling prospective study

A prospective navigational single-center study at MD Anderson to evaluate the use of comprehensive genomic profile directed therapy enrolled 500 patients with advanced malignancies (Wheler et al., 2016). Molecular testing was performed on 339 patients (68%) using comprehensive genomic profiling/next generation sequencing performed by Foundation Medicine. Overall, 188 patients were treated (37%), 122 received matched therapy (24%), and 66 (13%) received unmatched therapy to at least one of the molecular alterations found on molecular profiling. Patients with high degrees of drug matches (high Matching Score) to molecular alternations were found to have significantly longer survival (hazard ratio [confidence interval] 0.65 [0.43–1.0], $P = .05$) and frequency of stable disease more than 6 months, partial response, or complete response (22% vs. 9%, $P = .024$).

UC San Diego

Two studies from UC San Diego have been published. Between 25% and 36% of consented patients received matched therapy. Both studies showed improvement in outcomes with matching.

Predict

The University of California San Diego PREDICT (Profile Related Evidence Determining Individualized Cancer Therapy) is a registry-type master protocol that aims to learn more about personalized cancer therapy including response to treatment and side effects. The study reviewed 347 consecutive patients with advanced solid tumors who had next generation sequencing performed (Schwaederle et al., 2016). In total, 180 patients (52%) were treated: 87 patients (25%) were treated with matched therapy as compared to 93 patients (27%) treated with unmatched therapy. Patients who had therapy matched to molecular alterations had better outcomes with longer overall survival (15.7 vs. 10.6 months, $P = .04$) and response (stable disease for more than 6 months, partial response, and complete response: 34.5% vs. 16.1%, $P = .02$).

UC San Diego I-PREDICT

The Investigation of Molecular Profile-Related Evidence to Determine Individualized Therapy for Advanced or Poor Prognosis Cancers (I-PREDICT) is a two-institution (UCSD and more recently Avera), prospective navigational study of personalized cancer therapy aimed to use genomic testing of tumor tissue to provide matched therapy recommendations to physicians at the University of California San Diego (Sicklick et al., 2017). Preliminary results demonstrated that of the 47 patients evaluated, 40 (85%) had complete genomic profiling (next generation sequencing) available, 22 (47%) were treated, 17 (36%) received matched therapies, and 11% received unmatched therapies. Overall, 53% of the matched patients achieved stable disease >6 months/PR/CR. Median progression-free survival for matched patients was 4.7 as compared to 1.0 months without matched therapy ($P = .0019$). The study is ongoing.

Shiva

The SHIVA trial (Le Tourneau et al., 2015) was an open-label prospective randomized phase 2 study of refractory cancer completed in France to assess the efficacy of several molecularly targeted agents. Molecular profiling of each patient's tumor was determined using next generation sequencing and patients were included with alterations in hormone receptors, the PI3 kinase/AKT, mTOR pathway, or the RAF/MEK pathways and were matched to 10 prespecified regimens. These regimens included 11 targeted agents: dasatinib, erlotinib, everolimus, imatinib, lapatinib with trastuzumab, letrozole, sorafenib, tamoxifen, and vemurafenib. Patients were randomly assigned to receive matched therapy with a molecularly targeted agent or the physician's choice. Overall, 741 patients were screened for the study and 293 were enrolled with 191 patients treated (26%): 99 patients (13%) were assigned to receive molecularly targeted therapy and 92 (12%) were in the control group. Median progression free survival was 2.3 vs. 2.0 months (hazard ratio [95% confidence interval]: 0.88 [0.65–1.19], $P = .41$). The study suggested that molecular matching of therapies outside of approved uses was not beneficial. Other reviews of the study have suggested that it was limited by a small number of molecular alterations and the therapeutic options included, since approximately 80% of patients in SHIVA were matched to single-agent hormone modulators or mTOR inhibitors.

MOSCATO

The MOSCATO 01 trial (Massard et al., 2017) was a prospective trial characterizing genomic alterations in advanced cancers performed at the Goustave Roussey Institute in France. Patients had molecular profiling with array comparative genomic hybridization, NGS, or RNA sequencing. A total of 1110 patients were screened, 843 (76%) had molecular profiling, 411 (37%) had an actionable mutation, and 199 (18%) received matched therapy. Of the patients treated on matched therapies, 33% of patients had an improved outcome compared to their prior baseline reference progression-free survival ($P = .004$); 11% had objective responses.

SAFIR-01/UNICANCER

The SAFIR-01/UNICANCER (High Throughput Technologies to Drive Breast Cancer Patients to Specific Phase I/II Trials of Targeted Agents; Andre et al., 2014) study was a prospective evaluation of women with metastatic breast cancer at 18 French study sites aimed to identify genomic abnormalities and provide matched targeted therapies. Molecular testing was performed using comparative genomic hybridization and Sanger sequencing. The study enrolled 423 patients, 195 (46%) had targetable mutations, and 55 (13%) received a matched therapy. Of the 43 evaluable patients receiving a matched, targeted therapy 4 had a partial response and 9 had stable disease for more than 16 weeks. No comparison was made between matched and unmatched outcomes in the publication.

Impact/Compact

The Princess Margaret Cancer Center led the Integrated Molecular Profiling in Advanced Cancers Trial (IMPACT) and Community Molecular Profiling in Advanced Cancers Trial (COMPACT) which were prospective studies at Canadian sites led by the Princess Margaret Cancer Centre with the goal of determining outcomes with matched therapies for advanced solid tumors (Stockley et al., 2016). Molecular profiling was completed with next generation sequencing. A total of 1893 patients were enrolled, 89 patients (4.7%) were given matched therapies. The response rate was 19% with matched therapies compared to 9% with unmatched therapies ($P < .026$).

PROFILER

The Program to Establish the Genetic and Immunologic Profile of Patient's Tumor for All Types of Advanced Cancer (PROFILER) is a prospective, nonrandomized, multicenter, cohort study which aimed to implement a personalized medicine approach by determining the genetic and immunologic profile of tumors for patients with advanced cancers (Tredan et al., 2017). The study was led by Centre Leon Berard and conducted at three French sites. Molecular testing was performed with next generation sequencing and array comparative genomic hybridization. Of the 2676 patients consented, 940 (35%) had at least one actionable mutation, 143 patients (5%) of patients were treated with matched therapies, and 502 patient did not received matched therapies (19%). The overall 5 year survival rate was higher with matched therapy (34.8% vs. 28.1%).

Lung Cancer Mutation Consortium

The Lung Cancer Mutation Consortium was a prospective multisite study which enrolled 1537 patients with metastatic adenocarcinoma of the lung and evaluated patients for mutations (Kris et al., 2014). Of these, 733 patients (48%) were genotyped using multiplex genotyping, 617 (40%) were treated, 275 (18%) received a targeted therapy, and 342 patients (22%) did not receive a matched therapy. Overall survival improved from 2.4 years to 3.5 years ($P = .006$) with the use of a matched therapy.

The Lung Cancer Mutation Consortium II study (Aisner et al., 2016) was a prospective study which enrolled 980 patients and obtained molecular profiles using next generation sequencing. Of these, 191 patients (19%) were treated, 127 (13%) received targeted therapy, and 74 (8%) did not received targeted therapy. Overall survival was again improved from 1.5 to 2.8 years with the use of targeted therapy ($P = .039$).

MyPathway

The MyPathway trial (Hainsworth et al., 2017) is a multicenter, nonrandomized, prospective study sponsored by Genentech of patients with advanced solid tumors who progressed after standard therapy or for which there is no approved treatment which is ongoing at United States sites. Patients had at least one potentially actionable genetic alteration as determined by a CLIA certified laboratory. Overall, 251 patients have been enrolled and 230 (92%) were matched into four groups: erlotinib (*EGFR* mutation), vemurafenib (*BRAF V600E* mutation), vismodegib (Sonic hedgehog pathway mutation), or pertuzumab/trastuzumab (*HER2* amplification). A total of 52 patients (21%) had objective responses. The *HER2* group had a 38% (14 out of 37 patients) response rate while the *BRAF V600* mutated group had a 43% (6 out of 14 patients) response rate. The publication did not compare matched to unmatched therapies or the current response on matched therapy to prior response on unmatched therapy. The study is currently ongoing.

Other Studies

Vanderbilt Ingram Cancer Center conducted a retrospective study to determine actionable mutations in advanced cancers (Johnson et al., 2014). Molecular profiling was completed using next generation sequencing. Of 103 patients receiving genotyping, 86 (83%) had potentially actionable mutations, however only 18 patients (17%) were treated on matched therapies. Outcomes of matched compared to nonmatched therapies were not provided in the publication.

A prospective pilot study of the use of multiomic molecular profiling looked at 28 women with metastatic breast cancer (Jameson et al., 2014). Molecular testing was preformed using cDNA microarray, immunohistochemistry, fluorescence in situ hybridization, and reverse phase protein microarray analysis. Of these, 25 (89%) successfully completed multiomic molecular profiling (MMP) and were treated with matched therapy. A growth modulation index greater than 1.3 (progression-free survival on MMP-selected therapy/time to progression on last prior treatment) was seen in 44% of these patients.

The Cleveland Clinic performed a prospective study with next generation sequencing of 250 patients to determine accessibility of genomic driven therapy (Sohal et al., 2015). Of the 250 patients sequenced, 109 (44%) had a potential matched therapy, but only 24 (10%) received matched therapy. Lack of trial access and clinical deterioration were the most common reasons for not receiving a matched therapy. Overall outcomes for matched vs. unmatched therapies were not provided in the publication.

The NEXT screening program was a study at the Samsung Medical Center in Korea and was a prospective molecular-screening program with the goal of facilitating enrollment on 13 ongoing biomarker-guided clinical trials (Kim et al., 2017). Genomic alterations were determined by immunohistochemistry and DNA sequencing. The study screened and consented 654 patients of which 418 (64%) were eligible for cancer treatment or biomarker-driven clinical trials and 60 (9%) patients were treated on biomarker selected clinical trials. The study concluded that molecular based screening can facilitate improved enrollment on biomarker-guided clinical trials, but overall outcomes for matched vs. unmatched therapies were not provided.

Correlative-Only Precision Medicine Clinical Trials

Several precision medicine studies did not attempt to use genotyping results to match therapies and instead only performed correlations between response to therapies and specific molecular markers. Table 2 represents four studies with results. These studies were all disease specific, prospective studies. The median number of patients screened was 334 and ranged 237–344.

BATTLE

The BATTLE trial (biomarker-integrated approaches of targeted therapy for lung cancer elimination trial) was a prospective study with adaptive randomization of chemotherapy refractory nonsmall cell lung cancer patients at MD Anderson Cancer Center (Kim et al., 2011). Molecular alterations were determined using PCR-based genomic testing, immunohistochemistry, and fluorescent in situ hybridization. A total of 341 patients were enrolled. Patients were randomized to four therapies (erlotinib for EGFR, erlotinib with bexarotene for retinoid-EGFR signaling, sorafenib for KRAS/BRAF, or vandetanib for VEGFR) after molecular tumor biomarker assessments. A total of 59 patients received erlotinib, 54 received vandetanib, 37 received erlotinib with bexarotene, and 105 received sorafenib. The 8 week disease control rate was 46% and median progression free survival was 1.9 months. The benefit rate was 79% with sorafenib as compared to 14% with erlotinib in the mutant KRAS/BRAF marker group and patients with EGFR mutations had better responses to erlotinib, vandetanib, and erlotonib with bexarotene than sorfaenib. The authors concluded that treatment efficacy was related to the mechanism of action of the therapy in the presence of individual biomarkers.

BATTLE-2 was a follow-up of BATTLE performed at MD Anderson Cancer Center and Yale (Papadimitrakopoulou et al., 2016). An adaptive trial design was used to assign patients with nonsmall cell lung cancer to erlotinib, sorafenib, erlotinib with Akt inhibitor (MK-2206), or MEK inhibitor (AZD6244) with MK-2206. Molecular profiling was performed with fluorescence in situ hybridization. Overall, 334 patients provided consent, 274 underwent molecular profiling, and 200 patients were randomly assigned at received treatment on the four treatment arms. Patients with *KRAS* mutations had significantly longer progression free survival if they were not treated with erlotinib (HR 1.95, 95% CI: 1.00–3.77, $P = .04$), but overall survival did not differ (HR 0.26, 95% CI: 0.65–2.46; $P = .50$). Those with *KRAS* wild-type tumors had better overall survival with erlotinib treatment (HR 0.66, 95% 0.45–0.97, $P = .03$). The study concluded that biopsy-mandated, biomarker driven adaptive study design was feasible for pretreated nonsmall cell lung cancer.

I-SPY Studies

I-SPY 1 (investigation of serial studies to predict your therapeutic response with imaging and molecular analysis, NCT00043017; Esserman et al., 2012) was a prospective study of women with locally advanced breast cancer receiving neoadjuvant chemotherapy. The study enrolled 237 patients. Patients were tested for hormone receptors (estrogen, progesterone) and HER2 with immunohistochemistry. The trial evaluated molecular biomarkers of treatment, MRI results, pathologic residual disease at time of surgery, and 3 year disease free survival. Hormone-receptor positive/HER2 negative cancers had only a 9% pathologic complete response (pCR) as compared to the 45% seen with hormone receptor negative/HER2 positive tumors. MRI volume was the best predictor for residual disease after initial therapy.

I-SPY2 compared standard chemotherapy with and without the addition of novel drugs. Patients were tested for hormone receptors (estrogen, progesterone), HER2, and MammaPrint (a 70 gene predictive test for distant recurrence prior to therapy). Patients were either MammaPrint high-risk, ER-negative, or HER-2 positive as determined by immunohistochemistry. Patients received a paclitaxel with or without novel therapy or control followed by doxorubicin and cyclophosphamide. HER-2 positive patients received either trastuzumab (control), neratinib, MK-2206 with trastuzumab, T-DM1 with pertuzumab, AMG386 with trastuzumab, or pertuzumab with trastuzumab. HER2-negative patients received paclitaxel alone (control) or in combination with ABT-888, MK-2206, AMG479 with metformin, or AMG386. The study utilized an adaptive trial design to allow agents that do well within a molecular signature subgroup to move through the trial more quickly. Preliminary results showed the additional of velaparib to standard chemotherapy ($n = 72$ patients) giving a 51% pCR rate with chemotherapy as compared to 25% with chemotherapy alone ($n = 44$ patients) (Rugo et al., 2016). Neratinib addition to standard chemotherapy improved pCR rates to 56% from 33% (Park et al., 2016).

Ongoing Precision Medicine Studies Without Results

There are multiple studies ongoing to evaluate the benefit of matched therapies. Table 3 represents 18 studies in progress. Seven studies were for a specific disease and 11 studies were for advanced cancers. Of these studies, 15 were prospective studies and 3 were registry-style studies. Studies with preliminary results are described in the precision medicine clinical trials and studies with results section and included in both Tables 1 and 3.

Table 2 Precision medicine clinical trials with reported results (biomarkers as correlative studies only)

Year	*First author/ chairs*	*Trial name*	*Institute*	*Type of trial*	*Type of cancer*	*N (total screened)*	*% of patients matched*	*Type of biomarker*	*Outcome*	*Comment*	*References*

NCI Studies

NCI-MATCH

The National Cancer Institute-Molecular Analysis for Therapy Choice (NCI-MATCH, NCT02465060) trial is a phase 2 basket trial design where patients with advanced tumors who either have progressed on standard treatment or have rare tumors with no standard treatments are assigned to receive treatment based on genomic sequencing regardless of tumor type. There are 19 treatment arms which enroll patients with specific molecular alterations to receive a prespecified study drug. The first reported results from screening of 800 patients found only 9% with an actionable mutation for a study-targeted drug.

NCI-IMPACT

The NCI based MPACT study (Molecular Profiling-Based Targeted Therapy in Treating Patients with Advanced Solid Tumors, NCT01827384) is a randomized prospective study to evaluate molecular profiling-based targeted therapy in treating advanced solid tumors. Patients will have sequencing of tumor tissues and only those with targetable mutations will remain in the study. The remaining patients will be randomized 2:1 to receive a matched therapy or a physician determined treatment that does not target the detected mutation. A total of 180 patients are planned to receive treatment. The therapy options in the study are veliparib with temozolomide, MK-1775 (WEE1 inhibitor), everolimus, and trametinib. Reponses and outcomes will be compared between with matched therapies and nonmatched therapy arms.

NCI pediatric MATCH

The NCI and Children's Oncology Group have partnered for the Pediatric MATCH (Molecular Analysis for Therapy Choice, NCT03155620) trial a study of children and adolescents with advanced solid tumors who have not responded to treatment or progressed on standard therapy. Molecular testing will be performed on tumor tissue for screening and patients who have a mutation targetable by one of the treatment arms will be enrolled in the appropriate arm. Germline testing will also be performed on peripheral blood at the time of enrollment.

SPECTA Studies

The SPECTAcolor (Screening platform for clinical trials in advanced colorectal cancer, NCT01723969) is a registry-style clinical trial for advanced colorectal cancer which aims to provide rapid access to novel drugs in clinical trials though molecular testing of tumors. The study is run by the EORTC (European Organization for Research and Treatment of Cancer) at European sites and is currently ongoing.

The SPECTAlung (Screening patients with thoracic tumors for efficient clinical trial access, NCT02214134) is a registry-style clinical trial for thoracic tumors including lung cancer, mesothelioma, and thymic malignancies which aims to screen patients for molecular markers with the goal of understanding molecular characteristics of the disease. The study is run by the EORTC (European Organization for Research and Treatment of Cancer) at European sites and is currently ongoing.

ASCO TAPUR

The American Society of Clinical Oncology is sponsoring the TAPUR study (Targeted Agent and Profiling Utilization Registry, NCT02693535). This is a prospective study to facilitate access to approved targeted therapies for patients with advanced cancer whose standard treatment options have been exhausted and tumors harbor a genomic variant known to be a drug target. The study will assess response to matched therapies and precision medicine. The study is ongoing and has recruited over 100 patients.

AURORA

The AURORA study (Aiming to Understand Molecular Aberrations in Metastatic Breast Cancer, NCT02102165) is a registry-style study in multiple European hospitals which aims to recruit 1300 breast cancer patients to better understand the genetic aberrations in metastatic breast cancer and understand mechanisms of response to therapy to help identify better understand how to personalize therapy. The study is currently ongoing.

ALCHEMIST

The ALCHEMIST (Adjuvant Lung Cancer Enrichment Marker Identification and Sequencing Trials, NCT02194738) clinical trials are NCI based studies of adjuvant matched therapies for early-stage nonsmall cell lung cancer. Patients will receive either erlotinib or crizotinib if they have EGFR or ALK mutations, respectively. Those lacking either mutation will be treated with nivolumab.

BATTLE-FL

BATTLE-FL (A Biomarker-Integrated Targeted Therapy Study in Previously Treated Patients with Advanced Nonsmall Cell Lung Cancer: Front Line, NCT01263782) an adaptive design for patients receiving front-line therapy to define how bevacizumab, cetuximab, or cixutumumab improve progression-free survival when combined with pemetrexed. The study is ongoing.

DART

The DART study (Dual anti-CTLA-4 and anti-PD-1 blockade in rare tumors, NCT02834013) is a Southwest Oncology group clinical trial of ipilimumab and nivolumab. Rare tumors (less than 6 in 100,000 incidence per year) who are registered in NCI-MATCH and do not have a treatment option available can enroll. Patients are treated with combination therapy with ipilimumab and nivolumab. The study plans to enroll 300 patients.

Signature

The Novartis "Signature" program is a novel signal-finding clinical trial protocol series which are tissue-agnostic, mutations specific protocols (NCT02187783, NCT02186821). Eight ongoing single agent clinical protocols were presented at ASCO 2015 which included buparlisib (PI3 kinase inhibitor), dovintinib (multikinase inhibitor), binimetinib (MEK inhibitor), encorafenib (RAF inhibitor), ribociclib (CDK 4/6 inhibitor), BGJ398 (FGFR inhibitor), ceritinib (ALK inhibitor), and sonidegib (SMO inhibitor). The study uses a Bayesian adaptive design with interim analyses for evaluating futility after the accrual of 10 patients and evaluating success after 15–30 patients. The study is currently ongoing.

Lung-MAP

Lung-MAP is a phase 2–3 master protocol of advanced squamous nonsmall cell lung cancer (NCT02154490, NCT02785913, NCT02965378, NCT02785939, NCT02785952, NCT02926638, NCT02766335). It incorporates a common biomarker screening platform. Patients were assigned to a subgroup based on biomarkers and those qualifying for more than one subgroup were randomly assigned to subgroups to allow lower prevalence biomarkers to receive more patients. Those without biomarkers were assigned a no-match group. Four targeted therapies and one therapy for the no-match group were used. The study has undergone several changes since opening. The no-match sub-study arm was designed to investigate MEDI4736 and transitioned to nivolumab compared to nivolumab with ipilimumab. The rilotumumab and MEDI4736 arms were discontinued and the remaining three biomarkers arms are taselisib, palbociclib and AZD4547.

MD Anderson IMPACT2

The Randomized Study Evaluating Molecular Profiling and Targeted Agents in Metastatic Cancer: Initiative for Molecular Profiling and Advanced Cancer Therapy (IMPACT 2, NCT02152254) study is a randomized prospective study at MD Anderson to further establish the benefit of personalized treatments. Patients will be randomized to a targeted therapy arm where they will receive therapies matched to molecular targets identified on their tumors through a clinical trial. If a clinical trial is not available, patients will receive a commercially available FDA approved targeted therapy. The comparator arm will be standard of care treatment not selected based on molecular alterations.

WINTHER

The Worldwide Innovative Networking Consortium for personalized cancer therapy (WINTHER, NCT01856296) was designed for patients with advanced cancer to match targeted therapies to each individual's molecular profile (Rodon et al., 2015). Either next generation sequencing or transcriptomics, which compares tumor to normal tissue and bioinformatics algorithms to prioritize drug selection, was used for the two arms of the study. The study has completed enrollment (about 300 patients consented) and is undergoing analysis.

Challenges in Precision Medicine Trials

Many precision medicine trials assume that response to targeted therapy can be evaluated independently from tissue of origin and independent of other molecular aberrations in the tumor, thus enrollment can be increased by combining patients with different tumors in the same studies. However it is unclear if this assumption is true for all molecular pathways. As an example, a phase 2 basket study of *BRAF V600* mutation positive nonmelanoma cancers explored the role of responses to vemurafenib by cancer type (Hyman et al., 2015). A total of 122 patients with *BRAF* mutations were treated. Response rates were highest for non-small-cell lung cancer (42%) and Erdheim-Chester disease (43%), whereas cholangiocarcinoma had a 12% response rate and anaplastic thyroid cancer 29% response rate. Colorectal cancer had a 0% response to vemurafenib alone and 4% response rate when combined with cetuximab. The majority of *BRAF* mutated tumors thus responded well across a diverse spectrum of hematologic and solid cancers.

Given that new mutations can arise in a tumor over the course of therapy, different results may arise in patients earlier in their treatment course even with in the same histology, which can alter outcomes. While some studies will limit treatment to patients with very advanced disease or who are medically unfit to withstand additional treatment for the initial testing of targeted therapies, this approach may ultimately make it difficult to assess the utility of novel targeted therapies. This approach can lead to high post-screening attrition rates as a result of deteriorating clinical status or death.

Protocol flexibility is needed for precision medicine trials to eliminate ineffective drugs or introduce new agents or cohorts as a trial evolves. Study designs must identify active arms as early as possible while acquiring enough data to understand why the drug failed in other arms. It is important to understand the biology behind the successes and failures. Histology-agnostic trials are generally nonrandomized and interim analyses are limited by small sample sizes, unbalanced data, and the heterogeneity of responses seen among patients with different malignancies. Current basket trial designs assume data can be aggregated across histologies, but it is also important to make sure that there is similar efficacy prior to combining the data. Thus novel designs for interim analyses are needed. Adaptive trials designs, as have been employed by some of the precision medicine trials described above, are incorporated to modify the course of structure of the trial. Early assessments of the clinical benefit or safety of the drug can be made to modify the response. A trial can be stopped early or extended depending on the emerging results and arms or doses can be dropped if there is no benefit. This allows for the identification of patients who are responding to investigational drugs and allows the randomization of proportions of the trial population or the rates at which data are accrued to be changed. It permits inclusion of multiple stages of drug development in a single trial.

Appropriate outcome measures must also be considered. While rate and duration of response has traditionally been used, responses may be short-lived and may not work well as surrogates for survival. An alternative end point may include the ratio of progression-free survival with the targeted therapy compared to progression free survival of prior line of therapy. A value of greater than 1.3 was felt to be clinically meaningful. However if the progression-free survival differs significantly between tumors of different origins, this end point can be of limited value.

Patient screening and recruitment can also present challenges. There need to be viable means to identify low-incidence patient subpopulations and to direct patients to clinical trials. These can be linked to umbrella and basket studies and global studies that can accept subjects from diverse screening routes. Screening programs are dependent on networks, collaborators, and reliable partners. The molecular testing platforms should enable broad, robust, and cost-effective tumor and patient profiling for the studies.

Evaluating a large number of therapies in a diverse patient population in a trial that can involve multiple countries can present difficulties in starting the trial. Considerable delays can occur in study approval and activation in the sites. While international sites may have an expedited process, rules about testing novel therapies and off-label uses of approved drugs can present a challenges. For combination therapies, the coordination and collaboration of multiple pharmaceutical companies can also present a challenge. Delays in molecular sequencing and drug acquisition can also delay treatment in precision medicine trials.

Conclusions

Significant advances have been made in genomic profiling which has enabled the administration of therapies matched to molecular alterations. Clinical trials and studies have evaluated the benefit of matching therapies to genomic information and have almost exclusively established a benefit for a tissue-agnostic approach. While significant challenges still remain in the implementation of precision medicine clinical trials and therapies, multiple trials are ongoing providing new hope for patients with advanced and metastatic cancer.

Prospective Vision

Genomic profiling has unveiled a new reality in oncology. Metastatic tumors are complicated; thus traditional study designs are not a good fit. The heterogeneity of metastatic solid tumors necessitates patient-centered studies and a personalized, N-of-one, approach. End-stage heavily pretreated patients do not fare as well with targeted therapies. While imatinib improved survival in CML from 4 to 5 years to 20 or more, the response rate in blast phase is only 10%. Thus, genomically targeted therapy may be more effective earlier in the course of the disease. Immunotherapy has provided another major breakthrough in oncology treatments and can work synergistically with targeted therapy to activate the immune system. Tumors with high microsatellite instability (MSI-high) and high tumor mutational burden (TMB-high) are more likely to respond to therapy. Immunotherapy may work better with complex genomic alterations and in combination with targeted therapies. The United States Food and Drug administration has provided a landmark drug approval to pembrolizumab for MSI-high or mismatch repair deficient tumors, thus representing the first tissue-agnostic approval. FDA-approvals are being granted based on correlative data which may provide an opportunity to perform retrospective data mining for future drug approvals.

Definition

Non-Hodgkin lymphomas (NHLs) are one of the two groups of lymphomas (i.e., solid tumors of lymphoid tissues). NHLs are a large and very heterogeneous group of tumors, with more than 70 definitive or provisional entities listed in the current classification of the World Health Organization (WHO). They may originate from mature B cells (B-NHLs), T cells or NK cells (T/NK-NHLs), with the first of these categories (B-NHLs) accounting for up to 90% of all NHL cases. The most common NHL type is diffuse large B-cell lymphoma (DLBCL) followed by follicular lymphoma (FL). These two NHL subtypes taken together account for 50%–60% of all NHL cases. This entry, in addition to discussing clinical features and management of all NHLs in general, covers in detail these two NHL types.

Presentation and Diagnosis

Clinically, B-NHLs are categorized into low-grade and high-grade diseases. Low-grade NHLs are indolent, and tend to grow and spread slowly. They may transform into high-grade NHLs with time. High-grade NHLs are aggressive rapidly growing tumors, sometimes with a dramatic clinical course. Of the two NHL types discussed in this entry, FL is the most common among the low-grade NHLs (even though, a rare aggressive variant of FL exists) and DLBCL—among high-grade tumors.

 https://doi.org/10.1016/B978-0-12-801238-3.65271-6

The clinical manifestations of NHL vary depending on the location of the lymphomatous process, the rate of tumor growth, and the function of the organ being compromised or displaced by the malignant process.

Low-grade NHLs give few signs and symptoms. Painless and slowly progressing peripheral adenopathy is the most common clinical presentation. As it can spontaneously regress (temporarily), it can potentially be confused with a manifestation of an infectious condition. Primary extranodal involvement and B symptoms (temperature over 38°C, night sweats, and over 10% weight loss within 6 months) are not common at presentation but they are frequent in patients with advanced, malignant transformation or end-stage disease. Bone marrow is often involved and this may be associated with cytopenia. Fatigue and weakness are more common in patients with advanced disease. FL most commonly involves bone marrow (60%–70% of cases), the liver (50%), and the spleen (40%). B symptoms occur in about 20% of patients. Symptoms resulting from the bone marrow dysfunction, such as anemia, leukopenia, or thrombocytopenia, are rare at presentation but can appear in advanced disease. Lymphocytosis, reflecting blood involvement, may also be present. A majority of patients present with stage III or IV disease.

Most patients with high-grade NHL present with adenopathy. Extranodal involvement is present in over one third of patients, the most common sites being the gastrointestinal tract, genitourinary tract, skin, bone marrow, sinuses, thyroid, and central nervous system. B symptoms are present in 30%–40% of patients. DLBCL patients usually present with a rapidly growing cervical lymph node bulk or abdominal mass, giving varied symptoms related to tissue infiltration and organ obstruction caused by the growing mass. Pain in the enlarged lymph node or organ may be noted. B symptoms occur in about 40% (stage I-II) to 60% (stage III-IV) of patients at initial presentation. Generalized pruritus (itchy skin) may also be present. Extranodular and extramedullary involvement occurs in over 40% of patients. Other symptoms can include anorexia, lower limb edema caused by extensive pelvic lymphadenopathy, fatigue, and chest discomfort or shortness of breath due to mediastinal lymphadenopathy.

The initial workup in case of a suspected NHL includes a thorough physical examination which should evaluate for hepatosplenomegaly, the presence of effusions, evidence of neuropathy, and signs of obstruction (e.g., extremity edema, superior vena cava syndrome, or spinal cord compression). Lymph node chains must be carefully examined, including the cervical, supraclavicular, axillary, epitrochlear, inguinal, femoral, and popliteal nodes. The lymph nodes are examined for size, multiplicity, consistency, and tenderness (lymphomatous involvement typically results in a rubbery consistency). The tonsils and oropharynx are also thoroughly examined. Waldeyer ring involvement mandates complete evaluation of the nasopharynx, oropharynx, and hypopharynx by endoscopy.

Laboratory testing includes complete blood count (CBC) with a differential, a comprehensive metabolic panel including liver and kidney function tests, serum lactate dehydrogenase (LDH), and serum β2 microglobulin. An abnormal blood count warrants a peripheral blood smear. Elevated LDH correlates with increased tumor burden and indicates poor prognosis. The LDH value is one of the parameters used to calculate the International Prognostic Index (IPI), a clinical tool to predict NHL patients' prognosis. Abnormal liver function tests may indicate hepatic involvement, hypermetabolic tumor growth, and/or chronic inflammation. Suspected DLBCL patients with elevated LDH levels should be assessed for spontaneous tumor lysis syndrome (TLS), which includes measurements of uric acid, potassium, phosphorus, calcium, and renal function. Hyperuricemia is a common manifestation of high-turnover-rate (aggressive) NHL. As some of the NHL treatments may lead to reactivation of hepatitis B virus (HBV), HBV testing is also recommended.

A chest radiograph is informative in approximately one fourth of NHL patients. It may identify hilar or mediastinal adenopathy, pleural or pericardial effusions, and parenchymal involvement. A computed tomography (CT) scan (with intravenous contrast) of the neck, chest, abdomen, and pelvis is routinely used to detect adenopathy, hepatosplenomegaly, or filling defects in the liver and spleen. Currently, it is the most widely used test for initial staging, and also for assessing treatment response and for follow-up. A bone scan is indicated in patients with bone pain and/or elevated alkaline phosphatase levels. Bone lesions are particularly frequent in DLBCL. Upper gastrointestinal series are performed if gastrointestinal involvement is suspected.

Functional imaging of the whole body using positron emission tomography (PET) with F-18 2-deoxyglucose (FDG) is usually recommended to complement staging of all patients with aggressive lymphoma, including DLBCL.

As a number of medical conditions may be associated with enlarged lymph nodes, a pathological evaluation of an incisional or excisional lymph node biopsy (or of biopsies of other sites in case of extranodal disease) is essential to establish an accurate diagnosis of any of the NHL types. The utility of fine-needle aspiration (FNA) biopsy remains controversial. In most clinical guidelines, FNA alone is considered insufficient to establish diagnosis but it may have an added value when used in combination with other techniques, like immunohistochemistry and flow cytometry. Moreover, according to the expert panel of the US National Comprehensive Cancer Network (NCCN), FNA alone may be sufficient to establish relapse.

Bone marrow biopsy to evaluate bone marrow involvement is commonly recommended as part of the diagnostic workup, in particular for high-grade lymphomas. However, some data suggest that FDG-PET is more accurate in detecting bone marrow involvement than bone marrow biopsy. Lumbar puncture and the analysis of the cerebrospinal fluid may be necessary in some patients with high-risk disease. Differentiating between disease subtypes is made based on immunophenotyping by flow cytometry and/or immunohistochemistry. Complementary cytogenetic or molecular analyses to detect characteristic chromosomal translocations or genetic alterations, or to establish clonality, may also be necessary in some cases. For detailed information on cell surface and genetic markers as well as on staging and risk stratification, refer to the entry in the "Pathology and Genetics" section.

Management and Therapy

The management of NHL patients varies depending on the tumor type and localization. In particular, the management strategies are very different between those for indolent (low-grade) and those for aggressive (high-grade) disease. This section describes specifically the management of FL (the most common of indolent tumors) and DLBCL (the prototype of the aggressive ones).

Follicular Lymphoma

Most FL patients present with advanced and disseminated disease. However, FL usually progresses slowly, frequently giving no or mild symptoms, and the prognosis is good in most cases. Therefore, immediate therapeutic intervention is not always necessary.

The "wait and watch" ("watchful waiting") approach (observation) may often be a reasonable option in early-stage FL, in particular in localized asymptomatic disease but also in advanced-stage disease in patients with a life expectancy shorter than 15 years. Observation is also common practice for patients with advanced but low tumor burden disease. The Follicular Lymphoma International Prognostication Index (FLIPI) and the criteria of the Group for Follicular Lymphoma Studies (Fr. Groupe d'Etude des Lymphomes Folliculaires; GELF) are used to determine whether the patient needs immediate treatment or whether observation is a viable option (for more information on these, refer to the "Pathology and Genetics" entry).

Otherwise, involved site radiotherapy (ISRT) remains the standard of care for localized nonbulky stage I-II FL. Combinations of RT with chemotherapy and with chemoimmunotherapy, as well as biological therapy are also used and none of the approaches has been shown to be superior to others. Surgical resection may additionally be considered in symptomatic localized disease. In selected cases, a monotherapy with rituximab (Rituxan®, Biogen Idec and Genentec, USA), an FDA-approved monoclonal anti-CD20 antibody, may be considered to avoid the side effects of radiation. Patients with bulky stage I-II disease are managed with systemic therapy like stage III-IV patients.

Stage III and IV FL is considered to be an incurable disease. The therapeutic most frequently used as first-line treatment of later-stage FL, either as monotherapy or as part of a multiagent therapy, is rituximab. Adding rituximab to chemotherapy regimens has been shown to improve both progression-free and overall survival in FL patients. The European Society for Medical Oncology (ESMO) recommends rituximab monotherapy for stage III-IV patients with mild symptoms, and combined rituximab/chemotherapy for those with high tumor burden. These combined regimens are the following: rituximab with cyclophosphamide/doxorubicin/vincristine/prednisone (R-CHOP) and rituximab with bendamustine. Rituximab with cyclophosphamide/vincristine/prednisone (R-CVP) may also be considered but some reports suggest that it may be less effective than the other two regimens. Full courses of purine analogue-based schemes: fludarabine/cyclophosphamide (FC) or fludarabine/mitoxantrone (FM), are not recommended due to higher hematological toxicities, but a brief course of chemoimmunotherapy with full rituximab course is an alternative in elderly patients, with good efficacy and low toxicity. The R-CHOP regimen is recommended if there is any evidence of an aggressive FL type and/or transformation. A novel strategy, combining lenalidomide, an immunomodulatory agent, with rituximab for the initial management of FL is currently being evaluated in clinical trials.

Since the introduction of rituximab, single-agent systemic therapy with chlorambucil or cyclophosphamide, or with the purine analogs fludarabine and cladribine, is used increasingly less frequently but can still be effective in some patients. Antibody monotherapy with rituximab or using radio-immunoconjugates, like ibritumomab tiuxetan (Zevalin®), or treatment with chlorambucil plus rituximab, remain alternatives for lower risk patients or when conventional chemotherapy is contraindicated. Rituximab or radioimmunotherapy are recommended for consideration as maintenance therapy following the combined rituximab/chemotherapy regimen in patients with high-burden tumors. Combining rituximab with bortezomib (a proteasome inhibitor) and bendamustine may also provide some benefit as the first-line treatment of FL patients.

Myeloablative consolidation followed by autologous hematopoietic stem cell transplant (HSCT) prolongs progression-free survival after chemotherapy, but its benefit after a rituximab-containing induction is minor. Therefore, this approach is not recommended as the first-line therapy of responding patients.

Multiple options exist for the treatment of patients who relapse or progress after the first-line therapy. However, the relapse should be histologically evaluated to exclude transformation into an aggressive FL. Bendamustine is approved in the US for use in patients with rituximab-refractory indolent B-cell lymphoma, including FL. Many practitioners administer bendamustine in combination with rituximab. Fludarabine-based regimens are another option for patients who relapse after an alkylator-based therapy. However, they may not be suitable for heavily pretreated elderly patients in whom rituximab (in case of rituximab-sensitive disease) or radioimmunotherapy may be better options. For patients who are refractory to rituximab, the combination of bendamustine and obinutuzumab (type II anti-CD20 monoclonal antibody) was shown to be superior to bendamustine alone with respect to progression-free survival. Obinutuzumab is also under investigation in the frontline setting.

Allogenic or autologous HSCT may be considered in younger patients with relapsed or recurrent disease. Allogeneic HSCT can induce long-term remissions but is associated with high mortality. Autologous HSCT has a low transplant-associated mortality and prolongs progression-free survival. Still, most patients eventually relapse and there is an increased rate of secondary malignancies. Therefore, this option is only recommended for young patients with adverse presentations, including early relapse after first-line treatment. HSCT is usually performed following a high-dose chemotherapy. Subsequent rituximab maintenance therapy may improve the outcome. However, the utility of HSCT in the rituximab era is to be redefined.

A relatively novel option for the treatment of relapsed or refractory FL is idelalisib, an inhibitor of the phosphatidylinositol 3-kinase δ (PI3Kδ). Idelalisib is approved by FDA for treatment of relapsed FL which has not responded to at least two prior systemic therapies (double-refractory FL). Moreover, a variety of other novel therapeutic agents for FL treatment, such as inhibitors of Bruton's tyrosine kinase (BTK), antibody-drug conjugates, novel anti-CD20 monoclonal antibodies, chimeric antigen receptor T-cell therapy, and immune checkpoint inhibitors are being developed.

Diffuse Large B-Cell Lymphoma

DLBCL is curable in 50%–80% of cases. Localized nonbulky DLBCL (stage I and II disease) can be successfully managed by an abbreviated course of a rituximab-doxorubicin-containing regimen (R-CHOP) followed by ISRT. Another approach is full-course chemotherapy with or without subsequent RT. Bulky stage I–II disease as well as disseminated (i.e., stage III–IV) disease is treated with full-course CHOP chemotherapy, with the addition of rituximab if the tumor is CD20-positive. In patients with concurrent CNS disease, methotrexate is incorporated as part of the treatment plan. CNS prophylaxis should be applied in patients with a high risk of the CNS involvement.

Other chemotherapy regimens, like R-ACVBP (rituximab, doxorubicin, vindesine, cyclophosphamide, bleomycin and prednisolone) or DA-EPOCH (dose-adjusted etoposide, prednisone, vincristine, cyclophosphamide, adriamycin) are also used but there is no convincing evidence that they provide a benefit over R-CHOP treatment and they are not recommended by the existing clinical guidelines.

Complete restaging to assess response to treatment is mandatory, with FDG-PET/CT being the recommended standard for post-treatment assessment in DLBCL. Overall, over 30% of DLBCLs will ultimately relapse.

Few patients with limited refractory disease may possibly be salvaged with ISRT if the involved area is not extensive but this has never been evaluated in clinical trials. In most cases, salvage chemotherapy, followed by autologous HSCT in responsive patients, is the preferred approach for relapsed/refractory disease. Second-line chemotherapy regimens often employ high-dose cytosine arabinoside or gemcitabine, corticosteroids, and platinum-containing chemotherapeutic agents with or without etoposide. The most commonly used regimens are the following: DHAP (dexamethasone, high-dose cytarabine, cisplatin), ESHAP (etoposide, methylprednisolone, high-dose cytarabine, cisplatin), MIME (methyl-GAG, ifosfamide, methotrexate, etoposide), ICE (ifosfamide, carboplatin, etoposide), and GDP (gemcitabine, dexamethasone, cisplatin). Any of these regimens could be combined with rituximab if the patient is deemed to be responsive to this agent. However, the actual clinical impact of this practice is not clear. Patients who achieve at least partial remission following the salvage chemotherapy are considered for autologous HSCT. Allogeneic HSCT may be most reasonable in young patients who have a suitable donor match and who do not fall into the favorable categories for benefit from autologous transplantation. Patients who are not candidates for HSCT receive nonplatinum-based chemotherapy. However, enrolment in a clinical trial is the best option for these patients.

Progressing knowledge of pathological and molecular heterogeneity of DLBCL has stimulated a search for personalized molecular therapy approaches. For example, the activated B-cell (ABC) DLBCL subtype has been shown to have a worse prognosis when compared with germinal centre B-cell in patients treated by R-CHOP. This subtype is characterized by a constitutive activation of the NF-κB pathway which could be targeted by different agents, such as bortezomib and lenalidomide. Preliminary studies of treatment regimens involving these two agents have given promising results and phase II clinical trials are currently ongoing. Furthermore, ibrutinib, a novel oral BTK inhibitor, has shown selective activity in ABC-DLBC. Several clinical trials evaluating this agent for treatment of DLBCL and other lymphomas are under way. Finally, a number of recurrent genetic alterations found in DLBCL and other NHL lymphomas which have been identified by recent genomic analyses give hope that at least some of them may become either prognostic biomarkers or useful targets for next-generation NHL treatment.

Glossary

Follicular helper T cells (T_{FH} cells) Are resident T cells of the germinal center (GC) which are necessary for the formation and maintenance of the GC reaction, a hallmark of adaptive immunity T_{FH} cells play a major role in supporting and regulating the selection and survival of B cells in the GC. T_{FH} cells are CD3+ CD4+ cells that express BCL6, critical for maintaining the T_{FH} transcriptional program have surface expression of CXCR5, PD-1, and ICOS and secrete different cytokines and chemokines, in particular CXCL13 and IL-21.

Somatic hypermutation (SHM) An AID-dependent process that introduces point mutations and occasional small deletions or duplications at a very high rate into DNA sequences of IGVH and VL gene regions (variable regions of the heavy and light-chains IG genes) of germinal center (GC) B cells, is mechanistically linked to lymphomagenesis. Somatic hypermutation in normal GC B cells is not restricted to IGV regions but also targets the 5′ sequences of BCL6, a transcription repressor essential to the GC reaction expressed at high levels in GC B cells, as well as in the FAS gene. Some of these mutations may be selected during lymphomagenesis for their activity in deregulating BCL6 gene expression. In a large proportion of diffuse large B-cell lymphomas, an aberrant hypermutation activity may target multiple loci including the 5′ untranslated or coding sequences of several other protooncogenes, including MYC. Interestingly, the hypermutable genes are susceptible to chromosomal translocations in the same region, consistent with a role for hypermutation in generating translocations by DNA double-strand breaks. Thus, by mutating multiple genes, and by favoring chromosomal translocations, aberrant hypermutation may represent a major contributor to lymphomagenesis.

Ongoing SHM Analysis of the pattern of somatic hypermutations may indicate whether these occurred as a result of antigen selection. The presence of intraclonal variation within lymphoid neoplasms is taken as indicative of ongoing mutations, and therefore a relationship to the germinal center.

Definition and Principles of Classification

Lymphoid neoplasms represent a large group of clonal proliferations derived from immature or mature lymphoid cells. They encompass a variety of distinct diseases with different clinical presentations, pathological features and biological behavior. In general, leukemia is the term used for disseminated lymphoid tumors mainly involving the blood and the bone marrow, and lymphoma refers to lymphoid neoplasms presenting as tumors in lymph nodes or other hematopoietic or nonhematopoietic organs, but not infrequently overlapping presentations are encountered. In the World Health Organization (WHO) classification —the universal reference for the definition and diagnosis of hematological malignancies—the definition of disease entities incorporates multiple parameters: morphology, immunophenotype, genetic and molecular features, clinical characteristics, and, whenever possible, the postulated normal cell counterpart from which the tumor is derived (Fig. 1) (2017 #8370). Both lymphomas and lymphoid leukemias are included in this classification, since both solid and circulating phases are present in many lymphoid neoplasms, and distinction between them is artificial.

Lymphoid neoplasms derive from B cells, T cells or NK cells at various stages of differentiation and retain many features (i.e., normal genetic events, gene expression, immunophenotype, morphology, homing patterns) of their normal counterparts, which in large part dictate the clinical behavior of the diseases. Therefore, the knowledge of normal lymphoid differentiation provides a useful framework for understanding the biology of lymphomas (Fig. 2). There are two major categories of lymphoid neoplasms, based on stage of differentiation: precursor (lymphoblastic) neoplasms, derived from immature lymphoid cells, and peripheral or mature neoplasms, derived from mature lymphoid cells. The usual presentation for neoplasms derived from immature B or T lymphoid cells, which are primarily diseases of children, is an acute leukemia. Most mature lymphoid neoplasms present as lymphomas, or, less commonly, as chronic leukemias. Neoplasms derived from plasma cells (terminally differentiated B cells) constitute another group of usually primarily bone marrow-based lymphoid malignancies, with disease manifestations related to bone destruction, excess of monoclonal immunoglobulin production, inhibition of normal host resistance to infection, and/or tissue immunoglobulin deposition. Among lymphomas, Hodgkin lymphomas (HL) are segregated from all other forms, which constitute a much larger group referred to as non-Hodgkin lymphoma (NHL). There are two major groups of NHL, based on cell derivation: those derived from B cells (B-NHL), by far most frequent, and those derived from T cells or NK cells (T/NK-NHL), which account for $< 10\%$ of all NHLs in western countries and many parts of the world (Table 1). Overall there are more than 70 definitive or provisional NHL entities listed in the current WHO classification.

 https://doi.org/10.1016/B978-0-12-801238-3.65259-5

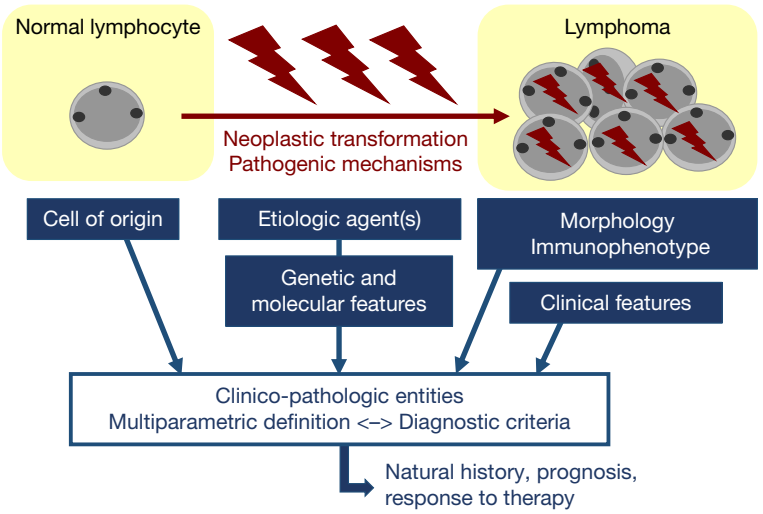

Fig. 1 Principles of lymphoma classification in the WHO classification.

Epidemiology

Worldwide, lymphomas are more common in developed countries with the highest incidence in the United States and in Europe. They are much less frequent in China, and have an intermediate incidence rate in South America, Africa and Japan. According to epidemiological data from the United States and United Kingdom, NHL represents the 6th most frequent cancer in those countries (4.3% of all cancers in the United States and 4% in the United Kingdom). For 2017 about 72,000 new NHL cases diagnoses and about 20,000 NHL-related deaths in the United States were estimated. Incidence is higher among men than women, and in the United States it is also higher in nonhispanic white people than in black people, while no significant variation by ethnicity is observed in the United Kingdom. For US patients, the median age at diagnosis is 67 years, the median age at death is 76 years and a overall 5 years survival of 71%. There has been a marked increase in NHL incidence over the past decades, with a near doubling of the incidence rate between 1975 and 1995. Since then, there has been little variation or even a trend toward a minimal decrease in incidence (in a range $<1\%$) in the United States, while in the United Kingdom, the NHL incidence has continued to slightly increase in the recent years, essentially in the older age groups. It is not clear whether this is a true increase in the incidence of the disease, or a reflection of improved medical surveillance of elderly people or improved diagnostic testing.

Etiology and Risk Factors

The etiology of NHL remains poorly understood. The best established factors affecting an individual's risk of developing NHL are immune disorders and infections. Other factors include genetic and racial features, familial predisposition, lifestyle factors, environmental or occupational exposures.

Immune Disorders

Increased incidence rates of NHL are observed in immunosuppressed populations (those receiving immunosuppressive treatment following solid organ transplantation, and individuals with the acquired immunodeficiency syndrome (HIV/AIDS)). The majority of immunodeficiency-related lymphoid malignancies are B-cell derived and frequently associated to EBV. Individuals with inherited defects of immune function, like ataxia-telangiectasia, Wiskott–Aldrich syndrome, X-linked lymphoproliferative disorder, severe combined immunodeficiency syndrome and others, are at increased risk of NHL as well. On the other hand, autoimmune disorders also represent a risk factor for the development of NHL. Evidence of an association is confirmed among individuals with Sjogren's syndrome, rheumatoid arthritis, systemic lupus erythematosis, autoimmune thyroiditis and celiac disease.

Infectious Agents

A variety of infectious agents has been identified as either linked to or truly causative of lymphomas (Table 2). Among viruses, the Epstein-Barr virus (EBV) is associated with the largest variety of lymphoproliferations. EBV is present in nearly 100% of endemic Burkitt lymphoma and in 40% of sporadic and HIV-associated cases, is detected in virtually all cases of extranodal nasal type T/NK-cell lymphoma, and is clearly implicated in the pathogenesis of lymphoproliferations occurring in the setting of immunodeficiency. The human herpesvirus-8 (HHV8) is found in association with different lymphoproliferative diseases linked to HIV

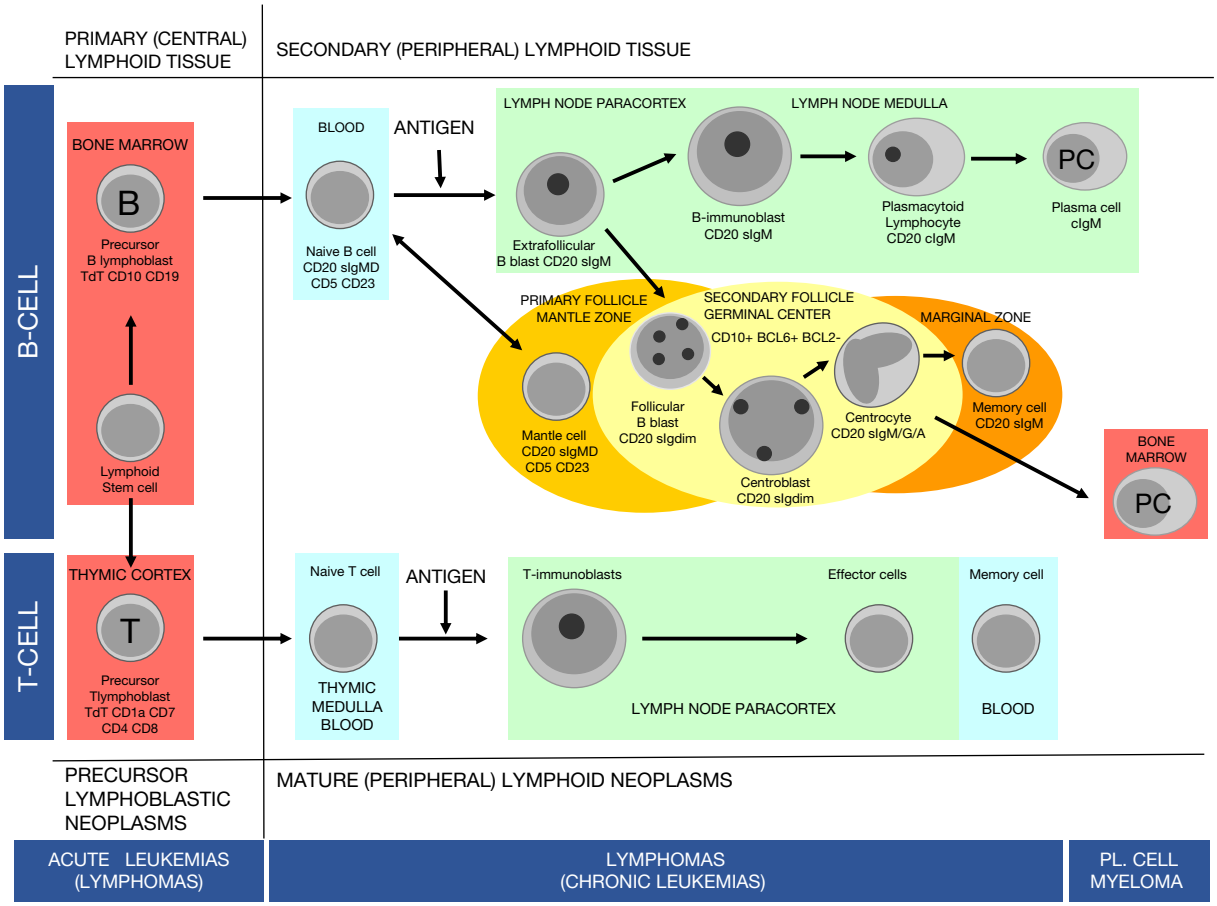

Fig. 2 Normal lymphoid differentiation and corresponding lymphoid neoplasms. Each stage occurs at a specific anatomic site and architectural nichewithin lymphoid organs, and is characterized by changes in surface antigen expression. The antigen-independent phase of lymphoid differentiation occurs in the primary lymphoid organs (bone marrow and thymus). A postulated common lymphoid stem cell gives rise to both B and T-cell lineages. The early stages are stem cells and lymphoblasts (precursor T and B cells), which are self-renewing. Antigen-independent differentiation results in mature, naïve T and B cells that are capable of responding to antigen that binds to their surface antigen receptors (T-cell receptor, TCR and B-cell receptor, BCR or surface immunoglobulin, sIg). Naïve B cells are found in the blood and in primary follicles and mantle zones of secondary follicles. Naïve T cells are found in the blood, in the thymic medulla and also in the paracortex of lymph nodes. On exposure to antigen in the secondary lymphoid organs (lymph nodes, spleen, mucosal-associated lymphoid tissue (MALT)), the naive lymphocyte undergoes "blast transformation," and becomes a large, proliferating cell, which gives rise to progeny that are antigen-specific effector or memory cells. Antigen-dependent B-cell differentiation may occur along two pathways: T-cell independent reactions (immunoblastic paracortical reaction leading to the generation of short-lived IgM secreting plasma cells) or the germinal center (GC) reaction, hallmark of T-cell dependent responses. B-blasts activated in the paracortex upon antigen encounter migrate to the center of a primary follicle, proliferate and differentiate into centroblasts which further mature to centrocytes. In the GC, B cells undergo somatic mutations of the variable region of the immunoglobulin (IGV) genes regions and class switching of the Ig heavy chain (IGH) gene allowing for expression of IgG, IgA or IgE. Only cells with favorable IGV gene mutations—that are those resulting in a higher affinity of the BCR for the antigen—are positively selected and survive. These centrocytes may then differentiate to effector cells (usually IgG or IgA secreting plasma cells) homing to the bone marrow, or to memory cells, which may collect into a marginal zone. Antigen-dependent T-cell differentiation occurs in the paracortex of the lymph node and results in expanded clones of effector CD4+ and CD8+ T cells (helper and cytotoxic) and memory cells that may pass into the blood. TdT: terminal deoxynucleotidyl transferase; CD: cluster of differentiation; sIg: surface immunoglobulin expression; cIg: cytoplasmic Ig expression.

infection (primary effusion lymphoma, HHV8-associated multicentric Castleman's disease, HHV8+ diffuse large B-cell lymphoma) as well as in the indolent and rare germinotropic lymphoproliferative disorder in immunocompetent individuals. HHV8 is capable of establishing a latent infection in B cells and its oncogenic mechanisms involve the promotion of cell survival and proliferation, through the release of cytokines and antiapoptotic factors. In multicentric Castleman's disease, viral protein IL6 produced by infected cells is as a major mediator of the systemic symptoms and of hypergammaglobulinemia associated to the disease.

The human T-cell leukemia virus type 1 (HTLV1) is causally linked to adult T-cell leukemia/lymphoma, a disease endemic in Japan and in the Caribbean area. The lifetime risk for development of ATLL among seropositive individuals is overall inferior to 5%, indicating the necessity for additional events for neoplastic transformation. Clonally integrated HTLV1 is found in all cases. The antisense gene product HBZ is thought to represent major driver of T-cell transformation by inducing chronic proliferation,

Table 1 2017 WHO classification of non-Hodgkin lymphomas

Precursor B-cell neoplasms
- B-lymphoblastic leukemia/lymphoma, NOS and multiple variants based on genetic abnormalities

Mature B-cell neoplasms
- *Predominantly disseminated*
  - Chronic lymphocytic leukemia/B-cell small lymphocytic lymphoma
  - Monoclonal B-cell lymphocytosis
  - B-cell prolymphocytic leukemia
  - Splenic marginal zone B-cell lymphoma
  - Splenic B-cell lymphoma/leukemia, unclassifiable[a]
  - Splenic diffuse red pulp small B-cell lymphoma[a]
  - Hairy cell leukemia
  - Hairy cell leukemia variant[a]
  - Lymphoplasmacytic lymphoma
  - IgM monoclonal gammopathy of undetermined significance
  - Heavy chain diseases
  - Plasma cell neoplasms
- *Primary extranodal*
  - Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT)
- *Predominantly nodal*
  - Follicular lymphoma (FL)
  - In situ follicular neoplasia
  - Duodenal-type FL
  - Testicular FL
  - Pediatric-type FL
  - Large B-cell lymphoma with *IRF4* rearrangement[a]
  - Primary cutaneous follicle center lymphoma
  - Mantle cell lymphoma
  - In situ mantle cell neoplasia
  - Nodal marginal zone B-cell lymphoma
  - Pediatric nodal marginal zone lymphoma[a]
  - Diffuse large B-cell lymphoma (DLBCL) not otherwise specified (NOS), germinal center B-cell type (GCB-DLBCL-NOS)
  - DLBCL-NOS activated B-cell type (ABC-DLBCL-NOS)
  - T-cell/histiocyte-rich large B-cell lymphoma
  - Primary DLBCL of the central nervous system
  - Primary cutaneous DLBCL, leg type
  - EBV-positive DLBCL-NOS
  - EBV-positive mucocutaneous ulcer
  - DLBCL associated with chronic inflammation
  - Fibrin-associated DLBCL
  - Lymphomatoid granulomatosis
  - Primary mediastinal (thymic) large B-cell lymphoma
  - Intravascular large B-cell lymphoma
  - ALK-positive DLBCL
  - Primary effusion lymphoma
  - Multicentric Castleman disease
  - HHV8-positive DLBCL-NOS
  - HHV8-positive germinotropic lymphoproliferative disorder
  - Burkitt lymphoma
  - Burkitt-like lymphoma with 11q aberration[a]
  - High-grade B-cell lymphoma with *MYC* and *BCL2* and/or *BCL6* rearrangements
  - High-grade B-cell lymphoma NOS
  - B-cell lymphoma unclassifiable with features intermediate between DLBCL and classical Hodgkin lymphoma

Immunodeficiency-associated lymphoproliferative disorders
- Posttransplantation lymphoproliferative disorders (PTLD)
  - Nondestructive PTLD (plasmacytic hyperplasia, infectious mononucleosis, florid follicular hyperplasia)
  - Polymorphic PTLD
  - Monomorphic PTLD
  - Other iatrogenic immunodeficiency-associated lymphoproliferative disorders

Precursor T-cell neoplasms
- T-lymphoblastic leukemia/lymphoma
- Early T-cell precursor lymphoblastic leukemia
- NK-lymphoblastic leukemia/lymphoma

Mature T-cell neoplasms
- *Disseminated/leukemic*
  - T-cell prolymphocytic leukemia
  - T-cell large granular lymphocytic leukemia
  - Chronic lymphoproliferative disorder of NK cells[a]
  - Aggressive NK-cell leukemia
  - Systemic EBV-positive T-cell lymphoma of childhood[a]
  - Chronic active EBV infection of T- and NK-cell type, systemic form
  - Adult T-cell leukemia/lymphoma
- *Nodal*
  - Angioimmunoblastic T-cell lymphoma
  - Follicular T-cell lymphoma
  - Nodal peripheral T-cell lymphoma with T follicular helper phenotype
  - Anaplastic large-cell lymphoma, ALK-positive
  - Anaplastic large-cell lymphoma, ALK-negative
  - Peripheral T-cell lymphoma, not otherwise specified
- *Extranodal*
  - Extranodal NK/T-cell lymphoma, nasal type
  - Enteropathy-associated T-cell lymphoma
  - Monomorphic epitheliotropic intestinal T-cell lymphoma
  - Indolent T-cell lymphoproliferative disorder of the gastrointestinal tract[a]
  - Hepatosplenic T-cell lymphoma
  - Subcutaneous panniculitis-like T-cell lymphoma
  - Breast implant-associated anaplastic large-cell lymphoma[a]
- *Cutaneous*
  - Mycosis fungoides
  - Sezary syndrome
  - Primary cutaneous CD30 + lymphoproliferative disorders
    - Lymphomatoid papulosis
    - Primary cutaneous anaplastic large-cell lymphoma
  - Primary cutaneous $\gamma\delta$ T-cell lymphoma
  - Provisional CD4+ or CD8+ entities[a]
  - Hydroa vacciniforme-like lymphoproliferative disorder
  - Severe mosquito bite allergy

[a]Provisional entities.

Table 2 Infectious agents associated with the development of NHL

Infectious agent	*Lymphoid neoplasm*
Epstein-Barr virus (EBV)	Burkitt lymphoma
	Posttransplantation lymphoproliferative disorders
	EBV-positive diffuse large B-cell lymphoma, NOS
	Plasmablastic lymphoma
	Lymphomatoid granulomatosis
	Angioimmunoblastic T-cell lymphoma[a]
	Extranodal NK/T-cell lymphoma, nasal type
	Pediatric EBV-positive T-cell neoplasms of childhood
Herpesvirus-8 (HHV8)	Primary effusion lymphoma
	HHV8-positive diffuse large B-cell lymphoma, NOS
	Multicentric Castleman disease
Human T-leukemia lymphoma virus-1 (HTLV1)	Adult T-cell leukemia/lymphoma
Hepatitis C virus (HCV)	Lymphoplasmacytic lymphoma
	Marginal zone lymphomas (splenic and nodal types)
Helicobacter pylori	Gastric MALT lymphoma
Borrelia burgdorferi	Cutaneous MALT lymphoma
Chlamydia psittaci, pneumonia and trachomatis	Ocular adnexal MALT lymphoma
Campylobacter jejuni	Intestinal MALT lymphoma associated to alpha chain disease

[a]EBV present in a population of B cells in the tumor but not in the neoplastic T cells; MALT: mucosa-associated lymphoid tissues; NOS: not otherwise specified.

apoptotic resistance, multiple organ invasion, and drug resistance. TAX oncoprotein activates multiple signaling pathways in infected T cells, but is not expressed in ATLL neoplastic cells in many cases Further genetic and epigenetic changes lead to development of malignancy.

Different types of B-NHL are associated with hepatitis C virus (HCV) infection (relative risk of about 1.5), including splenic and nonsplenic marginal zone lymphomas, lymphoplasmacytic lymphoma and diffuse large B-cell lymphomas in extranodal localizations. The pathophysiology of HCV-associated lymphomas involves two nonexclusive mechanisms of transformation: chronic antigenic stimulation and to a lesser extent direct transformation via insertional mutagenesis or expression of oncogenic proteins. Sustained virologic response obtained with antiviral treatments might induce the remission of indolent lymphomas.

Bacteria, or at least immune responses to bacteria, have also been implicated in the pathogenesis of extranodal B-cell marginal zone lymphoma of the MALT type. The most convincing and best documented example is that of gastric MALT lymphoma arising from acquired MALT induced by *Helicobacter Pylori* infection. In early stage, MALT lymphoma cells preserve B-cell properties and their growth may be driven by antigenic stimulation. In this condition, as lymphoma growth in vitro is dependent on the presence of T cells activated with *H. pylori* antigens, antibiotic treatment causes regression of the lymphoma in many patients. In later stages of gastric MALT lymphoma, acquisition of genetic abnormalities, such as t(11;18)(q21,q21) or t(1;14)(p22;q32) is associated with tumor escape from its growth dependency. Similarly, *Borrelia burgdorferi* has been implicated in the pathogenesis of cutaneous MALT lymphoma and *Chlamydia psittaci* in that of ocular adnexa MALT lymphoma. Intestinal MALT lymphoma and immunoproliferative small intestinal disease (IPSID)/alpha chain disease has been associated with mixed bacterial infections and more specifically with *Campylobacter jejuni* infection.

The development of pyothorax-related lymphoma, strongly associated with EBV infection, is closely related to antecedent *Mycobacterium tuberculosis* infection.

Inherited Factors

An increased risk of developing lymphoid malignancies has been reported for relatives of patients. In particular, chronic lymphocytic leukemia seems to comprise a relatively more substantial familial component than other entities. Genome-wide association studies have identified genetic variants at different loci that are associated to an increased risk of developing different types of B-cell NHL, and less frequent genetic determinants associated to specific diseases.

Lifestyle and Environmental Factors

Lifestyle factors like obesity and tobacco smoking have been suggested as risk factors for B-cell NHL. In particular, a high body-mass index has been consistently associated with an increased risk of diffuse large B-cell lymphoma. Several studies have suggested a possible protective effect of sun exposure and ultraviolet radiation. Exposure to herbicides and pesticides have been incriminated in the development of B-cell NHL, but despite numerous studies, no specific association has been found that is thought to be causal.

Genetics of NHL

In contrast to many carcinomas, which display random genomic instability, lymphomas tend to have relatively stable genomes and generally lack defects in DNA mismatch repair genes responsible of microsatellite instability. Conventional cytogenetics has been instrumental in identifying recurrent translocations and in cloning the major oncogenes involved in B-cell lymphomagenesis. Over the last years, technological and analytical advances in genetic, epigenetic and molecular profiling methods and next-generation sequencing technologies have markedly accelerated the characterization of lymphoma-associated molecular signatures and genetic profiles, and the discovery of genetic lesions, which collectively have greatly enhanced our understanding of lymphoma pathogenesis. These studies have revealed genetic events shared between different disease types, as well as extensive genetic heterogeneity within a single disease entity. A nonexhaustive list of common genetic alterations in lymphomas is presented in **Table 3**.

Chromosomal Translocations and Gene Fusions

Reciprocal chromosomal translocations represent a major mechanism of protooncogene activation in NHL, and are a hallmark of many types of B-cell lymphomas (**Table 3** and **Fig. 3**). Many translocations associated with NHL involve a protooncogene in the proximity of the chromosomal recombination site, whose expression is altered as a consequence of the juxtaposition to heterologous regulatory sequences derived from the partner chromosome, a mechanism referred to as transcriptional deregulation. The most common translocations involved in lymphoid neoplasms place a gene that is normally silent in resting cells under the influence of a promoter associated with either an immunoglobulin (IG) or T-cell receptor (TCR) gene, resulting in deregulated expression of the gene and giving the cell either a growth or a survival advantage. Examples include the t(14;18)(q32;q32) of follicular lymphoma, or the t(11;14)(q13;q32) of mantle cell lymphoma, which place the *BCL2* or *BCL1* gene under the IG promoter and deregulate their expression.

Translocations in B-NHL result from chromosomal breaks that are aberrant by-products of the enzymes that rearrange the IG gene segments to produce the B-cell receptor (BCR) in normal B cells, and are usually caused by either activation-induced deaminase (AID) or the recombination activating gene (RAG) complex. Physiologically, AID is the master regulator of antibody diversification involved in the initiation of somatic hypermutation (see Glossary) and IGH locus class switch recombination in germinal center B cells, while the RAG complex is involved in VDJ recombination of IG and TCR genes in immature lymphoid cells.

Translocations in B-NHL tend to associate preferentially but not exclusively with a specific type of lymphoma. Translocations involving the same protooncogene may involve different breakpoints and arise by different mechanisms in different lymphoma types. Some translocations are seen in all cases of a specific lymphoma type. Paradigms include the involvement of *MYC* in virtually all cases of Burkitt lymphoma and of *BCL1* in virtually all cases of mantle cell lymphoma; these translocations may therefore be useful as a diagnostic marker. Moreover, within specific histologic subtypes, specific gene rearrangements may identify prognostic groups, and hence their detection is useful for the characterization of these lymphomas.

An alternative mechanism of oncogene activation by chromosomal translocation consists of the juxtaposition of coding sequences derived from the two involved genes, resulting in gene fusion coding for a novel chimeric protein. This type of translocation which is common in myeloid and lymphoblastic neoplasms, is less frequent in mature NHL. For example, the t(2;5)(p23;q35) in anaplastic large-cell lymphoma, produces a hybrid nucleophosmin–ALK (anaplastic lymphoma kinase) protein, and there are alternative translocation partners to ALK. Another example is the t(11;18)(q21;q21) in MALT lymphoma, which produces a BIRC3(API2)-MALT1 fusion protein.

Translocations can be detected by cytogenetics showing derivative chromosomes, or by fluorescence in situ hybridization (FISH), using probes to specific chromosomes or segments, or by molecular techniques (PCR or RT-PCR). Since an important consequence of many translocations is the overexpression of a protein not ordinarily found in that cell type, immunohistochemistry can be used as a surrogate to detect the translocation-induced deregulated protein, for example, ALK or BCL2. Over the last years, with high-resolution deep sequencing technologies, paired-end sequencing, RNA sequencing and integration of mate-pair and RNA sequencing, have led to the discovery of several new fusion genes that are recurrent in NHL and which mechanistically may correspond to translocations, intrachromosomal deletions or inversions.

Genetic Imbalances

Genomic imbalances are common in NHL, in particular in subsets of diffuse large B-cell lymphoma, and comprise genomic gains and losses that correspond to deregulated expression of putative oncogenes (*BCL2*, *FOXP1*, *SPIB*, *REL*, *MDM2*) and tumor suppressor genes (*CDKN2A*, *REL*, *PTEN*, *MDM2*). Primary mediastinal large B-cell lymphoma is characterized by both rearrangements and/or copy-number variations of several genes mapping to 9p24 (*PDCD1LG1*, *PDCD1LG2*, and *JAK2*). Several lymphoma types show frequent 6q deletion (6q21-6q23 and 6q25-6q27) which encompasses several candidate tumor suppressor genes (*FOXO3A*, *PRDM1*, *HACE1*). Deletions of the long arm of chromosome 13 (13q14) found in a subset of chronic lymphocytic leukemias involve the microRNA cluster miR-15a/miR-16-1, which functions as a tumor suppressor by targeting *BCL2*.

Table 3 Common translocations and gene fusions in NHL

	Translocation-fusion	*Genes*	*Biologic function*	*Lymphoma*
			Anaplastic lymphoma kinase = tyrosine kinase	
				Anaplastic large cell lymphoma (75%)
	t(2;5)(p23;q35)	*NPM/ALK*	Nucleophosmin–ALK fusion	Diffuse large B-cell lymphoma (rare)
	t(1;2)(q21;p23)	*TPM3-ALK*	Tropomyosin 3–ALK fusion	Anaplastic large cell lymphoma (15%)
				Anaplastic large cell lymphoma (2%)
	t(2;17)(p23;q23)	*CLTC/ALK*	Clathrin heavy chain–ALK fusion	Diffuse large B-cell lymphoma, ALK+
	t(2;3)(p23;q21)	*TFG-ALK*	TRK-fused gene–ALK fusion	Anaplastic large cell lymphoma (2%)
ALK	inv (2) (p23;q35)	*ATIC-ALK*	ATIC enzyme–ALK fusion	Anaplastic large cell lymphoma (2%)
				Mantle cell lymphoma (virtually all)
				Hairy cell leukemia (some)
BCL1	t(11;14)(q13;q32)	*BCL1/IGH*	Cell cycle regulator	Multiple myeloma (15%)
	t(14;18)(q32;q21)	*BCL2/IGH*	Negative regulator of apoptosis	Follicular lymphoma (80%)
	t(2;18)(q11;q21)	*BCL2/IGK*		Diffuse large B-cell lymphoma (20%)
BCL2	t(18;22)(q21;q11)	*BCL2/IGL*		
BCL3	t(14;19)(q32;q13)	*BCL3/IGH*	NF-kappaB subunit	B-CLL/SLL (rare)
	t(3;14)(q27;q32)	*BCL6/IGH*		Diffuse large B-cell lymphoma (30%)
BCL6	der (3)(q27)	*BCL6/var*	Transcriptional repressor necessary for GC formation	
BCL10	t(1;14)(p22;q32)	*BCL10/IGH*	Activator of the NF-kappaB pathway	MALT lymphoma (<5%)
		ICOS-CD28	CD28 : TCR costimulatory receptor	
CD28	Fusions	*CTLA4-CD28*	TCR signaling	Peripheral T-cell lymphomas (overall 5%)
		CIITA-PD-L1	CIITA: MHC class II transactivator reduced MHC II	Mediastinal large B-cell lymphoma (38%)
CIITA	16p13.13 break apart	*CIITA-PD-L2*	expression in rearranged cases	Testicular large B-cell lymphomas (10%)
				MALT lymphoma (18%) (other than gastrointestinal & pulmonary)
	t(14;18)(q32;q21)	*MALT1/IGH*	Paracaspase, binds to BCL10	
MALT1	t(11;18)(q21;q21)	*BIRC3/MALT1*	Fusion protein increases NF-kB activity	MALT lymphoma (50%)
	t(8;14)(q24;q32)	*MYC/IGH*	Transcription factor regulating	Burkitt lymphoma (100%)
	t(2;8)(p11;q24)	*MYC/IGK*	Cell proliferation	Diffuse large B-cell lymphoma (10%)
MYC	t(8;22)(q24;q11)	*MYC/IGL*		
				Multiple myeloma (rare)
MUM1(IRF4)	t(6;14)(p25;q32)	*MUM1/IGH*	Transcription factor involved in plasma cell differentiation	Large B-cell lymphoma with IRF4 rearr.
			Transcription factor regulating B cell proliferation and	Lymphoplasmacytic lymphoma (rare)
PAX-5	t(9;14)(p13;q32)	*PAX5/IGH*	differentiation	Multiple myeloma (rare)
PDL1 (CD274)	9p24.1 break apart		PDL1/2: immune checkpoint inhibitors	Mediastinal large B-cell lymphoma (20%)
				Testicular large B-cell lymphoma
PDCD1LG			Overexpression of PDL1/PDL2	Central nervous system large B-cell lymphoma
			ITK: IL2-inducible T-cell kinase	Follicular peripheral T-cell lymphoma (20%)
			SYK: spleen tyrosine kinase	Angioimmunoblastic T-cell lymphoma (rare)
SYK	t(5;9)(q33;q22)	*SYK-ITK*	ITK-SYK mimics TCR signaling	

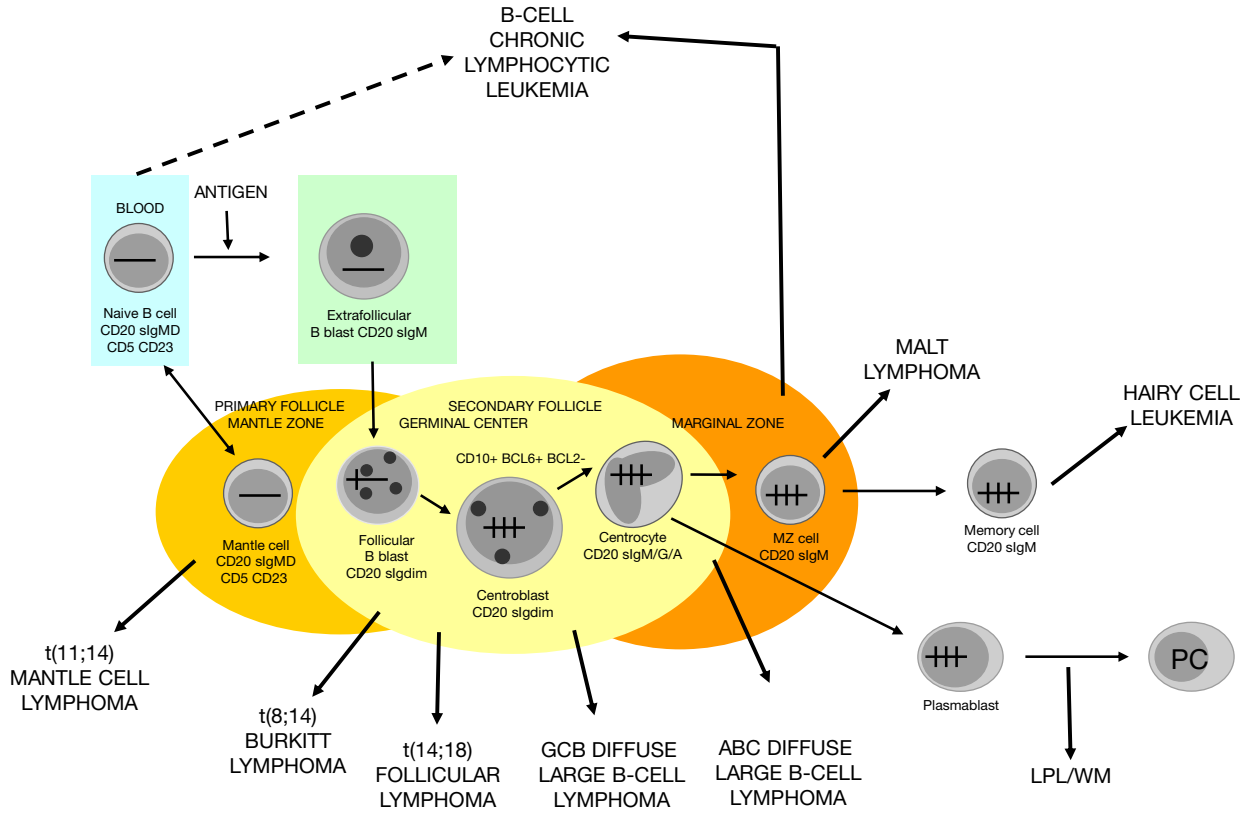

Fig. 3 Histogenetic and pathogenetic model of mature B-cell neoplasms. The follicular (T-cell dependent) and extrafollicular pathways of normal B-cell differentiation are represented. Rearrangement of the Ig heavy chain gene is symbolized with an horizontal bar in the nucleus, and somatic mutations in the IgV region are symbolized with vertical lines. The most common types of mature B-cell neoplasms are linked to their putative normal counterpart. The genetic lesion most frequently associated with each lymphoma category is also indicated.

Tumor Suppressor Genes

The tumor suppressor genes involved in the pathogenesis of NHL included *TP53*, *P16*, *RB1* and *ATM* (ataxia-telangiectasia mutated). Inactivation of tumor suppressor genes often appears as a secondary event associated with lymphoma evolution or transformation, rather than a primary genetic abnormality. The mechanisms of inactivation include point mutations, gross deletions and promotor hypermethylation; inactivation usually occurs through deletion of one allele and nonsense/missense mutation or hypermethylation of the other.

Mutational Landscapes

The mutational landscape of most common NHL have been extensively characterized over the past years. Even if an exhaustive descritpion of these is beyond the scope of this review and the most importnat mutaitons are mentioend in histotype-specific sections, it is worth mentioning some general points. The genomic landscapes of the most common NHL entities show wide heterogeneity within and across subtypes, but also similar altered pathways and mechanisms of oncogenesis overlapping across different entities. Various genes belonging to multiple functional pathways are mutated, and the pattern of mutations for each gene is variable: some genes are characterized by one or a few hotspot alterations, or the mutations may be more heterogeneous. Sometimes distinct mutations in the same gene may be either activating or loss-of-function, and mutations with apparently discordant functional impact may be encountered in different cases of the same disease. Some disease entities are associated to a very characteristic mutational profile, involving one or a few genes, while other diseases are genetically more heterogeneous.

Mature B-Cell Neoplasms

Mature B-cell neoplasms comprise over 80% of NHL. The most common types are follicular lymphoma and diffuse large B-cell lymphoma, which together account for more than half of all NHL. B-NHL entities comprise a range of morphologically, phenotypically, genetically and clinically distinct malignancies. The majority of B-NHL harbor somatically mutated IG genes and therefore are derived from germinal center (GC) or post-GC B cells. The correspondence to normal B-cell subpopulations initially assessed by

a combination of morphology and immunophenotype, has been refined by the comparison of gene expression signatures of lymphomas and normal B-cell subpopulations across the full range of normal B-cell differentiation. Fig. 4 illustrates the model of histogenesis and pathogenesis of B-cell neoplasms, and Table 4 summarizes the phenotypic, genetic and molecular features of most common mature B-cell neoplasms.

Clinically, B-NHL are categorized into those indolent or low-grade diseases, which tend to grow and spread slowly, and have few symptoms usually not requiring immediate chemotherapeutic intervention; and aggressive or high-grade lymphomas associated with a rapid growth and progressive clinical course. This clinical segregation corresponds to two broad categories of diseases and pathological entities. Indolent lymphoma essentially equates to small B-cell lymphoma entities, the most frequent and prototype being follicular lymphoma, followed by small lymphocytic lymphoma/chronic lymphocytic leukemia, lymphoplasmacytic lymphoma, marginal zone lymphoma (of extranodal, nodal and splenic types) and hairy cell leukemia. Mantle cell lymphoma, although composed usually of small B cells, is typically characterized by an aggressive behavior. Despite slow disease evolution and treatment responsiveness, indolent lymphomas essentially represent incurable chronic diseases, and encompass a cumulative risk of transformation to a high-grade lymphoma. Diffuse large B-cell lymphomas represent the prototype of aggressive B-cell

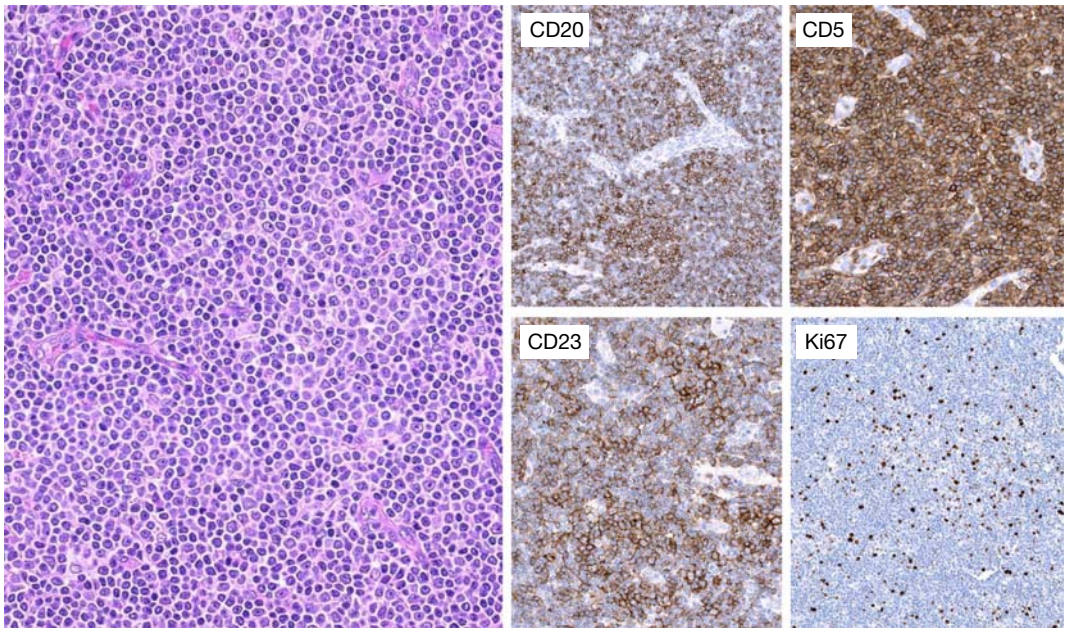

Fig. 4 Small lymphocytic lymphoma/chronic lymphoid leukemia. On a standard hematoxylin & eosin stained section, SLL shows a diffuse proliferation of small lymphocytes, admixed with a small number of larger cells, forming a proliferation center. The lymphoma cells are faintly positive for CD20, coexpress CD5 and CD23, and show a low proliferation fraction (<5%) by Ki67.

Table 4 Pathologic and genetic features of most common B-cell neoplasms

Neoplasm	*CD5*	*CD10*	*BCL6*	*BCL2*	*CD23*	*CD43*	*Cyclin D1*	*Genetic abnormalities*

+: positive in the vast majority of cases; +/−: positive in >50% of the cases, −/+: positive in <50% of the cases; −: usually negative.

lymphomas, while Burkitt lymphoma and high-grade B-cell lymphomas, not otherwise specified or "double hit" lymphomas, represent less common aggressive B-cell lymphoma entities.

Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma (B-CLL/SLL)

CLL is a neoplasm of small mature CD5+ CD23+ B cells with a blood count of at least 5 × 10e9 monoclonal B cells/L. It represents the most common leukemia of adults in western countries. SLL designates the same disease with tissue involvement and a lesser circulating count of monoclonal cells, and accounts for <5% of NHL. On blood smears, CLL cells appear like small lymphocytes with clumped chromatin and scant cytoplasm admixed with a small proportion of slightly larger prolymphocytes. In tissues (Fig. 4) SLL, is characterized by a diffuse accumulation of small lymphocytes, and the presence of proliferation centers comprising a continuum of smaller to larger cells (prolymphocytes and paraimmunoblasts). Proliferation centers represent a peculiar microanatomical site where CLL/SLL cells interact with accessory cells and the key site of CLL proliferation. CLL cells are positive for B-cell associated antigens, usually with weak expression of CD20 and surface IG expression, coexpress CD43 and are negative for cyclin D1.

CLL development is preceded by an asymptomatic phase named monoclonal B-cell lymphocytosis (MBL), defined by the presence of circulating CLL-like monoclonal B cells amounting to <5 × 10e9/L. MBL progresses to CLL at a rate of approximately 1%/year.

CLL/SLL comprises two disease subtypes based on the mutational status of the variable region of IG genes: the IGHV-mutated subtype (60% of the cases) associated to a good prognosis, and the IGHV-unmutated subtype (40% of the cases) that tend to have more advanced clinical stage at presentation and shorter median survival (8–10 vs. 15–25 years). Both mutated and unmutated subtypes display a gene expression signature that is related to the profile of CD27+ memory B cells, suggesting an origin from post-GC memory cells in mutated cases and from antigen-experienced B cells having developed outside the GC in the unmutated cases.

In CLL/SLL, chromosomal translocations are very uncommon but the t(14;18)(q32;q21) resulting in *IGH-BCL2* can be found in some cases. Deletion of 13q14 region is the most frequent genetic lesion, in 50%–60% of the patients, associated to the mutated subtype; trisomy 12 occurs in 15% of the cases independently of the mutational status; deletion of the 11q22-23 region (which encompasses the *ATM* gene) is found in 20% of the patients, preferentially with unmutated IGHV. Deletion of 17p (comprising *TP53*) is found in <10% of the patients, most commonly in unmutated CLLs, and is associated to a *TP53* mutation on the other allele in most instances, which imparts a bad prognosis. Besides *TP53*, other recurrently mutated genes include *NOTCH1* (NOTCH signaling pathway) and *SF3B1* (RNA processing machinery) in roughly 10% of patients each, and *BIRC3*, *POT1* and *MYD88* in <10% of the cases.

Clinical progression has been associated with histologically aggressive forms, characterized by expanded proliferation centers or increased proliferation fraction (Ki67 > 40%) or an increased proportion of prolymphocytes (>10%) in the peripheral blood. The sudden transformation of CLL into an aggressive disease—Richter's syndrome (RS)—occurs in 5%–10% of the cases. Histologically, most cases are represented by DLBCLs. Most RS represent clonal evolution of the preexisting SLL/CLL, but some are clonally unrelated to the CLL and represent secondary malignancies. A higher proportion of *TP53* alterations found in clonally related cases, and clonally unrelated RS are associated to a significantly longer survival compared to clonally related RS who do very poorly.

B-Cell Prolymphocytic Leukemia (B-PLL)

This extremely rare disease (<1% of B-cell leukemias) is a malignancy of B-prolymphocytes (medium-sized round lymphoid cells with a single, prominent nucleolus) affecting blood (and accounting for >55% of peripheral blood lymphoid cells), bone marrow and spleen. Patients typically present with very high white blood counts ($>100 \times 10^9$) and their median survival is 30–50 months. Cases of CLL with increased prolymphocytes or prolymphocytoid transformation, as well as lymphoproliferations associated to a t(11;14) translocation involving *CCND1* are by definition excluded. Numerical or structural abnormalities of the *MYC* gene are recurrently found in B-PLL.

Lymphoplasmacytic Lymphoma (and Waldenström's Macroglobulinemia) (LPL)

Lymphoplasmacytic lymphoma (LPL), a rare lymphoma occurring in older adults is a neoplasm of small lymphocytes, plasmacytoid, lymphocytes and plasma cells, usually involving the bone marrow and sometimes lymph nodes and spleen. A subset of cases occur in association with chronic HCV infection. The majority of LPL patients have Waldenström's macroglobulinemia, (WM), which is defined as bone marrow involvement by LPL and presence of an IgM serum paraprotein of any concentration, with or without hyperviscosity syndrome. More than 90% of LPL have *MYD88* L265P mutation, but this abnormality, which leads to NF-kappaB signaling, is not specific as it is also encountered in other small B-cell lymphomas and in a subset of DLBCLs. About 30% of the patients harbors somatic mutations in *CXCR4* (most commonly the nonsense truncating S338X, or frameshift mutations in the C-terminal domain) in addition to the activating *MYD88* L265P mutation, and this genotype tends to correlate with higher disease activity.

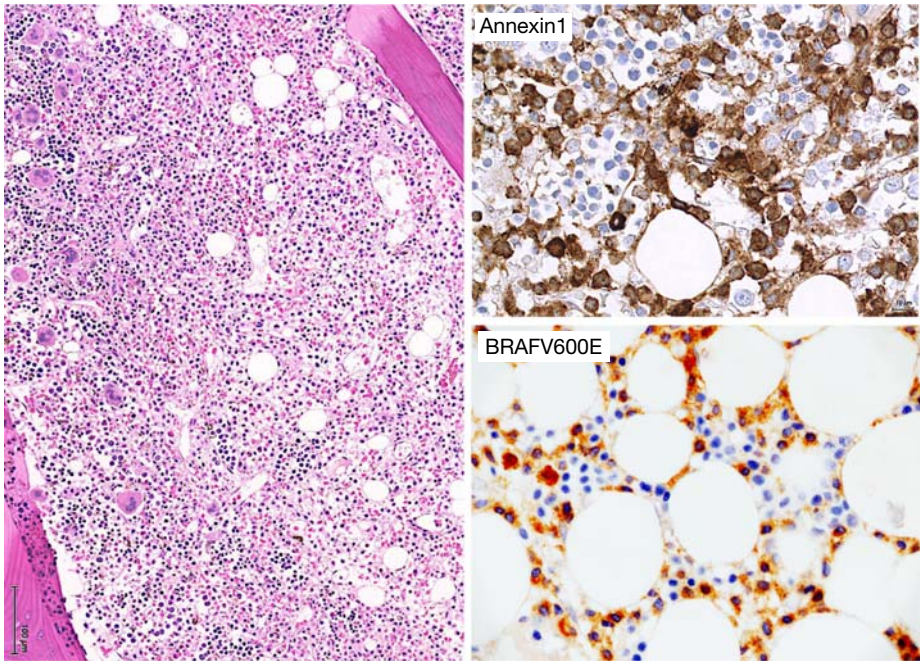

Fig. 5 Hairy cell leukemia. This bone marrow section shows a diffuse infiltrate by small lymphoid cells, which by immunochemistry are positive for Annexin1, and show expression of the *BRAF* V600E variant, as demonstrated by this mutation-specific antibody.

Hairy Cell Leukemia (HCL)

HCL (Fig. 5) is a rare lymphoid leukemia in older adults that has a distinct cytology (small lymphoid cells with an oval nucleus and abundant cytoplasm with "hairy" projections) and immunophenotype (expression of CD103, CD25, CD11c and annexin A1). Leukemic cells are present in low numbers in the peripheral blood but show a diffuse bone marrow and splenic red pulp infiltration, responsible of patients' pancytopenia and susceptibility to infections. Almost all cases carry a *BRAF* V600E kinase-activating mutation, which aberrantly activates the RAF-MEK-extracellular signal-regulated kinase (ERK) signaling pathway, leading to uncontrolled proliferation. Accompanying mutations of the *KLF2* transcription factor or the *CDKN1B* (p27) cell cycle inhibitor are recurrent in 16% of patients with HCL and likely cooperate with BRAF-V600E in HCL pathogenesis.

Marginal Zone Lymphomas (MZL)

Marginal zone lymphomas (MZL) of splenic, nodal and MALT type correspond to postgerminal center memory cells of marginal zone type that derive from and proliferate in splenic, nodal and extranodal tissues (Fig. 6).

Splenic marginal zone lymphoma (SMZL)

Splenic marginal zone lymphoma (SMZL) is a rare, indolent B-cell neoplasm involving the spleen by replacing the normal B-cell follicles and showing a marginal zone differentiation, which may have circulating neoplastic cells with short "villous" projections. Patients typically present with splenomegaly, bone marrow involvement and lymphocytosis, usually without peripheral lymphadenopathy. SMZL cells express IgM, IgD, B-cell antigens (CD19, CD20, CD22), BCL2 are usually CD5-negative, and typically lack CD10, CD43, CD23, BCL6, cyclin D1, CD11c and CD25.

Allelic loss of 7q21-32 allelic is detected in up to 40% of the cases. Other cytogenetic abnormalities include gains of 3q or 12q and 6q deletion. Recurrent mutations disrupting genes involved in the normal process of marginal zone differentiation, *NOTCH2* and *KLF2*, are found in 10%–25% and in up to 44% of the cases, respectively. These mutations, as well as infrequent *TP53* mutations, have been associated to adverse clinical outcome.

Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue type (MALT lymphoma)

Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue type (MALT lymphoma), the third most common type of B-cell lymphoma, occurs in organs that normally lack organized lymphoid tissue. About half involve the gastrointestinal tract, and they represent 40%–60% of lymphomas in the ocular adnexa, thyroid, lung, breast, and salivary gland; skin or soft tissue may also be the primary site. The majority of patients present with localized (stage I or II) extranodal disease. MALT

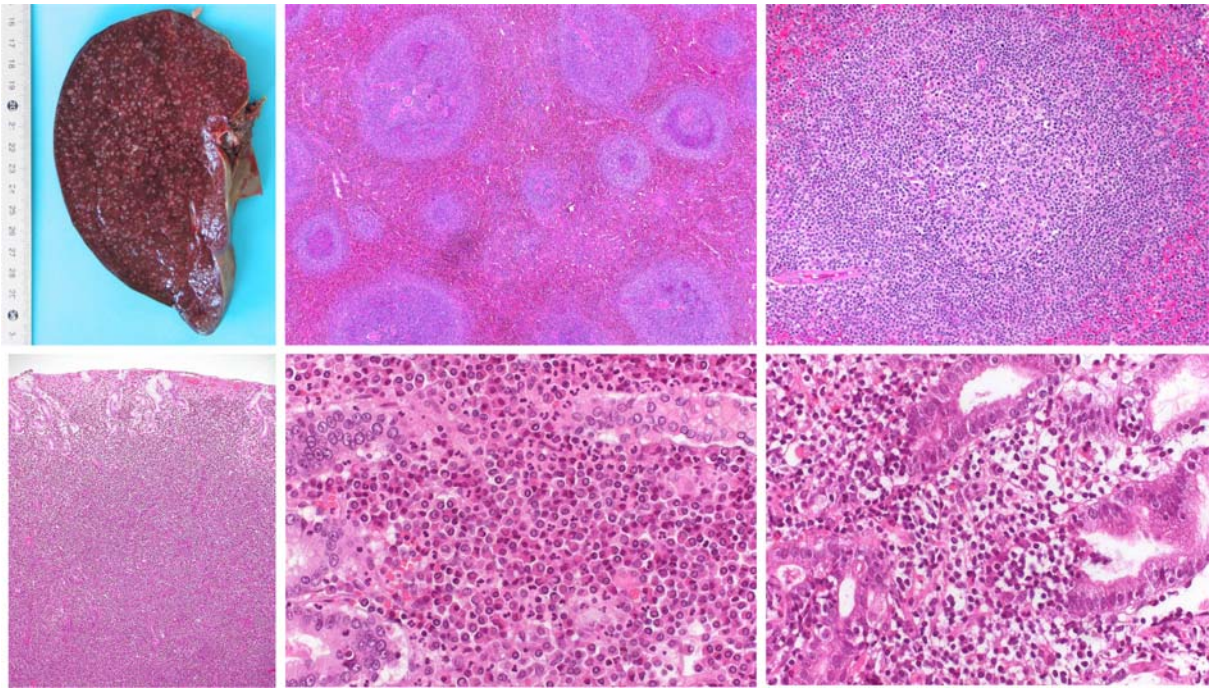

Fig. 6 Marginal zone lymphomas. Splenic marginal zone lymphoma (upper panels); gross picture of a splenectomy specimen showing increased size of the spleen, and micronodular pattern on the cut section; a low-power view of the splenic parenchyma shows a nodular expansion of the white pulp, with prominent marginal zones at their periphery. Gastric MALT lymphoma (lower panels): on a low-power view of a gastric section specimen, a diffuse lymphoproliferation obliterating the mucosa is seen, with a pale appearance. The middle panel shows a case with marked plasmacytic differentiation, and the right panel shows a mucosal infiltrate by lymphoma cells showing epitheliotropism with the formation of lymphoepithelial lesions.

lymphomas run an indolent natural course. Dissemination or recurrence may occur, often in other localized extranodal sites, with long disease-free intervals.

"Acquired MALT" secondary to autoimmune disease, in particular Sjögren syndrome or Hashimoto thyroiditis, or infection such as *H. pylori* gastritis, represents the substrate for lymphoma development. MALT lymphoma reproduces the morphologic features of normal MALT, with a polymorphous infiltrate of small lymphocytes, marginal zone (centrocyte-like) B cells, and plasma cells, admixed with scattered blast cells, occupying the marginal zone of reactive follicles and in some cases "colonizing" and disrupting these follicles. In epithelial tissues, neoplastic cells typically infiltrate the epithelium, forming so-called lymphoepithelial lesions. In MALT lymphomas, when clusters or sheets of blasts are present, a separate diagnosis of large B-cell lymphoma is made and these cases are associated with a worse prognosis. MALT lymphoma cells express sIg (M > G > A), lack IgD, and may show plasmacytoid differentiation (40% of the cases). They express B-cell antigens (CD19, CD20, CD22, CD79a), may rarely be positive for CD5, and do not express CD10 and BCL6 and cyclinD1.

The most common numerical chromosomal abnormality is trisomy 3 (about 60% of cases), but is not specific for this lymphoma type. Three main recurrent translocations are encountered (see **Table 2**). The t(11;18)(q21;q21) fusing *BIRC3(API2)* and *MALT1* is the most common, found in roughly 20% of the cases with the highest prevalence in lung (40%) and gastric (25%) MALT lymphomas. The t(11;18)(q21;q21) is a marker for cases of gastric MALT lymphomas that do not respond to *H. pylori* eradication, but these cases are less likely to undergo transformation to diffuse large B-cell lymphoma. The t(14;18)(q32;q21) leading to deregulated expression of the *MALT1* gene mainly occurs in a small proportion of MALT lymphomas of the ocular adnexa and lung and is rare in other localizations. The t(1;14)(p22;q32) causing overexpression of BCL10, is rare (< 5% of the cases, mostly gastric and pulmonary). These mutually exclusive translocations deregulate the activation of the canonical and/or noncanonical NF-kappaB pathways. Inactivation of *TNFAIP3* (*A20*) by 6q23 deletion and deleterious mutations, mainly seen in MALT lymphomas of the ocular adnexa, thyroid and salivary glands where translocations are infrequent, impairs the repression of NF-kappaB normally induced by TNFAIP3.

Nodal MZL

Nodal MZL is the least frequent form of MZL encompassing an adult type and a pediatric-type. It morphologically resembles nodal involvement by MZL of MALT type or splenic type, but without evidence of extranodal or splenic disease. The lymphoma cells frequently coexpress CD43. Some genetic features are shared with splenic and MALT lymphomas, including *NOTCH2* and *KLF2* mutations, but translocations associated to MALT lymphomas and 7q deletion are not seen.

Follicular Lymphoma (FL)

FL, the most common form of indolent lymphoma and second most common lymphoma in western countries, affects predominantly older adults. FL remains essentially an incurable disease; moreover, subsets of patients may progress toward transformation to a high-grade B-cell lymphoma and a subset of patients may progress or relapse early after receiving first-line therapy. Transformation of FL usually occurs by a nonlinear divergent evolution from a common progenitor cell, and is associated to a poor outcome.

FL is a neoplasm of follicular center B cells composed of a mixture of centrocytes and centroblasts, which usually has, at least partially, a follicular pattern (Fig. 7). Histological grading along a three-grade scale is based on the abundance of centroblasts by microscopic counting per high-power field (HPF). Grade 1 cases have 0–5 centroblasts per HPF, grade 2 cases have 6–16 centroblasts per HPF and grade 3 have >15. Grade 3 is further subdivided into 3a, when centrocytes are still present, and 3b, composed of centroblasts only, biologically closer to diffuse large B-cell lymphoma. The majority of cases are grade1–2. Several studies have shown a more aggressive course for grade3 FL, but the difference may be alleviated by the use of anthracycline-containing chemotherapy and/or rituximab. Most cases have a predominantly follicular pattern, and the presence of diffuse areas in grade 1–2 FL is thought to not be clinically significant, but diffuse areas of grade 3 qualify for a diagnosis of diffuse large B-cell lymphoma. Rare cases are predominantly diffuse, a variant frequently occurring as large inguinal tumors.

FL cells are usually sIg + (IgM > IgG > IgA). The tumor cells express pan-B-cell associated antigens (CD19, CD20, CD22, CD79a), are usually CD10+, BCL6+, BCL+, CD5− and CD43−. CD23 may be positive, in particular in the purely diffuse variant. Grade 3 FL may be negative for BCL2 and CD10. Meshworks of follicular dendritic cells (FDCs) are present in follicular areas and may be highlighted by CD21or CD23. IG heavy and light-chain genes are rearranged, with extensive and ongoing somatic mutations, similar to normal germinal center cells, and consistent with a germinal center derivation.

The pathogenesis of FL is driven by the t(14;18)(q32;q21) translocation which is the hallmark and most recurrent feature of FL, detected in 85%–90% of the cases and inducing ectopic BCL2 protein overexpression; and the genetic aberrations of epigenetic modifiers. The *BCL2* translocation is an early event occurring in the bone marrow in pre-B cells and is considered the initiating oncogenic hit, providing a survival advantage by activating an antiapoptotic program and favoring the acquisition of additional genetic lesions during repeated transits through germinal centers. As for alterations of epigenetic modifiers in FL, mono- or biallelic inactivation of the *KMT2D* (*MLL2*) histone H3K4 methyltransferase represents the most highly recurrent lesion (about 80% of the cases). Alterations in other chromatin modifiers include inactivating mutations of the histone acetyltransferases *CREBBP* and *EP300*, in about 60% and 10% of the cases, respectively, and activating mutations of *EZH2* histone H3K27 methyltransferase (about 25% of the cases). The deregulated epigenetic mechanisms have been implicated in predicting
